Figure 1: Parse tree for transformation from incorrect to correct sentences.

<sup>1</sup>Here S means start of the tree

The yield of the tree generates *few have arrived*, which is the required correction. This is the essence of decoding in hierarchical machine translation.

### 3.2 Implementation

The translation system being used is the Joshua Machine translation system (Li et al., 2010). The SMT based correction pipeline is a six step process in conformity with the Joshua decoder (Ganitkevitch et al., 2012). First we create the dataset in a input folder with six files such as:-

1. train.incorrect- Incorrect sentences in our training corpus
2. train.correct- Correct sentences in our training corpus
3. tune.correct- Incorrect sentences in our development set
4. tune.incorrect- Correct sentences in our development set
5. test.correct- Incorrect sentences in our testing set
6. test.incorrect- Correct sentences in our testing set

The pipeline starts with preprocessing the corpus, *i.e.*, tokenisation and lowercasing followed by word alignment. The result of word alignment is stored in training.align file. Then a file, “grammar.gz” is created by joshua that stores SCFG rules using information from the training.align file and the training corpus. This process is called grammar generation and is followed by the building of the language model.

For developing the language model, the Joshua MT system uses KenLM (Heafield, 2011) toolkit or BerkeleyLM. This is the end of the training process. The steps that follow in the pipeline are tuning and testing. Tuning iterates over the development set to obtain the best parameters for the translation model. At the end of tuning, the system obtains the optimized parameters that can be deployed into the translation model for testing. The testing phase translates sentences from test set to evaluate the overall BLEU score (Papineni et al., 2002).

## 4 Analysis of grammar rules extracted

In this section we look at how various grammar corrections have been handled. The various types of errors handled are article choice errors, preposition errors, word-form choice errors and word insertion errors as mentioned in Park and Levy (2011). Apart from these errors, we also discuss errors due to reordering and errors due to unseen verbs which have not been implemented in previous models.

### 4.1 Article choice errors

The article *a* has been replaced by *the* before proper nouns like *a amazon* and *a himalayas*. The grammar rules are:-

- $X \rightarrow a \text{ himalayas } X_1, \text{ the himalayas } X_1$
- $X \rightarrow a \text{ amazon } X_1, \text{ the amazon } X_1$

The rules suggest that *a himalayas* succeeded by a phrase  $X_1$  can be replaced by *the himalayas* followed by the same phrase.

### 4.2 Preposition errors

Preposition *at* has been replaced by *in* before a place like *at central London*. The grammar rule is:-

- $X \rightarrow X_1 \text{ at central London}, X_1 \text{ in central London}$

### 4.3 Unknown Verb correction

Lets say the training data has these sentences

- $He \text{ like milk} \rightarrow He \text{ likes milk}$
- $They \text{ hate the pollution} \rightarrow They \text{ hate pollution}$

This system will not be able to correct *He hate milk*, because hate needs to be corrected to hates and its grammar has no rule for *hate*  $\rightarrow$  *hates*. But it has a rule for *like*  $\rightarrow$  *likes*. From these two rules, the grammar extractor wont be able to derive *hate*  $\rightarrow$  *hates*. This can be solved by splitting *likes* to *like s*

- $He \text{ like milk} \rightarrow He \text{ like s milk}$

Now extractor will have a rule for this training sentence.

- $X \rightarrow He X_1 \text{ milk}, He X_1 \text{ s milk}$

- $X \rightarrow \text{hate, hate}$

Using these two rules it generates *He hate s milk* from *He hate milk*. Later we combine all the split verbs to get *He hate s milk*.

#### 4.4 Word insertion errors

As the name suggests these errors are due to missing words, e.g.,

- *The court deemed necessary that she respond to the summons.*  $\rightarrow$  *The court deemed it necessary that she respond to the summons.*

For this example the grammar rule extracted is :-

- $X \rightarrow X_1 \text{ deemed } X_2, X_1 \text{ deemed it } X_2$

#### 4.5 Reordering errors

Reordering errors arise due to incorrect ordering of the subject object verb, e.g.,

- Given Hindi sentence:- *सेन्ट्रल लन्डन मे गिरा हेलिकोप्टर*
- Transliteration of Hindi sentence is:- *sentrala landana me giraa helicopters*
- The correct translation of this sentence is:- *helicopter crash in central London*
- Output translation from Hindi-English translation system of this sentence:- *central down in London helicopter.*

If the output translation and correct translation is added to the training corpus of grammar correction system such as,

- *central down in London helicopter*  $\rightarrow$  *helicopter down in central London.*

we can obtain the correct translation.

### 5 Experiments

Now we present the data set and evaluation techniques for our experiment.

#### 5.1 Data set

We ran the grammar correction system on the NUS (NUS Corpus of Learner English) corpus (Dahlmeier et al., 2013). The dataset has been developed at NUS in collaboration with the Centre for English Language Communication (CELC). This is a parallel corpus of 50000 incorrect and correct sentences, all aligned. We took a subset of 4000 line training corpus, 3000 for training and 1000 for testing.

#### 5.2 Cleaning training corpus

This is a preprocessing step before training the grammar correction system. This was primarily due to the presence of noisy data like:-

1. HYPERLINK- <http://en.wikipedia.org/wiki/>
2. Bracketed information:- (DoD) {Common Access Card}
3. Citations:- (Ben, 2008)
4. Presence of sentence pairs without any changes.

### 6 Results

We present the results of SMT based grammar correction in table 1. The results show improvement in BLEU score with increase in the size of training corpus. The baseline is the system which passes incorrect sentences as such i.e., performs *no correction*. We wanted to check what the bleu score would be when no correction is incorporated.

Size of training corpus (sentences)	Size of tuning corpus (sentences)	Size of testing corpus (sentences)	BLEU score
Baseline			0.7551
1000	1000	1000	0.7668
2000	1000	1000	0.7679
3000	1000	1000	0.7744

Table 1: Variation of accuracy with variation of training size

### 7 Conclusion

We have shown how a hierarchical phrase-based MT system like Joshua could be used as a grammar correction system. We observed that increasing training data definitely increases accuracy because patterns in grammar correction keep repeating even if test data is completely different from training set. In future work, we would like to concentrate on “unknown word handling”.

## Abstract

This paper studies the performance of different parsers over a large Spanish tree-bank. The aim of this work is to assess the limitations of state-of-the-art parsers. We want to select the most appropriate parser for Subcategorization Frame acquisition, and we focus our analysis on two aspects: the accuracy drop when parsing out-of-domain data, and the performance over specific labels relevant to our task.

## 1 Introduction

Dependency parsing has been addressed from different perspectives, improving performance as better techniques are developed. Nevertheless, we may wonder whether those results are good enough to be useful for tasks that need parsed sentences as input. Depending on the task we want to tackle, we will prefer some labels to be correct with respect to others. For example, in tasks related to extraction of verb complements such as verb Subcategorization Frame (SCF) or Selectional Preference acquisition, we are specially interested in a parser that correctly detects and labels the arguments of the verbs, while we do not need to have a high accuracy in other kind of relations, such as specifiers or modifiers.

In this work, we present a study of the performance of different parsers, following the trend started by McDonald and Nivre (2007) and Hara et al. (2009). We want to maximize the performance of different systems, for Spanish, with the final goal of applying them to concrete tasks, in our case SCF acquisition. For this task, we need to develop a parser that performs well not only in terms of Labeled Attachment Score (LAS), but

also that labels verb complements correctly and that performs well when annotating data that is substantially different from the training corpus.

## 2 Motivation

This work was motivated by the intention of building a SCF acquisition system for Spanish (Padró et al., 2013). SCF acquisition consists of acquiring from data the kind of complements which a verb can appear with (Direct Object, Indirect Object, etc.) and how this complements are fulfilled (Noun Phrase, Clause, etc.). To perform this task, state-of-the-art systems (Briscoe and Carroll, 1997; Korhonen, 2002; Messiant, 2008) use parsed data, where the complements of the verbs are already detected. Thus, the first requirement to develop a SCF acquisition system is to have a parser to annotate the input data.

We started by training *MaltParser* (Nivre and Hall, 2005; Nivre et al., 2007b) for Spanish<sup>1</sup> using IULA Spanish LSP Treebank (Marimon et al., 2012), which is built from technical text. The results obtained in terms of LAS were high but when studying the performance of this parser in terms of which labels and complements were correctly detected, the results showed not to be good enough to lead to satisfactory results in SCF acquisition (Padró et al., 2013). For instance, Indirect Objects (IO) were parsed with F1 around 50%, which means that it will be very unlikely to correctly learn SCFs that contain the very relevant IO label.

Furthermore, we need a parser that performs well when annotating sentences of a domain different from the training Treebank. For that reason we evaluated the parser results over the Tibidabo Treebank (Marimon, 2010), which is made

<sup>1</sup>[http://www.iula.upf.edu/recurs01\\_mpars\\_uk.htm](http://www.iula.upf.edu/recurs01_mpars_uk.htm)

up domain-general texts. Testing on different tests sections that come from different domains is customary for English, where both PTB sections 22 and 23 are used, as well as the Brown corpus. This method is to our knowledge new for Spanish dependency parsing. The results show that, as expected, the performance of the parser over this corpus decreases, making even more difficult the extraction of SCFs.

Thus, we detected two main weaknesses of the parser system: the low performance on labels that may be very important for determined tasks and its dependency on the domain. With that in mind, we evaluated other state-of-the-art parsers (§3.2) to determine which parsers suffer less from these limitations.

### 3 Experiments

#### 3.1 Corpus

We ran our experiments using IULA Spanish LSP Treebank<sup>2</sup> (Marimon et al., 2012). This corpus (henceforth IULA) contains the syntactic annotation of 42,000 sentences (around 590,000 tokens) taken from domain-specific (technical literature) texts. We used the train and test partitions provided by the Treebank developers which are publicly available for replicability.<sup>3</sup>

Furthermore, we used the Tibidabo Treebank (Marimon, 2010) as an alternative test set. Tibidabo contains a set of sentences extracted from the Ancora corpus (Taulé et al., 2008), which was used in the CoNLL-X Shared Task of dependency parsing (Buchholz and Marsi, 2006).

The Tibidabo Treebank was annotated using the same guidelines as IULA Treebank. Therefore, it has the same functions and tag-set as IULA, but since the sentences come from a completely different corpus, it represents a good evaluation frame with regards to the influence of domain change.

In summary, we used a training set to train the different models and two different test sets to evaluate each model. See table 1 for details about the size of the different partitions.

The treebanks used in this work contain up to 25 different dependency relations. In this work we will pay special attention to verbal arguments, i.e., verb complements and subject. Thus, the labels we are interested in are SUBJ (subject), DO (Direct Object), IO (Indirect Object), OBLC (oblique

corpus	sentences	tokens
IULA - Train	33,679	471,624
IULA - Test	8,125	114,610
Tibidabo	3,376	41,620

Table 1: Sizes of the used corpora

complement, a prepositional phrase with bound preposition) and PP-DIR and PP-LOC, which mark prepositional phrases for direction and location respectively.

#### 3.2 Parsers

In what follows we briefly describe the dependency parsers used in our experiments, the parsing approach they belong to, and how we searched for the best possible configuration

##### 3.2.1 Transition-based parser - MaltParser and MaltOptimizer

*MaltParser* (Nivre and Hall, 2005; Nivre et al., 2007b) is a transition-based dependency parser generator. It was one of the best parsers in the CoNLL Shared Tasks in 2006 and 2007 (Buchholz and Marsi, 2006; Nivre et al., 2007a) and it contains four different families of transition-based parsers. A transition-based parser is based on an automaton that performs shift-reduce operations, whose transitions manage the input words in order to assign dependencies between them.

*MaltOptimizer* (Ballesteros and Nivre, 2012) is a system designed to optimize MaltParser models by implementing a search of parameters and feature specifications. MaltOptimizer takes a training set in CoNLL data format,<sup>4</sup> and provides an optimal configuration that includes the best parsing algorithm, parsing parameters and a complex feature model over the data structures involved in the parsing process.

MaltOptimizer searches the optimal model maximizing the score of a single evaluation measure, either LAS, LCM (Labeled complete match) or unlabeled evaluation measures. As we mentioned in section 2, our intention is to enhance the performance of specific labels and we have been willing to sacrifice some overall accuracy in favor of better specific models. To this end, we modified the MaltOptimizer source code to make it able to optimize over precision and recall for a specific

<sup>2</sup>[http://iula.upf.edu/recurs01\\_tbk\\_uk.htm](http://iula.upf.edu/recurs01_tbk_uk.htm)

<sup>3</sup><https://repositori.upf.edu/handle/10230/20408>

<sup>4</sup><http://ilk.uvt.nl/conll/#dataformat>

dependency label.<sup>5</sup> Besides improving the accuracy of the parser for a given dependency label, our intention was that we can enhance the general performance of the parser when we optimize over a dependency label which is very frequent. The idea is that the parsers have fewer candidate words for these frequent labels, and therefore, we provide better recall for the rest of labels, thereby reducing error propagation. In our experiments, besides optimizing over general LAS and LCM, we optimized for DO (a very frequent label) and for IO (a rare but relevant label).

In our experiments we ran MaltOptimizer using 5-fold cross-validation over the training corpus in order to ensure the reliability of the outcomes.

### 3.2.2 Maximum Spanning Tree Parser - MSTParser

*MSTParser* is an arc-factored spanning tree parser (McDonald et al., 2005; McDonald et al., 2006). It implements a graph-based second-order parsing model which scores all possible dependency arcs in the sentence and then extracts the dependency tree with the highest score. The score of the trees is calculated basically adding the score of every arc, having at the end a sum with the score of the whole tree.

### 3.2.3 Joint tagger Transition-based parser and Graph-based parser with Hash Kernel and Beam Search- Mate tools

The Mate-Tools provide two parser types: a graph-based (Bohnet, 2010) and a transition-based parser with graph-based re-scoring (completion model) that is able to perform joint PoS tagging and dependency parsing (Bohnet and Kuhn, 2012; Bohnet and Nivre, 2012). We refer to the graph-based parser as Mate-G, to the transition-based parser without graph-based re-scoring as Mate-T, and to the transition-based parser with enabled graph-based completion model to Mate-C. These parsers benefit from a passive-aggressive perceptron algorithm implemented as a Hash Kernel, which makes the parser fast to train and improves accuracy.

Mate-T provides joint PoS tagging and dependency parsing to give account for the interaction between morphology and syntax. It uses a beam search over the space of possible transitions and

<sup>5</sup>The source code and the package with the changes included in MaltOptimizer can be downloaded from: <http://nil.fdi.ucm.es/maltoptimizer/MaltOpt.Specific.zip>

keeps a  $k$  number of possible PoS tags for each word instead of basing its attachment decisions on hard previously calculated PoS tags.

Mate-C is essentially a transition-based parser that uses global information to score again the elements of the beam. The completion model depends on a set of graph parameters called second and third-order factors, which describe the dependency environment of the word, such as the second-order factor that gives account for the head, the dependent and the rightmost grandchild, or the third-order factor that lists the first two children of the dependent.

## 4 Results and Discussion

Table 2 summarizes the results obtained (in terms of LAS) with the different parsers over both test sets. The results obtained over IULA Test are very high, which is probably due to the specificity of the treebank. The results over Tibidabo Treebank can be seen as more general results, and they show how parsers trained with IULA treebank behave when applied to a different domain.

The results given in the table are those obtained with the configuration that leads to better LAS results over IULA Test. The same configuration is used to annotate Tibidabo. For MaltParser, the best LAS was obtained when optimizing the parser for the DO dependency label, which was obtained by applying the MaltOptimizer modifications that we explained in section 3.2.1. This therefore confirms our expectations that optimizing over very frequent labels may improve the overall accuracy<sup>6</sup>. The algorithm selected by MaltOptimizer was Covington non-projective, which is described by Covington (2001) and included in MaltParser by Nivre (2008). For the Mate parsers, we used the default training settings for the graph-based parser. For the transition-based parser, we used a beam size of 40 and 25 training iterations.

Parser	IULA Test LAS (%)	Tibidabo LAS (%)
Malt	93.16	89.04
MST	92.72	89.36
Mate-T	94.47	91.05
Mate-C	94.70	91.43
Mate-G	94.49	91.26

Table 2: Obtained LAS for each parser

<sup>6</sup>Optimizing over IO did not improve significantly the results over that complement nor overall LAS

In the table, we can see that the differences of performance assert the domain difference between the corpora and that Mate parsers clearly outperform the others. The best performance is obtained with Mate-C<sup>7</sup>.

It is not surprising that the best results are obtained with the Mate parsers since those parsers use enhanced parsing models. Nevertheless, to obtain these high results it was necessary to change the treebank configuration to use the short PoS (this is, just the category) in the position of the long PoS, and keep the long PoS (i.e, the morphology) in the feature column. When using the original configuration of the treebank (long PoS) the results obtained were much lower, and specially suffered from the domain change (LAS=93.69% for IULA Test and LAS=88.77% for Tibidabo). The Mate parsers were optimized for for the usage of CoNLL-09 data format which includes PoS tags and morphological features only. Under these conditions, the short PoS tags fit best into the PoS column and the fine grained tags into the morphologic column. The other parsers use CoNLL-X format. MST uses all columns for training, and Malt only uses the features provided in the feature model which is one of the outputs of MaltOptimizer, but changing the data did not improve the results, neither for Malt nor for MST.

#### 4.1 Specific Label Performance

The results obtained in terms of LAS are very satisfactory (the best parsing results reported for Spanish so far), specially for Mate parsers. Nevertheless, when we study the performance over concrete labels, we see that we can not rely on the parser for some of them. Table 3 presents the results for the labels we are interested in (§3.1). The table shows Precision, Recall and F1 scores obtained with Mate-C, which is the parser that performs better not only in terms LAS but also for individual complements. The table also shows the relative frequency of the complements in each corpus. Note that some of the studied complements are terribly infrequent.

Note that, from the labels we are interested in, just the frequent ones (SUBJ and DO) are annotated with high F1. OBLC has acceptable results, but the other complements are a big source of error, having low P and R. One of the goals of the

<sup>7</sup>All differences are significant (using T-test with  $\alpha$  set to 0.05) except between Mate-C and Mate-G over Tibidabo

Label	IULA Test				Tibidabo			
	Freq.	P	R	F1	Freq.	P	R	F1
SUBJ	5.90	93.23	93.43	93.33	7.35	89.12	88.66	88.89
DO	4.64	93.02	93.25	93.13	7.03	85.84	85.64	85.74
IO	0.09	67.90	51.89	58.83	0.46	66.67	48.42	56.10
OBLC	0.20	83.56	83.49	83.53	1.30	75.25	69.00	71.99
PP-DIR	0.05	56.67	43.59	49.28	0.18	57.14	16.44	25.53
PP-LOC	0.03	61.84	39.83	48.45	0.14	56.00	24.56	34.14

Table 3: Results for some labels with Mate-C. All figures are percentages.

present work was to see whether it was possible to build a parser that had better performance for the critical complements (specially in terms of Precision) even if it had worse LAS. Nevertheless, the results showed that even with the parser that performed better, the Precision and Recall of the infrequent complements is too low to obtain good results in subsequent tasks that require high label-specific performance, as shown by Padró et al. (2013) for SCF acquisition.

## 5 Conclusions and Future Work

This work studied the limitations of state-of-the-art parsers. We trained different systems over a large Spanish treebank and tested them over a treebank from a different domain. Our experiments show that though the obtained LAS is high, the performance over some concrete labels is very low in all cases, limiting the usability of the parsed data for tasks than rely on label-specific accuracy.

One important future line is to look for parser modifications that allow the system to perform better in the labels we are interested in. To do so, one idea would be to use semantic features to give more information to the parser like in (Agirre et al., 2012). We did some preliminary experiments in that line, using information about the semantic classes for common nouns (specifically for the classes human and location), but the results showed that this information did not lead to a better performance of the parser. This is probably due to the sparsity of this information, but it is still an interesting line to study, since it lead to good results in other cases (Agirre et al., 2012).

## Abstract

Many NLP tasks such as question answering and knowledge acquisition are tightly dependent on dependency parsing. Dependency parsing accuracy is always decisive for the performance of subsequent tasks. Therefore, reducing dependency parsing errors or selecting high quality dependencies is a primary issue. In this paper, we present a supervised approach for automatically selecting high quality dependencies from automatic parses. Experimental results on three different languages show that our approach can effectively select high quality dependencies from the result analyzed by a dependency parser.

## 1 Introduction

Knowledge acquisition from a large corpus has been actively studied recently. Knowledge is often acquired from the fundamental analysis. In particular, dependency parsing has been used for some tasks like case frame compilation (Kawahara and Kurohashi, 2006), relation extraction (Saeger et al., 2011) and paraphrase acquisition (Hashimoto et al., 2011). For these tasks, the accuracy of dependency parsing is vital. Although the accuracy of state-of-the-art dependency parsers for some languages like English or Japanese is over 90%, it is still not high enough to acquire accurate knowledge, not to mention those difficult-to-analyze languages like Chinese and Arabic.

Instead of using all the automatic parses, it is possible to use only high quality dependencies for knowledge acquisition. In this paper, we present a supervised approach for selecting high quality dependencies from automatic dependency parses. This method considers linguistic features that are related to the difficulty of dependency parsing. The experimental results on English, Chinese and

Japanese show that our proposed method can select dependencies of higher quality than baseline methods for all the languages.

## 2 Related Work

There have been a few approaches devoted to automatic selection of high quality parses or dependencies. According to selection algorithms, they can be categorized into supervised and unsupervised.

Supervised methods mainly focus on the construction of a machine learning classifier to predict the reliability of parses or dependencies based on various kinds of features both on syntactic and semantic level. Yates et al. (2006) created WOODWARD which is a Web-based semantic filtering system. Kawahara and Uchimoto (2008) built a binary classifier that classifies each parse of a sentence as reliable or not. Among supervised methods, ensemble approaches were also proposed. Reichart and Rappoport (2007) detected parse quality by a Sample Ensemble Parse Assessment (SEPA) algorithm. Another similar approach proposed by Sagae and Tsujii (2007) also selected high quality parses by computing the level of agreement on different parser outputs. Iwatate (2012) applied a tournament model on Japanese dependency parsing and then selected reliable dependencies by using SVM output. The work most related to ours is the work of Yu et al. (2008). They proposed a framework that selects high quality parses in the first stage, and then selected high quality dependencies from the filtered parses. In comparison, we consider that even some low quality sentences possibly contain high quality dependencies. Also, we take into account other aspects that can affect high quality dependency classification and create a new set of linguistic features for classification.

Also, unsupervised algorithms for detecting reliable dependency parses were proposed. Reichart

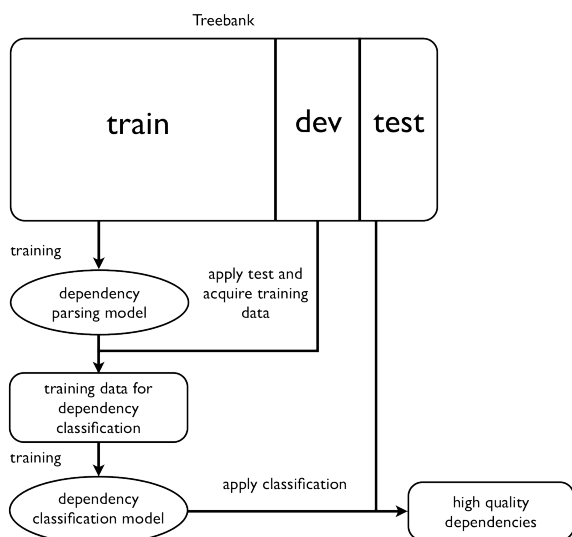

Figure 1: Overview of high quality dependency selection

and Rappoport (2009) proposed an unsupervised method for high quality parse selection, which was based on the idea that syntactic structures that are frequently created by a parser are more likely to be correct. Dell’Orletta et al. (2011) proposed ULISSE (Unsupervised LINGuisticallydriven Selection of dEpendency parses), which uses an unsupervised method in a supervised parsing scenario. Although unsupervised methods may solve the domain adaption issue and do not use any annotated data, the accuracy of selected parses, which is under 95%, still needs to be improved for knowledge acquisition tasks.

### 3 High Quality Dependency Selection

In this section, we present a framework of highly reliable dependency selection from automatic parses. Figure 1 shows the overview of our approach. We use a part of a treebank to train a parser and another part to train a binary classifier which judges a dependency to be reliable or not.

#### 3.1 Training Data for Dependency Classification

We collect training data from the same corpus which is also used in dependency parsing in the first stage. First, the training section is used to train a dependency parser and the development section is used to apply dependency parsing using the model trained by training section. From the parses of the development section, we acquire training data for dependency classification

by labeling each dependency according to the gold standard data. All the correct dependencies are defined as reliable and vice versa.

#### 3.2 Features for Dependency Classification

Most basic features consider that word pairs are much less likely to have a dependency relation when there are punctuation between them. On the other hand, based on the fact that dependencies with longer distance always show worse parsing performance (McDonald and Nivre, 2007), distance is another important factor that reflects the difficulty of judging whether two words have a dependency relation. Yu et al. (2008) used the features mentioned above and PoS features except the word features and did not use the context features, which are described later.

In addition to these basic features, we consider context features that are thought to affect the parsing performance. Table 2 lists these context features. In some more complex cases, it is also necessary to observe larger span of context. In order to learn such linguistic characteristics automatically, besides POS tags the head and modifier in a dependency, we also use their preceding and following one and two words along with their POS tags.

Another important fact is that verbal phrases in the dependency tree structure of a parse are normally the root node of the whole dependency tree or the parent node of a subtree. When a word pair that contains a verbal phrase between them, the two words are always on different sides of a parent node. Thus, these kinds of word pairs will always have no dependency link between them. This leads to the fact that argument pairs that have a verb between them rarely have a dependency relation. Observing whether there are verbal phrases between a head-modifier pairs can help judge whether the dependency between them is reliable.

The input of our high quality dependency selection method is a dependency tree. It is very natural to use tree-based features to identify the quality of dependencies. Based on a head-modifier dependency pair, we observe modifier’s modifiers, i.e. children nodes. We use the leftmost and rightmost of children nodes to represent all the children nodes. We also take head’s parent node into consideration, which we call a modifier’s grandparent node. Furthermore, children nodes of the

grandparent node which we call a modifier’s uncle nodes are also considered as other features. Similarly, we use leftmost and rightmost uncle nodes.

## 4 Experiments

### 4.1 Experimental Settings

We first experiment on English, Chinese and Japanese. For English, we employ MSTparser<sup>1</sup> as a base dependency parser and use sections 02 to 21 from Wall Street Journal (WSJ) corpus in Penn Treebank (PTB) to train a dependency parsing model. Then, we use section 22 from WSJ to apply the dependency parsing model to acquire the training data for dependency classification. MXPOST<sup>2</sup> tagger is used for English automatic POS tagging. For Chinese, we use CNP (Chen et al., 2009) parser to train a dependency parser using section 1 to 270, 400 to 931 and 1001 to 1151 from Penn Chinese Treebank (CTB). Sections 301 to 325 are used to apply dependency parsing to acquire training data for dependency classification. We use MMA (Kruengkrai et al., 2009) to apply both segmentation and POS tagging. Different from the previous two languages which take *words* as the basic unit, experiments on Japanese are based on the unit of the phrase segments *bunsetsu*. We first use JUMAN<sup>3</sup> for Japanese morphological analysis. Then KNP<sup>4</sup> is utilized for Japanese dependency parsing. Section 950112, 950113 and 9509ED from Kyoto Corpus are used to apply dependency parsing and acquire training data for dependency selection.

We employ SVM-Light<sup>5</sup> with polynomial kernel (degree 3) to solve the binary classification. In order to compare with previous work by Yu et al. (2008), we use the basic feature set as a baseline. For English, section 23 from WSJ is used as a test set. Section 271 to 300 from CTB, and section 950114 to 950117 and 9510ED to 9512ED from Kyoto Corpus are used to test the classification approach in Chinese and Japanese, respectively. are used to test the classification approach in Chinese and Japanese respectively.

<sup>1</sup><http://sourceforge.net/projects/mstparser/>

<sup>2</sup>[http://www.inf.ed.ac.uk/resources/nlp/local\\_doc/MXPOST.html](http://www.inf.ed.ac.uk/resources/nlp/local_doc/MXPOST.html)

<sup>3</sup><http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?JUMAN>

<sup>4</sup><http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?KNP>

<sup>5</sup><http://svmlight.joachims.org>

According to the output of the SVM, we only select dependencies that have the score higher than a threshold. Precision is calculated as the ratio of correct dependencies in retrieved ones. Recall is the ratio of correct dependencies in total. In Chinese and Japanese, we treat incorrect segmentations as incorrect dependencies. Note that the maximum recall value equals the precision of base dependency parser without dependency selection.

### 4.2 Experimental Results

#### 4.2.1 Effectiveness of Dependency Selection

Figure 2 shows the precision-recall curves of the classification using SVM for three languages. In these graphs, ‘basic’ means the method using the basic features, ‘context’ stands for the method with context information, and ‘context+tree’ means the method with additional tree-based features.

One of the biggest problems that most data-driven parsers are facing is the domain adaption problem. When they are applied to a text of a different domain, their accuracy decreases significantly. We applied the dependency parsing model trained on WSJ to the Brown corpus, and obtained an unlabeled attachment score of 0.832, which is significantly lower than the in-domain score by 8.1%. We applied the same dependency selection model trained on WSJ to the Brown corpus. Figure 4 shows the precision-recall curves of dependency selection on the Brown corpus. From the results, we can see that when the recall is 40% for example, high quality dependencies with a precision of over 95% can be acquired. This shows that our method works well on data from different domains. This fact creates a good way to acquire knowledge from a large raw corpus in different domains (e.g., the Web).

#### 4.2.2 Statistics of Selected Dependencies

In this section, in order to know what kind of dependencies are mainly selected, we show an investigation on the distribution of types of dependencies. Each dependency type in English and Chinese is represented by the coarse-grained POS pairs (the first two characters of POS names). Japanese dependencies are represented by the translated POS tags of *Bunsetsu* pairs. Figure 3 shows the statistics of POS pairs in three different languages. the leftmost graphs are drawn without selection. The middle and right graphs stand for

Figure 2: Precision-recall curves of dependency classification for English (left), Japanese (middle) and Chinese (right)

Figure 3: Statistics of POS tags of dependencies in different languages: dependencies without selection (left), dependencies when recall is 50% (middle), dependencies when recall is 20% (right)

the dependencies selected under different thresholds (i.e., recall is 20% and recall is 50% respectively). We found that dependencies with nouns are dominant in all the types for all the languages. Secondly, dependencies related to verbs which are very informative patterns account for a large proportion.

## 5 Conclusion and Future Work

In this paper, we proposed a classification approach for high quality dependency selection. We created new sets of features to select highly reliable dependencies from each parse through a parser. The experiments showed that our method worked for in-domain parses and also out-of-domain parses. We can extract high quality dependencies from a large corpus such as the Web and subsequently assist knowledge acquisition tasks,

Figure 4: Precision-recall curves of dependency selection on Brown corpus

such as subcategorization frame acquisition and case frame compilation (Kawahara and Kurohashi, 2010), which depends highly on the parse quality. We also plan to use a bootstrapping strategy to improve a dependency parser based on acquired high quality knowledge from large corpora.

## Abstract

This paper presents an extension of the standard approach used for bilingual lexicon extraction from comparable corpora. We study the ambiguity problem revealed by the seed bilingual dictionary used to translate context vectors and augment the standard approach by a Word Sense Disambiguation process. Our aim is to identify the translations of words that are more likely to give the best representation of words in the target language. On two specialized French-English and Romanian-English comparable corpora, empirical experimental results show that the proposed method consistently outperforms the standard approach.

## 1 Introduction

Over the years, bilingual lexicon extraction from comparable corpora has attracted a wealth of research works (Fung, 1998; Rapp, 1995; Chiao and Zweigenbaum, 2003). The main work in this research area could be seen as an extension of Harris's *distributional hypothesis* (Harris, 1954). It is based on the simple observation that a word and its translation are likely to appear in similar contexts across languages (Rapp, 1995). Based on this assumption, the alignment method, known as the *standard approach* builds and compares context vectors for each word of the source and target languages.

A particularity of this approach is that, to enable the comparison of context vectors, it requires the existence of a seed bilingual dictionary to translate source context vectors. The use of the bilingual dictionary is problematic when a word has several translations, whether they are synonymous or

polysemous. For instance, the French word *action* can be translated into English as *share*, *stock*, *lawsuit* or *deed*. In such cases, it is difficult to identify in flat resources like bilingual dictionaries, wherein entries are usually unweighted and unordered, which translations are most relevant. The standard approach considers all available translations and gives them the same importance in the resulting translated context vectors independently of the domain of interest and word ambiguity. Thus, in the financial domain, translating *action* into *deed* or *lawsuit* would probably introduce noise in context vectors.

In this paper, we present a novel approach which addresses the word ambiguity problem neglected in the standard approach. We introduce a use of a WordNet-based semantic similarity measure permitting the disambiguation of translated context vectors. The basic intuition behind this method is that instead of taking all translations of each seed word to translate a context vector, we only use the translations that are more likely to give the best representation of the context vector in the target language. We test the method on two comparable corpora specialized on the Breast Cancer domain, for the French-English and Romanian-English pair of languages. This choice allows us to study the behavior of the disambiguation for a pair of languages that are richly represented and for a pair that includes Romanian, a language that has fewer associated resources than French and English.

## 2 Related Work

Recent improvements of the standard approach are based on the assumption that the more the context vectors are representative, the better the bilingual lexicon extraction is. Prochasson et al. (2009)

used transliterated words and scientific compound words as ‘anchor points’. Giving these words higher priority when comparing target vectors improved bilingual lexicon extraction. In addition to transliteration, Rubino and Linarès (2011) combined the contextual representation within a thematic one. The basic intuition of their work is that a term and its translation share thematic similarities. Hazem and Morin (2012) recently proposed a method that filters the entries of the bilingual dictionary based upon POS-tagging and domain relevance criteria, but no improvements was demonstrated.

Gaussier et al. (2004) attempted to solve the problem of different word ambiguities in the source and target languages. They investigated a number of techniques including canonical correlation analysis and multilingual probabilistic latent semantic analysis. The best results, with a very small improvement were reported for a mixed method. One important difference with Gaussier et al. (2004) is that they focus on words ambiguities on source and target languages, whereas we consider that it is sufficient to disambiguate only translated source context vectors.

### 3 Context Vector Disambiguation

The approach we propose augments the standard approach used for bilingual lexicons mining from comparable corpora. As it was mentioned in section 1, when the lexical extraction applies to a specific domain, not all translations in the bilingual dictionary are relevant for the target context vector representation. For this reason, we introduce a WordNet-based WSD process that aims at improving the adequacy of context vectors and therefore improve the results of the standard approach.

A large number of WSD techniques were previously proposed in the literature. The most popular ones are those that compute semantic similarity with the help of existing thesauri such as WordNet (Fellbaum, 1998). This thesaurus has been applied to many tasks relying on word-based similarity, including document (Hwang et al., 2011) and image (Cho et al., 2007; Choi et al., 2012) retrieval systems. In this work, we use this resource to derive a semantic similarity between lexical units within the same context vector. To the best of our knowledge, this is the first application of WordNet to the task of bilingual lexicon extraction from comparable corpora.

Once translated into the target language, the context vectors disambiguation process intervenes. This process operates *locally* on each context vector and aims at finding the most prominent translations of polysemous words. For this purpose, we use monosemic words as a seed set of disambiguated words to infer the polysemous word’s translations senses. We hypothesize that a word is monosemic if it is associated to only one entry in the bilingual dictionary. We checked this assumption by probing monosemic entries of the bilingual dictionary against WordNet and found that 95% of the entries are monosemic in both resources.

Formally, we derive a semantic similarity value between all the translations provided for each polysemous word by the bilingual dictionary and all monosemic words appearing within the same context vector. There is a relatively large number of word-to-word similarity metrics that were previously proposed in the literature, ranging from path-length measures computed on semantic networks, to metrics based on models of distributional similarity learned from large text collections. For simplicity, we use in this work, the Wu and Palmer (1994) (WUP) path-length-based semantic similarity measure. It was demonstrated by (Lin, 1998) that this metric achieves good performances among other measures. WUP computes a score (equation 1) denoting how similar two word senses are, based on the depth of the two synsets ( $s_1$  and  $s_2$ ) in the WordNet taxonomy and that of their Least Common Subsumer ( $LCS$ ), i.e., the most specific word that they share as an ancestor.

$$WupSim(s_1, s_2) = \frac{2 \times depth(LCS)}{depth(s_1) + depth(s_2)} \quad (1)$$

In practice, since a word can belong to more than one synset in WordNet, we determine the semantic similarity between two words  $w_1$  and  $w_2$  as the maximum  $WupSim$  between the synset or the synsets that include the  $synsets(w_1)$  and  $synsets(w_2)$  according to the following equation:

$$SemSim(w_1, w_2) = \max\{WupSim(s_1, s_2); (s_1, s_2) \in synsets(w_1) \times synsets(w_2)\} \quad (2)$$

Then, to identify the most prominent translations of each polysemous unit  $w_p$ , an *average similarity* is computed for each translation  $w_p^j$  of  $w_p$ :

$$AveSim(w_p^j) = \frac{\sum_{i=1}^N SemSim(w_i, w_p^j)}{N} \quad (3)$$

Corpus	French	English
	396,524	524,805
Corpus	Romanian	English
	22,539	322,507

Table 1: Comparable corpora sizes in term of words.

where  $N$  is the total number of monosemic words and  $Sem_{Sim}$  is the similarity value of  $w_p^j$  and the  $i^{th}$  monosemic word. Hence, according to average relatedness values  $Ave\_Sim(w_p^j)$ , we obtain for each polysemous word  $w_p$  an ordered list of translations  $w_p^1 \dots w_p^n$ . This allows us to select translations of words which are more salient than the others to represent the word to be translated.

## 4 Experiments and Results

### 4.1 Resources

#### 4.1.1 Comparable corpora

We conducted our experiments on two French-English and Romanian-English comparable corpora specialized on the *breast cancer* domain. Both corpora were extracted from Wikipedia<sup>1</sup>. We consider the topic in the source language (for instance *cancer du sein* [breast cancer]) as a query to Wikipedia and extract all its sub-topics (i.e., sub-categories in Wikipedia) to construct a domain-specific *category tree*. Then, based on the constructed tree, we collect all Wikipedia pages belonging to one of these categories and use *inter-language links* to build the comparable corpus. Both corpora were normalized through the following linguistic preprocessing steps: tokenisation, part-of-speech tagging, lemmatisation, and function word removal. The resulting corpora<sup>2</sup> sizes are given in Table 1.

#### 4.1.2 Bilingual dictionary

The French-English bilingual dictionary used to translate context vectors consists of an in-house manually revised bilingual dictionary which contains about 120,000 entries belonging to the general domain. It is important to note that words has on average 7 translations in the bilingual dictionary. The Romanian-English dictionary consists of translation pairs extracted from Wikipedia.

<sup>1</sup><http://dumps.wikimedia.org/>

<sup>2</sup>Comparable corpora will be shared publicly

The resulting bilingual dictionary contains about 136,681 entries for Romanian-English with an average of 1 translation per word.

#### 4.1.3 Evaluation list

In bilingual terminology extraction from comparable corpora, a reference list is required to evaluate the performance of the alignment. Such lists are usually composed of about 100 single terms (Hazem and Morin, 2012; Chiao and Zweigenbaum, 2002). Here, we created a reference list<sup>3</sup> for each pair of language. The French-English list contains 96 terms extracted from the French-English MESH and the UMLS thesauri<sup>4</sup>. The Romanian-English reference list was created by a native speaker and contains 38 pair of words. Note that reference terms pairs appear at least five times in each part of both comparable corpora.

### 4.2 Experimental setup

Three other parameters need to be set up: (1) the window size, (2) the association measure and the (3) similarity measure. To define context vectors, we use a seven-word window as it approximates syntactic dependencies. Concerning the rest of the parameters, we followed Laroche and Langlais (2010) for their definition. The authors carried out a complete study of the influence of these parameters on the bilingual alignment and showed that the most effective configuration is to combine the Discounted Log-Odds ratio (equation 4) with the cosine similarity. The Discounted Log-Odds ratio is defined as follows:

$$Odds-Ratio_{disc} = \log \frac{(O_{11} + \frac{1}{2})(O_{22} + \frac{1}{2})}{(O_{12} + \frac{1}{2})(O_{21} + \frac{1}{2})} \quad (4)$$

where  $O_{ij}$  are the cells of the  $2 \times 2$  contingency matrix of a token  $s$  co-occurring with the term  $S$  within a given window size.

### 4.3 Results and discussion

It is difficult to compare results between different studies published on bilingual lexicon extraction from comparable corpora, because of difference between (1) used corpora (in particular their construction constraints and volume), (2) target domains, and also (3) the coverage and relevance of linguistic resources used for translation. To the best of our knowledge, there is no common benchmark that can serve as a reference. For this reason,

<sup>3</sup>Reference lists will be shared publicly

we use the results of the standard approach (SA) as a reference. We evaluate the performance of both the SA and ours with respect to Top20 F-Measure which computes the harmonic mean between precision and recall.

Our method provides a ranked list of translations for each polysemous word. A question that arises here is whether we should introduce only the best ranked translation in the context vector or consider a larger number of words, especially when a translations list contain synonyms. For this reason, we take into account in our experiments different number of translations, noted WN-T<sub>*i*</sub>, ranging from the pivot translation ( $i = 1$ ) to the seventh word in the translations list. This choice is motivated by the fact that words in the French-English corpus have on average 7 translations in the bilingual dictionary. The baseline (SA) uses all translations associated to each entry in the bilingual dictionary. Table 2a displays the results obtained for the French-English comparable corpus. The first substantial observation is that our method which consists in disambiguating polysemous words within context vectors consistently outperforms the standard approach. The maximum F-measure was obtained by LESK when for each polysemous word up to four translations (WN-T<sub>4</sub>) are considered in context vectors. This method achieves an improvement of +10% and over the standard approach.

Concerning the Romanian-English pair of lan-

guage, no improvements have been reported. The reason being that words in the bilingual dictionary are not heavily polysemous. Each word used to shape context vectors is associated to only one translation in the bilingual dictionary.

## 5 Conclusion

We presented in this paper a novel method that extends the standard approach used for bilingual lexicon extraction from comparable corpora. The proposed method disambiguates polysemous words in context vectors and selects only the translations that are most relevant to the general context of the corpus. Conducted experiments on a highly polysemous specialized comparable corpus show that integrating such process leads to a better performance than the standard approach. Although our initial experiments are positive, we believe that they could be improved in a number of ways. It would also be interesting to mine much more larger comparable corpora and focus on their quality as presented in (Li and Gaussier, 2010). We want also to test our method on bilingual lexicon extraction for a larger panel of specialized corpora, where disambiguation methods are needed to prune translations that are irrelevant to the domain.

yoshino@ar.media.kyoto-u.ac.jp

## Abstract

We present a novel scheme of predicate argument structure analysis that can be trained from partially annotated corpora. In order to allow partial annotation, this semantic role labeler does not require word dependency information. The advantage of partial annotation is that it allows for smooth domain adaptation of training data and improves the adaptability to a variety of domains.

## 1 Introduction

The predicate-argument (P-A) structure is one of the most fundamental and important representations in linguistics (Fillmore, 1968). Many applications use P-A structure as a component, for example, QA systems (Shen and Lapata, 2007), text mining systems (Wang and Zhang, 2009), and a spoken dialogue systems (Yoshino et al., 2011).

P-A structure analysis is regarded as a task of semantic role labeling (SRL). A semantic role represents a meaning of the components in P-A structure (i.e. Propbank (Palmer et al., 2005), FrameNet (Baker et al., 1998), and NAIST Text Corpus (NTC) (Iida et al., 2007b)). Traditional P-A structure analyzers estimate the semantic role labels for an input sentence by referring to a model trained on data annotated with not only semantic role labels but also dependency labels (Surdeanu et al., 2008; Hajič et al., 2009). Most of the previous approaches to P-A structure analysis assume full annotation for P-A structures and the lower layer labels: word boundaries, parts of speech (POS), and dependencies. Given a corpus fully annotated with them, the structural prediction approach was shown to be effective (Watanabe et al., 2010). However, this pre-annotation incurs high annotation costs which prevent us from adapting the analyzer to new domains. Having training data that are representative of a domain is essential for constructing a robust semantic role labeler (Pradhan et al., 2008) because the important information structures are specific to each domain (R.Grishman, 2003). Fully annotated corpus

in target domain is not available in realistic cases, and it is difficult to apply the current supervised approaches to a new domain.

When annotating only the domain-specific area, the use of a partially annotated corpus (Tsuboi et al., 2008; Sassano and Kurohashi, 2010) that allows incomplete annotations improves accuracy efficiently and reduce the number of annotations. The pointwise approach (Neubig and Mori, 2010) enables efficient use of such incomplete language resources in word segmentation tasks and requires only partial annotations for the relevant tasks and lower layer annotations on which they depend. We design a new P-A structure analysis method that enables us to directly estimate semantic role labels by referring to a model that is trained from a corpus that includes only partially annotated tag information without word dependencies.

## 2 Predicate argument structure analysis

In this section, we give a brief explanation of P-A structure and its problems. Then, we describe the typical method of structural prediction for this task based on supervised machine learning.

### 2.1 Predicate-argument (P-A) structure

A predicate-argument (P-A) structure is a relationship between a verbal expression and its arguments, such as the subject, the direct object, and the indirect object. Predicate  $P$  in a document  $D$  has arguments  $A_1, A_2, \dots, A_n$  that have a semantic role  $S_1, S_2, \dots, S_n$ . The notion we used is defined in NAIST Text Corpus (NTC) (Iida et al., 2007b), Japanese text corpora annotated with coreference and P-A relations, which include annotations of subject, direct object, and indirect object. Every case has a property of **depend** or **zero**, and these P-A structure relations are annotated not only predicates, but also event nouns (Komachi et al., 2007).

**Figure 5** shows an example of P-A structures in the NTC. These tags have two properties, one is **depend** or **zero**, the other is *intra* or *inter*. **depend** or **zero** indicates whether or not the argument has a dependency on the predicate, and *intra*

or *inter* indicates whether or not the argument and the predicate exist in the same sentence. NTC also includes annotations of coreference, which we converted into P-A structure tags. As shown in **Figure 1**, P-A structure is located in a higher layer of linguistics that approaches natural language understanding (NLU), and this structure depends on some more basic but much more frequent linguistic phenomena: word boundaries, part of speech (POS), and word dependencies.

Figure 1: Size of linguistic phenomena.

## 2.2 Typical solution

The typical solution divides the P-A structure prediction into two problems: semantic role labeling (SRL) (Johansson and Nugues, 2008; Björkelund et al., 2009) and zero-anaphora resolution (Iida et al., 2007a; Sasano and Kurohashi, 2009).

The typical approach requires three preprocessing steps: word segmentation, POS tagging, and dependency parsing. After the preprocessing, the task of SRL improves assigning semantic role labels to the edges in word dependencies. A semantic role labeler performs two tasks: predicate sense estimation, and SRL. Zero-anaphora resolution is treated as an independent problem from the SRL task in the previous research. The zero-anaphora problem is caused by the ellipsis of shared words, and it is a gap in a sentence that has an anaphoric function (Iida et al., 2007a). Some semantic relationships exist in which there is no dependency relationship between their arguments and predicates; this is called zero anaphora.

The task of P-A structure analysis goes beyond the syntactic problem and comes down to a semantic problem to fill in the words that are semantically omitted. Various special approaches can be applied after SRL to solve this problem (Sasano and Kurohashi, 2009; Iida and Poesio, 2011; Hayashibe et al., 2011). Some approaches adopt a *Salience Reference List* (Nariyama, 2002) based on the 1-best argument decision model.

## 2.3 Open problems in P-A structure analysis

Existing approaches require full annotation of word boundaries, POS tags, and word dependencies to use them as features. Most previous approaches to P-A structure tasks assume full annotation for these lower layers. However, the number of linguistic phenomena decreases as we go higher up the NLP layers as shown in Figure 1. Thus, to prepare only one training example for an existing

Translation 1: The Yankees beat the Mariners.

Translation 2: As a result, the Yankees (omitted) reached to the top.

Figure 2: Example of training data made from partially annotated corpus.

P-A structure analyzer, we need to annotate the entire document. To make it worse, these kinds of annotations are costly and difficult for untrained annotators. This difficulty interferes with efficient language resource preparation and reduces domain portability. However, the accuracy of P-A structure analysis increases in accordance with the data size. This indicates that we can realize an improvement just by easily preparing more training data for the target domain document.

## 3 Partial annotation for P-A structures

Partial annotation allows annotators to focus on efficient examples in the target domain document, and to maximize the cost-effectiveness of annotation. For automatic word segmentation and POS tagging, the scheme allows partial annotation of corpus (Tsuboi et al., 2008; Neubig and Mori, 2010; Neubig et al., 2011) and achieves high accuracy and domain portability though annotation of domain-specific areas. Neubig et al. (2011) report that a comparable accuracy to a CRF-based sequential labeling method can be achieved without referring to the estimated labels for unlabeled words. They call this method a pointwise approach. Even with the pointwise assumption, we can estimate labels as accurately as sequential labeling just by referring to the appropriate features.

We design a P-A structure analyzer that directly estimates the semantic role labels by referring to a model that is trained from a corpus. It includes only partially annotated POS tags but not with dependency information for the following reasons. Automatic estimation of POS tags achieves high accuracy in domain adaptation cases, and the annotation cost is small (Neubig et al., 2011), but the accuracy for dependency parsing (Flannery et al., 2011; Sassano and Kurohashi, 2010) is not sufficiently high. However, handcraft annotation cost of dependency is so high, and it disturbs rapid preparation of annotation data.

We show an example of a partially annotated corpus in **Figure 2**. The annotation of “reach” is incomplete, and the information that can be referred to by an analyzer is the fully annotated word boundaries, POS tags, and partially annotated P-A tags. Word boundaries and POS tags are output by

Table 1: Features of SRL:  $w_p$  is a predicate,  $w_a$  is an argument candidate,  $t_i$  is the POS tag of  $w_i$ .

type	feature
word 1-gram	$w_{p-3}, w_{p-2}, w_{p-1}, w_p, w_{p+1}, w_{p+2}, w_{p+3}, w_{a-3}, w_{a-2}, w_{a-1}, w_a, w_{a+1}, w_{a+2}, w_{a+3}$
word 2-gram	$w_{p-1}w_p, w_pw_{p+1}, w_{a-1}w_a, w_a w_{a+1}$

pairwise	Pairs of POS tags located -2 – +2. Pairs of <b>arg</b> candidate and <b>pred</b> .
distance	Number of <b>pred</b> between the candidate and <b>preds</b>
binary	(1) Closest candidate that has target particle on the right side or not. (2) First candidate that has target particle on the right side or not. (3) The predicate has a slot of target semantic case or not.

a domain-adapted morphological analyzer, and the annotator tags three P-A tags.

## 4 Pointwise P-A structure analysis

In our proposed scheme, syntactic ambiguity resolution and predicate sense disambiguation are not used, in order to achieve easy adaptation. We propose two sequential processes for P-A structure analysis that is trained from partially annotated corpora. Following the discussion in Section 3, we do not assume the dependency structures.

### 4.1 Case existence detection

The first step in the proposed sequential analysis is case existence estimation. The given semantic cases differ according to the type of the predicate. This predicate and semantic case behavior strongly affects the SRL task.

The oracle of the case existence is used for SRL features. For example, the predicate “bet” in Figure 5 contains information indicating that the predicate has two kinds of argument: “subject, zero” and “direct object depend.” We assume that the case existence for each predicate can be estimated with case frames (Kawahara and Kurohashi, 2006). A case frame is a set of a predicate and its potential arguments. It is known that the case frames contribute to the P-A structure analysis performance (Sasano et al., 2008).

### 4.2 SRL and zero-anaphora resolution

The second step is SRL that includes zero-anaphora resolution. We handle the problem with a direct approach for SRL that is redefined as a binary classification problem for the pair of an argument candidate and a predicate. Labeled pairs of argument (**arg**) and predicate (**pred**) are used as positive training example and unlabeled pairs are used as negative training example. In the example of Figure 5, the pair of “fate” and “party” is

a positive example Y, and pairs of “fate” and other candidates are negative examples N.

The features used for classification are listed in **Table 1**. We use simple  $n$ -gram features based on words and POS tags. The pairwise features are POS pairs located at positions from -2 to +2, and pairs of the predicate and the argument candidates. The distance between the argument candidate and the predicate is used as a feature. We used the number of predicates between the predicate and the argument candidate as this feature. Binary features (1) and (2) are based on a previous study on “Centering” theory (Grosz et al., 1995). In this theory, subjects are frequently omitted, and the first candidate tends to be a subject. By contrast, objects are not omitted, and the last candidate tends to be an object. To apply the theory to a pointwise approach, we define features that are independent of syntactic structure. Finally, the result of the processing described above is used as a binary feature (3).

### 4.3 Issues in partial annotation

Two problems arise in applying the classifier to a partially annotated corpus without dependency. First, in existing studies P-A structure analysis leverages a property of the P-A tags **depend** and **zero** (Iida et al., 2007b). Here, **depend** represents that the P-A tag is added on the edge of dependency, and **zero** means the pair of the predicate and argument does not have a relationship of dependency (=zero anaphora). However, it is impossible to use dependency information in our framework, and the attribution makes it difficult to detect the property of the P-A tag. To cope with this problem, we use sentence boundaries, which are trivial in unlabeled documents, for grouping the training set. The other problem is how to create training examples from incomplete annotations. To allow the incomplete annotation perfectly, we incorporate positive examples that are clearly annotated.

## 5 Evaluations

We conducted three experiments to evaluate the proposed method: SRL, corpus size discrimination, and domain adaptation.

### 5.1 Experimental settings

We use the NTC (Iida et al., 2007b) which is annotated with P-A relations and coreferences. The NTC is constructed from Japanese newspaper articles, and has two domains: news and editorials. In the NTC, there are three different types of annotation on pairs of predicates and their arguments: subject, direct object, and indirect object. Every tag has a property of **depend** or **zero**. The

total		<b>0.602</b>	<b>0.366</b>	<b>0.455</b>
cf. ( <i>inter</i> )	subject	0.221	0.273	0.244
	d. obj.	0.050	0.101	0.066
	i. obj.	0.030	0.023	0.026

NTC has lower layer annotations: word boundaries, POS, and segment-based dependencies. We used the word segments and POS tags as-is, and constructed P-A classifiers. We evaluated the proposed SRL in the newspaper article domain. We used linear support vector machine (SVM) (Fan et al., 2008) with the one-versus-rest method, by using the features described in Table 1.

## 5.2 Evaluation of SRL

The results using 5-fold cross validation are listed in **Table 2** and **3**. Evaluations that are classified with the existing *depend* and *zero* property are given in Table 2. Classifiers used in “w.o. feat. (3)” do not refer to case existence features (the binary feature (3) in Table 1). We can see that case frames play a large role in improving the labeling accuracy. This *depend* and *zero* property is based on the dependency, which cannot be referred to in the pointwise approach. As an alternative, we used sentence boundaries for the tag classification and Table 3 shows the result. The bottom “cf.” rows in Tables 2 and 3 are the result of the previous work (Sasano and Kurohashi, 2011) for comparison<sup>1</sup>. In the comparison, the accuracies of our work are comparable to the accuracies of the previous work. By comparing the total F mea-

<sup>1</sup>Sasano and Kurohashi discussed this task, but the article is written in Japanese. They evaluated the accuracy for zero anaphora in two models: *intra* and *inter*, and we calculated the weighted mean of them for fair comparison.

Figure 3: Effect of corpus size in *intra* case.

Figure 4: Effect of corpus size in *inter* case.

sure in Table 2 (0.413) and that in Table 3 (0.455), we can say that this *intra* and *inter* property works better than the *depend* and *zero* property in our pointwise classifier.

## 5.3 Effect of corpus size

We show the relationship between the training corpus size and the accuracy in **Figures 3** and **4**. The horizontal axes of these graphs are the log-scaled corpus size. The graphs show that P-A structure analysis accuracy increases linearly in proportion to the log-scaled data size and do not saturate. This result supports our framework of efficient resource usage.

## 6 Conclusion

We presented a novel scheme of P-A structure analysis based on the pointwise approach that makes it possible to use partially annotated corpora. This paper can be seen as an extension of the pointwise approach to a higher NLP layer that allows us to concentrate annotation work on the focused task. The results indicated that our scheme reduces the cost of constructing language resource and makes it easy to adapt the P-A structure analyzer while maintaining comparable accuracy to current analysis frameworks.

In future work, we plan to evaluate our pointwise P-A resolution method in the domain adaptation case in terms of personal costs of annotation and investigate improving accuracy by using other estimated information.

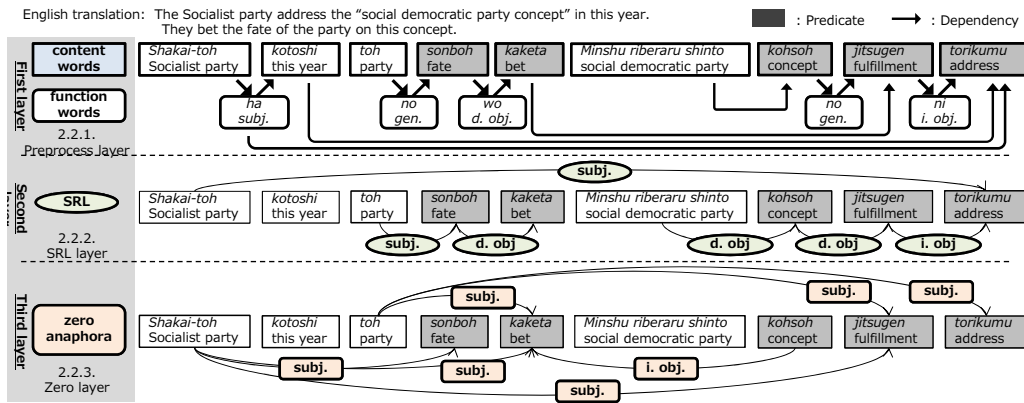

Figure 5: Example of P-A structure analysis.

## A Figure 5 shows an example of P-A

## Abstract

We present a method of statistical dialogue management using a directed intention dependency graph (IDG) in a partially observable Markov decision process (POMDP) framework. The transition probabilities in this model involve information derived from a hierarchical graph of intentions. In this way, we combine the deterministic graph structure of a conventional rule-based system with a statistical dialogue framework. The IDG also provides a reasonable constraint on a user simulation model, which is used when learning a policy function in POMDP and dialogue evaluation. Thus, this method converts a conventional dialogue manager to a statistical dialogue manager that utilizes task domain knowledge without annotated dialogue data.

## 1 Introduction

Statistical approaches based on reinforcement learning, such as the Markov decision process (MDP) and partially observable Markov decision process (POMDP), have been successfully applied to dialogue management (Levin et al., 2000; Williams and Young, 2007; Li, 2012). These approaches allow us to consider all possible future actions of a dialogue system, and thus to obtain a new optimal dialogue strategy which could not be anticipated in conventional hand-crafted dialogue systems. Moreover, the statistical dialogue framework can be combined with conventional rule-based dialogue management in hybrid systems, (Williams, 2008; Lee et al., 2010), which combine the optimal dialogue strategy in the statistical approach with the lower cost of data and maintenance of the rule-based approach.

Our research focuses on a practical application of a hybrid statistical dialogue management based

on POMDP to conventional rule-based dialogue management via the use of an intention dependency graph (IDG). The IDG derives from the conventional rule-based dialogue system (Dahl et al., 1994; Bohus and Rudnicky, 2003), and it constrains the transition matrix and provides a user simulation as a substitute for dialogue data.

The object of POMDP optimization is to produce a policy that maps from user states to system actions such that the overall expected cost of the dialogue is minimized. Such optimization typically requires data from dialogue corpora, which are manually annotated with task-oriented dialogue-act tags. On the other hand, the benefit of a hybrid approach is that human domain knowledge can be used to constrain the possible user states in the dialogue manager. We follow this idea by using an IDG, which expresses the task-domain knowledge through a directed graph of states from more general intention categories to more specific parameters of the intention categories. **Figure 1** shows an example of such a graph, where each node is associated with a (potentially partial) user intention. In previous studies, this kind of domain knowledge is used to restrict the user state and system action state space (Lemon et al., 2006; Williams, 2008; Young et al., 2010; Varges et al., 2011). However, our approach does not restrict the possible system action states, but transfers the information structure to the definition of user simulation and state transition probabilities. The system is allowed to consider all possible system actions by following the user states that reflect the IDG.

## 2 Statistical dialogue management

The main random variables involved at a dialogue turn  $t$  are as follows.  $s^t = i \in \mathcal{I}_s$  is the hidden true user state at turn  $t$ . It is constrained by the hidden user goal  $g \in \mathcal{I}_g$  and the true user state at the previous turn.  $o^t = l \in \mathcal{I}_s$  is the observation

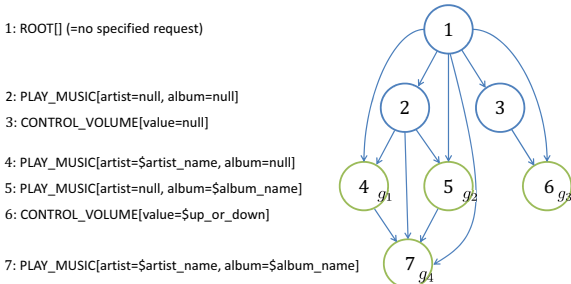

Figure 1: An example of a directed intention dependency graph.

of the user state by the system. It includes errors caused by automatic speech recognition (ASR), natural language understanding (NLU) and intention understanding (IU). Uncertainty on the observation  $o^t$  caused by errors in the preprocessor (ASR, NLU, and IU) is encompassed in the conditional probability  $O_{li}^t = p(o^t = l | s^t = i)$ .  $a^t = k \in \mathcal{K}$  is the system action.  $\hat{k}$  is the optimal system action that is acquired in the learning step. The goal of statistical dialogue management is to output an optimal system action  $\hat{a}^t = \hat{k}$  given an observation  $o^t$ , based on the probability of  $s^t$  in a soft decision manner. The probability of the user state  $s^t$  given an observation sequence  $o^{1:t}$  from 1 to  $t$  with confidence  $O^{1:t}$  is denoted by  $b_i^t = p(s^t = i | o^{1:t}; O^{1:t})$ , and referred to as ‘‘belief’’. To avoid clutter, we will usually omit  $O^{1:t}$ .

## 2.1 Belief update

We consider a belief update equation based on the graphical model shown in **Figure 2**, assuming that the system actions  $a^{1:t}$  are given. We can obtain the following update equation from  $b_i^t$  to  $b_{i'}^{t+1}$ :

$$b_{i'}^{t+1} = p(s^{t+1} = i' | o^{1:t+1}) \quad (1)$$

$$\propto \sum_i p(o^{t+1}, i' | i) (b_i^t)^\beta, \quad (2)$$

where  $\beta$  is a forgetting factor for the belief, and  $0 \leq \beta \leq 1$ . Then, by introducing the system action  $a^t = k$  based on the sum rule, we can rewrite  $p(o^{t+1}, i' | i)$  in Eq. (2) as follows:

$$\begin{aligned} \sum_k p(o^{t+1}, i', k | i) &= \sum_k p(o^{t+1}, i' | i, k) \delta_{\hat{k}k} \\ &= p(o^{t+1} | i') p(i' | i, \hat{k}) \end{aligned} \quad (3)$$

where  $p(k | i) = \delta_{\hat{k}k}$  is obtained by the decision making step in the POMDP. We rewrite the distributions in Eq. (3) as follows:  $p(i' | i, \hat{k}) = T_{ii'\hat{k}}$

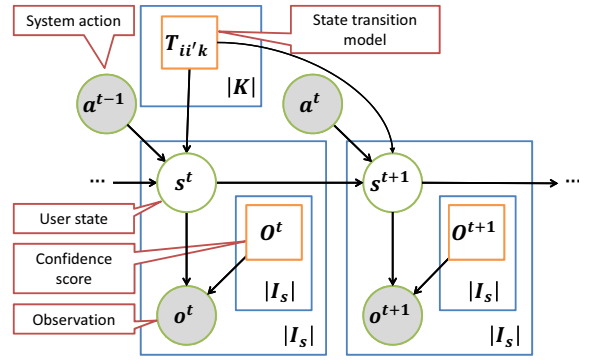

Figure 2: Graphical model of user state sequences given system actions  $a^{t-1}$  and  $a^t$ . This graphical model shows user behavior that is observed from the system.

and  $p(o^{t+1} = l | i') = O_{li'}^{t+1}$ .  $T_{ii'\hat{k}}$  are the user state transition probabilities given system action  $\hat{k}$ , and  $O_{li'}^{t+1}$  are the confidence scores given by the pre-processor. In conventional studies, the state transition probabilities  $T_{ii'\hat{k}}$  are learned from annotated data. In our scheme, the probabilities can be obtained by using the IDG, as described in Section 3.4. We finally obtain

$$b_{i'}^{t+1} \propto O_{li'}^{t+1} \sum_i T_{ii'\hat{k}} (b_i^t)^\beta. \quad (4)$$

Once the system estimates the belief  $b_i^t$ , it can output the optimal action  $\hat{a}^t$  as  $\hat{a}^t = \pi^*(\{b_i^t\}_{i=1}^{|I_s|})$ .  $\pi$  is called a policy function, and  $\pi^*$  is an optimal policy function pre-computed in the learning step described in the following Section.

## 2.2 Learning step

The aim of the learning step in reinforcement learning is to acquire the best policy  $\pi^*$ . Many algorithms formulated to solve the reinforcement learning problem have been proposed (Shani et al., 2013). While most advanced algorithms require transition probabilities  $T_{ii'\hat{k}}$  that are calculated using annotated corpora, our approach aims at learning a POMDP without any data. We thus use one of the most basic algorithms, Q-learning (Watkins and Dayan, 1992), as it can acquire the policy without using transition probabilities. Q-learning relies on the estimation of a Q-function  $Q(b^t, a^t)$ , which computes the expected future reward of a system action  $a^t$  at dialogue turn  $t$  given the current belief  $b^t = \{b_i^t\}_{i=1}^{|I_s|}$  of the user state. The Q-function can be obtained by iterative updates on training dialogue data. The up-

dates do not involve the transition probabilities  $T_{ii'k}$ , thus we can acquire the optimal policy without requiring knowledge of this function. Given the Q-function, the optimal policy is determined as  $\pi^*(b^t) = \arg \max_{a^t} Q(b^t, a^t)$ .

### 3 Dialogue management using intention dependency graph

#### 3.1 Intention dependency graph

An intention dependency graph (IDG) is a representation of a user’s intention in a hierarchy, with broad categories of the intention at the top, and specific instantiations of those categories at the bottom, as shown in **Figure 1**. A child node in the graph represents a more specific intention than the parent node, so that the flow from top to bottom represents the completion of the full specification of an intention. However, the graph is not necessarily a tree, and hence there may be multiple paths from a parent node to any descendent node. A node that is fully specified and actionable by the system can be considered a user goal. In node 7, which is a child of node 2, both the album and artist are specified, and the system has enough information to perform the desired action. Such a graph is automatically generated from task knowledge that is usually designed by hand for a conventional rule-based dialogue manager (Dahl et al., 1994; Bohus and Rudnicky, 2003), as a graphical user interface, and can be obtained by forming a taxonomy of the possible system actions. In our context, a node in this graph represents a hypothesis of the user’s intention and/or goal.

#### 3.2 User simulator

Training a statistical dialogue management system in the absence of large amounts of dialogue data requires a user simulator to ensure adequate coverage of possible user states. In a general dialogue, the system action and the user state would follow a dialogue history and lead toward a user goal. The simulator thus samples user states  $s^{t+1} = i$ , at every time step, tending toward a user goal  $g$ , and depending on the previous system action  $a^t = k$ . Thus, our approach defines the sampling distribution  $p(i|g, k)$  by using IDG. Our approach gives uniform distribution to hypotheses that are outputted by the IDG. We show an example IDG in **Figure 1** and a dialogue example in **Figure 6** of Appendix.

#### 3.3 Learning without any annotated data

We discuss the learning for the POMDP that uses our IDG. In our task, no data can be referred to and we cannot calculate the transition probability that is generally calculated from an annotated data for the belief update. This property makes it impossible to establish the exact value of the state-value function. In standard POMDP learning, sampling belief point approaches that select a small set of representative belief points such as point-based value iteration (PBVI) can be applied (Pineau et al., 2003). However, it is difficult to sample a small set of belief points without any tagged data. Therefore, we calculate the action-value function  $Q(b^t, a^t)$ , and simulate the noise with a grid-based approach (Lovejoy, 1991; Bonet, 2002). The grid-based approach can select points in accordance with a grid and a noise parameter  $\eta$  that is released from the data. In our learning approach, a sample of belief  $b_i^t = p(s^t = i|o^{1:t}, O^{1:t})$  is given by  $p(o^{t+1} = l|i') = O_{li'}^{t+1}$  where

$$O_{li'}^{t+1} = \begin{cases} 1 - \eta & l = i' \\ \frac{\eta}{|\mathcal{I}_s|-1} & l \neq i'. \end{cases} \quad (5)$$

We tried noise  $\eta = \{0.0, 0.2, 0.4, 0.6, 0.8, 1.0\}$ . The resulting policy does not reflect the belief update, but we can use the belief update method that follows the IDG.

#### 3.4 State transition and belief update

The state transition probability  $T_{ii'k}$  is one of the most important components of the belief update in the POMDP framework. To obtain the transition probabilities, we usually require user state and system action data with annotated tags. However, we cannot calculate the probability because of the lack of annotated data. Therefore, we define the state transition probability by using an IDG similar to user simulation, as discussed in Section 3.2. By employing time-invariant user goal  $g$ , time-variant user state  $s^t = i$  and time-variant best system action  $a^t = \hat{k}$  in Section 2, we can represent the state transition probabilities, as follows:

$$p(i'|i, \hat{k}) = \sum_g p(i'|g, i, \hat{k})p(g|i, \hat{k}) \quad (6)$$

We approximate  $p(i'|g, i, \hat{k})$  by user simulator  $p(i'|g, \hat{k})$ . This means that the next user state  $i'$  does not depend on the previous user state  $i$ . We approximate  $p(g|i, \hat{k}) \simeq p(g|i)$  because the user

Figure 3: Average rewards of Figure 4: The effect of forgetting Figure 5: The effect of forgetting 10000 dialogues between the ob- factor  $\beta$  as regards the average re- factor  $\beta$  as regards the average di- tained dialogue manager and the wards of 10000 dialogues. al- ogue turns of 10000 dialogues. user simulator.

goal  $g$  can be estimated from the user state  $i$  by using the IDG. As a result, Eq. (6) is approximated as,

$$(6) \cong \sum_g \underbrace{p(i'|g, \hat{k})}_{\text{simulator}} \underbrace{p(g|i)}_{\text{goal model}} \quad (7)$$

Here, **simulator** is the user simulator that is defined in Section 3.2, and **goal model** is a goal estimation model that can be calculated from an IDG. Our user simulator does not perform in accordance with  $p(s^{t+1} = i'|g, a^t = \hat{k})$  exactly, but our model uses the track back of the user simulator that is defined in Section 3.2. The probability of a goal estimation model is defined as  $p(g|i)$ , which expresses possible goals given a user state  $s^t = i$ .

## 4 Evaluations

We evaluate our statistical dialogue management approach, which uses the IDG. These are experimental evaluations with the user simulator that follows Section 3.2. In the experiment, we used an IDG that had 957 states including 667 goals.

### 4.1 Evaluation of average reward

We evaluated dialogue managers in terms of the average reward for 10000 dialogues between the user simulator and the obtained dialogue manager. We simulated uniformly distributed noises that are defined on Eq. (5) for observation. We tried six grids that suppose a uniform distribution given by Eq. (5). The parameters ( $\eta = \{0.0, 0.2, 0.4, 0.6, 0.8, 1.0\}$ ) were sampled in the Q-learning of the POMDP. We used parameters  $\gamma = 0.8$  and  $\epsilon = 0.2$ . The belief update defined in Section 3.4 was used for the dialogue evaluation. For comparison, we prepared an MDP based

dialogue manager that learned from observations without any noise. The average rewards result is shown in **Figure 3**. In this experimental result, the POMDP dialogue manager performed better than the MDP based dialogue manager (MDP) in noisy cases. The effects of forgetting factor  $\beta$  in terms of average reward and average dialogue turn are shown in **Figure 4** and **Figure 5**. In this graph, the proposed POMDP framework, which includes state transition probabilities, works best at the point  $\beta = 0.2$ . These figures show that the approach depended on the forgetting factor and the robust setting of  $\beta$  is left to future work.

**Figure 7** in Appendix shows an example of dialogue between the user simulator and the dialogue manager. This example was obtained with  $\eta = 0.8, \beta = 0.2$ .

## 5 Conclusion and discussion

We have proposed a dialogue management framework that uses a directed IDG. The IDG is hand-crafted during the construction of the conventional rule-based dialogue system, and our approach can easily adapt rule-based systems to a statistical dialogue management framework. The proposed framework does not require annotated dialogue data in the initial deployment that are essential for the typical statistical dialogue management framework, and this enables rapid and easy adaptation. The proposed scheme is developed purely based on a probability process, and the framework can be extended to use annotated data to estimate model parameters, which will be future work. Ongoing work includes evaluation with real user or realistic user simulator that is constructed from dialogue logs.

## Abstract

This paper proposes an example driven approach to improve the quality of MT system outputs. Specifically, We extend the system combination method in SMT to combine the examples by two strategies: 1) estimating the confidence of examples by the similarity between source input and the source part of examples; 2) approximating target word posterior probability by the word alignments of the bilingual examples. Experimental results show a significant improvement of 0.64 BLEU score as compared to one online translation service (Google Translate).

## 1 Introduction

Statistical Machine Translation (SMT), state-of-the-art solution, has remarkable success with the support of the large-scale bilingual corpora to boost the translation quality at present. However, due to the long tail effect of human language, statistical anomalies in the training data can cause that tons of desired translation knowledge could not be statistically learned from the large-scale bilingual corpora. As a result, bulks of the specific translation requirements not well addressed still perplex machine translation academia and industry.

Combining the examples with machine translations output is a good solution to improve translation quality for this issue. Several methods have been proposed in recent years. One approach tries to replace relevant chunks, taking advantage of Translation Memory (TM). Its motivation is to store and to retrieve similar translation examples for a given input, then to avail of examples to replace the similar chunks into the input by the threshold of similar score (Smith and Clark, 2009; Koehn and Senellart, 2010) or by the decision of an automatic classifier (He et al., 2010; Ma et al., 2011). Another approach

tries to enhance phrase table of SMT, integrating collected bilingual pairs into the phrase table (Biçici and Clark, 2009; Simardand Isabelle, 2010; DauméIII and Jagarlamudi, 2011).

Different to the above studies in which the EBMT and SMT function in a pipeline style, the work in this paper tries to integrate the SMT results and translation examples in a unified framework. In parallel to the system combination in SMT, we try to integrate the translation examples into the confusion network, allowing each word in both SMT results and examples to compete for the optimal output. In order to achieve the goal, the proposed method introduces some new features to bridge the statistical and example translation.

This paper presents an approach to repairing the translation errors via retrieving translation examples from examples corpus. The effectiveness of our method is validated on the standard test set of Olympics task in IWSLT 2012 Evaluation Campaign. Experimental results show that an absolute increase of 0.64 BLEU score is observed after repairing original translations. This significant improvement suggests the proposed strategy as a promising solution to the subtle task of integrating example knowledge into statistical model outputs, as well as a practical way to boost current MT service.

## 2 Repairing Translations with Improved Confusion Network

Repairing translation can be viewed as a process of translation knowledge fusion. As illustrated in Fig.1, the proposed approach consists of following steps. We first obtain an online translation system output  $E_0$  for a given input sentence  $F$ . Then we retrieve the top- $n$  examples  $\{ \langle ex\_F_i, ex\_E_i \rangle \mid (i \in \{1, 2, \dots, n\}) \}$  from bilingual examples corpus which are most similar to  $F$ . Then taking the translation  $E_0$  as the initial skele-

ton, we construct a confusion network by adding the top- $n$  examples into the skeleton incrementally by the word alignments relation between the current skeleton and the  $i$ -th example  $ex_{E_i}$ . The key step is to estimating the word confidence. In this work, we design a feature based on example confidence and word posterior probability by word alignment of examples. Finally, we decode the confusion network by the classic features used in MT combination and new features via a log-linear model.

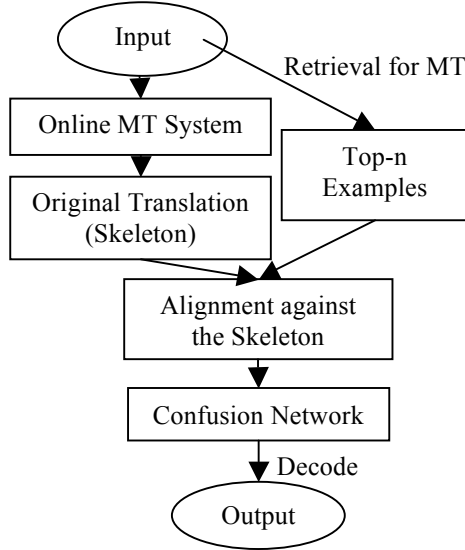

Figure 1. Framework of Repairing Incorrect Translation by Examples

## 2.1 Estimating Example Confidence

We use a word-based vector space model to retrieve examples from bilingual corpus, by comparing the deviation of angles between the source part of each example vector  $ex_{F_i}$  and the source input vector  $F$ . The Cosine Similarity of the vectors is applied to measure the similarity between the source input sentence  $F$  and the each  $plex_{F_i}$ , as calculated by:

$$CosSim(ex_{F_i}, F) = \frac{ex_{F_i} \cdot F}{\|ex_{F_i}\| * \|F\|} \quad (1)$$

where  $ex_{F_i} \cdot F$  is the intersection between the vector  $ex_{F_i}$  and the vector  $F$ .  $\|ex_{F_i}\|$  is the norm of the vector  $ex_{F_i}$  and  $\|F\|$  is the norm of the vector  $F$ . To balance the word recall and precision of examples, we filter the examples by simply keeping top- $n$  similar examples for fusion.

Obviously, a reasonable assumption is that the target example has a higher confidence to occur in the final output if the corresponding source part of example has a higher similarity with the source input sentence. Therefore, we estimate the

confidence  $C_i$  of each target example  $ex_{E_i}$  ( $i \in \{1, 2, \dots, n\}$ ) by the Cosine Similarity score between the source part of example  $ex_{F_i}$  and the source input  $F$ .

## 2.2 Estimating Word Posterior Probability by Word Alignment of Examples

To penalize the irrelevant information from examples, we estimate word posterior probability by word alignment between source words and target words in examples. For word alignment between bilingual pairs in SMT, the most popularly used is the IBM model (Brown et al., 1993) in the toolkit GIZA++ (Och et al., 1999), combined with symmetric heuristics.

We estimate the word posterior probability according to word alignments of examples. We create a counter for each word, which might involve in the final translation. The words can come from target parts of examples or the skeleton translation.

For each word, its counter works as follows: 1) Initialize the counter as 0. 2) Keep the counter unchanged if the word either comes from the original translation or does not appear in alignments. 3) Increase the counter by one if its corresponding source word in alignments also appears in the source input sentence. 4) Decrease the counter by one if its corresponding source word in alignments does not disappear in the source input sentence.

Then we estimate posterior probability of the word  $w$  for each fusing translation  $E_i$  by the counter value as following formula:

$$p(w|E_i) = \frac{1}{1 + e^{-c}} \quad (2)$$

where  $c$  is the counter value. The value of  $E_i$  is defined as follows:

$$E_i = \begin{cases} ex_{E_i}, & i = 1, 2, \dots, n \\ E_0, & i = 0 \end{cases} \quad (3)$$

## 2.3 Features for Fusion

In the practice of translation fusion under SMT system combination framework, six common features are used to guide the decoding:

**Language model:** probability from an N-gram language model.

**Word penalty:** penalty depending on the size (in words) of the hypothesis.

**Null-arc penalty:** penalty depending on the number of null-arcs crossed in the confusion network to obtain the hypothesis.

**N-gram agreement:** the value which is equal to the counts of N-gram matches between fusing translations (examples and original translations) and the hypothesis divided by the number of the fusing translations.

**N-gram probability:** a kind of like language model trained on the top-n examples.

**Word confidence:** the production of word posterior probability and the confidence of the fusing translation where the word come from.

The practical effect is that the word posterior probability is computed with a simple method at the cost of estimating the word confidence from original translation roughly. To solve this problem, an original word penalty feature is introduced into our method.

**Original word penalty:** penalty depending on the number of words from the original translation. The feature indicates the degree of repairing original translation.

In addition, although the incremental TER alignment is used in constructing the confusion network to avoid most of alignment errors, overcoming the noise from the examples is critical. So we adopt repetitive word penalty to debilitate this effect.

**Repetitive word penalty:** penalty depending on the number of repetitive words in the hypothesis.

### 3 Experiments

#### 3.1 Experimental Settings

Our experiments are carried out on the HIT dataset in the OLYMPICS task of IWSLT 2012 Evaluation Campaign (Federico et al., 2012). We take the training dataset as examples corpus, which contains 52,603 pairs of Chinese-English sentences. Development and test dataset provided by the task contain 2,057 and 998 pairs of Chinese-English sentences, respectively. The Chinese text is segmented by Stanford Word Segmentation (Chang et al., 2008). Detailed statistics of the corpus are shown in Table 1.

	sent	Segment(zh) Token(en)
Example corpus	52,603	495,638 (zh) 527,599 (en)
Dev	2,057	19,457(zh) 20,782(en)
Test	998	10,047(zh) 11,004(en)

Table 1. The Description of HIT dataset

The original MT outputs of develop set and test set come from Google Translate services. The 5-gram English target language model has been trained on Example corpus using SRILM (Stolcke, 2002). The model parameters are trained by MERT (Och, 2003). The 500-best list is created at each MERT iteration and is appended to the n-best lists created at previous iterations. The results are evaluated by BLEU-4 (Papineni et al., 2002) score.

To grasp the distribution of test set on similar score, the composition of test subsets based on similar scores is calculated, which is shown in Table 2.

	Sent	Segment	Segment/Sent
[0.9,1.0)	36	235	6.53
[0.8,0.9)	209	1,394	6.67
[0.7,0.8)	423	3,218	7.61
[0.6,0.7)	720	6,407	8.90
[0.5,0.6)	931	9,121	9.80
[0.4,0.5)	923	9,462	10.25
(0.0,0.4)	570	5,917	10.38

Table 2. Composition of test subsets based on similar scores

#### 3.2 Evaluating Translation Quality

In our experiments, firstly we re-rank the retrieval examples corpus by the Cosine Similarity score and empirically retrieve the top-15 similar examples for each source sentence in development and test dataset. Secondly, using the Google Translate services to translate the source sentence in test and development set, we obtain the results of its translations (Original). Then we tune the model parameter on the development dataset, and decode on the test dataset to generate new translations (Repaired). For the comparison, we list two results of our baseline method: One is the result of original translation (Original); the other baseline is the result of replacing original translations by the example with max similar score (Replaced). When combining the top-15 similar examples and original translation, the BLEU score of word-level oracle system (Oracle) is shown in Table 3, and the best system (IWSLT12\_Best) on the dataset in IWSLT 2012 Evaluation Campaign is also listed.

As we can see from Table 3, we still obtain significantly inferior results compared to the original translation if we replace all the Google translations by the most similar examples, which is reflected by an absolute 8.55 point drop on the test set in BLEU score. On the other hand, our repairing method, which can repair original

translation result automatically in word-level, leads to an increase of 0.64 absolute BLEU point on the test set.

Model	BLEU%
<i>Original</i>	18.77
<i>Replaced</i>	10.22
<i>Repaired</i>	<b>19.41*</b>
<i>IWSLT12 Best</i>	19.17

Table 3. Comparison with others on BLEU score (\* significant at 0.005-level compared with the score of Original)

The experimental results show that our retrieval examples driven method appears to be effective in repairing incorrect translation with significant improvement in translation quality. Replacing by the most similar example cannot improve the translation quality when the similar score is low. Combing the examples with original translation improves the translation quality. In this sense, it is promising to correct translation by the examples via the proposed method.

### 3.3 The Effect of Example Similarity

We compare our method (Repaired) with two baselines (Original and Replaced) in different similar score region. We evaluate the translations by BLEU score. The results are listed in Table 4.

	<i>Original</i>	<i>Replaced</i>	<i>Repaired</i>
(0.9, 1.0)	17.23	<b>36.99</b>	22.98
(0.8, 0.9]	20.92	<b>27.20</b>	21.44
(0.7, 0.8]	19.90	15.03	<b>20.23*</b>
(0.6, 0.7]	18.55	9.12	17.71
(0.5, 0.6]	18.38	4.22	17.50
(0.4, 0.5]	18.76	1.78	17.54
(0.0, 0.4]	18.25	0.80	17.20

Table 4. BLEU in different similar score region (\*significant at 0.005-level compared with the score of Original)

From Table 4, we can see when the similar score is greater than 0.8, replacing the original translation by the most similar example has a serious advantage on BLEU score. When the similar score declines, the BLEU score also drops sharply. When the similar score region is (0.7, 0.8], our method has a significant improvement of absolute 0.33 BLEU score compared with original. And when the similar score declines bellow 0.7, the original translation is better. But it is remarkable that the result is generated by un-tuned parameters model.

### 3.4 Feature Analysis

In the experiment, we investigated the contribution of our different feature sets. After removing one feature, we retune the weights of features on the development set and re-decode on the test set. We evaluate the outputs of these models by BLEU, and list the results in Table 5.

Model	BLEU%
<i>Repaired</i>	19.41
Without word penalty	19.39
Without N-gram agreement	19.33
Without language model	19.23 <sup>^</sup>
Without repetitive word penalty	19.21 <sup>^</sup>
Without null-arc penalty	19.10 <sup>^</sup>
Without original word penalty	19.01 <sup>^</sup>
Without word confidence	18.98 <sup>^</sup>
Without N-gram probability	18.71 <sup>^</sup>

Table 5. Contribution of Features (^significant at 0.05-level compared with the repaired score)

As shown in Table 5, the performance drops significantly ( $p < 0.05$ ) when language model, repetitive word penalty, null-arc penalty, original word penalty, word confidence, N-gram probability is removed from the feature set respectively. And word penalty and N-gram agreement have weak effects on the results. It is remarkable that our specific features repetitive word penalty, original word penalty, and word confidence can bring the improvement of 0.20, 0.40, and 0.43 BLEU point than that without them respectively.

## 4 Conclusion

In this paper, we introduce statistical confusion network for translation example fusion to improve the current online MT quality. We estimate the posterior of the word translation by the example similarity and introduce some new features to enhance the log-linear model optimization for the best translation. We check our method on the HIT dataset in the OLYMPICS task of IWSLT 2012 Evaluation Campaign. The Experimental results indicate that proposed method enhance the Chinese-English translations by Google, with a significant 0.64 absolute improvement according to BLEU score.

## Abstract

We present a phrase-based method to extract parallel fragments from the comparable corpora. We do this by introducing a force decoder based on the hierarchical phrase-based (HPB) translation model to detect the alignments in comparable sentence pairs. This method enables us to extract useful training data for statistical machine translation (SMT) system. We evaluate our method by fragment detection and large-scale translation tasks, which show that our method can effectively extract parallel fragments and improve the performance of the state-of-the-art SMT system.

## 1 Introduction

Parallel corpora are valuable resources for training a statistical translation system. In most cases, it has been an effective way to build state-of-the-art statistical models using a large scale of parallel corpora. However, the parallel corpora only exist in particular domains for a few number of language pairs, such as international conference recordings and legal texts. Since comparable corpora exist in large quantities with many languages, and the exploitation in them for extracting parallel data can be very useful for SMT system, the acquisition of parallel data from comparable corpora has caught much attention.

Various methods (Zhao and Vogel, 2002; Munteanu and Marcu, 2005; Abdul-Rauf and Schwenk, 2009; Smith et al., 2010) have been previously proposed to extract parallel data from comparable corpora at the sentence level. These methods share the same framework, which firstly identifies candidate document pairs and then extracts parallel sentences from the obtained documents. However, it is found that most of these sentences are comparable sentence pairs (Hong et

al., 2010), which embed non-parallel fragments or even lack translations. Consider the comparable sentence pair from Chinese to English in Figure 1. Methods for extracting parallel sentences will bring in noise when these bilingual sentences are retained. But discarding them is also not a wise choice, as there are still some useful parallel fragments as the underlines shown in the figure.

中国 政府 开始 大力 发展 中国 的 经济。

And developing the economy of China is the practical choice for the Chinese government.

Figure 1: Example of comparable sentence pairs. The parallel fragments are marked by underlines.

In order to deal with this problem, further efforts (Munteanu and Marcu, 2006; Quirk et al., 2007; Kumano et al., 2007; Lardilleux et al., 2012) were made to obtain parallel data at the fragment level. The work of (Riesa and Marcu, 2012) detected parallel fragments using the hierarchical alignment model. However, this approach obtains fragments from parallel sentence pairs, which limits its application in comparable corpora. (Hewavitharana and Vogel, 2011) have explored several alignment approaches to detect parallel fragments embedded in comparable sentences. However, these approaches extract fragments mainly using the lexical features and considering the words in parallel fragments are independent, which make it difficult to measure the alignments exactly.

In this paper, we present a phrase-based method, which considers both the lexical and phrasal features, to extract parallel fragments from comparable corpora. We introduce a force decoder based on the HPB translation model to detect parallel fragments for each sentence pair. The results show that our method can effectively extract parallel fragments from the comparable corpora.

ra and significantly improve the performance on Chinese-to-English translation tasks.

## 2 Parallel Fragments Extraction

### 2.1 HPB Translation Model

The HPB translation model (Chiang, 2005) has shown strong abilities in SMT for its capability in generalization. It is based on the weighted synchronous context-free grammar (SCFG). And the translation rule is represented as:

$$X \rightarrow \langle \alpha, \gamma, \sim \rangle \quad (1)$$

where  $X$  is a non-terminal,  $\alpha$  and  $\gamma$  are source and target strings with terminals and non-terminals.  $\sim$  describes a correspondence between the non-terminals in  $\alpha$  and  $\gamma$ .

Two glue rules are added so that it prefers combining hierarchical phrases in a serial manner:

$$S \rightarrow \langle S_1 X_2, S_1 X_2 \rangle \quad (2)$$

$$S \rightarrow \langle X_1, X_1 \rangle \quad (3)$$

### 2.2 Force Decoding based on HPB model

The force decoding can be seen as a bilingual parsing process that generates derivation trees from both sides of the sentence pair with an existing HPB model.

Let  $\mathbf{e} = e_1^M$  and  $\mathbf{f} = f_1^N$  be the source and target sentences in comparable corpora. For each of the sentence pair  $\mathbf{e}$  and  $\mathbf{f}$ , the decoding process enumerates all of the possible bilingual derivation trees  $\Phi$  with HPB rules from bottom to top. At each node in these derivation trees, the decoder generates alignments by recursively combining phrases generated from the current node's children, and builds up larger and larger alignments. It should be noted that these nodes can be generated only if the alignments are exactly contained in both elements of the sentence pair. The derivation process works similarly to a CKY parser, moving bottom-up and generating larger constituents. However, the force decoder generates derivation trees for both of the bilingual sentences simultaneously and these trees do not have to span the entire sentences, especially in the non-parallel sentences, which is quite different with the CKY parser.

Still considering the comparable sentence pair in Figure 1. Figure 2 gives an example of extracting one of the parallel fragments by force decoding with the following HPB rules:

$$X \rightarrow \langle \text{发展 } X_1, \text{developing } X_1 \rangle$$

$$X \rightarrow \langle X_1 \text{ 中国}, \text{China} \rangle$$

$$X \rightarrow \langle X_1 \text{ 经济}, \text{the economy} \rangle$$

$$X \rightarrow \langle X_1 \text{ 的 } X_2, X_2 \text{ of } X_1 \rangle$$

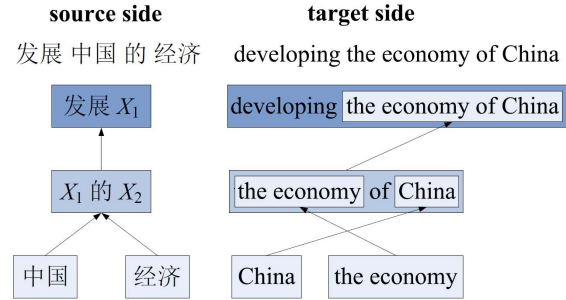

Figure 2: Example of derivation trees in force decoding. To give better illustration, the non-terminal rules from parent nodes are combined with the rules from child nodes on the target side.

It can be seen that the bilingual derivation trees, which represent the source and target fragments, are generated simultaneously. At the first derivation step, it is found that the Chinese words “中国” and “经济” from the source side can be translated into English as “China” and “the economy”, which are exactly contained in the target sentence. Then we keep these words as the nodes in bilingual derivation trees, and continue to generate parent nodes by combining these child nodes bottom-up. The derivation process continues until there are no bilingual nodes that meet the words in both of bilingual sentences. At last, we will get the parallel fragments “发展中国的经济” and “developing the economy of China” from the top of the derivation trees.

### 2.3 The Extension of HPB Rules

In our force decoding framework, there are some words that do not have translation rules, such as the out-of-vocabulary (OOV) words. This case could make up a large portion in the comparable corpora. To overcome this drawback, the HPB model has to be trained on a large scale of training data with a large vocabulary. Even so, there are still some of the words that may lack translations. We suppose these words can be translated into any of the sequential words in target sentences and add a special rule to our HPB model:

$$X \rightarrow \langle e_i, f_{(i', j')} \rangle, 1 \leq j' - i' \leq 2 \quad (4)$$

where  $i$  is the position of the word that do not have translation rules in source side,  $i'$  and  $j'$  are the start and end positions of the phrasal segment in target sentence. Here we restrict the length of the phrasal segment because larger segment tend to bring in noise in force decoding.

Moreover, in order to better evaluate the alignments between the parallel fragments, we extend the original HPB rules inspired by the work of (Čmejrek et al., 2009):

$$\langle X_1, X_1 f \rangle, \langle X_1, f X_1 \rangle, \langle X_1 e, X_1 \rangle, \langle e X_1, X_1 \rangle \quad (5)$$

$$\langle X_1 X_2, X_2 X_1 \rangle \quad (6)$$

in which rules (5) allow the HPB rules to insert and delete a single word, and rule (6) expands the standard glue rules and enables the aligning phrasal segments swap their constituents.

## 2.4 The Verification of Parallel Fragments

For each bilingual sentence pair, we can generate various alignment derivation trees. The derivation trees from source side are isomorphic to the target side because of the characteristic of SCFG.

In order to better evaluate the alignment for the derivation trees, each HPB rule in force decoding is associated with a score that is computed via the following log linear formula:

$$w(X \rightarrow \langle \alpha, \gamma, \sim \rangle) = \prod_i \phi_i(f, e)^{\lambda_i} \quad (7)$$

where  $\phi_i(f, e)$  is a feature describing one particular aspect of the rule associated with the source and target phrases ( $f, e$ ), and  $\lambda_i$  is the corresponding weight of the feature. Following the standard HPB model, features used in our force decoding are relative-frequency phrase translation probability  $P(f|e)$  and its inverse  $P(e|f)$ , lexically weighted phrase translation probability  $lex(f|e)$  and its inverse  $lex(e|f)$ .

Moreover, we consider the score of the special rule is:

$$w(X \rightarrow \langle e_i, f_{i',j'} \rangle) = \omega \times e^{-|j'-i'|} \quad (8)$$

in which,  $\omega$  is the weight of the special rule.

After generating the derivation trees, we recursively traverse these trees at each node top-down, and extract parallel fragments from both sides with the following constraints:

1) The node in the derivation tree has a score greater than a threshold  $\tau$ .

2) The node that represents the words from source side whose span is greater than 2.

The first constraint forces us to extract fragments with high alignment scores, as there are some alignment errors in HPB rules. And the second constraint makes us be more confident in the alignment scores over the larger fragments. The recursive traversal from derivation trees stops, once a fragment pair has been extracted.

For each sentence pair, different parallel fragments are extracted from derivation trees. Then we combine these fragments if there are overlaps in both source and target side. Otherwise, we keep these fragments as independent pairs.

## 3 Experiments

In our experiments, we compared our fragments extraction method with the PESA method explored by (Hewavitharana and Vogel, 2011), which is based on the lexical features.

### 3.1 Data and Evaluation Setup

We used the parallel corpora from LDC<sup>1</sup> to train our HPB model in force decoding. The HPB model was trained following (Chiang, 2007) with word alignment by running GIZA++ (Och and Ney, 2003). We downloaded comparable data from the online news sites: the BBC, and Xinhua News. The candidate sentence pairs (**Raw**) had been extracted following the approach of (Munteanu and Marcu, 2005) as we only focused on the performance of parallel fragments extraction. The sizes of these corpora are listed in Table 1.

Data Sets	#Sentences	#Chinese	#English
LDC	3.4M	64M	70M
Raw	2.6M	42M	49M

Table 1: Numbers of sentences and words for the parallel and comparable corpora.

We evaluated the quality of the extracted parallel fragments in two different ways:

**Fragments Evaluation** We obtained manual alignments for 600 sentence pairs and extracted parallel segments up to 10 words that are consistent with the annotated word alignment. We also removed the segments less than 3 words for the

<sup>1</sup>LDC2002E18, LDC2002T01, LDC2003E07, LDC2003E14, LDC2003T17, LDC2004T07, LDC2004T08, LDC2005T06, LDC2005T10, LDC2005T34, LDC2006T04, LDC2007T09.

constraint as described in Section 2. Then we tested the performance with the manual annotation.

**Translation Evaluation** We evaluated the fragments on Chinese-to-English translation tasks. We used a HPB translation system with a 4-gram language model trained on about 4 billion words of English using SRI Language Toolkit (Stolcke, 2002). We tuned parameters of the SMT system using minimum error-rate training (Och, 2003) to maximize the BLEU-4 (Papineni et al., 2002) on NIST 2005, and evaluated on the standard test sets, NIST 2006 and NIST 2008.

## 3.2 Experimental results

### 3.2.1 Performance on Fragments Extraction

We first compared the our method (HPB-FD) with PESA by fragments extraction. To give credit to our fragments extraction, we used partial matches to evaluate the performance of our extract method, following the way of (Hewavitharana and Vogel, 2011). The precision and recall were defined based on the tokens in the extracted target fragments that were also exists in the reference. And the F1 score was calculated in the standard way.

	<b>Exact</b>	<b>P</b>	<b>R</b>	<b>F1</b>
PESA	60.36	88.42	84.74	86.54
HPB-FD	74.12	94.36	88.90	91.55

Table 2: The results for fragments extraction with PESA and HPB-FD.

Table 2 gives the performance of PESA and our HPB-FD method. The results are presented as percentages of: exact matches found (**Exact**), precision (**P**), recall (**R**) and **F1**. It can be seen that our method can effectively extract parallel fragments from the comparable corpora. Comparing to PESA, our extraction method has higher scores in both Exact and F1 measure. This demonstrates that extracting fragments by our force decoding method can be more effectively to evaluate parallel fragments in comparable corpora.

### 3.2.2 Performance on Machine Translation

We then evaluated the extracted parallel fragments with the HPB translation system. In the baseline system, translation model (LDC) was trained on the LDC corpora that had been cleaned and thought to be less noisy. In the contrast experiments, we trained three translation models. The first model (LDC+Raw) was trained on the LDC

with the extracted comparable sentences. The second model (LDC+PESA) was trained on the LDC and fragments that were extracted by PESA. And the third (LDC+HPB-FD) was trained on LDC and fragments that were extracted by HPB-FD. Table 3 lists the BLEU scores obtained by different training data.

	<b>NIST 2006</b>	<b>NIST 2008</b>
LDC	28.07	26.12
LDC+Raw	28.20(+0.13)	26.05(-0.07)
LDC+PESA	28.65(+0.58)	26.62(+0.50)
LDC+HPB-FD	<b>29.01(+0.94)</b>	<b>26.93(+0.81)</b>

Table 3: The translation performance with different training data. BLEU score gains are significant with  $p < 0.01$ .

Comparing to the baseline system, all the adding training data get stable improvements in translation performance except for the comparable sentences. It suggests that the simple increment in training data does not always lead to better performance. The superiority of parallel corpora confirms that, the quality is more important than quantity in collecting training data. Moreover, comparing to the parallel fragments extracted by PESA, our method get better translation results in both translation tasks, which also suggests our method can effectively extract parallel fragments from comparable corpora for the SMT system.

## 4 Conclusions

Parallel data in the real world is increasing continually. However, we cannot always get the translation performance improved by simply enlarging our training data. The collection of parallel data is expensive, and to our best knowledge, there is not a unified method to detect parallel fragments automatically.

We have presented an effective phrase-based method, which combines the lexical and phrasal features, for extracting parallel fragments from comparable corpora. The similarity between the source and target fragments is measured by the force decoding based on the existing HPB model. Experimental results show that our method can effectively detect the parallel fragments and achieve significant improvements over the baseline HPB translation system on the large scale Chinese-to-English translation tasks.

## Abstract

In this paper we present a hybrid approach to resolve Entity-pronoun references in Hindi. While most of the existing approaches, syntactic as well as data-driven, use phrase-structure syntax for anaphora resolution, we explore use of dependency structures as a source of syntactic information. In our approach, dependency structures are used by a rule-based module to resolve simple anaphoric references, while a decision tree classifier is used to resolve more ambiguous instances, using grammatical and semantic features. Our results show that, use of dependency structures provides syntactic knowledge which helps to resolve some specific types of references. Semantic information such as animacy and Named Entity categories further helps to improve the resolution accuracy.

## 1 Introduction

In various approaches on anaphora resolution syntax has been used as an important feature. Some well-known syntax based approaches include Hobbs algorithm (Hobbs, 1986) and the Centering approach (Brennan et al., 1987). Various rule based and data driven approaches have been proposed which use syntactic information as an important feature.

Most of the earlier works have used phrase-structure parse as a source of syntactic information. However, dependency structures are more suitable representations for relatively free word order languages such as Hindi (Bharati et al., 1995; Melčuk, 1988) and hence research in many such languages has focused on development of dependency based resources resulting in better availability of dependency data for such languages. In this paper, we explore the possibility of using dependency structure for anaphora resolution in Hindi.

However, we do not intend either to propose dependency as an alternative to phrase structure or to compare the usability of the two frameworks.

(Prasad and Strube, 2000) is one of the most important approach for anaphora resolution in Hindi. They applied a discourse salience ranking to two pronoun resolution algorithms, the BFP and the S-List algorithm. (Dakwale and Sharma, 2011) reported the best performance for Hindi in Anaphora Resolution tool contest in Indian languages(ICON-2011). They propose a hybrid approach with limited linguistic knowledge such as NER categories and verb similarity.

Two earlier approaches explore the use of dependency relations for anaphora resolution. For Hindi, (Uppalapu and Sharma, 2009) extends the S-List algorithm by using two different lists in place of a single list. For English, (Björkelund and Kuhn, 2012) explores the possibility of using dependency relations as a feature for co-reference resolution in a learning based approach. Both the approaches are limited in their exploration of dependency for anaphora resolution as they only use dependency relations either as a salience for ranking the candidate referents or as an additional feature in a learning based approach. We discuss how resolution of different types of Entity-pronoun references in Hindi can benefit from dependency relations and semantic information. We present a hybrid approach to resolve Entity-pronoun references in Hindi which combines a rule-based system that uses dependency structures and relations and further improvement is achieved with semantic information such as animacy.

## 2 Data set and Grammatical Framework

In this work we use the data from the ‘Hindi/Urdu Dependency Treebank’ (Bhatt et al., 2009). It is a rich corpus with various linguistic information. The dependency annotation in this treebank is based on the Computational Paninian Grammar

(CPG-henceforth) framework, as is explained in (Begum et al., 2008) and (Bharati et al., 1995). This framework is based on the notion of ‘*karaka*’ which are syntactio-semantic relations representing the participant elements in the action specified by the verb and it emphasizes the role of case endings or markers such as post-positions and verbal inflections.<sup>1</sup> Table 1 shows some of the relevant relations and their rough correspondence to the traditional grammatical relations in English.

Label	CPG relation	Grammatical/thematic equivalent
k1	<i>karta</i>	Subject
k2	<i>karma</i>	Object
k4	<i>sampradan</i>	Experiencer/reciever
k7p(or k2p)	<i>adhikaran</i>	Location
r6	<i>sambandh</i>	Genitive

Table 1: CPG relations and equivalents

We use a part of the treebank which is also annotated with animacy information for Noun phrases as described in (Jena et al., 2013). Also, we used NE-Recognizer for Hindi to get the Named entity categories. The treebank has been annotated with anaphora links for all the pronouns as per the scheme described in (Dakwale et al., 2012). The size of the data that we use for our experiments is 325 documents, containing 4970 pronouns out of which 3233 pronouns are annotated as entity pronouns

### 3 System Description

The hybrid approach in our system is different from other hybrid approaches, in the way that instead of a rule based filtering followed by instance classification, our system includes a rule-based resolution module followed by a decision tree classifier for the remaining unresolved pronouns.

Anaphoric reference type can be classified into abstract (event) references where an anaphora refers to an event or a proposition and concrete (entity) references where it refers to a concrete entity like noun phrase (person,place etc), quantifiers etc. In this work, we focus on resolving only entity pronouns, hence the mention detection or anaphoricity determination step is not required for our system. Certain pronominal forms based on their different syntactic behaviour, can be resolved quite successfully with some specific rules using the dependency information. Therefore, we categorize pronominal forms in four types: Reflexive,

<sup>1</sup>The detailed description of these relations is given in Hindi Dependency tagset (<http://ltrc.iiit.ac.in/MachineTrans/research/tb/dep-tagset.pdf>)

Figure 1

Locative, Relative and Personal pronouns. The pronouns which are identified as concrete in the data are passed to the rule-based resolution module in which different rules depending on the category of the pronoun are applied to identify the correct referent. If none of the possible rules apply to a pronoun, it is passed to the classifier which uses a learning algorithm to identify the referent.

### 3.1 Rule based resolution module

The rule based module attempts to resolve the pronoun, using the dependency relations and other information, based on the category of the pronoun, which is decided using an exhaustive list of pronoun categories. We describe below some of the important rules used for different pronoun categories.

#### 3.1.1 Reflexives

In Hindi *Possessive reflexives* are the most frequent reflexives which are only used in possession relation within the same clause and are different from third person possessive pronouns. Unlike English reflexives, they are not inflected with the gender and number of the possessor, but that of the possession. They include [अपना (*apana*), अपनी (*apanii*), अपने (*apane*)] (own). There are *Non-possessive reflexives* which can be used in any participant position, but mostly used in object position. They include [अपने आप(*apane-aap*), स्वयम्(*swayam*), खुद(*khud*)] representing ‘one-self’. As it can be well derived from the binding theory, the referent of the reflexive pronoun is the accessible subject in its own governing category. Also, the ‘k1’ relation of CPG-based framework roughly corresponds to ‘SUBJECT’ of the traditional framework, thus the referent of the reflexive pronoun in most cases is the ‘k1’ of the same clause, i.e. that child node of the root verb of the clause, which has a dependency relation ‘k1’.

- (1) विजय<sub>i</sub> ने रवि को अपनी<sub>i</sub> किताब दी  
vijay.ERG ravi.DAT his.POSS.REF book gave  
‘vijay<sub>i</sub> gave (his own)<sub>i</sub> (POSS.REF) book to ravi.’

Figure (1) shows the dependency structure of example (1). The root verb of the clause containing possessive reflexive अपनी (*his*) is दी (*gave*) which has a descendant node विजय (*vijay*) with a dependency relation ‘k1’ with the verb. Thus it should be selected as the referent of the pronoun.

### 3.1.2 Place pronouns

Locative pronouns refer to location or places. They include वहाँ (‘there’) and यहाँ (‘here’). In CPG-based framework (as discussed in section 2), separate labels are used to represent the locative case, thus it can help in identifying the referents of these pronouns. To resolve place pronouns, we use dependency relations and Named entity Categories. Thus, place pronoun can be resolved by selecting the noun phrase nearest to the pronoun which has ‘LOCATION’ as NER-Category or the nearest NP with the dependency label ‘k7p’ or ‘k2p’. For ex :

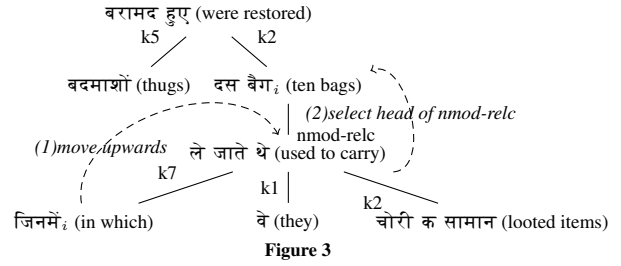

- (2)  $[\text{NER}=\text{LOC}]$  बिहार में सूखे की स्थिति गंभीर है। आज  
 bihar.LOC drought's situation critical is. today  
 प्रधानमंत्री ने वहाँ का दौरा किया।  
 prime minister there visited  
 ‘Situation of drought is critical in bihar. Today Prime minister visited there.’

Figure (2) shows the dependency structure of example(2). Noun phrase with NER category as ‘LOCATION’ nearest to the pronoun वहाँ (*there*) is (*bihaara*), thus it can be selected as the referent. In absence of NE category, dependency relations can be used to identify the referent.

### 3.1.3 Relative pronouns

In Hindi, relative pronouns include जो (which) and its case forms such as जिसे (to which), जिससे (from which) etc. In the CPG-based framework, relative clauses are marked with a relation ‘nmod-relc’, i.e. the relative clause is attached below that noun phrase which is relativized by the clause and the relation is labeled as ‘nmod-relc’. Thus, the referent of the relative pronoun should be selected as the noun-phrase to which the clause containing relative pronoun is attached. Consider following example

- (3) बदमाशों से दस बैग बरामद हुए जिनमें वे चोरी का  
 From thugs ten bags restored in which they looted  
 सामान ले जाते थे  
 items used to carry

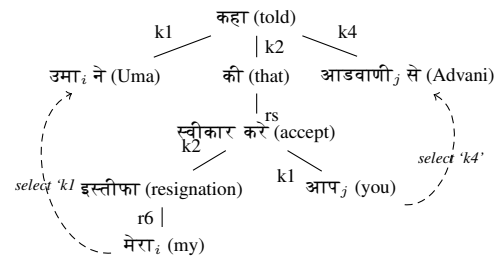

‘Ten bags<sub>i</sub> were restored from the thugs in which<sub>i</sub> they used to carry the looted items.’

Figure (3) shows the dependency structure of example (3), in which the relative pronoun is (‘which’) and the head of the relative clause is the verb ‘ले जाते थे’ (*used to carry*) which in turn is attached below the NP node (‘ten bags’) with a relation ‘nmod-relc’, which is selected as the referent of the relative pronoun.

### 3.1.4 Personal pronouns

All personal pronouns in Hindi are marked for number, respect and case. We consider resolution of first and second person pronouns separate from third person pronouns.

In the news corpus data, first and second person pronouns mostly occur in the narrative or attributional clauses (those subordinate clauses whose main clause has an attribution root verb such as बोल (*to tell*), कह (*to say*), बता (*to tell*) etc). If the first person pronoun is a part of attributional clause then its reference is the speaker of that clause. It is almost always ‘k1’ of the main clause. Similarly the referent of a second person pronoun in an attributional clause, is mostly the ‘k4’ or experiencer of the main clause. For ex :

- (4) उमा ने आडवाणी से कहा की आप  
 Umaa.ERG advaani.DAT said that you.HONORIFIC.ACC  
 मेरा इस्तीफा स्वीकार करे  
 my resignation accept  
 ‘Umaa<sub>i</sub> said to advaani<sub>j</sub> that you<sub>j</sub> accept my<sub>i</sub> resignation.’

Figure (4) shows the dependency structure of example (4), in which (*you*) is second person pronoun in the attributional clause rooted at (*accept*), hence its referent is selected as the ‘k4’ of the main clause i.e. (*advani*). Similarly for the first person

pronoun (*my*), referent is selected as ‘k1’ of the main clause i.e. (*Umaa*).

References of third person pronouns mostly are inter-clausal or inter-sentential. For third person anaphora, we adopt re-ordering of the candidate elements based on the salience of dependency relations, similar to (Uppalapu and Sharma, 2009). However, with two modifications : First, they consider the salience ordering ( $k1 > k2 > k3 > k4 > others$ ) to rank the candidate elements, similar to ordering of the grammatical relation (*subject > direct object > indirect object > adjunct*) as in (Prasad and Strube, 2000). We adopt a slightly modified ordering of the relations ( $k1 > k2 > r6 > k4 > k3 > others$ ) based on the relative frequency of the dependency relations for animate entities. Second, we also use animacy along with number to prune the candidate NP list. For ex :

- (5)  $[_{k1,h}$  उमा $_i$  ने $]$   $[_{k7}$  पहले $]$   $[_{k4,h}$  शिवराज $_j$  को $]$   $[_{k2,rest}$  पत्र $]$   
 Uma.ACC first shivraaj.ACC letter  
 लिखा। फिर  $[_{k1,h}$  उन्होंने $_i$   $[_{k4,h}$  उन्हें $_j$   $[_{k3,rest}$  कोर्ट से $]$   
 wrote. later she.HON.ACC him.HON from court  
 $[_{k2,rest}$  नोटिस $]$  भिजवाया  
 notice sent.CAUSATIVE

‘First uma<sub>i</sub> wrote a letter to shivraaj<sub>j</sub>. Later she<sub>i</sub> sent a court notice to him<sub>j</sub>’

In the above example there are two pronouns in the second sentence : first is उन्होंने<sub>i</sub> (*she*) (gender neutral). Salience based ordering of the possible referents for this pronouns is : [(*umaa*), पत्र (*letter*), (*shivraaj*)]. Since the top element i.e. (*umaa*) agrees with the pronoun in number and animacy, it is selected as the referent for (*she.ACC*). Thus the ordered list of candidates becomes : [पत्र (*letter*), (*shivraaj*)]. The second pronoun is (*him*) (gender neutral), but the top element in the list (*letter*) doesn’t agree with pronoun either in number or animacy. However, the next element in the list (*shivraaj*) agrees with the pronoun for both features, hence it is selected as the referent of the pronoun. If a pronoun could not be resolved within the two sentence, it is passed for learning based resolution.

### 3.2 Classifier module

We use the approach of (Soon et al., 2001) for classification. For training, a positive instance is created by pairing each anaphora and its actual antecedent, and negative instances are created by pairing the anaphora with multiple preceding non-antecedent Noun phrases. For testing, unlabeled instances are created by pairing the anaphora with all the Noun-phrases in upto 3 previous sentences. Testing instances are classified as positive

or negative based on the model learned in the training phase. Positively labeled instances are then re-ranked based on the decision-tree-confidence-factor as described in (Witten and Frank, 2005). The NP-candidate corresponding to the highest ranked instance is proposed as the referent of the pronoun.

#### 3.2.1 Features

Following features are used for classification:

- Number : singular, plural, honorific
- Named Entity categories: ‘Person’, ‘Organization’, ‘Location’, ‘Number’
- Distance feature: #NP chunks and #sentences between the pronoun and the candidate NP.
- Animacy : ‘human’, ‘animate’, ‘rest’.

## 4 Evaluation

We divide the treebank data approximately into ratio 2:1 for training and testing respectively. The training data contains 2162 entity pronouns and the test data contains 1071 entity pronouns.

### 4.1 Results

Table (2) shows the accuracies for different types of pronouns resolved by the rule-based module.

	Total pronouns	Correct Resolved	Accuracy
Reflexive Pronoun	156	129	.82
Relative Pronouns	80	68	.85
Locative Pronouns	48	37	.77
1st and 2nd person Pronouns	81	76	.93
Third person Pronouns	706	343	.48
Overall (Rule based system)	<b>1071</b>	<b>653</b>	<b>.60</b>

Table 2: Accuracy of the rule-based system

Results in Table 2 show that performance of the rule based system is quite high for all types of pronouns except for third person personal pronouns. This motivates us to use a learning based approach for the pronouns which remain unresolved in the first module. Table (3) shows the overall performance of the hybrid system achieved over the rule-based system by using different sets of features. The best performance (**0.70**) is achieved with a combination of all the features.

	Total	Correct	Accuracy
Rule based system(RB)	1071	653	.60
RB+Distance	1071	696	.64
RB+Distance+Agreement	1071	713	.66
RB+Distance+Animacy	1071	731	.68
RB+Dist+Animacy+Agreement	<b>1071</b>	<b>753</b>	<b>.70</b>

Table 3: Accuracy of the hybrid system

We provide a tentative comparison of our approach with two earlier systems : (Dakwale and Sharma, 2011) and (Uppalapu and Sharma, 2009).

Though an exact comparison is not possible due to unavailability of the data used in those systems.

	Total	Correct	Accuracy
Uppalapu-S	142	123	.86
Uppalapu-L	100	64	.64
(Dakwale and Sharma, 2011)	258	134	.52
Our system	<b>1071</b>	<b>753</b>	<b>.70</b>

**Table 4:** Resolution results of the three systems. Uppalapu-S and Uppalapu-L are the results of (Uppalapu and Sharma, 2009) for short and long story data respectively

## 4.2 Discussion and Error analysis

Table (4) shows that our system has achieved noticeable improvement over (Dakwale and Sharma, 2011), which is a knowledge poor approach using limited information. However, our system uses treebank data with information such as dependency and animacy.

(Uppalapu and Sharma, 2009) presents results for two sets of data, i.e. long and short stories. The overall accuracy of our approach is better than the accuracy for their long story data, although it is lower than theirs for their short story data. We have presented our results on treebank data which contains news articles from various domains with average size of 20 sentences, above results show that our approach performs consistently better even for longer texts and domain independent data. Also, the performance of the system for third person pronouns is relatively lower than that of other types of pronouns. Table 5 shows a break-up of the distribution of third person pronouns into two forms: Proximal and Distal, and their accuracies. The accuracy for resolution of proximal pronouns is exceptionally low than that of distal pronouns which can be attributed to the ambiguity in the resolution of distal pronouns which can refer to animate as well as inanimate objects

	Total	Correct	Accuracy
Proximal	132	43	.32
Distal	574	394	.68
Total Third person	706	437	.61

**Table 5:** Separate results for proximal and distal third person

## 5 Conclusion and Future Work

The rule based system achieved a substantial accuracy of 60% which implies that dependency relations can help achieve an acceptable resolution performance for Hindi, and the use of decision tree classifier demonstrated a substantial improvement of 10% over the rule based system's accuracy. This shows that semantic features like animacy and Named entity categories provide important linguistic information for anaphora resolution.

In the current work, we have focused only on the resolution of entity pronoun references. In fu-

ture we aim at the identification of reference type and resolution of event anaphora. We also aim to conduct experiments with dependency structures for anaphora resolution in other Indian languages such as Telugu, Bengali etc.

# Structure Cognizant Pseudo Relevance Feedback

Arjun Atreya V, Yogesh Kakde, Pushpak Bhattacharyya, Ganesh Ramakrishnan

CSE Department, IIT Bombay, Mumbai

{arjun,pb, ganesh}@cse.iitb.ac.in, yrkakde@gmail.com

## Abstract

We propose a structure cognizant framework for pseudo relevance feedback (PRF). This has an application, for example, in selecting expansion terms for general search from subsets such as Wikipedia, wherein documents typically have a minimally fixed set of fields, *viz.*, *Title*, *Body*, *Infobox* and *Categories*. In existing approaches to PRF based expansion, weights of expansion terms do not depend on their field(s) of origin. This, we feel, is a weakness of current PRF approaches. We propose a per field EM formulation for finding the *importance* of the expansion terms, in line with traditional PRF. However, the final weight of an expansion term is found by weighting these *importance* based on whether the term belongs to the title, the body, the infobox or the category field(s). In our experiments with four languages, *viz.*, English, Spanish, Finnish and Hindi, we find that this structure-aware PRF yields a 2% to 30% improvement in performance (MAP) over the vanilla PRF. We conduct ablation tests to evaluate the importance of various fields. As expected, results from these tests emphasize the importance of fields in the order of title, body, categories and infobox.

## 1 Introduction

The ruling paradigm for Information retrieval (IR) (Manning et al., 2009) is *Pseudo Relevance feedback (PRF)*. In PRF, an assumption is made that the top retrieved documents are relevant to the query for picking expansion terms. Zhai and Lafferty (2001) show that using pseudo relevance feedback on monolingual retrieval improves the

overall result considerably over the retrieval without PRF. In case of retrieval for languages with little web content, Chinnakotla et al., (2010) show that taking help of another language to expand query helps in better performance.

The motivation for our work is as follows. Every document in the web collection has certain structure associated with it *viz.*, title, body, links, *etc.* Each of these fields has different level of importance in the document. For instance, document title broadly describes the whole document, whereas the body of the document contains the details. Content in these fields have different scales of contribution in uniquely representing that document in the collection. Hence it is important to consider the structure of a document while extracting expansion terms from it.

Structure based PRF, of course, draws on the basic theory of PRF as in Zhai and Lafferty (2001), which is based on expectation maximization (EM). We formulate a per field EM to get the weights of expansion terms and subsequently take their weighted sum in a spirit similar to mixture models.

## 2 Related Work

Approaches based on the use of external resources like wordnet for query expansion, though extensively studied, have been eventually dropped (Gong et al., 2005; Qiu and Frei, 1993). Several works have also used structure of documents for query expansion. These works propose the technique of first choosing relevant documents and finding expansion terms, therefrom, using co-occurrence, meta tags *etc.* Al-Shboul and Myaeng (2011) use categories of Wikipedia pages to cluster documents and retrieve the relevant cluster for query. This approach gives better recall at the cost of precision.

Anchor texts in Wikipedia pages pointing to a category same as the query category are picked

as expansion terms in Ganesh and Verma (2009). This work exploits the structure only in the form of anchor texts and category information.

Techniques to disambiguate query terms based on disambiguation pages of Wikipedia are proposed in (Xu et al., 2009; Lin et al., 2010). Once disambiguated, the page is considered for picking expansion terms. Other literatures that deal with PRF based IR are (Milne. et al., 2007; Lin and Wu, 2008; Lv and Zhai, 2010; Jiang, 2011).

### 3 Our System

We make use of Wikipedia as an external document collection for picking expansion terms. Reasons for this are: *a*) open source *b*) well-defined structure *c*) authenticity due to crowdsourcing and review, *d*) coverage across domains and languages *e*) ever growing. Four fields from the Wikipedia document are considered *viz.*, *title*, *body*, *categories* and *infobox*.

Our problem statement is:

*Given a query Q in a language L, retrieve relevant results from any document collection (WWW/dataset) in L using Wikipedia documents in L for generating expansion terms.*

The process of PRF based retrieval involves the following steps.

1. Retrieve ranked list of Wikipedia documents for a given query  $Q$ - *RetrievalModel* (Section 3.1)
2. Pick expansion terms from the top  $k$  retrieved documents- *ExpansionModel* (Section 3.2)
3. Obtain a modified query  $Q'$  by combining the expansion terms with the query terms- *AggregationModel* (Section 3.3)
4. Retrieve ranked list of documents for the modified query  $Q'$ - *RetrievalModel* (Section 3.1)

#### 3.1 Retrieval Model

Language model based retrieval is used in (Ponte and Croft, 1998) and (Croft, 2003). For every document  $D$ ,  $\theta_D$  is the probability distribution of terms. Similarly,  $\theta_Q$  is for the query  $Q$ . The "distance" between the query and a document,  $D_{KL}$  is calculated as equation 1.

$$D_{KL}(\theta_Q|\theta_D) = - \sum_w P(w|\theta_Q) \log P(w|\theta_D) \quad (1)$$

The more the relevance of  $D$ , the less is  $D_{KL}(\theta_Q|\theta_D)$ .

#### 3.2 Expansion Model

This model picks expansion terms that get combined with the query. Choosing expansion terms involves selecting a set of relevant documents and identifying terms that uniquely represent them. We use the retrieval model mentioned in section 3.1 to pick top  $k$  documents.

There exist many off-the-shelf expansion models to choose expansion terms from (Ganesh and Verma, 2009; Al-Shboul and Myaeng, 2011). None of these, however, exploit the structure of relevant documents. (Zhai and Lafferty, 2001) explain one of the state of art techniques to choose expansion terms using EM algorithm without considering the structure of a document. In Zhai and Lafferty (2001), a set of relevant documents  $R$  is retrieved and all terms in these documents are considered as observations. Since  $R$  is a subset of the document collection  $C$ , all terms in  $R$  also appear in  $C$ . Both  $R$  and  $C$  act as sources for generating terms.

Given a document, the content in each field of the document represents the document with different levels of importance. In our expansion model, we use Wikipedia as the source of expansion terms. Every Wikipedia document is composed of four fields *title*, *body*, *category* and *infobox*.

Expansion terms are picked independently from each field of the Wikipedia document. We run EM algorithm on each field as explained in Zhai and Lafferty (2001). We formulate an EM algorithm for picking expansion terms from *Title* field instead from a document as the whole. *Body*, *Categories* and *Infobox* fields follow the same formulation. The probability of all title terms in  $R$  ( $P_{R_{tk}}$ ) is maximized using EM algorithm. Similarly, body terms, category terms and infobox terms are also maximized.

The output of interest in an iterative EM algorithm is the set of expansion terms for every field. EM algorithm gives the weights of the expansion terms, indicating their importance. Weighted combination of these sets of expansion terms from different fields of the document leads to the final set of expansion terms. Empirically decided weights ( $\alpha$ 's) are used for combining expansion terms from different fields as shown in the equa-

	Dataset	Query set	No.of documents
English	FIRE 2010	76-125(50)	1,25,586
Spanish	ELRA-E0036	41-200(160)	4,54,045
Finnish	ELRA-E0036	91-250(160)	55,344
Hindi	FIRE 2010	76-125(50)	95,216

Table 1: Details of Experimental Setup; numbers in parenthesis indicate the number of queries

tion 2.  $\alpha_x$  indicates the importance given to the document field  $x$ .

$$P_{Rk} = \alpha_t \cdot P_{R_tk} + \alpha_b \cdot P_{R_bk} + \alpha_c \cdot P_{R_ck} + \alpha_i \cdot P_{R_ik} \quad (2)$$

where  $\alpha_t + \alpha_b + \alpha_c + \alpha_i = 1$

### 3.3 Aggregation Model

Once expansion terms are picked from Wikipedia documents, they are merged with initial query terms. Introducing expansion terms increases the possibility of topic drift for the intended information need. Hence, it is important to give more weight to query terms compared to expansion terms. The equation 3 indicates the aggregation of query  $Q$  with the expansion terms  $E$  to get the modified query  $Q'$  with  $\lambda$  as the weight given to the query over the expansion terms.

$$Q' = \lambda Q + (1 - \lambda)E \quad (3)$$

## 4 Experimental Setup

We conduct experiments to evaluate the effect of document structure on expansion terms, using ELRA-E0036<sup>1</sup>(part of CLEF) and FIRE 2010<sup>2</sup> datasets. Experiments are done in four languages, English, Spanish, Finnish and Hindi. Following are the set of experiments conducted:

*NORF- No relevance feedback*: This is the simplest form of retrieval without using any expansion.

*PRF- Pseudo relevance feedback without using the structure of a document*: This is traditional PRF. All terms in Wikipedia are considered to be equally important, and the naive expansion model of (Zhai and Lafferty, 2001) is used to find expansion terms.

*StructPRF- Pseudo relevance feedback using the structure of a document*: This is our proposed model. Structure of Wikipedia documents is used for finding expansion terms using the model described in section 3.2.

<sup>2</sup><http://www.isical.ac.in/~fire/data.html>

	<i>NORF</i>	<i>PRF</i>	<i>StructPRF</i>
English	0.1758	0.2022 (+15%)	0.2189 (+24.5%)
Spanish	0.0433	0.1352 (+212%)	0.1778 (+310%)
Finnish	0.1532	0.2477 (+61.6%)	0.2517 (+64.3%)
Hindi	0.2321	0.2364 (+1.8%)	0.2529 (+9%)

Table 2: MAP scores; plus(+) indicates improvement over *NORF*

	<i>NORF</i>	<i>PRF</i>	<i>StructPRF</i>
English (2761)	1888	2080	2138
Spanish (2694)	391	1818	1919
Finnish (1377)	243	875	974
Hindi (915)	748	780	785

Table 3: Relevant documents retrieved; numbers in parenthesis indicate the actual relevant documents

Table 1 describes the experimental details. For every query, 1000 results are retrieved and used for evaluation. All languages use their respective Wikipedia content for picking expansion terms.

## 5 Results

MAP scores are shown in table 2. *StructPRF* has an overall improvement in MAP of 8% for English, 30% for Spanish, 2% for Finnish and 7% for Hindi over *PRF*. Figure 1 shows average precision values of all queries at different result positions for all languages. It is observed that there is a definite improvement in precision values for *StructPRF* over *PRF*. As we go down the list of retrievals ( $P@k$ , with  $k$  increasing), the improvement in *StructPRF* decreases but never gets below *PRF* and *NORF*.

Figure 2 depicts precision vs. recall curves for all languages. The results indicate that the *StructPRF* has a better precision for most recall val-

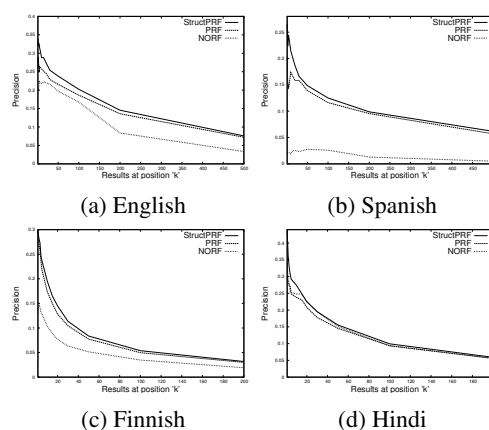

Figure 1:  $P@k$  Values

	English	Spanish	Finnish	Hindi
<i>NoTitle</i>	0.1953(-11%)	0.1179(-33%)	0.1914(-23%)	0.2086(-17%)
<i>NoBody</i>	0.2059(-6%)	0.1383(-22%)	0.2333(-8%)	0.2185(-13%)
<i>NoCategories</i>	0.2172(-0.7%)	0.1436(-19%)	0.2358(-7%)	0.2209(-12%)
<i>NoInfobox</i>	0.2178(-0.5%)	0.1467(-17%)	0.2449(-3%)	0.2234(-11%)

Table 4: MAP scores for ablation tests; minus(-) indicates percentage decrease from *StructPRF*

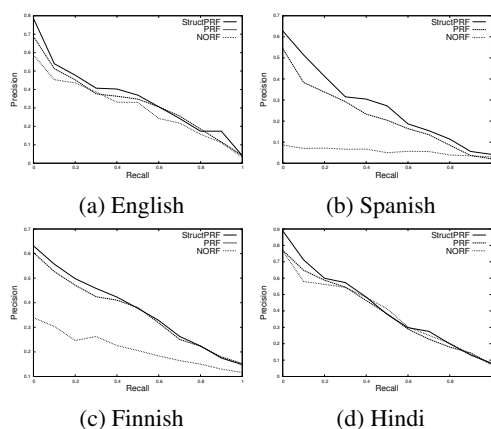

Figure 2: Precision-Recall Curve

ues. At 60% to 80% recall, precision of *PRF* is better than *StructPRF* in English. This indicates that most of the relevant documents are pushed higher up the order in the result set. For Spanish and Finnish, *StructPRF* consistently outperforms *PRF*. In Hindi, between 40% to 60% recall, *PRF* has a higher precision than *StructPRF*. This is again because of the relevant documents being pushed higher in the ranked list.

Analyzing query wise performances of *NORF*, *PRF* and *StructPRF* for all languages, we observed that *StructPRF* has best precision compared to other two for  $\approx 60\%$  of queries in all languages.

Table 3 shows that there is an improvement in the number of relevant documents retrieved by *StructPRF* compared to *PRF* for all languages. *StructPRF* has an improvement of 2.8%, 5%, 11% and 0.8% recall in English, Spanish, Finnish and Hindi respectively over *PRF*.

From these results it is evident that structure cognizant PRF benefits retrieval performance in terms of both precision and recall.

## 6 Ablation Tests

In ablation tests, we "disable" one field, that is, do not take expansion terms from a field, and get the MAP score. For instance, *NoTitle* has body, cat-

egories and infobox with equal weights (*i.e.*, 1/3) and weight of the title field as 0.

Table 4 lists the MAP scores for all cases of ablation. The name of each of these cases indicates the field "disabled". It is observed that the worst degradation in MAP occurs on disabling the *Title* field. This happens for all languages. The degradation decreases in the order of *Title*, *Body*, *Categories* and *Infobox*.

The above observation translates to setting values for  $\alpha_t$ ,  $\alpha_b$ ,  $\alpha_c$  and  $\alpha_i$  described in section 3.2 as  $\alpha_t > \alpha_b > \alpha_c > \alpha_i$  with  $\alpha_t + \alpha_b + \alpha_c + \alpha_i = 1$ . Hence the choice of  $\alpha$ 's for experimentation are 0.4, 0.3, 0.2 and 0.1 for  $\alpha_t$ ,  $\alpha_b$ ,  $\alpha_c$  and  $\alpha_i$  respectively.

The fields being important in the order of *Title*, *Body*, *Categories* and *Infobox* is quite intuitive. This is because the *Title* represents the content of the document with a few words. Hence, the *Title* field has a larger impact as compared to the *Body* field. Though *Categories* and *Infobox* have lesser words, like *Title*, they refer to a generic context of the query.

## 7 Conclusions and Future Direction

In this paper, we have explored the usage of document structure for PRF. We proposed an expansion model that considers each field of the document with different levels of importance in picking expansion terms. This structure cognizant PRF is compared with both traditional PRF and with no-feedback, for four languages, English, Spanish, Finnish and Hindi. Experimental results show that using structure helps in getting considerable improvement in both precision and recall over traditional PRF. Ablation tests reveal the relative importance of the fields, with "title" field proving more important than others.

In our work, we combine expansion terms obtained from every field of a document in a decoupled way, that is, through separate per field EMs. In future, we would like to explore tight coupling of document fields (EM over individual per-field EM).

# Cross-domain answer ranking using importance sampling

Anders Johannsen Anders Søgaard

University of Copenhagen

{ajohannsen, soegaard}@hum.ku.dk

## Abstract

We consider the problem of learning how to rank answers across domains in community question answering using stylistic features. Our main contribution is an importance sampling technique for selecting training data per answer thread. Our approach is evaluated across 30 community sites and shown to be significantly better than random sampling. We show that the most useful features in our model relate to answer length and overlap with question.

## 1 Introduction

Community Q&A (cQA) sites are rich sources of knowledge, offering information often not available elsewhere. While questions often attract the attention of experts, anyone can chip in, and as a result answer quality varies a lot (Fichman, 2011). cQA sites deal with this problem by engaging the users. If people like an answer or find it useful, they vote it up, and if it is wrong, unhelpful or spammy, it gets a down vote and is sometimes removed altogether. To a large degree the success of cQA can be attributed to this powerful content filtering mechanism. The voting induces a ranking of the answers, and that is the ranking we wish to reproduce in this paper.

We are interested in learning a ranking model based on textual or stylistic features only, extracted from the question and the answer candidate, because willfully ignoring information about user behavior and other social knowledge available in cQA sites makes our model applicable in a wider range of circumstances. Outside the world of cQA, automatic answer ranking might, for instance, be used to prioritize lists of answers found in FAQs or embedded in running text. In other words, we are interested in learning *a reranking model that is generally applicable to question answering systems*.

Part of what makes one answer preferable to another is how effective it is in communicating its advice. There may be plenty of answers that in some technical sense are correct and yet are not especially helpful. For instance, if the kind of advice we are looking for involves a procedure, an answer structured as “First ... Then ... Finally” would probably be of greater use to us than an answer with no discernible temporal structure. Our features capture aspects of the discourse surface structure of the answer. If the model is supposed to be generally applicable to question answering it also needs to exhibit *robust performance across domains*. Learning that mentions of specific Python modules correlate with answer quality in Stack Overflow does not help us answer questions in the cooking domain. We need to limit ourselves to features that transfer across domains. We further hypothesize a link between question type and answer structure (e.g. good answers to how-to questions look different from good answers to questions that ask for definitions), and test this experimentally by choosing training data for our ranker according to question similarity.

Our contribution is thus two-fold. We evaluate various stylistic feature groups on a novel problem, namely cross-domain community answer ranking, and introduce an importance sampling strategy that leads to significantly better results.

**Setup** Given a question and a list of answers the task is to predict a ranking of the answers matching the ranking induced by community voting. We approach this as a pairwise ranking problem, transforming the problem into a series of classification decisions of the form: does answer *a* rank ahead of *b*? We wish to train a model that maintains good performance across domains, and our evaluation reflects this goal. We use a leave-

one-out procedure where one by one each domain is used to evaluate the performance of a ranking model trained on the rest of the domains. Testing is thus always out-of-domain, and the setup promotes learning a generic model because the training set is composed of a variety of domains.

The rest of the paper is organized as follows. In the next section we introduce the cQA corpus. Section 3 describes several classes of motivated, domain-independent features. Our experiments with ranking and domain adaptation by similarity are described in Section 5, and the results are discussed in Section 6. Before the conclusion we review related work in Section 8.

## 2 The STACKQA corpus

We collected a corpus, the STACKQA corpus, consisting of questions paired with two or more answers from 30 individual cQA sites on different topics<sup>1</sup>. All sites are a part of the Stack Exchange network, sharing both the technical platform and a few very simple guidelines for how to ask a question. In the FAQ section of all sites, under the heading of "What kind of questions should I not ask here?", an identical message appears: "You should only ask *practical, answerable questions based on actual problems that you face*. Chatty, open-ended questions diminish the usefulness of our site and push other questions off the front page." It is, in other words, not a discussion club, and if a dubious question or answer enters the system, the community has various moderation tools at disposal. As a consequence, spam is almost non-existent on the sites.

## 3 Feature sets

Below we describe our six groups of features. Previous studies have shown that most of these features are correlated with answer quality, see (Jeon et al., 2006; Zhou et al., 2012; Harper et al., 2008; Su et al., 2010; Aji and Agichtein, 2010).

**Discourse** We use the discourse marker disambiguation classifier of Pitler and Nenkova (2009) to identify discourse uses. We have features which count the number of times each discourse marker appears.

**Length** This group has four features that measure the length of the answer in tokens and sen-

<sup>1</sup>We use the August 2012 dump from <http://www.clearbits.net/torrents/2076-aug-2012>

tences as well as the difference between the length of the question and the length of the answer. An additional two features track the vocabulary overlap between question and answer in number of lexical items, one including stop-words and one excluding these.

**Lexical diversity** An often used measure of lexical diversity is the type-token ratio, calculated as the vocabulary size divided by the number of tokens. We use a variation, the lemma-token ratio, which works on the non-inflected forms of the words.

**Level and style** For most readers understanding answers with long compound sentences and difficult words is a demanding task. We track difficulty of reading using the Flesch-Kincaid reading level measure and the closely related average sentence length and average token length. Three additional stylistic features capture the rate of inter-sentence punctuation, exclamation marks, and question marks. Finally, a feature gives the number of HTML formatting tokens.

**Pronouns** Scientific text almost never uses the pronoun "I", but other genres have different conventions. In cQA, where one person gives advice to another, "I" and "you" might feel quite natural. We capture personal pronoun use in six features, one for every combination of person and number (e.g. first person, singular).

**Word categories** These features build on groups of functionally related words. Examples of categories are transition words (213), which is a non-disambiguated superset of the discourse markers, phrases that introduce examples (49), comparisons (66), and contrast (6). Numbers in parenthesis indicates how many words there are in each category. For each category we count the number of token occurrences and the number of types.<sup>2</sup>

## 4 Importance sampling

The cQA sites contain abundant training data, but the sites are diverse and heterogeneous. We hypothesize that training our models on similar threads from different domains will improve our models considerably. We measure similarity with

<sup>2</sup>The word lists are distributed as a part of the LightSIDE essay assessment software package found at <http://lightsidelabs.com/>

respect to direct questions, disregarding any explanatory text. One complication is that the question text may have more than one sentence with a question mark after it—in fact, each thread contains 2.2 sentences ending with question marks, on average. To assess the similarity between two question threads  $Q$  and  $Q'$ , we take the maximum similarity between any of their question sentences:

$$\text{sim}(Q, Q') = \max_{q \in Q, q' \in Q'} \text{sim}(q, q')$$

The similarity function used is a standard information retrieval TF\*IDF-weighted bag-of-words model. Table 1 shows an example of the similar questions found by this method.

Since importance sampling requires a separately trained classifier for each question thread, we evaluate on a small set of 500 question threads per domain.

## 5 Experiments

For each site we sample up to 5000 question threads that contain between 2 and 8 answers. When more than one answer have the same number of votes, making it impossible to rank the answers unambiguously, one of the tied answers is kept at random. The number of threads used for training is varied from 50 to 5000 to obtain learning curves. We compare importance sampling against random sampling. Because this procedure is random, we repeat it three times and report an average performance figure.

The baseline for evaluating our feature model is a TF\*IDF weighted bag-of-words model with each answer normalized to unit length.

We rank the answers by applying the pairwise transformation (Herbrich et al., 1999) and learn a classifier for the binary relation  $\prec$  (“ranks ahead of”). Training data consists of comparisons between pairs of answers in the same thread.

We report  $F_1$  score for the binary discrimination task and Kendall’s  $\tau$  for the ranking. In Kendall’s  $\tau$  1.0 means perfect fidelity to the reference ordering, -1.0 is a perfect ordering in reverse, and .0 corresponds to a random ordering.

## 6 Results

Table 3 shows that importance sampling leads to significantly better results.

The ablation results in Table 2 show that the largest negative impact comes from removing the

length-related features. Leaving them out, the performance drops to .136 (from .210) in the ranking fidelity measure.

## 7 Discussion

The fact that no feature group independently contributes to the classification performance, apart from the length related features, is interesting, but note that even with the length related features removed, the system is still significantly better than the bag-of-words baseline.

The relatively low performance raises two questions, discussed below. How much trust should we put into the user rankings, which are the gold standard in the experiments? And what is the maximum performance we can expect?

There is no guarantee that people who submit votes are experts. For this reason, Fichman (2011) dismiss the “best answer” feature of cQA, adding that askers often select the best answer guided by social or emotional reasoning, rather than by facts. In a case study on Stack Overflow (part of the StackExchange network), Anderson et al. (2012)

Thread count	Kendall's $\tau$			F1		
	Baseline	System	System+Sim	Baseline	System	System+Sim
50	.070	.075	.099	.355	.522	.536
100	.107	.084	.129	.381	.528	.551
250	.121	.095	.166	.518	.533	.571
500	.135	.124	.199	.529	.549	.588
1000	.146	.158	.229	.557	.566	.603
5000	.161	.215	<b>.253</b>	.578	.595	<b>.615</b>

Table 3: Ranking performance. Baseline is a bag-of-words model, and System uses the full feature set described in the paper. System+Sim uses the same feature model as System but with importance sampling. Results are an average over domains, and all differences between System+Sim and System are significant at  $p < .01$  using the Wilcoxon ranksum test.

find that voting activity on a question is influenced by a number of factors presumably not connected to answer quality, such as the time before the first answer arrives, and the total number of answers.

With respect to the maximum attainable performance, an important consideration is that an answer is judged on other factors than how well it is written. When seeking a solution to a practical problem, the best answer is the one that solves it, no matter how persuasive the other answers are. This holds particularly true for cQA sites that advise people only to ask questions related to actual, solvable problems. The textual model is strong mainly if we have multiple alternative answers, which are indistinguishable with respect to facts, but differ in how their explanations are structured.

## 8 Related work

Moschitti and Quarteroni (2011) consider the problem of reranking answers in question-answering systems. They use kernelized SVMs, noting that the kernel function between (question, answer) pairs can be decomposed into a kernel between questions and a kernel between answers:  $K(\langle q, a \rangle, \langle q', a' \rangle) = K(q, q') \oplus K(a, a')$ . They share the intuition behind our approach, that pairs with more similar questions should have higher weight, but we sample data points instead of weighting them and use different similarity functions. Choi et al. (2012) establish a typology of questions in social media, identifying four different varieties: information-seeking, advice-seeking, opinion-seeking, and non-information seeking. For our purposes their categories are probably too broad to be useful, and they require manual annotation.

Agichtein et al. (2008) identify high quality answers in the Yahoo! Answers data set. In addition to a wide range of social features, they have three groups of textual features: punctuation and typos, syntactical and semantic complexity, and grammaticality.

Shah and Pomerantz (2010) evaluate answer quality on Yahoo! Answers data. They solicit quality judgements from Amazon Mechanical Turk workers who are asked to rate answers by 13 criteria, such as readability, relevancy, politeness and brevity. The highest classification accuracy is achieved using a combination of social and text length features.

Lai and Kao (2012) address the problem of matching questions with experts who are likely to be able to provide an answer. Their algorithm is tested on data from Stack Overflow.

He and Alani (2012) investigate best answer prediction using StackExchange's Serverfault and cooking communities as well as a third site outside the network.

## 9 Conclusion

In this paper we report on experiments in cross-domain answer ranking. For this task we introduced a new corpus, a feature representation and an importance sampling strategy. While the questions and answers come from a cQA setting, models learned from this corpus should be more widely applicable.

## Abstract

In this paper, we address the problem of the morphological analysis of an Arabic dialect. We propose a method to adapt an Arabic morphological analyzer for the Tunisian dialect (TD). In order to do that, we create a lexicon for the TD. The creation of the lexicon is done in two steps. The first step consists in adapting a Modern Standard Arabic (MSA) lexicon. We adapted a list of MSA derivation patterns to TD. The second step consists in improving the resulting lists of patterns and roots by using TD specific roots and patterns. The proposed method has been tested and has achieved an F-measure performance of 88%.

## 1 Introduction

The Arabic Dialect (*AD*) is a collection of spoken varieties of Arabic. It is used in everyday communication. So, it is so important to consider it in the new technologies like dialogue systems, telephone applications, etc. (Zribi et al., 2013). The majority of these applications need a morphological analysis to segment words and to exploit their morphological features.

Many important works have focused on the morphological analysis of the Arabic language, mainly on Modern Standard Arabic (*MSA*). *AD* has not received much attention due to the lack of dialectal tools and resources (Duh and Kirchhoff, 2005). However, there are differences between *MSA* and *AD*, they are considered as two related languages.

Therefore, we suggest in this paper to exploit and adapt an *MSA* morphological analyzer (*MA*) to Tunisian Dialect (*TD*). The adaptation is done in two steps. The first step is to adapt an *MSA* lexicon to *TD* and to improve the resulting lexicon with *TD* specific roots and derivation patterns<sup>1</sup>. The second step is to integrate the

resulting lexicon into the *MSA* morphological analyzer.

The paper has 5 main sections. Section 2 presents a lexical study of the *TD*. We present in section 3 an overview of previous works. We describe in section 4 our method for adapting *MSA* resources to *TD*. In section 5, we give the results of the system evaluation, and finally, we discuss some analysis errors.

## 2 TD lexical study

*TD* is characterized by a phonology, a morphology, a syntax and a lexicon which have differences and similarities compared to *MSA* and even to other Arabic dialects (Zribi et al., 2013). There are many regional varieties. In this paper, we focus on the standard *TD* (the dialect used in the media that is the most understood by all Tunisians).

### 2.1 STAC corpus presentation

In order to develop and test our method, we created the *STAC* corpus by recording and manually transcribing some radio and TV broadcasts. *STAC* corpus consists of 3 hours and 20 minutes of speech. The corpus relates to various fields: politics, health, social issues, religious issues and others. *STAC* corpus is composed of about 27,144 words. We used  $\frac{3}{4}$  of the corpus for the training of our method. This portion of the corpus contains 443 distinct nouns and 235 distinct verbs. We used the rest of the corpus to test the performance of our system (see section 5). We used *OTTA* conventions (Zribi et al., 2013) while transcribing and annotating our *STAC* corpus. It is to be noted that we respect in this paper the *OTTA* conventions (Zribi et al., 2013) when writing examples of words in *TD*.

<sup>1</sup> The Arabic derivation system consists to use a set of patterns and roots to generate words. To generate the word “يكتب”, *yaktibu*, *he write*, we replace the *r<sub>i</sub>* letters in the

following pattern “*yar<sub>1</sub>r<sub>2</sub>ir<sub>3</sub>u*” with the letters of the root “*ktb*” by respecting the order of letters. (a,i,u) represent the Arabic short vowels. The Arabic orthographic transliteration used in this paper is presented in (Habash et al., 2007).

## 2.2 Classification of the TD lexicon

The linguistic study of the words composing our TD corpus shows that its lexicon can be classified into four classes. *The first class (C1)* includes words that are derived from MSA roots via the application of the derivation patterns of MSA. These patterns are generally modified compared to those of MSA. They witness small changes, mainly, in vowels and in some letters forming these patterns (some letters are added, deleted or modified). For example, the derivation patterns (يُفَعِّلُ,  $yir_1r_2ar_3$ ) and (فَعَّيَاةُ,  $r_1r_2aAyap$ ) are the result of some changes of the pattern (يُفَعِّلُ,  $yar_1r_2ar_3u$ ) and the pattern (فَعَّيَاةُ,  $r_1ir_2Ar_3ap$ ). This class presents 85.13% of our STAC corpus. *The second class (C2)* includes words that are derived from TD specific roots via the application of patterns following the MSA derivation patterns (the patterns used in *(C1)*). For example, the verb (يَنْقُزُ,  $ynagiz$ , “he jumps”) is derived from the Tunisian root (نَقَزَ,  $ngz$ ) and the pattern (يُنْفَعِّلُ,  $yr_1ar_2ir_3$ ). This class presents 8% of our STAC corpus. *The third class (C3)* includes words that are derived from the MSA roots with the application of TD specific patterns. These patterns do not match with MSA patterns. For example, the word (فَهْوَاجِي,  $qahwaAjiv$ , “a waiter”) is derived from the MSA root (فَهْو,  $qhw$ ) and the derivation pattern (فَعَّلَاجِي,  $r_1ar_2r_3aAjiv$ ). This class presents 4.26% of our STAC corpus. *The fourth class (C4)* contains words which are derived from foreign languages specifically French. For example, the word (يُدَوِّشُ,  $ydawis$ ) is derived from the French sentence (il prend une douche, “he is having a shower”). This class presents 2.62% of our STAC corpus.

From this study, we deduce that to create a TD lexicon, we should determine the list of TD patterns and apply them to the list of MSA roots, or determine the list of TD roots, and apply the patterns of the MSA to generate a TD lexicon.

## 3 Related works

Arabic dialects can be considered as under-resourced languages because of the absence of tools and resources. Therefore, we will study some works dealing with the automatic processing of under-resourced languages. Among these works, we cite the works of Borin (2002), Das and Petrov (2011), Lindström and Müürisep (2009), Shalónova and Golénia (2010), etc. Some of these works ((Rambow et al, 2005), (Lindström and Müürisep, 2009), (Das and Petrov, 2011), etc.) are based on resources and

tools of cognate languages that are adapted for the processing the under-resourced language. Other works ((Yang et al., 2007), (Shalónova and Golénia, 2010), etc.) are based on a small amount of data for the analysis of under-resourced languages. Hana (2008) adopted this approach to propose a method for the morphological analysis of Czech language. He used a small list of words accompanied by information about their lemma and tags to develop a Guesser. The role of the Guesser is to deduce from a corpus the lemma-stem-paradigm candidates for each unknown word. These candidate paradigms are, then, validated and added to a lexicon. Hana (2008) utilized the resulting lexicon for developing a Czech MA. Some works have tackled the task of the morphological analysis of AD. The general idea of these works is to adapt existing tools designed for MSA. Among these works, we cite the work of Salloum and Habash (2011) and Almeman and Lee (2012) who added a list of dialectal affixes to two MSA MA (*BAMA* (Buckwalter, 2004) and *Al-Khalil* (Boudlal et al, 2011)). Habash et al. (2012) transformed an Egyptian dialect lexicon into a tabular form that is compatible the MA SAMA (Graff et al., 2009). Habash and Rambow (2006) developed *MAGEAD*, a MA for the Arabic language and its dialects.

We propose in this work to adapt a MSA MA. We propose first to adapt an MSA lexicon to TD and to improve the resulting lexicon with TD specific roots and patterns. Then, we integrate the resulting lexicon into the MSA MA.

## 4 Adapting MSA resources to TD

Our goal in this paper is to develop a TD morphological analyzer taking advantage of the existing resources of the Arabic language. Like previous works on AD morphological analyzers, we propose to adapt an existing MA analyzer and to create the necessary resources for its adaptation. We do not limit to add dialectal affixes, but we propose to incorporate a lexicon to a MA for MSA. Given that we don't have such a lexicon, we exploit the points of similarity between TD and MSA for its creation. First, we start from MSA lexicon to generate a small lexicon for the TD. We use this list for building a TD lexicon. The process of creation of TD lexicon is similar to the ending-based Guesser module of Hana (2008) that suggests a lemma-stem-paradigm candidate for each word in the corpus. Our method for building our TD lexicon is composed of

two main steps: the transformation of MSA patterns into TD patterns, and the extraction of TD specific roots and patterns. We detail in this section the different steps of our method. Then, we present the list of TD function words, affixes and clitics.

**Transformation of MSA patterns into TD patterns:** The first step of our method consists in determining from a set of MSA patterns the corresponding patterns in TD. Firstly, we classify the roots of the lexicon. Indeed, the Arabic roots can be classified according to several criteria: the number of root letters, the presence and the number of defective letters, etc. We adopt in our work the classification based on the presence and the number of defective letters. The study of TD morphology done by Ouerhani (2009) shows that the verbs belonging to the Mahmoudz class (which includes the roots containing the letter ء) share the same patterns and features and follow the same rules when they are transformed in TD. This deduction is also applicable to other root classes. For example, the verbs (بدأ, *badā>a*, “he started”) and (ملا, *malā>a*, “he filled”) in MSA that have respectively the roots (بدء, *bd'*) and (ملء, *ml'*) are transformed into (بدأ, *bdA*) and (ملا, *mlA*) in TD. These verbs follow the same derivation pattern in MSA (فَعَلَ, *r<sub>1</sub>ar<sub>2</sub>ar<sub>3</sub>a*) as in TD (فَعَا, *r<sub>1</sub>r<sub>2</sub>aA*) keeping the same morphological features. For each class of roots and for each MSA pattern, we determine the corresponding TD derivation pattern(s) and, we update their lists of features. In the case of verbs, we determine for each person and for each aspect, the different patterns in TD. For example, the MSA pattern (فَعَلَ, *r<sub>1</sub>ar<sub>2</sub>ir<sub>3</sub>a*) belonging to the Defective class (which includes the roots ending with defective letters) is transformed into (فَعَى, *r<sub>1</sub>r<sub>2</sub>aY*) in TD. In the case of nouns, we determine for each type (noun, adjective, etc.) and for each gender, the different patterns in TD. For example, for the Mahmoudz class, the derivation pattern (فَاعِلَةٌ, *r<sub>1</sub>aAr<sub>2</sub>ir<sub>3</sub>ap*) in MSA is transformed to (فَائِلَةٌ, *r<sub>1</sub>Ayr<sub>3</sub>ap*) in TD. The result of this step is a TD lexicon composed of 6,092 patterns (nominal and verbal) and 6,030 roots. Six hundred and fifty patterns were kept from the MSA lexicon during this step. This lexicon covers the first class (C1).

**Root and pattern extraction:** After converting MSA patterns to TD, the next step is intended to enhance the coverage of TD lexicon. This step is composed of two phases. The first phase consists in extracting TD specific roots. The aim of this step is to cover the second class (C2). We try to extract roots from a training

corpus which contains specific TD words such as the verb (نَجَزَ, *nagiz*, “he jumped”) and the noun (كَرْهَبَةٌ, *karhbap*, “a car”). To perform these tasks, we proceed as follows: We analyze all the words of the corpus using the lexicon generated in the first step. If there is no analysis, we try to extract roots for these words corresponding to patterns derived from the first step. The extracted roots are saved in a temporal list. If the frequency of a root is greater than two, we add this root to the lexicon. For example, using the verbal patterns (يَفْعَلُ, *yar<sub>1</sub>r<sub>2</sub>ir<sub>3</sub>*) and (فَعَّلَ, *r<sub>1</sub>ar<sub>2</sub>r<sub>3</sub>ir<sub>4</sub>*), we can extract respectively the root (نَجَزَ, *ngz*) and the root (يَنْجِزُ, *yngz*) for the unrecognized word (يَنْجِزُ, *ynagiz*, “he jumps”). Similarly, using the nominal patterns (تَفْعِيلَةٌ, *tar<sub>1</sub>r<sub>2</sub>ir<sub>3</sub>ap*) and (تَفَعَّلَةٌ, *tr<sub>1</sub>ar<sub>2</sub>r<sub>3</sub>ir<sub>4</sub>ap*), we can extract respectively the root (نَجَزَ, *ngz*) and the root (نَجِيزُ, *ngyz*) for the unknown word (تَنْجِيزَةٌ, *tangyzap*, “a jump”). The frequency of the root (نَجَزَ) is equal to 2. So, we consider that the root of the words (نَجِيزَةٌ and يَنْجِزُ) is (نَجَزَ). In the second phase, we adopt the same idea as in the first phase. It consists to extract TD specific patterns. We aim in this step to cover the third class (C3). We use in this phase the list of roots derived from the first step. The difference between the root extraction step and this step is the validation of generated patterns by an expert. The expert determines the morphological features corresponding to the patterns.

**Function words and affixes:** Based on our training corpus and the MSA lexicon, we determined the list of TD clitics and the list of function words. From the MSA lexicon, we determined the possible translations for each function word. We noted that some MSA function words are transformed into TD function word(s) and/or clitics but some others cannot be translated to TD. For example, the future particle (سوف, *swf*, “I will”) can be translated to (باش, *bA\$*, “I will”). However, the Arabic preposition (من, *mn*, “from”) keeps the same form in TD but in some cases it is transformed to a proclitic (م, *m*, “from”). Similarly, we determine from the MSA lexicon the possible translations for each affix and clitic. Some MSA clitics are transformed into TD function word(s) and/or clitics and some others don't have an equivalent in TD. For example, the future prefix (س, *s*, “I will”) is transformed in TD to (باش, *bA\$*, “I will”). However, the interrogation prefix “أ” is transformed to a suffix (شي, *\$y*, “what”). We note also the definition of many other affixes and clitics: such as the new form (و, *w*, “him”) of the enclitic (ه, *h*,

“him”). We obtained 289 function words, and 66 affixes and clitics for the TD.

## 5 Implementation and evaluation

We have chosen the MSA MA *Al-Khalil* (Boudlal et al, 2011) to adapt it for analyzing TD. We selected *Al-Khalil* because it had been elated the best MA among ten morphological analyzers in a competition held in ALESCO in 2010. We also used its lexicon for generating the TD lexicon. It is composed of 7,503 roots and 3,681 unvoveled patterns. To enable *Al-Khalil* to analyze TD, we integrated the TD lexicon in its morphological analysis process. Moreover, we added new rules in the process of word tokenization (e.g. rules for segmenting the new enclitic “ج”). We have corrected, also, some gaps in *Al-Khalil* (e.g. no difference between affixes and clitics in the segmentation process).

### 5.1 Results and discussion

To test the performance of our system, we used our training corpus STAC (see section 2.1). To our knowledge, there is no existing TD MA to compare with, we, therefore, used the MSA version of *Al-Khalil* as a baseline to compare the performance of our TD MA. The system’s performance is evaluated in two ways. Firstly, the system is tested according to the number of words recognized by the analyzer. We calculate the number of words for which the analyzer attributes at least one correct analysis. The objective of this evaluation is to measure the analyzer’s coverage of the different classes of the TD lexicon. To measure the correctness of the results given by our TD MA, we tried another evaluation. The system’s performance was evaluated with reference to the generated analysis. We calculated the number of correct analyses given for each word. An analysis is considered correct if all of its features (part-of-speech, mood, gender, number, root, pattern, etc.) are fully correct.

In the evaluation process, we calculated the performance of the system using the TD lexicon generated in the first step of our method. Then, we evaluated the system using the lexicon resulting from the second step. Table 1 shows the results of the evaluation.

	Baseline		Step 1		Step 2	
	Eval1	Eval2	Eval1	Eval2	Eval1	Eval2
Recall	54%	70%	78%	86%	79%	89%
Precision	70%	65%	52%	60%	77%	80%
F-measure	54%	63%	67%	77%	78%	88%

Table 1 : Evaluation results

The two evaluations processes show that the second step of creation of the lexicon has improved the result of the TD MA. First, we used the MSA version of *Al-Khalil* (Boudlal et al, 2011). We obtained an F-measure equal to 63%. This result justifies the importance of the shared part between MSA and TD. Then, the evaluation of the first step of our method shows an improvement in the results. Indeed, the system can cover 86% of the words of the test corpus. We obtained an improvement of about 14% in F-measure metric. Finally, the evaluation of the system by using the lexicon resulting from the second step shows also an improvement of results. We got an overall F-measure equal to 88%. The results show clearly that the extraction root and pattern module has an improvement effect (about 10%). The failure in the analysis of some words can be explained by the lack of some patterns and/or roots in the training corpus. In addition, the wrong extraction of roots presents another cause of analysis failure. Certainly, the errors generated by the step of extraction of roots were caused by the use of the same patterns for different root classes. As a consequence, the system proposed different roots for the same conjugated verb. Some incorrect roots were added to the lexicon. So these wrong roots increase the number of incorrect analyses of some words. For example, the extraction of roots module has extracted the root (ينقر, *ynagiz*, “he jumps”) from the verbs (ينقر, *ynagiz*, “he jumps”) and (ينقروا, *ynagzuwA*, “they jump”). This root is automatically added to the TD lexicon. We note that the root (ينقر, *yngz*) is wrong. Other cases of failure were caused by the foreign origin of certain words (words derived from foreign languages such as French).

## 6 Conclusion

In this paper, we have proposed an original method to create a lexicon for TD. This method is based on two steps: the first step converts MSA patterns to TD ones; the second step extracts roots and patterns. The resulted lexicon was integrated in the *Al-Khalil* MA. This system has shown encouraging results (F-measure = 88.86%). As for our perspectives, we intend to extend the TD lexicon by covering words derived from foreign languages. Then, we plan to develop a module allowing the disambiguation of the output of the system by applying machine learning techniques.

# Disambiguating explicit discourse connectives without oracles

Anders Johannsen Anders Søgaard  
University of Copenhagen  
{ajohannsen, soegaard}@hum.ku.dk

## Abstract

Deciding whether a word serves a discourse function in context is a prerequisite for discourse processing, and the performance of this subtask bounds performance on subsequent tasks. Pitler and Nenkova (2009) report 96.29% accuracy ( $F_1$  94.19%) relying on features extracted from gold-standard parse trees. This figure is an average over several connectives, some of which are extremely hard to classify. More importantly, performance drops considerably in the absence of an oracle providing gold-standard features. We show that a very simple model using only lexical and predicted part-of-speech features actually performs slightly better than Pitler and Nenkova (2009) and not significantly different from a state-of-the-art model, which combines lexical, part-of-speech, and parse features.

## 1 Introduction

Discourse relations structure text by linking segments together in functional relationships. For instance, someone might say "Saber-toothed tigers are harmless *because* they're extinct", making the second part of the sentence serve as an explanation for the first part. In the example the discourse connective *because* functions as a lexical anchor for the discourse relation. Whenever an anchor is present we say that the discourse connective is *explicit*.

Complicating the matter, phrases used as discourse connectives sometimes appear in a non-discourse function. For instance, "and" may be either a simple conjunction, as in "sugar and salt", or a discourse relation suggesting a temporal relationship between events, for instance "he struck the match and went away". The Penn Discourse

Figure 1: A picture of the problem. 10% of connectives account for roughly 75% of occurrences

Treebank (PDTB) (Prasad et al., 2008) distinguish 100 types of explicit connectives—a subset of these are listed in Table 2. The type of relationship is selected from a hierarchical structure where the four top-level categories are Comparison, Contingency, Temporal, and Expansion.

Discourse relations are important for many applications and, since the PDTB was released, much effort has gone into developing tools for recreating the annotations of the resource automatically. Recently two ambitious end-to-end parsers have appeared which transform plain text to full PDTB-style annotations (Lin et al., 2010; Ghosh, 2012). Both systems share a pipelined architecture in which the output of one component becomes the input to the next. A crucial first step in their processing is correctly identifying explicit discourse connectives; when unsuccessful subsequent steps fail.

An accuracy in the high nineties seems to suggest that the problem is almost solved. For the task of discourse connective disambiguation this unfortunately does not hold true, because, as we argue here, the task benefits from being seen and evaluated as a number of smaller tasks, one for each

connective type. Figure 1 shows why: the distribution of connectives follows a power law such that the majority of occurrences comes from relatively few but highly frequent connective types. If we do not take into account the uneven sizes of the categories, our performance figure ends up saying very little about how well we are doing on most of the connectives, because it is being dominated by the performance on a few high-frequency items.

In this paper we look in more detail on the evaluation of the discourse connective disambiguation task, in particular how two commonly used feature models perform on individual discourse connectives. The models are Pitler and Nenkova (2009) (P&N), and its extension by Lin et al. (2010) (Lin). Motivated by our findings we advocate the use of macro-averaging as a necessary supplement to micro-averaging. Additionally, we perform our experiments in a more realistic setting where access to oracle gold-standard annotations is not assumed. The observed performance drop from oracle to predicted parses leads us to propose a new model, which approximates the syntactical information of the parse trees with part-of-speech tags. Although these features are less powerful in theory, the model has comparable macro-average performance in realistic evaluation.

The rest of the paper is structured as follows. In the next section we give reasons why low-frequency connectives should not be overlooked. Section 3 describes our experiments, and Section 4 reports on the results. The discussion is in Section 5, followed by a review of related work in Section 6. Section 7 concludes the paper.

## 2 The importance of the long tail

Are there any compelling reasons to pay attention to the lower-frequency connectives when high-frequency connectives overwhelmingly dominate? As noted in the caption to Figure 1, the top 10 account for above 75% of the occurrences and top 20 for above 90%. So why should we care?

It turns out that the low-frequency connectives are quite evenly distributed among texts. In the Wall Street Journal part of the Penn Treebank, 70% of articles that contain explicit markers contain at least one marker not in the top 10. Not counting very short texts (having only two or fewer explicit connectives of any type), the number rises to 87%. While low performance on less frequent connectives does not hurt a token-level

macro-average much, it still means that you are likely to introduce errors in something like 70% of all WSJ articles. These errors percolate leading to erroneous text-level discourse processing.

In Webber and Joshi (2012) the prime example of a discourse application is automatic text simplification. Here, ignoring the long tail of discourse connectives would be out of the question, because it is precisely those less familiar expressions — which people encounter rarely and have weaker intuitions about — that would benefit the most from a rewrite. Two other examples, also cited in Webber and Joshi (2012), are automatic assessment of student essays (Burstein and Chodorow, 2010), and summarization (Thione et al., 2004). In student essays we encourage clear argumentative structure and rich vocabulary; failing to recognize that in an automatic system would not qualify as fair evaluation. And summarization is often performed over news wire, which, as shown in the PDTB, has a high per-article incidence of connectives not in top 10. Additionally, some low-frequency connectives like “ultimately” and “in particular” are strong cues for text selection.

Another reason to suspect that low-frequency connectives are important comes from an observation about the distribution of connectives in biomedical text. Ramesh and Yu (2010) report an overlap of only 44% between the connectives found in the The Biomedical Discourse Relation Bank (Prasad et al., 2011), a 24 article subset of the GENIA corpus (Kim et al., 2003), and the PDTB. The intersection contains high-frequency connectives, such as “and”, “however,” “also,” and “so”. Connectives specific to the biomedical domain include “followed by,” “due to,” and “in order to”, and the authors speculate that the unique connectives encode important domain specific knowledge.

## 3 Experiments

Our experiments are designed to shed light on three aspects of discourse connective disambiguation: 1) error distribution wrt. connective type; uneven performance builds a strong case for averaging over connective types instead of averaging over data points; 2) performance loss in the absence of an oracle; and 3) performance of simple model based on cheaper and more reliable annotations.

We experiment with three different feature sets,

all of which model syntactical aspects of the discourse connective.

The P&N and Lin feature sets are chosen to represent state-of-the-art. The high accuracy of P&N at 96.29% is frequently cited as an encouraging result, see Huang and Chen (2011; Alsaif and Markert (2011; Tonelli and Cabrio (2012; Zhou et al. (2010). Besides discourse parsing P&N has been used for tasks as diverse as measuring text coherence (Lin et al., 2011) and improving machine translation (Meyer and Popescu-Belis, 2012). The POS+LEX feature set is proposed as an alternative model. The baseline always predicts the majority class.

**P&N** This feature set derives from parse trees and replicates the features of Pitler and Nenkova (2009). Starting from the potential discourse connective, the features include the highest category in the tree subsuming only the connective called the self-category, the parent of that category, the left sibling of the self-category, and the right sibling of the self-category. A feature fires when the right sibling contains a VP, and another if there is a trace node below the right sibling. Note that the trace feature will never fire outside of the gold parse setting since state-of-the-art parsers do not predict trace nodes.

Importantly, there is a feature for the identity of the connective and interaction features between the connective and the syntactical features in effect allowing the model to fit parameters specific to each connective. Furthermore, combinations of the syntactical features are allowed, but they cannot be connective-specific.

**Lin** The feature set augments P&N with part-of-speech and string features for the tokens adjacent to the connective, as well as the part-of-speech of the connective itself. The part-of-speech features for the adjacent tokens interact with the part-of-speech of the connective, and the string features interact with the indicator feature for the connective. It also adds a syntax feature: the path to the root of the parse tree.

**POS+LEX** The simple feature set builds on part-of-speech tags and tokens. Part-of-speech tags are captured using a window of two tokens around the marker, and the lexical features are the same as Lin. Like P&N there is a feature for the identity of the connective as well as interaction

Model	Micro		Macro	
	Oracle	Pred.	Oracle	Pred.
Baseline	72.7	72.7	53.9	53.9
P&N	93.0	90.7	85.3	80.7
Lin	95.2	92.9	86.7	83.6
POS+LEX	89.7	89.7	82.5	83.5

Table 1: Comparing  $F_1$  score on oracle and predicted features using macro and micro averaging. A Wilcoxon signed rank test shows that the macro-averaged difference between POS+LEX and Lin10 using predicted features is not significant at  $p < 0.01$ .

features between the identity feature and other features.

In keeping with Pitler and Nenkova (2009) our learner is a maximum entropy classifier trained on sections 2-22 of the WSJ using ten-fold cross-validation.

### 3.1 Parsing Wall Street Journal

To obtain a version of the WSJ corpus containing fully predicted parses we use the Stanford Parser<sup>1</sup> training a separate model for each section. To parse a specific section we train on everything but that section (e.g. for parsing section 5 the training set is section 0-4 and 6-24). Average  $F_1$  on all sections is 85.87%. Although the very best state-of-the-art parsers<sup>2</sup> report  $F_1$  of above 90%, our parsing score greatly exceeds typical performance on real-life data, which is almost always out-of-domain with respect to 1980s WSJ. Thus this setting still compares favourably to performance in the wild.

## 4 Results

A summary of the results is found in Table 1. For a subset of frequent and less frequent connectives, Table 2 lists individual  $F_1$  scores. In all of the feature sets we see a marked drop moving from micro-average (average over instances) to macro-average (average over connective types)—P&N, for instance, goes from 93.0% to 85.3%. This shows that the scores of less frequent connectives are somewhat lower than frequent ones. When

features are derived from predicted parses performance also fall, from 93.0% to 90.7% with micro-average, and even more dramatically with macro-average, where it goes from 85.3% to 80.8%. Given that we are interested in real life performance this last figure is the most interesting.

## 5 Discussion

In NLP applications we cannot assume the existence of oracles providing us with gold-standard features. Often switching to predicted features introduces greater uncertainty. If the parser often confuses two non-terminals that are important for connective disambiguation we lose predictive power. Thus, on the P&N model, the average conditional entropy per feature given the class (how surprising the feature is when we know the answer) increases by 8.8% when the oracle is unavailable. In contrast there is almost no difference between the conditional entropy of the POS model with oracle features and without, indicating that the errors made by the tagger are not confusing in the disambiguation task.

Predicted parse features are associated with uncertainty even when used in combination with words and part of speech. Comparing the number

of times the Lin model changes an incorrect prediction of POS+LEX to a correct one and the number of times it introduces a new error by changing a correct prediction to an incorrect one, we observe that corrections almost always come with a substantial number of new errors. In fact, 58 connectives have at least as many new errors as corrections.

Predicted parse features also contribute to feature sparsity, because of the greater variability of automatic parses. On the other hand, they are more expressive than part of speech, and in the example below, where only Lin correctly identifies 'and' as a discourse connective, part of speech simply does not contain enough information.

“A whole day goes by **and** no one even knows they're alive.

## 6 Related work

Atterer and Schütze (2007) present similar experiments for prepositional phrase attachment showing that approaches assuming gold-standard features suffer a great deal when they are evaluated on predicted features. Spitkovsky et al. (2011) also caution against the use of gold-standard features, arguing that for unsupervised dependency parsing using induced parts of speech is superior to relying on gold-standard part-of-speech tags.

This work also relates to Manning (2011) who point out that even though part-of-speech tagging accuracy is above 97% the remaining errors are not randomly distributed but in fact occur in just the cases we care most about.

## 7 Conclusion

Discourse connective disambiguation is an important subtask of discourse parsing. We show that when realistic evaluation is adopted — averaging over connective types and not relying on oracle features — performance drops markedly. This suggests that more work on the task is needed. Moreover, we show that in realistic evaluation a simple feature model using part-of-speech tags and words performs just as well as a much more complex state-of-the-art model.

## Abstract

Rare term vector replacement (RTVR) is a novel technique for dimensionality reduction. In this paper, we introduce an updating algorithm for RTVR. It is capable of updating both the projection matrix for the reduction and the reduced corpus matrix directly, without having to recompute the expensive projection operation. We introduce an effective batch updating algorithm, and present performance measurements on a subset of the Reuters newswire corpus that show that a 12.5% to 50% split of the documents into corpus and update vectors leads to a three to four fold speed-up over a complete rebuild. Thus, we have enabled optimized updating for rare term vector replacement.

## 1 Introduction

Rare term vector replacement (RTVR) is a recently developed linear dimensionality reduction technique for term frequency vectors (Berka and Vajteršic, 2011). It is easily and rapidly computed, patent-free, and produces a semantically meaningful multivariate space with a significantly reduced dimensionality. Furthermore, the method has been parallelized for data and task parallelism (Berka and Vajteršic, 2013).

The construction of this representation is based on document-scope term cooccurrences. Rare terms that occur only in  $\delta$  documents or fewer are eliminated by replacing them with the average vectors of the documents that contain them. The replacement vectors of the rare terms are added to the original document vectors. Then, all rows for rare terms are dropped from all vectors. Only the common terms remain of the original term frequency vector space. By Zipf's law (Powers, 1998), we know that this operation will eliminate

a high number of terms and lead to a highly condensed representation. The performance of the replacement now depends on the applicability of the *cluster hypothesis* (Raiber and Kurland, 2012; Rijsbergen, 1979), i.e., that documents in close proximity are semantically related. If the cluster hypothesis holds, then the centroid of the containing documents will act as a succinct representation of all documents containing the replacement term.

The most prominent techniques for dimensionality reduction of text data in published literature are latent semantic indexing (LSI), see (Deerwester et al., 1990) and the related COV approach (Kobayashi et al., 2002). These two methods are applications of a principal component analysis to text using unbiased and biased correlation measures. Factor analysis based on the SVD applied to automated indexing has been reported as probabilistic latent semantic analysis (PLSA) (Hofmann, 1999). Updating operations for LSI are well understood (Zha and Simon, 1999), and are also being developed for PLSA (Bassiou and Kotropoulos, 2011), or other dimensionality reduction methods such as the kernel PCA (Mastronardi et al., 2010).

Through the connection between PLSA and Latent Dirichlet Allocation (LDA) (Girolami and Kabán, 2003), topic models are also related to dimensionality reduction. Positive matrix factorization methods are also used in various text analysis tasks (Zhang, 2010). Structurally, the generalized vector space model (GVSM) (Wong et al., 1985), is similar to RTVR because of the construction of index vectors by linear combination. The random index vector representation (Kanerva et al., 2000) is also based on cooccurrences, but operates on random initial vectors. Random projections can be used to further accelerate it (Sakai and Imiya, 2009), but this approach should be seen as complementary because it can be applied to other methods as well.

Our contribution is the following. In this paper, we rigorously define an algorithm for updating rare term vector replacement. Using our approach, both the replacement vectors and the reduced corpus matrix are updated directly. It is not necessary to explicitly recompute the projection into the reduced-dimensional space.

The remainder of this paper is structured as thus. Our main contribution is the updating algorithm in Section 2. Section 3 contains a theoretic and empirical performance evaluation. Lastly, we summarize our findings in Section 4.

## 2 Updating RTVR

Updating RTVR has to support the three basic operations of content management: (1) adding new documents, (2) changing existing documents, and (3) deleting obsolete documents.

The replacement vectors are weighted centroids, or weighted average vectors, of the document vectors containing their terms. The reduced document vectors are also linear combinations of the truncated original document vectors and the replacement vectors. At its core, the update algorithm is therefore a running average computation. We will use the mathematical notation summarized in Table 1 to describe the algorithm.

A key complication lies in the fact that the occurrence counts of the terms change. This means that some rare terms may become common terms, and therefore become part of the reduced-dimensional, projected term space. Dually, some common terms may become rare terms, and drop out of the projected space. We will refer to these terms as *promoted* and *demoted terms*  $P$  and  $Q$ . For demoted terms, we need to compute the replacement vectors from scratch during the update. But for all rare terms that are involved in an update, in the old or new vector, we need to change the replacement vector. These terms are called *affected (rare) terms*  $A_T$ .

We can represent changing a document by a tuple  $(i, v)$  containing a corpus matrix column  $i \in \{1, \dots, n\}$  and a new term frequency vector  $v \in \mathbb{R}^{m'}$ , where  $m'$  is the new number of terms. The other two updating operations can be cast into the same form by introducing two abstract symbols. We let  $\nu$  denote the pseudo-column for adding new documents, i.e.,  $(\nu, d_{n+1})$  denotes a new document that will be added as a new column of the corpus matrix. For deletions, we let  $\epsilon$  denote

$T$	set of terms
$D$	set of documents
$m$	number of terms
$n$	number of documents
$C$	corpus matrix
$\mathcal{D}(t_i)$	set of documents containing $t_i$
$\mathcal{T}(d_j)$	non-zero terms in document $d_j$
$N_i$	occurrence count for term $t_i$
$\delta$	occurrence count threshold
$E$	set of rare terms
$\tau_E$	vector truncation removing indices in $E$
$k$	reduced dimensionality
$\pi$	index permutation mapping common features to reduced feature indices
$R$	replacement vectors
$\lambda$	normalizing factors
$\hat{C}$	reduced corpus
$U$	bulk update
$(i, v)$	update $v$ for $d_i$
$(\nu, v)$	insertion of document vector $v$
$(i, \epsilon)$	deletion of document $d_i$
$\text{old}(i, v)$	old vector for $i$ (or zero)
$\mathcal{T}_o(i, v)$	terms in the old vector
$\text{new}(i, v)$	new vector for $i$ (or zero)
$\mathcal{T}_n(i, v)$	terms in the new vector
$\mathcal{T}(i, v)$	terms in both vectors
$\mathcal{T}(U)$	all terms $\bigcup_{(i,v) \in U} \mathcal{T}(i, v)$ in $U$
$N'$	new occurrence counts
$E'$	new rare terms
$k'$	new reduced dimensionality
$\pi'$	new index permutation
$P$	promoted terms $\{t \in E \mid t \notin E'\}$
$Q$	demoted terms $\{t \in E' \mid t \notin E\}$
$A_T$	affected terms $\mathcal{T}(U) \setminus (P \cup Q)$
$\sigma$	index permutation to remove demoted terms
$e_i$	$i$ -th standard base

Table 1: Mathematical Notation

an empty pseudo-vector for the deletion of an old document, i.e.,  $(i, \epsilon)$  signifies the deletion of the document in column  $i$ .

We associate every update  $u = (i, v) \in U$  with two term frequency vectors. If the update is not an add document request, i.e.,  $i \neq \nu$ , it is associated with an old document vector  $\text{old}(i, v) = C_{1:m,i}$ . If it is not a deletion, i.e.,  $v \neq \epsilon$ , it is associated with a new document vector  $\text{new}(i, v) = v$ . We

will need to identify the terms in the old vector  $\mathcal{T}_o(i, v)$ , in the new vector  $\mathcal{T}_n(i, v)$ , and the joint set  $\mathcal{T}(i, v)$ . All terms in the old and new vectors for the entire update  $U$  is defined as  $\mathcal{T}(U)$ .

Our updating algorithm proceeds in three phases: (1) preparing the update, (2) downdating the reduced corpus and updating the replacement vectors, and (3) updating the reduced corpus. In Algorithm 1, we analyze a batch update and prepare the required sets of features and an index permutation  $\sigma$  to compact the reduced space.

Let us assume that we have a procedure  $\text{Compact}(A, m', n, \sigma)$ , which applies the permutation  $\sigma$  to the row indices of a matrix. If we have a matrix  $A \in \mathbb{R}^{m \times n}$  and compute  $A' := \text{Compact}(A, m', n, \sigma) \in \mathbb{R}^{m' \times n}$ , it holds that  $A'_{i,j} = A_{\sigma(i),j}$ . Let us further assume that truncation of the new elimination terms  $\tau_{E'}$  respects the new index order established with  $\sigma$ , i.e., the implementation uses the global index permutation  $\pi'$  mapping all new features to indices in  $\{1, \dots, k'\}$ .

We downdate the reduced corpus and update the replacement vectors with Algorithm 2. For existing documents, we downdate the reduced corpus by subtracting any terms that will change in the course of the update in Line 1. We then update

the replacement vectors by adding the new document vector to any affected or demoted features in Line 2. Documents that do not change contribute to the construction of replacement vectors for demoted terms, which need to be built from scratch, in Line 3. These have to be inserted into rows  $k''$  to  $k'$  of the reduced space, as done in Line 4. We add in any new documents in Line 5 and normalize the resulting replacement vectors.

Algorithm 3 updates the reduced vectors by adding all replacement vectors that have changed in Line 1. The exception are the promoted terms on rows  $k''$  to  $k'$ , which must be added for all rare terms that were otherwise unaffected by the update in Line 2. We then handle all deletions and insertions in Lines 3 and 4.

### 3 Performance Evaluation

Regarding the asymptotic complexity of our updating algorithm, we note the following. Assuming amortized constant time for set testing and insertion (Sedgewick, 2002), that the update is smaller than the corpus, i.e.,  $\|U\| < \|D\|$ , and that the number of documents is greater than the number of terms, i.e.,  $n > m$ , the update algorithm can be executed with a complexity of  $O((\|D\| + \|U\|) \overline{nnz} k' + mk')$ , where  $\overline{nnz}$  is the expected number of non-zero elements in any document vector.

Since the performance is heavily dependent on the actual distribution of the non-zero elements, the observed performance may differ somewhat from this formal analysis. We have conducted performance measurements using an Intel i5-2557 with 4 GB or RAM running Max OS X 10.7.5. We have used the first 23,149 documents with 47,236 terms of the Reuters Corpus Volume I, version 2, in the pre-vectorized form (Lewis et al., 2004).

We randomly selected between 12.5% and 50% of all vectors for the batch update, using the remaining documents for the initial build. Table 2 summarizes our performance measurements averaged across ten runs per row.

The results clearly show that the updating algorithm outperforms a complete rebuild with the original construction algorithm by three-fold to four-fold performance improvement. Because smaller updates require less processing in the updating, and the workload for the rebuild remains the same, smaller batches have a larger speed-up than smaller batches.

---

**Algorithm 2:** Downdating the Reduced Corpus and Updating the Replacement Vectors

---

```

for  $t_i \in A_T$  do  $R_{*,i}^* = \lambda_i$ ;
 $R' = \begin{bmatrix} \text{Compact}(R, k'', m, \sigma) \\ 0 \end{bmatrix} \in \mathbb{R}^{k' \times m}$ ;

## 4 Summary & Conclusions

In this paper, we have introduced an algorithm for updating rare term vector replacement. Our empirical performance evaluation demonstrates that batch updating is faster than a complete rebuild by a factor of three to four for our experiments. In our future research, we intend to develop hybrid updating algorithms similar to (Tougas and Spiteri, 2008). These algorithms initially compute fast, approximate updates, which are only later replaced by exact updates for efficiency. The final PCA of the augmented corpus  $\hat{C}$  reported in (Berka and Vajteršic, 2011) remains an open problem in updating RTVR.

## Abstract

Morphology is the study of internal structure of words and is an essential early step in many NLP applications such as parsing and machine translation. Researchers working in Hindi NLP have either used the widely popular paradigm based analyzer (PBA) or extensions of it. In this work, we undertook a comprehensive evaluation of PBA using the data from the Hindi Treebank (HTB) and presented a new morphological analyzer trained on the HTB. Our morphological analyzer has better coverage and accuracy when compared to the existing analyzers for Hindi. An oracle system that takes the best values from the PBA's output achieves only 63.41% for lemma, gender, number, person and case. Our statistical analyzer has an accuracy of 84.16% for these morphological attributes when evaluated on the test section of the Hindi Treebank.

## 1 Introduction

Morphological analysis is the task of analyzing the structure of morphemes in a word and is generally a prelude to further complex NLP tasks such as parsing, machine translation, semantic analysis etc. These tasks need an analysis of the words in the sentence in terms of lemma, affixes, parts of speech (POS) etc.

Hindi is a morphologically rich language with a relatively free word order. Previous efforts in Hindi morphological analysis concentrated on building rule-based systems that give all the possible analyses for a word form irrespective of its context in the sentence. The paradigm based analyzer (PBA) by Bharati et al. (1995) is one of the most widely used applications among researchers in the Indian NLP community. In paradigm

based analysis, words are grouped into a set of paradigms depending on the inflections they take. Each paradigm has a set of add-delete rules to account for its inflections and words belonging to a paradigm take the same inflectional forms. Given a word, the PBA identifies the *lemma*, *coarse POS tag*, *gender*, *number*, *person*, *case marker*, *vibhakti*<sup>1</sup> and *TAM* (tense, aspect, modality). Being a rule-based system, the PBA takes a word as input and gives all the possible analyses as output. (Table 1 presents an example). It doesn't pick the correct analysis for a word in its sentential context.

Goyal and Lehal's analyser (2008), which is a re-implementation of the PBA with few extensions, has not done any comparative evaluation. Kanuparthi et al. (2012) built a derivational morphological analyzer for Hindi by introducing a layer over the PBA. It identifies 22 derivational suffixes which helps in providing derivational analysis for the word whose suffix matches with one of these 22 suffixes.

The large scale machine translation projects<sup>2</sup> that are currently under way in India use shallow parser built on PBA and an automatic POS tagger. The shallow parser prunes the morphological analyses from PBA to select the correct one using the POS tags from the tagger. Since it is based on PBA, it suffers from similar coverage issues for out of vocabulary (OOV) words.

The PBA, developed in 1995, has a limited vocabulary and has received only minor upgrades since then. Out of 17,666 unique words in the Hindi Treebank (HTB) released during the 2012 Hindi Parsing Shared Task (Sharma et al., 2012), the PBA does not have entries for 5,581 words (31.6%).

NLP for Hindi has suffered due to the lack of a

<sup>1</sup>Vibhakti is a Sanskrit grammatical term that encompasses post-positionals and case endings for nouns, as well as inflection and auxiliaries for verbs (Pedersen et al., 2004).

high coverage automatic morphological analyzer. For example, the 2012 Hindi Parsing Shared Task (Sharma et al., 2012) held with COLING-2012 workshop had a gold-standard input track and an automatic input track, where the former had gold-standard morphological analysis, POS tags and chunks of a sentence as input and the automatic track had only the sentence along with automatic POS tags as input. The morphological information which is crucial for Hindi parsing was missing in the automatic track as the existing analyzer had limited coverage.

In this work, we present a statistical morphological analyzer for Hindi trained on HTB and compare it with PBA. The analyzer predicts the *lemma*, *gender*, *number*, *person* (GNP) and *case marker* for all the words in a given sentence by training separate models on the HTB for each of them. Other grammatical features such as TAM (tense, aspect, modality) and *vibhakti* are predicted using heuristics on fine grained POS tags of the input sentence. Our system has significantly better accuracy than analyzers based on PBA and is robust enough to produce analyses for OOV words.

## 2 Statistical Morphological Analyzer (SMA)

The output of a morphological analyzer depends on the language that it is developed for. Analyzers for English (Goldsmith, 2000) predict just the lemmas and affixes mainly because of its restricted agreement based on semantic features such as animacy and *natural* gender. But in Hindi, agreement depends on *lexical* features such as *grammatical* gender, number, person and case. Hence, it is crucial that Hindi analyzers predict these along with TAM and vibhakti which have been found to be useful for syntactic parsing (Ambati et al., 2010; Bharati et al., 2009a).

MorphFeature	Values
Gender	masculine, feminine, any, none
Number	singular, plural, any, none
Person	1, 1h, 2, 2h, 3, 3h, any, none
CaseMarker	direct, oblique, any, none

Table 2: Morph features and the values they take

Hindi has syntactic agreement (of GNP and case) of two kinds: modifier-head agreement and noun-verb agreement. Modifiers, including determiners, agree with their head noun in gender, number and case, and finite verbs agree with some noun in the sentence in gender, number and person (Kachru, 2006). Therefore, apart from lemma and POS tags, providing gender, number and person is also crucial for syntactic parsing.<sup>3</sup>

With the existing morph analyzer (PBA) performing poorly on OOV (unknown to PBA) words and the availability of an annotated treebank, we set out to build a high-coverage automatic Hindi morph analyzer by learning each of the seven morphological attributes separately from the Hindi Treebank. During this process, it was realized that vibhakti and TAM can be better predicted using heuristics on fine-grained POS tags than by training on the HTB.

In the rest of the section, we discuss the methods to predict each of the seven morphological attributes. Table 2 lists the values that each of the morph attributes take in HTB. The HTB consists of 15,102 sentences (334,287 words) annotated with morphological features, POS tags, chunks and dependency relations. In this work, we only use morph and POS information.

### 2.1 Lemma prediction

The PBA uses a large vocabulary along with paradigm tables consisting of add-delete rules to find the lemma of a given word. All possible add-delete rules are applied on a given word form and the resulting lemma is checked against the vocabulary to find if it is right or not. If no such lemma exists (for OOV words), it returns the word itself as the lemma.

While the gender, number and person of a word form varies according to the context (due to syntactic agreement with head words), there are very

<sup>3</sup>While nouns, pronouns and adjectives have both GNP and case associated with them, verbs only have GNP. TAM is valid only for verbs and vibhakti (post-position) is only associated with nouns and pronouns.

Analysis	Test Data - Overall(%)				Test Data - OOV of SMA(%)			
	Baseline	F-PBA	O-PBA	SMA	Baseline	F-PBA	O-PBA	SMA

L-lemma, G-gender, N-number, P-person, C-case, V/T-Vibhakti/TAM

Table 3: Accuracies of SMA compared with F-PBA, O-PBA and baseline systems.

few cases where a word form can have more than one lemma in a context. This makes lemma simpler to predict among the morphological features, provided there is access to a dictionary of all the word forms along with their lemmas. Unfortunately, such a large lemma dictionary doesn't exist.

In this work, we perceived lemma prediction from a machine translation perspective, with the characters in the input word form treated as the source sentence and those in the lemma as the target. The strings on source and target side are split into sequences of characters separated by space. The phrase based model (Koehn et al., 2007) in Moses is trained on the parallel data created from the training part of HTB. The translation model accounts for the changes in the affixes (sequence of characters) from word form to lemma whereas the language model accounts for which affixes go with which stems. In this perspective, the standard MT experiment of switching source and target to attain better accuracy would not apply since it is unreasonable to predict the word form from the lemma without taking the context into account.

## 2.2 Gender, Number, Person and Case Prediction

Unlike lemma prediction, we use a liblinear classifier (Fan et al., 2008) to build linear SVM classification models for GNP and case prediction.

Though knowing the syntactic head of a word helps in enforcing agreement (and thereby accu-

rately predicting the correct GNP), parsing is usually a higher level task and is not performed before morphological analysis. Hence, certain cases of GNP prediction are similar in nature to the standard chicken and egg problem.

The following features were tried out in building the models for gender, number, person and case prediction:

- Word
- Lexical category
- Last 3 characters
- Last 4 characters
- Next word
- Previous word
- Lemma
- Word Length
- Character N-grams of the word

## 2.3 Vibhakti and TAM

Vibhakti and TAM are helpful in identifying the *karaka*<sup>4</sup> dependency labels in HTB. While nouns and pronouns take vibhakti, verbs inflect for TAM. Both TAM and vibhakti occur immediately after the words in their respective word classes.

Instead of building statistical models for vibhakti and TAM prediction, we built a system that uses heuristics on POS tag sequences to predict the correct value. The POS tags of words following nouns, pronouns and verbs give an indication as to what the vibhakti/TAM are. Words with PSP (postposition) and NST (noun with spatial and temporal properties) tags are generally considered as the vibhakti for the preceding nouns and

<sup>4</sup>karakas are syntactico-semantic relations which are employed in Paninian framework (Begum et al., 2008; Bharati et al., 2009b)

Data	#Sentences	#Words
Training	12,041	268,096
Development	1,233	26,416
Test	1,828	39,775

Table 4: HTB statistics

pronouns. A postposition in HTB is annotated as PSP only if it is written separately (*usane/PRP* vs *usa/PRP ne/PSP*). For cases where the postposition is not written separately we rely on the treebank data to get the suffix. Similarly, words with VAUX tag form the TAM for the immediately preceding verb.

The PBA takes individual words as input and hence does not output the entire vibhakti or TAM of the word in the sentence. It only identifies these values for those words which have the information within the word form (e.g. *usakA he+Oblique*, *kiyA do+PAST*).

In the sentence,

```
rAma/NNP kA/PSP kiwAba/NN
cori/NN ho/VM sakawA/VAUX
hE/VAUX,
```

PBA identifies *rAma*'s vibhakti as *0* and *ho*'s TAM as *0*. Whereas in HTB, vibhakti and TAM of *rAma* and *ho* are annotated as *0\_kA* and *0\_saka+wA.hE* respectively. Our approach determines this information precisely.

### 3 Experiments and Results

The Hindi treebank released as part of the 2012 Hindi Parsing Shared Task is used to evaluate our models. All the models are tuned on development data and evaluated on test data. Table 4 shows the word counts of training, development and test sections of HTB.

Our approach to Hindi morphological analysis is based on handling each of the seven attributes (*lemma, gender, number, person, case, vibhakti* and *TAM*) separately. However, evaluation is performed on individual attributes as well as on the combined output. The models are compared with a baseline system and two versions of the PBA wherever relevant. The *baseline* system takes the word form itself as the lemma and selects the most frequent value for the rest of the attributes.

Since PBA is a rule-based analyzer which gives more than one analysis for words, we use two versions of it for comparison. The first system is

the oracle PBA (referred further as O-PBA) which uses an oracle to pick the *best* analysis from the list of all analyses given by the PBA. The second version of the PBA (F-PBA) picks the *first* analysis from the output as the correct analysis.

Table 3 presents the accuracies of four systems (baseline, F-PBA, O-PBA and SMA) in predicting the morphological attributes of all the words in the HTB's test data and also for OOV words of SMA (i.e. words that occur in the test section but not in training section of HTB)<sup>5</sup>. The accuracies are the percentages of words in the data with the correct analysis. It may be noted that our system (SMA) performs significantly better than the best analyses of PBA and the baseline system in all the experiments conducted.

The existing Hindi POS tagger<sup>6</sup> was found to be 95% accurate when evaluated on the entire HTB data. We got similar results when we had run the entire set of experiments using these automatic POS tags.

### 4 Conclusion and Future work

In conclusion, our paper presented a robust state-of-the-art statistical morphological analyzer for Hindi which outperforms previous analyzers by a considerable margin. A comprehensive evaluation was carried out for our system by comparing it with the existing analyzers. The analyzer we have developed achieved an accuracy of 82.03% for lemma, gender, number, person, case, vibhakti and TAM. Being a statistical model, it even analyzes OOV words thereby extending the coverage of the analyzer. We also evaluated the effect of morphological features (predicted by our system) on dependency parsing and found them to improve the parsing accuracy.

The agreement phenomenon in Hindi provides challenges in predicting gender, number and person of words in their sentential context. These can be better predicted if dependency relations are given as input. However, the standard natural language analysis pipeline forbids using parse information during morphological analysis.

This provides an opportunity to explore joint modelling of morphological analysis and syntactic parsing for Hindi. We plan to experiment this as part of our future work.

<sup>5</sup>OOV words for SMA need not be *out of vocabulary* for PBA's dictionaries.

## Abstract

We propose an unsupervised approach to learning non-concatenative morphology, which we apply to induce a lexicon of Arabic roots and pattern templates. The approach is based on the idea that roots and patterns may be revealed through mutually recursive scoring based on hypothesized pattern and root frequencies. After a further iterative refinement stage, morphological analysis with the induced lexicon achieves a root identification accuracy of over 94%. Our approach differs from previous work on unsupervised learning of Arabic morphology in that it is applicable to naturally-written, unvowelled text.

## 1 Introduction

Manual development of morphological analysis systems is expensive. It is impractical to develop morphological descriptions for more than a very small proportion of human languages. In recent years a number of approaches have been proposed that learn the morphology of a language from unannotated text. The Morpho Challenge and similar competitions have further motivated researchers to devise techniques for unsupervised learning of language.

Previous work in unsupervised morphology learning has mostly addressed concatenative morphology, in which surface word forms are sequentially separated or segmented into morpheme units. However, some languages (in particular Semitic languages) have another type of word formation in which morphemes combine in a non-concatenative manner, through the interdigitation of a root morpheme with an affix or pattern template. Unsupervised learning of non-concatenative morphology has received comparatively little attention.

In this paper we describe a conceptually simple yet effective unsupervised approach to learning non-concatenative morphology. We apply our approach to inducing an Arabic lexicon of trilateral roots and pattern templates. Lexicon acquisition is based on the idea that roots and affix patterns may be revealed by their converses, i.e. roots are identified from occurrences of patterns and conversely patterns are recognized from root frequencies. Subsequently, the lexicons are iteratively improved by refining the morpheme strengths computed in the previous step.

The paper is organized as follows. We survey previous related work (Section 2), and then give a brief introduction to Arabic root and pattern morphology (Section 3). We explain our basic technique for unsupervised lexicon induction in Section 4, followed by the refinement procedure (Section 5). Section 6 describes how the lexicon is used for morphological analysis. Finally, we present an evaluation (Section 7) and conclusions (Section 8).

## 2 Related Work

Beesley (1996) describes one of the first morphological analysis systems for Arabic, based on finite-state techniques with manually acquired lexicons and rules. This kind of approach, although potentially producing an efficient and accurate system, is expensive in time and linguistic expertise, and lacks robustness in terms of extendibility to word types not in the dictionary (Ahmed, 2000).

Darwish (2002) describes a semi-automatic technique that learns morphemes and induces rules for deriving stems using an existing dictionary of word and root pairs. It is an easy to build and fairly robust method of performing morphological analysis. Clark (2007) investigates semi-supervised learning using the

complex broken plural structure of Arabic as a test case. He employs memory-based algorithms, with the aim of gaining insights into human language acquisition.

Other researchers have applied statistical and information-theoretic approaches to unsupervised learning of morphology from raw (unannotated) text corpora. Goldsmith (2000, 2006) and Cruetz and Lagus (2005, 2007) use the Minimum Description Length (MDL) principle, considering input data to be ‘compressed’ into a morphologically analysed representation. An alternative perspective adopted by Schone and Jurafsky (2001) induces semantic relatedness between word pairs by Latent Semantic Indexing.

Most work on unsupervised learning of morphology has focused on concatenative morphology (Hammarström and Borin, 2011). Studies that have focussed on non-concatenative morphology include that of Rodriguez and Čavar (2005), who learn roots from artificially generated text using a number of orthographic heuristics, and then apply constraint-based learning to improve the quality of the roots. Xanthos (2008) deciphers roots and patterns from phonetic transcriptions of Arabic text, using MDL to refine the root and pattern structures.

Our work differs from these previous approaches in that (1) we learn intercalated morphology, identifying the root and transfixes/incomplete pattern for words, and (2) we start from ‘natural’ text without short vowels or diacritical markers.

### 3 Root and Pattern Morphology

Words in Arabic are formed through three morphological processes: (i) fusion of a root form and pattern template to derive a base word; (ii) affixation, including inflectional morphemes marking gender, plurality and/or tense, resulting in a stem; and (iii) possible attachment of a final layer of clitics. Our work addresses the first two of these processes.

As an example of word formation in Arabic, the word *ktAby* is formed from the root *Ktb* and the pattern *--A-y*, where *y* is an inflectional marker and *A* is the derivational infix marker for nouns.

During analysis, we decompose each word *w* into a set of tuples encoding all *k* possible combinations of a root (of at least 3 letters) and associated pattern (Eq. 1)

$$d(w) \rightarrow \{(r^x, p^x)\} \quad (\text{Eq. 1})$$

where *x* ranges from 1 to *k*. For example, the decomposition of the word *yErf* is shown in Figure 1.

$$yErf \rightarrow \left\{ \begin{array}{l} \langle y E r, \quad - - - f \rangle, \\ \langle y E f, \quad - - r - \rangle, \\ \langle y r f, \quad - E - - \rangle, \\ \langle E r f, \quad y - - - \rangle, \\ \langle y E r f, \quad - - - - \rangle \end{array} \right\}$$

Figure 1. Decomposition of a word into all possible combinations of roots and patterns.

## 4 Building Lexicons Using Contrastive Scoring

Based on the idea that roots and patterns may be revealed by their converses, we score a pattern based on the frequency of occurrence of the roots, and score a root according to the number of occurrences of patterns. We score each morpheme and then rescore it weighted by previous scores. Our technique resembles the *hubs and authorities* algorithm originally devised for rating Web pages (Kleinberg, 1999), which assigns to each Web page two scores: its hub value and its authority. These two values are updated in a similar mutually recursive manner as we describe for roots and patterns.

### 4.1 Frequency-Based Scoring

The initial scoring function is simple: firstly, we aggregate over the number of occurrences of a root radical sequence in a word  $w_i$ , for words  $i=1,2,\dots,N$  in the input dataset. The function for scoring each pattern in the target word,  $t$ , is given in equation (Eq. 2).

$$S(p_t^x) = \sum_{i=1}^N (1 | r_t^x = r_{w_i}^y) \quad (\text{Eq. 2})$$

The function for scoring the root,  $r_t^x$ , in each target word,  $t$ , with pattern,  $p_t^x$ , is given in equation (Eq. 3).

$$S(r_t^x) = \sum_{i=1}^N (1 | p_t^x = p_{w_i}^y) \quad (\text{Eq. 3})$$

We choose this as our baseline, to which we compare subsequent enhancements.

## 4.2 Scaling

Since pattern strength is computed based on root occurrence frequency and vice-versa, each pattern and root has a different score range due to the distinct distributions of patterns and roots. In order to make the scores comparable and contribute equally, we scale the scores in one lexicon with respect to the other.

We take the pattern lexicon as reference and scale each root,  $r_u$  ( $u=1,2,\dots,R$  entries in root lexicon) by the ratio of the maximum pattern score to the maximum root score:

$$SS(r_u) = S(r_u) \left( \times \frac{\max(S(p))}{\max(S(r))} \right) \quad (\text{Eq. 4})$$

## 4.3 Iterative Rescoring

Having obtained initial scores for the root and pattern lexicons, they are improved through an iterative rescoring process. We rescore each morpheme lexicon in a similar manner to equations (Eq. 2) and (Eq. 3), but weighted with the normalized score for each morpheme of previous scores. This is an iterative process starting with the initial score,  $S_0$ , calculated using frequency counts (as in section 4.1). Let  $S_j$  be the new score based on previous scores, and scaled scores,  $S_{j-1}$  and  $SS_{j-1}$ , respectively, for iterations  $j=0,1,2,\dots,n$ ,

$$S_j(r_t^x) = \sum_{i=1}^N \left( S_{j-1}(p_i^x) / \max(S_{j-1}) \mid p_i^x = p_{w_i}^y \right) \quad (\text{Eq. 5})$$

$$S_j(p_w^x) = \sum_{i=1}^N \left( SS_{j-1}(r_i^x) / \max(SS_{j-1}) \mid r_i^x = r_{w_i}^y \right) \quad (\text{Eq. 6})$$

Here we have normalized the score with respect to the maximum value for the reference pattern lexicon, thus keeping the magnitude of the rescored value in range.

## 5 Refinement

The refinement phase considers the overall strength of occurrence of each morpheme in the vocabulary. Thus, if a certain root morpheme is a true morpheme then all the pattern morphemes it occurs with would have higher scores since they also would be true morphemes. In such a case, this phase would increase the overall average strength for the root. The scores

obtained from the frequency-based method (Section 4) are frequency counts or weighted frequency counts. The scoring and rescoring in this refinement step differs in that it evaluates each root by averaging over scores of the corresponding patterns it occurs with in the dataset. We again iteratively refine based on the previous scores for  $k=0,1,2,\dots,m$  iterations,

$$S_j(r_t^x) = \frac{1}{f_r} \sum_{i=1}^N \left( S_{k-1}(p_{w_i}) \mid r_t^x = r_{w_i} \right) \quad (\text{Eq. 7})$$

where  $f_r$  is the number of words with root  $r$ , from a total of  $N$  vocabulary words. Similarly, for the pattern rescoring with the best so far pattern,  $p_w^b$ ,

$$S_j(p_w^x) = \frac{1}{f_p} \sum_{i=1}^N \left( S_{k-1}(r_{w_i}) \mid p_w^x = p_{w_i} \right) \quad (\text{Eq. 8})$$

Here we sum over the score of counterpart morphemes based on the match of the target morpheme in a vocabulary word, unlike the rescoring step, where we match the corresponding roots.

## 6 Morphological Analysis

A word,  $w_i$ , is analysed into its potential root and pattern template by considering every possible combination of trilateral root and corresponding pattern pairs,  $\langle r^x, p^x \rangle$ , as defined in equation (Eq. 1). Each analysis is scored with the sum of the scores for the root,  $r^x$ , and pattern,  $p^x$ , in the root lexicon and pattern lexicon, respectively. While combining scores we again apply scaling as in equation (Eq. 4) in order to guarantee equal contributions from each morpheme. The analysis,  $x$ , with the highest score, as calculated in equation (Eq. 9), is selected and is output.

$$\max_{x=1..n} \left( S(r_w^x) + SS(p_w^x) \right) \quad (\text{Eq. 9})$$

Since we are considering text without diacritics, due to the absence of short vowels, we only expect words to contain single letter infixes. Hence we also experiment with an alternative configuration of the word decomposition,  $\langle r^z, p^z \rangle$  in which only those tuples with single character infixes in patterns are considered for analysis, and all other tuples are dropped. We refer to this configuration as 'IF1' in the following evaluation.

## 7 Evaluation

The evaluation dataset comes from the Quranic Arabic Corpus (QAC),<sup>1</sup> which contains approximately 7370 undiacritized, stemmed token types. Although for evaluation purposes we use the stemmed vocabulary provided by QAC, such stemmed words could be obtained using existing techniques for unsupervised concatenative morphology learning (e.g. Poon *et al.*, 2009).

More than 7192 words (95% of the total vocabulary) are tagged with their root forms since the Quran consists mostly of words of derivable forms, with very few proper nouns. Sometimes alterations in root radicals take place, for example, in hollow roots, when moving from a root containing a long vowel to the surface word, the long vowel might change its form to another type or get dropped. Such words with hollow roots or reduplicated radicals, whose characters do not match every radical of the root, were excluded from the evaluation as they are beyond the scope of the learning algorithm. After these exclusions, 5468 word and root evaluation pairs remain.

### 7.1 Root Identification

We evaluate morphological analysis through correct identification of the root. Accuracy is measured in terms of the percentage of roots that are correctly identified.

Figure 2. Results for iterative scoring and refinement.

Using the initial frequency-based scoring function (Section 4.1), we obtain a baseline (BL) accuracy of 74.1%. Figure 2 shows the results of

the rescoring (RSc) and refinement (Ref) phases, with  $n=5$  and  $m=5$  iterations respectively (NoP  $n+m$ ). There is a sudden improvement in accuracy after the first rescoring phase, and gradual improvement thereafter until the fifth. The refinement phase shows a similar trend, with a sudden improvement in accuracy at NoP 5+1. Here too the improvement is more gradual after each further iteration.

Configuration	Total Correct	Percentage Correct (%)
Baseline (BL)	4055	74.2
RSc_NoP1	4444	81.2
RSc_NoP5	4539	83.0
RSc_Ref_NoP5+1	4940	90.3
RSc_Ref_NoP5+5	5123	93.6
RSc_Ref_IF1	5159	<b>94.3</b>

Table 1. Results at key stages.

Table 1 shows the number of correct results at key stages. Rescoring and refinement each improve accuracy by 7 percentage points on their first iteration. This shows the advantage of using weighted morpheme scores. The subsequent iterations give total improvements of approximately 3 points. The IF1 configuration yields a further improvement of 0.75 points, indicating that some irrelevant analyses have been filtered out. With all the enhancements, the overall accuracy of 94.3% is an improvement of more than 20 percentage points over the baseline.

## 8 Conclusions and Future Directions

We have presented a novel, unsupervised approach to learning non-concatenative morphology. The approach learns trilateral roots and pattern templates, based on the idea that each may be revealed by their converses, using a mutually recursive scoring method. A subsequent refinement phase further increases accuracy.

The approach could be extended to roots beyond trilateral by adapting the scoring function to accommodate for morpheme length. In the future, we intend to apply the method to learning other kinds of morphological structures.

### Acknowledgments

We thank the referees for valuable comments, and in particular pointing out the correspondence to the hubs and authorities algorithm.

## Abstract

Finding contradiction text is a fundamental problem in natural language understanding. Previous work on finding contradiction in text incorporate information derived from predicate-argument structures as features in supervised machine learning frameworks. In contrast to previous work, we combine shallow semantic representations derived from semantic role labeling with binary relations extracted from sentences in a rule-based framework. Evaluation experiments conducted on standard data sets indicated that our system achieves better recall and F1 score for contradiction detection than most of baseline methods, and the same recall as a state of the art supervised method for the task.

## 1 Introduction

Contradiction detection (CD) in text is a fundamental task in natural language understanding, and necessary for many applications (De Marneffe et al., 2008; Voorhees, 2008). For instance, contradictions need to be recognized by question answering systems or multi-document summarization systems (Harabagiu et al., 2006). The task is to detect whether the contradiction relationship exists in a pair of a text  $T$  and a hypothesis  $H$ .

There are several approaches to the CD task. Contradiction detection can be formalized as a binary classification problem (Harabagiu et al., 2006; De Marneffe et al., 2008). The main effort of work which adopt this approach is to find out effective features for recognizing contradiction. The other approach is using functional relations indicated by verb or noun phrases for detecting contradiction (Ritter et al., 2008).

Beyond string-based matching approaches, one can approach to the CD task by applying logical

inference techniques. Although the logical inference approach may obtain good precision, it is not widely used for the task due to the fact that full predicate-logic analysis is currently not practical for wide-coverage semantic processing (Burchardt et al., 2009). Given that fact, (Burchardt et al., 2009) pointed out that using shallow semantic representations based on predicate-argument structures and frame knowledge is an intuitive and straightforward approach to textual inference tasks.

In contrast to previous work which integrate predicate-argument structures as features in machine learning-based systems (Harabagiu et al., 2006; De Marneffe et al., 2008), this paper combines shallow semantic representations derived from semantic role labeling with binary relations extracted from sentences for the CD task. The proposed system consists of two modules. The first module relies on the alignment of semantic role (SRL) frames extracted from the text and the hypothesis in each pair while the second one performs contradiction detection over binary relations extracted from the pair. If the SRL-based module fails to identify the contradiction relationship in the pair, the second module will be applied. We expect that the second module will improve the coverage of the first one. Evaluation experiments on standard data sets obtained from RTE challenges (Giampiccolo et al., 2007; Giampiccolo et al., 2008; Bentivogli et al., 2009) show that the proposed system achieves better recall and F1 score for contradiction detection than most of baseline methods, and the same recall as a state of the art supervised method for the task.

## 2 Linguistic Analysis

After parsing the text and the hypothesis of a pair by using Stanford CoreNLP<sup>1</sup>, we utilize SENNA

<sup>1</sup>Stanford CoreNLP is available online on: <http://nlp.stanford.edu/software/corenlp.shtml>

package<sup>2</sup> (Collobert et al., 2011) for semantic role labeling. Then, we extract SRL frames from the output of SENNA. An SRL frame consists of a verb predicate and a list of SRL elements.

In the system, we use REVERB (Fader et al., 2011) – a tool which can automatically identify and extract binary relations from English sentences. The input of REVERB is a POS-tagged and NP-chunked sentence and its output is a set of extraction triples of the form  $(arg1, R, arg2)$ , in which  $R$  represents the relation phrase between two arguments:  $arg1$  and  $arg2$ .

REVERB cannot extract some useful relations such as “isA” relations which specify the equivalent relation of two objects. In addition, in some cases, relation phrases of two extraction triples cannot be compared without using inference rules that specify the entailment relationship between two triples. Therefore, we propose several simple heuristic methods to extract additional binary relations from a text segment.

First, we extract “isA” relations from three information sources: i) co-reference resolution information; ii) noun phrases which the ending parts are recognized as a named entity;; and iii) “abbrev” relations in dependency parses.

Second, entailment rules or inference rules which specify directional entailment relations between two text fragments have been shown to be useful for RTE and question answering (Berant et al., 2011). In this study, we transform triples generated by REVERB by looking up the corpus of 30,000 entailment rules between typed predicates obtained from (Berant et al., 2011).

### 3 Contradiction Detection by Matching Semantic Frames

Let us denote an SRL frame by a tuple  $S = \{V, E_1, \dots, E_k\}$ , where  $V$  is used to denote the verb predicate; and  $E_i$  represents the  $i$ -th SRL element in the frame. Each SRL element has a type and underlying words. Types of SRL elements follow the annotation guideline in PropBank (Palmer et al., 2005). SRL elements can be arguments or modifiers (adjuncts). We denote two sets of SRL frames of  $T$  and  $H$  by  $T = \{S_i^{(t)}\}_{i=1}^m$  and  $H = \{S_j^{(h)}\}_{j=1}^n$ , in which  $m$  and  $n$  are the number of SRL frames extracted from  $T$  and  $H$ , respectively.

<sup>2</sup>SENNA is available online on: <http://ml.nec-labs.com/senna/>

### 3.1 Contradiction Detection Model

The contradiction detection model consists of a contradiction function  $\mathcal{F}_S(T, H)$  which calculates the contradiction measurement for the pair  $(T, H)$  on their SRL frames. Then,  $\mathcal{F}_S(T, H)$  is compared with a threshold value  $t_1$ . If  $\mathcal{F}_S(T, H) \geq t_1$ , we determine that  $T$  and  $H$  are contradictory.

In order to define the contradiction function  $\mathcal{F}_S(T, H)$ , we rely on the assumption that  $T$  and  $H$  are contradictory if there exists an event indicated by an SRL frame in  $H$ , which is incompatible with an event indicated by  $T$ . Formally, the function  $\mathcal{F}_S(T, H)$  is defined as following:

$$\mathcal{F}_S(T, H) = \max_{S_i^{(t)} \in T, S_j^{(h)} \in H} \mathbf{f}(S_i^{(t)}, S_j^{(h)}), \quad (1)$$

where  $S_i^{(t)}$  and  $S_j^{(h)}$  are two SRL frames in  $T$  and  $H$ , respectively; and  $\mathbf{f}(S_i^{(t)}, S_j^{(h)})$  is a contradiction function defined on the two SRL frames.

Next, we define the function  $\mathbf{f}(S_1^{(t)}, S_2^{(h)})$  of two SRL frames  $S_1^{(t)} \in T$  and  $S_2^{(h)} \in H$ . For concreteness, we denote  $S_1^{(t)} = \{V_1, E_1^{(1)}, \dots, E_k^{(1)}\}$  and  $S_2^{(h)} = \{V_2, E_1^{(2)}, \dots, E_\ell^{(2)}\}$ .

The function  $\mathbf{f}(S_1^{(t)}, S_2^{(h)})$  relies on the alignment of SRL elements across two frames. Since the number of SRL elements in an SRL frame is not very large, we propose a greedy alignment algorithm that considers all possible pairs of an SRL element in  $S_1^{(t)}$  and an SRL element in  $S_2^{(h)}$ . The core part of the greedy algorithm is the similarity measure between two SRL elements. We apply the local lexical level matching method (Dagan et al., 2007) to calculate the similarity of two SRL elements. In addition, we utilize co-reference resolution information by substituting mentions found in an SRL element with their equivalent mentions in the corresponding co-reference chain.

After generating the alignment between elements of two SRL frames, we define the contradiction function  $\mathbf{f}(S_1^{(t)}, S_2^{(h)})$  as follows.

From the rationale that two events are not contradictory if they are not related, we filter out “not contradictory” SRL frame pairs by calculating their relatedness. The relatedness of two SRL frames is defined as product of the relatedness of their verb predicates and SRL elements:

$$R(S_1^{(t)}, S_2^{(h)}) = R(V_1, V_2) \times \max_{i,j} R(E_i^{(1)}, E_j^{(2)}), \quad (2)$$

where  $R$  represents the relatedness between two items;  $E_i^{(1)} \in S_1^{(t)}$  and  $E_j^{(2)} \in S_2^{(h)}$  are SRL elements;  $V_1$  and  $V_2$  are verbs of  $S_1^{(t)}$  and  $S_2^{(h)}$ , respectively.

The relatedness of two verbs is assigned to 1.0 if their relation is found in WordNet (Fellbaum, 1998) or in VerbOcean database (Chklovski and Pantel, 2004). In other cases, we employ WordNet::Similarity package (Pedersen et al., 2004) to compute the similarity of two verbs. The relatedness of two SRL elements  $E_i^{(1)}$  and  $E_j^{(2)}$  is defined as the local lexical level matching score.

The relatedness of two SRL frames is compared with a threshold. If it is below the threshold, then  $S_1^{(t)}$  and  $S_2^{(h)}$  are not related.

If two SRL frames are related, we consider two situations: 1) two verb predicates are matching and 2) Two verb predicates are opposite. Note that if two verb predicates are neither matching nor opposite,  $f(S_1^{(t)}, S_2^{(h)})$  is also assigned to 0.

In the system, that two verbs are matching are determined by utilizing synonyms in WordNet and WordNet-base semantic similarity. If two verb are matching, the function  $f(S_1^{(t)}, S_2^{(h)})$  is defined based on the alignment generated in the alignment process. We use the incompatibility of aligned arguments and modifiers such as temporal, location, or negation modifiers to calculate  $f(S_1^{(t)}, S_2^{(h)})$ .

In the second case, two verbs are opposite if they are found as antonym verbs in WordNet or opposite verbs in VerbOcean. In this case, the contradiction function  $f(S_1^{(t)}, S_2^{(h)})$  is defined as the similarity of their SRL elements. We define the element-based similarity of two frames as the product of similarity scores of the aligned elements having the same type.

#### 4 Contradiction Detection by Relation Matching

The main idea of this module is as follows. In the first step, we extract triples from  $T$  and  $H$  by using REVERB tool and our heuristics. Next, we compare each triple in  $H$  with every triple in  $T$ , and determine whether the contradiction relationship exists in some pairs of triples.

Formally, we denote a extraction triple by  $(x, r, y)$  where  $x$  and  $y$  respectively represent the first and second argument, and  $r$  represents the relation phrase of the triple.

We denote  $T = \{(x_i^{(t)}, r_i^{(t)}, y_i^{(t)})\}_{i=1}^m$  and  $H =$

$\{(x_j^{(h)}, r_j^{(h)}, y_j^{(h)})\}_{j=1}^n$ . Here,  $m$  and  $n$  are respectively the numbers of triples in  $T$  and  $H$ . The contradiction detection task is reduced to searching for incompatible triple pairs across  $T$  and  $H$ . We define the contradiction function on triples of  $T$  and  $H$  as follows.

$$\mathcal{F}_T(T, H) = \max_{T_i \in T; H_j \in H} \mathbf{g}(T_i, H_j), \quad (3)$$

where  $T_i$  is the  $i$ -th triple of  $T$ ;  $H_j$  is the  $j$ -th triple of  $H$ ; and  $\mathbf{g}(T_i, H_j)$  is the contradiction function of the two triples  $T_i$  and  $H_j$ .

The function  $\mathbf{g}(T_i, H_j)$  is based on the mismatch of two triples  $T_i$  and  $H_j$ . We consider three cases as follows. If their relation phrases and first arguments are matching, the mismatch of second arguments will be calculated. If two relation phrases are matching and roles of arguments in the two triples are exchanged,  $\mathbf{g}(T_i, H_j)$  is assigned to 1.0. However, this rule is not applied for “isA” (equivalent) relations. In contrast, if two relation phrases are opposite, the similarity measures of first arguments and second arguments are taken into account.

In the procedure for calculating  $\mathbf{g}(T_i, H_j)$ , we need to determine whether two relation phrases  $r_i^{(t)}$  and  $r_j^{(h)}$  are matching or not. If the surface and base forms of two relation phrases are different, we use WordNet to detect whether main verbs of  $r_i^{(t)}$  and  $r_j^{(h)}$  are synonyms. In order to check if two relation phrases  $r_i^{(t)}$  and  $r_j^{(h)}$  are opposite or not, we utilize antonym relations in WordNet and opposite relations in VerbOcean.

In the module, that two arguments are matching is checked by using their similarity. The similarity score of two arguments is computed by the same method as that for computing the similarity of two SRL elements. When we detect the contradiction of two arguments, we use the contradiction rule as follows. Two arguments are contradictory if they include two entities having the same type but different values. Especially, we take into account four categories: NUMBER, DATE, TIME, and LOCATION. In other cases, we use the similarity of two arguments as the evidence for contradiction detection.

## 5 Evaluation Experiments

### 5.1 Data Sets

In experiments, we evaluate the proposed method on the test sets of the three-way subtask at RTE-

Table 1: Label distribution in three test sets

Data Set	Contradiction	Entailment	Unknown	Total
RTE-3 Test	72	410	318	800
RTE-4 Test	150	500	350	1000
RTE-5 Test	90	300	210	600

3, RTE-4, and RTE-5 competitions (Giampiccolo et al., 2007; Giampiccolo et al., 2008; Bentivogli et al., 2009). The development sets provided at each competition are used to tuned threshold values in two CD modules of the system. The three-way subtask requires participant systems to decide whether the entailment, contradiction, or unknown relationship exists in a pair. Since in this study, we focus on contradiction relationship in a text pair, entailment and unknown labels in data sets are converted into non-contradiction labels. Table 1 provides statistics on the test sets of three-way subtask in RTE-3, RTE-4, and RTE-5.

The data sets used in experiments are unbalanced, so the average accuracy over all labels is not an appropriate evaluation measures. Therefore, we use Precision, Recall, and F1 scores of the contradiction label as evaluation measures.

## 5.2 Baseline Methods

The first baseline method is the method presented in (De Marneffe et al., 2008), which employed supervised machine learning techniques for the CD task. To the best of our knowledge, (De Marneffe et al., 2008) is the only contradiction detection-focused work that evaluates on data sets of RTE challenges.

The second baseline is the BLUE system of Boeing’s team (Clark and Harrison, 2009) at RTE-4 and RTE-5 competitions. The BLUE system adopted the logical inference approach to RTE, which performs inference on logic-based representations of the text and the hypothesis in a pair. We use best scores among submitted runs of the BLUE system at each competition.

In experiments, we also compare the results achieved by our system with average results of submitted systems for three-way subtask at RTE-3, RTE-4 and RTE-5 challenges. The numbers submitted systems in RTE-3, RTE-4 and RTE-5 for the three-way subtask are 12, 34, and 24 submissions, respectively.

In order to assess the effectiveness of the two-stage system scheme, we separately run each CD module on the three data sets and compare the re-

sults with those of the combined system.

## 5.3 Experimental Results

Table 2 provides experimental results achieved on test sets of RTE-3, RTE-4, and RTE-5 challenges by our system and baseline methods. As shown in results, the proposed system consistently obtained better recall values and F1 scores than those of baseline methods except the supervised machine learning-based method in (De Marneffe et al., 2008). Compared with the method presented (De Marneffe et al., 2008), our system achieves the same recall but lower precision.

The results shown in Table 2 indicated that the SRL-based module consistently achieved better recall and F1 score than those of the triple-based module. A possible explanation is that the information contained in shallow semantic representations is richer than that of extraction triples, so the SRL-based module covers more contradiction phenomena than the triple-based module. As expected, the combined system consistently obtained better recall and F1 score than each separate module. Experimental results confirmed our observation that the second backup module increases the coverage of contradiction phenomena for our system.

## 6 Conclusion

In this paper, we have presented a new rule-based method for finding contradiction in text, which combines shallow semantic representations with binary relations extracted from sentences. We define contradiction measurements on the predicate-argument structures and binary relations extracted from the text and the hypothesis in a pair. We deal with the low-coverage problem of semantic role resources by using a backup module which exploits extraction triples. Experimental results achieved on standard data sets showed that our proposed system obtained better recall and F1 score for contradiction detection than most of baseline methods.

Table 2: Experimental results on three data sets

Method	RTE-3 Pilot			RTE-4 Test			RTE-5 Test		
	P	R	F1	P	R	F1	P	R	F1
De Marneffe (2008)	22.95	19.44	21.04	–	–	–	–	–	–
BLUE system	–	–	–	41.67	10.0	16.13	42.86	6.67	11.54
Average result	10.72	11.69	11.18	25.26	13.47	13.63	26.40	13.70	14.79
SRL-based	13.41	15.27	14.28	22.41	17.33	19.55	22.72	16.67	19.23
Triple-based	22.58	9.72	13.59	26.3	10.0	14.49	19.48	16.67	17.96
<b>Two-stage (our system)</b>	<b>14.0</b>	<b>19.44</b>	<b>16.27</b>	<b>23.0</b>	<b>22.67</b>	<b>22.82</b>	<b>21.14</b>	<b>28.89</b>	<b>24.4</b>

## Abstract

Bilingual lexicons of proper names play a vital role in machine translation and cross-language information retrieval. Word alignment approaches are generally used to construct bilingual lexicons automatically from parallel corpora. Aligning proper names is a task particularly difficult when the source and target languages of the parallel corpus do not share a same written script. We present in this paper a system to transliterate automatically proper names from Arabic to Latin script, and a tool to align single and compound words from English-Arabic parallel texts. We particularly focus on the impact of using transliteration to improve the performance of the word alignment tool. We have evaluated the word alignment tool integrating transliteration of proper names from Arabic to Latin script using two methods: A manual evaluation of the alignment quality and an evaluation of the impact of this alignment on the translation quality by using the open source statistical machine translation system Moses. Experiments show that integrating transliteration of proper names into the alignment process improves the F-measure of word alignment from 72% to 81% and the translation BLEU score from 20.15% to 20.63%.

## 1 Introduction

Bilingual lexicons of proper names play a vital role in Machine Translation (MT) and Cross-Language Information Retrieval (CLIR). Word alignment approaches are generally used to construct bilingual lexicons automatically from parallel corpora. Aligning proper names requires both recognition of the proper names present in

the parallel corpus and their alignment (Abuleil and Evens, 2004). This task is particularly difficult when the source and target languages of the parallel corpus do not share a same written script. A solution to this issue consists in writing the proper names present in the parallel corpus in the same written script. This operation is named transliteration and consists in replacing each grapheme of a writing system by another grapheme or a group of graphemes of another writing system, regardless of pronunciation.

In order to study the impact of using transliteration to improve the performance of a word alignment tool, we present in this paper a system to transliterate automatically proper names from Arabic to Latin script, and a tool to align single and compound words from English-Arabic parallel texts.

The remainder of the paper is organized as follows: Section 2 recalls in some previous work addressing tasks of transliteration and bilingual lexicon extraction from parallel corpora. In section 3, we present briefly the system for automatic transliteration of proper names from Arabic to Latin script. Section 4 describes the process of using transliteration in the word alignment tool. We present in section 5 the experimental protocol we followed and discuss the obtained results. We finally conclude and present directions for future work in section 6.

## 2 Related Work

In order to build bilingual lexicons from parallel corpora automatically, several word alignment approaches have been explored (Daille *et al.*, 1994; Blank, 2000; Barbu, 2004). These approaches align proper names correctly when the source and target languages of the parallel corpus

share a same written script. Recent research works for aligning proper names when the source and target languages do not share a same written script have focused on automatic alignment of transliterations in order to enrich bilingual lexicons of named entities. These include (Al-Onaizan and Knight, 2002) and (Sherif and Kondrak, 2007) who worked on the Arabic-English alignment, (Tao *et al.*, 2006) who worked on Arabic, Chinese and English, and (Shao and Ng, 2004) who used the information resulted from transliterations based on pronunciation. They combined the obtained information from the translation context and those generated from Chinese and English transliteration. This technique allowed processing some specific infrequent words. Some other systems assign for a given name only one transliteration such as the generative model for English words written in Japanese (Katakana) to Latin transcription (Knight and Graehl, 1997). This approach was adapted by (Stalls and Knight, 1998) to translate English words written in Arabic into English. (AbdulJaleel and Larkey, 2003) proposed a system based on a statistical approach to transliterate English names into Arabic. This system has several limitations as it uses the computation of the most probable form supposed to be the correct one. Indeed, this hypothesis is not always valid in all the Arab countries and dialects. To avoid pronunciation and dialect varieties, (Alghamdi, 2005) proposed a system to transliterate vowelized Arabic names into English. This system is based on a dictionary of Arabic names in which the pronunciation is set using vowels added to listed names with an indication of their equivalents in English. This approach has a strong limitation when used in word alignment as it proposes only one transliteration for a given name. Recently, (Saadane *et al.*, 2012) proposed an approach to transliterate proper names from Arabic to Latin script which takes into account phonological and linguistic aspects. The authors reported an improvement of the F-measure of their French-Arabic word alignment tool from 82% to 86%.

### 3 Transliteration of Proper Names from Arabic to Latin Script

The transliteration system of proper names from Arabic to Latin script used in this study (Saadane *et al.*, 2012) is based on a finite-state automaton. This automaton switches from one state to another according to the outward transitions of the

current state and the currently processed letter of the Arabic word. The transliteration process is composed of the following main steps:

1. **Transliteration:** Each proper name is, first, split or not into several elements according to its type and the particles which do not compose the name itself are transcribed. Then, transliteration rules are applied to transliterate the names themselves. These rules are applied in a certain order based on the number of consonants of the proper name. For example, the compound name “عبد الرشيد” is, first, split into “عبد + ال + رشيد”, second, the particles “عبد” and “ال” are transcribed into “abd” and “al”, and finally the name “رشيد” is transliterated into rachid, rashid, etc.
2. **Normalization:** This step consists in performing some post-processing on the generated transliterations such as changing the first letter into capital.
3. **Weighting:** This step consists in assigning weights to the rules used to generate the list of transliterations in order to display the results sorted from the most likely to the least likely. Results of some search engines are exploited to compute these weights based on the number of occurrences for each generated transliteration of the proper name.

### 4 Alignment of Proper Names from English-Arabic Corpora

Word alignment from parallel corpora consists, on the one hand, in identifying words present in the source and target texts, and, on the other hand, in establishing correspondences between these words. The word alignment tool evaluated in this study (Semmar *et al.*, 2010), first, identifies single words and compound words present in the parallel corpus using the linguistic analyzer LIMA (Besançon *et al.*, 2010), and, second, establishes correspondence relations between these words using the following steps:

1. Look-up of words which are present in an existing English-Arabic lexicon composed of 149495 entries;
2. Matching of words which are cognates;
3. Matching of words which have the same grammatical categories;
4. Establishing correspondence relations between compound words.

We describe below only the step 2 which illustrates the process of using transliteration of proper names from Arabic to Latin script in English-Arabic word alignment.

Proper names alignment consists, first, in searching words present in the source and target sentences which have the grammatical category “Proper Name” by using the results of the linguistic analyzer LIMA, and, second, in identifying words which are cognates. Several research works have shown that using cognates can improve both sentence alignment (Simard *et al.*, 1993) and word alignment (Kondrak, 2005). In our implementation, we consider, in a first step, that pairs of words which share the first four characters as cognates. This step uses the results of the transliteration into Latin script of all the proper names present in the Arabic corpus and can identify, for example, that the proper name “Kosovo” and the transliteration of the Arabic word “كوسوفو” (“kosoufou”) are cognates. However, this step does not detect pairs of words such as “Algeria” and “aljazair” (transliteration of the Arabic word “الجزائر”). To take into account this kind of pairs of words, we used the Jaro–Winkler distance  $DJW$  (Winkler, 1990), a similarity measure based on the number of letters in common between the string of the word of the source language  $ws$  and the string of the word of the target language  $wt$ .

$$DJ(ws, wt) = \begin{cases} 0 & \text{if } m = 0 \\ \frac{1}{3} \left( \frac{m}{|ws|} + \frac{m}{|wt|} + \frac{m-t}{m} \right) & \text{otherwise} \end{cases}$$

where:

- $m$  is the number of matching characters. Two characters from  $ws$  and  $wt$  respectively, are considered matching only if they are the same and not farther than:

$$\left( \frac{\max(|ws|, |wt|)}{2} \right) - 1$$

- $t$  is the number of transpositions which is equal to the half of number of characters in  $ws$  that do not line up (by index in the matched subsequence) with identical characters in  $wt$ .
- $|ws|$ ,  $|wt|$  are lengths of the strings corresponding to the words  $ws$  and  $wt$ .

Jaro–Winkler similarity measure is a variant of the Jaro distance metric  $DJ$  (Jaro, 1989).

$$DJW(ws, wt) = DJ(ws, wt) + (lp(1 - DJ(ws, wt)))$$

where:

- $l$  is the length of common prefix at the start of the string up to a maximum of 4 characters.
- $p$  is a constant scaling factor for how much the score is adjusted upwards for having common prefixes.

In order to identify the values of  $l$  and  $p$  which provide the best alignment, we checked manually the result of the transliteration of 254 proper names. This evaluation showed that, if  $l$  is equal to 2 and  $p$  is equal to 0.1, the words  $ws$  and  $wt$  are cognates when the value of the Jaro–Winkler distance is the highest. Table 1 presents results after running our word alignment tool on the English sentence “Condemning all violations of human rights in Kosovo which have affected all ethnic groups in Kosovo.” and its Arabic translation “وإذ تدن كل ما ارتكب في كوسوفو من انتهاكات لحقوق الإنسان طالت جميع الفئات العرقية في كوسوفو.”

Lemmas of words of the source sentence	Lemmas of words of the target sentence
condemn	أَذَانَ
violation	إِنْتِهَاكَ
human	إِنْسَانَ
right	حَقَّ
Kosovo	كوسوفو
affect	طَالَ
ethnic	عَرَقِيَّةَ
group	فِئَةَ
Kosovo	كوسوفو
violation_human_right	إِنْتِهَاكَ حَقَّ إِنْسَانَ
human_right	حَقَّ إِنْسَانَ
ethnic_group	فِئَةَ عَرَقِيَّةَ

Table 1. Results of single words and compound words alignment

The word “Kosovo” was aligned using cognates matching after transliteration, the words “condemn”, “human”, “affect” and “group” were aligned using grammatical categories matching and the other single words exist in the English-Arabic lexicon. The compound words “violation\_human\_right”, “إِنْتِهَاكَ حَقَّ إِنْسَانَ”, “human\_right”, “حَقَّ إِنْسَانَ”, “ethnic\_group” and “فِئَةَ عَرَقِيَّةَ” are first recognized by LIMA respectively from the source sentence and the target sentence, and then aligned using lexical and syntactic transfer rules between source and target languages (Ozdowska, 2004).

## 5 Experimental Results and Evaluation

The impact of using transliteration of proper names on the quality of alignment and machine translation has been evaluated according to the two following approaches:

- A manual evaluation comparing the results of our word aligner with a reference alignment;
- An automatic evaluation by integrating the results of our word aligner tool in the training corpus used to build the translation table of the statistical MT system Moses (Koehn *et al.*, 2007).

In order to evaluate the alignment quality manually, we used 500 English-Arabic aligned sentences extracted from the MT evaluation MEDAR<sup>1</sup> package and we followed the evaluation framework defined in (Mihalcea and Pedersen, 2003). Table 2 summarizes the results of our word aligner in terms of precision and recall. The first line describes the performance of the word aligner when it does not integrate transliteration and the second line mentions its performance when it uses transliteration. As we can see, the results demonstrate that using transliteration improves both precision and recall of word alignment. These results confirm those obtained by (Sajjad *et al.*, 2003) related to the improvement of alignment quality when integrating transliteration into the GIZA++ word aligner.

Alignment	Precision	Recall	F-measure
without using transliteration	0.90	0.60	0.72
with the use of transliteration	0.91	0.73	0.81

Table 2. Results of the evaluation of single and compound words alignment

The unavailability of a reference alignment of a significant size for single and compound words does not allow us to compare our approach with the state-of-the-art work. That's why we decided to study the impact of the use of transliteration in word alignment by integrating the results of our word aligner in the training corpus used to extract the translation model of Moses. The initial training corpus is composed of 75000 pairs of English-Arabic sentences extracted from the

<sup>1</sup> The MT evaluation MEDAR package is available on <http://www.medar.info/index.php>.

MEDAR corpus (2631654 English words and 2344878 Arabic words). We added to this corpus around 28000 pairs of single and compound words corresponding to the results of our word aligner which integrates transliteration applied on 1000 pairs of English-Arabic sentences. We also specified a language model for the target language using a corpus composed of 100000 Arabic sentences (3155516 words). The performance of the statistical machine translation system Moses is evaluated using the BLEU score on a test corpus composed of 500 pairs of sentences. Note that we consider one reference per sentence. The obtained results show that the inclusion in the training corpus of word alignment results integrating transliteration has improved the translation BLEU score from 20.15 to 20.63 (a gain of 0.48 points).

In order to assess statistical significance of the obtained results, we use the paired bootstrap resampling method (Koehn, 2004) which estimates the probability (*p-value*) that a measured difference in BLEU scores arose by chance by repeatedly (10 times) creating new virtual test sets by drawing sentences with replacement from a given collection of translated sentences. We carry out experiments using this method to compare the translation results without using transliteration and with the use of transliteration. At a 95% confidence interval (CI), the results vary from insignificant (at  $p > 0.05$ ) to highly significant. The *p-value* obtained is equal to 0.02 and therefore the improvement achieved by using transliteration is statistically significant.

## 6 Conclusion

We presented briefly in this paper a system to transliterate proper names from Arabic to Latin script and we proposed a tool to automatically align word pairs from an English-Arabic parallel corpus. We integrated the transliterated proper names into the cognates matching step and we obtained a gain of 9% on word alignment F-measure and a gain of 0.48 points in translation BLEU score. These encouraging results can be improved in a number of ways. First, we plan to affect a weight for each word pair in order to filter the word alignment results and to integrate them directly in the translation table of Moses. We also plan to use, on the one hand, the linguistic analyzer LIMA to lemmatize texts of the bilingual corpus, and on the other hand, factored models and a flexor to generate adequate surface forms from lemmas.

## Abstract

In this paper, we propose a new semi-supervised approach for Arabic word sense disambiguation. Using the corpus and Arabic Wordnet<sup>1</sup>, we define a method to cluster the sentences containing ambiguous words. For each sense, we generate a cluster that we use to construct a semantic tree. Furthermore, we construct a weighted directed graph by matching the tree of the original sentence with semantic trees of each sense candidate. To find the correct sense, we use a similarity score based on three collocation measures that will be classified using a novel voting procedure. The proposed method gives a high rate of recall and precision.

## 1 Introduction

The human language is so complex to be learned. The syntactic form of words, the relation between a specific word form and its meaning are the basic parts of an intelligent system for the natural language processing.

In this work we aim to solve the task of identifying the sense of the ambiguous word. This task is called Word Sense Disambiguation (WSD), which is one of the oldest problems in natural language processing (NLP) (Agirre and Edmond, 2006). This work is part of a general framework of Arabic speech (Zouaghi, 2008).

In this work, we combine a supervised and an unsupervised method for Arabic word sense disambiguation. The innovative part in this work is

the construction of a semantic tree for each sense of the ambiguous word. Also we define a voting procedure that gives a weight for the score measure.

This paper is organized as follows. Section two describes the proposed method. The experimental results are described in section three. Finally this paper is concluded in section four.

## 2 Proposed method

We propose a semi-supervised method for Arabic word sense disambiguation.

For the unsupervised part of the proposed method, we use Arabic Wordnet (Black et al., 2006) and the corpus to construct sense clusters (group of sentences) characterizing a specific sense of the ambiguous word. Furthermore we construct a semantic tree for each sense of the ambiguous word.

The disambiguation procedure is based on the step of matching the semantic tree with the tree of the original sentence. We use a score measure (based on three collocation measures) to find the closest semantic tree to the tree of the sentence to be disambiguated.

The supervised part uses a voting procedure that will rank collocation measures during a classification task. The sense given by the measure having the highest rank will be attributed to the ambiguous word. In what follows we describe with more details each step cited above.

### 2.1 Construction of the sense clusters

In the first we apply some pre-treatment steps to glosses of the ambiguous word (definitions and synonyms extracted from Arabic wordnet) and sentences containing the ambiguous word (collected from the used corpus). Using the Kho-

---

<sup>1</sup> Arabic Wordnet is a concept dictionary with mappings between word definitions.

ja stemmer and the approximate string matching, we are able to construct the sense clusters. Some pre-treatment steps will be applied to these clusters. In what follows, we detail the steps of the proposed method.

**Pre-treatment:** Using the corpus we collect sentences containing the ambiguous word, we have to search the root of the ambiguous word (exp: for the word “العين” “alayn” we have to search the root “عين” “ayn”). The segmentation of these sentences is based on punctuation (., :, !, ?, etc.) and on the number of the words that have to be more than three.

Subsequently, we eliminate the stop-words that occur frequently in the corpus and they have no significant relation to the sense of the word. We use a general stop-list containing 29,985 stop-words, this list were elaborated by Arabic linguistics and judged as sufficient for the task of WSD.

**Root extraction:** We use the Khoja stemmer (Khoja,1999) for words contained in the glosses of the ambiguous word. Its advantage is that it uses a large linguistic data such as the list of verbal and noun patterns, stop-words, list of diacritic characters, etc.

For a specific word, this stemmer extracts the longest suffix and prefix, which will be matched with the existing list of patterns to extract the root. We notice that we use the list of stop-words in addition to the already used list (detailed in the previous paragraph).

**Sense Clustering:** The basic idea of Sense clustering is that the sentences representing the meaning of a particular sense are grouped in the same cluster  $C_i$  (Cluster of the  $i^{\text{th}}$  sense of the ambiguous word).

The list of sentences extracted from the corpus will be classified into clusters using the roots of the words containing in each gloss. To find the possible occurrences of the roots, we use the approximate string matching algorithm (Elloumi, 1998).

In the first we fill a matrix of the two words to be compared  $w_i$  and  $w_j$ . After that we use the step of back-tracking, to find the shortest common subsequence.

The words containing the common subsequence will be considered as occurrences of the stem. The Sentences containing the occurrences of stems obtained from glosses are grouped into

clusters representing each sense of the ambiguous word.

## 2.2 Semantic Tree construction

A text can be represented by Trees or graphs (co-occurrence graphs (Agirre and Sorora, 2007), collocation graphs (Klapaftis and Manandhar, 2008), semantic graphs (Plaza and Diaz, 2011)) that differs in the structure of text representation.

The first step is to transform the sentences of the clusters to binary trees,  $T = (N, E, R, RC, LC, L)$ , where:

- $N$  is a set of nodes,  $N = \{n_1 \dots n_2\}$ . Each node corresponds to a concept in the binary Tree.
- $E$  is a set of edges that represents the relation between the node  $n_i$  to the node  $n_j$ .
- $R$  is the root of the tree which is the ambiguous word.  $RC$  is the set of right children which are the words occurring on the right of the ambiguous word.
- $LC$  is the set of left children which are the words occurring on the left of the ambiguous word.
- $L$  is a function assigning the level of the nodes, it corresponds to their position regarding the ambiguous word.

Expect the root, each node of the tree has exactly one child. We denote  $\langle R, RC, LC \rangle$  a binary tree.

The second step is to merge all the obtained trees corresponding to the sentences contained in the same cluster. Accordingly, we obtain a semantic tree,  $ST = (N, E, R, C, L, Nb, H)$ , where:

- $C$  is the set of merged nodes,  $C = \{c_1, \dots c_n\}$ . The right and left child of each binary tree will be linked to the root of the semantic tree.
- $Nb$  is a function that returns the number of nodes in the semantic tree.
- $H$  is a function that returns the height of the semantic tree.

The step of merging trees uses an algorithm of breadth-first traversal, to find the repeated node that may have a higher level, same level or a lower level.

## 2.3 WSD procedure

In the first, we apply some pre-treatment steps to the original sentence containing the ambiguous word. The process of disambiguation is based on three steps:

### Step 1: Weighted directed graph construction:

We add edges weighted by the collocation measures between the nodes  $N_i$  of the tree of the original sentence (called  $T_{os}$ ) and the nodes  $N_j$  of the semantic tree of each sense (called  $ST_{S_k}$ , where  $S_k$  corresponds to the  $k^{th}$  sense).

This step called matching allows us to obtain a weighted directed graph. After eliminating stopwords, we extract the roots of the words contained in the original sentence. These roots are the nodes of the tree and the level in the tree  $T_{os}(N)$  will be affiliated corresponding to their position regarding the ambiguous word.

Each node of the tree extracted from the original sentence is matched with the nodes of the same level in the semantic tree of a particular sense. The links used for the matching step appear as a dashed line. They are weighted using one of the three collocation measures (Maning and Schütze, 1999) detailed in what follows:

#### The T-test

The T-test is measured as follows (see equation 1).

$$wc_{ij} = T = (\bar{x} - \mu) / \left( \sqrt{\frac{s^2}{N}} \right) \quad (1)$$

The mean of the distribution  $\mu$  is measured by multiplying  $P(w_i)$  to  $P(w_j)$ , where  $P(w)$  = number of occurrences of  $w$  in the corpus / Total number of words in the corpus.  $\bar{x}$  (sample mean) is equal to  $s^2$  (sample variance), measured by dividing the number of occurrences of the two words together by the total number of words in the corpus.

#### The Mutual Information

This measure determines how much a word can be informative for another word. The mutual information is measured as follows (see equation 2):

$$wc_{ij} = MI = \log_2 \frac{P(w_i, w_j)}{P(w_i) P(w_j)} \quad (2)$$

#### The Chi-Square $\chi^2$

The equation 3 in what follows details the measure of  $\chi^2$ .

$$wc_{ij} = \chi^2 = \frac{N \times (c_{1,1} \times c_{2,2} - c_{1,2} \times c_{2,1})^2}{(c_{1,1} + c_{1,2}) \times (c_{1,1} + c_{2,1}) \times (c_{1,2} + c_{2,2}) \times (c_{2,1} + c_{2,2})} \quad (3)$$

The basic principle is to count  $C_{1,1}$  (the number of occurrences of  $w_i$  and  $w_j$  together),  $C_{1,2}$  (the number of occurrences of  $w_i$  without  $w_j$ ),  $C_{2,1}$  (the number of occurrence of  $w_j$  without  $w_i$ ) and  $C_{2,2}$  (the number of bigrams in the corpus that don't contains  $w_i$  or  $w_j$ ).

**Step 2: Semantic similarity measure:** We define a score measure that allows us to choose the closest semantic tree  $ST_{S_k}$  to the tree of the orig-

inal sentence  $T_{os}$ . The score measure is defined in what follows (see equation 4).

$$\text{Score} = \sum_{N_i \in T_{os}} \left( \sum_{N_j \in ST_{S_k}} \left( \frac{wc_{ij}}{ST_{S_k}(L(N_j))} \right) / \text{Nb}(ST_{S_k}) \right) / \text{Nb}(T_{os}) \quad (4)$$

The score measure is the average of the product between nodes of  $ST_{S_k}$  and  $T_{os}$ . Where  $\text{Nb}(T_{os})$  is the total number of nodes in  $T_{os}$  and  $\text{Nb}(ST_{S_k})$  is the total number of the nodes linked to each node of  $ST_{S_k}$ .  $ST_{S_k}(L(N_j))$  corresponds to the level of the node  $N_j$  contained in the semantic tree  $ST_{S_k}$ .

As a result we give the sense that corresponds to the semantic tree that obtains the highest score.

The weights obtained by the collocation measures  $wc_{ij}$  are normalized to low weights between 0 and 1.

**Step 3: Voting procedure:** The idea is that during the classification task, we ranked measures of collocation according to the correct attribution of the sense.

In the case where the three collocation measures agree on the same result, then the given sense will be attributed to the ambiguous word and the rank of the collocation measure will not be changed.

In the case where more than one measure agrees on the attribution of a sense, then, we have to choose the sense having the majority of votes. The rank of the measures that vote for the attributed sense will be increased and the rank of the other measures will be decreased.

The final case is where all the measures do not give the same result. The result given by the measure having the highest rank (attributed during the last N tests) will be used to attribute the sense of the ambiguous word. In what follows, we detail results given by the described method.

## 3 Experimental Results

### 3.1 Used resources and tested data

Due to our need to maximize the keywords that define a specific sense, we use Arabic Wordnet (AWN) (Black et al., 2006) which is a dictionary. Words are arranged semantically instead of alphabetically. Synonymous words are grouped together to form synonym sets.

Also we collect a large corpus from newspaper articles, which were recorded from different corpus that are available on the net. In total, we collect a corpus that counts 123,854,642 words.

For the missed senses in the corpus, we collect from the net the contexts containing these senses and we added them to the used corpus.

### 3.2 Obtained Results

In the table 1 below, we report the statistics of the tested data and the obtained rate (Precision, Recall, F-Score) given by the voting procedure (VP) and the collocation measures for 127 ambiguous words. In total we test 42,316 sentences.

For each sense we test 40 sentences. For the classification part of the voting procedure, we use 20 samples per sense (labeled data). In total, we have 4,582 tagged samples. We haven't found an important difference between the sense tags, the agreement between the annotators is in the average of 95%.

$w_{c_j}$	#correct disambiguated sentences	Recall	Precision	F-Score
$T_{test}$	31,298	0,739	0,754	0,747
MI	29,783	0,703	0,718	0,710
$\chi^2$	32,122	0,759	0,774	0,766
VP	35,145	0,830	0,830	0,830

Table1. Performances of our method.

We remark that the F-score obtained by applying the voting procedure is higher than those obtained by any one of the collocation measures.

There is not a big difference between the Precision and the Recall obtained by any of the used collocation measures. This can be explained by the fact that the majority of the tested words were disambiguated. However, the best collocation measure is the  $\chi^2$ , otherwise the voting procedure increases the F-score by 6,4%.

We measure the performance of our method under the number of nodes in ST. The obtained results indicate that for semantic trees with at least 500 nodes, the performance of our method increases consistently. However, the F-Score reaches the top and becomes stable for semantic tree sizes between 2,000 and 3,000 nodes. We conjecture that more the semantic tree is enriched by the nodes, more the F-Score increases.

### 3.3 Comparison with other works

In order to contextualize the obtained results in the current state of the art, fifty ambiguous words that are used in the experimental study of this work were evaluated in previous works of Arabic WSD:

- Supervised works which are the naïve bayesian algorithm, the Decision List and the K Nearest Neighbor (Merhbene et al., 2012).
- Based knowledge works which are the original Lesk algorithm and the modified Lesk algorithm that uses Arabic Wordnet and five similarity measures (Zouaghi et al., 2011).
- Unsupervised work for Arabic WSD based on a combination between some information retrieval measures and the Lesk algorithm (Zouaghi et al., 2012) and (Merhbene et al., 2010).

Compared to our method, we note that the Lesk algorithm is limited to dictionary definitions that we use. Therefore, the absence of certain words can radically change the results. The modified Lesk algorithm using the Leacock and Chodorow measure (Leacock and Chodorow, 1998) is the most performed between based knowledge methods with a rate of Precision equal to 67,73%.

The supervised methods need an important amount of tagged data to achieve satisfactory results. They need to be applied in specific domains. The K nearest neighbor algorithm achieves the best rate of Precision (52,02%).

Finally, compared to the unsupervised method of Arabic WSD, the rate of precision is enhanced by 10% using more 117 ambiguous words.

## 4 Conclusion and future work

This paper describes a novel approach for the disambiguation of the Arabic language based on the weighted directed graph.

During the step of disambiguation, we match the tree of the sentence to be disambiguated with each semantic tree of the senses candidate. The obtained weighted directed graph uses three collocation measures that will be classified using a novel supervised voting procedure. Results show that our method achieves a very high recall and precision (83%).

In the future works, we propose to test more ambiguous words, using more tested data and resources to confirm the positive obtained results.

## Abstract

Simultaneous translation is the challenging task of listening to source language speech, and at the same time, producing target language speech. Human interpreters achieve this task routinely and effortlessly, using different strategies in order to minimize the latency in producing target language. Toward modeling the human interpretation process, we propose a novel input segmentation method using the phrase alignment structure of the language pair. We compare and contrast three incremental decoding and two different input segmentation strategies, including our proposed method, for simultaneous translation. We present accuracy and latency tradeoffs for each of the decoding strategies when applied to audio lectures from the TED collection.

## 1 Introduction

In simultaneous speech translation, it is important to keep the delay between a source language chunk and its corresponding target language chunk (referred to as *ear-voice span*) minimal in order to continually engage the listeners. Simultaneous human interpreters are able to generate target speech incrementally with very low ear-voice span by using a variety of strategies (Chernov, 2004) such as anticipation, cognitive and linguistic inference, paraphrasing, etc. However, current methodologies for simultaneous translation are far from being able to exploit or model such complex phenomena. Quite often, models trained for consecutive translation are repurposed for incremental translation.

One of the first attempts at incremental *text* translation was presented by Furuse and Iida (1996) using a transfer-based MT approach and more recently by Sankaran et al. (2010) using a phrase-based approach. On the other

hand, incremental *speech* translation has been addressed in simultaneous translation of lectures and speeches (Hamon et al., 2009; Fügen et al., 2007). Some previous work (Cettolo and Federico, 2006; Rao et al., 2007; Matusov et al., 2007) addressed source text (reference or ASR hypothesis) segmentation strategies in speech translation. Constraining the search process during decoding to be monotonic (Tillmann and Ney, 2000) is one way of reducing latency and promoting incrementality. However, finding the optimal segmentation of the complete source string using dynamic programming is still slow.

By shifting the focus of the task to appropriate segmentation of incoming text, consecutive translation models have been used with good success to simulate incremental translation, such as incremental speech-to-speech translation (Bangalore et al., 2012) which focuses on translating the partial hypotheses generated based on the silences detected by a speech recognizer. However, studies on human interpreters show that in only a few cases the interpreters encode the chunks of speech as uttered in the source: the mean proportion of silence-based chunking by interpreters is 6.6% when the source is English, 10% when it is French, and 17.1% when it is German (Pöschhacker, 2002). As an alternative to silence-based segmentation, in this work, we propose a novel approach for segmenting the incoming text that exploits the alignment structure between words (phrases) across a language pair. We compare the two segmentation methods in three different decoding strategies. We perform our investigation within an English-French phrase-based speech translation system trained and tested on TED talks released as part of the IWSLT evaluation (Federico et al., 2011).

## 2 Non-incremental and Incremental Translation

The objective in machine translation is to translate a source sentence  $\mathbf{f} = f_1^J = f_1, \dots, f_J$  into target sentence  $\mathbf{e} = e_1^I = e_1, \dots, e_I$ . Given the in-

put sentence  $\mathbf{f}$ , we choose the sentence with highest probability among all possible target sentences. Since, it is intractable to estimate the conditional probability distribution  $\Pr(\mathbf{e}|\mathbf{f})$  over sentences, we simplify the problem as mapping between sentential sub-units (words or phrases) and represent the correspondence across these units using an alignment structure,  $\mathbf{a} = a_1^J = a_1, \dots, a_J$ .

$$\hat{\mathbf{e}}(\mathbf{f}) = \arg \max_{\mathbf{e}} \left\{ \sum_{\mathbf{a}} \Pr(\mathbf{e}, \mathbf{a}|\mathbf{f}) \right\} \quad (1)$$

In an incremental translation framework, we do not observe the entire string  $\mathbf{f}$ . Instead, we observe segments of the string. A sentence pair  $(f_1^J, e_1^J)$  can be segmented into  $K$  phrase pairs  $\mathbf{s} = s_1^K = s_1, \dots, s_K$ ,

$$s_k = (i_k; b_k, j_k) \quad \forall k = 1, \dots, K \quad (2)$$

where  $i_k$  is the end position of the word in target phrase  $k$  and  $(b_k, j_k)$  represent the start and end positions of the source phrase aligned with the target phrase  $k$ . To achieve the highest *monotonicity* in incremental translation, we may restrict the decoding problem to strictly generate *monotonic phrases* by satisfying the constraint,  $b_k = j_{k-1} + 1 \quad \forall k = 1, \dots, K$ . We also constrain the source and target phrases to be ordered monotonically, meaning that if a source phrase at position  $j$  is translated to a target phrase at position  $i$ , then a source phrase at position  $j' > j$  will be translated to a target phrase at position  $i' > i$ . We call such phrase pairs to be a *monotonic phrase alignment* for a sentence pair. Figure 1 shows an example of a word alignment matrix, all possible phrase pairs, and all possible monotonic phrase alignments (4 alignments) for the parallel sentences  $\mathbf{e}$ - $\mathbf{f}$ , shown with different line styles. For instance, the monotonic phrase alignment shown with dark lines has three phrase pairs  $s_1 = (0; 0, 0)$ ,  $s_2 = (3; 1, 3)$ ,  $s_3 = (4; 4, 5)$ . Grey dotted-line phrases are not monotonic. In Section 3.2 we present a source sentence segmentation approach that makes use of the monotonic phrase alignments information.

### 3 Segmentation of ASR output for MT

In this section, we describe two alternative methods to split the input sentence into partial segments for incremental translation. Since the ASR component is not the main focus of our study, we do not explain the ASR system we used in detail. Our ASR system uses context-dependent HMMs

Figure 1: Word alignment matrix for two parallel sentences and their monotonic phrase alignments.

with Vocal Tract Length Normalization (VTLN) to build its acoustic model from 1119 talks we harvested from the TED website. We used the AT&T FSM toolkit (Mohri et al., 1997) to train a trigram language model for English from the permitted data in IWSLT 2011 evaluation. We reached 78.8% and 77.4% ASR word accuracies on the IWSLT dev2010 and tst2010 sets respectively.

#### 3.1 Silence-based Segmentation

The output of automatic speech recognition includes silence information that is typically discarded before passing the source string into the machine translation component. We use any silence, irrespective of the frame length, as a segmentation marker. The average length of a segment using this strategy is  $4.28 \pm 3.28$  words.

#### 3.2 Monotonic Phrase-Based Segmentation

In this section, we present an approach to split the source sentence into segments that can be monotonically translated to the target language. To prepare the training data for our segmentation model, we extracted monotonic phrase alignments from the set of all possible phrase alignments of a sentence pair in the word alignment matrix produced by GIZA++ using dynamic programming. We used 90% of the total parallel sentences and their extracted monotonic phrase alignments as training set, and reserved the rest 10% as development set. To get more meaningful alignments, we restricted those to the alignments of length at least 4.

Having the above training data, we trained a binary classifier, which was applied independently at each word in the sentence, to decide whether that word is a segment boundary or not. We used a discriminative log-linear model to train the classifier and we used the perceptron algorithm (Collins, 2002) to train the model parameters. Fisher and

Roark (2007), successfully used a discriminative log-linear model using the perceptron algorithm for automatic discourse segmentation task.

The task is to learn a mapping from inputs  $x \in X$  to outputs  $y \in Y$ , where  $X$  is the set of sentences and  $Y$  is the set of possible monotonic alignments of the sentences. Given a set of training examples  $(x_i, y_i)$ , a function  $\mathbf{GEN}(x)$  that enumerates a set of possible monotonic alignments of  $x$ ,  $\bar{\alpha} \in \mathbf{R}^d$  a parameter vector, and representation  $\Phi$  that maps each  $(x, y) \in X \times Y$  to a feature vector  $\Phi(x, y)$ , there is a mapping from an input  $x$  to an output  $F(x)$  defined by the formula:

$$F(x) = \arg \max_{y \in \mathbf{GEN}(x)} \Phi(x, y) \cdot \bar{\alpha} \quad (3)$$

The model learns the parameter values  $\bar{\alpha}$  during the training, and the decoding algorithm searches for the  $y$  that maximizes 3. The feature vector  $\Phi(x, y)$  represents arbitrary features of the alignments. In our study, the feature set contains word, position of the word in the sentence, and segment length. For example, one feature might be (word='cat', position=8, seg\_length=3, seg\_boundary = true), which returns 1 if the current word is 'cat', it is the 8th word in the sentence, it is the 3rd word in the segment, and it is marked as a segment boundary, and returns 0 otherwise.

We evaluated our segmentation model with precision, recall and F1-score, defined in Eq. 4. Suppose a sentence of length  $n$  has  $m$  segment boundaries in the gold standard and  $k$  segment boundaries in the system output. Assume  $t$  out of  $k$  guessed boundaries are correct. Since we might have multiple valid segmentations for a sentence in our training data, we chose the gold standard to be the valid segmentation which has the minimum Levenshtein edit distance with the system output.

$$P = \frac{t}{k}, R = \frac{t}{m}, F1 = \frac{2PR}{P+R} = \frac{2t}{k+m} \quad (4)$$

We achieved  $P = 70.51\%$ ,  $R = 91.52\%$ , and  $F1 = 75.89\%$  on the development set. The average length of a segment using this strategy is  $6.56 \pm 4.73$  words.

## 4 Decoding Strategies

We used three different decoding strategies for translating the ASR outputs. We tried each of these three techniques for incremental as well as regular (non-incremental) translation.

First, we used the Moses toolkit (Koehn et al., 2007) for statistical machine translation. Minimum error rate training (MERT) was performed on the development set (dev2010) to optimize the feature weights of the log-linear model used in translation. During decoding, the unknown words were preserved in the hypotheses. The parallel text for building the English-French translation model – around 6.3 million parallel sentences – was obtained from several corpora: Europarl (Koehn, 2005), jrc-acquis corpus (Steinberger et al., 2006), Opensubtitle corpus (Tiedemann and Lars Nygaard, 2004), WMT11 Gigaword (Callison-Burch et al., 2011), WMT11 News (Callison-Burch et al., 2011), and Web crawling (Rangarajan Sridhar et al., 2011) as well as human translation of proprietary data.

Second, we used a finite-state implementation of translation without reordering. We represent the phrase translation table as a weighted finite state transducer (FST) and the language model as a finite-state acceptor. The weight on the arcs of the FST is the dot product of the MERT weights with the translation scores. Our FST-based translation is the equivalent of phrase-based translation in Moses without reordering.

In addition to Moses and FST decoders, we used the incremental beam search decoder introduced by Sankaran et al. (2010) for translating in regular and incremental modes. This decoder modifies the beam-search decoding algorithm for phrase-based MT aiming at efficient computation of future costs and avoiding search errors. In Section 6 we show the results of translating our data using these three decoding strategies, referred to as Moses, FST and IncBeam decoders.

## 5 Data

In this work, we focus on the speech translation of TED talks. Over the past couple of years, the International Workshop on Spoken Language Translation (IWSLT) has been conducting the evaluation of speech translation on TED talks for English-French. We leverage the IWSLT TED campaign by using identical development (dev2010) and test data (tst2010).

## 6 Experiments and Results

We compare the results in terms of accuracy of translation and latency of generating partial outputs. We translated and evaluated each of 11 test

sets independently and we report the average values. In incremental mode, we ran Moses with *continue-partial-translation* option which enables chunk translation to be conditioned on history. In contrast, FST performs a chunk-wise translation which is independent of history.

		Moses	FST	IncBeam
Regular	ASR	18.67	18.11	17.73
	Transcript	22.66	22.11	21.32
Incr. silence seg.	ASR	17.41	16.88	17.33
Incr. monotone seg.	ASR	17.64	17.09	17.40

a) Reference translation has punctuations

		Moses	FST	IncBeam
Regular	ASR	23.04	22.58	22.00
	Transcript	28.38	27.75	26.63
Incr. silence seg.	ASR	21.66	21.12	21.38
Incr. monotone seg.	ASR	21.69	21.26	21.48

b) Reference translation has no punctuations

Table 1: Accuracy (BLEU) of English-French MT models on reference transcripts and ASR outputs

Table 1 shows translation accuracies in terms of BLEU scores. We consider the regular decoding as the baseline. Since we know the entire source input in advance, our baseline, obviously, has the highest accuracy but also the highest latency. For the baseline, we translated the ASR output and the reference transcript of the utterance. As shown in the "Regular" row, the accuracy on the ASR output drops by around 4% compared to that on the reference text. Since ASR outputs and the training data for our translation model do not contain punctuations, we also measured the accuracy against the references with removed punctuations.

Incremental translation of monotone-based segments gets a slightly higher accuracy than the silence-based segments for all the three decoders. In both regular and incremental decoding settings, the BLEU scores of Moses are higher than other two decoders. The FST decoder is better than the IncBeam decoder in regular setting; on the other hand the performance of the IncBeam decoder is better than the FST decoder and comparable to Moses in the two incremental settings. Both Moses and IncBeam decoders use reordering knowledge as well as history of translation in the incremental decoding settings, whereas the FST decoder lacks the latter.

In Table 2, we present the average speed of translating ASR output chunks. For each sentence the speed is calculated as the total time taken to translate the chunks divided by the number of

	Moses	FST	IncBeam
Regular	2.35	2.06	17.68
Incr. silence seg.	0.68	1.75	6.43
Incr. monotone seg.	0.87	1.59	8.60

Table 2: Speed of generating target chunks (sec)

chunks of the sentence. The speed reported in the table is then calculated by taking the average of speeds of all sentences in the test set. This measurement provides a good indication of latency in real-time translation. We note that we do not compare the delay of the decoders with each other due to differences in implementation and invoking the decoders, instead we compare the delays of each decoder by itself in three modes of translation.

Comparing the accuracy values in Table 1 and latency values in Table 2 shows that in incremental decoding using the Moses and IncBeam decoders, we get some gain in accuracy but we lose some speed in monotone-based model compared to the silence-based model.

The interesting achievement is in incremental translation of monotone-based segments using the FST decoder. In this condition, we not only achieve an improvement in accuracy, but we also get a reduction in latency compared to the translation of silence-based segments. When translating each chunk independently, a meaningful segmentation of the input toward increasing the monotonicity yields a better performance in simultaneous translation than a silence-based segmentation.

## 7 Conclusions

In this paper we introduced a novel incoming text segmentation approach aiming at increasing the monotonicity of simultaneous translation. Using our proposed framework, we could achieve a point in segmenting and decoding the ASR output which enables simultaneous speech translation with a good accuracy/latency trade-off, even without relying on the history of translation. For future work we plan to improve our monotone-based segmentation model by using richer feature sets which for example include syntactic knowledge of the language. We are also interested in exploring our techniques on translating the languages with different word orders such as English/Japanese.

## Abstract

We focus on improving the translation of the English pronoun *it* and English reflexive pronouns in an English-Czech syntax-based machine translation framework. Our evaluation both from intrinsic and extrinsic perspective shows that adding specialized syntactic and coreference-related features leads to an improvement in translation quality.

## 1 Introduction

Machine Translation (MT) is an extremely broad task and can be decomposed along various directions. One of them lies in using specialized translation models (TMs) for certain types of language expressions. For instance, different types of named entities often receive specialized treatment in real translation systems. This paper deals with introducing specialized TMs for two types of pronouns: the pronoun *it* and reflexive pronouns. The models are integrated into an English-Czech syntax-based MT framework.

Several works have previously focused on translating pronouns. The linguistic study of Morin (2009) investigated the translation of pronouns, proper names and kinship terms from Indonesian into English. Onderková (2010) has conducted a corpus-based research on possessive pronouns in Czech and English, focusing especially on their use with parts of the human body.

From the perspective of MT, translating personal pronouns from English to morphologically richer languages, such as French (Le Nagard and Koehn, 2010), German (Hardmeier and Federico, 2010) and Czech (Guillou, 2012) has recently aroused higher interest. In these languages, one usually has to ensure agreement in gender and number between the pronoun and its direct antecedent, which requires a coreference resolver to be involved.

In this work, we make use of the English-to-Czech translation implemented within the TectoMT system (Žabokrtský et al., 2008). In contrast to the phrase-based approach (Koehn et al., 2003), TectoMT performs a tree-to-tree machine translation. An input English sentence is first analyzed into its deep-syntactic representation, which is subsequently transferred into Czech. The pipeline ends with generating a surface form of the Czech translation from its deep representation.

The deep syntactic representation of a sentence in TectoMT follows the Prague tectogramatics theory (Sgall, 1967; Sgall et al., 1986). It is a dependency tree whose nodes correspond to content words. Personal pronouns missing on the surface are reconstructed in special nodes. All nodes are assigned semantic roles and coreference relations are annotated.

Originally, translation of both *it* and reflexive pronouns was treated by rules in TectoMT. The English deep representation of *it* was translated as *to* and a simple heuristics determined if it is being expressed on the surface. Similarly, reflexives were always translated as *se*. This paper evaluates the translation quality reached using specialized classifiers for these pronouns. Unlike the related work on pronouns in MT, we focus on improving the lexical choice, not tuning other components that affect generating a particular surface form (e.g. coreference resolution).

## 2 Linguistic analysis

We started with an analysis of how the pronouns under investigation are translated<sup>1</sup> in two Czech-English parallel treebanks – Prague Czech-English Dependency Treebank 2.0 (Hajič et al., 2011, PCEDT) and CzEng 1.0 (Bojar et al., 2012).

<sup>1</sup>Note that besides the means mentioned below, there are other ways of translating these pronouns. However, in most cases they can be replaced by one of the variants listed with no harm to the quality of the Czech output.

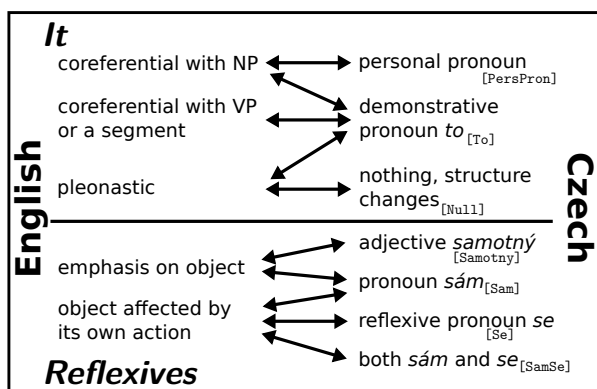

Figure 1: The mapping of the types of English *it* (top) and reflexive pronouns (bottom) to their Czech counterparts.

## 2.1 Translating *it* from English to Czech

In English, three coarse-grained types of *it* are traditionally distinguished: referential *it* pointing to a noun phrase in the preceding or following context, anaphoric *it* referring to a verbal phrase or a larger discourse segment, and non-referential pleonastic *it*, whose presence is imposed only by the syntactic rules of English.

There are three prevailing ways of translating *it* into Czech, also three different ways prevail. Personal pronouns or zero forms<sup>2</sup>, whose gender and number are determined by their antecedent, are the most frequent variant (referred to as the `PersPron` class in the following). Another way is using the Czech demonstrative pronoun *to*, which is a neuter singular form of the pronoun *ten* (`To` class). The third option results in fact no lexical counterpart in the Czech translation, the English and Czech sentences thus having a different syntactic structure (`Null` class).

The mapping between English and Czech types is shown in Figure 1. The `To` class is particularly overloaded. Even if a given occurrence of *it* corefers with a noun phrase, translating it to *to* does not require identifying the antecedent since the gender and number of *to* are always fixed (see Example 1).

- (1) Some investors say Friday’s sell-off was a good thing. “*It* was a healthy cleansing,” says Michael Holland.

Někteří investoři říkají, že páteční výprodej byla dobrá věc. “Byla *to* zdravá očista,” říká Michael Holland.

<sup>2</sup>Czech is a pro-drop language.

## 2.2 Translating reflexive pronouns from English to Czech

According to the *Longman Dictionary of Contemporary English*,<sup>3</sup> reflexive pronouns are typically used in two scenarios: to show that the object is affected by its own action and to emphasize that the utterance relates to one particular thing, person etc. (see Example 2).

- (2) The Gambia’s President *himself* participated in the hunt last year.

The most usual Czech counterparts of English reflexives comprise the Czech reflexive pronoun *se* (`Se` class), the adjective *samotný* (`Samotny` class) and the pronoun *sám* (`Sam` class), all in various morphological forms. Moreover, *sám* often appears with *se* to emphasize that the action affecting the object is performed by the object itself (`SamSe` class). Figure 1 illustrates the correspondence between English usages and Czech expressions.

## 3 Data

To train and intrinsically evaluate TMs for *it* and English reflexives, we have extracted data from the entire PCEDT and 11 sections of CzEng. Both treebanks follow the annotation style based on the Prague tectogramatics theory (Sgall, 1967; Sgall et al., 1986). While PCEDT consists of 50,000 sentence pairs annotated mostly manually, the annotation of CzEng with 15 million parallel sentences is entirely automatic. Both treebanks have been provided with a fully automatic alignment of Czech and English nodes (Mareček et al., 2008), which is, however, prone to errors for *it* and its Czech counterparts. Since they are pronouns, they can replace a wide range of content words and their meaning is inferred mainly from the context. The situation is better for verbs as their usual parents in dependency trees: since they carry meaning in a greater extent, their automatic alignment is of a higher quality.

We took advantage of this property and the gold annotation of semantic roles in PCEDT, obtaining Czech translations as the argument of the Czech verb aligned with the English parent verb that fills the same semantic role as the given *it*. Using this approach, we succeeded in reaching the Czech counterpart in more than 60% of instances. The rest had to be done manually.

<sup>3</sup><http://www.ldoceonline.com>

<i>It</i>	Train	Test	Reflexives	Train	Test
PCEDT sections	00–19	20–21	CzEng sections	00–09	98
PersPron	576	322	Se	6,305	652
To	231	138	Sam	2,271	205
Null	133	83	SamSe	1,361	129
			Samotny	804	89
Total	940	543	Total	10,741	1,075

Table 1: Distribution of classes in the data sets.

Czech counterparts of English reflexive pronouns have been collected directly from the alignment in CzEng, ignoring the cases where the aligned Czech word does not fall in one of the classes mentioned in Section 2.2.

The overall statistics of the train and the test set are shown in Table 1. The disproportion of training instances for *it* results from the manual annotation of classes, which could not be completely finished due to time reasons. In order to maintain the overall distribution, we also had to limit the number of automatically annotated classes.

Given the observation (see Section 2), we designed features to differentiate between the ways *it* and reflexives are translated.

### 3.1 Features for *it*

The translation mapping in Figure 1 suggests that identifying the English type of *it* might be informative. We thus constructed a binary coreference-related feature based on the output of the system NADA (Bergsma and Yarowsky, 2011) giving an estimate of whether an instance of *it* is coreferential.

Some verbs are more likely to bind with *it* that refers to a longer utterance. Such *it* is relatively consistently translated as a demonstrative *to*. However, PCEDT is too small to be a sufficient sample from a distribution over lexical properties. Hence, we took advantage of CzEng and collected co-occurrence counts between a semantic role that the given *it* fills concatenated with a lemma of its verbal parent and a Czech counterpart having the same semantic role (denoted as *csit*). We filtered out all occurrences where *csit* was neither a personal pronoun nor *to*. For both possible values of *csit* a feature is constructed by looking up frequencies for a concrete occurrence in the co-occurrence counts collected on CzEng and quantized into 4–5 bins following the formula:

$$\text{bin}\left(\log\left(\frac{\text{count}(\text{semrole} : \text{parent} \wedge \text{csit})}{\text{count}(\text{semrole} : \text{parent})\text{count}(\text{csit})}\right)\right).$$

Linguistic analysis suggested including syntax-

Figure 2: Examples of syntactic features capturing typical constructions with a verb *be*.

oriented patterns related to the verb *to be* such as those shown in Figure 2. For instance, nominal predicates<sup>4</sup> tend to be translated as *to* even if *it* is coreferential. On the other hand, an adjectival predicate followed by a subordinating clause introduced by the English connectives *to* or *that* usually indicates a pleonastic usage of *it* translated as a null subject.

### 3.2 Features for reflexive pronouns

Here we focused on distinguishing between the two most frequent meanings (see Section 2.2). Ideally, the POS tag of the parent would be a sufficient feature because reflexives in the second meaning should depend on a noun. However, since we deal with automatically parsed trees we had to support the parent POS tag by the POS tag of the immediately preceding word. Moreover, another feature indicates if the preceding word is a noun and agrees with the pronoun in gender and number.

Furthermore, we observed that *sám* rarely appears in other case than nominative. Although this feature exploits the target side, we can use it since the case of the governing Czech noun is already known at the point when reflexives are translated.

Last but not least, the morpho-syntactic pattern (including a possible preposition) in which the reflexive pronoun appears is a valuable feature.

## 4 Experiments and Evaluation

To mitigate a possible error caused by a wrong classifier choice, we built several models based on various Machine Learning classification methods including Maximum Entropy implemented in the AI::MaxEntropy Perl library,<sup>5</sup> logistic regression with one-against-all strategy from Vowpal Wabbit<sup>6</sup> as well as decision trees, k-NN and SVM from Scikit-learn library (Pedregosa et al., 2011).

<sup>4</sup>The verb *to be* has an object.

<sup>5</sup><http://search.cpan.org/~laye/AI-MaxEntropy-0.20>

<sup>6</sup><http://hunch.net/~vw>

	<i>It</i>		Reflexives	
	Train	Test	Train	Test
Baseline	60.70	59.30	58.70	60.65
AI::MaxEntropy	85.99	<b>76.61</b>	76.37	77.77
VW (passes=20, l2=10e-5)	89.99	76.43	76.98	77.77
sklearn:decision-trees	93.36	73.66	81.78	76.37
sklearn:k-NN (k=10)	82.51	73.30	77.64	76.74
sklearn:SVM (kernel=linear)	90.83	75.51	76.55	<b>78.14</b>

Table 2: Accuracy of both translation models on the training and test data.

We compare our results with a majority class baseline (`PersPron` and `Se` classes) in Table 2. The results show a 17% gain when our approach is used.

The specialized models have been integrated in the TectoMT system and extrinsically evaluated on the English-Czech test set for the WMT 2011 Translation Task (Callison-Burch et al., 2011).<sup>7</sup> This data set contains 3,003 English sentences with one Czech reference translation, out of which 430 contain at least one occurrence of *it* and 52 contain a reflexive pronoun.

The new approach was compared to the original TectoMT rule-based pronoun handling heuristics (see Section 1). The shift from the original settings to the new translation models results in 166 changed sentences with *it* and 17 changed sentences with English reflexives. In terms of BLEU score, we observe a marginal drop from 0.1404 to 0.1403 using the new approach. However, BLEU may be too coarse for this kind of experiment.

In order to give a more realistic view, we carried out a manual evaluation. All 17 modified sentences for reflexives and 50 randomly sampled changed sentences containing *it* were presented to one annotator who assessed which of the two systems gave a better translation. Table 3 shows that improved sentences dominate in both cases. Overall, the improved sentences account for around 8.5% of all sentences with *it* and 23% sentences containing a reflexive pronoun.

## 5 Discussion

Looking into the types of improvements and errors in the manually evaluated sentences, we have found that the new model for *it* opted for a different translation only in cases where the original system decided to express *to* on the surface. In 13 out of 24 improvements, the new model for *it* succeeded in correctly resolving the `Null` class

<sup>7</sup><http://www.statmt.org/wmt11/test.tgz>

	<i>It</i>	Reflexives
new better than old	24	12
old better than new	13	0
equal quality	13	5

Table 3: The results of manual evaluation on sentences translated by TectoMT in the original settings and using the new translation models

while in the remaining 11 cases, the corrected class was `PersPron`. It took advantage mostly of the syntax-based features in the former case and the coreference-related feature in the latter.

Regarding the reflexive pronouns the pronoun was used in its emphasizing meaning in all but two altered sentences. This accords with the design of features, which are mainly targeted at revealing this usage of reflexives. Moreover, the feature indicating if a Czech noun is in nominative case has proved to be particularly useful, correctly driving the lexical choice between *sám* and *samotný*. The majority of errors stem from incorrect activation of syntactic features due to parsing and POS tagging errors.

## 6 Conclusions

In this work, we presented specialized translation models for two types of English pronouns: *it* and reflexives. Integrating them into an English-Czech syntax-based MT system TectoMT we succeeded in improving the concerned sentences measured by human evaluation.

Generally, it is intractable to design a specific feature set for every word. However, this work shows on two examples that the correct translation of some words depends on many linguistic aspects, e.g. syntax and coreference and that is worth taking these aspects into account.

## Acknowledgments

This work has been supported by the Grant Agency of the Czech Republic (grants P406/12/0658 and P406/2010/0875), the grant GAUK 4226/2011 and EU FP7 project Khresmoi (contract no. 257528). This work has been using language resources developed and/or stored and/or distributed by the LINDAT-Clarin project of the Ministry of Education of the Czech Republic (project LM2010013).

## Abstract

Beside the word order problem, word choice is another major obstacle for machine translation. Though phrase-based statistical machine translation (SMT) has an advantage of word choice based on local context, exploiting larger context is an interesting research topic. Recently, there have been a number of studies on integrating word sense disambiguation (WSD) into phrase-based SMT. The WSD score has been used as a feature of translation. In this paper, we will show that by bootstrapping WSD models using unlabeled data, we can bootstrap an SMT system. Our experiments on English-Vietnamese translation showed that BLEU scores have been improved significantly.

## 1 Introduction

Conventional phrase-based systems use local context information from phrase table and language model. Though phrase based SMT achieves a jump in translation quality in comparison with word based SMT, there are still cases in which local context cannot capture correctly the meanings of source words. WSD can use features from much larger contexts and those features can overlap each other. The idea of integrating WSD into SMT rises naturally from this perspective. Previously, Varea et al. (2001) directly used context sensitive lexical models, applying these models for re-ranking n-best for their word-based maximum entropy model (MEM) SMT and achieving slight improvements in translation quality.

Chan et al. (2007) made use of WSD for hierarchical phrase-based translation for Chinese-English by utilizing two new WSD features for SMT and proposing an algorithm for scoring synchronous rules. Phrases which do not exceed a

length of two were computed WSD models. Their experiments showed that WSD can improve SMT significantly.

Simultaneously with Chan et al. (2007), Carpuat and Wu (2007) used a similar approach to the problem. The main difference was that they focused on conventional phrase-based SMT in Koehn et al. (2003) and used only one WSD feature for SMT. The limit of phrase length was the same as the value used by their SMT system. Their experiments led to the same conclusion: WSD can improve SMT.

However, approaches based on statistic frequently against deficiencies of parallel and specific domain corpora. Only a few popular languages are derived continuous financial support and interest of researchers. Therefore, it becomes an immense obstacle to apply these approaches for the remaining languages.

Recently, there are several approaches to address this impediment. Ambati et al. (2011) applied multi-strategy methods in active learning for machine translation by combining several techniques in sentence selection process. They attained significantly results while parallel training data was scarce.

In this paper, we present our study on this topic. First, by integrating WSD as a model of SMT system as shown in the Figure 1, we present how we use WSD for SMT. Then we demonstrate a method to bootstrap WSD models by using unlabelled data. Finally, we show our experimental results. We analyse various settings of WSD-SMT integration. Our results give a thorough view into the problem.

## 2 WSD for SMT

### 2.1 WSD Task

In order to use WSD for SMT, the precondition is that training data must be large enough.

Figure 1: Integrating WSD into phrase-based SMT system

Manually-created data sets such as SENSEVAL and SemCor, which are often used in WSD studies, are too small for applications like machine translation. We overcome this difficulty by using an approach based on Carpuat and Wu (2007) and Chan et al. (2007) to extract training data from bilingual data. Word alignment information serves as a map between source words and target words. Target words are seen as senses. Since word alignment usually performs incorrectly, the resulting WSD training data is noisy. When carrying out this research, we consider WSD for word and phrase levels.

## 2.2 WSD Training Data Generation

A procedure for WSD-training-data extraction:

Input: a bilingual corpus, a POS-tagged version of the source text and word alignment information.

Output: WSD training sets for source phrases.

- Step 1: Collect phrase pair instances associated with position in the bilingual corpus. Group phrase pairs according to source phrase.
- Step 2: For each group, generate a training set for its corresponding source phrase.

Phrase pairs (s,t) which are consistent with the word alignment will be generated. The criteria of consistence with word alignment in Koehn et al. (2003) are as follows: First, there exists links from words of s to words of t. Second, for every word outside s, there is no link to any word of t. Third, for every word outside t, there is no link to any word of s.

When extracting WSD training data from a bilingual corpus, the number of training sets resulting from the extractive procedure is often much larger than vocabulary size of the source

text. Additionally, raw data extracted from a bilingual corpus is a miscellany of semantic, lexical, morphological, an syntactic ingredients. It is very different from conventional WSD data style. This data can be refined in several ways such as lemmatization.

## 2.3 WSD Features

In our work, we use six kinds of knowledge and represent them as subsets of features, as follows:

- *bag-of-words*,  $F_1(l, r) = \{w_{-l}, \dots, w_{+r}\}$ : We investigate three sets of this knowledge including  $F_1^a = F_1(-5, +5)$ ,  $F_1^b = F_1(-10, +10)$ ,  $F_1^c = F_1(-100, +100)$ , corresponding to small, medium and large size respectively.
- *collocation of words*,  $F_2 = \{w_{-l} \dots w_{+r}\}$ : As a result of the work in Le and Shimazu (2004) we choose such collocations that their lengths (including the target words) are less than or equal to 4, it means  $(l + r + 1) \leq 4$ .
- *ordered words*,  $F_3 = \{w_i | i = -l, \dots, +r\}$ : We choose  $l = r = 3$
- *collocation of POSs*,  $F_4 = \{p_{-l} \dots p_{+r}\}$ : Like collocation of words, we choose their lengths including the target words are less than or equal to 4.
- *ordered POSs*:  $F_5 = \{p_i | i = -l, \dots, +r\}$ : We choose  $l = r = 3$

In cases that we are working with a training set of a source phrase, features will be extracted from surrounding context of that phrase.

## 2.4 Integration

After having been trained, WSD models can be used as a feature for SMT as shown in the Figure 1. Since we use a log linear translation model, the use of a new feature is easy. Feature's weight is tuned using minimum error rate training (MERT) in Och (2003). In decoding phase, when translation options are generated, their WSD score is computed and then can be used in searching process. Among other features, this new feature is sensitive to large contexts.

Given a source phrase, the simplest way is to train its own WSD model and then apply that model in new contexts. The number of WSD models is equal to the number of source phrases in the SMT phrase table. An alternative is to score a phrase using shorter phrases. That means only WSD models for phrases whose length is smaller than a threshold to be trained. This setting could

reduce computational time. Suppose that we are considering a phrase pair  $(s, t)$  in which  $s$  is a source phrase,  $t$  is a target phrase. If this phrase pair can be split into a sequence  $(s_i, t_i)$  of  $n$  sub phrase pairs which are consistent with the word alignment of  $(s, t)$ , then the probability of  $t$  given  $s$  and its context can be computed using (1) here

$$P_{wsd}(t|s) \approx \prod_{i=1}^n P_{wsd}(t_i|s_i) \quad (1)$$

$P_{wsd}(t_i|s_i)$  calculates the probability of  $t_i$  conditioning on  $s_i$  and its surrounding context. If there are more than one possible split, we use a greedy method. This method gives preferences to sub phrases according to their length and score.

### 3 Using Unlabelled Data

#### 3.1 Basic Algorithm

Suppose that we have two data sets, one labelled (eg., the data extracted from a bilingual corpus) and the other unlabelled. First, a classifier is trained using the labelled data set, then it can be used to classify the unlabelled data set. Among newly labelled examples, the ones with high score will be chosen to enlarge the training data. These steps are repeated until a stopping condition is matched. Stopping condition can be a maximum number of iterations, or a minimum increase in classification accuracy, etc.

Input:  $L$  = a labelled data set.

$U$  = an unlabelled data set.

Output:  $L_{new}$ , a new labelled data set.

1. Train a classifier  $C$  using  $L$ .
2. For each  $u \in U$ :
  - a. use  $C$  to classify  $u$ .
  - b. find the label assigned with highest score.
  - c. if the score is above a threshold, choose  $u$ .
3.  $L_{new} = L \cup \{u \in U : u \text{ has been labelled}\}$ .  
and  $U_{new} = \{u \in U : u \text{ unlabelled}\}$ .
4. If the stopping condition is not matched, repeat from step 1, else stop.

#### 3.2 A New Algorithm with Sense Distribution Control

A problem with the basic algorithm is that after extension, the resulting labelled data set can be highly imbalanced in sense distribution with dominating senses, due to which the classification accuracy decreases. To handle the problem, the change of sense distribution during extending process should be controlled. We propose to use the

relative entropy or Kullback-Leibler distance in Cover and Thomas (2006) to measure the change in sense distribution and control the amount of new examples. After extending using the previous algorithm, we will remove examples one by one until the KL distance is smaller than a threshold. The threshold need not to be a fixed number.

Algorithm: Input: a labelled data set  $L_{initial}$  and its expanded set  $L_{new}$ .

Output: a labelled data set  $L_{extending}$  whose sense distribution is controlled

1.  $p = (p_1, p_2, \dots, p_n)$  and  $q = (q_1, q_2, \dots, q_n)$  are sense distributions over  $L_{initial}$  and  $L_{new}$ .
2. Compute the Kullback Leibler distance between  $p$  and  $q$ :  $\Delta = KL(p, q) = \sum_i^n p_i \log(\frac{p_i}{q_i})$
3. Repeat
  - a. for each  $u \in L_{new}$ :
    - compute  $t = (t_1, t_2, \dots, t_n)$ , the sense distribution over  $T = L_{new} \setminus \{u\}$ , then compute  $KL(t, p)$
    - find  $u_m$  minimizing  $KL(t, p)$ , then  $u_m$  is the element that when removing it, the KL distance decreases a maximum amount.
  - b. Remove  $u_m$  from  $L_{new}$
  - c. Compute  $KL(p, q)$
4. The iteration stop when  $KL(p, q) < \frac{\Delta}{2}$
5.  $L_{extending} = L_{new}$ .
6. Return  $L_{extending}$ .

### 4 Evaluation

#### 4.1 Corpora and Tools

The corpus in our experiments is English-Vietnamese bilingual corpus from several different fields which includes approximately 135,000 sentence pairs. It is divided into three parts: training, developing and testing in Table 1. We used the developing set in the evaluation of MERT of SMT system in all experiments. In addition to the testing set extracted from the bilingual corpus, we used an additional corpus consisting of ambiguous words that are labelled by evaluators to test the external domain. The rate of Out-of-Vocabulary in testing sets is roughly 2%.

In our experiments, the British National Corpus (BNC) in Clear (1993) has been used for our expansion. We used a word-segmentation program in Nguyen et al. (2003), Moses in Koehn et al. (2007), GIZA++ in Och and Ney (2000), SRILM in Stolcke (2002), a rule-based morpho-

logical analyser in Pham et al. (2003) and Natural Language Toolkit in (Bird et al., 2009) for segmenting Vietnamese sentences, learning phrase translations, creating word alignment, learning language models, analysing morphology and exploiting BNC respectively.

	Number of sentences	Average length of sentences	Number of words
<b>Training corpus</b>			
English	131,118	15.9	2,096,073
Vietnamese	131,118	17.0	2,236,847
<b>Developing corpus</b>			
English	218	15.4	3,367
Vietnamese	218	16.5	3,609
<b>Testing corpus</b>			
English	2,000	17.8	35,797
Vietnamese	2,000	19.4	38,814
<b>External-domain testing corpus</b>			
English	123	18.7	2,308

Table 1: Statistics for training, testing and developing corpora

## 4.2 Experiments and results

	Without WSD	WSD integration	WSD integration with BNC
BLEU	34.93	35.43	36.47
NIST	7.4491	7.4937	7.7971

Table 2: BLEU scores of SMT based on phrase-based with WSD and BNC-extended WSD

As indicated from the Table 2, that SMT system utilizes WSD with expanded information of BNC corpus leads to the high translation quality with growths by 1.04 and 1.54 in BLUE score and 0.3034 and 0.3488 in NIST score in comparison with non-extended WSD integrated SMT system and baseline SMT system. Let consider the example:

Input: *hard water is water that has high mineral content (in contrast with soft water).*

SMT: **chăm\_chi**/(hard) nước/(water) là/(is) nước/(water) cao/(high) nội\_dung/(content) khoáng\_sản/(mineral) trái/(in contrast) với/(with) nước/(water) mềm/(soft) .

SMT + WSD: **khó**/(hard) nước/(water) là/(is) nước/(water) có/(has) hàm\_lượng/(content) khoáng\_sản/(mineral) cao/(high) mềm/(soft) (ngược\_lại)/(in contrast) với/(with) nước/(water).

SMT + WSD + BNC: nước/(water) rất **cứng**/(hard) là/(is) nước/(water) cao/(high) hàm\_lượng/(content) khoáng\_sản/(mineral) trái/(in contrast) với/(with) mềm/(soft) ra nước/(water).

Clearly, ambiguous words in above example were translated precisely in the target language when utilizing WSD and BNC. In the first example, the word *hard* in *hard water* is translated to *cứng* (a type of water) which is more accurate than *chăm chi* (a personality) and *khó* (a difficulty).

## 4.3 The impact of context on WSD and WSD on SMT system

In many cases, the evaluation result of WSD is incorrect, resulting in the effect on the translation outcome of SMT. Below are two main reasons for this phenomenon: First, after the BNC expansion, the context could not embrace all possible cases due to limitation of contexts of BNC. Second, in several situations, information contexts of surrounding sentences should be used to determine labels of ambiguous words, whereas the system only uses the information in one sentence.

Besides, in the integration of WSD system into SMT system, WSD system occupies only a certain weight thus translation results are depend majorly on other models such as language model, translation model even though WSD gave precise results.

## 5 Conclusions

In this paper, we indicated a considerable effect of WSD which is bootstrapped on SMT system. The analyses and results on experiments point out that the approach of enhancing quality of WSD model contributes to the improvement of translation quality. The explanation for the increase of BLEU point is the impact of sparse data on the training set in WSD model. The expansion of training data from BNC whereby not only increases the degree of accurateness of WSD system but also improves the quality of translation. In the future, we would like to continue to experiment with the expansion of the training set on other sources to enhance the quality of translation.

## Acknowledgments

# Orthographic and Morphological Processing for Persian-to-English Statistical Machine Translation

Mohammad Sadegh Rasooli and Ahmed El Kholly and Nizar Habash

Center for Computational Learning Systems

Columbia University, New York, NY

{rasooli, akholly, habash}@cccls.columbia.edu

## Abstract

In statistical machine translation, data sparsity is a challenging problem especially for languages with rich morphology and inconsistent orthography, such as Persian. We show that orthographic preprocessing and morphological segmentation of Persian verbs in particular improves the translation quality of Persian-English by 1.9 BLEU points on a blind test set.

## 1 Introduction

In the context of statistical machine translation (SMT), the severity of the data sparsity problem, typically a result of limited parallel data, increases for languages with rich morphology such as Arabic, Czech and Turkish. The most common solution, other than increasing the amount of parallel data, is to develop language-specific preprocessing and tokenization schemes that reduce the overall vocabulary and increase the symmetry between source and target languages (Nießen and Ney, 2004; Lee, 2004; Oflazer and Durgar El-Kahlout, 2007; Stymne, 2012; Singh and Habash, 2012; Habash and Sadat, 2012; El Kholly and Habash, 2012). In this paper, we work with Persian, a morphologically rich language with limited parallel data. Furthermore, Persian’s standard orthography makes use of a combination of spaces and semi-spaces (zero-width non-joiners), which are often ignored or confused, leading to orthographic inconsistencies and added sparsity. We address the orthographic challenge of inconsistent spacing with a supervised learning method which successfully recovers near all spacing errors. We also present a set of experiments for morphological segmentation to help improve Persian-to-English SMT. We show that the combination of orthographic cleanup and morphological segmentation for verbs in particular improves over a simple preprocessing baseline.

## 2 Related Work

Much work has been done to address data sparsity in SMT employing a variety of methods such as morphological and orthographic processing (Nießen and Ney, 2004; Lee, 2004; Goldwater and McClosky, 2005; Oflazer and Durgar El-Kahlout, 2007; Stymne, 2012; Singh and Habash, 2012; Habash and Sadat, 2012; El Kholly and Habash, 2012), targeting specific out-of-vocabulary phenomena with name transliteration or spelling expansion (Habash, 2008; Hermjakob et al., 2008) or using comparable corpora (Prochasson and Fung, 2011). Our approach falls in the class of orthographic and morphological preprocessing.

Previous research on Persian SMT is rather limited despite some early efforts (Amtrup et al., 2000). A few parallel corpora have been released, such as (Pilevar et al., 2011; Farajian, 2011). We conduct our research on an unreleased Persian-English parallel corpus (El Kholly et al., 2013a; El Kholly et al., 2013b).

In terms of preprocessing efforts, Kathol and Zheng (2008) use unsupervised Persian morpheme segmentation. Other attempts to improve Persian SMT use syntactic reordering (Gupta et al., 2012; Matusov and Köprü, 2010) and rule-based post editing (Mohaghegh et al., 2012). El Kholly et al. (2013a) and El Kholly et al. (2013b) also address resource limitation for Persian-Arabic SMT by pivoting on English.

Our approach is similar to Kathol and Zheng (2008), except that we do not use unsupervised learning methods for segmenting morphemes and we explore POS-specific processing instead of segmenting all words. We make extensive use of available resources for Persian morphology such as the Persian dependency treebank (Rasooli et al., 2013), the Persian verb analyzer tool (Rasooli et al., 2011a), the Persian verb valency lexicon (Rasooli et al., 2011c), and the PerStem Persian segmenter (Jadidinejad et al., 2010).

### 3 Persian Orthography and Morphology

#### 3.1 Orthography

Persian is written with the Perso-Arabic script. Unlike Arabic, some Persian words have inter-word zero-width non-joiner spaces (or semi-spaces). Many writers incorrectly write the semi-spaces as regular spaces (Shamsfard et al., 2010). This causes data inconsistency and some word-sense ambiguity, e.g., if the word نام آشنا<sup>1</sup> *nAm\_ĀšnA*<sup>1</sup> ‘reputed’ (adjective) is written with regular spaces, its meaning becomes ‘the familiar name’. While humans may be able to recover, typical natural language processing tools will fail since they expect standard Persian spelling.

#### 3.2 Morphology

Persian has a heavily suffixing affixational morphology with no expression of grammatical gender (Amtrup et al., 2000). We give a brief description of Persian adjectives, nouns and verbs and compare to English.

**Adjectives** Persian adjectives have a limited inflection space: they may be simple, comparative or superlative. In comparative and superlative forms (except for Arabic loan words), a suffix attaches to the adjective: *+tar*<sup>2</sup> ‘+er’ for comparative and *+tarīn* ‘+est’ for superlative adjectives. English uses both suffixes (‘+er/+est’) and multi-word construction with ‘more/most’, in addition to some irregular cases such as ‘good’, ‘better’, and ‘best’. As such, it might be hard to define a consistent preprocessing scheme for adjectives in Persian with respect to English.

**Nouns** Nouns are generally similar to English. For example, like English, a suffix marks plural number: mostly *+ha* and sometimes *+ān*. Exceptions include Arabic broken plural loan words. Unlike English, Persian has a suffixing indefinite marker (*+i*) comparable in meaning to English’s ‘a’ or ‘an’ indefinite particles. In Persian noun phrases consisting of a noun followed by one or more adjectives, the indefinite suffix attaches to the last adjective.

**Verbs** A verb in Persian may be inflected in different combinations for tense, mood, aspect, voice and person. There are many interesting

phenomena in Persian verbs, e.g. the past tense stem is used with another auxiliary verb to create the future form. When an auxiliary verb is used, prefixes attach to the auxiliary verb instead of the root. The negative marker (*+n*) ‘not’ and the object pronouns are attached to the verbs, leading to more than 100 verb conjugated forms (Rasooli et al., 2011b). For example, the verb *نمی خواندمش* *nmy\_xwAndmš* can be tokenized to *n+ my+ xwAnd +m +š* ‘I was not reading it’ [lit. ‘not+ was(continuous)+ read(past)+I+it’]. Persian is a pro-drop language; almost half of the verbs in the Persian dependency treebank do not have an explicit subject (Rasooli et al., 2013). By comparison, English has a much simpler verbal morphology with explicit subject realization. This suggests that tokenizing Persian verbs may be helpful to Persian-English SMT in that it reduces sparsity and increases symmetry with English.

### 4 Space Correction

In standard Persian orthography, semi-space characters show inter-word boundaries. Around 8% of all tokens in Persian dependency treebank have semi-spaces (Rasooli et al., 2013). However, in real Persian text, many of these semi-spaces are written as regular space. Although semi-space restoration may actually increase sparsity by creating more compounded forms of words, it is an important step to allow the use of Persian morphological resources that expect their presence.

In order to improve the quality of spacing in Persian texts, we use a language-modeling approach to correct spacing errors. The approach relies on the existence of a lexicon of semi-spaced words. The lexicon provides a mapping model from the regular-spaced versions of the words to their correct semi-spaced version. Starting with a sentence, we identify all sequences of regularly spaced words that can be mapped to semi-spaced versions. An expanded lattice version of the sentence including both forms is then decoded with a language model to select the path with the highest probability.

In terms of resources, we use the Peykare corpus (Bijankhan et al., 2011) and Persian dependency treebank (Rasooli et al., 2013) to create the semi-space lexicon and language model. The training data consists of about 398 thousand sentences and 89 million tokens (12 million types). To construct the lexicon, we extract all words with semi-spaces in the training data. We further extend the lexicon to cover known semi-space inflections for seen words, such as plural suffixes in nouns,

<sup>1</sup>We use the Habash-Soudi-Buckwalter Arabic transliteration (Habash et al., 2007) in the figures with extensions for Persian as suggested by Habash (2010). We show semi-spaces with underscore character.

<sup>2</sup>Suffixes that require a semi-space are marked in the transliteration with an underscore.

superlative and comparative suffixes in adjectives and prefixing continuous markers in verbs. The language model is a trigram model with back-off.

We use the development part of the Persian dependency treebank for tuning the n-gram model. On the test part of the Persian dependency treebank, we replace every semi-space with regular space and try to predict the semi-spaces with our model. The baseline accuracy (of having no semi-spaces) on the test set is 92.2%. Our system’s accuracy is 99.43%. The precision, recall and F-score of producing semi-spaces are 93.11%, 99.98% and 96.42%, respectively. The recall of our approach is almost perfect, but the precision is not as good, suggesting that we over assign semi-space. There are two common errors in the results. The first problem is with the hard distinction between adjectives and verbs, e.g., خراب شده *xrAb šdh* ‘dilapidated’ vs. خراب شده *xrAb šdh* ‘has destroyed’. The second problem is with errors in the training data, especially from the Peykare corpus (Bijankhan et al., 2011).<sup>3</sup>

## 5 Morpheme Segmentation

In this section, we present the two different morphological segmentation methods: PerStem and VerbStem.

**PerStem** As a baseline method for morphological segmentation, we use the off-the-shelf Persian segmenter, PerStem (Jadidinejad et al., 2010).<sup>4</sup> PerStem is a deterministic tool employing a set of regular expressions and rules for segmenting Persian words. PerStem separates most affixes for all parts-of-speech when applicable. PerStem has been used by other researchers for tokenization purposes (El Kholy et al., 2013a; El Kholy et al., 2013b).

**VerbStem** As discussed in Section 3, Persian verbs are particularly problematic for Persian-English SMT because of their rich morphology and differences from English. We experiment with targeting Persian verbs for segmentation. To identify which words are verbs, we use a simple maximum likelihood POS tagging model built on the

<sup>3</sup>Peykare is not actually written with semi-spaces. However, each word unit (consisting of one or more tokens) is written on one line and it is almost straightforward to standardize the corpus and add the semi-spaces. Unfortunately, some word lines in this corpus have two or more words that should have been written on separate lines, which leads to false examples of inserted semi-spaces, e.g., هنگامی که *hngAmy\_kh* ‘when that’ should be written with regular space instead of semi-space.

<sup>4</sup><http://sourceforge.net/projects/perstem/>

Peykare corpus (Bijankhan et al., 2011). For analysis and segmentation, we use an available Persian verb analyzer tool (Rasooli et al., 2011a)<sup>5</sup> and extend it with a deterministic segmentation algorithm to allow us to generate the needed tokens.<sup>6</sup> For each verb, we segment the negative marker, continuous marker, subject pronoun, object pronoun, participle marker, and prefix marker from the verb stem. We add spaces to the end of prefixes and beginning of suffixes, e.g., نمی خواندمش *nmy\_xwAndmš* would be segmented into *n my\_xwAnd m š*.<sup>7</sup> In our segmentation scheme, we do not perform any reordering nor try to address compound verbs in Persian.

Both the POS model and the Persian verb analyzer/segmenter expect the input text to have standard semi-space usage. Thus, we have to apply this step after semi-space correction. Figure 1 presents an example in different representations.

## 6 MT Evaluation

**Experimental Settings** We conduct several experiments using different segmentation decisions: **Raw** is original text; **Raw-RS** is Raw text but with regular spaces replacing all semi-spaces; **PerStem** is text processed with PerStem; **Clean-SS** is text with automatically corrected semi-spaces; and **VerbStem** is text processed with the verb segmentation method discussed in the previous section. Figure 1 compares three versions of the same sentence processed in different methods.

We use a Persian-English parallel corpus consisting of about 160 thousand sentences and 3.7 million words for translation model training (El Kholy et al., 2013a; El Kholy et al., 2013b). Word alignment is done using GIZA++ (Och and Ney, 2003). For language modeling, we use the English Gigaword corpus with 5-gram LM implemented with the KenLM toolkit (Heafield, 2011). All experiments are conducted using the Moses phrase-based SMT system (Koehn et al., 2007) with a maximum phrase length of 8. The decoding weight optimization uses a set of 1,000 sentences extracted randomly from the parallel corpus. We use only one English reference for tuning. We report results on a dev set and a blind test set, both with 268 sentences and three English references.

<sup>5</sup><https://github.com/rasoolims/PersianVerbAnalyzer>

<sup>6</sup>We also update the verb list in the Persian verb analyzer using the Persian verb valency lexicon [version 3.0.1] (Rasooli et al., 2011c).

<sup>7</sup>We considered adding plus sign to the end of prefixes and beginning of suffixes, but this representation did worse in SMT experiments.

VerbStem	Az frdA <b>n my trs m</b> crAkh dyrwz rA <u>dyd h</u> Am w Amrwz rA dwst dAr m from tomorrow , not afraid because i have seen yesterday and today i love
Reference	<b>i 'm not afraid</b> of tomorrow because <i>i have seen yesterday</i> and i like today

Figure 1: Example output from three systems and one of the references from the dev set. As seen in the bolded and underlined words, the VerbStem system captures linguistic information and produces better translation quality.

Method	Raw	Raw-RS	PerStem	Clean-SS	VerbStem
BLEU	33.0	33.6	32.6	32.2	<b>33.7</b>

Table 1: SMT results on the dev set.

Model	BLEU	METEOR	TER
Raw-RS (Baseline)	31.4	31.2	<b>60.9</b>
VerbStem (Best model)	<b>33.3</b>	<b>32.2</b>	61.1

Table 2: Results from the baseline and the best system on the blind test set.

**Results and Discussion** The results of SMT experiments on the dev set are shown in Table 1. VerbStem is our best system. Simply replacing all spaces (Raw-RS) does rather well and is plausibly the strongest simplest baseline we can compare to. PerStem and Clean-SS underperform the baseline. Clean-SS is the worst system (as expected since it increases sparsity), but it is necessary as a step for VerbStem. The improvement in VerbStem is possibly the result of reduced sparsity and increased symmetry between English and Persian. Verb segmentation makes a lot of information explicit, such as negation, subject pronoun (especially since Persian as a pro-drop language) and object pronoun.

We apply VerbStem to the blind test set and compare it to Raw-RS. Table 2 shows the blind test results using BLEU-4 (Papineni et al., 2002), METEOR (Lavie and Agarwal, 2007) and TER (Snover et al., 2006). VerbStem produces a higher BLEU score improvement over the Raw-RS baseline on the blind test compared to the dev set. This may suggest that our dev set is easier in general. Although our best system does well in Figure 1, the best result still suffers from suboptimal word order. The position of the verb in Persian (as an SOV language) is very problematic when translating to English (an SVO language) especially for long sentences.

## 7 Conclusion and Future Directions

Our experiments show that segmenting Persian verbs improves translation quality. However, the translation output of all current systems in this paper suffer from word order problems. In the future, we plan to investigate how to improve word order in the translation output using a variety of techniques such as hierarchical phrase-based models (Chiang, 2005; Kathol and Zheng, 2008; Cohn and Haffari, 2013), or models employing parsers to be developed using the Persian dependency treebank (Collins et al., 2005; Elming and Habash, 2009; Carpuat et al., 2010).

## Abstract

Integrating language resources is a critical part in building natural language processing applications. Processing pipeline and service composition are two approaches for sharing and combining language resources. However, each approach has its drawback. While the former lacks consideration about property rights of language resources, the later is not efficient to process and transfer huge amount of data through web services. In this paper we address the issue of interoperability between two approaches to mutually complement their disadvantages. We show an integration of service composition and processing pipeline, and how the integration can be used to help developers seamlessly build NLP applications. We then present a case study that adopts the integration to integrate two representative frameworks: the Language Grid and UIMA.

## 1 Introduction

The creation of language resources (LRs) remains a fundamental activity in the field of language technology. The number of language resources has been increasing year by year. Based on these resources, developers build advanced Natural Language Processing (NLP) applications (hereafter referred to as the applications) such as Watson and Siri by combining some of these resources. However, it is difficult for developers to collect and combine the most suitable set of language resources in order to achieve the developers' goals.

There are two types of language resource coordination frameworks supporting developers sharing and combining language resources and tools: Framework-based processing pipeline such as GATE (Cunningham et al. 2002) and UIMA (Ferrucci et al., 2004) and framework-based service

composition such as the Language Grid (Ishida, 2006). Interoperability between components in one framework is dealt by defining Common Data Exchange or standard interface for components. For example, UIMA defines Common Analysis Structure as data exchange between components, the Language Grid defines standard interfaces in a ontology for their language services (Hayashi, 2007). Interoperability among formats of two processing pipeline frameworks UIMA and GATE is explored in (Ide et al., 2009a). This paper addresses the issue of how to bridge the gap between two data structures of common data exchange format. In this work we focus on interoperability of two different types of frameworks.

Therefore, this paper realizes interoperability between those two types of frameworks to mutually complement their disadvantages. To this end, we address the following issues:

- Integration between two types of frameworks: Service composition and processing pipeline. The integration provides ability to wrap components of one framework as components of another. This will lead to more language resources and tools becoming available in both frameworks, facilitating the development process of NLP applications.
- A case study of integration two representative frameworks: The Language Grid and UIMA is implemented to realize the integration concept framework.

The remainder of this paper is organized as follows: in section 2 we will briefly discuss features of the two types of language resource coordination frameworks. The integration of the service composition and processing pipeline will be presented in section 3. We show a case study on integration between the Language Grid and UIMA in section 4. Finally, section 5 concludes this paper.

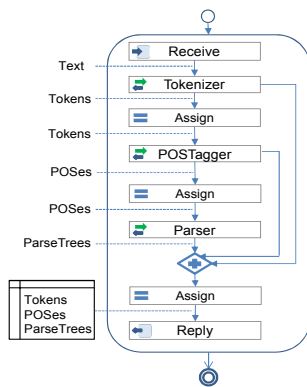

Figure 1: Service composition approach

## 2 Language Resource Coordination Frameworks

### 2.1 Service Composition Approach

In this approach, language resources are wrapped as web services that users can combine to create customized composite language services for their need. Figure 1 shows a composite service composing three language services: Tokenizer, POSTagger and Parser. Each service in the workflow is defined by an interface with input and output. Interoperability between services in a workflow is ensured by conforming interfaces of the services. Output of a previous service and input of the later service in the workflow must be compatible.

Language resources available on these frameworks are provided by variety of providers. For instance, PANACEA currently has more than 160 services provided by 11 service providers. On the Language Grid, over 170 services are provided by 140 groups from 17 countries. Providers need to protect their resources with intellectual rights, so that they can configure permission and monitor usage statistics of their resources. Service composition approach provides access control functionality to deal with this issue. This advantage encourages providers to share their language resources, increasing availability of language services.

### 2.2 Processing Pipeline Approach

This approach focuses on providing a setting for creating analysis pipelines, oriented towards linguistic analysis and stand-off annotation model. The purpose of these frameworks is to combine language resources to analyze huge amounts of data at the local environment.

Processing tools are combined into a pipeline to analyze documents. Each tool is defined as an annotator to annotate the document with anno-

Figure 2: Processing pipeline approach

tations represented as stand-off annotation. The document together with annotations is formed in a Common Data Exchange Format (CDEF). The CDEF document is then exchanged between components in the pipeline. Figure 2 shows a pipeline of three annotators: Tokenizer, POSTagger, and Parser. The pipeline enriches input text with three annotation types: Token, POS, and ParseTree.

A disadvantage of this approach is the lack of access control to share language resources distributedly with intellectual rights. This limits the availability of language resources.

## 3 Integration of Service Composition and Processing Pipeline

### 3.1 Mapping Service Interface Invocation and Stand-off Annotation

The CDEF data structure is defined based on widely used de-facto standards such as TEI (Vanhoutte, 2004), CES (Ide, 2000), and *common interface format* being developed under the context of ISO committee TC 37/SC 4 (Ide, 2009b). CDEF basically consists of two parts: one representing document text, and the other representing annotations. Figure 3 shows an example of CDEF in XML-based format:

- `<doc>`: represents the document, the `id` attribute is used to distinguish documents when a pipeline processing with multiple documents.
- `<annotations>`: represents all annotations produced by a pipeline. An annotation is described by `<annot>` tag, the `type` attribute indicates type of the annotation, two attributes `begin` and `end` define annotation's offset and the `componentID` attribute shows the annotator producing this annotation. The structure of the annotation is defined by feature structure (`fs`) tag and feature (`f`) tags.

Each language service has its own interface with input and output. For an annotator in processing pipeline, we can assume that it's input

```

<?xml version="1.0" encoding="UTF-8"?>
<annotatedDoc>
  <doc id="1" mimeType="text"
    docString="Text of the document"/>
  <annotations>
    <annot type="POS" docID="1" begin="1"
      end="5" componentID="POSTager">
      <fs>
        <f name="lemma" value="Text"/>
        <f name="postag" value="noun"/>
        ...
      </fs>
    </annot>
    ...
  </annotations>
</annotatedDoc>

```

Figure 3: Structure of common data exchange

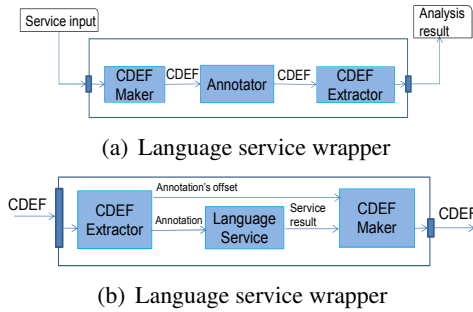

Figure 4: Wrappers

and output are CDEF. The mapping is defined to map input/output of language services with annotation types in CDEF. We define CDEF Maker and CDEF Extractor to conduct the mapping and create two wrappers: Language Service Wrapper and Annotator Wrapper as shown in Figure 4(a) and Figure 4(b) respectively. The former is used to wrap an annotator as a language service, the later is used to wrap a language service as an annotator:

- CDEF Extractor manipulates with CDEF to extract annotation and maps it with input/output of a language service. The Extractor uses XML parsing technique such as DOM and SAX to parse CDEF document and extract annotation. the annotation type and offset are extracted from the element `<annot>`. The annotation structure with features and values is extracted from `<fs>` node and sub-nodes `<f>`s. The Extractor then maps the annotation with a corresponding language service type which is served as input or output of a language service.
- CDEF Maker maps input/output of language services to annotation types and creates CDEF document. When wrapping an annotator as a language service with defined input and output, CDEF Maker first finds the offset of the defined input in the original text and then maps it with an annotation. Finally, it creates CDEF document from the original text and the annotation. In case of the input is

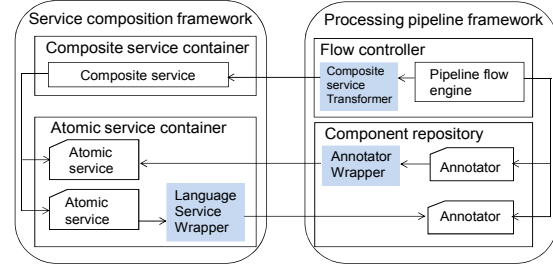

Figure 5: Integration Framework

text, the CDEF document is created with only *doc* part. When wrapping a language service as an annotator, CDEF Maker maps structure of the language service output with structure of a corresponding annotation type and use annotation's offset, extracted by CDEF Extractor, to create an annotation. This annotation is then added to the CDEF document.

### 3.2 Integration Framework

Integration framework enables users easily combine both types of components: language service and annotator. Users can use annotators to create composite services, use language services in a pipeline flow, or use both in composite services or in pipeline flows. It also provides ability to create a pipeline flow from a composite service.

Figure 5 illustrates integration of service composition and processing pipeline. A wrapper system consisting of Language Service Wrapper and Annotator Wrapper is used in this integration framework. Annotator providers use the Language Service Wrapper to wrap an annotator as a language service. This service is then shared with access control in the service composition framework. Users who have access rights to the system can invoke this service or can use this service to compose composite services. The language service providers use the Annotator Wrapper to wrap a language service into an annotator, this annotator can be executed and combined in a pipeline flow.

Language resources are shared as language services with intellectual rights, it is easy to create composite services. However, pipeline flow has better performance when processing large amounts of data compared to composite service. We define Composite Service Transformer to transfer composite services into pipeline flows. A composite service contains information about binding services. From the binding services, names, providers and sequence of language resources using in the composite service can be ex-

tracted. The transformer uses this information to build an abstract pipeline flow of these language resources. Later on, developers will negotiate with the providers to get the concrete language resources for the pipeline.

#### 4 Case study: Integration of the Language Grid and UIMA

Using the integration framework concept, we integrate the Language Grid and UIMA. We implement two wrappers: Language Service Wrapper and Analysis Engine Wrapper. The former is used to wrap an analysis engine as a language service, while the later is used to wrap language service into an Analysis Engine. A composite service transformer is also implemented to help developers transfer composite services to UIMA flows.

CAS is common data exchanged between UIMA components. We implement CAS Maker and CAS Extractor to manipulate with CAS document and create the wrappers:

- CAS Extractor extracts annotation from CAS document and maps with input/output types of language services.
- CAS Maker maps the input/output types of language services with UIMA annotation types and creates CAS documents which are served as input/output of an analysis engine.

We use some libraries from the Language Grid and UIMA such as *jp.go.nict.langrid.client.ws\_1.2.\** and *org.apache.uima.\** to manipulate with the Language Grid types and UIMA CAS. We also defined a new language service interface in the Language Grid to represent an analysis engine. This service interface has *analyze* operation with input is a string representing document, and output is a collection of annotations.

A mapping between UIMA annotation types and the Language Grid types is defined. We collect popular UIMA types defined for popular NLP functionalities. For each UIMA type we find a corresponding type in the Language Grid and create a mapping between these two types. For example, a *uima.annotation.Lemma* annotation can be mapped with *langrid.types.Morphem* type in the Language Grid, since these types contain similar morphological information such as *partOfSpeech*.

Composite Service Transformer extracts information about language resources used in a composite service and builds an UIMA flow by creating a descriptor file of the flow from the infor-

mation. This process may be complex, since it is transformation between two different types of flow. To facilitate the transformer, we adapt UIMA Flow Engine into the Language Grid Composite Service Container (Murakami et al. 2011), so that users can use this engine to create composite services. This kind of composite service is much easier to be transferred into an UIMA flow.

Analysis engines are wrapped as web services and shared in the Language Grid. Developers can easily collect and combine services to build a workflow for their application. However, using web services, transformation of huge data is not efficient. After testing the workflow with small amount of data and examine the output, if it satisfies the users requirement, then this workflow is transferred to a UIMA flow. Moreover, with the integration we can create hybrid applications combining analysis engines and language services.

The integration of UIMA and the Language Grid enhances the number of language resources available in both frameworks. Especially, this increases the number of language services related NLP in the Language Grid, and increases the robustness of the Language Grid.

#### 5 Conclusion

In this paper we proposed an integration of two types of language resource coordination frameworks: framework-based service composition and framework-based processing pipeline. The main contributions of this paper are as follows:

- The integration framework increases availability of language resources. Thus, it facilitates the process of creating applications.
- Integration of the Language Grid and UIMA is implemented to realize the framework.

In this paper, the type mapping between different frameworks is manually created. This technique is not very sufficient, due to the significant increase in number of types. Our future work will focus on using ontologies or extendable type system for a better approach of the type mapping.

# Improving Calculation of Contextual Similarity for Constructing a Bilingual Dictionary via a Third Language

Takashi Tsunakawa    Yosuke Yamamoto    Hiroyuki Kaji  
Graduate School of Informatics, Shizuoka University  
3-5-1 Johoku, Naka-ku, Hamamatsu, Shizuoka 432-8011, Japan  
{tuna, kaji}@inf.shizuoka.ac.jp

## Abstract

A novel method is proposed for measuring contextual similarity by “weighted overlapping ratio (WOR)” to construct a bilingual dictionary of a new language pair from two bilingual dictionaries sharing one language. The WOR alleviates the effect of a noisy seed dictionary resulting from merger of two bilingual dictionaries via a third language. Combined use of two word-association measures for extracting contexts from corpora is also proposed to compensate their weaknesses. Experiments on constructing a Japanese-Chinese dictionary via English show that the proposed method outperforms the conventional method based on cosine similarity.

## 1 Introduction

With the growth of communication via the Internet, people have more chance to access documents written in various languages. The number of Internet users in the Arabic, Russian, and Chinese languages have increased at least tenfold times in the last decade. It was sufficient in the past to bridge the gap between English and another language by using bilingual resources and services. For directly accessing Web contents written in various languages, however, multilingual dictionaries, translation, and information retrieval are required.

The present study focuses on a so-called triangulation approach for constructing a bilingual dictionary by merging two bilingual dictionaries sharing one language. For example, if Chinese-to-English and English-to-Arabic dictionaries are available, a Chinese-to-Arabic dictionary can be derived by collecting pairs of Chinese and Arabic terms (hereafter, “term pairs”) that have

common English translations. A serious problem with this approach, however, is how to filter out false term pairs, caused by polysemy of English terms. To validate each term pair as translations, we calculate the context similarity between the terms on the basis of the distributional hypothesis (Harris, 1954).

In triangulation approach, calculation of the context similarity in different languages is required. Previous studies have calculated context similarities by context vector projection onto another language by using a seed bilingual dictionary. Though this approach is effective, translation perplexity caused by context vector projection may cause negative effects described in Section 3.3. Instead of projection, our proposed method avoids this problem by using a “weighted overlapping ratio,” which directly maps words in context vectors in different languages.

## 2 Related work

Tanaka and Umemura (1994) proposed a triangulation method of constructing a bilingual dictionary. Their method has been augmented by using semantic classes (Bond et al., 2001) and parts of speech and cognates (Zhang et al., 2005).

Several methods of constructing a bilingual dictionary from contextual similarity have been proposed (Rapp, 1995; Kaji and Aizono, 1996; Tanaka and Iwasaki, 1996; Fung and Yee, 1998; Rapp, 1999; Sammer and Soderland, 2007). Most of them are based on context vector projection. Rapp (1999) replaced a word in the context vector with the translation first appeared in the dictionary, while Fung and Yee (1998) gave each translation a weight inversely proportional to the order of the translation in the dictionary. As another provision for translating context vectors,

mutual projection of context vectors was proposed (Fišer et al., 2011). Adapting a seed bilingual dictionary to the domain of comparable corpora has been proved to be effective (Kaji, 2005; Morin and Prochasson, 2011).

Other approaches (Déjean and Gaussier, 2002; Daille and Morin, 2005; Hazem et al., 2011) proposed methods based on identification of second-order affinities. Kaji et al. (2008) created a correlation matrix of context words versus translations. Vulić and Moens (2012) proposed a bilingual LDA model in which the term pairs are obtained on the basis of similar distributions of language-independent latent topics.

### 3 Proposed method

The proposed method is overviewed in Figure 1. Each step of the proposed method is described in the following subsections.

#### 3.1 Merging bilingual dictionaries

It is supposed that a bilingual dictionary between a source language  $S$  and a target language  $T$  can be constructed via a third language  $P$ . A bilingual dictionary,  $D_{L,L'}$ , between two languages,  $L$  and  $L'$ , can be defined as a set of term pairs  $\{(w_l, w_{l'})\} \subseteq L \times L'$ , where term  $w_l \in L$  can be translated as term  $w_{l'} \in L'$ .<sup>1</sup>

It is assumed that two bilingual dictionaries,  $D_{S,P}$  and  $D_{P,T}$ , are available. The merged bilingual dictionary between  $S$  and  $T$ , namely,  $D_{S,T}$ , is obtained from

$$\{(w_s, w_t) | \exists w_p: (w_s, w_p) \in D_{S,P} \wedge (w_p, w_t) \in D_{P,T}\}.$$

Note that term  $w_s$  cannot necessarily be translated into term  $w_t$  because of polysemy of term  $w_p$ . Such term pair  $(w_s, w_t)$  makes “noise” in the merged dictionary.

$D_{S,T}$  is used as a candidate set of term pairs to be ranked. It is also used as a seed bilingual dictionary to calculate the similarity of contexts in languages  $S$  and  $T$ .

#### 3.2 Extracting context

Spurious term pairs in the merged bilingual dictionary should be removed. The similarity of senses of each term pair is estimated by comparing their contexts. We represent the context of term  $w$  as a *weighted set of associated words*, i.e., words that are semantically or topically related with  $w$ . The weighted set of associated words,

<sup>1</sup> We describe that the vocabulary set of a language  $L$  also as  $L$  in short.

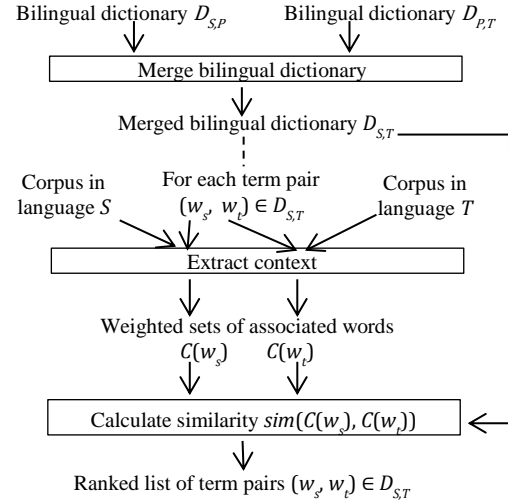

Figure 1. Overview of proposed method

$C(w)$ , is denoted as  $\{w_1/\alpha_1, w_2/\alpha_2, \dots, w_K/\alpha_K\}$  where  $w_k$  is an associated word of  $w$ , and  $\alpha_k$  is its weight assigned by the word-association measure based on their co-occurrence frequencies.

#### (1) Using a single word-association measure

Among words that co-occur with  $w$  in the corpus, only words that have association measure scores in the top- $M\%$ <sup>2</sup> are kept as associated words. The word-association measures employed are log-likelihood ratio (LLR), pointwise mutual information (MI), chi-squared score ( $\chi^2$ ), and discounted log-odds ratio (LOR) (Laroche and Langlais, 2010).

#### (2) Using combination of word-association measures

Each association measure has its own weakness in capturing word association. For example, LLR tends to overestimate frequent words, while MI tends to do infrequent ones. In general, infrequent associated words have less possibility to be matched when comparing two sets of associated words. A combination of these measures is expected to compensate for each weakness.

Associated words whose first association measure is in the top- $M_1\%$  and second is in the top- $M_2\%$  are kept. A weight corresponding to each associated word is given by the second measure. Two kinds of combinations are considered: LLR-MI and LLR-LOR, which respectively represent the first and second measures.

### 3.3 Calculating similarity between weighted sets of associated words

<sup>2</sup> A fixed threshold value of the association score was not used for keeping associated words because the proposed method obtained better results in our experiment.

A problematic case of context vector projection is illustrated in Figure 2. For calculating contextual similarity, such as a cosine, the context vectors<sup>3</sup> must be projected onto associated-word dimensions in the same language. In this approach, associated words are duplicated by translation perplexity. In this example, each word associated with the Japanese word “石油” sekiyu ‘petroleum’ has several possible English translations. It yields unnecessary Chinese associated words such as “力” li ‘power’ and “细胞” xibao ‘cell (in the biological sense),’ and then falsely decreases the cosine value because the norm of the projected vector increases.<sup>4</sup>

To avoid this problem, two sets of associated words are directly compared. For two weighted sets of associated words,  $C(w_s) = \{w_k/\alpha_k\}$  and  $C(w_t) = \{w'_l/\alpha'_l\}$ , a *weighted overlapping ratio* (WOR) is defined as:

$$\text{sim}(C(w_s), C(w_t)) = \frac{1}{2} \left\{ \frac{\sum_{k \in P} \alpha_k}{\sum_k \alpha_k} + \frac{\sum_{l \in Q} \alpha'_l}{\sum_l \alpha'_l} \right\}$$

where  $P = \{k | \exists w'_l: (w_k, w'_l) \in D_{S,T}\}$ ,  $Q = \{l | \exists w_k: (w'_l, w_k) \in D_{T,S}\}$ , and  $D_{S,T}$  and  $D_{T,S}$  are seed bilingual dictionaries between languages  $S$  and  $T$ . Term pairs  $(w_s, w_t)$  in the merged dictionary are ranked in order of their WORs. An example calculation of WOR is shown in Figure 3. The side effect from a noisy seed dictionary is considered to be moderated, since an unnecessary term is added only once per noisy term.

## 4 Experiments

Experiments on constructing a Japanese-Chinese bilingual dictionary via English as a third language were carried out. Note that this approach is applicable for any language combinations. We report three kinds of comparison: WOR vs. cosine similarity, word-association measures, and newspaper corpus vs. Wikipedia corpus.

Window size  $W$  for counting co-occurrence frequencies was fixed to 10. Five-fold cross validation was conducted for optimizing parameters for choosing associated words ( $M$ ;  $M_1$  and  $M_2$ ).<sup>5</sup>

<sup>3</sup> The weighted set of associated words is compatible to the context vector with dimensions of associated words in the vector space model.

<sup>4</sup> Rapp (1999) substituted each associated word to only a single translation. In that case, however, a noisy seed dictionary significantly decreases the probability that the translation is appropriate.

<sup>5</sup> The optimized values were as follows:  $M = 1.02$  (%) for LOR and  $M_1 = 13.5$ ,  $M_2 = 9.4$  (%) for MI-LLR.

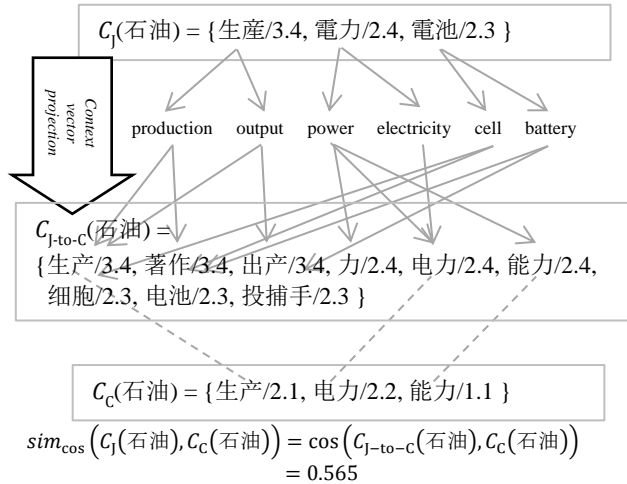

Figure 2. Calculation of contextual similarity by context-vector projection

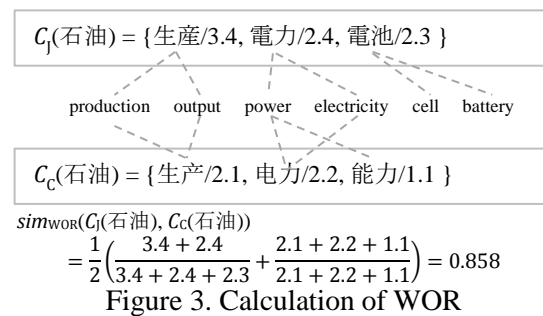

Figure 3. Calculation of WOR

The final evaluation score is output by averaging all five results.

### 4.1 Experimental settings

Two sets of comparable corpora were employed for our experiment: newspaper and Wikipedia. The newspaper set consists of the Mainichi Shimbun Corpus (2000-2010; 22.3GB) and the Xinhua News Corpus in LDC Chinese Gigaword (2000-2010; 4.24GB). The Wikipedia set consists of Japanese and Chinese Wikipedia articles dumped on September 2012 (Japanese: 821k articles; 3.1GB / Chinese: 520k articles; 0.7GB).

EDR Japanese-to-English/English-to-Japanese dictionaries and LDC Chinese-to-English dictionary<sup>6</sup> were used as input dictionaries. Each EDR dictionary has 376k word pairs, including 161k English distinct words and 221k Japanese distinct words. The LDC dictionary consists of 82k distinct word pairs.

3,000 term pairs (each term occurs at least 2,500 times in the corpus) were randomly extracted as the test data from the merged Japanese-Chinese dictionary. Each term pair was labeled as *translation* or *non-translation* by ma-

<sup>6</sup> The English-to-Chinese dictionary was obtained by inverting the LDC dictionary.

majority decision of three human annotators. The test set consists of 1,053 *translation* pairs and 1,947 *non-translation* pairs.

Precision  $P$  and recall  $R$  for the term pairs with the top- $\delta\%$  of WORs or cosine values were calculated. Some *translation* term pairs could not be correctly judged because those terms are sometimes only used for representing different senses from a sense in the comparable corpus. The recall therefore does not reach a higher value compared with the precision value. For this reason, an  $F_\beta$ -score with  $\beta = 0.5$  was adopted as the final evaluation score so as to emphasize precision as twice as important as recall. The best  $F_{0.5}$ -scores were obtained when  $\delta = 20$  (%) (see Table 1).

## 4.2 WOR vs. cosine similarity

To confirm the effect of WOR, it was compared with the conventional cosine by context vector projection. The best evaluation scores are listed in Table 2. WOR outperformed the cosine measure on both corpus sets.

The merged dictionary for comparing associated words can also be substituted by existing bilingual dictionaries between languages  $S$  and  $T$  if available. To examine the effect of using the noisy seed bilingual dictionary, additional experiments in using the EDR Japanese-Chinese dictionary (223k term pairs) as a seed dictionary were conducted. The  $F_{0.5}$ -score by WOR with this setting was 0.743, while 0.721 by cosine measure. The drop in the  $F_{0.5}$ -score by using the merged dictionary as the seed were 1.4 points by WOR, which were smaller than the drop (3.0 points) obtained by the cosine. This result shows that WOR is more robust than the cosine in the case that a noisy seed dictionary is used.

## 4.3 Single measure vs. combination of measures

Experiments on using all word association measures were carried out. Among the single word-association measure, the highest  $F_{0.5}$ -score of 0.689 was obtained by LOR as listed in Table 2, and it confirmed a previous comparative experiment (Laroche and Langlais, 2010). Both combinations of the multiple association measures outperformed LOR on the newspaper set. These results indicate that the weakness that LOR covered could also be covered by LLR.

## 4.4 Newspaper vs. Wikipedia as the comparable corpus

The characteristics of the results obtained from

$\delta$ (%)	$P$	$F_{0.5}$
10	0.908	0.611
20	0.833	<b>0.729</b>
30	0.744	0.723
40	0.640	0.659
50	0.567	0.605

Table 1. Evaluation scores attained some values of  $\delta$  (%) (settings: WOR, LLR-MI, newspaper)

	Corpus set	Newspaper		Wikipedia	
	Measure	$P$	$F_{0.5}$	$P$	$F_{0.5}$
WOR	LLR	0.721	0.631	0.664	0.646
	MI	0.704	0.616	0.711	0.691
	LOR	0.788	0.689	0.792	0.693
	$\chi^2$	0.717	0.622	0.717	0.632
	LLR-MI	<b>0.833</b>	<b>0.729</b>	<b>0.796</b>	<b>0.696</b>
	LLR-LOR	0.829	0.725	0.708	0.688
cosine	LLR	0.622	0.609	0.708	0.531
	LLR-MI	0.783	0.691	0.775	0.684

Table 2. Evaluation scores

each comparable corpus set described in Section 4.1 were examined. As listed in Table 2, combinations of the multiple measures did not achieve significant improvement on the Wikipedia corpus set. Meanwhile, the overall performance of Wikipedia did not significantly degrade in comparison with the newspaper set, although larger corpora give more appropriate associated word sets for each term pair. One reason for that result is the high comparability of Wikipedia data.

## 5 Concluding remarks

A novel method for constructing bilingual dictionaries via a third language is proposed. It applies a novel context similarity criterion, namely, a “weighted overlapping ratio” (WOR) for alleviating negative effects from translation perplexity. In addition, a method for combining word-association measures is developed. Experiments demonstrated the effectiveness of the proposed method: the proposed method achieved the highest  $F_{0.5}$ -score 0.729, thereby outperforming the  $F_{0.5}$ -score 0.691 by the conventional cosine-similarity method in the case of projecting context vectors onto English.

A future direction is applying word-sense-disambiguation techniques to associated words. By separating polysemous associated words into some classes corresponding to each sense, we could avoid the negative effect from unrelated senses of the associated words.

## Abstract

We propose a new rule-based pre-ordering method for Japanese-to-English statistical machine translation that employs heuristic rules in two-stages. This two-stage framework contributes to experimental results that our method outperforms conventional rule-based methods in BLEU and RIBES.

## 1 Introduction

Reordering is an important strategy in statistical machine translation (SMT) to achieve high quality translation. While many reordering methods often fail in long distance reordering due to computational complexity, a promising technology called *pre-ordering* (Xia and McCord, 2004; Collins et al., 2005) has been successful for distant English-to-Japanese translation (Isozaki et al., 2010b). However, this strong effectiveness has not been shown for Japanese-to-English translation.

In this paper, we propose a novel rule-based pre-ordering method for the Japanese-to-English translation. The method utilizes simple heuristic rules in two-stages<sup>1</sup>: the inter-chunk and intra-chunk levels. Thus the method can achieve more accurate reorderings in Japanese. The translation experiments in patent domain showed that our method outperformed conventional rule-based methods, especially on the word reorderings. Our claims in this paper are summarized as follows:

1. The inter-chunk pre-ordering that relies on PAS analysis contributes to improvements in translation quality.
2. The intra-chunk pre-ordering which converts postpositional phrases into prepositional phrases further improves translation quality.
3. Thus, our two-stage framework is more effective than other pre-ordering methods.

<sup>1</sup>In this paper, we refer to Japanese *bunsetsu* as a “chunk”, a grammatical and phonological unit consists of noun, verb, or adverb followed by dependents such as particles.

## 2 Related Work

Japanese-to-English is challenging because the grammatical forms of the two languages are totally dissimilar. For instance, English is a head-initial language, and utilizes subject-verb-object (SVO) word orders, while Japanese is a *pure* head-final language, and utilizes subject-object-verb (SOV).

Komachi et al. (2006) proposed a rule-based pre-ordering method to convert SOV into SVO via a PAS analyzer. This method pre-orders inter-chunk level word orders in a single-stage, via the PAS analyzer which produced dependency trees and tagged each S, O, and V label. Then SOV sequences are converted into SVO. However, since the non-labeled words are left untouched, the effectiveness of this method is limited to simple SOV labeled matrix sentences without multiple clauses.

Katz-Brown and Collins (2008) proposed a two-stage rule-based pre-ordering method. In the first stage, SOV sequences are converted into SVO via the dependency analyzer. In the second stage, each chunk word order is naively reversed<sup>2</sup>.

Neubig et al. (2012) proposed a statistical model that was capable of learning how to pre-order word sequences from human annotated or automatically generated alignment data. However, this method has very large computational complexity to model long distance reordering.

## 3 Two-stage Pre-ordering Method

Here, we describe a new pre-ordering method which employs heuristic rules in two-stages. In the first stage, we reorganize and extend the rules described in (Komachi et al., 2006; Katz-Brown and Collins, 2008). In the second stage, we propose a new rule to consider chunk internal word orders. More precisely, **we apply four rules**: three rules for the first stage (Rule 1-1, 1-2, 1-3) and one

<sup>2</sup>Since the rule for S has not been described in detail, we provide a definition: S is a chunk followed by a topic-marker.

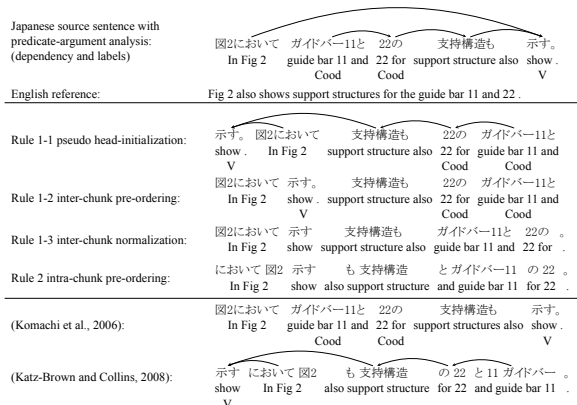

Figure 1: Pre-ordering Examples.

rule for the second stage (Rule 2). Each rule corresponds to the different linguistic nature between English and Japanese.

### 3.1 Rule 1-1 pseudo head-initialization

To output Japanese in head-initial sequences, this rule modifies Japanese dependency trees to the order that a head chunk comes first and its dependent children follow, by default. In the example, the sentence verbal head “示す show(s)” is moved to the leftmost position.

### 3.2 Rule 1-2 inter-chunk pre-ordering

This rule converts SOV into SVO. The rule can also handle a sentence which has no subject and object, due to a parsing error or a pro-drop that frequently occurs in Japanese. If there is V (a verbal head), then we apply this rule after Rule 1-1.

First, we move V instead of S or O, as we already have VSO sequences generated in Rule 1-1. Therefore, we placed V after the subject ( $V x^* S y^* \rightarrow x^* S V y^*$ ) or before the object in case a subject is not found ( $V x^* O y^* \rightarrow x^* V O y^*$ ).

Second, in the case where we only have V (without S and O), we move V before the rightmost chunk ( $V x^* y \rightarrow x^* V y$ ) to avoid head-initial outputs. In the example, since there is no subject and object, the verbal head “示す show(s)” is moved to immediately before its second dependent. On the other hand, V has been incorrectly placed in the rightmost in Komachi et al. (2006) and the leftmost in Katz-Brown and Collins (2008).

### 3.3 Rule 1-3 inter-chunk normalization

If there are coordinate clauses or punctuations, then we apply this rule after Rule 1-2. Basically,

we keep coordinate clauses and punctuations unchanged from the original word orders, by placing the coordinate clauses to the leftmost position and the punctuations to the rightmost position ( $x^* Punc y^* Cood z^* \rightarrow Cood x^* y^* z^* Punc$ ). In addition, in order to avoid comma-period sequences, we remove all commas immediately before a period.

In the example, the period “。” is moved to the rightmost position, unlike Komachi et al. (2006). And the coordinate clause “ガイドバー11と22の the guide bar 11 and 22” is restored to the original position in the source, by moving the clause to the rightmost position. While Katz-Brown and Collins (2008) does not have such a rule to restore the coordinate clause, Komachi et al. (2006) can keep it unchanged because that method does not move non-labeled words.

### 3.4 Rule 2 intra-chunk pre-ordering

For every chunk, we swap function and content words to organize pseudo prepositional phrases (Content Function  $\rightarrow$  Function Content). In the example, the chunk “ガイドバー11と the guide bar 11 AND” has three words: the two content words “ガイドバー11 the guide bar 11” and the function word “と AND”. Thus the chunk is reversed as “と ガイドバー11 AND the guide bar 11”.

### 3.5 Differences to Conventional Rules

Komachi et al. (2006) did not employ Rule 1-1 and only employed Rule 1-2. In this example, the head “support structures” should be followed by the dependents “guide bar 11 and 22”, but these words are left untouched. Katz-Brown and Collins (2008) employed Rule 1-1, the most of Rule 1-2, and a rule to keep punctuations as it partially treated by Rule 1-3. However, they did not have the exceptional rule to move verb from the first position for non-subject sentences, as described in Rule 1-2. In the example, this method misplaced the sentence verbal head “show” to the first position, and the coordination clause “guide bar 11 and 22” has also been mixed.

## 4 Experiments

### 4.1 Experimental Setup

In order to compare pre-ordering methods, we conducted Japanese-to-English translation experiments on a fixed data set and SMT system.

For the common data set, we used the NTCIR-9 PatentMT Test Collection Japanese-to-English Machine Translation Data<sup>3</sup> package that contains approximately 3.2 million sentence pairs for training, 500 sentence pairs for development, and 2,000 sentence pairs for testing. The Japanese sentences are tokenized by MeCab 0.994<sup>45</sup>. In addition, we employed two parser configurations for Japanese parsing: (1) the KNP configuration used KNP 4.01<sup>6</sup> (Sasano and Kurohashi, 2011) for both dependency and PAS analyzer; (2) the CaboCha+SynCha configuration used CaboCha 0.65<sup>7</sup> (Kudo and Matsumoto, 2002) for dependency analysis and SynCha 0.3<sup>8</sup> (Iida and Poesio, 2011) for PAS analysis.

For the common SMT system, we used SRILM

<sup>3</sup><http://research.nii.ac.jp/ntcir/permission/ntcir-9/perm-en-PatentMT.html>

<sup>4</sup><http://mecab.googlecode.com/svn/trunk/mecab/doc/index.html>

<sup>5</sup>Since (unlike English) the Japanese language does not utilize spaces to delineate word boundaries, MeCab was used to perform the required Japanese tokenization.

1.7.0 (Stolcke et al., 2011), MGIZA++ 0.7.3 (Gao and Vogel, 2008), Moses 0.91 (Koehn et al., 2007)<sup>9</sup>, and two popular evaluation metrics for Japanese-to-English: BLEU (Papineni et al., 2002) and RIBES (Isozaki et al., 2010a).

For the pre-ordering methods, we implemented rule-based methods proposed by (Komachi et al., 2006) and (Katz-Brown and Collins, 2008). In addition, an implementation<sup>10</sup> of statistical method proposed by Neubig et al. (2012) are used<sup>11</sup>. We did not use any pre-ordering in the baseline.

### 4.2 Experimental Results

Table 1 shows the experimental results for Japanese-to-English patent document translations that compare the following pre-ordering methods: the baseline (no pre-ordering), Komachi et al. (2006), Katz-Brown and Collins (2008), Neubig et al. (2012), our proposed method. We also conducted ablation tests, which consisted of a comparison of all Rule 1-2, 1-3, and 2, shown in Table 2.

The experimental results show that our proposed method outperformed all the other pre-ordering methods in terms of the BLEU and RIBES, which scored 30.65 and 72.26 points, respectively. This indicates that our two-stage pre-ordering method is better than conventional rule-based pre-ordering methods in the following aspects we found:

1. Our method and Komachi et al. (2006), both of which rely on PAS, were better than Katz-Brown and Collins (2008) which utilizes deterministic rules to obtain SOV labels.
2. Our intra-chunk pre-ordering gained a further improvement in translation accuracy as shown in Table 2. Nevertheless, we observed a 0.3 point drop in BLEU and a 0.9 point

<sup>9</sup>the following configurations are used in the system: 6-gram for language modeling, msd-bidirectional-fe for re-ordering, and MERT (Och, 2003) for tuning. After reviewing our preliminary findings, distortion limits were set to 20 for the baseline and (Komachi et al., 2006), and 10 for others.

<sup>10</sup><http://www.phontron.com/lader/>

<sup>11</sup>Only 10,000 sampled lines were used for training due to its computational complexity: During the training process, it consumed 120 GB of memory space for almost entire month.

improvement in RIBES by adding Rule 2 to Rule 1-2 and Rule 1-3, even though this combination yields better translations for native speakers. This phenomenon can be explained by the characteristic difference between BLEU and RIBES. While RIBES has a good correlation to human judgments, BLEU is said to have an uncorrelated, erratic behavior for Japanese-to-English translation (Isozaki et al., 2010a).

3. Our heuristic rules can cover more pre-ordering issues (as shown in Figure 1), and achieved further improvement in Rule 1-2 and Rule 1-3 as shown in Table 2.

In addition, as shown in Table 3, there was a 0.6 point statistically significant difference between two parser configurations (KNP and CaboCha+SynCha) in BLEU for our method. We suppose that one possible explanatory factor is the coordination structural accuracy to utilize Rule 1-3, because KNP tends to output more accurate coordination structures than CaboCha. However, it will be necessary to analyze our results in further detail to produce more definite conclusions. In any case, since such differences have been achieved simply by switching parsers, we believe that a better parsing method can be expected to produce better translation results in the future.

### 4.3 Pre-ordering Evaluation

We employed Kendall’s  $\tau$  rank correlation coefficient and its distribution as our pre-ordering criteria as described in Isozaki et al. (2010b). As shown in Figure 2, our proposed method produced much better correlation distribution than the baseline<sup>12</sup>.

Table 4 shows experimental results conducted on a news document that contains 150,000 sentence pairs created by (Utiyama and Isahara, 2003). Similar to the results shown in Table 1, our method outperformed the baseline.

## 5 Error Analysis and Discussion

Figure 3 shows an example within the proposed method. The intra-chunk rule Rule 2 moved the postposition “in” before the noun “Fig.7” and thus it makes the prepositional phrase “in Fig.7”. Also

<sup>12</sup>The average value of  $\tau$  in the proposed method is 0.575 against 0.391 in the baseline, and the percentages of sentences which have value of 0.8 or higher were 33.9% in our proposed method and 10.2% in the baseline. This 20% difference represents great reduction of word order differences.

Proposed: でここは各記号示す及び表1に図7、いる表してをもの次の。 Here each symbol show and Table 1 in Fig.7, represent the things following.
Translated Result: In this case, the respective symbols shown in Table 1 and Fig.7 represents the followings.

Figure 3: Successful Pre-ordering Example

the coordination structure “Table 1 and Fig.7” is kept. There is still a minor verb agreement error which the verb “represent” is translated as “represents”. However, the most of errors are given via parsing process. For instance, of the first 30 sentences in the test data, we found 21 SOV tagging errors and 9 critical dependency errors, despite CaboCha is reported to have 89.8% accuracy for overall dependencies. Other methods could not translate this example correctly.

Besides, we also found that our deterministic rules cannot handle some difficult Japanese constructions. As a result, incorrect reordering had been conducted. For example, many Japanese sentences have a *topic* with a *topic-object-verb* construction, instead of subject-object-verb, because Japanese is a *topic-prominent* language. In the same 30 sentences, 18 sentences formed the topic-object-verb construction, and 4 sentences have been found as the topic-subject-object-verb construction.

## 6 Conclusion

In this paper, we proposed a new rule-based pre-ordering method for Japanese-to-English statistical machine translation, and we showed that our two-stage pre-ordering scheme was capable of solving more complex pre-ordering problems than conventional methods. From the experimental results, we found that our proposed method outperformed existing rule-based pre-ordering methods in terms of standard evaluation metrics.

## Abstract

This paper proposes a novel approach to resolve the English article error correction problem, which accounts for a large proportion in grammatical errors. Most previous machine learning based researches empirically collected features which may bring about noises and increase the computational complexity. Meanwhile, the predicted result is largely affected by the threshold setting of a classifier which can easily lead to low performance but hasn't been well developed yet. To address these problems, we employ genetic algorithm for feature selection and confidence tuning to reinforce the motivation of correction. Comparative experiments on the NUCLE corpus show that our approach could efficiently reduce feature dimensionality and enhance the final  $F_1$  value for the article error correction problem.

## 1 Introduction

Grammatical errors in English are common in written issues especially for learners of English as a second language (L2 learners). As a result, automatic grammatical error correction (GEC) sprung up and has attracted more and more research attention recently. Among various error types, article errors account for a large proportion (over 12% in NUCLE) and are very difficult to be corrected.

Articles in the English language include indefinite article *a* and *an*, definite article *the* and zero article *empty* which means no article is used in this position. Articles are determiners of noun phrases which are indispensable in English grammar. Article errors are common in written English including wrong use, missing, and un-

necessary use of articles. For example, in the following sentence “*Over these years, it had helped humans to improve the accessibility in the forms of cards to gain access to certain places.*” there are two *thes* in which the first one is required but the second one is unnecessary. It is difficult for L2 learners to judge whether an article is necessary or not, or which article is needed. These errors are highly correlated with the context features around noun phrases. Errors occur frequently in various written issues which motivates researchers to exploit automatic error correction.

There are two main approaches for English article error correction. One of them is the external language materials based approach. Although there are minor differences on strategies, the main idea of this approach is to use frequencies such as n-gram counts as a filter and keep those phrases that have relatively high frequencies. Typical researches are shown by (Yi et al., 2008) and (Bergsma et al., 2009). Similar methods also exist in HOO shared tasks<sup>1</sup> such as the web 1TB n-gram features used by (Dahlmeier and Ng, 2012a) and the large-scale n-gram model in (Heilman et al., 2012). The other is machine learning based approach in which syntactic and semantic context features are utilized to train classifiers. Han et al. (2006) take maximum entropy as their classifier and apply some simple parameter tuning methods. Felice and Pulman (2008) present their classifier-based models together with a few representative features. Seo et al. (2012) invite a meta-learning approach and show its effectiveness. Dahlmeier and Ng (2011) introduce an alternating structure optimization based approach.

---

<sup>1</sup> <http://clt.mq.edu.au/research/projects/hoo/hoo2012>

As far as we know, most machine learning based approaches collect their features empirically and mainly depend on the feature selection of the classifiers which may bring about noises and increase the computational complexity when the feature dimensionality goes excessive. Moreover, discussions about the setting of threshold in classifiers are insufficient. Some work made simple adjustments on predicted thresholds after training their classification models like (Han et al., 2006; Dahlmeier and Ng, 2012a). Tetreault and Chodorow (2008) proceed from the different confidence of predicted categories which is similar to the approach employed in our work. We consider it is crucial to measure the differences between predicted scores of each category especially for GEC task on those documents with relatively high quality because in many cases, to keep the original form are actually the best choice.

In this paper, we focus on the machine learning based approach on error annotated corpus and propose a novel strategy to solve article error correction problem. Primarily, we extract a large number of related syntactic and semantic features from the context. With the help of genetic algorithm, a best feature subset is selected out which could greatly reduce the feature dimensionality. For each testing instance, according to the predicted confidence scores generated by the classifier, our tuning approach measures the trade-off between scores in order to enhance the confidence to a certain category. We didn't include any external corpora as references in our work which is to be further exploited. Experiments on NUCLE corpus show that our approach could efficiently reduce feature dimensionality and take full advantage of predicted scores generated by the classifier. The evaluation result shows our approach outperforms the state-of-the-art work (Dahlmeier and Ng, 2011) by 2.2% in  $F_1$  on this corpus.

There are two main contributions in our work: one is that we add feature selection before training and testing which reduces feature dimensionality automatically. The other is that we make use of the differences of confidence scores between categories and discuss about various tuning approaches which may affect the final performance.

The remainder of this paper is arranged as follows. The next section introduces feature extraction and selection. Section 3 describes model training and confidence tuning. Experiments and analysis are arranged in Section 4. Finally, we give our conclusion in Section 5.

## 2 Feature Extraction and Selection

We take article correction as a multi classification task. Three categories including *a/an*, *the* and *empty* are assigned to specify the correct article forms in corresponding positions (*a* and *an* are distinguished according to pronunciation of the following word). For training, developing and testing, all noun phrases (NPs) are chosen as candidates to be corrected. We extract related features based on the context of an NP and do feature selection afterwards.

### 2.1 Feature Extraction

A series of syntactic and semantic features are extracted with the help of NLP tools like Stanford parser (Klein and Manning, 2003), Stanfordner (Finkel et al., 2005) and WordNet (Fellbaum, 1999). We adopt syntactic features such as the surface word, word n-gram, part-of-speech (POS), POS n-gram, constituent parse tree, dependency parse tree, name entity type and headword; semantic features like noun category and noun hypernym. Some extended features are extracted based on them and some previous work (Dahlmeier and Ng, 2012b; Felice and Pulman, 2008).

Through feature extraction, we get over 90 groups of different features. After binarization, the dimensionality exceeds to about 350 thousand in which many features occur only once. We tried to prune all sparse features but found the performance fell off greatly while a manual deletion of several of them could instead improve the result. We infer that the sparse features may become useful when serving as an element of some feature subset which motivates us to carry out feature selection.

### 2.2 Feature Selection

Feature subset selection is conducted in this module to select out wrapped features. Genetic algorithm (GA) has been proven to be useful in selecting wrapped features in previous work (ElAlami, 2009; Anbarasi et al, 2010) and is applied in our work.

The features are encoded into a binary sequence in which each character represents one dimension. We use the number "1" to denote that this dimension should be kept while the number "0" means that dimension should be dropped in classification. A binary sequence such as "0111000...100" is able to denote a combination of feature dimensions. GA functions on the feature sequences and finally decides

which feature subsets should be kept. Following the steps of traditional GA, our approach includes generation of initial individuals, crossovers, mutations and selection of descendants for each generation.

The fitness function is the evaluation metric  $F_1$  described in §4.1. After feature selection, we reduced our feature dimensionality from 350 thousand to about 170 thousand which greatly reduced complexity in training. As expected, there are still a great number of sparse features left.

### 3 Training and Tuning

#### 3.1 Training Using Maximum Entropy

All noun phrases (NPs) are chosen as candidate instances to be corrected. For NPs whose articles are erroneous with annotations, the correct ones are their target categories, and for those haven't been annotated (error-free), their target categories are the observed articles. These NPs contain two basic types: *with* and *without* wrong articles. Two examples are shown below:

*with: #/empty big apples* ~ Category *empty*

*without: the United States* ~ Category *the*

For each category in *a*, *the*, and *empty*, we use the whole *with* instances and randomly take samples of *without* ones, making up the training instances for each category. We consider all the *with* samples useful because each of them has an observed wrong article which indicates that the correct article is easily misused as the wrong one. Different ratios of *with* : *without* are experimented in our work to see how much the number of *without* samples, which is mentioned in previous work (Dahlmeier and Ng, 2011), affects the result in our model.

Maximum entropy (ME) is employed for classification which has been proven to have good performance for heterogeneous features in natural language processing tasks. We have also tried several other classifiers including SVM, decision tree, and Naïve Bayes but finally found ME performs better.

#### 3.2 Confidence Tuning

ME returns with confidence of each category for a given testing instance. However, for different instances, the distributions of predicted scores vary a lot. In some instances, the classifier may have a very high predicted score to a certain category which means the classifier is confident enough to perform this prediction while for some other instances, two or more categories may

share close scores, the case of which means the classifier hesitates when telling them apart.

Our confidence tuning strategy (Tuning) on the predicted results is based on a comparison between the observed category and the predicted category. It is similar to the “thresholding” approach described in (Tetreault and Chodorow, 2008). The main idea of this confidence tuning strategy is: the selection between *keep* and *drop* is based on the difference between confidence of the predicted category and the observed category. If this difference goes beyond a threshold  $t$ , the prediction is proposed while if it is under  $t$ , we won't do any corrections. The confidence threshold is generated through hill-climbing in development data aiming at maximizing  $F_1$  of the result.

## 4 Experiments

### 4.1 Data Set and Evaluation Metrics

The NUCLE corpus (Dahlmeier and Ng, 2011) introduced by National University of Singapore contains 1414 essays written by L2 students with relatively high proficiency of English in which grammatical errors have been well annotated by native tutors. It has a small proportion of annotated errors which is much lower than other corpora. Only about 1.8% of articles contain errors in this corpus. The corpus provides the original texts as well as annotations which we make use of to generate training and developing samples. We divide the whole corpus into 80%, 10% and 10% for training, developing and testing to make our approach comparable with the previous work.

The performance is measured with precision, recall and  $F_1$ -measure where precision is the amount of predicted corrections that are also corrected by the manual annotators divided by the whole amount of predicted corrections. Recall has the same numerator with precision while its denominator is the amount of manually corrected errors.

### 4.2 Experiment and Analysis

In our experiments, we firstly compare the results of the baseline system (without GA and tuning, labeled as ME) and GA to see how much GA contributes to the performance. And also, we list the results of our initial strategy that all sparse features were deleted from the feature space (-SF). The comparisons are shown in Table 1 (all the *without* instances are used without sampling). The results show the effectiveness of GA and the usefulness of the sparse features.

Secondly, we tried several *with: without* ratios in the composition of training instances to see how much the selection of instances affects the result in our model. Figure 1 describes the comparative results under different ratios and the results with or without confidence tunings (discussed next).

Model	Prec.	Rec.	F <sub>1</sub>
ME(-SF)	4.29	66.67	8.05
ME	4.46	65.80	8.35
ME+GA	5.42	68.68	<b>10.06</b>
ME+Tuning(-SF)	13.33	26.17	17.66
ME+Tuning	15.85	28.20	20.03
ME+GA+Tuning	20.19	23.04	<b>21.53</b>

Table 1. Experiments on feature selection.

This experiment is conducted without the intervention of GA. Different from the conclusion in the previous work, we find that, there are not obvious differences between results under different ratios in our model. Before tuning, the differences are tiny, and after tuning, we believe it is mainly due to the advantage of the tuning strategy that eliminates the effects of randomness to a great extent. It is also interesting to see the improvement of F<sub>1</sub> always follows the increase of precision and decrease of recall which is good for the trend of correction without human intervention. We use all the *without* instances in our following experiments to avoid other randomness.

Figure 1. Comparisons before and after tuning. (*1:all* means to use the whole negative samples which is about *1:13*).

The best result of our model is achieved with GA and confidence tuning (ME+GA+Tuning in Table 1). Through experiments, we notice that the contribution of confidence tuning accounts for the largest proportion which directly enables our model outperform the previous state-of-the-

art work (precision of 26.44%, recall of 15.18%, and F<sub>1</sub> of 19.29% by (Dahlmeier and Ng, 2011)) by about 2.2% which is a big improvement in this task. Besides, the performance on the test set keeps that on the developing set which achieves precision of 20.97%, recall of 21.25%, and F<sub>1</sub> of 21.11%.

At last, we make comparisons on four threshold tuning strategies to verify the appropriateness of the thresholding approach applied in this paper. The five approaches labeled as *no-tuning*, *self-tuning*, *all-tuning*, *self-diff*, and *all-diff* in Table 2 correspond to the following four strategies. **(1)** Choose the category with the maximum predicted score; **(2)** Assign each category a fixed threshold beyond which a score goes most, that category is predicted; **(3)** Assign a fixed threshold for all categories beyond which a score goes most, that category is predicted; **(4)** Similar to (2) except that the threshold is the difference between scores of the predicted maximum and the observed category; **(5)** Similar to (3) except that the threshold is the difference between scores of the predicted maximum and the observed category.

Tuning method	Prec.	Rec.	F <sub>1</sub>
no-tuning	5.42	68.68	10.06
self-tuning	20.38	21.04	20.90
all-tuning	22.04	15.88	18.47
self-diff(our)	20.19	23.04	<b>21.53</b>
all-diff	22.82	17.00	19.49

Table 2. Different tuning strategies

It is noticeable that to assign a threshold for each category always performs better than to use a single threshold. We infer that the tuning strategies based on difference perform better mainly because they consider that the observed category should have a relatively high confidence if it is error-free even it is not the maximum.

## 5 Conclusion

In this paper, we introduce feature selection and confidence tuning for the article error correction problem. Comparative experiments show that our approach could efficiently reduce feature dimensionality and enhance the final F<sub>1</sub> value. However, for automatic grammatical error correction, there is still a long way to go. More resources and methods need to be exploited in the next stage for further performance improvement.

## Abstract

We introduce an online framework for discriminative learning problems over hidden structures, where we learn both the latent structure and the classifier for a supervised learning task. Previous work on leveraging latent representations for discriminative learners has used batch algorithms that require multiple passes through the entire training data. Instead, we propose an online algorithm that efficiently jointly learns the latent structures and the classifier. We further extend this to include multiple views on the latent structures with different representations. Our proposed online algorithm with multiple views significantly outperforms batch learning for latent representations with a single view on a grammaticality prediction task.

## 1 Introduction

Natural language data is implicitly richly structured, and making use of that structure can be valuable in a wide variety of NLP tasks. However, finding these latent structures is a complex task of its own right. Early work used a two-phase pipeline process, in which the output of a structure prediction algorithm (e.g. a noun phrase finder) acts as fixed input features to train a classifier for a different task (e.g. grammaticality prediction). Chang et al. (2009), Das and Smith (2009), Goldwasser and Roth (2008), and Mccallum and Bellare (2005) have shown that this approach can propagate error from the structured prediction to the task-specific classifier. Recent work has combined unsupervised learning of (latent) structure prediction with a supervised learning approach for the task. Work in this vein has focused on jointly

\*This research was partially supported by an NSERC, Canada (RGPIN: 264905) grant and a Google Faculty Award to the third author.

learning the latent structures together with the task-specific classifier (Cherry and Quirk, 2008; Chang et al., 2010). Chang et al. (2010) in particular introduce a framework for solving classification problems using constraints over latent structures, referred to as Learning over Constrained Latent Representations (LCLR). We extend this framework for discriminative joint learning over latent structures to a novel online algorithm. Our algorithm learns the latent structures in an unsupervised manner, but it can be initialized with the model weights from a supervised learner for the latent task trained on some (other) annotated data. This can be seen as a form of domain adaptation from the supervised latent structure training data to the different classification task.

We evaluate our algorithm in comparison to the LCLR batch method on a grammaticality test using a discriminative model that learns shallow parse (chunk) structures. Our online method has standard convergence guarantees for a max-margin learner, but attains higher accuracy. Furthermore, in practice we find that it requires fewer passes over the data.

We also explore the use of allowing multiple views on the latent structures using different representations in the classifier. This is inspired by Shen and Sarkar (2005), who found that using a majority voting approach on multiple representations of the latent structures on a chunking task outperformed both a single representation as well as voting between multiple learning models. We show that the multiple-view approach to latent structure learning yields improvements over the single-view classifier.

## 2 The Grammaticality Task

To evaluate our algorithms, we use a discriminative language modeling task. A well-known limitation of  $n$ -gram LMs is that they are informed only by the previously seen word histories of a

fixed maximum length; they ignore dependencies between more distant parts of the sentence. Consider examples generated by a 3-gram LM:

- chemical waste and pollution control ( amendment ) bill , all are equal , and , above all else .
- kindergartens are now .

These fragments are composed of viable trigrams, but a human could easily judge them to be ungrammatical. However, if a language model used latent information like a shallow syntactic parse, it could also recognize the lack of grammaticality.

Discriminative models can take into account arbitrary features of data, and thus may be able to avoid the shortcomings of  $n$ -gram LMs in judging the grammaticality of text. In the case of language modeling, however, there is no obvious choice of categories between which the model should discriminate. Cherry and Quirk (2008) show that by following the pseudo-negative examples approach of Okanohara and Tsujii (2007), they can build a syntactic discriminative LM that learns to distinguish between samples from a corpus generated by human speakers (positives) and samples generated by an  $n$ -gram model (negatives).

Our approach is similar to Cherry and Quirk (2008), but they use probabilistic context-free grammar (PCFG) parses as latent structure, use a latent SVM as the learning model (we use latent passive-aggressive (PA) learning), and they handle negative examples differently. Instead of PCFG parsing, we use a chunking representation of sentence structure, which can be seen as a shallow parse, in which each word in the sentence is tagged to indicate phrase membership and boundaries.

Our model simultaneously learns to apply multiple sets of chunk tags to produce chunkings representing sentence structure and to prefer the shallow parse features of the human sentences to those sampled from an  $n$ -gram LM. The latent chunker will assign chunk structure to examples that yield the widest margin between the positive (grammatical) and negative (ungrammatical) examples.

### 3 Latent Structure Classifier

Our classifier is trained by simultaneously searching for the highest scoring latent structure while classifying data instances. Here we extend the latent learning framework due to Chang et al. (2010) from a batch setting to an online setting that uses passive-aggressive (PA) updates (Crammer and Singer, 2001).

### 3.1 PA Learning

The latent structure classifier training uses a decision function that searches for the best structure  $z_i^* \in Z(x_i)$  for each training sentence  $x_i$  with a space of possible structures  $Z(x_i)$  according to feature weights  $\mathbf{w}$ , i.e.:

$$f_w(x_i) = \arg \max_{z_i} \mathbf{w} \cdot \phi(x_i, z_i) \quad (1)$$

where  $\phi(x_i, z_i)$  is a feature vector over the sentence-parse pair. The sign of the prediction  $y_i^* \mathbf{w} \cdot \phi(x_i, z_i^*)$  determines the classification of the sentence  $x_i$ .

Using PA max-margin training (Crammer and Singer, 2001), we incorporate this decision function into our global objective, searching for the  $\mathbf{w}$  that minimizes

$$\frac{1}{2} \|\mathbf{w}\|^2 + \sum_{i=1}^X \ell(\mathbf{w} \cdot (f(x_i), y_i)), \quad (2)$$

where  $\ell$  is a loss function; we use hinge loss. At each iteration, for each example  $x_i$  we find and update according to a new weight vector  $\mathbf{w}'$  that minimizes:

$$\frac{1}{2} \|\mathbf{w} - \mathbf{w}'\|^2 + \tau(1 - y_i(\mathbf{w}' \cdot \phi(x_i, z_i^*))), \quad (3)$$

where  $\mathbf{w}$  is the previous weight vector,  $z_i^*$  is the structure found by Eqn. (1),  $y_i \in \{-1, 1\}$  is the example's true label (ungrammatical/grammatical), and  $\tau \geq 0$  is a Lagrange multiplier proportional to the example loss, thus penalizing classification examples in proportion to the extent that they violate the margin (see Alg. 1).

### 3.2 Optimization Method

Since Eqn. (3) contains an inner max over  $z_i^*$ , it is not convex for the positive examples, since it is the maximum of a convex function (zero) and a concave function  $(1 - y_i(\mathbf{w}' \cdot \phi(x_i, z_i^*)))$ . In hinge loss, driving the inner function to higher values minimizes the outer problem for negative examples, but maximizes it for the positives. So, as in LCLR, we hold the latent structures fixed for the positive examples but can perform inference to solve the inner minimization problem for the negatives.

### 3.3 Online Training

Our online training method is shown as algorithm 1. It applies the structured prediction and PA update of section 3 on a per-example basis in a variant of the cutting plane algorithm discussed in

```

1 initialize  $w_0$ 
2 for  $t = 0, \dots, T - 1$  do
3   for each training example  $x_i$  in  $X$  do
4     repeat
5       find  $z_i^* = \arg \max_{z_i} w_t \cdot \phi(x_i, z_i)$ 
6       let  $y_i^* = w_t \cdot \phi(x_i, z_i^*)$ 
7       let loss  $l_t = \max\{0, 1 - y_i y_i^*\}$ 
8       let multiplier  $\tau_t = \frac{l_t}{\|\phi(x_i, z_i^*)\|^2}$ 
9       update  $w_{t+1} := w_t + \tau_t y_i \phi(x_i, z_i^*)$ 
10    until  $y_i > 0$  or ( $y_i^* = y_i$  if  $y_i < 0$ );
11 return  $w_T$ 

```

Algorithm 1: Online PA algorithm for binary classification with latent structures.

Joachims and Yu (2009). Since for the positive examples the latent structures are fixed per-iteration, it does a single search and update step for each example at each iteration. For negative examples it repeats the prediction and PA update for each example until the model correctly predicts the label (i.e. until  $y_i^* = y_i$ ). Because of the intractability to compute all possible negative structures, we use the approximation of the single-best structure for each negative example. We re-decode the negative examples until the highest scoring structure is correctly labeled as negative. This approximation is analogous to the handling of inference over negative examples in the batch algorithm described in Chang et al. (2010). In the batch version, however, updates for all negative examples are performed at once and all are re-decoded until no new structures are found for any single negative example.

### 3.4 Multiple Views on Latent Representations

Shen and Sarkar (2005) find that using multiple chunking representations is advantageous for the chunking task. Moreover, they demonstrate that the careful selection of latent structure can yield more helpful features for a task-specific classifier. We thus perform inference separately to generate distinct latent structures for each of their five chunking representations (which are mostly from (Sang and Veenstra, 1999)) at line 5 of Alg. 1; at line 6 we evaluate the dot product of the weight vector with the features from the combined outputs of the different views.

Each of the views use a different representation of the chunk structures, which we will only briefly describe due to space limitations; for more detailed information, please see Shen and Sarkar (2005). Each representation uses a set of tags to label each token in a sentence as belonging to a non-overlapping chunk type. We refer to the chunking

Token	IOB1	IOB2	IOE1	IOE2	O+C
In	O	O	O	O	O
early	I	B	I	I	B
trading	I	I	I	E	E
in	O	O	O	O	O
Hong	I	B	I	I	B
Kong	I	I	E	E	E
Monday	B	B	I	E	S
,	O	O	O	O	O
gold	I	B	I	E	S
was	O	O	O	O	O
quoted	O	O	O	O	O
at	O	O	O	O	O
\$	I	B	I	I	B
366.50	I	I	E	E	E
an	B	B	I	I	B
ounce	I	I	I	E	E
.	O	O	O	O	O

Table 1: The five different chunking representations for the example sentence “In early trading in Hong Kong Monday , gold was quoted at \$ 366.50 an ounce .”

schemas as IOB1, IOB2, IOE1, IOE2, and O+C. The total set of tags for each of the representations are B- (current token begins a chunk), I- (current token is inside a chunk), E- (current token ends a chunk), S- (current token is in a chunk by itself), and O (current token is outside of any chunk). All chunks except O append the part-of-speech tag of the token as a suffix. Table 1 shows the different chunking schemas on an example sentence.

Each of these chunking schemas can be conceived as a different kind of expert. Of the inside/outside schemas, the IOB variants focus on detecting where a chunk begins; the IOE variants focus on the chunk’s end. O+C gives a more fine-grained representation of the chunking.

We use dynamic programming to find the best chunking for each representation. The features of  $\phi(x, z)$  are 1-, 2-, 3-grams of words and POS tags paired with the chunk tags, as well as bigrams of chunk tags. We use entirely separate chunk tags for each representation. E.g., although each representation uses an “O” tag to indicate a word outside of any phrase, we consider the “O” for each representation to be distinct.

We combine the multiple views in two different ways: 1) we simply concatenate the features from each structured prediction view into a larger feature vector and the weights are trained on the supervised learning task, and 2) before training on the supervised learning task we first convert all representations to a common representation, O+C (since it includes the union of the tagging distinctions from all 5 views, it does not cause loss of

information from any single view), and then we perform a majority vote for each tag in the prediction. We convert the winning sequence of predicted tags back to each representation and concatenate the features from each view as before and train on the supervised learning task.

## 4 Experiments

For the chunkers we used the CONLL 2000 tagset (23 chunk tags), modified for the five chunking representations of (Shen and Sarkar, 2005). We initialized the weights using a perceptron chunker. The chunker-classifier can either be started with a zero weight vector or with weights from training on the chunking task. For the latter, we used weights from supervised discriminative training against gold-standard chunking. To transfer the weights to the classifier, we scaled them to the range of values observed after training the zero-initialized chunker-classifier. For training data we used the English side of the HK Chinese-English parallel corpus, using 50,000 sentences as positive examples. For negative examples we used the pseudo-negative approach of Okanohara and Tsujii (2007): we trained a standard 3-gram language model on the 50,000 sentences plus 450,000 additional sentences from the same corpus. From this we sampled 50,000 sentences to create the negative training data set.

We evaluated the discriminative LMs on the classification task of distinguishing real grammatical sentences from generated pseudo-negative sentences. As test data we used the Xinhua data from the English Gigaword corpus. We used the first 3000 sentences as positive examples. For negative examples we trained a 3-gram LM on the first 500,000 examples (including those used for positive data). We used this 3-gram LM to generate five separate 3000 example negative data sets. To account for random variation due to using pseudo-negatives, results are reported as a mean over the positive data paired with each negative set. We evaluated our algorithms against LCLR as a baseline.<sup>1</sup> Table 2 shows that our online algorithm with

<sup>1</sup>We implemented two batch baselines. The first is a strict implementation of the LCLR algorithm as in Chang et al. (2010), with per-outer-iteration example caching (LCLR); we use a PA large-margin classifier instead of an SVM. However, we found that this algorithm severely overfits to our task. So, we also implemented a variant (“LCLR-variant”) that skips the inference step in the inner loop. This treated the latent structures from the inference step of the outer loop as fixed, but relabeled and updated accordingly until convergence, then resumed the next outer iteration.

Model	Accuracy %
LCLR	90.27
LCLR-variant	94.55
online single-view	98.75
+ multi-view	98.70
+ majority vote	98.78

Table 2: Classification accuracy after 40 outer iterations.

multiple views significantly outperforms the previous approaches. We omit a detailed experimental report of the behaviour of the online algorithm due to lack of space, but our findings were 1) that the batch models were slower to improve than the online versions on test-set accuracy, and 2) the online algorithm requires fewer updates total in training compared to the batch version.

## 5 Related and Future Work

As discussed, our work is most similar to Chang et al. (2010). We expand upon their framework by developing an efficient online algorithm and exploring learning over multiple views on latent representations. In terms of the task, max-margin LMs for speech recognition focus on the word prediction task (Gao et al., 2005; Roark et al., 2007; Singh-Miller and Collins, 2007). This focus is also shared by other syntactic LMs (Chelba and Jelinek, 1998; Xu et al., 2002; Schwartz et al., 2011; Charniak, 2001) which use syntax but rely on supervised data to train their parsers. Charniak et al. (2003) and Shen et al. (2010) use parsing based LMs for machine translation which are not whole-sentence models and they also rely on supervised parsers. Our focus is on using unsupervised latent variables (optionally initialized from supervised data) and training whole-sentence discriminative LMs. Our chunker model is related to the semi-Markov model in Okanohara and Tsujii (2007), but ours can take advantage of latent structures. Our work is related to Cherry and Quirk (2008) but differs in ways previously described.

In future work, we plan to apply our algorithms to a wider range of tasks, and we will present an analysis of the properties of online learning algorithms over latent structures. We will explore other ways of combining the latent structures from multiple views, and we will examine the use of joint inference across multiple latent representations.

## Abstract

Various successful methods for synonym acquisition are based on comparing context vectors acquired from a monolingual corpus. However, a domain-specific corpus might be limited in size and, as a consequence, a query term's context vector can be sparse. Furthermore, even terms in a domain-specific corpus are sometimes ambiguous, which makes it desirable to be able to find the synonyms related to only one word sense. We introduce a new method for enriching a query term's context vector by using the context vectors of a query term's translations which are extracted from a comparable corpus. Our experimental evaluation shows, that the proposed method can improve synonym acquisition. Furthermore, by selecting appropriate translations, the user is able to prime the query term to one sense.

## 1 Introduction

Acquiring synonyms or near synonyms is important for various applications in NLP, like, for example, paraphrasing and recognizing textual entailment (Bentivogli et al., 2009).

For these tasks, lexical resources like WordNet are often used to improve performance. Although these resources provide good coverage in general domains, they lack vocabulary specific to certain domains. Other problems are the limited availability and size of lexical resources for languages other than English.<sup>1</sup>

As a consequence, various previous works (Grefenstette, 1994) among others, suggest to acquire synonyms and other semantically

related words automatically from a monolingual corpus. The key assumption is that semantically similar words occur in similar context.

In general the larger the size of the monolingual corpus, the better and more detailed, we can extract the context, or context vectors for each relevant word (Curran and Moens, 2002). However, in a specific domain, the given monolingual corpus might be limited to a small size which leads to sparse context vectors. Another problem is that even for a specific domain, words can be ambiguous, which makes it unclear for which sense we are searching a synonym. For example, in the automobile domain, the ambiguous Japanese word バルブ (bulb, valve) has the synonyms 電球 (bulb) or 弁 (valve), depending on the meaning intended by the user.<sup>2</sup>

Our work tries to overcome both of these problems by enriching a context vector of a query word using *the context vectors of its translations* obtained from a comparable corpus in a different language. This way, some of the zero entries of a sparse context vector can be filled, and also disambiguation of the query word is possible. For example, if the desired query word is バルブ (bulb, valve), the user can select the auxiliary translation "valve" in order to mark the "valve" sense of the query word. Then, our system enforces the common parts of the context vector of バルブ (bulb, valve) and the context vector of "valve". Subsequently, when comparing the resulting context vector to synonym candidates' context vectors, the synonym 弁 (valve) will get a higher similarity score than the synonym 電球 (bulb).

In two experiments, we compare the proposed method to the baseline method which uses only the context vector obtained from the monolingual corpus. In the first experiment, the proposed method

<sup>1</sup>For example, the coverage of words for the English WordNet is 147,278 words, whereas for Japanese WordNet's coverage is only 93,834 words.

<sup>2</sup>To show the English meaning of a Japanese word, we place the English translations in brackets, directly after the Japanese word.

use all translations of a query term. In the second experiment, we use only the translations related to a certain sense of the query term. In both experiments the proposed method outperforms the baseline method, which suggests that our method is able to overcome sparsity and ambiguity problems.

In the following section we briefly embed our work into other related work. In Section 3, we explain our method in detail, followed by the two empirical evaluations in Section 4. We summarize our contributions in Section 5.

## 2 Related Work

Most work on synonym acquisition like (Grefenstette, 1994; Curran and Moens, 2002; Weeds and Weir, 2005; Kazama et al., 2010; Lin, 1998), contains basically of two steps: context vector extraction, and context vector comparison. In the first step, for the query term and each synonym candidate a context vector is extracted from the monolingual corpus. The context vector contains for example in each dimension how often the word co-occurred with another word in a certain syntactic dependency position. In the second step the query term's context vector is compared with each synonym candidate's context vector, for example by using the cosine similarity.

The problem of sparse context vectors, i.e. many dimensions in the context vector which contain zero entries, can be addressed by truncated Singular Value Decomposition and other matrix smoothing techniques (Turney and Pantel, 2010). We note that these smoothing techniques are complementary to our method since they could be applied after the context vector combination described in Section 3.2.

The additional use of bilingual (or multilingual) resources for synonym acquisition is also considered in (Van der Plas and Tiedemann, 2006) and (Wu and Zhou, 2003). Their work defines the context of word  $w$  in a certain sentence, as the translation of word  $w$ , in the corresponding translated sentence. However, their methods require bilingual (or multilingual) parallel corpora. For a word  $w$ , they create  $w$ 's context vector by using all word translations of  $w$ , wherein the word translations are determined by the word alignment in the parallel corpus. The weighting of each dimension of the context vector is determined by the number of times word  $w$  and its translation are aligned.

The methods described in (Hiroyuki and Morimoto, 2005; Li and Li, 2004) also use comparable corpora and word translations for disambiguating a certain query word. Their methods distinguish word senses by differences in word translations. For example, the senses of plant (factory, vegetation) are distinguished by the translations 工場 (factory) and 植物 (vegetation). Given a text snippet in which the ambiguous word occurs, their methods select the appropriate sense by finding an appropriate translation. In contrast, our method does not use a text snippet to disambiguate the meaning of the query word. Instead, our method uses one or more translations of the query word to find appropriate synonyms. For example, given the query word "plant" and the translation 工場 (factory) we expect to acquire synonyms like "manufacture", "factory" and so forth.

## 3 Proposed Method

We assume the user tries to find a synonym for the query term  $q$  in language A and provides additional translations of term  $q$  in language B. We name these translations as  $v_1, \dots, v_k$ . Furthermore we assume to have a pair of comparable corpora, one in language A and one in language B, and a bilingual dictionary.

We denote  $\mathbf{q}$  as the context vector of the term  $q$  in language A. A context vector  $\mathbf{q}$  contains in each dimension the degree of association between the term  $q$  and another word in language A which occur in the corpus written in language A. Therefore the length of context vector  $\mathbf{q}$  equals the number of distinct words in the corpus. We will use the notation  $\mathbf{q}(x)$  to mean the degree of association between the term  $q$  and the word  $x$  which is calculated based on the co-occurrence of term  $q$  and word  $x$  in the corpus.

We denote  $\mathbf{v}_1, \dots, \mathbf{v}_k$  as the context vectors of the terms  $v_1, \dots, v_k$  in language B. A context vector  $\mathbf{v}_i$ ,  $1 \leq i \leq k$ , contains in each dimension the degree of association between the term  $v_i$  and a word in language B.

### 3.1 Context Vector Translation

In the first step we estimate the translation probabilities for the words in language B to the words in language A for the words listed in the bilingual dictionary. For that purpose, we build a language model for each language using the comparable corpora, and then estimate the translation prob-

abilities using expectation maximization (EM) algorithm described in (Koehn and Knight, 2000). This way we get the probability that word  $y$  in language B has the translation  $x$  in language A, which we denote as  $p(x|y)$ .

We write these translation probabilities into a matrix  $T$  which contains in each column the translation probabilities for a word in language B into any word in language A. We use the translation matrix  $T$ , in order to translate each vector  $\mathbf{v}_i$  into a vector which contains the degree of association to words in language A. We denote this new vector as  $\mathbf{v}'_i$ , and calculate it as follows:

$$\mathbf{v}'_i = T \cdot \mathbf{v}_i \quad (1)$$

This way we get the translated context vectors  $\mathbf{v}'_1, \dots, \mathbf{v}'_k$ .

### 3.2 Context Vector Combination

In the second step, we combine the context vectors  $\mathbf{v}'_1, \dots, \mathbf{v}'_k$  and the context vector  $\mathbf{q}$ . Note that the dimension of a vector  $\mathbf{v}'_i$  and the vector  $\mathbf{q}$  is in general different, since  $\mathbf{v}'_i$  contains only the degree of association to the words listed in the bilingual dictionary.

We could now combine all context vectors additively, similar to monolingual disambiguation like in (Schütze, 1998). However, this would ignore that actually some dimensions are difficult to compare across the two languages. For example, it is difficult to translate the Japanese word *かける* (hang, put, bring,...) because of its many different meanings depending on the context. Therefore we combine the context vectors to a new context vector  $\mathbf{q}^*$  as follows: If a word  $x$  in language A is in the dictionary, we set

$$\mathbf{q}^*(x) := \mathbf{q}(x) + \sum_{i=1}^k \{(1 - c_x)\mathbf{q}(x) + c_x \cdot \mathbf{v}'_i(x)\}, \quad (2)$$

otherwise we set

$$\mathbf{q}^*(x) := (k + 1) \cdot \mathbf{q}(x). \quad (3)$$

$c_x \in [0, 1]$  is the degree of correspondence between word  $x$  and its translations in language B. The intuition of  $c_x$  is that, if there is a one-to-one correspondence between  $x$  and its translations, then we will set  $c_x$  to 1, and therefore consider the context vectors  $\mathbf{v}'_1$  and  $\mathbf{q}$  as equally important to describe the degree of association to word  $x$ . On

the other hand, if there is a many-to-many correspondence, then  $c_x$  will be smaller than 1, and we therefore rely more on the context vector of  $\mathbf{q}$  to describe the degree of association to word  $x$ . In case there is no translation available, we can rely only on the context vector of  $\mathbf{q}$ , and therefore set  $c_x$  to zero, see Formula (3).

Formally we set  $c_x$  as the probability that word  $x$  is translated into language B and then back into word  $x$ :

$$c_x = p(\bullet|x)^T \cdot p(x|\bullet) \quad (4)$$

where  $p(\bullet|x)$  and  $p(x|\bullet)$  are column vectors which contain in each dimension the translation probability from word  $x$  into the words of language B, and the translation probabilities from words in language B to word  $x$ , respectively. These translation probabilities are estimated like Section 3.1.

Finally, note that the vector  $\mathbf{q}^*$  is not rescaled. Depending on the vector comparison method, it might be necessary to normalize the vector  $\mathbf{q}^*$ . However, we will use in our experiments the cosine similarity to compare two context vectors, so the result does not change if we normalize or rescale  $\mathbf{q}^*$  by any non-zero factor.

## 4 Experiments

We extract synonyms from a corpus formed by a collection of complaints concerning automobiles compiled by the Japanese Ministry of Land, Infrastructure, Transport and Tourism (MLIT).<sup>3</sup> Our proposed method additionally consults a comparable corpus which is a collection of complaints concerning automobiles compiled by the USA National Highway Traffic Safety Administration (NHTSA).<sup>4</sup> The Japanese corpus contains 24090 sentences that were POS tagged using MeCab (Kudo et al., 2004). The English corpus contains 47613 sentences, that were POS tagged using Stepp Tagger (Tsuruoka et al., 2005), and use the Lemmatizer (Okazaki et al., 2008) to extract and stem content words (nouns, verbs, adjectives, adverbs).

For creating the context vectors, we use the co-occurrence counts of a word's predecessor and successor from the dependency-parse tree. These co-occurrence counts are then weighted using the

<sup>3</sup><http://www.mlit.go.jp/jidosha/carinf/rcl/defects.html>

<sup>4</sup><http://www-odi.nhtsa.dot.gov/downloads/index.cfm>

log-odds-ratio (Evert, 2004).<sup>5</sup> For comparing two context vectors we use the cosine similarity. The baseline method is the same as the proposed method except that it does not use Formula (2) and (3) to include information from the translations. As a bilingual dictionary, we use a large-sized Japanese-English dictionary with 1.6 million entries.<sup>6</sup>

In the first experiment we assume that the user wants to acquire all synonyms irrespectively of the difference in senses. Therefore, our gold-standard includes all words which occur in the corpus and which belong to any Japanese WordNet (Bond et al., 2009) synset to which the query term belongs. The gold-standard contains in total 234 Japanese words as query terms.<sup>7</sup> Our proposed method uses as auxiliary translations *all* English translations that correspond the query term and that are listed in our bilingual dictionary. For example, for the query term バルブ (bulb, valve), the proposed method uses the translations "bulb" and "valve".

The results in Table 1 (top) show that in average our method improves finding all synonyms for a query. The improvement can be accounted to the effect that our method enriches the sparse context vector of a Japanese query term.

In our second experiment, we assume that the user is interested only in the synonyms which correspond to a certain sense of the query term. For each query term we include into the gold-standard only the words belonging to one synset, which was randomly chosen. For example, for the ambiguous query term バルブ (bulb, valve) the gold-standard includes only the synset { 弁 (valve) }. That corresponds to a user looking for the synonyms of バルブ (bulb, valve) restricted to the sense of "valve". For selecting an appropriate translation, we use the cross-lingually alignment between the synsets of the Japanese and English WordNet (Bond et al., 2009; Fellbaum, 1998). Our proposed method will use as auxiliary translations only the query term's translations *that are listed in the corresponding English synset*. For example, for the query term バルブ (bulb, valve), the proposed method uses only the translation "valve".

The results in Table 1 (bottom) show a clear im-

<sup>5</sup>In preliminary experiments the log-odds-ratio best among other measures like point-wise mutual information, tf-idf and log-likelihood-ratio.

<sup>6</sup>This bilingual dictionary is not (yet) publicly available.

<sup>7</sup>Each query term as in average 2.3 synonyms which might correspond to different synsets in WordNet. In average, a query term's synonyms belong to 1.2 different synsets.

provement in recall by our proposed method. A pair-wise comparison of our proposed method and the baseline shows a statistically significant improvement over the baseline ( $p < 0.03$ ).<sup>8</sup> For example, we found that for the query term バルブ (bulb, valve), the baseline ranks 球 (bulb) at rank 3 and 弁 (valve) at rank 4, whereas the proposed method ranked 弁 (valve) at rank 3, and 球 (bulb) at rank 5. This suggests that our method can also help to disambiguate the context vector of an ambiguous query term.

All Senses					
Method	Top 1	Top 5	Top 10	Top 20	Inv. Rank
Baseline	0.10	0.24	0.29	0.37	0.29
Proposed	0.10	0.24	0.33	0.43	0.32
One Sense					
Method	Top 1	Top 5	Top 10	Top 20	Inv. Rank
Baseline	0.10	0.25	0.30	0.37	0.26
Proposed	0.10	0.26	0.35	0.45	0.30

Table 1: Recall at different ranks and inverse rank for gold-standard which considers all senses (top) and only one sense (bottom) for each query term. Recall at rank  $n$  is the number of correct synonyms which occur in the list from 1 to  $n$ , divided by all correct synonyms for a query. Inverse rank is the sum of the inverse ranks of each correct synonym for a query. All figures are the average over all query terms in the gold-standard.

## 5 Conclusions

We introduced a new method that combines a query term's context vector with the context vectors of the query term's translations acquired from a comparable corpus. This way our method is able to mitigate problems related to a query term's sparse context vector, and also helps to resolve its ambiguity.

The experiments showed that our method can improve synonym acquisition, when compared to a baseline method which does not use any comparable corpus.

We also demonstrated that our method can help to find the synonyms that are related to only one sense of the query term, by appropriately restricting the query term's translations. This way, our method can also be used to automatically populate resources like WordNet in languages different than English.

<sup>8</sup>We use the sign-test (Wilcoxon, 2009) to test the hypothesis that the proposed method ranks higher than the baseline.

# Exploring Verb Frames for Sentence Simplification in Hindi

Ankush Soni Sambhav Jain Dipti Misra Sharma

Language Technologies Research Centre

IIIT Hyderabad

{ankush.soni, sambhav.jain}@research.iiit.ac.in, dipti@iiit.ac.in

## Abstract

Systems processing on natural language text encounters fatal problems due to long and complex sentences. Their performance degrades as the complexity of the sentence increases. This paper addresses the task of simplifying complex sentences in Hindi into multiple simple sentences, using a rule based approach. Our approach utilizes two linguistic resources viz. verb demand frames and conjuncts' list. We performed automatic as well as human evaluation of our system.

## 1 Introduction

Cognitive and psychological studies, performed on 'human reading' states that the effort in reading and understanding a text increases with the sentence complexity (Klein and Kurkowski, 1974). The modern natural language processing applications are not much different, in this respect, from humans. Processing complex sentences with high accuracy has always been a challenge in computational linguistics. This calls for techniques aiming at automatic simplification of sentences (Chandrasekar et al., 1996).

The sentence complexity can be mainly classified into 'lexical complexity' and 'syntactic complexity'. In context of natural language applications, lexical complexity can be handled significantly by utilizing various resources like lexicons, dictionary, thesaurus etc. and substitute infrequent words with their frequent counterparts (De Belder et al., 2010). To address syntactic complexity, one can analyse the structure of the sentence and then apply proper operations to simplify the structure.

There are many applications of sentence simplification in NLP applications. Machine Translation systems when dealing with highly diverge language pairs face difficulty in translating long and complex sentences.

For Parsing, it has been shown by McDonald and Nivre(2007) that syntactic parsing of long sentence and Identifying long distance dependencies is still a challenging task for modern day parsers. So, it looks intuitive to break down the sentence into smaller parts and use the simplified sentences for the task of parsing and Machine translation.

In case of Automatic summarization, after simplifying sentences, it is likely that the accuracy of sentence extraction based summarization systems improves as smaller units of information are being extracted.

We present a rule based approach for sentence simplification in Hindi. Our proposed system takes a sentence and returns a set of simple sentences, smaller in length. We have taken care to produce sentences which keep the meaning close to the original sentence.

This paper is structured as follows: In Section 2, we discuss the related works for sentence simplification. Section 3 talks about complex sentence. Section 4 describes the linguistic resources we used. In section 5, we discuss our algorithm. Section 6 outlines evaluation of the system. In section 7, results are being talked about. Section 8 gives the error analysis and in Section 9, we conclude and talk about future works in this area.

## 2 Related Work

Chandrasekar et al.(1996) proposed Finite state grammar and Dependency based approach for sentence simplification. Automatic induction of rules for text simplification is discussed by Chandrashekar and Srinivas (1997). A pipelined approach for text simplification has been presented by (Siddharthan, 2002). Sudoh et al. (2010) proposed divide and translate technique to address the issue of long distance reordering for machine translation. Doi and Sumita (2003) used splitting techniques for simplifying sentences and then utilizing the output for machine translation. Poorn-

ima et al. (2011) proposed a rule based Sentence Simplification for English to Tamil Machine translation system.

Though several attempts, in the past, have been carried out for English, we find few work on other languages. We find, no reported work on sentence simplification for Hindi, which is the language under focus in our work.

### 3 Complex Sentence

Here we are addressing sentence complexity in the context to NLP applications, and our objective is to propose resolutions which could, in general, assist and improve the performance of the NLP systems. In general, complex sentences have more than one clause (Kachru, 2006) and these clauses are combined using connectives. In the context of dependency parsing, it has been illustrated by McDonald and Nivre(2007) that the sentence length increases the complexity of a sentence, as it is difficult to process on larger sentences. On experimenting for the Hindi language, we found that as the length of the sentence increases, number of verb chunks in the sentence also increases. Based on the above observation, we consider number of verb chunks as a criterion to define complex sentences. Also, we encounter the presence of conjuncts in long sentences and concede it as the second criterion representing a complex sentence.

To consolidate, for our approach we consider a sentence to be complex based on the following criteria:

- Criterion1 : Length of the sentence is greater than 5.
- Criterion2 : Number of verb chunks in the sentence is more than 1.
- Criterion3 : Number of conjuncts in the sentence is greater than 0.

Table 1 shows classification of a sentence based on the possible combinations of 3 criteria mentioned above.

### 4 Linguistic Resources

A list of conjuncts and verb frames form crucial resources for splitting a complex sentence into simple sentences.

Table 1: Classification of a sentence as simple or complex

Criterion1	Criterion2	Criterion3	Category
No	No	No	Simple
No	No	Yes	Simple
No	Yes	No	Simple
No	Yes	Yes	Simple
Yes	No	No	Simple
Yes	No	Yes	Complex
Yes	Yes	No	Complex
Yes	Yes	Yes	Complex

Table 2: verb-frame

arc-label	necessity	vibh(Case)	lex-cat	src-pos
<i>k1</i> (Doer)	mandatory	0	noun	1
<i>k2</i> (Experiencer)	mandatory	0	noun	1

#### 4.1 Connectives and Conjuncts List

Coordinating conjuncts are used to conjoin two independent clauses. Hindi coordinating conjuncts includes (*ora, athva, yaa, evam, para, magara, lekina, kintu, parantu, tatha, jabaki, va*). On the basis of the conjuncts joining two independent clauses we split the sentence for simplification.

#### 4.2 Verb Frames

Verb frames or verb subcategorization frames, categorizes the verb on the basis of their argument demands. For Hindi, verb frames have been discussed in Begum et al. (2008) . The verb frames show mandatory *karaka*<sup>1</sup> relation for a verb, i.e, the arguments of a verb. Verb demand frame is represented in a tabular form shown in Table 2. A verb frame shows :

1. *karaka* : dependency arc labels
2. *Necessity* of the argument ( mandatory(m) or optional(o) )
3. *Vibhakti* : post-position or the case associated with the nominal
4. *Lexical category* of the arguments.
5. *Position* of the demanded nominal with respect to verb (left(l) or right(r))

The Verb demand frames are built for the base form of a verb. The demands undergo a subsequent change based on the *tense, aspect* and *modality* (TAM) of the verb used in the sentence. The knowledge about the transformations induced on the base form of a verb by TAM is stored in

<sup>1</sup>*karakas* are the typed dependency labels in Computational Paninian Framework(Bharati and Sangal, 1993)

form of *transformation charts* for each distinct TAM.

## 5 Sentence Simplification Algorithm

We present a rule based method for simplification of complex sentences. Our approach comprises two stages. The work flow of our approach is shown in Figure 1. In the first stage, we get the structural representation of the input using shallow parser.

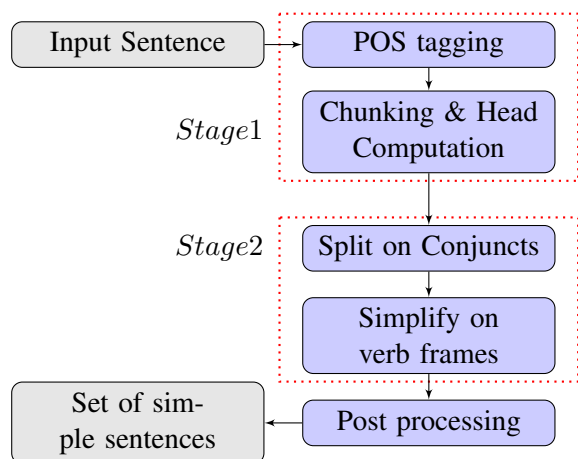

Figure 1: Flow-chart showing the work flow of sentence simplification system.

In the second stage, by applying predefined rules on the output of first stage, we identify the complexity in the sentence and simplify them on the basis of Conjuncts' list and Verb frames

### 5.1 Splitting on Conjuncts

In the first module, we split the sentence on the basis of Conjuncts. We identify the conjunct joining two independent clauses, break the sentence and pass it on to the second module for further simplification.

### 5.2 Simplification using Verb frames

After splitting the sentences on the basis of conjuncts, we simplify the generated sentences if they are complex. Once the type of sentence (complex or simple) is identified, multiple simple sentences are generated by converting non-finite verbs(VGNF) and gerunds(VGNN) to finite verb (VGF). Generally the arguments of VGNF and VGNN are shared with the main verb, therefore it is difficult for a machine to identify the implicit arguments of those verb and thus breaking the sen-

Table 3: karaka chart

arc-lbl	necessity	vibh	lex-cat	src-pos
k1	mandatory	0	noun	1
k2	mandatory	0	noun	1

tence and assigning arguments of those verbs explicitly helps in simplifying the sentence.

For conversion of VGNF to VGF, first, the head of the chunk (VGNF) is identified using shallow parser output. Verb frame of the root form of non-finite verb is used and transformations are carried out in accordance with the TAM of the finite verb of main clause. We follow the similar procedure in case of conversion from VGNN to VGF, with a difference that pronouns are generated in the place of VGNN.

Example of VGNF:

**Input:**

- (1) *ram khana khakar mohana ko bulata*  
 ram food eat-do mohana call  
*hai*  
 is

'After eating food, Ram calls for Mohana'

**Output:**

- (2) a. *ram khana khata hai*  
 ram food eat is  
 'Ram eats food'
- b. *ram mohana ko bulata hai*  
 ram mohana calls is  
 'Ram calls mohana'

In Input there is a VGNF (*khakar*), and needs to be converted to VGF

Here, in Input root word of *khakar* is '*kha*' and TAM of VGF in main clause is '*ta - hai*'. Verb frame of '*kha*' with '*ta*' as TAM is shown in Table 3:

Here, we can see that '*kha*' has 2 requirements 'k1' and 'k2' and both should be to the left of the verb as indicated by src-pos column. So, we will look for the argument to the left of the verb and accordingly form a sentence. For the verb '*kha*' in Input, '*Ram*' will act as k1 and '*khaana*' will act as k2. Now, we are left with a finite verb '*bulata*'. For the verb - '*bulata*' in Input, *Ram* will act as 'k1' and '*Mohana ko*' will act as 'k2'

with mandatory vibhakti 'ko'. As we can see here, *Ram* is the shared argument.

Example for VGNN

**Input:**

- (3) *karyasthalon para anusashana*  
workplaces at discipline  
*banae rakhna jaruri hai*  
maintain important is  
'It is important to maintain discipline at workplaces.'

**Output:**

- (4) a. *anusashana banana hai*  
discipline maintain is  
'Discipline is to be maintained'  
b. *karyasthalon para yah behad*  
workplaces at this very  
*jaruri hai*  
important is  
'This is very important at workplaces.'

Here '*banae rakhna*' is VGNN chunk with '*banana*' as verb and '*rakhna*' as auxiliary verb.

## 6 Evaluation

The evaluation of sentence simplification task is a difficult problem. The evaluation should address the following two factors: Readability (Adequacy and fluency) and Simplification. To consider these factors we perform both automatic as well as human evaluation.

### 6.1 Data

Our testing data set consists of 100 complex sentences taken randomly from the Hindi treebank (Bhatt et al., 2009; Palmer et al., 2009).

### 6.2 Automatic Evaluation

We used BLEU score (Papineni et al., 2002) for automatic evaluation of our system. Higher the BLEU score, closer the target set is to the reference set. The maximum attainable value is 1 while minimum possible value is 0.

For our Automatic evaluation we adopted the same technique as Specia (2010) using BLEU metric. We performed these 3 tests:

1. Computing BLEU Score between target set and reference set.
2. Computing BLEU Score between source set

Table 4: Bleu-score for the 3 data sets

System	Gold	Bleu-score
Target	Reference	0.805
Source	Reference	0.771
Target	Source	0.750

and reference set.

3. Computing BLEU Score between target set and source set.

## 6.3 Human Evaluation

To ensure the simplification quality subjective evaluation was done by human subjects. 20 sentences were randomly selected from the testing data-set of 100 sentences. Output of these 20 sentences, from the target set were manually evaluated by 3 subjects, who have done basic course in linguistics, for judging 'Readability' and 'Simplification' quality on the scale of 0–3, 0 being worst to 3 being the best for readability.

For Simplification performance, scores were given according to following criteria :

- 0 = None of the expected simplifications performed.
- 1 = Some of the expected simplifications performed.
- 2 = Most of the expected simplifications performed.
- 3 = Complete Simplification.

After taking input from all the participants the results are averaged out and shown in the section 7.2.

## 7 Results

### 7.1 Automatic Evaluation

Table 4 presents the result from automatic evaluation conducted on the lines of Specia (2010).

As it is evident from the results shown, that reference set matches more to target set (**0.805**) than to source set (**0.771**). From this we can conclude that simplification performed by our system is likely to be correct.

### 7.2 Human Evaluation

The readability and simplification score averaged over the three subjects is **1.85** and **2.07** respectively.

## 8 Error Analysis

Out of the 100 sentences put to test, 61 sentences are simplified by the system. 23 cases out of the unhandled cases were already simple as per our definition in section 3. On closer inspection we find 9 out of the remaining 16 unhandled cases are due to the presence of ‘complex predicates’. Complex predicates occur in form of nominal+verb combination and thus have a generative property. Due to their generative nature it is practically challenging to create verb demand frames for them. The remaining 7 cases are found to have POS and Chunking errors. On manually evaluating the output it was found that the quality of the output is affected by the dependency relations of arguments. The verb frame cannot capture the dependency of the required arguments thus leaving out few of the important dependencies.

## 9 Conclusion and Future Work

We present a rule based system for sentence simplification in Hindi. Our evaluation results show an average readability of **1.85** in the scale of 0-3, while **2.07** on the scale of 0-3 in system performance on simplification. Given the fact that this is the first attempt for Hindi we find our results satisfactory and have reason to believe that such a system will be beneficial in NLP Applications like parsing and MT. In the future our immediate effort would be on handling the complex predicates. We would like to try heuristics to capture the dependencies of the argument of verbs. We would also like to evaluate the impact of our tool on MT and parsing in the future.

## Acknowledgements

We would like to thank Kunal Sachdeva, Rahul Sharma, Rajesh Chaturvedi, Rishabh Srivastava and Riyaz Ahmad Bhat for their useful comments and feedback which helped to improve this paper.

## Abstract

This paper presents a joint model for learning morphology and part-of-speech (PoS) tags simultaneously. The proposed method adopts a finite mixture model that groups words having similar contextual features thereby assigning the same PoS tag to those words. While learning PoS tags, words are analysed morphologically by exploiting similar morphological features of the learned PoS tags. The results show that morphology and PoS tags can be learned jointly in a fully unsupervised setting.

## 1 Introduction

The morphology of a word is an important indicator that determines its PoS tag, meanwhile the PoS tag of a word helps in identifying the correct morphological segmentation of the word. This relationship between morphology and syntax has been beneficial in both morphology learning with the exploitation of the syntactic features and in PoS tagging with the adoption of morphological features.

There has been a number of research that have performed PoS tagging by making use of morphological information (Clark (2003), Hasan and Ng (2009), Abend et al. (2010), Christodoulopoulos et al. (2011), etc.). There has been also a number of other research that have performed morphological segmentation by adopting syntactic information (Hu et al. (2005), Can and Manandhar (2009), Lee et al. (2011), etc.). However, there is a small number of research that combines two tasks in a single framework.

Sirts and Alumäe (2012) share a similar goal

with us in joining PoS tagging and morphological segmentation in a single framework. They use hierarchical Dirichlet process for infinite HMMs to induce both PoS tags and morphological segmentation. Their model is type-based, whereas our model is token based. In our model, we use finite mixture models for PoS tagging and Dirichlet processes for segmentation.

## 2 Model Definition

The generative story of the model goes as follows:

1. Draw a PoS tag  $c_i$ .
2. Generate a word  $w_i$  that belongs to  $c_i$ .
3. Generate the context  $c_{i-1,i+1}$  of the word  $w_i$  from  $c_i$ .
4. From the possible splits of  $w_i$ , generate a suffix  $m_i$  conditioned on  $c_i$ , such that  $w_i = s_i + m_i$ , where  $s_i$  denotes the stem.

The generative story is summarised as follows:

$$p(c_i, c_{i-1,i+1}, w_i, s, m) = p(c_i)p(c_{i-1,i+1}|c_i) \\ p(w_i|c_i)p(m|c_i)p(s)$$

### 2.1 PoS Tagging

The model adopts a finite mixture model for PoS tagging (see Figure 1). Each mixture component represents a PoS tag that shares a set of features with other members in the same component. Each mixture component  $c_i$  consists of 1. a distribution over contexts and 2. a distribution over words. Each context is a PoS tag pair  $\langle c_{i-1}, c_{i+1} \rangle$  where the previous word  $w_{i-1}$  belongs to  $c_{i-1}$  and the following word  $w_{i+1}$  belongs to  $c_{i+1}$ . We employ a token-based approach for PoS tagging due to the significance of the context. The model is

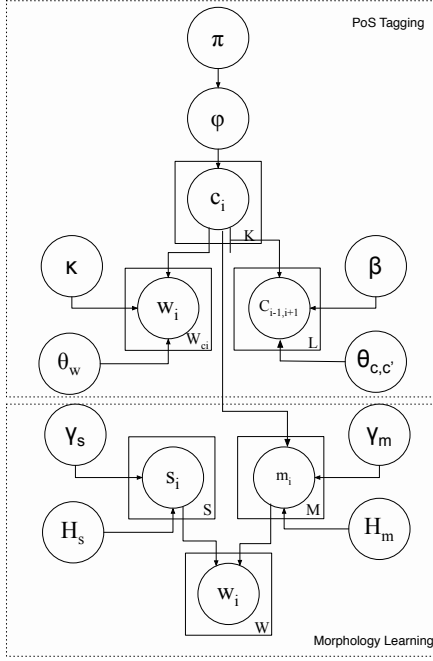

Figure 1: The complete joint model.

defined formally as follows:

$$c_i \sim \text{Mult}(\phi) \quad (1)$$

$$\phi \sim \text{Dir}(\pi) \quad (2)$$

$$w_i | c_i \sim \text{Mult}(\theta_w) \quad (3)$$

$$\theta_w \sim \text{Dir}(\kappa) \quad (4)$$

$$c_{i-1,i+1} | c_i \sim \text{Mult}(\theta_{c,c'}) \quad (5)$$

$$\theta_{c,c'} \sim \text{Dir}(\beta) \quad (6)$$

Class indicators  $c_i$  are drawn from a Multinomial distribution with parameters  $\phi$  (which have a Dirichlet prior distribution with hyperparameters  $\pi$ ). Each  $c_i$  involves a set of words  $w_i$  drawn from a Multinomial distribution with parameters  $\theta_w$  (which have a Dirichlet prior distribution with hyperparameters  $\kappa$ ). Each  $c_i$  also involves a distribution over contexts  $c_{i-1,i+1}$  drawn from a Multinomial distribution with parameters:  $\theta_{c,c'}$  (which have a prior distribution with hyperparameters  $\beta$ ).

## 2.2 Morphology Learning

We model morphology using a Dirichlet process (DP) in order to split each word into a stem and a suffix (see Figure 1). Stems are generated by  $DP(\gamma_s, H_s)$  with concentration parameter  $\gamma_s$  and base distribution  $H_s$ , whereas suffixes are generated by  $DP(\gamma_m, H_m)$  with concentration parameter  $\gamma_m$  and base distribution  $H_m$ . Hence, the

model is defined formally as follows:

$$s_i \sim DP(\gamma_s, H_s)$$

$$m_i | c_i \sim DP(\gamma_m, H_m)$$

Base distributions are length priors that favour shorter morphs (Creutz and Lagus, 2005):

$$H_x(x_i) = p(c_{ij})^{|x_i|} \quad (7)$$

where  $x_i$  is a morph and  $|x_i|$  is the length of  $x_i$  in letters. Each character has a probability of  $p(c_{ij})$ , where characters are assumed to be distributed uniformly in the alphabet. We also assume that each morph ends with a special character; i.e. end of morph marker.

Here,  $DP(\gamma_s, H_s)$  is a global Dirichlet process where stems may belong to any PoS tag, whereas  $DP(\gamma_m, H_m)$  is defined locally for each PoS tag. The reason is that stems are shared amongst different PoS tags. However, words belonging to the same PoS tag usually have similar endings, thereby leading to local distributions.

## 3 Inference

In our model, we assign values to the hyperparameters  $\pi, \kappa, \beta, \gamma_s, \gamma_m$  empirically, and we integrate out the parameters  $\phi, \theta_w, \theta_{c,c'}$  by using the Multinomial-Dirichlet conjugacy.

We use Gibbs sampling to infer POS tags, stems and suffixes. We perform inference in two steps: 1. a PoS tag is sampled for the word, 2. a stem and a suffix are sampled for the word.

### 3.1 Inferring PoS tags

Each word's PoS tag is sampled subject to its context. Let a word be  $w_i$  and imagine that it occurs in context  $\langle w_{i-1}, w_{i+1} \rangle$  where  $w_{i-1}$  belongs to  $c_{i-1}$  and  $w_{i+1}$  belongs to  $c_{i+1}$ . We define the sampling probability of  $c_i$  for  $w_i$  as follows:

$$p(c_i | \langle w_{i-1}, w_{i+1} \rangle, w_i) \propto \frac{p(\langle w_{i-1}, w_{i+1} \rangle, w_i | c_i) p(c_i)}{p(w_i | c_i) p(\langle w_{i-1}, w_{i+1} \rangle | c_i)} p(c_i)$$

We also assume that  $\langle w_{i-1}, w_{i+1} \rangle$  and  $w_i$  are independent since it is possible to remove  $w_i$  from  $\langle w_{i-1}, w_{i+1} \rangle$  and insert another word instead.

In order to calculate  $p(w_i | c_i)$ ,  $w_i$  is removed from the corpus:

$$p(w_i | c_i^{-w_i}, \kappa) = \frac{n_{w_i, c_i^{-w_i}} + \kappa}{N_{c_i}^{-w_i} + W_{c_i}^{-w_i} \alpha} \quad (8)$$

where  $c_i^{-w_i}$  denotes the mixture component  $c_i$  that excludes  $w_i$ ,  $n_{w_i, c_i^{-w_i}}$  is the number of the word-tag pairs  $\langle w_i, c_i \rangle$ ,  $N_{c_i}^{-w_i}$  is the number of word

Figure 2: Many-to-1 accuracy scores obtained from corpora of size 24K, 36K, 48K, 60K, 72K, 84K, 96K, 120K, and 250K.

tokens having the PoS tag  $c_i$ ,  $W_{c_i}^{-w_i}$  is the number of word types that are tagged with  $c_i$ .  $p(c_i)$  is computed as follows:

$$p(c_i | \mathbf{c}^{-w_i}, \pi) = \frac{n_{c_i}^{-w_i} + \pi}{N^{-w_i} + K\pi} \quad (9)$$

where  $N^{-w_i}$  denotes the number of word tokens in the model excluding  $w_i$ ,  $K$  is the number of class indicators (i.e. number of PoS tags).

In order to mitigate the sparsity within the context probabilities, we use the approximation introduced by Clark (2000):

$$p(\langle w_{i-1}, w_{i+1} \rangle | c_i) = \frac{p(\langle c_{i-1}, c_{i+1} \rangle | c_i)}{p(w_{i-1} | c_{i-1})p(w_{i+1} | c_{i+1})} \quad (10)$$

where,  $p(\langle c_{i-1}, c_{i+1} \rangle | c_i)$  is computed such that:

$$p(\langle c_{i-1}, c_{i+1} \rangle | c_x, c_y, c_z, c_i, \beta) = \frac{n_{c_{i-1}, c_i, c_{i+1}} + \beta}{k_{c_i} + L\beta} \quad (11)$$

Here,  $c_x$  is  $c_i^{-\langle c_{i-1}, c_{i+1} \rangle}$ ,  $c_y$  is  $c_{i-1}^{-\langle c_{i-2}, c_i \rangle}$ ,  $c_z$  is  $c_{i+1}^{-\langle c_i, c_{i+2} \rangle}$ ,  $k_{c_i}$  is the number of contexts in  $c_i$ , and  $L$  denotes the possible number of different contexts in the model (i.e.  $K * K$ ).

### 3.2 Inferring Morphology

Two latent variables are inferred for morphology: stems and suffixes. The sampling probability for morphology is defined as follows:

$$p(w_i = s_i + m_i | s^{-i}, \mathbf{m}_{c_i}^{-i}) = p(s_i | s^{-i})p(m_i | \mathbf{m}_{c_i}^{-i}) \quad (12)$$

where  $s^{-i}$  is the set of stems excluding  $s_i$ ,  $\mathbf{m}_{c_i}^{-i}$  is the set of suffixes assigned with  $c_i$  excluding  $m_i$ .

The conditional probability of a stem is:

$$p(s_i | s^{-i}, \gamma_s, H_s) = \frac{f^{s^{-i}} + \gamma_s H_s(s_i)}{T^{s^{-i}} + M^{s^{-i}} \gamma_s} \quad (13)$$

Figure 3: Variation of Information (VI) obtained from corpora of size 24K, 36K, 48K, 60K, 72K, 84K, 96K, 120K and 250K.

where  $f^{s^{-i}}$  is the frequency of the stem type  $s_i$  already generated,  $T^{s^{-i}}$  is the number of all stems in the model, and  $M^{s^{-i}}$  is the number of stem types generated excluding  $s_i$ . Similarly, the conditional probability of a suffix is computed as follows:

$$p(m_i | \mathbf{m}_{c_i}^{-m_i}, \gamma_m) = \frac{f_{c_i}^{m^{-i}} + \gamma_m H_m(m_i)}{T_{c_i}^{m^{-i}} + M^{m^{-i}} \gamma_m} \quad (14)$$

where  $f_{c_i}^{m^{-i}}$  is the frequency of the suffix type  $m_i$  already generated in  $c_i$ ,  $T_{c_i}^{m^{-i}}$  is the number of all suffixes assigned with PoS tag  $c_i$ , and  $M^{m^{-i}}$  is the number of suffix types already generated excluding  $m_i$ .

In the algorithm, initially each word is assigned a PoS tag and split randomly. The algorithm goes through each word by sampling a PoS tag, a stem, and a suffix. All constituents of the respective word (tag, stem, suffix, context, contexts of adjacent words) are removed from the model beforehand. This process is repeated for a number of iterations until a convergence is ensured.

## 4 Experiments & Evaluation

We used small portions of the Penn WSJ treebank (Marcus et al., 1993) for the experiments. We manually set the hyperparameters and concentration parameters for each experiment:  $\pi = 10^{-6}$ ,  $\beta = 10^{-6}$ ,  $\kappa = 10^{-6}$ ,  $\gamma_s = 10^{-6}$ ,  $\gamma_m = 10^{-6}$ . These values were set empirically through several experiments. We also inserted a special character at the end of each sentence and assigned it a distinct PoS tag. No other words could be assigned this tag.

### 4.1 PoS Tagging Results

In our experiments we fixed the number of PoS tags to 45, which is the number of PoS tags in

	V-measure	Many-to-one
Christ.1 <sup>1</sup>	48.6	57.8
Joint	41.11	59.67
Clark <sup>2</sup>	63.8	68.8
Christ.2 (Best Pub.) <sup>3</sup>	67.7	72.0

<sup>1</sup> Christodoulopoulos et al. (2011)

<sup>2</sup> Clark (2003)

<sup>3</sup> Christodoulopoulos et al. (2010)

Table 1: PoS tagging scores.

	missing	extra	wrong	correct
Joint	0.72%	28.55%	10.13%	60.60%
Morfessor	15.07%	7.23%	10.22%	67.48%

Table 2: Morphological segmentation scores.

Penn WSJ treebank. We applied many-to-one accuracy by assigning each result tag a gold standard tag having the highest frequency among the words assigned with this result tag (see Figure 2). Second, we applied one-to-one accuracy which have similar results with many-to-one scores.

We also measured the variation of information (VI) (Rosenberg and Hirschberg, 2007) (see Figure 3). Although there is not a smooth decrement in VI measure, it improves with the larger datasets in average<sup>1</sup>.

Results show that determiners, modal verbs, prepositions, pronouns, conjunctions, and numbers are discovered generally correctly. The most common error type is due the confusion of nouns and adjectives. Normally, nouns are distributed over several PoS tags. Verbs and adverbs are also generally confused and spread over different tags.

We report our results with a comparison to other systems in Table 1 by using a dataset of 250K words. We use a small portion of Penn WSJ treebank for the comparison. The dataset involves 250K words where the number of word types is 20957. The other systems are also tested on a small portion of WSJ involving 16850 word types, which is reported in Christodoulopoulos et al. (2011).

Our system outperforms Christodoulopoulos et al. (2011) with the many-to-one evaluation, whereas Christodoulopoulos et al. (2011) perform better than our system based on V-measure evaluation. It should be noted that Clark (2003) and Christodoulopoulos et al. (2010) are both type-based.

<sup>1</sup>Although, Figure 3 shows that results for 36k words are better than results for 48k words, this could be due to the particular choice of training sets we used.

Figure 4: Confusion matrix shows the correlation between found morphs and true morphs. The shades reflect the number of matchings.

## 4.2 Morphological Segmentation Results

We performed the evaluation of morphological segmentation on verbs. We adopted some heuristics that strip off common verb endings such as *-ed*, *-d*, *-ing*, *-s*, *-es* from verbs in order to build the gold standard. Irregular verbs are introduced exceptionally and left as they are.

The results obtained from the 96K setting were used for the evaluation. We ran Morfessor Baseline (Creutz and Lagus, 2002; Creutz and Lagus, 2005; Creutz and Lagus, 2007) on the verbs in the same dataset. Table 2 gives the scores where *missing types* refers to the case that gold standard suggests a suffix but no suffix is identified in the results, *extra suffixes* means that gold standard does not identify any suffixes but the results contain suffixes, *wrong suffixes* implies that both gold standard and results identify suffixes but they are not the same, and *correct types* means that both gold standard and results contain suffixes and they match. Our model identifies 12257 suffix types, whereas Morfessor Baseline identifies 2309 due to undersegmentation. In addition, confusion matrix that depicts the result morphs against true morphs is given in Figure 4.

## 5 Conclusion

We proposed a model that jointly learns PoS tags and morphology. The results show that learning PoS tags and morphology can be performed cooperatively.

## Abstract

We report on experiments designed to investigate the role of syntactic features in the task of quality estimation for machine translation, focusing on the effect of parser accuracy. Tree kernels are used to predict the segment-level BLEU score of English-French translations. In order to examine the effect of the accuracy of the parse tree on the accuracy of the quality estimation system, we experiment with various parsing systems which differ substantially with respect to their Parseval f-scores. We find that it makes very little difference which system we choose to use in the quality estimation task – this effect is particularly apparent for source-side English parse trees.

## 1 Introduction

Much research has been carried out on quality estimation (QE) for machine translation (MT) (Blatz et al., 2003; Ueffing et al., 2003; Specia et al., 2009; Callison-Burch et al., 2012), with the aim of solving the problem of how to accurately assess the quality of a translation without access to a reference translation. Approaches differ with respect to the nature of the quality scores being estimated (binary, 5-point or real-valued scales; human evaluations versus automatic metrics), the learning algorithms used or the feature set chosen to represent the translation pairs. The aspect of the task that we focus on is the feature set, and, in particular, the role of syntactic features. We ask the following: *To what extent is QE for MT influenced by the quality of the syntactic information provided to it? Does the accuracy of the parsing model used to provide the syntactic features influence the accuracy of the QE system?* We compare two pairs of parsing systems which differ with respect to their Parseval f-scores by around 17 absolute points in

a QE system for English-French MT and find that it makes little difference which system we use.

## 2 Related Work

Features extracted from parser output have been used before in QE for MT. Quirk (2004) uses a feature which indicates whether a full parse for a sentence can be found. Gamon et al. (2005) use part-of-speech (POS) tag trigrams, CFG production rules and features derived from a dependency analysis of the MT output. Specia and Giménez (2010) use POS tag language model probabilities of the MT output 3-grams. Hardmeier et al. (2012) combine syntactic tree kernels with surface features to produce a system which was ranked second in the WMT 2012 shared task on QE for MT (Callison-Burch et al., 2012). Rubino et al. (2012) explore source syntactic features extracted from the output of a hand-crafted broad-coverage grammar/parser and a statistical constituency parser. Avramidis (2012) builds models for estimating post-editing effort using syntactic features such as parse probabilities and label frequency. Like Hardmeier et al. (2012), we use tree kernels to represent the output of a parser, but unlike all the previous works, we explicitly examine the role of parser accuracy.

There have been some attempts to investigate the role of parser accuracy in downstream applications. Johannson and Nugues (2007) introduce an English constituency-to-dependency converter and find that syntactic dependency trees produced using this converter help semantic role labelling more than dependency trees produced using an older converter despite the fact that trees produced using the older converter have higher attachment scores than trees produced using the new converter. Mollá and Hutchinson (2003) find significant differences between two dependency parsers in a task-based evaluation involving an answer extraction system but bigger differences be-

tween the two parsers when evaluated intrinsically. Quirk and Corston-Oliver (2006) demonstrate that a syntax-enhanced MT system is sensitive to a decrease in parser accuracy obtained by training the parser on smaller training sets. Zhang et al. (2010) experiment with a different syntax-enhanced MT system and do not observe the same behaviour. Both Miyao et al. (2008) and Goto et al. (2011) evaluate a suite of state-of-the-art English statistical parsers on the tasks of protein-pair interaction identification and patent translation respectively, and find only small (albeit sometimes statistically significant) differences between the parsing systems. Our study is closest to that of Quirk and Corston-Oliver (2006) since we are taking one parser and using it to train various models with different training set sizes.

### 3 Parsing

For parsing we use the LORG parser (Attia et al., 2010)<sup>1</sup> which learns a latent-variable probabilistic context-free grammar (PCFG-LA) from a treebank in an iterative process of splitting the treebank non-terminals, estimating probabilities for the new rules using Expectation Maximization and merging the less useful splits (Petrov et al., 2006), and which parses using the max-rule parsing algorithm (Petrov and Klein, 2007).

In order to investigate the effect of parsing accuracy, we train two parsing models – one “higher-accuracy” model and one “lower-accuracy” model – for each language. We use training set size to control the accuracy. For English, the higher-accuracy model is trained on Sections 2-21 of the Wall Street Journal (WSJ) section of the Penn Treebank (PTB) (Marcus et al., 1994) (approx 40k sentences). For French, the higher-accuracy model is trained on the training section of the French Treebank (FTB) (Abeillé et al., 2003) (approx 10k sentences). For the lower-accuracy models, we first select four random subsets of varying sizes from the larger training sets for each language<sup>2</sup> and measure the performance of the resulting models on the standard parsing test sets<sup>3</sup> using Parseval  $F_1$  – see Table 1. All parsing models are trained with 5 split/merge cycles.

The worst-performing models for each language are those trained on 100 training sentences.

<sup>1</sup><https://github.com/CNGLdlab/LORG-Release>

<sup>2</sup>Each smaller subset is contained in all the larger subsets.

<sup>3</sup>WSJ Section 23 and the FTB test set.

However, these models fail to parse about 10 and 2 percent of our English and French data respectively. Since the failed sentences are not necessarily parallel in the source and translation sides, this could affect the downstream QE performance. Therefore, we opt to employ as our “lower-accuracy” models the second smallest training set sizes, which are 1K sentences for English and 500 for French. For both languages, the difference in  $F_1$  between the lower-accuracy and higher-accuracy models is about 17 points. In order to measure how different the parses produced by these models are on our QE data, we compute their  $F_1$  relative to each other. The  $F_1$  for the English model pair is 71.50 and for French 63.19.

### 4 Quality Estimation

To minimise the effect of domain variation, we use a QE dataset for the domain on which our parsers have been trained (newswire). Since there are very few human QE evaluations available for English-French in this domain, we instead attempt to predict automatic metric scores. We experiment with BLEU, METEOR and TER, but due to space restrictions and the similar behaviour observed, we report only BLEU score predictions. We randomly select 4500 parallel segments from the News development data sets released for the WMT13 translation task.<sup>4</sup> To remain independent of any one MT system, we translate the dataset with the following three systems, randomly choosing 1500 distinct segments from each:

- ACCEPT<sup>5</sup>: a phrase-based Moses system trained on training sets of WMT12 releases of Europarl and News Commentary plus data from Translators Without Borders (TWB)
- SYSTRAN: a proprietary rule-based system
- Bing<sup>6</sup>: an online translation system

The translations are scored at the segment level using segment-level BLEU. The data set is randomly split into 3000 training, 500 development, and 1000 test segments. Model parameters are tuned using the development set.

We encode syntactic information using tree kernels (Collins and Duffy, 2002; Moschitti, 2006) because they allow us to use all subtrees of the

Table 1: Parser  $F_1$ s for various training set sizes: the sizes in bold are selected for the experiments.

parsed sentences as features in an efficient way, thus obviating the need for manual feature engineering. We use SVMLight-TK<sup>7</sup> (Moschitti, 2006), a support vector machine (SVM) implementation of tree kernels. The trees we use are constituency trees obtained by the parsing models described in Section 3, and their conversion to dependency trees using the Stanford converter for English (de Marneffe and Manning, 2008) and Const2Dep (Candito et al., 2010) for French. The labels must be removed from the arcs in the dependency trees before they can be used in SVMLight-TK – the nodes in the resulting tree representation are word forms and dependency relations, omitting part-of-speech tags.<sup>8</sup> Based on preliminary experiments on our development set, we use subset tree kernels.

We build a baseline system with features provided for the WMT 2012 QE shared task (Callison-Burch et al., 2012): we use Europarl v7 and News Commentary v8 (Koehn, 2005) to extract n-gram frequency, language model and word alignment features. This is considered a strong baseline as the system that used just these features was ranked higher than many of the other systems.

## 5 Experiments and Results

We build a QE system using constituency and dependency parse tree kernels of the source and translation sides, exploring first the higher-accuracy parse trees. Table 2 shows the performance of this system ( $CD-ST_H$ ) compared to the system trained on the baseline features ( $B-WMT$ ). We also compare to another baseline ( $B-Mean$ ) which always predicts the mean of the segment-level BLEU scores of the training instances. We evaluate performance using Root Mean Square Error (RMSE) and Pearson correlation coefficient ( $r$ ). To test the statistical significance of the performance differences (at  $p < 0.05$ ), we use paired bootstrap resampling (Koehn, 2004).

$CD-ST_H$  achieves statistically significantly bet-

<sup>7</sup><http://disi.unitn.it/moschitti/Tree-Kernel.htm>

<sup>8</sup>A word is a child of its dependency relation to its head and this dependency relation is the child of the head word.

ter RMSE and Pearson  $r$  than both baselines, which shows the usefulness of tree kernels in QE. We combine  $CD-ST_H$  and  $B-WMT$ <sup>9</sup> – this system  $B+CD-ST_H$  performs statistically significantly better than both systems individually, suggesting that tree kernels can also be useful in synergy with non-syntactic features.

	RMSE	Pearson $r$
B-Mean	0.1626	0
B-WMT	0.1601	0.1766
$CD-ST_H$	0.1581	0.2437
$B+CD-ST_H$	0.1570	0.2696

Table 2: Baselines, higher-accuracy parse tree kernels and combinations

We now investigate the impact of the intrinsic quality of the parse trees on the QE system. We build a similar model to  $CD-ST_H$  but with the lower-accuracy model described in Section 3. This system is named  $CD-ST_L$  in Table 3.  $CD-ST_H$  is also presented in this table for ease of comparison. Surprisingly,  $CD-ST_L$  performs only slightly lower than  $CD-ST_H$  and the difference is not statistically significant.

To better understand the behaviour of these systems, we break them down into their components: source constituency trees, target constituency trees, source dependency trees and target dependency trees. We first split based on the parse type and then based on the translation side.

$C-ST_H$  and  $C-ST_L$  in Table 3 are the systems with the constituency trees of both source and translation sides with higher- and lower-accuracy parsing models respectively. Although the difference is not statistically significant, the system with lower-accuracy parse trees achieves better scores than the system with higher-accuracy trees.  $D-ST_H$  and  $D-ST_L$  are built with the dependency trees of the higher- and lower-accuracy parsing models respectively. Unlike the constituency systems, the system with higher-accuracy parses performs better. However, the difference is not statistically significant. These results suggest that the intrinsic accuracy of neither the constituency

<sup>9</sup>The combination is carried out using vector summation.

nor the dependency parses is crucial to the performance of the QE systems. We now further split these systems based on the translation sides.

$C-S_H$  and  $C-S_L$  use the higher- and lower-accuracy constituency trees of only the source side. Similar to when constituency trees of both sides were used ( $C-ST_H$  and  $C-ST_L$ ), the system built on the lower-accuracy parses performs better although the difference is not statistically significant. The system using higher-accuracy constituency trees of the translation side ( $C-T_H$ ) achieves better scores than the one using the lower-accuracy ones ( $C-T_L$ ), but, again, this difference is not statistically significant.

$D-S_H$  and  $D-S_L$  are the systems using the dependency trees of only the source side. Again, there is a small, statistically insignificant gap between the scores of these systems. On the other hand, there is a bigger performance gap between the systems built on the higher- and lower-accuracy dependency trees of the translation side:  $D-T_H$  and  $D-T_L$ . Although this is the only large difference observed among all settings, it is surprisingly not statistically significant.<sup>10</sup>

	RMSE	Pearson r
CD-ST <sub>H</sub>	0.1581	0.2437
CD-ST <sub>L</sub>	0.1583	0.2350

Table 3: QE systems with higher- and lower-accuracy trees (C: constituency, D: dependency, ST: Source and Translation,  $H$ : Higher-accuracy parsing model,  $L$ : Lower-accuracy parsing model)

One may argue that the way the parser accuracy is varied here could impact the results – a parser with similar  $F_1$  but different output may lead to a different conclusion. It is possible to test this by using the parsing model from a lower split/merge (SM) cycle. For example, the models from the first SM cycle with a 10K training set size

<sup>10</sup>The high scores of  $D-T_H$  seem to be happening by chance, because on the development set, on which the parameters are tuned, the scores are much lower.

for English and a 2.5K training set size for French score 73.04 and 70.22  $F_1$  points on their respective test sets. While these scores are close to those of the lower-accuracy models used above, their outputs are different: the parses with the two lower-accuracy English models achieve only 66.46  $F_1$  against each other and with the two French ones 66.51  $F_1$ . We use the parse trees of these alternative lower-accuracy parsing models to build a new QE system. The RMSE is 0.1585 and Pearson r is 0.2316. These scores are not statistically significantly different compared to  $CD-ST_H$ , strengthening our conclusion that intrinsic parse accuracy is not crucial for QE.

Another question is to what extent we require a linguistically realistic syntactic structure which retains some form of regularity no matter how accurate. To answer this question, we build random tree structures for source and translation segments. The random tree for a segment is generated by recursively splitting the sentence into random phrases and randomly assigning them a syntactic label.<sup>11</sup> We parse the source and translation segments using this method and build a QE system with the output trees. The RMSE and Pearson r are 0.1631 and -0.0588 respectively. This shows that tree kernels still require the regularity encoded in the lower- and higher-accuracy trees.

## 6 Conclusion

We explored the impact of parse quality in predicting automatic MT evaluation scores, comparing the use of constituency and dependency tree kernels built from the output of parsing systems with a large accuracy gap when measured using Parseval  $F_1$ . This large difference in  $F_1$  did not have a knock-on effect on the QE task. Our next step is to carry out the experiments in the opposite direction (French-English) so that we better understand why the translation side trees were not as useful as the source side trees. Using other intrinsic parser evaluation metrics might also prove useful.

## Acknowledgements

This research has been supported by the Irish Research Council Enterprise Partnership Scheme (EPSPG/2011/102 and EPSPD/2011/135) and the computing infrastructure of the Centre for Next Generation Localisation at Dublin City University.

<sup>11</sup>The English random model achieves an  $F_1$  of around 0.5 and the French model an  $F_1$  of 0.2.

## Abstract

A variety of methods have been proposed for attribute-value extraction from semi-structured text with consistent templates (strict semi-text). However, when the templates in semi-structured text are inconsistent (weak semi-text), these methods will work poorly. To overcome the template-inconsistent problem, in this paper, we proposed a novel method to leverage site-level knowledge for attribute-value extraction. First, we use a graph-based random walk model to acquire site-level knowledge. Then we utilize such knowledge to identify weak semi-text in each page and extract attribute-value pairs. The experiments show that, comparing to the baseline method which does not utilize site-level knowledge, our method can improve the extraction performance significantly.

## 1 Introduction

Among types of relations, attributes (e.g. nationality, date of birth) have emerged as one of the most popular types (Alfonseca et al., 2010), as they capture properties of respective objects (or instances) (e.g. *Kobe Bryant*). Generally, an attribute relation consists of an object, an attribute and its associated value (e.g. *Kobe Bryant - date of birth - August 23, 1978*, where “*August 23, 1978*” is the value of “*date of birth*”). In this paper, we call such a relation an object-attribute-value (OAV) tuple. Many methods have been proposed to extract attributes from semi-structured text (Cafarella et al., 2008)(Venetis et al., 2011)(Crescenzi et al., 2001)(Arasu and Garcia-Molina, 2003) and unstructured text like webpages and Web search query logs (Reisinger and Paşca, 2009)(Paşca et al., 2010)(Pasca and Van Durme, 2007). Semi-structured text (strict semi-text) often has distinctive HTML tags and consistent templates like

HTML tables (eg: Wikipedia infoboxes). However, a lot of user-generated semi-structured text with weak structures exist, where their templates generating records are inconsistent and the HTML tags in these templates are less distinctive. In this paper, we focus on the issue of extracting attribute-value (AV) pairs from semi-structured text with inconsistent templates (weak semi-text).

In previous work, Yoshinaga and Torisawa (Yoshinaga and Torisawa, 2007) extracted AV pairs of given objects from semi-structured text. They induced templates via a set of attributes obtained beforehand and used the templates to extract AV pairs. There are two constraints of their method. First, it heavily depends on the initial set of attributes. However, the quality and coverage of the initial set of attributes is hard to control. Second, they hold the assumption that attributes in the same block of semi-structured text are generated with the same template which weak semi-text does not satisfy. Their method mainly concentrated on extraction from semi-structured text with consistent templates (strict semi-text). When facing the weak semi-text with inconsistent templates, it will fail to obtain satisfactory results.

To resolve the problem of inconsistent templates, we propose an unsupervised method by leveraging site-level knowledge to extract AV pairs from weak semi-text. We explore the intrinsic structure connection among pages of the same website to address the problem. We make a two-stage effort: The first stage is to acquire knowledge that reveals the intrinsic similar structures among similar pages of the same site (site-level knowledge); the second stage is to leverage site-level knowledge to assist the AV pair extraction in weak semi-text.

In the paper, we present a novel approach that leverages site-level knowledge to extract instances’ attributes and their values from weak semi-text. To the best of our knowledge, little

Figure 1: System overview.

work has addressed the problems to extract AV pairs from weak semi-text. The experimental results show that, when facing weak semi-text, our method outperforms the baseline method which does not leverage site-level knowledge.

## 2 System Description

The system consists of two parts: the site-level extraction and the page-level extraction (Figure 1). Site-level extraction aims to obtain site-level knowledge from pages of a website. Page-level extraction leverages obtained site-level knowledge to help the AV pair extraction from each page.

### 2.1 Site-level Extraction

We describe details of the modules in site-level extraction (Figure 1).

#### 2.1.1 Weak Semi-block Identification and Attribute Template Learner

We first segment a webpage into several blocks based on the paragraph HTML tags. Then we align the initial attributes to text of each block. The aligned attributes are used to induce templates to extract more attributes. A template is composed of a prefix and a separator. The separator is referred to the character or word next to the matched attribute and the prefix means characters previous to it. We take the string which begins at the head of first html tag before the matched attribute and ends at the head of the matched attribute as the template's prefix. For example a HTML fragment "...<div class="spctrl"></div> 性别(Sex): 男(Male)...", in it, "性别(Sex)" is the attribute, "</div> " is the prefix and ":" is the separator, the template is "</div> WC: " where WC is a placeholder for the attribute. And we set the prefix's window size as 15. If no html tag has been found within the window, then the template of this attribute is abandoned. Finally, we obtain a collection of templates of the weak semi-block.

We employ heuristic rules based on aligned attributes number and types and templates number

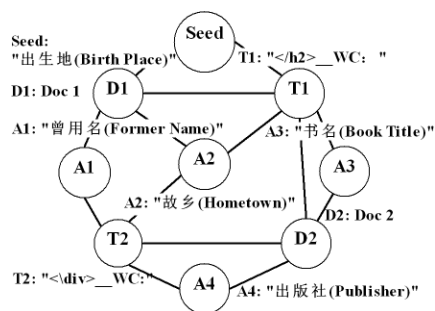

Figure 2: An example of our constructed graph.

to judge whether a block is a weak semi-block or not. Settings of two rules are discussed in the experiment at Section 5.4.1. They are: i) number of strings matched to initial attribute list is no smaller than  $t_1$ , and ii) sum of attributes' probabilities having been matched to strings in the text is larger than  $t_2$ . We represent them with a parameter vector  $T = (t_1, t_2)$ .

#### 2.1.2 Attribute Extraction

The obtained templates are used to extract more attributes in each block. Intuitively, more frequent a template is found in a weak semi-block, more likely a string extracted by that template is an attribute. Based on this idea, templates with higher frequencies will have higher priority than those with the lower frequencies when extracting attributes. After we run through all the pages of the site, we get a collection of templates and attributes. Then we rank them to obtain site-level knowledge.

#### 2.1.3 Ranker

To rank obtained templates and attributes to get site-level knowledge, we use the graph walk based technique (Wang and Cohen, 2007)(Wang and Cohen, 2009).

In the graph (Figure 2), attributes in initial attribute list are used as seeds. And these seeds are used to match the attributes in weak semi-block of a document (or a page) to learn templates. Then these templates are used to extract new attributes from the weak semi-block of a document (or a page). Intuitively, we consider that seeds appearing frequently are with high quality, templates derived by these seeds are tend to have good quality, and documents containing these seeds and templates are also deemed as high quality. Inversely, high quality documents also produce high quality attributes and high quality templates.

We utilize random walk with restart (RWR) to provide relevance score between two nodes (Tong et al., 2006). After the computation, we rank the attributes and templates by their probabilities in the final state vector.

We further refine the obtained ranked attributes by filtering obvious errors and the low ranks (site-level attributes) and generalize the top ranked templates by some rules (site-level templates). Site-level attributes and site-level templates composed the site-level knowledge.

## 2.2 Page-level Extraction

This section describes modules in page-level extraction (Figure 1).

### 2.2.1 Weak Semi-block Identification and AV Pair Extraction

To identify weak semi-block, we take the advantage of site-level knowledge to make several empirical rules based on the alignment of site-level templates and text of each block. The strings extracted by the templates are attribute candidates (*AttCandi* for short). We think only *AttCandies* extracted by authentic templates are correct attributes. A template is regarded as authentic once an *AttCandi* extracted by it exists in the site-level attributes. In the extraction of attribute’s values, we follow the method in (Yoshinaga and Torisawa, 2007) with the hypothesis that an attribute immediately precedes its value, and another AV pair immediately follows those values.

### 2.2.2 Object Extraction

we need to obtain **objects** of AV pairs to form attribute relations (**OAV tuples**) mentioned in Section 1 (eg: *Kobe Bryant - DateOfBirth - August 23, 1978*). We inspect several sampled pages and find their shared unique HTML template of objects for AV pair in their own pages. And then use this shared template to extract objects in each pages.

## 3 EXPERIMENTS

### 3.1 Experiment Settings

We carry out the experiments on 3 million Baidu Baike<sup>1</sup> (Baik for short) pages. In them, 1/3 of the pages (observed from our sampling) contain weak semi-text. For pre-processing, we remove infoboxes in each page which are strict semi-text.

<sup>1</sup><http://baike.baidu.com/>

Figure 3: P/R curves with different  $T = (t1, t2)$ .

We evaluate on two aspects where site-level knowledge takes effect, they are: 1) weak semi-block identification in page-level extraction; 2) AV pair extraction in page-level extraction. We randomly sample 300 pages for manually labeling. 99 in them contain weak semi-blocks, and 1022 OAV tuples are labeled in the 99 pages. We use the manually labeled data as benchmark.

### 3.2 The Baseline

To demonstrate the effectiveness of incorporating the site-level knowledge, we implement a baseline system similar to Yoshinaga and Torisawa (Yoshinaga and Torisawa, 2007), which does not utilize the site-level knowledge. For comparison with our method, unlike their work which obtains initial attributes via search engine by manually generated regular expressions (it is hard to repeat precisely), we use the same initial attributes (attributes in infoboxes of Chinese Wikipedia) with our system as input.

### 3.3 Evaluation on Weak Semi-text

#### 3.3.1 Evaluation on Weak Semi-block Identification (Ours vs. Baseline)

For weak semi-block Identification, we vary parameter vectors  $T = (t1, t2)$  (Section 3.1) to show the selection of parameters. We set  $t1 = \{x : 1 \leq x \leq 10\}$ ,  $t2 = \{0, 0.001, 0.002\}$ . Details of their effects to precision curves and recall curves are shown in Figure 3.

Since the contradiction between precision and recall in figure 3, we think high precision is more important comparing to high recall. For that, if we fail to recall a weak semi-block, we still have chance to get the same features this weak semi-block contains from others in the same site and recall it when doing page-level extraction with the help of site-level knowledge, however, if we identify the incorrect weak semi-block, the incorrect knowledge in it will be added to site-level knowledge which will bring amount of errors to our results when utilizing it to help page-level extrac-

Table 1: Performances of weak semi-block location.

	Output number	Correct	Precision	Recall	F-measure
<i>Baseline</i> $T_\beta$	12	12	<b>1.0</b>	0.121	0.216
<i>Baseline</i> $T_\gamma$	59	50	0.847	0.505	0.633
<i>Baseline</i> $T_\alpha$	38	36	0.947	0.364	0.526
<i>SiteExt</i> $T_\alpha$	100	96	0.96	<b>0.970</b>	<b>0.965</b>

Table 2: Strict and loose precision (P), recall (R) and F-measure (F) comparison of OAV tuple acquisition.

	P-strict	R-strict	F-strict	P-loose	R-loose	F-loose
<i>Baseline</i> $T_\beta$	0.822	0.159	0.266	0.888	0.171	0.287
<i>Baseline</i> $T_\gamma$	0.691	0.356	0.470	0.736	0.380	0.501
<i>Baseline</i> $T_\alpha$	<b>0.856</b>	0.307	0.452	<b>0.918</b>	0.330	0.485
<i>SiteExt</i> $T_\alpha$	0.844	<b>0.770</b>	<b>0.805</b>	0.887	<b>0.810</b>	<b>0.847</b>

tion. Therefore, we choose  $T$  as  $T_\alpha = (4, 0.001)$ , for our system (**SiteExt**), which gives a relatively higher recall with a high precision (Figure 3).

We compared *SiteExt* $T_\alpha$  with  $T = T_\alpha$  and the baseline system which respectively uses  $T_\alpha$ ,  $T_\beta = (7, 0.001)$  and  $T_\gamma = (2, 0)$ . The weak semi-block identification module of the baseline system is the same with the weak semi-block identification module of SiteExt in site-level extraction (Section 3.2). Therefore the results in these two modules are the same. From Figure 3, we can see that *Baseline* $T_\beta$  brings the highest recall within the ones bringing highest precision, and *Baseline* $T_\gamma$  brings the highest precision within the ones bringing highest recall.

Table 1 shows that *SiteExt* $T_\alpha$ 's performance has a dramatic improvement comparing to other baseline systems which do not leverage site-level knowledge. The reason is that site-level knowledge captures attributes and templates specific to Baike. Meanwhile, weak semi-blocks in each page of the same site also share these features. As a result, we can identify more weak semi-blocks and reduce the incorrect ones with the same initial attribute set.

### 3.3.2 Evaluation on Object-Attribute-Value (OAV) tuples (SiteExt vs. Baseline)

We then evaluate the results of OAV tuple extraction. For different items in an OAV tuple, we select different similarity-computing methods. Because objects and attributes in an OAV tuple are always short phrases only with several words, we consider them as correct when their similarity meets a strict merit. On the other side, the value often contains descriptive contents which have more words. A small size of noises is acceptable. Therefore, besides the strict merit, we further select a loose

merit. The two merits are shown in (3) and (4).

$$S_{loose} = \frac{\text{len}(wd(V_{bm} \cap wd(V_{ext})))}{\min(\text{len}(wd(V_{bm})), \text{len}(wd(V_{ext})))} \quad (1)$$

$$S_{strict} = \frac{\text{len}(wd(V_{bm} \cap wd(V_{ext})))}{\max(\text{len}(wd(V_{bm})), \text{len}(wd(V_{ext})))} \quad (2)$$

Where  $V_{bm}$  and  $V_{ext}$  separately denote the string of an attribute's value in benchmark and in our extraction results,  $wd(V)$  is a set of different words in  $V$ , and  $\text{len}(s)$  means sum of words in a set  $s$ . In the experiment, we set the thresholds both as 0.75. When all the similarity scores of three items (object, attribute, value) exceed the threshold, the extracted OAV tuple is regarded as correct.

Table 2 shows the performance of different systems. Comparing to *Baseline* $T_\alpha$ , *SiteExt* $T_\alpha$  has great improvements in recall and has a slightly loss in precision. *SiteExt* $T_\alpha$  outperforms the other two baseline systems in both precision and recall. The experiment results prove that site-level knowledge is quite essential and effective to promise a good performance when extracting OAV tuples from weak semi-text of the same website. The two systems use the same initial attribute set as input, our method can identify more weak semi-blocks and extract more OAV tuples. It also proves that our method is less sensitive to the initial attribute set.

## 4 Conclusion

In this paper, we propose a novel approach that acquires site-level knowledge via a graph-based random walk model and leverages such knowledge to extract attribute relations from weak semi-text. Experimental results show that we can significantly improve the performance of identifying weak semi-text and OAV tuple extraction.

# Optimum parameter selection for K.L.D. based Authorship Attribution for Gujarati

**Parth Mehta**

DA-IICT, Gandhinagar

parth.mehta126@gmail.com

**Prasenjit Majumder**

DA-IICT, Gandhinagar

prasenjit.majumder@gmail.com

## Abstract

We examine several quantitative techniques of authorship attribution that have gained importance over the time and compare them with the current state of the art Z-score based technique. In this paper we show how comparable the existing techniques can be to the Z-score based method, simply by tuning the parameters. We try to find the optimum values for number of terms, smoothing parameter value and the minimum number of texts required for creating an author profile.

## 1 Introduction

Authorship attribution and author profiling have a long standing history dating back to 19th century (Mosteller and Wallace, 1964). While authorship attribution deals with determining whether or not a given author has written the given article, author profiling aims at determining the age, gender, education level, etc. of the author from his article (Koppel et al., 2002). In the current work we focus only on authorship attribution. Authorship attribution techniques can be broadly classified into *linguistic techniques* and *Statistical techniques*. Until early 90's majority of the work done was from a linguistic perspective. Only after (Holmes, 1994) did statistical methods gain importance. There were many attempts to solve this particular problem using various statistics of texts like mean sentence length, term frequency distributions (Zipf, 1932), word lengths, character frequencies (Peng et al., 2003), vocabulary richness, etc. Rudman (1998) proposed nearly 1000 different measures that could be used. A whole new field of study called stylometry evolved from these type of studies. In 2002, (Burrows, 2002) proposed a novel technique based on Z-score that covered many of the above features, specially vocabulary difference and difference in term distribution

into a single measure. Later, Savoy(2010) modified this Z-Score that improved the result drastically and this technique is currently the state of the art for authorship attribution. In this paper we compare three major statistical techniques for authorship attribution to the state of the art Z-score based technique.

## 2 Corpus Details

The absence of a replicable and reliable corpora daunts the field of authorship attribution and more so for Indian languages. To the best of our knowledge the only work available to date for Indian languages is by (Bagavandas and Manimannan, 2008) where the corpus consisted of 55 Tamil articles, 32 of which were attributed and 23 disputed and there were only three possible authors. Having this fact in mind and following the steps of (Savoy, 2012) the authors developed a corpora consisting of 5039 newspaper articles from the newspaper *Gujarat Samachar*. These articles consist of 49 different weekly articles, from the supplements *Shatdal* and *Ravi Purti*, written by 40 distinct authors in the time period of 01-Dec-2011 to 1-Dec-2012 and is made available on our website<sup>1</sup>, along with the details of articles and authors. These articles span various categories like Science and Technology, short stories, Health and Fitness, Politics, etc. Though our corpus is more biased towards fiction(short stories & novels) this should not affect the performance because, unlike categories like health or art, stories seldom have a large overlap of vocabulary. Mean length of the documents was found to be 972 (Minimum: 85 Maximum: 1774, Median: 909,Standard deviation: 382). These texts were all available in the standard UTF-8 format and hence the only pre-processing that we did was to remove the punctuations, numerals and author names from the text. Except this no other pre-

<sup>1</sup><http://irlab.daiict.ac.in/tools.php>

processing was done, each morphological variant was treated as a unique term and also there was no word sense disambiguation to distinguish between same words having different meaning. Concept of capitalization does not exist as such in Gujarati language. Our experiments being completely statistical in nature can be replicated very easily without any knowledge of Gujarati language.

### 3 Experiment details

We compare four different Authorship attribution methods mentioned in (Savoy, 2012), namely Delta method, Chi-squared method, Z-Score based method and Kullback Leibler divergence based method. Our aim is to examine whether or not tuning the parameters of K.L.D. based method can produce results comparable to the state of the art Z-score based method. In this section we briefly describe each of the four methods and then explain the parameters that can affect K.L.D. based authorship attribution. All these methods are profile based methods i.e. for each of the  $N$  authors we create an author profile  $A_k$  where  $k \in \{1, \dots, N\}$ . These profiles are created from the documents for which the true author is already known. Disputed document  $Q$  is then compared to each author profile  $A_k$  using a metric  $D(Q, A_k)$  and is attributed to that author for whom  $D$  is minimum. In other words for given query text  $Q$  and author profiles  $A_k$

$$A_{correct} = \underset{k \in N}{\operatorname{argmin}} \{D(Q, A_k)\} \quad (1)$$

The distance function  $D$  depends on the method used and is defined separately for each method and so is true for the author profile  $A_k$ .

The parameters in these experiments that are to be set heuristically include the value of the smoothing technique and smoothing parameter ( $\lambda$ ) for that technique, the minimum number of texts( $N$ ) that have to be used in order to create a reasonably good author profile and the number of terms( $X$ ) considered to create the author and document profiles. Due to several studies readily available, we directly use Lidstone smoothing technique without further experimentation. Our main aim is to find the optimum value of these parameters for a corpus of Gujarati articles.

### 3.1 Delta Method

Delta method was first proposed by (Savoy, 2012). It uses a term-document index along with Z-score defined by equation 2 below

$$Z_{score}(t_{ij}) = \frac{tf_{ij} - mean_i}{sd_i} \quad (2)$$

Z-score is calculated for each term  $t_{ij}$  where  $i \in \{1, \dots, T\}$  and  $j \in \{1, \dots, M\}$ .  $T$  and  $M$  are the total number of unique terms and total number of documents in the corpus respectively.  $tf_{ij}$  is the term frequency of term  $i$  in document  $j$ ,  $mean_i$  and  $sd_i$  are the mean and standard deviation of frequency of term  $t_i$  in the entire corpus. Using this we can represent each document as a vector of Z-scores for each of its terms. Hence each document can be represented as a vector  $d_j = [Z_{score}(t_{1j}), Z_{score}(t_{2j}), \dots, Z_{score}(t_{mj})]$  for a particular value of  $j$ . Having this representation for each document an author profile  $A_k$  can then be created by taking the mean of these vectors for all the articles known to be written by that particular author.

Next we represent the query text  $Q$  in the same manner, as a vector of Z-scores. We then find the author profile that is closest to  $Q$  using equation 1, the distance function being defined as below.

$$D_1(Q, A_j) = \frac{1}{T} \cdot \sum_{i=1}^T |Z_{score}(t_{iq}) - Z_{score}(t_{ij})|$$

$t_{iq}$  denotes term  $t_i$  in query text, and  $t_{ij}$  denotes term  $t_i$  in author profile  $j$ .

### 3.2 Chi-Squared distance based method

Chi-Squared distance based method is based on the well known Pearson's  $\chi^2$  test, used to compute the similarity between two distributions. In this method a document is represented as a vector  $d_j = [p(t_{1j}), p(t_{2j}), \dots, p(t_{mj})]$ , where  $p(t_{ij})$  is normalised frequency of term  $t_i$  in a given document  $j$ . Author profile  $A_k$  is prepared by first combining all the documents pertaining to a particular author  $k$ , and then calculating the normalised frequency for this combined document. Considering  $Q$  and  $A_k$  as term distributions we can now use  $\chi^2$  distance to find the degree of similarity between the two. The distance function in this case is as shown below

$$D_2(Q, A_k) = \sum_{i=1}^T \frac{(q(t_i) - a_k(t_i))^2}{a_k(t_i)}$$

where  $q(t_i)$  is the normalised frequency for term  $t_i$  the query text  $Q$  and  $a_k(t_i)$  is that for the  $k^{th}$  author profile.

### 3.3 Z-Score based method

This method is currently the state of the art method for authorship attribution using quantitative analysis. It was proposed by Savoy (2012) and is a modification of the Delta method mentioned in section 3.1. One of the two major modifications is the method of calculating Z-Score. Savoy (2012) proposed using the expected value of term frequency and the expected standard deviation compared to the sample mean and sample standard deviation that were used in Delta method. So in this case any term  $t_{ij}$ ,  $i^{th}$  term in  $j^{th}$  document, is considered to be drawn from a binomial distribution with parameters  $n_0$  and  $p(t_i)$ .  $n_0$  is the length of the document for which  $t_{ij}$  is to be estimated and  $p(t_i)$  is the probability of term  $t_i$  occurring in the entire corpus. Hence the expected value for  $t_{ij}$  is  $n_0.p(t_i)$  and the expected standard deviation is  $\sqrt{n_0.p(t_i).(1 - p(t_i))}$ . The modified Z-score can then be calculated as

$$Z_{score}^*(t_{ij}) = \frac{tf_{ij} - n_0.p(t_i)}{\sqrt{n_0.p(t_i).(1 - p(t_i))}} \quad (3)$$

This Z-Score can then be used in the same way as used in Delta method. Another change in this method as compared to the Delta method is the distance function used.

$$D_3(Q, A_j) = \frac{1}{T} \cdot \sum_{i=1}^T \left( Z_{score}^*(t_{iq}) - Z_{score}^*(t_{ij}) \right)^2$$

where  $t_{iq}$  denotes term  $t_i$  in query text, and  $t_{ij}$  denotes term  $t_i$  in author profile  $j$ .

### 3.4 K.L.D. based method

K.L.D. based method is somewhat similar to the Chi-squared distance method in that this method also looks upon normalised word frequencies as a probability distribution. The author profiles and document profiles in this case are exactly the same as that in the Chi-squared distance based method. Kullback Leibler Divergence between the two probability distributions, namely author profile  $A_k$  and query text  $Q$  is defined as below

$$D_{KL}(Q||A_k) = \sum_{i=1}^T \ln \left( \frac{a_k(t_i)}{q(t_i)} \right) q(t_i)$$

where  $q(t_i)$  is the normalised frequency for term  $t_i$  the query text  $Q$  and  $a_k(t_i)$  is that for the  $k^{th}$  author profile. Author with profile  $A_k$  with minimum divergence from  $Q$  is considered to be the author for the disputed text.

## 4 Results and Evaluation

In this section we present the results of applying these four aforementioned techniques on our corpus. We also include one more technique apart from these four in which we use Delta method albeit with distance function  $D_3$ . We use the same evaluation strategy used by Savoy (2012). At a time we choose one article to be the disputed text  $Q$  and use all other articles to create the author profiles  $A_k$ . This is repeated for every article present in the corpus. Accuracy is then calculated in two ways: by finding the total number of articles attributed correctly irrespective of the authors (micro average) and by finding the accuracy for each author individually and then defining the overall accuracy as the average of these individual values (macro average). While experimenting with the number of texts required to create an author profile, for each article we select  $p$  articles from each author to create the author profiles. The concept of macro and micro average remain the same. But since we are selecting these  $p$  articles randomly, we perform a 10-fold cross validation to assure statistically significant results. In this case we report mean accuracy. Table 1 below shows the result for using different values of  $\lambda$ , with  $X$  and  $N$  remaining constant. All the terms with  $tf > 10$  and  $df > 2$ , were considered for the  $Z_{score}$  and  $K.L.D.$  based approaches while for Delta method top 400 terms were considered. For the chi-square based method the condition  $tf > 2$  was used. All these conditions are based on the best performing parameter value as found by (Savoy, 2012) and hence would make a good starting point. Above this we consider only those terms that belong to at least two author profiles so as not to make the task trivial. The size of the training set for this experiment was  $N = N_{max}$  i.e. all the available articles (except the query text  $Q$ ) are used to create the author profile. For each experiment the best performing parameter value is considered to be the baseline and other values are compared against them for statistically significant difference, using a two sided sign test.

Method	Parameter	Micro-Average	Macro-Average
Z-Score	$\lambda = 0$	86.14%	87.38% <sup>†</sup>
	$\lambda = 0.1$	<b>88.73%</b>	<b>90.45%</b>
Delta ( $D_1$ )	$\lambda = 0$	26.10% <sup>†</sup>	24.69% <sup>†</sup>
Delta ( $D_3$ )	$\lambda = 0$	84.24% <sup>†</sup>	86.00% <sup>†</sup>
KLD	$\lambda = 0.01$	77.17% <sup>†</sup>	70.38% <sup>†</sup>
	$\lambda = 0.001$	88.57%	85.44% <sup>†</sup>
$\chi^2$ Method	$\lambda = 0$	12.15% <sup>†</sup>	14.73% <sup>†</sup>

Table 1: Effect of variation in  $\lambda$

<sup>†</sup> Significant performance difference ( $\alpha = 1\%$ , two-sided sign test)

For further experiments we consider only the best performing value of the smoothing parameter and show that with proper feature selection, *i.e.* by selecting proper number of terms, K.L.D. based approach can give results comparable to the state of the art Z-score based approach. Chi-squared method and Delta method (using  $D_1$  distance) perform poorly and hence we do not consider them in further experimentation. All further experiments are performed only on Z-Score based method, Delta method (using  $D_3$  distance) and K.L.D. based method.

Method	Parameter	Micro-Avg	Macro-Avg
Z-Score	$tf > 10, df > 3$	88.73%	90.45% <sup>†</sup>
	$tf > 100, df > 3$	84.33% <sup>†</sup>	86.45% <sup>†</sup>
Delta ( $D_3$ )	Top 100 terms	76.10% <sup>†</sup>	74.69% <sup>†</sup>
	Top 400 terms	84.24% <sup>†</sup>	86.00% <sup>†</sup>
KLD	$tf > 10, df > 3$	88.57% <sup>†</sup>	85.44% <sup>†</sup>
	$tf > 100, df > 3$	90.55%	88.75%
	$tf > 1000, df > 3$	<b>91.35%</b>	<b>91.73%</b>

Table 2: Effect of variation in  $X$

<sup>†</sup> Significant performance difference ( $\alpha = 1\%$ , two-sided sign test)

Table 2 shows the variation in performance of these methods when the number of terms are varied. For Z-score based method and K.L.D. based method we choose terms based on their term frequencies in the corpus. We keep document frequency constant because increasing it would lead to selection of only those terms which are prevalent across more number of documents. These terms will make the author profiles less distinguishable and result in poor overall performance. For Delta method fewer number of terms always perform better (Burrows, 2002). Hence we use 100 and 400 terms respectively as done by (Burrows, 2002) and followed by (Savoy, 2012)

Further we investigate the effect of reducing the training set *i.e.* the number of texts used to create author profile. For this we select the smoothing parameter and the number of terms that performed best in the previous two experiments. For Z-Score based method we use the criteria  $tf > 10, df > 3$ , for K.L.D. based method we use  $tf > 1000, df > 3$  and for delta method we use top 400 most frequent terms. Table 3 shows the performance of the three systems as we vary the size of training set.  $N_{max}$  refers to the maximum number of articles that can be used to create the author profiles. In our case it is  $N_k - 1$ , where  $N_k$  is the total number of documents for the  $K^{th}$  author. Clearly when the size of the training set is small K.L.D. based method fares much better than all other techniques.

Method	Parameter	Micro-Average	Macro-Average
Z-Score	$N = 10$	52.14% <sup>†</sup>	54.17% <sup>†</sup>
	$N = 40$	82.39% <sup>†</sup>	84.45% <sup>†</sup>
	$N = N_{max}$	88.73%	90.45%
Delta	$N = 10$	22.10% <sup>†</sup>	23.69% <sup>†</sup>
	$N = 40$	64.14% <sup>†</sup>	65.50% <sup>†</sup>
	$N = N_{max}$	84.24% <sup>†</sup>	86.00% <sup>†</sup>
KLD	$N = 10$	72.35% <sup>†</sup>	75.34% <sup>†</sup>
	$N = 40$	90.25%	91.03%
	$N = N_{max}$	<b>91.35%</b>	<b>91.73%</b>

Table 3: Effect of variation in  $N$

<sup>†</sup> Significant performance difference ( $\alpha = 1\%$ , two-sided sign test)

## 5 Conclusion

Looking at the above results we can conclude that for Gujarati newspaper articles K.L.D. based authorship attribution with proper parameter selection is comparable to the current state of art Z-score based method when sufficient number of articles are available as a training set. But when the number of training examples are less then K.L.D. based method outperforms the Z-score based method. This might be because by normalising each of the terms' frequency,  $Z_{score}$  effectively considers each term to be of same importance. This might not be true as the distribution of terms that occur in most of the documents should ideally be a better signature as compared to the terms that occur in only a few documents of the author. *K.L.D.* inherently takes into account the occurrence frequency by weighting each term with the probability of its occurrence and hence performs better.

## Abstract

Classical approaches to sentiment classification exploit only textual features in a given review and are not aware of the personality of the user or the public sentiment toward the target product. In this paper, we propose a model that can accurately estimate the sentiment polarity by referring to the *user leniency* and *product popularity* computed during testing. For decoding with this model, we adopt an approximate strategy called “two-stage decoding.” Preliminary experimental results on two real-world datasets show that our method significantly improves classification accuracy over existing state-of-the-art methods.

## 1 Introduction

Document-level sentiment classification estimates the sentiment polarity for a given subjective text (hereafter, review). Traditionally, researchers have tried to estimate the sentiment polarity from only the textual content of the review (Pang and Lee, 2004; Li et al., 2011). However, since reviews are written by a user to express his/her emotion toward a particular product, taking the users and products into consideration would play an important role in solving this task.

Recently, the increase of opinionated text within social media, e.g., *Twitter*, has motivated researchers to exploit the user or product information in the sentiment classification task. Some researchers take advantages of the friend relation in a social network because friends are likely to hold common tastes (Tan et al., 2011; Seroussi et al., 2010; Speriosu et al., 2011). Others incorporate user- or product-specific  $n$ -gram features (Li et al., 2011; Seroussi et al., 2010). Although these studies have showed that user or product information is useful for sentiment classification, they implicitly

assume that the same users or products appear in both training and testing data. Thus, to train such a model, a large amount of the reviews should be labeled for each user and each product. In a real-world scenario, however, this is unrealistic since new users and products are ceaselessly emerging and labeling reviews written by such users (or on such products) is impractical.

In the real world, different users have different rating standards, while different products receive different rating tendencies. For example, a critical person is likely to point out flaws and gives negative ratings, while a popular product receives more praise than negative feedback. We refer to these user- or product-specific polarity biases as *user leniency* and *product popularity*, respectively. A sentiment classifier would resort to these biases when textual features are not reliable enough to estimate the sentiment polarity.

In this study, we build a model that automatically computes and uses *user leniency* and *product popularity* for sentiment classification. We represent these biases with two types of real-valued global features. Because these features and the labels of the test reviews mutually depend on each other, it is challenging to globally optimize a configuration of polarity labels for a given set of reviews. We here adopt a two-stage decoding strategy (Krishnan and Manning, 2006) for resolving the mutual dependencies in our model.

We evaluated our method on two real-world datasets (Blitzer et al., 2007; Maas et al., 2011). Experimental results demonstrated that the proposed method significantly improved the classification accuracy against the state-of-the-art methods (Dredze et al., 2008; Seroussi et al., 2010).

The remainder of this paper is organized as follows. We first discuss some related work in Section 2. We describe our method in Section 3. We then report experimental results in Section 4. Finally, we conclude our study in Section 5.

## 2 Related Work

Recently, social media such as *Twitter* has attracted much attention from researchers because it is now apparently the major source of subjective text on the Web. The traditional text-based methods, such as Pang *et al.* (2002), could not easily handle such short and informal text (Jiang *et al.*, 2011).

Tan *et al.* (2010) and Speriosu *et al.* (2011) exploited the user network behind a social media website (*Twitter* in their case) and assumed that friends give similar ratings towards similar products. Seroussi *et al.* (2010) proposed a framework that computes users' similarity on the basis of their usage of text and their rating histories. They then classify a given review by referring to ratings given for the same product by other users who are similar to the user in question. However, such user networks are not always available in the real world.

Li *et al.* (2011) incorporate user- or product-dependent  $n$ -gram features into a classifier. They argue that users use a personalized language to express their sentiment, while the sentiment toward a product is described by product-specific language. This approach, however, requires the training data to contain reviews written by test users and written for test products. This is infeasible since labeling reviews requires too much manual work.

## 3 Method

Given a set of reviews,  $\mathcal{R}$ , our task is to estimate label  $y_r \in \{+1, -1\}$  for each review,  $r \in \mathcal{R}$ , with estimation function  $g(\mathbf{x}_r)$ :

$$g(\mathbf{x}_r) = \mathbf{w}^T \mathbf{x}_r, \quad (1)$$

$$y_r = \begin{cases} +1 & \text{if } g(\mathbf{x}_r) > 0 \\ -1 & \text{otherwise} \end{cases},$$

where  $\mathbf{x}_r$  is  $r$ 's feature vector and  $\mathbf{w}$  is the weight vector.

### 3.1 Idea

Our interest is to exploit user leniency and product popularity to improve sentiment classification. We encode each of them into two real-valued global features, which are detailed in Section 3.2. Since these global features depend on the labels of the input reviews, we cannot independently estimate the labels of reviews. We then discuss a decoding strategy in Section 3.3.

Note that we assume to know which reviews are written by the same user and which are written on the same product. This assumption is realistic nowadays since user information is available in many real-world datasets (Blitzer *et al.*, 2007; Pang and Lee, 2004), while product information can be extracted from text if not available (Qiu *et al.*, 2011). We should emphasize here that our method does not require user profiles, product descriptions, or any sort of extrinsic knowledge on the users and products.

### 3.2 Features

The review  $r$ 's feature vector,  $\mathbf{x}_r$ , is composed of local features ( $\mathbf{x}_r^l$ ) and global features ( $\mathbf{x}_r^g$ ), such that  $\mathbf{x}_r = (\mathbf{x}_r^l, \mathbf{x}_r^g)$ . In this study, we use word  $n$ -grams ( $n = 1, 2$ ) in the textual content of the review as local features, while we encode the user leniency and product popularity into global features. We introduce four global features to capture the user leniency and product polarity:

$$\mathbf{x}_r^g = \{f_{-u}^+, f_{-u}^-, f_{-p}^+, f_{-p}^-\},$$

where the first two features,  $f_{-u}^+$  and  $f_{-u}^-$ , represent the user leniency as the ratio of positive and negative reviews written by the same user of  $r$ , while the other two features,  $f_{-p}^+$  and  $f_{-p}^-$ , represent the product popularity as the ratio of positive and negative reviews on the same product of  $r$ . The global features are thereby computed as:

$$f_{-u}^+(r) = \frac{|\{r_j \mid y_j = +1, r_j \in N_u(r)\}|}{|N_u(r)|},$$

$$f_{-u}^-(r) = \frac{|\{r_j \mid y_j = -1, r_j \in N_u(r)\}|}{|N_u(r)|},$$

$$f_{-p}^+(r) = \frac{|\{r_j \mid y_j = +1, r_j \in N_p(r)\}|}{|N_p(r)|},$$

$$f_{-p}^-(r) = \frac{|\{r_j \mid y_j = -1, r_j \in N_p(r)\}|}{|N_p(r)|},$$

where  $N_u(r)$  represents a set of reviews written by the same user as  $r$  and  $N_p(r)$  represents a set of reviews written for the same product as  $r$ , respectively:

$$N_u(r) = \{r' \mid u_r = u_{r'} \wedge r \neq r'\},$$

$$N_p(r) = \{r' \mid p_r = p_{r'} \wedge r \neq r'\}.$$

### 3.3 Decoding

Because global features are computed for each user or product, we want to process as many test

reviews at once so that they include many reviews for each user or on each product to compute reliable global features. However, because the possible ways of assigning labels to a given set of reviews,  $\mathcal{R}$ , is  $2^{|\mathcal{R}|}$  and the two types of global features introduce complex label dependencies to be resolved, exact decoding is computationally expensive even with dynamic programming. In this study, we thus resort to an approximate decoding strategy called “two-stage decoding” (Krishnan and Manning, 2006). It splits the decoding process into a local decoding stage and a global decoding stage. Each stage takes linear time with respect to the number of reviews processed. This strategy is thereby scalable to a larger number of test reviews.

At the first stage, all the global features are set to 0, and only local features are used to classify the reviews. In the second stage, labels estimated in the first stage are used to compute the values of the global features. The labels are then revised by using both local and global features. In our case, the two-stage decoding at first uses only word  $n$ -gram features to estimate the labels of reviews. The estimated labels are used to compute user leniency features and product popularity features. Then, the decoding revises the labels considering both the word  $n$ -gram features and the user leniency and product popularity features.

### 3.4 Training

We train a binary classifier as the score estimation function in Eq. 1, considering word  $n$ -gram features, user leniency features, and product popularity features. The values of global features are computed by using the gold labels. We assume that a value of the user leniency feature or product popularity feature for a review whose user has no other reviews or whose product has no other reviews is set to 0.

## 4 Experiments

We evaluated our method in terms of accuracy on two real-world datasets (Blitzer et al., 2007; Maas et al., 2011) for a document-level sentiment classification task.

For each review, we at first use OpenNLP<sup>1</sup> to detect sentence boundaries and tokenize each sentence in order to obtain word  $n$ -gram features. Following Pang *et al.* (2002)’s settings, we take nega-

<sup>1</sup><http://opennlp.apache.org/>

Dataset	Blitzer	Maas
No. of reviews	188,350	50,000
No. of users	123,584	n/a
No. of products	101,021	7,036
No. of reviews/user	1.5	n/a
No. of reviews/products	1.9	7.1

Table 1: Dataset statistics.

tion (such as *n’t* and *cannot*) into consideration. Because features with low frequency are unreliable, any  $n$ -gram that appears less than six times in the training data are ignored.

We adopted a confidence weighted linear classifier (Dredze et al., 2008) as our binary classifier. This is because it has been reported to perform best on the sentiment classification task (Dredze et al., 2008).

### 4.1 Datasets

We used two datasets that were developed by Blitzer *et al.* (2007) and Maas *et al.* (2011). The datasets contain user/product and only product information. The statistics of the two datasets are summarized in Table 1.

The original Blitzer dataset contains more than 780,000 reviews (88% positive, 12% negative), which were collected from amazon.com across several domains, such as books, movies and games. We automatically delete reviews written by the same user on the same product, which results in about 740,000 reviews. Then, the reviews are balanced for positive and negative labels (94,175 reviews for each) to maintain consistency with the setting in other existing works.

The Maas dataset has 25,000 positive and 25,000 negative reviews on movies. The dataset provides a URL for each review, which represents the sentiment target, a movie. We thus use the URL as a unique identifier for the movie. The user information cannot be fully recovered, so we only model the product dependency on this dataset.

Our method performs best when the reviews written by/on the same user/product are in the same set (training or testing) since we can compute more reliable global features when we have more reviews written by/on the same user/product. In the two datasets, reviews were originally ordered by user or product. To prevent a seemingly unfair accuracy gain under this particular splitting, we randomly shuffled the reviews and performed

Method	Accuracy (%)	
	Blitzer	Maas
Seroussi <i>et al.</i> (2010)	89.37	n/a
Maas <i>et al.</i> (2011)	n/a	88.89 <sup>3</sup>
baseline	90.11	91.35
proposed	91.01 <sup>&gt;</sup>	92.68 <sup>&gt;&gt;</sup>

Table 2: Accuracy on review datasets. Accuracy marked with “>>” or “>” was significantly better than baseline ( $p < 0.01$  or  $0.01 \leq p < 0.05$  assessed by McNemar’s test).

a 2-fold cross-validation.

## 4.2 Results

In this section, we report the accuracy of our sentiment classifier. Accuracy is measured as the number of correctly classified reviews divided by the number of all the reviews. We prepared two baseline classifiers to see the advantage of our classifier. As one baseline, we used a confidence-weighted linear classifier (Dredze *et al.*, 2008) that takes only textual features into account. As another baseline, we implemented a user similarity-based method proposed by Seroussi *et al.* (2010).<sup>2</sup> The similarity of users is computed by using a word  $n$ -gram Jaccard distance (called “AIT” in Seroussi *et al.* (2010)). When the user of an input review is unseen in the training data, a default classifier, which is trained with all the training reviews, is used to classify the review.

Table 2 shows the experimental results. The proposed method significantly improved the classification accuracies across the two datasets. A larger improvement was acquired on the Maas dataset because the average number of reviews for each product in the dataset was larger than that in the Blitzer dataset.

**Impact of size on test reviews** In our method, since global features play a key role, acquiring

<sup>2</sup>We built user-specific classifiers for users who wrote reviews with positive polarity and negative polarity more than a pre-specified threshold. After several trials, the threshold was set to be 5 to gain the best performance.

<sup>3</sup>This result was computed under a different splitting from ours. Under Maas *et al.* (2011)’s splitting, the accuracy for the baseline and proposed method was 90.83% and 92.29%. The main difference between our baseline and their method is the features. They use only unigram features, while we use unigram and bigram as features. Using only unigram features under their splitting, the accuracy of the baseline method was 87.8%.

Figure 1: Accuracy when we changed the size of test reviews processed at once by our classifier.

more reliable global features is our major concern to make the improvement more significant.

We thus performed 2-fold cross-validation with the same splitting for the Blitzer dataset, while changing the size of test reviews processed at once to investigate the impact of test review size on classification accuracy. In this experiment, we split the test reviews into equal-sized smaller subsets and applied our classifier independently to each of the subsets.

As shown in Figure 1, when we processed a larger number of test reviews at once, the accuracy increased. This result confirms our expectations.

## 5 Conclusion

We presented a model that captures and uses user leniency and product popularity for sentiment classification. Different from the previous studies that are aware of the user and product of the review, our model does not require the training data to contain reviews written by the test users or written on the test products. To infer labels under our proposed model, we investigated a two-stage decoding strategy.

We conducted experiments on two real-world datasets to demonstrate the effectiveness of our proposed method. The method performed more accurately than did the baseline method, which only uses  $n$ -gram features, and an existing user-aware approach. We also showed that processing more test reviews at once lead to better accuracy.

We plan to publish our code and datasets.<sup>4</sup> A detailed exploration of this work will be reported in Gao *et al.* (2013).

# A Generalized LCS Algorithm and Its Application to Corpus Alignment

Jin-Dong Kim

Database Center for Life Science (DBCLS), ROIS, Japan  
jdkim@dbcls.rois.ac.jp

## Abstract

The paper addresses the problem of text variation which often hinders interoperable use or reuse of corpora and annotations. A systematic solution is presented based on a variation of Longest Common Sequence algorithm. An empirical experiment with 20 full text articles shows it works well with a real world application.

## 1 Introduction

Corpus with annotation is regarded indispensable for the development of natural language processing (NLP) technology. As so, many corpora with annotation have been developed, and many groups are working with new annotation projects.

As various annotated corpora accumulate in the field, reusability and interoperability is becoming an important issue (Cohen et al., 2005; Johnson et al., 2007; Campos et al., 2012). Among others, Wang et al. (2010) reports that there are a number of corpora that claim to have annotations for protein or gene names, e.g. Genia (Kim et al., 2003), Aimeid (Bunescu et al., 2004), and Yapex (Franzén et al., 2002), and that, however, the protein annotations in those corpora are substantially different to each other, which calls for an interoperable interpretation of the annotations for integrative reuse of them. Rebholz-Schuhmann et al. (2011) investigates aggregation of variable named entity annotations in large scale, which also show the importance of interoperable use of corpus annotation.

There also have been efforts for the interoperability of corpora and annotations from a perspective of encoding and representation, e.g., Linguistic Annotation Framework (LAF) (Ide and Romary, 2004) and Open Linguistics<sup>1</sup>. Without a doubt, those efforts contribute to improving the interoperability of corpora and annotation.

Figure 1: Text variations and annotation to them

This paper addresses another type of problem, *text variation*, which often hinders interoperable use or reuse of corpora and annotations in real world applications. As far as the author knows, it is the first attempt to develop a definite and systematic solution to the problem.

The problem of text variant is explained in detail in Section 2, while the solutions are presented in Section 3 and 4 After discussions on its real world application in Section 5, the paper is concluded in Section 6.

## 2 Task definition

Figure 1 illustrates a simple example of the problem to be addressed: A, B and C are text variants from the same document; The position index of the equivalent text spans, “TGF-beta”, “TGF-&beta;”, and “TGF- $\beta$ ”, are different to each other; And, the annotations made to the spans are not directly interoperable, although they are made to conceptually the same span of the same document.

Note that the example is extremely simplified for the ease of understanding. In reality, the problem is much more complex: a text, as the tar-

get of annotation, is often as long as hundreds, or thousands of characters, or even much longer, and a single local variant affects the entire remaining portion of the text, in a cumulative way.

Nowadays, the widespread use of Unicode is one of the reasons of text variant, particularly when it comes to text processing, because many NLP tools, e.g., syntactic parsers, cannot handle Unicode characters properly. Thus, during many annotation projects, Unicode characters, e.g., Greek letters, are spelled out into ASCII alphabets, like *beta* in Figure 1 A. Sometimes, extra symbols, e.g., ‘&’ and ‘;’, are inserted to delimit Unicode-origin sequences, like in B.

Suppose that two independent annotation projects took the text of C into their corpora, and their preprocessors spelled out Greek letters differently like in A and B. The projects may produce different annotations according to their interest and perspectives. While those annotations may serve their goals individually, further benefit, e.g., reuse, comparison, or aggregation, can be gained from interoperable use of them. In the example, we want the annotations,  $(0, 8, \text{Protein})^2$  from A and  $(0, 10, \text{Signaling\_molecule})$  from B, to be transferable to C, or to each other. However, the variation of text poses a challenge: we need to compute the mapping between variations of text.

For standoff annotation, a text defines a one-dimensional Cartesian coordinate system, whereon any position on the text is specified. We thus cast the problem to the task of finding a mapping function from a one-dimensional Cartesian coordinate system to another, when they are filled with comparable values (characters). In Figure 2,  $\delta_{A \rightarrow C}$  is a mapping function from A to B, which enables transferring the annotation to the source text.  $\delta_{C \rightarrow A}$  is the mapping for the opposite direction. Once those functions are obtained, any annotation produced by the project A can be transferred to the original text, and vice versa.

### 3 LCS for text mapping

For most cases, text mapping can be computed using Longest Common Sequences (LCS) algorithms (Bergroth et al., 2000). LCS is a well

<sup>2</sup>Throughout the paper, we make the span specification in the style of BioNLP shared task (Kim et al., 2009), where the beginning of a span is specified by the number of characters preceding the span, and the end by the number of characters up to the end of the span.

Figure 3: The LCS table for “TGF- $\beta$  acts” and “TGF-beta acts”. The place of text variation is indicated in gray

known problem, based on which the UNIX command, *diff*, is implemented. Algorithm 1 is a dynamic algorithm to compute the length of LCS of any two strings. Figure 3 shows the resulted LCS table for example strings. From the LCS table, the *diff* between the two strings - see Figure 4<sup>3</sup> - can be read out by Algorithm 2.

---

#### Algorithm 1 LCS computation

---

```

1: function LCS( $X[1..m], Y[1..n]$ )
2:    $C = \text{ARRAY}(0..m, 0..n)$ 
3:   for  $i := 0..m$  do
4:      $C[i, 0] := 0$ 
5:   end for
6:   for  $j := 0..n$  do
7:      $C[0, j] := 0$ 
8:   end for
9:   for  $i := 1..m$  do
10:    for  $j := 1..n$  do
11:      if  $X[i] = Y[j]$  then
12:         $C[i, j] := C[i - 1, j - 1] + 1$ 
13:      else
14:         $C[i, j] := \text{MAX}(C[i, j - 1], C[i - 1, j])$ 
15:      end if
16:    end for
17:  end for
18: end function

```

---

Algorithm 1 has time and space complexities of  $O(mn)$ , where  $m$  and  $n$  are the length of the strings. For many real world applications, Hunt-

<sup>3</sup>In the first column, the minus (‘-’) and plus (‘+’) signs indicate *deletion* and *insertion* operations, respectively.

---

**Algorithm 2** Reading out *diff* from LCS table
 

---

```

1: D = STACK
2: i := m
3: j := n
4: while i ≠ 0 or j ≠ 0 do
5:   if i > 0 and j > 0 and X[i] = Y[j] then
6:     PUSH(D, ['=', X[i], Y[j]])
7:     i := i - 1
8:     j := j - 1
9:   else if j > 0 and (i = 0 or C[i, j-1] > C[i-1, j]) then
10:    PUSH(D, ['+', nil, Y[j]])
11:    j := j - 1
12:   else
13:    PUSH(D, ['-', X[i], nil])
14:    i := i - 1
15:   end if
16: end while

```

---

McIlroy algorithm (Hunt and McIlroy, 1976) is frequently used, which regularly beats the complexities of the dynamic algorithm with typical inputs. Once the *diff* in Figure 4 is obtained, getting the mapping  $\delta_{C \rightarrow A}$  is straightforward.

=	0	T	0	T
=	1	G	1	G
=	2	F	2	F
=	3	-	3	-
-	4	$\beta$		
+			4	b
+			5	e

+			7	a
=	5		8	
=	6	a	9	a
=	7	c	10	c
=	8	t	11	t
=	9	s	12	s

Figure 4:  $\text{diff}(C, A)$

The LCS algorithm works fine when text variations occur only in isolation individually as in Figure 4. Sometimes, however, text variations occur successively, causing what we call the *successive variation* problem. It is illustrated in the *diff* result in Figure 5, where two Unicode characters, ‘ $\beta$ ’ and ‘ $\text{^-}$ ’<sup>4</sup> appear successively. The source position, 5, needs to be precisely mapped to the target position, 8, which however the LCS-diff algorithms cannot find: while the mapping,  $\delta(4) \rightarrow 4$ , is obvious, there is no clue as to which position, among 5, 6, 7 and 8, the next one,  $\delta(5)$  to be mapped to.

#### 4 Generalized LCS algorithm

To address the problem of *successive variations*, we need to inform the algorithm of equivalent sequences, e.g.,  $\beta$  and *beta*. We call a collection of

<sup>4</sup>long hyphen in Unicode

=	0	T	0	T
=	1	G	1	G
=	2	F	2	F
=	3	-	3	-
-	4	$\beta$		
-	5	-		
+			4	b
+			5	e
+			6	t
+			7	a
+			8	-
=	6	i	9	i
=	7	n	10	n
=	8	d	11	d
=	9	u	12	u
=	10	c	13	c
=	11	e	14	e
=	12	d	15	d

Figure 5: The result of LCS-Diff for “*TGF- $\beta$ -induced*” and “*TGF-beta-induced*”

equivalent sequences a *dictionary*, and modify Algorithm 1 as follows:

```

1: function GLCS(X[1..m], Y[1..n], D)
   ...
11-1: a, b := S(X[1..i], Y[1..j], D)
11-2: if a > 0 then
12:   C[i, j] := C[i-a, j-b] + 1

```

As indicated in line 1, it is invoked with a dictionary, *D*, which is a list of equivalent sequences, e.g., ( $\alpha$ , *alpha*), ( $\beta$ , *beta*), and so on. The 11’t line of Algorithm 1, which performs the comparison of the last characters, is modified to perform a general suffix comparison. The suffix comparison function, *S*, first performs the last-character-comparison for trivial cases, and performs a suffix comparison in variable length when the character comparison fails. The suffix comparison relies on the dictionary, *D*: if the two strings have matching suffixes in the end according to the dictionary, it returns the length of the suffixes, which is received by *a* and *b* in the modified algorithm.

Following is the modification to Algorithm 2:

```

5-1: a, b := S(X[a..i], Y[b..j])
5-2: if i > 0 and j > 0 and a > 0 then
6-1:   if a = b = 1 and X[i] = Y[j] then
6-2:     push(D, ['=', X[i], Y[j]])
6-3:   else
6-4:     for p := i-a+1..i do
6-5:       push(D, ['-', X[p], nil])
6-6:     end for
6-7:     for q := j-b+1..j do
6-8:       push(D, ['+', nil, Y[q]])
6-9:     end for
6-10:  end if
7:   i := i - a
8:   j := j - b

```

Using it, the *diff* of the successive variation example is obtained as in Figure 6, where the mapping

=	0	T	0	T
=	1	G	1	G
=	2	F	2	F
=	3	-	3	-
+	4	$\beta$	4	b
+			5	e
+			6	t
+			7	a
-	5	-	8	-
+	6	i	9	i
=	7	n	10	n
=	8	d	11	d
=	9	u	12	u
=	10	c	13	c
=	11	e	14	e
=	12	d	15	d

Figure 6: The result of GLCS-Diff for “*TGF-beta-induced*” and “*TGF-beta-induced*”

of ‘-’ and ‘-’ is properly represented, solving the problem of successive variations.

As the modified algorithm generalizes the last-character-comparison to the variable-length-suffix-comparison, we call it a *generalized LCS (GLCS)* algorithm. With an empty dictionary, GLCS works exactly the same as LCS. Using a *suffix tree* algorithm, GLCS has the worst case time complexity,  $O(mnl)$ , where  $l$  is the length of the longest entry in the dictionary.

While the performance of GLCS relies on the dictionary, in fact, it works well even with an incomplete dictionary. For example, to get the result in Figure 6, having either ( $\beta$ , *beta*) or (-, -) in the dictionary is enough. This feature contributes to the robustness of GLCS in real world applications.

## 5 Application and evaluation

The proposed solution is implemented into PubAnnotation<sup>5</sup>, a storage system for corpora and annotations. The system is developed to share corpora and annotations developed by several annotation projects. The system maintains a collection of texts taken from a number of sources, e.g., PubMed<sup>6</sup> and PubMed Central<sup>7</sup>, and supplies them to the annotation projects. The annotations produced by the annotation projects are collected back to PubAnnotation for sharing.

As the annotation projects are conducted by different groups independently, when the resulted annotations are submitted to the storage system, the

<sup>5</sup><http://pubannotation.org>

<sup>6</sup><http://www.ncbi.nlm.nih.gov/pubmed>

<sup>7</sup><http://www.ncbi.nlm.nih.gov/pmc/>

base texts often have been varied from the original, due to, e.g., Unicode-ASCII conversion, tokenization, or accidental insertion or deletion of characters. PubAnnotation handles all the mapping and alignment by using the LCS and GLCS algorithms. For performance, LCS is implemented using Hunt-McIlroy algorithm, and GLCS is implemented as presented in this paper. While using LCS as default, GLCS is only invoked when successive variations are detected. Because successive variations seldom occur, the cost for running GLCS is negligible. Yet, securing a solution for successive variations is important. When experimented with 10 full papers with 54,938 words and 6,007 annotation instances, the text mapping and annotation alignment took less than 10 seconds.

The accuracy of mapping and alignment is thoroughly verified using 10 full text papers with 58,360 words and 7,315 span annotations. Two versions of dictionary for GLCS were prepared: (A) one for all the standard set of Unicode characters<sup>8</sup>, and (B) another only for the Unicode characters for whitespace and punctuation symbols. The system successfully aligned all the annotations even with the smaller one, (B). It indicates that when successive variations occur, in most cases, whitespace or punctuation symbols are mixed in it. At least it was the case in our application.

Another 10 full text papers with 54,369 words and 5,729 annotations were used for further verification. While keeping using the dictionary (B), the system is implemented to alert when an unsolvable case is detected. During the processing of the 10 papers, the alert was issued only once, which was caused by the Unicode sequence,  $\Delta\Delta$ . When the larger dictionary, (A), was used, the problem was not observed. So, it is true that the more complete the dictionary is, the higher the accuracy will be. The empirical results also suggest that, together with the alerting system, the proposed solution works reasonably well, even with minimal size of dictionary.

## 6 Conclusions

The solution presented in this paper is freely available as an open source Ruby library and also as a free service through the PubAnnotation storage system. We expect it to contribute to reduce the cost of community for interoperable use of corpora and annotations.

<sup>8</sup>As implemented in the standard *unicode* library.

## Abstract

In this paper, we propose a semantic naïve Bayes classifier (SNBC) to improve the conventional naïve Bayes classifier (NBC) by incorporating “document-level” semantic information for document classification (DC). To capture the semantic information from each document, we develop semantic feature extraction and modeling algorithms. For semantic feature extraction, we first apply a log-Bilinear document modeling (LBDM) algorithm to transform each word into a semantic vector, and then apply principal component analysis (PCA) to the semantic space formed by the word vectors to extract a set of semantic features for each document. For semantic modeling, a semantic model is constructed using the semantic features of the training documents. In the testing phase, SNBC systematically integrates the semantic model and the conventional NBC to perform DC. The results of experiments on the 20 News-groups and WebKB datasets confirm that, with the semantic score, SNBC consistently outperforms NBC with various language modeling approaches.

## 1 Introduction

Document classification (DC) is an important task in the information retrieval (IR) and natural language processing (NLP) areas. In recent years, many approaches have been developed for DC. Among them, a category of approaches views DC as a traditional ranking problem. These approaches first represent a document with a feature vector, known as the vector space model (VSM), and then machine learning algorithms can be applied to accomplish classification. Notable examples belonging to this category include support vector machine (Joachims, 1998), decision tree (Comite *et al.*, 2003), logistic regression (Genkin *et al.*, 2005), and k-nearest neighbor (Kwon and Lee, 2003).

Another successful category of approaches is based on the naïve Bayes classifier (NBC). NBC assumes that a document is generated from a probabilistic model. In the offline training process, the model parameters are estimated from a set of training documents. When performing DC, NBC calculates a conditional probability  $P(c|d)$  (the posterior probability that document  $d$  belongs to class  $c$ ) and classifies the test document to the class that gives the highest  $P(c|d)$ . When calculating  $P(c|d)$ , NBC makes word independence (bag-of-words) assumptions and decomposes  $P(c|d)$  to a product of individual word probabilities. These word probabilities are usually characterized by a statistical language model. In practice, unigram language modeling (ULM) is a popular choice due to its effectiveness and computational efficiency (Peng and Schuurmans, 2003; Bai and Nie, 2004; Wu and Wang, 2012). However, since NBC with ULM only considers frequencies of words occurring in a class, it may suffer from the problems of data sparseness and word usage diversity, leading to performance degradations for DC. To deal with the data sparseness (zero probability) problem of ULM, many smoothing techniques, such as Laplace (Bai and Nie, 2004) and Jelinek-Mercer (Jelinek and Mercer, 1980) smoothing techniques have been developed.

The latent topic language modeling (LTM) approaches use a set of latent topics to decompose the relationships between documents and classes. Successful examples include latent semantic analysis (LSA) (Bellegarda, 2005; Deerwester *et al.*, 1990), probabilistic latent semantic analysis (PLSA) (Hofmann, 1999a; Hofmann, 1999b), and latent Dirichlet allocation (LDA) (Blei 2011; Griffiths and Steyvers, 2004; Blei *et al.*, 2003). For these approaches, classification scores are not computed directly based on the frequencies of the words but instead based on a set of latent topics along with the likelihoods that each class generates the respective topics. The use of latent topics effectively tackles the word usage diversity problem for ULM and performs DC in a concept matching manner.

Although NBC with LTM approaches have taken

the semantic information into account, the document-level semantic cues are not directly incorporated for the DC task (LTM approaches only extract the word frequency information from documents). In this paper, we intend to enhance the NBC-based approaches by incorporating document-level semantic information for DC. In the training phase, we estimate the parameters of the semantic model by using the training documents. In the testing phase, a semantic score is computed based on the given test document with a particular class. The final decision of DC is made based on a combined score from the semantic model and the traditional NBC. Since the proposed framework is derived based on the NBC framework, we name it “semantic NBC” (SNBC). We conduct experiments on two sets of corpora, namely 20 Newsgroups and WebKB. Experimental results demonstrate that SNBC consistently outperforms NBC with various language modeling approaches.

The remainder of this paper is organized as follows. Section 2 defines the notations and briefly reviews the related work. Section 3 introduces the proposed SNBC framework. Section 4 describes our experimental setup and discusses experimental results. Finally, we conclude this work in Section 5.

## 2 Related Work

In this section, we present notation and terminology to be used in the following discussions and review related work to the proposed SNBC framework.

### 2.1 Notation

The basic unit in a DC task is word, which is denoted as  $w$ , where  $w \in \mathbf{V}$ , and  $\mathbf{V}$  denotes the vocabulary set. A document is a sequence of words, and we denote a document by  $d$ , where  $|d|$  represents the total number of words in the document. A class is a predefined document class, and we denote a class by  $c$ . Assuming that we have  $|\mathbf{C}|$  distinct classes, the goal of DC is to classify a test document  $d_{test}$  into a specific class  $c$ , where  $c \in \mathbf{C}$ .

### 2.2 Naïve Bayes Classifier with Language Modeling

NBC performs DC in two stages: training and testing. In the training stage, a generative model is estimated based on the training documents for each class. In the testing stage, NBC calculates the posterior probability of each class given the evidence of the test document and selects the class that gives the highest probability

$$\hat{c} = \underset{c}{\operatorname{argmax}} P(c|d). \quad (1)$$

By applying Bayes' theorem on  $P(c|d)$ , we have

$$P(c|d) = \frac{P(d|c)P(c)}{P(d)} \propto P(d|c)P(c), \quad (2)$$

where  $P(d|c)$  is the likelihood of document  $d$  under class  $c$ . Since NBC assumes that words in  $d$  are independent to each other,  $P(d|c)$  can be decomposed as

$$P(d|c) = \prod_{w \in d} P(w|c)^{n(w,d)}, \quad (3)$$

where  $P(w|c)$  is the class unigram probability, which indicates the likelihood of word  $w$  occurring in the class  $c$ , and  $n(w,d)$  denotes the frequency of word  $w$  occurring in  $d$ . Generally, a unigram language model (ULM) is used for calculating  $P(w|c)$ . However, ULM may encounter a data sparseness (zero-probability) problem. To deal with this problem, many smoothing techniques have been developed. Laplace and Jelinek-Mercer smoothing techniques are two successful examples.

The Laplace smoothing technique calculates  $P(w|c)$  by

$$P_{La}(w|c) = \frac{1+n(w,c)}{|\mathbf{V}| + \sum_{w \in \mathbf{V}} n(w,c)}, \quad (4)$$

where  $n(w,c)$  denotes the frequency of word  $w$  occurring in class  $c$ .

The Jelinek-Mercer smoothing technique calculates  $P(w|c)$  by

$$P_{JM}(w|c) = \lambda \frac{n(w,c)}{\sum_{w \in \mathbf{V}} n(w,c)} + (1-\lambda)P_{BG}(w), \quad (5)$$

where  $P_{BG}(w)$  is a background language model obtained from the entire training corpus. The tunable parameter  $\lambda$  in Eq. (5) can be determined based on a set of development data. Although many studies have proven that NBC with ULM can provide satisfactory performance, the method has a limitation: the classification process is based on literal term matching and only considers frequencies of words occurring in a class. Thus, NBC with ULM usually suffers from the issue of word usage diversity and polysemy, which can degrade the DC performance.

### 2.3 Latent Topic Modeling

In contrast to literal term matching, a latent topic language modeling (LTM) incorporates a set of latent topic variables to decompose the relationships between documents and classes. PLSA (Hofmann, 1999a; Hofmann, 1999b) and LDA (Blei, 2011; Griffiths and Steyvers, 2004; Blei *et al.*, 2003) are two representative LTM approaches. For PLSA,  $P(d|c)$  is formulated as

$$P_{\text{PLSA}}(d|c) = \prod_{w \in d} \left[ \sum_{k=1}^K P(w|T_k) P(T_k|c) \right]^{n(w,d)}, \quad (6)$$

where  $T_k$  is the  $k^{\text{th}}$  latent topic variable, and  $K$  denotes the total number of latent topics. The word-topic likelihood  $P(w|T_k)$  and topic-class likelihood  $P(T_k|c)$  can be estimated beforehand by maximizing the total log-likelihood of the training data. For traditional NBC with ULM, the model implicitly assumes that each word in a document is drawn from a single topic distribution. On the contrary, LTM generalizes the idea to allow a mixture of latent topics, which can overcome the word diversity problem of ULM.

LDA shares a same concept as PLSA that uses a set of latent topic variables to model  $P(w|c)$ . The major difference between LDA and PLSA is that PLSA assumes the parameters of topic models to be fixed and unknown, while LDA considers the parameters as random variables that follow a Dirichlet distribution. Because LDA uses a complex form for latent topic modeling, the estimation of model parameters is hard to be solved by an exact inference. To simplify the estimation, a variety of approximation algorithms, such as the variational Bayesian expectation maximization (VBEM) (Blei, 2011; Blei *et al.*, 2003) and Gibbs sampling (Griffiths and Steyvers, 2004) algorithms, have been proposed.

## 2.4 Log-Bilinear Document Modeling

Log-Bilinear document modeling (LBDM) (Maas and Ng, 2010; Maas *et al.*, 2011) can be considered as a relaxed version of LTM. LBDM attempts to learn the word representation with a semantic space and use training documents to constrain those semantically similar words to be represented in near vicinity. The major difference of LBDM and LTM is that LBDM aims to directly parameterize the model for capturing word representations, while LTM focuses on estimating a set of latent topics (Maas and Ng, 2010).

For matching the empirical distribution of words in each document, LBDM introduces a document specific variable  $\theta$  and defines the probability of a document as

$$\begin{aligned} P(d) &= \int P(d, \theta) d\theta \\ &= \int P(\theta) \prod_{w \in d} P(w|\theta)^{n(w,d)} d\theta, \end{aligned} \quad (7)$$

where

$$P(w|\theta) = \frac{\exp(\theta^T \phi_w + b_w)}{\sum_{w' \in \mathbf{V}} \exp(\theta^T \phi_{w'} + b_{w'})}, \quad (8)$$

where  $\phi_w$  is a vector representation of word  $w$ , and  $b_w$  denotes a bias for word  $w$ . LBDM assumes that  $\phi_w$  and  $\theta$  are in  $\mathfrak{R}^\beta$ , and the variable  $\theta$  is modeled by a Gaussian prior density. The probability  $P(w|\theta)$  indicates how close the vector representation of word  $w$ ,  $\phi_w$ , is to  $\theta$ .

Assuming that we are dealing with the entire set of document collection,  $\mathbf{D}$ , the word representation matrix  $\mathbf{R} \in \mathfrak{R}^{\beta \times |\mathbf{V}|}$  (the  $i^{\text{th}}$  column vector of  $\mathbf{R}$  denoting the vector representation of the  $i^{\text{th}}$  word in the vocabulary) and word bias  $\mathbf{b} \in \mathfrak{R}^{|\mathbf{V}|}$  (the  $i^{\text{th}}$  component of  $\mathbf{b}$  denotes the bias term for the  $i^{\text{th}}$  word in the vocabulary) can be estimated by

$$\begin{aligned} \{\hat{\mathbf{R}}, \hat{\mathbf{b}}\} &= \arg \max_{\mathbf{R}, \mathbf{b}} P(\mathbf{D}; \mathbf{R}, \mathbf{b}) \\ &= \arg \max_{\mathbf{R}, \mathbf{b}} \prod_{d \in \mathbf{D}} \int P(\theta_d) \prod_{w \in d} P(w|\theta_d; \mathbf{R}, \mathbf{b})^{n(w,d)} d\theta_d. \end{aligned} \quad (9)$$

The integral over  $\theta_d$  in Eq. (9) is intractable. To simplify the estimation, we assume that the posterior distribution is highly peaked around the MAP estimate of  $\theta_d$ . By adding regularization terms for  $\mathbf{R}$  and  $\theta_d$  and taking the logarithm, the parameters of LBDM are approximately estimated by

$$\begin{aligned} \{\hat{\mathbf{R}}, \hat{\mathbf{b}}\} &= \arg \max_{\mathbf{R}, \mathbf{b}} \left[ \sum_{d \in \mathbf{D}} \sum_{w \in d} n(w,d) \log P(w|\hat{\theta}_d; \mathbf{R}, \mathbf{b}) \right. \\ &\quad \left. + \lambda \|\mathbf{R}\|^2 + \lambda \|\hat{\theta}_d\|^2 \right], \end{aligned} \quad (10)$$

where  $\hat{\theta}_d$  denotes the MAP estimate of  $\theta_d$  for each document  $d \in \mathbf{D}$ . Since the objective function in Eq. (10) is not convex, a coordinate ascent process is performed to estimate the parameters. The estimation process first optimizes the word representations ( $\mathbf{R}$  and  $\mathbf{b}$ ) with keeping the MAP estimates  $\hat{\theta}_d$  of each document fixed. Next, we find the new MAP estimate for each document with keeping the word representations fixed. The two estimation processes are performed iteratively until reach convergence.

When performing DC, for the class  $c$ , the MAP estimate of the variable  $\hat{\theta}_c$  is estimated by using the word representations  $\mathbf{R}$ ,  $\mathbf{b}$ , and a pseudo-document, which is a collection of the entire set of training documents belonging to class  $c$ . Next, the similarity between a document and a class  $c$  is determined by

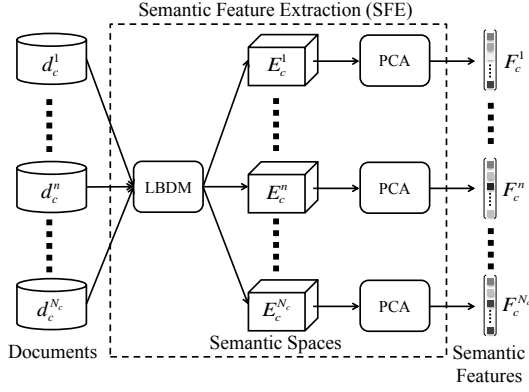

Fig. 1. Semantic feature extraction (SFE) for the  $c^{\text{th}}$  class

$$\begin{aligned}
 P(d|c) &= \prod_{w \in d} P(w|\hat{\theta}_c)^{n(w,d)} \\
 &= \prod_{w \in d} \left( \frac{\exp(\hat{\theta}_c^T \phi_w + b_w)}{\sum_{w' \in \mathbf{V}} \exp(\hat{\theta}_c^T \phi_{w'} + b_{w'})} \right)^{n(w,d)}.
 \end{aligned} \tag{11}$$

### 3 Semantic Naïve Bayes Classifier

NBC with LTM models has taken the semantic information into account and been confirmed effective for DC. However, the “document-level” semantic cues are not directly incorporated. In other words, documents are only treated as a sequence of words when determined the similarity between a class and a document (*cf.* Section 2). To exploit the semantic information of documents, we propose a semantic NBC (SNBC) framework in this paper. In what follows, we articulate the derivation of SNBC and the implementation process of SNBC to perform DC.

#### 3.1 Literal and Semantic Models of SNBC

As presented in Section 2, NBC performs DC by conducting literal term matching (Eqs. (1)-(3)). To incorporate document-level semantic information, we divide  $P(d|c)$  into two parts, namely the literal part and the semantic part, and reformulate Eq. (1) as

$$\begin{aligned}
 \hat{c} &= \arg \max_c P(c|d) \\
 &= \arg \max_c P(d|c)P(c) \\
 &= \arg \max_c P(d_s, d_l|c)P(c),
 \end{aligned} \tag{12}$$

where  $d_s$  and  $d_l$  denote the semantic and literal parts, respectively. By assuming that the literal and semantic parts are conditionally independent given a class, we have

$$P(d_s, d_l|c) = P(d_s|c)P(d_l|c). \tag{13}$$

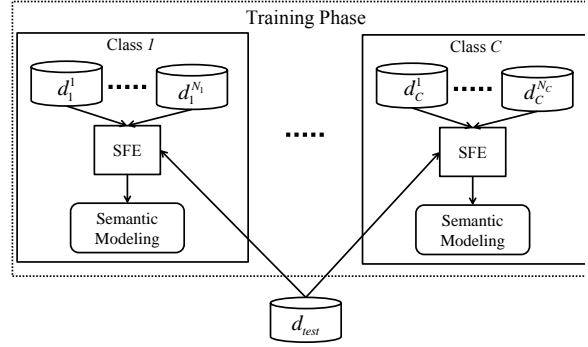

Fig. 2. Semantic modeling and semantic score calculation for a test document

As presented in Section 2,  $P(d_l|c)$  can be estimated by NBC with any language modeling approaches. The calculation of semantic model,  $P(d_s|c)$ , will be detailed in the next section.

#### 3.2 Document-level Semantic Information Capturing

This section describes the semantic feature extraction, semantic modeling, and semantic score calculation procedures in the SNBC framework.

##### 3.2.1 Semantic Feature Extraction

As introduced in Section 2, LBDM can transform a word into a semantic vector representation. In the proposed SNBC framework, we incorporate LBDM to perform semantic feature extraction (SFE). Fig. 1 illustrates the SFE process. Assume that we have  $N_c$  documents in the  $c^{\text{th}}$  class. For the  $n^{\text{th}}$  document, we apply LBDM to represent each word into a semantic vector. The collection of word vectors in that document then forms a semantic subspace for that document, denoted as  $E_c^n$ . Next, we apply principal component analysis (PCA) on  $E_c^n$  to extract its principal vectors,  $F_c^n$ . Finally, we use the principal vectors  $F_c^n$  to capture main directions of semantic topics of the document  $d_c^n$ . In this paper, we only use the eigenvector with the largest eigenvalue as the semantic feature for  $d_c^n$ . We will study the use of multiple eigenvectors in our future work.

##### 3.2.2 Semantic Modeling and Score Calculation

Figure 2 illustrates the semantic modeling process, which can be divided into training and testing stages. In the training stage, we use the semantic features of the training documents to estimate a semantic model, where each class is modeled by a semantic distribution. In this paper, we use the Gaussian mixture model (GMM) for semantic modeling. Because each class may include several sub-topics (e.g., tennis, basketball, and boxing are all categorized in the sports class), we believe that GMM is a suitable model to characterize the semantic distribution for

Fig. 3. SNBC score calculation for a test document

each class. The semantic features of the training documents belonging to each class are used to train the GMM for that class. In the testing stage, for each class, the class specific SFE is performed to extract the semantic feature of the test document. Next, the extracted feature is tested on the class specific GMM to obtain the semantic score,  $P(d_s | c)$ , indicating the semantic likelihood of document  $d$  on class  $c$ . Since the covariances for different GMMs may vary, we design a normalization algorithm to compensate the variations of semantic likelihoods by

$$P(d_s | c) = \frac{\sum_{m=1}^{M_c} \pi_m N(F_c | \mu_m, \Sigma_m)}{\sum_{m=1}^{M_c} \pi_m N(\mu_m | \mu_m, \Sigma_m)}, \quad (13)$$

where  $F_c$  is the semantic feature of the test document  $d_{test}$  for the  $c^{\text{th}}$  class, and the GMM model of class  $c$  has  $M_c$  Gaussian components with mean vectors  $\{\mu_1, \dots, \mu_{M_c}\}$ , covariance matrices  $\{\Sigma_1, \dots, \Sigma_{M_c}\}$ , and mixture weights  $\{\pi_1, \dots, \pi_{M_c}\}$ .

### 3.3 SNBC Score Calculation

With NBC and the semantic model, we can calculate the final SNBC score by multiplying scores from three different information sources, namely the class prior, semantic information, and literal language modeling, as illustrated in Fig. 3. We further use  $\alpha$  to control the scale of semantic information. Therefore, the classification rule for SNBC becomes

$$\hat{c} = \underset{c}{\operatorname{argmax}} P(d_s | c)^\alpha P(c) \prod_{w \in d} P(w | c)^{n(w,d)}, \quad (14)$$

where the class prior,  $P(c)$ , is simply kept uniform in this paper.

## 4 Experiments

This section describes our experimental setup, performance measure, and experimental results.

### 4.1 Experimental Setup

We conducted the DC experiments on 20 Newsgroups (20Ng) and WebKB datasets (<http://web.ist.utl.pt/acardoso/datasets/>) (Cardoso-cachopo and Oliveira, 2003). The pre-processing steps include stemming, removing stop words, and removing numbers and words with occurrence below four. 20Ng contains roughly 20,000 documents, which distribute approximately even across 20 classes. These documents are randomly divided into 60% for training and 40% for testing. WebKB originally contains seven different categories, and we use four major classes in the experiments. Finally there are around 4,200 documents, which are randomly divided into two thirds for training and one third for testing. Albeit that the way to systemically determine the values of the parameters in various machine learning approaches is still an open issue and needs further investigation and proper experimentation, the parameters in the following experiments are set empirically as follows. The number of latent topics and the dimension of LDBM are set to 10, which gives the optimal result in our preliminary experiments. For semantic modeling, the number of GMMs equals to the number of classes, and each GMM is characterized by 20 Gaussian components. The parameter  $\alpha$  is set to 0.6.

### 4.2 Performance Measure

In the following DC experiments, we use the standard F1-score measure for evaluation. F1-score ( $F$ ) can be decomposed into two parts, namely recall ( $R$ ) and precision ( $P$ ).

$$R = \frac{\# \text{correct positive prediction}}{\# \text{positive examples}}, \quad (15)$$

$$P = \frac{\# \text{correct positive prediction}}{\# \text{positive prediction}}, \quad (16)$$

$$F = \frac{2 \times R \times P}{R + P}. \quad (17)$$

To evaluate the average F1-scores across all the classes, we adopt micro-averaged and macro-averaged F1-scores (Yang, 1999). The micro-averaged F1-score assigns a same weight across different classes while the macro-averaged F1-score gives each class a specific weight according to the number of documents within that class.

### 4.3 Experimental Results

First, we evaluate the performance of conventional NBC with various language models, including ULM with Jelinek-Mercer smoothing (JM), LDA, and LBDM; their average F1-scores evaluated on WebKB and 20Ng are listed as JM, LDA, and LBDM, respectively, in the upper three rows in Tables 1 and 2. From Tables 1 and 2, we observe that LDA outperforms JM and LBDM in most cases. The results indicate that topic modeling performs better than other language modeling approaches, which is consistent with many previous studies (Blei *et al.*, 2003).

Next, we combine the above three NBC systems, namely JM, LDA, and LBDM, with the semantic information (as presented in Section 3.3); the corresponding results are listed as SNBC (JM), SNBC (LDA), and SNBC (LBDM), respectively, in the lower three rows of Tables 1 and 2. From the experimental results, we note that SNBC consistently outperforms conventional NBC systems. The improvements from NBC to SNBC have been confirmed statistically significant based on the t-test (Agresti and Franklin, 2008). The superscript \* in Tables 1 and 2 indicates that the corresponding improvement is significant at the 0.05 confidence level. Our experimental results confirm that the document-level semantic information provides complementary knowledge to the NBC with LTM and thus improve its performance for DC.

## 5 Conclusions

This paper has proposed a semantic naïve Bayes classifier (SNBC) that incorporates document-level semantic information to improve the performance of the conventional NBC for the DC task. The SNBC framework includes a semantic feature extraction scheme to extract the semantic information of a training/test document and a semantic modeling algorithm to compute the semantic score for a given document. In the testing phase, SNBC combines the semantic score and the language modeling score to perform DC. Our experiments have been conducted on the 20 Newsgroups and WebKB datasets. The results demonstrated that SNBC can improve the DC performance in terms of Micro-F1 and Macro-F1 scores for NBC with various language modeling techniques. The performance improvement of SNBC over NBC confirms the effectiveness of integrating document-level semantic information into the conventional NBC. Notably, this study adopts LBDM to prepare semantic features; other semantic extraction methods, such as PLSA and LDA, can also be used to prepare semantic features. More experiments on SNBC using different semantic extraction methods will be conducted and compared with other existing state-of-the-art approaches in the future.

Table 1. F1-scores of NBC and SNBC on the WebKB dataset

Models	Micro-F1	Macro-F1
JM	0.8381	0.8258
LDA	0.8388	0.8253
LBDM	0.8187	0.8133
SNBC(JM)	0.8491	0.8403
SNBC(LDA)	0.8603	0.8496
*SNBC(LBDM)	0.8488	0.8346

Table 2. F1-scores of NBC and SNBC on the 20Ng dataset

Models	Micro-F1	Macro-F1
JM	0.8131	0.8070
LDA	0.8190	0.8122
LBDM	0.8144	0.8072
SNBC(JM)	0.8293	0.8152
SNBC(LDA)	0.8305	0.8213
*SNBC(LBDM)	0.8346	0.8251

## Abstract

We propose a novel approach to abstractive Web summarization based on the observation that summaries for similar URLs tend to be similar in both content and structure. We leverage existing URL clusters and construct per-cluster word graphs that combine known summaries while abstracting out URL-specific attributes. The resulting topology, conditioned on URL features, allows us to cast the summarization problem as a structured learning task using a lowest cost path search as the decoding step. Early experimental results on a large number of URL clusters show that this approach is able to outperform previously proposed Web summarizers.

## 1 Introduction

Abstract Web summaries, which describe the topics and functionalities of Web pages at an *abstract* level, play an essential part in the discovery of new sites and services on the Web. Such summaries are intrinsically difficult to obtain using the content of Web pages. As such, the most successful methods for generating them are effectively extractive and based on the identification of likely abstractive content from linking pages. These *URL-centric* techniques however require a significant amount of redundancy in linking content (Delort et al., 2003).

In this paper, we propose a *summary-centric* approach to Web summarization based on the observation that summaries for similar URLs exhibit both similar content and structure. This similarity is apparent when analyzing summaries from a single ODP category, examples of which are

shown in Table 1. We can see there that summaries of semantically related URLs tend to share common concepts and differ mostly at the level of target-specific attributes. Given a previously unseen URL  $U$ , such a cluster could thus be used as a source of potentially relevant terms for that URL’s summary. In particular, these relevant terms include abstract terms, which may not otherwise be observed in the input data. We propose a graph-based summarization framework that can leverage this phenomenon.

## 2 Proposed Framework

Given a reference cluster  $C$ , we represent the space for summary generation as a graph  $G_C = (V_C, E_C)$ . This graph is obtained by fusing training summaries in  $C$  into a word graph. Each summary  $g_i$  is mapped to a path between the shared source and sink nodes. Each word  $g_i^j$  is thus mapped to a node  $N_k$  and each pair of neighboring words  $(g_i^j, g_i^{j+1})$  to a directed edge  $(N_k, N_l)$ . Notably, we add nodes as needed to guarantee that individual summaries are cycle-free. Figure 1 shows a simple summary graph.

### 2.1 Node Alignment

During the graph construction, nodes from distinct paths are iteratively combined to elicit the structural and content commonalities between summaries in the reference cluster. Following (Filippova, 2010) unambiguous nodes — i.e. nodes whose surface form match exactly and for which only one candidate exists — are always aligned, while ambiguous nodes are aligned to the candidate node with maximum context overlap. When there is no context overlap, a new node is added to the graph.

## 2.2 Template Slots

The content of reference summaries is likely to be only partially relevant to a previously unseen URL. In particular, certain paths in the summary graph may contain nodes whose surface form is target-specific. We use the following heuristic to decide on the presence of template slots in a summary:

- Adverbs, adjectives and named entities are treated as slots.
- Any term occurring in at least 25% of paths will not be treated as a slot;

Similarly to (Barzilay and Lee, 2003), slot identification is performed prior to alignment.

## 3 Features

In this section we present the feature sets used to condition the summary graph topology on a target URL  $U$ . Two aspects of the graph need to be trained, namely edge costs and slot locations. We introduce features for both.

### 3.1 Edge Feature Templates

We use the following feature templates to represent the compatibility between  $U$  — represented by its text modalities, as listed in Table 2 — and a specific edge in the summary graph.

**Edge prior** Probability of appearance of edge  $e_{ij}$  in reference paths (summaries).

**Edge appearance + Modality** Frequency of edge  $e_{ij}$  in each modality  $M_k$ . We consider that  $e_{ij}$  appears in  $M_k$  if its source and sink co-occur in  $M_k$ .

**Source/Sink prior** Probability of Source/Sink node  $N_i$  in reference paths (summaries).

**Source/Sink appearance + Modality** Indicates whether Source/Sink node  $N_i$  occurs in  $M_k$ .

**Modality + n-gram** Compatibility between the edge  $e_{ij}$ , the modality  $M_k$  and the n-gram  $n_l$ , where  $n$  is in the range  $[1, 3]$ .

### 3.2 Slot Features

To allow for the use of supervised methods in learning optimal edge costs we need a graph whose structure remains unchanged from one training instance to the next. The fillers of slot locations are thus described using features that are not surface-based:

**Semantic Type** We only consider fillers compatible with the host slot.

**Modality appearance** Frequency of filler candidate in modality  $M_k$ .

**Content HTML Context** HTML (Style + Structural) context of filler candidate in the content of  $U$ .

## 4 Learning Model

Using the summary graph topology and the features defined above we express the abstract Web summarization task as a structured learning problem. Specifically, we seek to obtain edge weights such that the cost of individual reference summaries — which, as we saw earlier, are mapped to paths — is minimized. Given a set of features  $\mathcal{F}$ , the optimal set of feature weights  $w^*$  is such that:

$$w^* = \arg \min_w \sum_{g \in \mathcal{R}(U)} Cost_w(g) \quad (1)$$

Since our core constraint in building the summary graph is that each summary should map to a cycle-free path, identifying the optimal summary given a set of edge weights reduces to solving a lowest cost path problem:

$$w^* = \arg \min_w \sum_{g \in \mathcal{R}(U)} \sum_{i=1}^{|g|} \sum_{f_k \in \mathcal{F}} Cost_{f_k}(e_{g_{i-1}g_i}) \quad (2)$$

Modality	Feature Types	Description
URL content	$n$ -gram ( $n \in [1, 3]$ ) $n$ -gram + context	$n$ -grams generated from the target page content $n$ -gram with HTML context (immediately surrounding HTML tag)
URL title	1-gram	1-grams generated from the target URL title
URL words	1-gram	1-grams generated from the target URL string (e.g. "nytimes", "com")
URL anchor text	$n$ -gram ( $n \in [1, 3]$ )	$n$ -grams generated from the anchor text for the target URL

Table 2: Modality and features used to represent a target URL  $U$ .

In this setting, generation is achieved by running the decoder using the optimal set of edge weights.

#### 4.1 Structured Perceptron

One way to solve this learning problem is to use a structured perceptron algorithm (Collins, 2002) where weights  $w$  control the linear contribution of individual features to the aggregate cost of edges.

$$Cost_{f_k}(e_{ij}) = w_k^{e_{ij}} \cdot f_k \quad (3)$$

The structured perceptron algorithm is shown in Algorithm 1. At every iteration, decoding is achieved via a search for the shortest path based on the edge costs induced by the current weights  $w^*$ . Following recent work on structured learning (Huang et al., 2012), we do not require this search to be exact, but to guarantee that each iteration results in a valid update. Our decoder thus uses beam search (beam size  $b = 5$ ) combined with an early update procedure, the latter helping in significantly speeding up model training.

---

#### Algorithm 1 Structured Perceptron

---

**Require:**  $\{u^i, g^i\}_{i=1}^n$   
1:  $w^* \leftarrow \{0\}$   
2: **for**  $i = 1 \rightarrow T$  **do**  
3:   **for**  $j = 1 \rightarrow n$  **do**  
4:      $g^* \leftarrow ShortestPath_{G^{w^*}}(u^i)$   
5:      $w^* \leftarrow w^* + \phi(u^i, g^i) - \phi(u^i, g^*)$   
6:   **end for**  
7: **end for**

---

#### 4.2 Slot Filling

During the inference phase, we substitute slot locations with alternate paths, each containing a candidate filler for the slot. Each of these paths is associated with the slot features discussed earlier, however the feature weights of each slot are shared, thus allowing the learning algorithm to converge towards appropriate weights for filler selection.

### 5 Evaluation

We compare the performance of our model against a reimplementations of the two summarization al-

gorithms - content-based and context-based - proposed in Delort et al. (2003). We apply our summarization algorithms and the baselines to a random sample of 56 ODP categories comprising at least 50 entries. For each category, we split the set of available summaries into training (90%) and testing (10%), train the summarization algorithms on the training set, and report (macro) average performance on the testing set.

ROUGE (Lin, 2004) results comparing both our proposed summarization model and the baseline systems to the ODP ground truth are provided in Table 3. The summary-graph model, both with and without slot-filling, shows significant improvements compared to the baselines in terms of ROUGE-1 and ROUGE-L scores. ROUGE-2 performance, however, is not on par with the baselines. Long-distance sequence similarity (ROUGE-L) being higher, we believe this could indicate the inability of our model to capture target-specific bi-grams that have little or no support in the training summaries. Allowing the topology of the summary-graph to adapt to its target, for instance by introducing missing edges supported by the input data, should help alleviate this issue. Finally, the performance of the model with slot filling shows slight improvement over the basic model, however we observed that the system frequently fails in extracting slot fillers. Future work will focus on acquiring more filler candidates and better features to model them.

### 6 Previous and Related Work

The work presented in this paper is linked to previous research in Web summarization and T2T language generation. Most works on the former have been on extractive methods, owing to the complexity of Web content but also to the need for compressed versions of Web pages. Other works have in fact eluded the question of generation to instead focus on the extraction of salient keywords from Web sites (Glover et al., 2002; Zhang et al., 2004). In the context of Web search engines, the compression task is constrained further by the amount of *SERP real estate* available for any single snip-

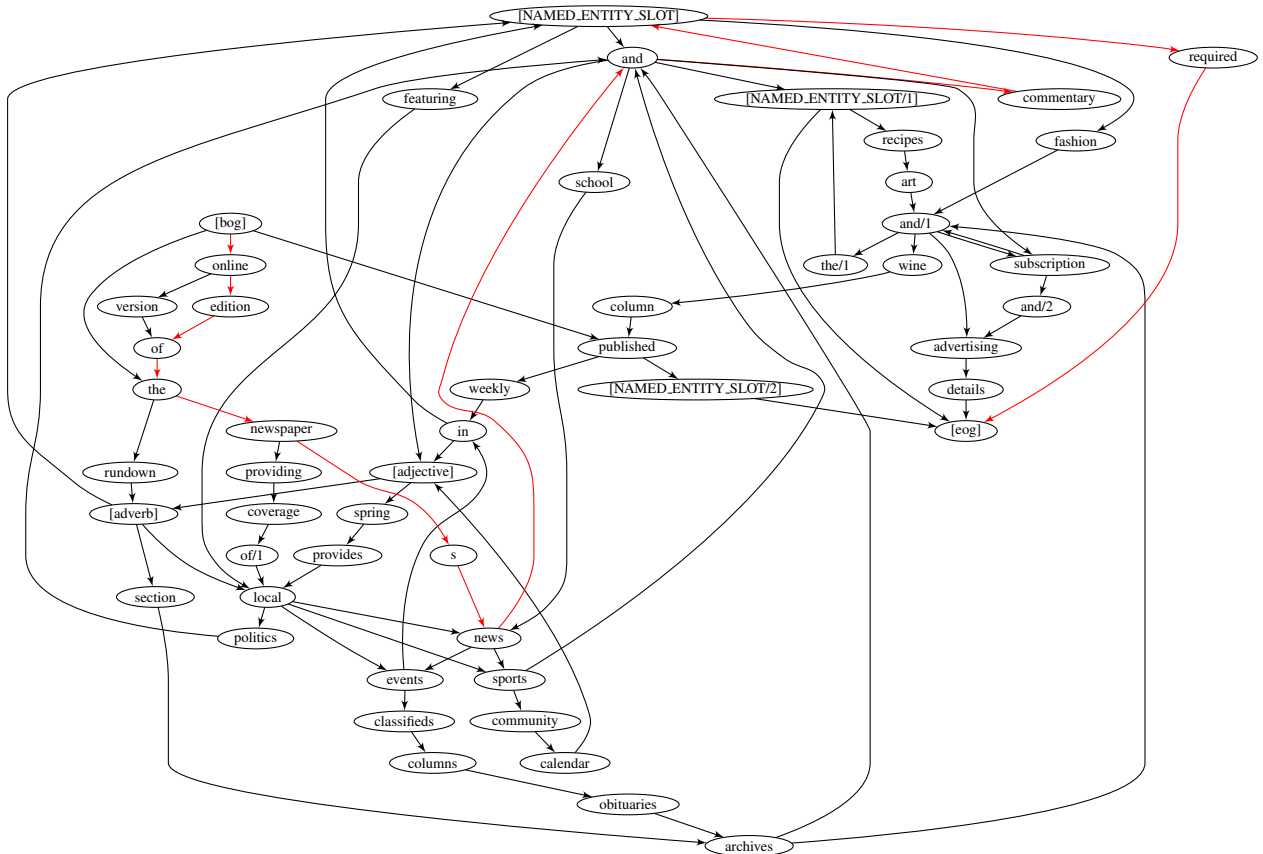

Figure 1: Summary graph associated with a subset of /News/Newspapers/Regional/United\_States/New\_York. The path for the URL <http://www.nytimes.com> is shown in red

Summarization System	ROUGE-1	ROUGE-2	ROUGE-L
Delort - Content	0.07163	0.04492	0.06574
Delort - Context	0.06783	0.03979	0.06197
Summary-graph	0.16222†	0.02775	0.14370†
Summary-graph + slot filling	0.16832†	0.02702	0.14729†

Table 3: Performance of summarization algorithms. † indicates statistically significant improvements (according to a paired t-test with  $p < 0.05$ ) compared to the provided baselines.

pet and how content may be truncated (Clarke et al., 2007). Sun et al. (2005), in particular, leveraged the ODP hierarchy to mitigate data scarcity for certain URLs, however they did not exploit ODP summaries themselves. Several efforts have focused on producing Web summaries using the content of linking pages as a source of descriptive content. Amitay and Paris (2000) assumes full summaries can be readily found on a single page linking to the target site. Delort et al. (2003) makes less stringent assumptions and seeks to combine descriptive content from multiple linking pages. Closer to our work, Berger and Mittal (2000) proposed a generative solution embracing the noisiness of Web data and trained directly over ODP (URL,summary) pairs. Finally our work relates to T2T generation as we seek to generate well-

formed sentences without resorting to semantic representations of either the input or output contents. Graph-based models similar to ours have been used for tasks ranging from string reconstruction (Wan et al., 2009) to sentence fusion and compression (Filippova and Strube, 2008; Filippova, 2010).

## 7 Conclusion and Future Work

We have introduced a word graph model for the task of Web summarization, and showed that per-cluster word graphs make it possible to combine abstractive and extractive behaviors. A limitation of our model is the need for existing reference clusters from which we build our summary graphs. Future work will investigate the dynamic production of such clusters.

## Abstract

We describe a first experiment on the identification and extraction of computer-interpretable guideline (CIG) components (activities, actors and consumed artifacts) from clinical documents, based on clinical entity recognition techniques. We rely on MetaMap and the UMLS Metathesaurus to provide lexical information, and study the impact of clinical document syntax and semantics on activity recognition.

**Keywords.** Clinical entity recognition, computer interpretable guideline, UMLS Metathesaurus.

**Introduction.** Clinical practice guidelines are systematically developed documents specifying the activities, resources and personnel required to cure or treat a specific illness or medical condition (Field and Lohr (1990)). The need to instantiate them into clinical protocols and workflows has given rise to *computer-interpretable guidelines* (CIGs) (De Clercq et al. (2008)), i.e., formal representations of the care process or plan, and to several natural language processing (NLP) techniques aimed at automating the costly manual CIG generation process (Kaiser et al. (2007), Serban et al. (2007)). All NLP approaches leverage on annotated biomedical resources (e.g., the CLEF corpus from Roberts et al. (2007) and Mykowiecka and Marciniak (2011)), or on frameworks such as cTAKES (Savova et al. (2010)). The key lexical-semantic resource in this domain is the US National Library of Medicine’s Unified Medical Language System (UMLS) Metathesaurus (Bodenreider (2004)), complemented by its front-end MetaMap (Aronson and Lang (2010)).

In this paper we conduct a first experiment on how to apply entity recognition techniques inspired by Abacha and Zweigenbaum (2011), to

recognize CIG components in medical documents. The process dimension of CIGs consists of four pillars: **(1)** *activities* to be executed; **(2)** the *resources* they use or consume; **(3)** the *actors* that execute them; **(4)** *control flows and gates* that temporally constrain activities. We focus in this paper on activities, the main building block of CIGs, and to a lesser extent on resources and actors. All these components are denoted by content words and can be used to build CIG fragments. We rely on MetaMap annotations and evaluate our techniques over an UMLS-annotated clinical corpus.

**CIGs and Activities.** Activities are entities difficult to identify with current resources: within clinical documents, in fact, not only verbs (**VBs**) but also proper nouns (**PNs**), common nouns (**NNs**) and, more in general, noun phrases (**NPs**)<sup>1</sup> can refer to them. Figure 1 shows an example from the type-2 diabetes guideline of the National Institute for Health and Clinical Excellence (NICE) (NICE - NHS (2009)) expressing a conditional CIG/process fragment, annotated automatically with MetaMap. To correctly extract the “deep” intended representations it is necessary to recognize that the two entities “blood glucose control” and “oral glucose-lowering medication” are activity tokens. MetaMap annotations provide a clue, but we still need to “filter out” the “clinical attribute” UMLS annotation. We want to understand how this information can be used for this task within an entity recognition framework.

**Clinical Entity Recognition.** Let  $\vec{c}$  denote a vector of clinical *entity type labels*, and  $\vec{\alpha}$  a vector of input *noun phrases (NPs)* or *entities*. The goal of *clinical entity recognition*, see Abacha and Zweigenbaum (2011), can be formulated as the task of finding the best scoring vector of clinical

<sup>1</sup>In this paper we refer to the Penn Treebank part-of-speech (POS) notation as described by Marcus et al. (1993).

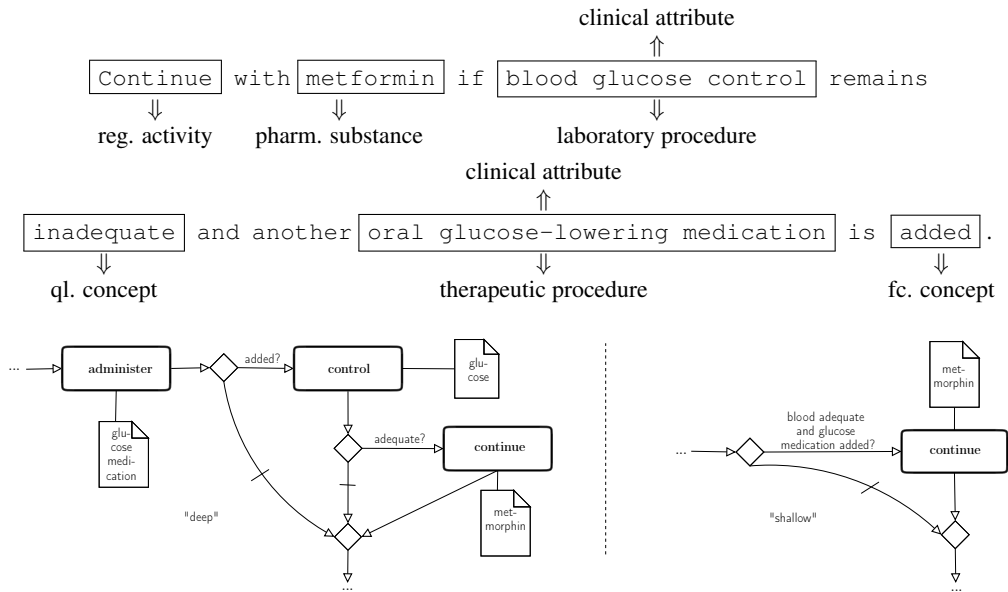

Figure 1: **Top:** MetaMap UMLS (automated) annotations of the NICE diabetes guideline fragment; boxes surround entities, annotations are MetaMap’s. **Bottom:** Two candidate CIG fragments (represented in Business Process Modeling Notation (BPMN), see Ko et al. (2009)): to the left, the intended “deep” CIG, to the right a “shallow” CIG. Control flows (diamonds) specify the acceptable orderings of the activities (rounded rectangles); activities consume resources (folded-corner rectangles).

entity type labels:  $\vec{c}^* = \arg \max \{ \vec{c} \mid \mu(\rho(\vec{\alpha}, \vec{c})) \}$ , where  $\mu(\cdot)$  denotes a *recognizer* built using a classification model (e.g., a logistic regression algorithm), and  $\rho(\cdot, \cdot)$  is a feature extraction function. In the following paragraphs we study this task w.r.t. the set {activity, resource, actor, other} of entity types.

**The SemRep corpus.** Since no UMLS annotated clinical guideline corpora are available for research purposes, we ran our experiments over the SemRep corpus by Kilicoglu et al. (2011), a small annotated clinical corpus whose domain largely overlaps with that of guidelines. It consists of 500 clinical excerpts (MedLine/PubMed) and contains 13,948 word tokens manually annotated by clinicians and domain experts, covering the whole clinical domain. UMLS concept types annotate a total of 827 NPs.

**Features.** The focus of our experiments is to understand the predictive power of syntax and semantics for CIG entity recognition, and in particular for activity recognition. Intuitively, both syntax and semantics can contribute to the prediction of clinical entity types, but it is not a priori clear which one contributes more. Similarly to Zhou and He (2011) we used the Stanford parser (see Klein and Manning (2003)) to extract syn-

tactic features, and MetaMap to extract semantic features. We harvested clinical types by mapping UMLS concept types returned by MetaMap to their subsuming clinical types. In the top of Table 1 we show a sample of UMLS concept types subsumed by “activity”, “resource”, “actor” and “other”, whereas in its bottom we summarize the extracted features, described in detail below.

By mining the NPs sentence parse trees, we extracted the following syntactic features: depth of nesting (*nest*); position in the phrase (*pos*); occurrence in a subordinated phrase (*sub*). The intuition behind these features is that certain types may correlate strongly with syntax (e.g., one would expect “resource” to annotate an object NP).

The semantic features were extracted by computing several measures of label overlap and frequency. The rationale of these features is that, while MetaMap outputs many possible clinical meanings of the constituent NNs of an NP entity, giving rise to multiple “activity”, “resource”, “actor” and “other” annotations per NN and NP, it tends to output meanings that are semantically related (within the UMLS Metathesaurus hierarchy) to the NP’s intended type.

We measured the raw frequency *freq* of the NP entity type *c* in the SemRep corpus, the degree of annotation overlap *hd* between the bag of possi-

activity	actor	resource	other
laboratory procedure	professional society	manufactured object	qualitative concept

feature $F$	description	value $f$
<i>nest</i>	nesting level in tree	integer $\in \mathbb{N}$
<i>pos</i>	position w.r.t. verb	subject, predicate
<i>sub</i>	occurs in clause?	yes, no
<i>freq</i>	freq. of label in corpus	integer $\in \mathbb{N}$
<i>lf</i>	rel. freq. of label in <b>NP</b>	real $\in [0, 1]$
<i>hd</i>	head/ <b>NP</b> overlap	real $\in [0, 1]$
<i>ls</i>	label/ <b>NP</b> overlap	real $\in [0, 1]$
<i>class</i>	<b>NP</b> entity type	act., actor, res., other

Table 1: **Top:** CIG entity labels and sample UMLS concept types they subsume. **Bottom:** **NP** features considered; the class label is the *dependent* feature we want to predict.

bly repeated labels *labs* collected using MetaMap from all the **NNs** in an **NP**, and the bag of possibly repeated labels of its head noun *labsh*. In addition, we computed the relative frequency *lf* of the **NP** entity type  $c$  w.r.t. *labs*:

$$hd = \frac{||labs \cap labsh||}{||labs|| + ||labsh||} \quad lf = \frac{||labs \cap \{c\}||}{||labs||} \quad (1)$$

where  $|| \cdot ||$  and  $\cap$  denote resp. bag cardinality and intersection. The intuition behind these two features is that the intended type will tend to prevail within the annotations of an **NP**, and in particular among its head **NN** and its modifiers. Finally, we took into account the taxonomical structure of the UMLS Metathesaurus and defined the following label/**NP** overlap *ls*:

$$ls = \frac{||labs \cap sub(c)||}{||labs|| + ||sub(c)||} \quad (2)$$

where *sub(c)* is the bag of all the UMLS concept types that are subsumed by the entity type label  $c$ . The *ls* feature measures how similar are the MetaMap **NP** annotations to the UMLS hierarchy subsumed by  $c$ . In all cases, a simple Laplace smoothing was applied.

**Evaluation Framework.** In our experiments the main goal was to evaluate activity recognition features rather than classifier design and evaluation. We thus relied on standard classification models from the known Weka<sup>2</sup> data mining framework. We trained and evaluated the following classifiers: (i) logistic classifier (Logit), (ii) support vector machine (SVM), (iii) naive Bayes classifier

<sup>2</sup>[www.cs.waikato.ac.nz/~ml/weka/](http://www.cs.waikato.ac.nz/~ml/weka/)

(Bayes), (iv) neural network (Neural), and (v) decision tree (Tree). To measure the significance of each single feature, we removed each time a feature  $F_i$  from the space  $\{F_1, \dots, F_7\}$  of syntactic and semantic *independent* features from Table 1 and retrained and reevaluated the classifiers w.r.t. the feature space  $\{F_1, \dots, F_{i-1}, F_{i+1}, \dots, F_7\}$ .

In parallel to this, we studied the impact of context over activity recognition, and its interplay with our features. To this end we considered a baseline scenario, in which context is restricted to **NPs**, and a scenario in which we take into consideration all the annotated **NPs** of a SemRep sentence. This distinction is important since SemRep is a small and sparsely annotated corpus, for which enhanced feature spaces may not prove informative. These two scenarios were modeled as follows. **(1)** A set of **NP** observations: for each **NP**  $\alpha$  in SemRep, we extracted the feature vector  $(f_1^\alpha, \dots, f_7^\alpha, c^\alpha)^T$ . **(2)** A set of sentence observations: for each vector  $(\alpha_1, \dots, \alpha_k)^T$  of annotated **NPs** in a SemRep sentence, we extracted feature vectors  $(f_1^{\alpha_1}, \dots, f_7^{\alpha_1}, c^{\alpha_1}, \dots, f_1^{\alpha_k}, \dots, f_7^{\alpha_k}, c^{\alpha_k})^T$ .

For each combination of classifier feature and scenario, we performed a 10-fold cross-validation to measure precision (Pr), recall (Re), F1-measure, and the overall accuracy (Ac) of the classifiers for the activity recognition task<sup>3</sup>.

**Results and Discussion.** The baseline scenario (see Figure 2, left) shows a drop in average precision, recall, F-measure and accuracy when *hd* and *freq* are disregarded, and a minor drop when *ls* is disregarded. The removal of syntactic features on the other hand has a smaller effect. Considering sentence context (see Figure 2, center), we can observe a greater impact for *sub*, and a minor drop when *ls* is disregarded. But sentence context gives rise also to a clear decrease in average classifier performance. Thus *sub*, while significant, is less useful than the semantic features.

This last observation is substantiated by corpus evidence. One way to see how, is to focus on the distribution of syntax relatively to corpus domain. Syntactic structures can be approximated by function words<sup>4</sup> (e.g., subordinators (**INs**) such as “if”

<sup>3</sup>For reasons of space, we present here a summary of the results obtained; for a more detailed description, please refer to [www.inf.unibz.it/~cathorne/vericlig/ijcnlp2013-exp.pdf](http://www.inf.unibz.it/~cathorne/vericlig/ijcnlp2013-exp.pdf)

<sup>4</sup>For the POS tagging we relied on a Natural Language Toolkit (NLTK) 3-gram tagger by Bird et al. (2009), trained over the (POS annotated) Brown corpus.

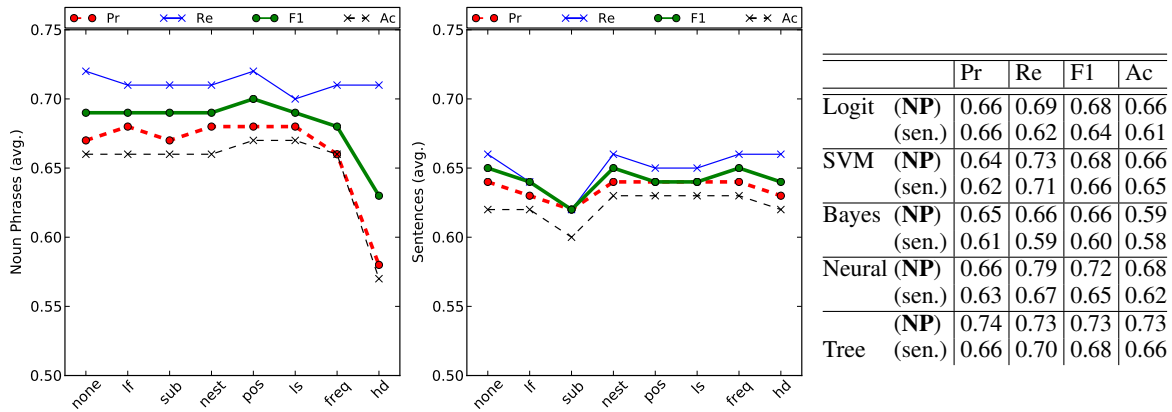

Figure 2: **Left, Center:** Results of 10-fold cross-validation by scenario. On the  $y$ -axis, activity recognition precision, recall, F1-measure and classifier accuracy (classifier averages). On the  $x$ -axis, the feature(s) removed. The tag “none” means that no feature was removed. **Right:** Results for the original (complete) feature space, by classifier and label context (noun phrase **NP** or sentence *sen.*).

corpus	size (words)	domain	rel. freq.
Brown	1,391,708	news	0.16

diabetes2	7,109	clinical	0.16
eating dis.	5,078	clinical	0.17
schizophrenia	5,367	clinical	0.18

$\chi^2$	$p$	df.	$t$ -score	$p$	df.
43.13	0.00	2	1.03	0.36	5

Table 2: **Top:** Function word relative frequency across corpora and domains. **Bottom:** Statistical tests ( $\chi^2$ -test of independence and  $t$ -test).

or “then”, coordinators (**CCs**) such as “or”).

We compared to SemRep: (i) a subset of the Brown corpus (Francis and Kucera (1964)), (ii) a corpus of business process specifications (Friederich et al. (2011)), (iii) a subset of the NICE diabetes-2 guideline (NICE - NHS (2009)), (iv) a subset of the NICE eating disorders guideline (NICE - NHS (2004)), and (v) a subset of the NICE schizophrenia guideline (NICE - NHS (2010)). We run the following statistical tests (see Gries (2010)) at  $p = 0.01$  significance: **(1)** a  $t$ -test (null hypothesis: cross-corpora function word mean relative frequency is 0.20); **(2)** a  $\chi^2$ -test of independence (null hypothesis: function word distribution is correlated to corpus domain). The test results (see Table 2) show that syntax is uniform across domains, and thus has a more limited impact relatively to semantics.

Syntax, however, can be leveraged to optimize prediction results when exploited by classifiers

sensitive to categorical data. The classifier that performed better overall was the decision tree (see Figure 2, right), which seems to exploit better the more limited impact of *sub*, *pos*, and *nest*.

**Conclusions and Further Work.** We have conducted preliminary experiments on automatic clinical activity recognition using MetaMap and entity recognition techniques. We experimented our techniques on the SemRep gold standard UMLS-annotated corpus. Our experiments suggest that the semantic environment of an entity is more useful for this task. Corpus analysis on SemRep and other corpora seems to confirm this observation. In the future, we plan to consider more powerful classification models for NLP, such as conditional random fields (CRFs), able to exploit possible dependencies among features. We plan to focus on document semantics, by considering more complex semantic features (based on, e.g., thesaurus-based similarity metrics). Finally, to better cope with data sparseness we intend to consider a bigger corpus by integrating SemRep with, e.g., the i2b2 clinical corpus as suggested by Abacha and Zweigenbaum (2011).

**Acknowledgments.** The present work has been done within the context of the VERICLIG project<sup>5</sup>, supported by a grant from the Free University of Bozen-Bolzano Foundation.

# Large-scale text collection for unwritten languages

Florian R. Hanke and Steven Bird

Department of Computing and Information Systems, University of Melbourne  
florian.hanke@gmail.com, sbird@unimelb.edu.au

## Abstract

Existing methods for collecting texts from endangered languages are not creating the quantity of data that is needed for corpus studies and natural language processing tasks. This is because the process of transcribing and translating from audio recordings is too onerous. A more effective method, we argue, is to involve local speakers in the field location, using an audio-only translation interface that is portable and easy to use. We present encouraging early results of an experimental investigation of the efficiency of creating translations using this method, and report on the quality of the resulting content.

## 1 Introduction

Language documentation aims to “provide a comprehensive record of the linguistic practices characteristic of a given speech community” (Himmelman, 1998). In a typical language documentation workflow, a linguistic event is recorded, then metadata is added concerning participants, location, language, and so forth. Later, the recording is transcribed, glossed at the word or morpheme level, and then a translation is provided. Not all of these activities occur in the field: usually recording, metadata capture, and some transcription work take precedence over word-level glosses and phrasal translations (Thieberger, 2011).

Woodbury (2007) argues that for an archive entry to be analysable for a future linguist, multiple kinds of translations are needed, for example audio recordings of UN-style simultaneous oral translations, or sentence by sentence translations. The typical workflow of documentary linguistics does not produce the amount of data required for large-scale corpus-based analysis of the language once it is no longer spoken (Abney and Bird,

2010). In addition, the typical workflow necessitates the creation of transcriptions before any annotations can be made, for example in ELAN,<sup>1</sup> a popular software tool for linguistic annotation (Berez, 2007).

We propose to add a new path to this workflow (see Figure 1) to facilitate crowdsourcing of translations, whether by local (typically village-based) speakers or by geographically distributed speakers from the diaspora (Reiman, 2010; Bird, 2010; Zaidan and Callison-Burch, 2011). To this end, we have developed mobile phone software with easy-to-use interfaces for collecting oral translations.

Figure 1: Current and proposed workflows for early oral annotation.

In this paper, we focus on a single activity, oral translation, via one of the mentioned interfaces, a “phonecall” interface. We have developed software that runs on mobile phones, and which has been successfully deployed in off-grid indigenous village settings. It can be used by linguists and native speakers to rapidly collect a substantial amount of high-quality, time-aligned bilingual audio. We report on an experimental investigation of the efficiency of creating translations, and the quality of the translated content.

## 2 Oral translation using Aikuma

Oral translation is the process of listening to a segment of audio in a source language and spontaneously producing a spoken translation in a second language. Typically, a body of recordings has already been collected in the (unwritten) source language, and the content of these recordings is to be made accessible to speakers of a more widely spoken language.

Aikuma is an Android application which supports the recording of audio sources, along with phrase-by-phrase oral translation.<sup>2</sup> Aikuma aims to make the recording of high quality translations a simple and natural process. To achieve naturalness, we adopt the metaphor of a phone call. The process does not use the touch screen or any buttons, but relies exclusively on audio and proximity sensors for control.

For example, let us assume we have an original recording of someone telling a story. As soon as this user holds the phone up to his or her ear, the original recording will start playing. This is achieved by using the proximity sensor present in all Android phones. The recording will continue to play as long as the user holds the phone up to their ear. At any moment during the recording, the user is free to speak their translation of what they have heard. The phone is continually monitoring the microphone input and as soon as the user starts speaking, the phone stops playback and begins recording. This enables a wide range of translations: UN-style oral free, phrase-by-phrase, or literal translations (Woodbury, 2007). When the user stops speaking for two seconds, the phone stops recording. It then rewinds the source recording by 650 ms, to ensure that the user does not miss any speech that overlapped with the segment boundary. Finally, it resumes playing the next part of the source. The process is repeated until the end of the source.

The phone's storage now contains the source audio file, along with the translation file and a mapping file. The translation file contains the concatenated recordings of the oral translations. The mapping file specifies how each segment of oral translation corresponds to the source audio. Users can listen to the original, or the translation, or interleaved playback of the original with the translation.

To evaluate our approach, we performed an

<sup>2</sup><http://github.com/langtech/aikuma>

experiment, then made improvements, then performed a second experiment. Both experiments were conducted in March 2013 in the Interface Design Laboratory at the University of Melbourne.

## 3 Experiment 1

### 3.1 Subjects and Materials

The participants of experiment 1 were seven Brazilian university students, aged 19 to 31. All had received four years of instruction in English as a second language.

The following procedure was carried out. Participants were given a one-minute demonstration of the Aikuma app. Then they were free to try it for up to two minutes on a test recording. We used low-end Huawei phones with a touchscreen. As an original source recording, we used an interview of Brazilian Tom Jobim, dating from the 1980s.<sup>3</sup> The participants then used the interface to translate the original source recording.

### 3.2 Results

The efficiency of the system was surprisingly high: on average, a translation of the 6:19 min long original required 6:38 min. Total length ranged from 12:05 min to 14:31 min, with an average of 12:57 min, a factor of 2.07 times the original's length.

This was a far lower duration than we expected, as the provided translations included mid-speech pauses, speech disfluencies and repaired utterances. It also included the 2 second pause detection times of the system, roughly adding 2-3 minutes to the translation. We could not reasonably expect the translation to be similar in size to the original.

Regarding quality, while we are aware that BLEU scores (Papineni et al., 2001) cannot be used for evaluating the absolute quality, we nevertheless tried to get an impression of the quality by running a single-reference BLEU against the translations.

### 3.3 Problems and improvements

What caused the short durations and low translation scores?

During the experiment, we noted that participants were struggling to translate parts of the interview. After transcribing and analysing the translations (cf. section 5.2), we discovered that many sentences were simply not translated at all, or only

<sup>3</sup><http://www.youtube.com/watch?v=iEofKzw7ZUg>

partially translated. Out of 85 sentences, the participants on average had not fully translated 36.3 sentences (Table 1).

Using our observations of participants and their BLEU scores, we analysed the problems with the approach. The original recording quality was too low, leading to many missing sentences. This in turn resulted in very low BLEU scores.

<i>Particip.</i>	A	B	C	D	E	F	G
<i>Missing</i>	36	32	35	38	41	40	32
<i>BLEU</i>	6.6	11.3	7.5	9.1	13.5	11.8	10.9

Table 1: Missing sentences and BLEU scores.

The participants remarked that hearing the interview for the first time was distracting: Jobim was a popular Brazilian musician who had a gift for storytelling. Participants simply got carried away by the story itself.

This feedback resulted in the following improvements. To mitigate problems with the missing context, we added an additional step to the procedure: before translating, participants would listen once to the entire recording. To avoid problems with poor audio quality, we decided to use a more recent recording which was of perfect audio quality and upgrade to slightly more expensive, but still entry-level HTC phones.<sup>4</sup>

## 4 Experiment 2

### 4.1 Subjects and Materials

Ten native speakers of Brazilian Portuguese, aged 20 to 32, from all areas of Brazil participated. One of the participants was a professional interpreter with a NATII accreditation.<sup>5</sup>

All had achieved a TOEFL score of at least 90 points,<sup>6</sup> the requirement to study at the University of Melbourne. They had at least four years of English lessons in high school. Most had only arrived recently and had two or more months of recent experience in speaking the language. Some have had more intensive exposure to English.

We used a high quality audio recording of a recent interview by Celsinho Cotrim with the first Brazilian female judge, Luislinda Valois<sup>7</sup>. The speakers are from the state of Bahia, speak relatively clearly and with a more neutral accent. This

<sup>4</sup>Priced at US\$ 160.

<sup>5</sup><http://www.naati.com.au/accreditation.html>

<sup>6</sup>TOEFL scores, <http://www.ets.org/toefl/ibt/scores>

<sup>7</sup><http://www.youtube.com/watch?v=oYK6uoyNGqA>

is representative of a realistic recording from the Aikuma system, data from a language archive, or a linguistic field recording.

The recording is spoken in Portuguese, has a total duration of 5:06 min and contains 90 sentences or phrases and 806 words in total. We selected this interview for various reasons: the content is of moderate complexity; the recording contains dialogue; the two speakers are not of the same gender, making it easier to distinguish their voices.

Some expressions can not be translated literally but have to be translated idiomatically. One example of this is the Brazilian idiom: ‘*Meus pais nunca abriram o mão do educação*’, literally ‘My parents would never open the hand of education’, which means ‘My parents would never drop education’.

### 4.2 Method

Given the feedback in the pilot experiments, we improved the process as follows:

For the training run, we used the same recording as used in the pilot experiment. We also demonstrated the newly introduced concept of removing the phone to stop playback if they needed to re-hear a particular segment. Removing the phone and putting it back on the ear would rewind the recording to the beginning of the last segment. During training, as soon as they seemed to have grasped the concept of translation, we stopped the training. On average, this took 1-2 minutes.

To provide context for the following translation, we asked the participants to listen to the entire original recording once, without performing any translation. None of the translators noted having problems understanding the audio or content.

We then instructed the participants to translate the original carefully without omitting any content. In case they encountered words where they did not know the English translation, we asked them to simply repeat the Portuguese word. If the English translation for a given word or expression was not known, we asked them to paraphrase. We instructed them to decide themselves where to segment the text, we specifically did not tell them to segment on sentence boundaries. Participants were then asked to translate the original recording a second time.

## 5 Results

We obtained 20 oral English translations, two per speaker, of the same Brazilian Portuguese source recording. All of these translations were carefully transcribed. From the audio recordings, we extracted a few key metrics from the recordings themselves.

### 5.1 Efficiency

To measure efficiency, we calculated the total time it took to listen to the original plus the time to translate it twice. The silences that are necessary for the interface to work are included in the duration of the task. Translation of the 5:06 min original took on average 15:39 min, a factor of roughly 3. In total, including preparation and listening, the process took slightly more than 35 minutes on average (Figure 2).

Figure 2: Durations of the recordings (s). The vertical line denotes the duration of the original.

### 5.2 Quality

#### 5.2.1 Preparation of recorded translations

To analyse and compare the translations, we prepared transcriptions of the original Brazilian Portuguese audio and all 20 English translations.

To evaluate translation quality, we used the Human-targeted Translation Error Rate (HTER), which requires a comparison between the resulting hypothesis translations and a number of reference translations (Snover et al., 2006). For this purpose, we prepared a parallel translation (Table 2). Due to speech disfluencies and repaired utterances, such as ‘um’ and ‘green I mean blue’ (Levelt, 1983), the process itself, and varying sentence segmentation the resulting transcriptions needed to be processed further for evaluation.

#### 5.2.2 HTER

HTER uses human annotators to create a specific targeted reference sentence for each translated hypothesis sentence. Each hypothesis sentence is edited by a bilingual editor until it is fluent and

Brazilian Portuguese	English
Eu sou mulher mais feliz do mundo	I am the happiest woman in the world
No importa por que	It does not matter why
Mas eu acho que sou	But I think I am

Table 2: Example reference translation.

has the same meaning as the source sentence.<sup>8</sup> As a targeted reference sentence has to be created for every hypothesis sentence, HTER is very resource intensive.

As we did not have the necessary resources to perform this analysis on all recordings (100 hours for 22 translations), we selected three example translations based on their BLEU scores (not mentioned) the lowest and highest result, and the expert’s translation.

For each of the selected translations, a bilingual annotator created targeted reference sentences. Then, we performed a TER on the six translations (Table 3).

Participant	Best	Worst	Expert
Run 1	0.16	0.23	0.18
Run 2	0.10	0.24	0.08

Table 3: Participant HTER scores in runs 1 and 2.

We found that the changes in HTER scores between translation runs agree with the BLEU score changes: both the “best” user and the expert receive an improved (numerically lower) score, while the “worst” user does not.

Regarding absolute scores, the expert comes out ahead of the “best” user. We assume that this is a result of the expert’s sophisticated use of English which was not present in the BLEU references.

## 6 Conclusions

We have investigated a new method for rapid translation of spoken language materials. The method can be used by amateur translators and offers a faster method for preserving endangered language data while there is still time. Our experiments indicate that the resulting translations are of sufficient quality to be useful in downstream NLP tasks.

<sup>8</sup>The standard HTER process only uses an untargeted reference in the target language to enable editing by monolingual editors.

## Abstract

Recognizing Chinese Named entities from the Web is challenging, due to the lack of labeled data and differences between Chinese and English. We propose a semi-supervised approach which leverages seed entities and the large unlabeled data to learn templates. Some high-quality templates are generated iteratively to extract new named entities based on the model of quality metrics. Experimental results show that our approach significantly outperforms the baseline method and it is robust against the changes of the Web.

## 1 Introduction

Compared to English Named Entity Recognition (NER), Chinese NER is more difficult. For example, although capitalization plays an very important role in English NER, this language-specific feature is useless in Chinese NER. Moreover, the lack of space between words in Chinese often makes the work based on word segmentation (Sun et al., 2002) failure. Especially, there are a lot of new words and ambiguous words in the Web text, which increase the error of word segmentation. The loss of precision propagates to NER.

Currently, NER is mainly based on supervised models. Such models perform well in single domain (Wang, 2009; Du et al., 2010). Unfortunately, the data of the Web is open-domain and always changing. The performance of them degrades badly, since the distribution of the Web data is different from that of the training data. For instance, the average F1 score of the Stanford NER, which is trained on the CoNLL03 shared task data set and achieves state-of-the-art performance on that task, drops from 90.8% to 45.8% on tweets (Liu et al., 2011). Despite a high-quality training data set, which has the same distribution as the Web data

and covers all kinds of domains, can improve the performance of NER, as far as we know, there are no such labeled data. Furthermore, named entities change over the time, especially person names and company names. (Tsuchiya et al., 2009) shows that 20%~30% of named entity types are replaced with new ones every year in Mainichi Newspaper articles. Such change is even more obvious in the Web data and leads to the unreliable labeled data. Constantly annotating new data is time-consuming and expensive.

In this paper, we propose a semi-supervised approach that uses self-learning templates to solve above problems. Instead of annotating a massive amount of data, we leverage a small number of named entities and the large unlabeled data to discover new named entities that can not be identified using the training data. Experiments show that our approach raises the F1 from 75.9% to 88.6% on the Chinese Web data without retraining the existing model, and it is robust against the changes of the data. Since no language-specific knowledge is used, our approach can easily be extended to other languages.

## 2 Related Work

There have been many approaches proposed to solve the problem of the lack of annotated data. (Wu et al., 2009; Chiticariu et al., 2010) focus on domain adaptation, which aims to reuse the knowledge among different domains. (Ling and Weld, 2012; Rüd et al., 2011; Han and Zhao, 2010) leverage information from external knowledge sources, such as Wikipedia, WordNet and search engine, to compensate for the insufficient training data. Some work builds crowdsourcing services to label data by human. For example, Amazon Mechanical Turk<sup>1</sup> provides a platform to obtain data in various domains such as email

<sup>1</sup><https://www.mturk.com/mturk/welcome>

(Lawson et al., 2010), medicine (Yetisgen-Yildiz et al., 2010) and Twitter (Finin et al., 2010).

The work based on context templates is more closely related to our approach. (Etzioni et al., 2005) extracts named entities via domain-specific templates, which are learned from predefined templates. (Whitelaw et al., 2008) builds training data utilizing templates generated by millions of seeds. Although context templates are used to improve the perform of NER in our approach, they are learned automatically from the unlabeled data and we only use several seed entities.

### 3 Approach based on self-learning Templates

#### 3.1 Overall Framework of Our Approach

The main idea of our approach is that learning the high-quality templates in the bootstrapping process.

The details are shown in Algorithm 1, where the pair  $\langle name, type \rangle$  represents an entity, named  $name$ , in class  $type$ . # denotes a placeholder for entity. The substring, like  $t_{s-2}t_{s-1}name_s^{(i)}t_{s+1}t_{s+2}$ , denotes the  $i^{th}$  NE in the set of seed entities and its context of four tokens long. First, for each entity  $e$  in  $E_{seed}$ , we find sentences containing  $e$  and create a temporary set of templates. Second, for each candidate template, we relocate all possible named entities  $E_{temp}$  in  $C_{corpus}$ . Third, computing the quality of templates and adding the high-scoring ones into template set  $TS_{template}$ . Lastly, we compute the confidence of candidate entities that are generated in above process, and remove the entities whose confidence are below the threshold from the set of entities. The value of threshold will be discussed in Section 4.

#### 3.2 Features of Template

Given a candidate template, we define three statistical features to measure the quality of it.

**effectiveness ( $f_1$ ):** This feature reflects whether a candidate template is prone to mistakes. We assume that tokens outside of  $E_{seed}$  are not named entities. It is a reasonable assumption in practice, because the loss caused by assumption will become lower and lower with the increase of  $E_{seed}$ . The effectiveness is calculated as

$$f_1(T, c) = p(e|T_c) \cdot p(T_c) = \frac{\#(\text{correct } e|T_c)}{\sum_i \#(e|T_c^{(i)})} \quad (1)$$

#### Algorithm 1 Framework of Templates Learning

---

**Input:** a set of NEs:  $E_{seed} = \{ \langle name, type \rangle \}$ ; unlabeled web pages:  $C_{corpus}$

**Output:**  $E_{seed}; TS_{template}$

- 1: Initialize  $C_{corpus}: \phi$
- 2: Initialize  $TS_{candidate}: \phi$
- 3: Initialize  $TS_{template}: \phi$
- 4: **while**  $E_{seed}$  keep growing (or below the predefined number of loops) **do**
- 5:   **for** each  $entity^{(i)} = \langle name^{(i)}, type^{(i)} \rangle \in E_{seed}$  **do**
- 6:     Add all sentences containing  $name^{(i)}$  to  $C_{corpus}$
- 7:     Create templates  $\langle t_{-2}t_{-1}\#t_{+1}t_{+2}, type \rangle$  when the substring  $t_{s-2}t_{s-1}name_s^{(i)}t_{s+1}t_{s+2}$  belongs to some sentence in  $C_{corpus}$  and add them to  $TS_{candidate}$
- 8:   **end for**
- 9:   **for** each candidate template
- 10:      $T^{(i)} = \langle t_{-2}t_{-1}\#t_{+1}t_{+2}, type \rangle \in TS_{candidate}$  **do**
- 11:       Extract all matching tokens  $\langle token, type \rangle$  while the substring  $t_{-2}t_{-1}token_{+1}t_{+2}$  belongs to some sentence in  $C_{corpus}$  and add them to  $E_{temp}$
- 12:     **end for**
- 13:     **for** each template  $T^{(i)} \in TS_{candidate}$  **do**
- 14:       Calculate the score  $(T^{(i)}, score)$
- 15:        $= evaluation(TS_{candidate}|C_{corpus}, E_{seed}, E_{temp}, )$
- 16:       **if**  $score > \delta$  **then**
- 17:         Add  $T^{(i)}$  to  $TS_{template}$
- 18:       **end if**
- 19:     **end for**
- 20:     Find new candidate NEs  $E_{candidate}$  using  $TS_{template}$  from the remaining unlabeled data
- 21:     Select high-quality NEs:
- 22:      $E'_{seed} = filter(E_{candidate}|TS_{template})$
- 23:     Update:  $E_{seed} = E_{seed} \cup E'_{seed}$
- 24: **end while**

---

where  $\#(e|T_c^{(i)})$  denotes the number of correct entities extracted by the  $i^{th}$  template in class  $c$ .

**discrimination ( $f_2$ ):** This feature is used for measuring how close a candidate template is related to a class. The value is computed as

$$f_2(T, c) = tf(T, c) \cdot \left( 1 + \log \frac{\#C}{1 + \#c_j} \right) \quad (2)$$

where  $tf(T, c)$  denotes the normalized frequency of template, that is divided by the maximum frequency,  $\#C$  is the number of classes in  $E_{seed}$ , and  $\#c_j$  is the number of classes that template  $T$  appears.

**diversity ( $f_3$ ):** The more different and correct NEs in a class extracted by template  $T$ , the more likely other good NEs within the same class will be extracted by it. This feature is computed as

$$f_3(T, c) = \frac{\#\{(\text{correct } e|T_c) \wedge (\text{different } e|T_c)\}}{\#(\text{correct } e|T_c)} \quad (3)$$

#### 3.3 Quality Metrics Model of Templates

Since the proposed features are not independent of each other, we propose an approach in which the value of a feature is adapted according to the values of other features. Although it is similar to (Wei et al., 2010), we improve it by only updating a part of templates to reduce the computational cost.

Formally, given a set of candidate templates  $TS_{candidate} = \{T^{(1)}, T^{(2)}, \dots, T^{(n)}\} \subset R^m$ , let  $f_k : TS_{candidate} \rightarrow R$  denote the ranking function on the  $k^{th}$  feature, where  $f_k \in F = \{f_1, f_2, f_3\}$ . Our goal is to combine all features to produce ranking list that are better than any individual feature and then return the templates with high ranking scores.

Following the traditional manifold ranking process (Zhou et al., 2004) with one ranking function. 1) Defining the similarity matrix  $W$  on the template set  $TS_{candidate}$ :  $W_{ij} = similarity(T^{(i)}, T^{(j)})$ . 2) Symmetrically normalizing  $W$  by  $S = D^{-1/2}WD^{-1/2}$  in which  $D$  is the diagonal matrix with (i, i)-element equal to the sum of the  $i^{th}$  row of  $W$ . 3) Iterating  $F(t+1) = \alpha SF(t) + (1-\alpha)F(0)$  until a global stable state, where  $\alpha$  is trade-off parameter in (0, 1),  $F(0)$  denotes the initial ranking results and  $F(t)$  denotes the ranking results of the  $t^{th}$  round.

For two ranking functions  $f_1$  and  $f_2$ , the ranking score of  $f_1$  will be changed after combining the ranking score of  $f_2$ . Considering the cost of consistency both the ranking results in initial  $f_1$  and the feedback from  $f_2$ , we define the cost function caused by refining  $f_1$  with  $f_2$  in the  $(t+1)^{th}$  round iteration as

$$\varphi(f_1|f_2) = \frac{1}{2} \left( \sum_{i,j=1}^n W_{ij} \left\| \frac{1}{\sqrt{D_{ii}}} f_1^{(t+1)}(T^{(i)}) - \frac{1}{\sqrt{D_{jj}}} f_2^{(t)}(T^{(j)}) \right\|^2 + \mu \sum_{i=1}^n \left\| f_1^{(t+1)}(T^{(i)}) - f_1^{(0)}(T^{(i)}) \right\|^2 \right) \quad (4)$$

where  $f_1^{(0)}$  denotes the initial ranking scores of  $f_1$ . Let the best refined ranking score is  $f^*$ , we have

$$\frac{\partial}{\partial f_1} \varphi(f_1|f_2) |_{f_1=f^*} = f^* - S \cdot f_2^{(t)} + u(f_1^* - f_1^{(0)}) = 0 \quad (5)$$

$$f^* = \frac{1}{1+\mu} \cdot S \cdot f_2^{(t)} + \frac{\mu}{1+\mu} \cdot f_1^{(0)} \quad (6)$$

Let  $\alpha = \frac{1}{1+\mu}$ , then we have

$$f^* = \alpha \cdot S \cdot f_2^{(t)} + (1-\alpha) \cdot f_1^{(0)} \quad (7)$$

Therefore, we can iteratively compute the ranking scores in the  $(t+1)^{th}$  round to find the best  $f^*$  shown as follows, which is proven to be convergent (Wei et al., 2010).

$$f_1^{(t+1)} = \alpha \cdot S \cdot f_2^{(t)} + (1-\alpha) \cdot f_1^{(0)} \quad (8)$$

In our case, due to the templates with low ranking scores on  $f_2$  are helpless to refine the results

ranked on  $f_1$ . We omit the templates in  $f_2$  that fall below the threshold and feedback the rest templates, signaled by  $Top-f_2$ , to  $f_1$ . Then, the normalized matrix  $S$  can be simplified as a block matrix  $\begin{pmatrix} S_{Top-f_2} & 0 \\ 0 & 0 \end{pmatrix}$ . The equation above can be rewritten as

$$f_1^{(t+1)}(Top-f_2) = \alpha \cdot S_{Top-f_2} \cdot f_2^{(t)}(Top-f_2) + (1-\alpha) \cdot f_1^{(0)}(Top-f_2) \quad (9)$$

Moreover, if we only improve the identical templates, the similarity matrix  $W_{Top-f_2}$  and normalized matrix  $S_{Top-f_2}$  degrade to identity matrices, the final iteration equation is

$$f_1^{(t+1)}(Top-f_2) = \alpha \cdot f_2^{(t)}(Top-f_2) + (1-\alpha) \cdot f_1^{(0)}(Top-f_2) \quad (10)$$

### 3.4 Confidence of Candidate NEs

There may be still noisy in the set of candidate NEs despite using the high-quality templates to find new entities. Therefore, we also need to filter out the non-NEs for the further processing to insure the high accuracy. This section corresponds to the line 19 of Algorithm 1. We utilize the pointwise mutual information (PMI) (Etzioni et al., 2005) to measure the closeness between extracted NEs and templates.

Given an extracted named entity  $e$  and a template  $T$ , the PMI score is computed as

$$PMI(e, T) = \frac{Hits(e+T)}{Hits(e)} \quad (11)$$

where  $Hits(\cdot)$  denotes the number of sentences searched in the whole unlabeled corpus.

The confidence of  $e$  extracted by template  $T_c$  belonging to class  $c$  can be expressed as

$$confidence(entity, c) = \frac{1}{\#T_c} \sum_i PMI(entity, T_c^{(i)}) \quad (12)$$

where  $\#T_c$  denotes the number of templates in class  $c$ .

## 4 Experiments

### 4.1 Data Set

We conducted experiments on a real data set collected from the Web, which is from August 1<sup>th</sup> 2012 to August 31<sup>th</sup> 2012<sup>2</sup>. The details of the data set are given in Table 1. Two fine-grained categories of *Person* are considered: *Singer* and *Athlete*. Note that the NER on fine-grained categories is more difficult than that on coarse-grained

<sup>2</sup>During the preprocessing step, HTML tags and ads are eliminated from the data.

categories such as *Person*, *Location* and *Organization*. We randomly selected 8,955 sentences and manually labeled them as test data, which contains 232 singers and 1,807 athletes. The labeled data is further split into two parts: one for training the baseline system and the other for testing. The test data set includes 65 singers and 406 athletes. We trained a linear CRF model (Lafferty et al., 2001) as the baseline using the BILOU scheme (Ratinov and Roth, 2009).

	News	Forum	Microblog
Number	1,087,926	420,278	49,037,301

Table 1: The composition of the data set.

## 4.2 Experimental Analysis

Table 2 gives some examples of learned templates. Using the learned templates and extracted named entities, an additional recognizer can be built very easily. It can discover some new named entities that are left out by models trained on labeled data. We performed experiments to make comparison between baseline system and AD\_NER system, which integrates additional recognizer into the CRF model. The results are shown in Table 3~5, where  $p$  is the threshold of confidence score of candidate entity.

Template	Q_score	Num. of NEs
<i>Singer</i>		
欢、#、庾(Huan, #, Geng)	0.9000	60
#演唱(sing)	0.8109	279
天后#, (diva)	0.6620	319
听着#的歌(listen to the song)	0.6120	9
演唱#的歌(sing a song)	0.5820	16
<i>Athlete</i>		
冠军#, (champion)	0.9059	2340
名将#, (famous athlete)	0.8711	481
选手#, (player)	0.8382	2440
战胜#夺冠(win)	0.7724	123
选手#在比(in a competition)	0.6423	274

Table 2: Examples of templates and their qualities (Q\_score) and the number of extracted named entities.

	Precision	Recall	F1
Baseline	93.1	41.5	57.4
AD_NER( $p = 0.001$ )	71.3	83.1	76.8
AD_NER( $p = 0.01$ )	75.4	88.4	<b>81.4</b>
AD_NER( $p = 0.1$ )	90.6	47.7	62.5

Table 3: Results on *Singer*.

	Precision	Recall	F1
Baseline	97.8	65.9	78.8
AD_NER( $p = 0.001$ )	79.9	91.5	85.3
AD_NER( $p = 0.01$ )	92.8	88.3	<b>90.5</b>
AD_NER( $p = 0.1$ )	93.9	71.4	81.1

Table 4: Results on *Athlete*.

	Precision	Recall	F1
Baseline	97.3	62.3	75.9
AD_NER( $p = 0.001$ )	76.2	90.0	82.5
AD_NER( $p = 0.01$ )	91.3	86.1	<b>88.6</b>
AD_NER( $p = 0.1$ )	93.2	67.8	78.5

Table 5: Overall experimental results.

From Table 3 and Table 4, we find the best performance of baseline on *Singer* is 57.4%, 21.4% lower than that on *Athlete*. This can be explained as the scale of labeled data impacts the performance of supervised method, because, in Table 1, the instances of *Singer* is not as sufficient as *Athlete*. However, the performance of our approach in the two categories remains stable. This illustrates that the large-scale unlabeled data is useful in the case of a lack of training data.

As shown in Table 5, the best F1 of AD\_NER is 88.6%, which is 12.7% higher than F1 of baseline. Although there is a somewhat loss of precision, we obtain a large number of named entities. Moreover, the cost of our approach is lower than automatic annotation, since we do not need to retrain the supervised model. It is more effective when labeled data is complex and hard to construct while unlabeled data is abundant and easy to access. In the practice, our proposed approach can easily remain up-to-date and extend the well-trained supervised model without fine-tuning or any human intervention.

We further find that the overall precision of AD\_NER with threshold at 0.1 is only 1.9% higher than that with threshold at 0.01, but the loss of recall is 18.3%. For this reason, the threshold can be set to 0.01.

## 5 Conclusion

In this paper, we propose an approach to build an additional named entity recognizer that can assist the existing supervised models. The experimental results on the real data set from the Web show that our method improves the F1 score from 75.9% to 88.6%.

## Abstract

Although parallel sentences rarely exist in quasi-comparable corpora, there could be parallel fragments that are also helpful for statistical machine translation (SMT). Previous studies cannot accurately extract parallel fragments from quasi-comparable corpora. To solve this problem, we propose an accurate parallel fragment extraction system that uses an alignment model to locate the parallel fragment candidates, and uses an accurate lexicon filter to identify the truly parallel ones. Experimental results indicate that our system can accurately extract parallel fragments, and our proposed method significantly outperforms a state-of-the-art approach. Furthermore, we investigate the factors that may affect the performance of our system in detail.

## 1 Introduction

In statistical machine translation (SMT) (Brown et al., 1993; Koehn et al., 2007), since translation knowledge is acquired from parallel data, the quality and quantity of parallel data are crucial. However, except for a few language pairs, such as English-French, English-Arabic, English-Chinese and several European language pairs, parallel data remains a scarce resource. As non-parallel corpora are far more available, extracting parallel data from non-parallel corpora is an attractive research field.

Most previous studies focus on extracting parallel sentences from comparable corpora (Zhao and Vogel, 2002; Utiyama and Isahara, 2003; Munteanu and Marcu, 2005; Tillmann, 2009; Smith et al., 2010; Abdul-Rauf and Schwenk, 2011). Quasi-comparable corpora that contain far more disparate very-non-parallel bilingual docu-

ments that could either be on the same topic (in-topic) or not (out-topic) (Fung and Cheung, 2004), are available in far larger quantities than comparable corpora. In quasi-comparable corpora, there are few or no parallel sentences. However, there could be parallel fragments in comparable sentences that are also helpful for SMT.

Previous studies for parallel fragment extraction from comparable sentences have the problem that they cannot extract parallel fragments accurately. Some studies extract parallel fragments relying on a probabilistic translation lexicon estimated on an external parallel corpus. They locate the source and target fragments independently, making the extracted fragments unreliable (Munteanu and Marcu, 2006). Some studies develop alignment models for comparable sentences to extract parallel fragments (Quirk et al., 2007). Because the comparable sentences are quite noisy, the extracted fragments are not accurate.

In this paper, we propose an accurate parallel fragment extraction system. We locate parallel fragment candidates using an alignment model, and use an accurate lexicon filter to identify the truly parallel ones. Experimental results on Chinese-Japanese corpora show that our proposed method significantly outperforms a state-of-the-art approach, which indicate the effectiveness of our parallel fragment extraction system. Moreover, we investigate the factors that may affect the performance of our system in detail.

## 2 Related Work

(Munteanu and Marcu, 2006) is the first attempt to extract parallel fragments from comparable sentences. They extract sub-sentential parallel fragments by using a Log-Likelihood-Ratio (LLR) lexicon estimated on an external parallel corpus and a smoothing filter. They show the effectiveness of fragment extraction for SMT. This study has the drawback that they do not locate the source

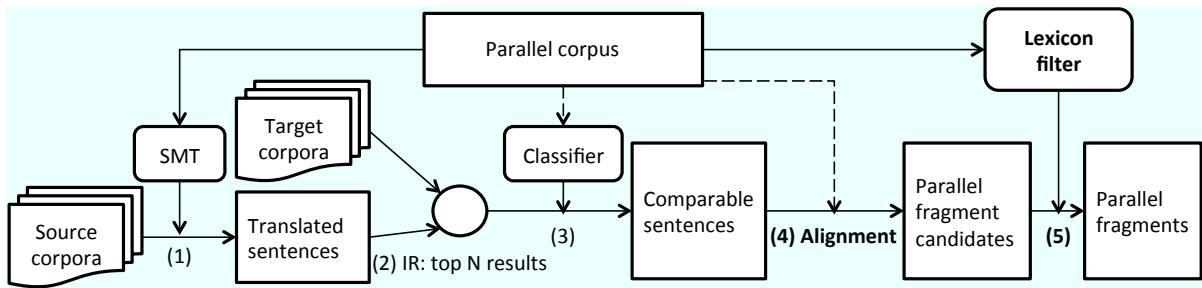

Figure 1: Parallel fragment extraction system.

and target fragments simultaneously, which cannot guarantee that the extracted fragments are translations of each other. We solve this problem by using an alignment model to locate the source and target fragments simultaneously.

Quirk et al. (2007) introduce two generative alignment models for extracting parallel fragments from comparable sentences. However, the extracted fragments slightly decrease MT performance when appending them to in-domain training data. We think the reason is that because the comparable sentences are quite noisy, the alignment models cannot accurately extract parallel fragments. To solve this problem we only use alignment models for parallel fragment candidate detection, and use an accurate lexicon filter to guarantee the accuracy of the extracted parallel fragments.

Besides the above studies, there are some other efforts. Hewavitharana and Vogel (2011) propose a method that calculates both the inside and outside probabilities for fragments in a comparable sentence pair, and show that the context of the sentence helps fragment extraction. However, the proposed method only can be efficient in a controlled manner that supposes the source fragment was known, and search for the target fragment. Another study uses a syntax-based alignment model to extract parallel fragments from noisy parallel data (Riesa and Marcu, 2012). Since their method is designed for noisy parallel data, we believe that the method cannot accurately extract parallel fragments from comparable sentences.

### 3 Proposed Method

#### 3.1 System Overview

Figure 1 shows an overview of our parallel fragment extraction system. We first apply comparable sentence extraction using a combination method

of (Abdul-Rauf and Schwenk, 2011) (1)(2) and (Munteanu and Marcu, 2005) (3), which were originally used for extracting parallel sentences from comparable corpora. We translate the source sentences to target language with a SMT system trained on a parallel corpus (1). Then we use the translated sentences as queries for IR. We retrieve the top 10 target documents for each source sentence using Indri<sup>1</sup>, and use all sentences in the documents as comparable sentence candidates (2). Next, we identify the comparable sentences from the candidates using a classifier trained on a part of a parallel corpus<sup>2</sup> following (Munteanu and Marcu, 2005) (3).

As the noise in comparable sentences will decrease MT performance, we further apply parallel fragment extraction. We apply two steps to accurately extract parallel fragments. We first detect parallel fragment candidates using bidirectional IBM models (Brown et al., 1993) with symmetrization heuristics (Koehn et al., 2007) (4). The generative alignment models proposed by Quirk et al. (2007) may be more efficient for parallel fragment candidate detection, we leave this for future work. Then we filter the candidates with probabilistic translation lexicon to produce accurate results (5). We present the details of our proposed method in following sections.

#### 3.2 A Brief Example

Figure 2 shows an example of comparable sentences extracted from Chinese-Japanese quasi-comparable corpora by our system. The alignment results are computed by IBM models. We notice that the truly parallel fragments “lead ion selective electrode” and “potentiometric titration method” are aligned, although there are some incorrectly aligned word pairs. We think this kind

<sup>1</sup><http://www.lemurproject.org/indri>

<sup>2</sup>In our experiments, we used 5k parallel sentences.

Figure 2: Example of comparable sentences with alignment results computed by IBM models (Parallel fragment candidates are in dashed rectangles, parallel fragments are in rectangles with solid line border).

of alignment information can be helpful for fragment extraction. What we need to do is develop a method to identify the true parallel fragments from the aligned fragments.

### 3.3 Parallel Fragment Candidate Detection

We treat the longest spans that have monotonic and non-null alignment as parallel fragment candidates. The reason we only consider monotonic ones is that based on our observation, ordering of IBM models on comparable sentences is unreliable. Quirk et al. (2007) also produce monotonic alignments in their generative model. Monotonic alignments are not sufficient for many language pairs. In the future, we plan to develop a method to deal with this problem. The non-null constraint can limit us from extracting incorrect fragments. Similar to previous studies, we are interested in fragment pairs with size greater than 3. Taking the comparable sentences in Figure 2 as an example, we will extract the fragments in dashed rectangles as parallel fragment candidates.

### 3.4 Lexicon-Based Filter

The parallel fragment candidates cannot be used directly, because many of them are still noisy as shown in Figure 2. Aiming to produce accurate

results, we use a lexicon-based filter. We filter a candidate parallel fragment pair with a probabilistic translation lexicon. The lexicon-pair may be extracted from a parallel corpus, or from comparable corpora using some state-of-the-art approaches such as (Vulić et al., 2011). In this study, we use the lexicon extracted from a parallel corpus. Different lexicons may have different effects for filtering. Here, we compare three types of lexicon. The first lexicon we use is the IBM Model 1 lexicon, which is obtained by running GIZA++<sup>3</sup> that implements sequential word-based statistical alignment model of IBM models.

The second lexicon we use is the LLR lexicon. Munteanu and Marcu (2006) show that the LLR lexicon performs better than the IBM Model 1 lexicon for parallel fragment extraction. One advantage of the LLR lexicon is that it can produce both positive and negative associations. Munteanu and Marcu (2006) develop a smoothing filter applying this advantage. We extract the LLR lexicon from a word-aligned parallel corpus using the same method as (Munteanu and Marcu, 2006).

The last lexicon we use is the SampLEX lexicon. Vulić and Moens (2012) propose an associative approach for lexicon extraction from par-

<sup>3</sup><http://code.google.com/p/giza-pp>

allel corpora that relies on the paradigm of data reduction. They extract translation pairs from many smaller sub-corpora that are randomly sampled from the original corpus, based on some frequency-based criteria of similarity. They show that their method outperforms IBM Model 1 and other associative methods such as LLR in terms of precision and F-measure. We extract SampleLEX lexicon from a parallel corpus using the same method as (Vulić and Moens, 2012).

Aiming to gain new knowledge that does not exist in the lexicon, we apply a smoothing filter similar to (Munteanu and Marcu, 2006). For each aligned word pair in the fragment candidates, we set scores to the words in two directions according to the extracted lexicon. If the aligned word pair exists in the lexicon, we set the corresponding translation probabilities as scores. For LLR lexicon, we use both positive and negative association values. If the aligned word pair does not exist in the lexicon, we set the scores in both directions to  $-1$ . There is the one exception that the aligned words are the same number, punctuation or abbreviation. In this case, we set the scores to 1 without considering the existence of the word pair in the lexicon. After this process, we get *initial scores* for the words in the fragment candidates in two directions.

We then apply an averaging filter to the *initial scores* to obtain *filtered scores* in both directions. The averaging filter sets the score of one word to the average score of several words around it. We think the words with initial positive scores are reliable, because they satisfy two strong constraints, namely alignment by IBM models and existence in the lexicon. Therefore, unlike (Munteanu and Marcu, 2006), we only apply the averaging filter to the words with negative scores. Moreover, we add another constraint that only filtering a word when both the left and right words around it have positive scores, which can further guarantee accuracy. For the number of words used for averaging, we used 5 (2 preceding words and 2 following words). The heuristics presented here produced good results on a development set.

Finally, we extract parallel fragments according to the *filtered scores*. We extract word aligned fragment pairs with continuous positive scores in both directions. Fragments with less than 3 words may be produced in this process, and we discard them like previous studies.

## 4 Experiments

In our experiments, we compared our proposed fragment extraction method with (Munteanu and Marcu, 2006). We manually evaluated the accuracy of the extracted fragments. Moreover, we used the extracted fragments as additional MT training data, and evaluated the effectiveness of the fragments for MT. We conducted experiments on Chinese–Japanese data. In all our experiments, we preprocessed the data by segmenting Chinese and Japanese sentences using a segmenter proposed by Chu et al. (2012) and JUMAN (Kurohashi et al., 1994) respectively.

### 4.1 Data

#### 4.1.1 Parallel Corpus

The parallel corpus we used is a scientific paper abstract corpus provided by JST<sup>4</sup> and NICT<sup>5</sup>. This corpus was created by the Japanese project “Development and Research of Chinese–Japanese Natural Language Processing Technology”, containing 680k sentences (18.2M Chinese and 21.8M Japanese tokens respectively). This corpus contains various domains such as chemistry, physics, biology and agriculture etc.

#### 4.1.2 Quasi-Comparable Corpora

The quasi-comparable corpora we used are scientific paper abstracts collected from academic websites. The Chinese corpora were collected from CNKI<sup>6</sup>, containing 420k sentences and 90k articles. The Japanese corpora were collected from CiNii<sup>7</sup> web portal, containing 5M sentences and 880k articles. Most articles in the Chinese corpora belong to the domain of chemistry, while the Japanese corpora contain various domains such as chemistry, physics and biology etc. Note that since the articles in these two websites were written by Chinese and Japanese researchers respectively, the collected corpora are very-non-parallel.

### 4.2 Extraction Experiments

We first applied sentence extraction on the quasi-comparable corpora using our system, and 30k comparable sentences of chemistry domain were extracted. We then applied fragment extraction on the extracted comparable sentences. We compared our proposed method with (Munteanu and

<sup>4</sup><http://www.jst.go.jp>

<sup>5</sup><http://www.nict.go.jp>

<sup>6</sup><http://www.cnki.net>

<sup>7</sup><http://ci.nii.ac.jp>

Method	# fragments	Average size (zh/ja)	Accuracy
Munteanu+, 2006	28.4k	20.36/21.39	(1%)
Only (IBM Model 1)	18.9k	4.03/4.14	80%
Only (LLR)	18.3k	4.00/4.14	<b>89%</b>
Only (SampLEX)	18.4k	3.96/4.05	87%
External (IBM Model 1)	28.7k	4.18/4.33	81%
External (LLR)	26.9k	4.17/4.33	85%
External (SampLEX)	28.0k	4.11/4.23	82%

Table 1: Fragment extraction results (Accuracy was manually evaluated on 100 fragments randomly selected from fragments extracted by different methods, based on the number of exact match).

Marcu, 2006). We applied word alignment using GIZA++. External parallel data might be helpful for alignment models to detect parallel fragment candidates from comparable sentences. Therefore, we compared two different settings to investigate the influence of external parallel data for alignment to our proposed method:

- **Only:** Only use the extracted comparable sentences.
- **External:** Use a small number of external parallel sentences together with the comparable sentences (In our experiment, we used chemistry domain data of the parallel corpus described in Section 4.1.1, containing 11k sentences).

We also compared IBM Model 1, LLR and SampLEX lexicon for filtering. All lexicons were extracted from the parallel corpus.

Table 1 shows the results for fragment extraction. We can see that the average size of fragments extracted by (Munteanu and Marcu, 2006) is unusually long, which is also reported in (Quirk et al., 2007). Our proposed method extracts shorter fragments. The number of extracted fragments and the average size are similar among the three lexicons when using the same alignment setting. Using the external parallel data for alignment extracts more fragments than only using the comparable sentences, and the average size is slightly larger. We think the reason is that the external parallel data is helpful to improve the recall of alignment for the parallel fragments in the comparable sentences, thus more parallel fragments will be detected.

To evaluate accuracy, we randomly selected 100 fragments extracted by the different methods. We manually evaluated the accuracy based on the number of exact match. Note that exact

match criteria has a bias against (Munteanu and Marcu, 2006), because their method extracts sub-sentential fragments which are quite long. We found that only one of the fragments extracted by “Munteanu+, 2006” is exact match, while for the remainder only partial matches are contained in long fragments. Our proposed method have a accuracy over 80%, while the remainder are partial matches. For the effects of different lexicons, LLR and SampLEX shows better performance than IBM Model 1 lexicon. We think the reason is the same one reported in previous studies that LLR and SampLEX lexicon are more accurate than IBM Model 1 lexicon. Also, LLR lexicon performs slightly better than SampLEX lexicon in this experiment. The accuracy of only using the comparable sentences for alignment are better than using the external parallel data, except for IBM Model 1 lexicon. We think the reason is that the external parallel data may have a bad effect on the precision of alignment for the parallel fragments in the comparable sentences.

### 4.3 Translation Experiments

We further conducted Chinese-to-Japanese translation experiments by appending the extracted fragments to a baseline system. For comparison, we also conducted translation experiments by appending the extracted comparable sentences. For decoding, we used the state-of-the-art phrase-based SMT toolkit Moses (Koehn et al., 2007) with default options, except for the distortion limit (6→20). The baseline system used the parallel corpus (680k sentences). We used another 368 and 367 sentences from the chemistry domain for tuning and testing respectively. We trained a 5-gram language model on the Japanese side of the parallel corpus using the SRILM toolkit<sup>8</sup>.

<sup>8</sup><http://www.speech.sri.com/projects/srilm>

System	BLEU
Baseline	38.64
+Sentences	39.16
+Munteanu+, 2006	38.87
+Only (IBM Model 1)	38.86
+Only (LLR)	39.27 <sup>†</sup>
+Only (SampLEX)	39.28 <sup>†</sup>
+External (IBM Model 1)	<b>39.63<sup>†*</sup></b>
+External (LLR)	39.22
+External (SampLEX)	39.40 <sup>†</sup>

Table 2: Results for Chinese-to-Japanese translation experiments (“<sup>†</sup>” and “<sup>‡</sup>” denotes the result is better than “Baseline” significantly at  $p < 0.05$  and  $p < 0.01$  respectively, “\*” denotes the result is better than “+Munteanu+, 2006” significantly at  $p < 0.05$ ).

Translation results evaluated on BLEU-4, are shown in Table 2. We can see that appending the extracted comparable sentences have a positive effect on translation quality. Adding the fragments extracted by (Munteanu and Marcu, 2006) has a negative impact, compared to appending the sentences. Our proposed method outperforms both “+sentences” and “Munteanu+, 2006”, which indicates the effectiveness of our proposed method for extracting useful parallel fragments for MT.

We compared the phrase tables produced by different methods to investigate the reason for different MT performance. We found that all the methods increased the size of phrase table, meaning that new phrases were acquired from the extracted data. However, the noise contained in the data extracted by “+sentences” and “Munteanu+, 2006” produced many noisy phrase pairs, which may decrease MT performance. Our proposed method extracted accurate parallel fragments, which led to correct new phrases. Among all the settings of our proposed method, “+External (IBM Model 1)” showed the best performance. The reason for this is that it extracted more correct parallel fragments than the other settings, thus more new phrase pairs were produced.

Surprisingly, the translation performance after appending the fragments extracted by our proposed method only using the comparable sentences for alignment shows comparable results when using LLR and SampLEX lexicon for filtering, compared to the ones using the external parallel data for alignment. We think the reason

is that the extracted fragments not only can produce new phrases, but also can improve the quality of phrase pairs extracted from the original parallel corpus. Because the fragments extracted only using the comparable sentences are more accurate than the ones using the external parallel data, they are more helpful to extract good phrase pairs from the original parallel corpus. This result indicates that external parallel data is not indispensable for the alignment model of our proposed method.

## 5 Conclusion and Future Work

In this paper, we proposed an accurate parallel fragment extraction system using alignment model together with translation lexicon. Experiments conducted on Chinese-Japanese data showed that our proposed method significantly outperforms a state-of-the-art approach and improves MT performance.

Our system can be improved in several aspects. Firstly, we only use IBM models for parallel fragment candidate detection, alignment models such as the ones proposed by (Quirk et al., 2007) could be more effective. Secondly, currently our proposed method cannot deal with ordering, an alignment model that is effective for ordering even on comparable sentences should be developed. Thirdly, although the experimental results indicate that external parallel data is not indispensable for the alignment model, we still use a parallel corpus for comparable sentence selection and lexicon filtering. An alternative method is constructing a large bilingual dictionary from comparable corpora, and use it for comparable sentence selection and lexicon filtering. Finally, although our proposed method is designed to be language and domain independent, the effectiveness for other language pairs and domains needs to be verified.

## Abstract

We propose a simple and effective method to build a *meta-level* Statistical Machine Translation (SMT), called meta-SMT, for system combination. Our approach is based on the framework of *Stacked Generalization*, also known as *Stacking*, which is an ensemble learning algorithm, widely used in machine learning tasks. First, a collection of *base-level* SMTs is generated for obtaining a meta-level corpus. Then a meta-level SMT is trained on this corpus. In this paper we address the issue of how to adapt stacked generalization to SMT. We evaluate our approach on English-to-Persian machine translation. Experimental results show that our approach leads to significant improvements in translation quality over a phrase-based baseline by about 1.1 BLEU points.

## 1 Introduction

Currently, there exist a number of commercial and research Machine Translation (MT) systems, which are developed under different paradigms such as rule-based, example based, statistical machine translation, trained using different algorithms, e.g., phrase-based SMT, hierarchical phrase-based SMT, syntax-based SMT with different types and amounts of training data. With the emergence of these various structurally different systems, system combination methods have taken a great importance during the past few years.

There are several techniques for combining multiple SMT systems to achieve higher translation quality, e.g. sentence-level combination

(Hildebrand and Vogel, 2008) simply selects "the best" of the provided translations and phrase-level combination (Matusov et al., 2006; Rosti et al., 2007) can generate new translations differing from all original translations.

Most of the state-of-the-art SMT system combination methods require multiple SMT systems based on different models. Since it is not easy to have multiple SMT systems, in this work we focus on applying stacking algorithm on a single SMT system rather than multiple SMT systems.

We try to increase the performance of an SMT system by introducing a meta-level SMT which can learn how to decrease or modify translation errors on the translation outputs of original SMT system. This task is also known as automatic post-editing (APE) which is a well-studied topic in machine translation community (Simard et al., 2007a; Béchara et al., 2011). To do this, we use stacked generalization which is an ensemble learning algorithm

Ensemble Learning is a machine learning paradigm where multiple learners are trained to solve the same problem. An *ensemble* is viewed as a collection of learners which are usually called *base learners*. Base learners are usually generated from training data by a *base learning algorithm* which can be decision tree, neural network or other kinds of machine learning algorithms. Most ensemble methods use a single base learning algorithm to produce *homogeneous* base learners, but there are also some methods which use multiple learning algorithms to produce *heterogeneous* learners. The concept of ensembles appeared in classification literature has subsequently been studied in several frameworks, including *stacked generalization* (Wolpert, 1992),

*bagging* (Breiman, 1996b), *boosting* (Scharfire, 1990), *model averaging* (Perrone et al., 1993), *forecast combining* (Granger, 1989) and so on.

Previous work have tried to introduce some of these frameworks into SMT (Xiao et al., 2010), none of them adapt stacked generalization to SMT. While stacked generalization has been extensively investigated in machine learning, its adaption to SMT is not a trivial task. In this paper, we show how to make stacked generalization work for a single SMT system.

Stacked generalization is a general method of using a meta-level model to combine base-level models to achieve higher accuracy. However, this algorithm is introduced for combining multiple models, we focus our attention to utilize this algorithm in order to improve only a single SMT system. The basic idea of stacked generalization is to perform cross-validation on the base-level dataset in order to create a meta-level dataset. Then a meta-level model is trained on it. Finally, this system can generate better outputs than original system that is trained on the whole original dataset.

## 2 Background

Given a source sentence  $s$ , the goal of SMT is to find a target sentence  $t$  among all possible target strings  $t_1$ , that maximizes the probability:

$$t = \arg \max_{t_1} \{\text{pr}(t_1 | s)\}$$

Where  $\text{pr}(t_1 | s)$  is the probability that  $t_1$  is the translation of the given source string  $s$ . The target string  $t_1$  is a machine translation for  $s$ . In meta-SMT, a monolingual two-side corpus consists of these machine translations along with correct human translations. So, given a machinery output  $t$ , the goal of meta-SMT is to find a target sentence  $\hat{t}$ , that maximizes this probability:

$$\hat{t} = \arg \max_{t_2} \{\text{pr}(t_2 | t)\}$$

Where  $\text{pr}(t_2 | t)$  is the probability that  $t_2$  is the correct final translation of the given machine translated string  $t$  and both of  $t_2$  and  $t$  are in the same language. The target sentence  $\hat{t}$  is a final machine translation for  $s$ .

In the next section, we are going to describe stacked generalization for classification tasks and

in section 3, we present a general solution to adapting this algorithm to SMT.

### 2.1 Stacking for Classification

Wolpert (1992) introduced a novel approach for combining multiple classifiers, known as stacked generalization or stacking. The key idea is to learn a meta-level (or level-1) classifier based on the output of base-level (or level-0) classifiers, estimated via cross-validation as follows:

Define  $D = \{(x_i, y_i), i = 1, \dots, K\}$  as a data set, also referred to as level-0 data, where  $x_i$  is a feature vector representing the  $n$ th instance and  $y_i$  is the class value, and  $L_1 \dots L_N$  a set of different learning algorithms. During a  $J$ -fold cross-validation process,  $D$  is randomly split into  $J$  disjoint almost equal parts  $D_1, \dots, D_J$ . Define  $D^j$  and  $D \setminus D^j$  to be the test and training sets for  $j$ th fold of a  $J$ -fold cross-validation. At each  $j$ th fold,  $j = 1 \dots J$ , given the  $L_1 \dots L_N$  learning algorithms, we invoke each of them on the data in the training set  $D \setminus D^j$  to induce classifiers  $C_1(j) \dots C_N(j)$ . Then, these classifiers are applied to the test part  $D^j$ . The concatenated predictions of the induced classifiers on each feature vector  $x_i$  in  $D^j$ , together with the original class value  $y_i(x_i)$ , form a new  $MD^j$  of meta-level vectors.

At the end of the entire cross-validation process, the union  $MD = \cup_j MD^j, j = 1 \dots J$ , constitutes the full meta-level data set, also referred to as level-1 data, which is used for applying a learning algorithm  $L_M$  and inducing the meta-level classifier  $C_M$ . The learning algorithm that is employed at meta-level could be one of the  $L_1 \dots L_N$  or a different one. Finally, the learning algorithms are applied to the entire data set  $D$  inducing the final base-level classifiers  $C_1 \dots C_N$  to be used at runtime. In order to classify a new instance, the concatenated predictions of all base-level classifiers  $C_1 \dots C_N$  form a meta-level vector that is assigned a class value by the meta-level classifier  $C_M$ . In the next section we adapt this framework to SMT.

## 3 Adapting Stacking to SMT

Stacking is composed of two phases and we adapt it to SMT as follows:

First, a typical *SMT paradigm* is trained using  $J$ -fold cross-validation based on a bilingual cor-

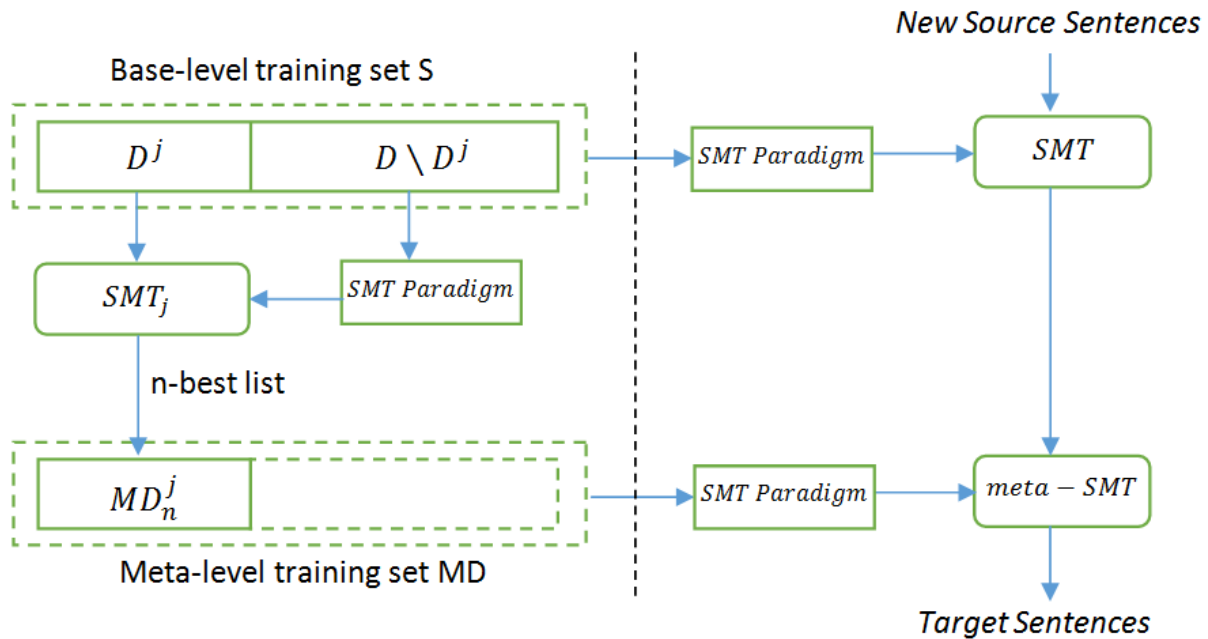

Figure 1. Stacking framework for SMT.

-pus. A popular setting of  $J$  is 5 and in this case it is called as *5-fold cross-validation*. We use this setting in our work. At the end of this step, 5 different systems are built based on 5 different training sets, called  $SMT_j, j = 1, \dots, 5$ . Then, the  $n$ -best outputs of these systems are collected to create a new corpus called meta-level corpus  $MD$ . For example, if we have a training corpus of  $N$  sentences and we use 3-best outputs of each system in cross-validation process, the effective size of the meta-level corpus will be  $3 \times N$ . In this new corpus, all the generated translations from the source sentences are paired to correct human translations.

Second, this corpus is used with another SMT paradigm -we call it *meta-SMT*- that could be identical to the SMT paradigm we used in cross-validation process or another SMT paradigm, in order to provide the final translation. In this algorithm, any SMT paradigm could be used in base-level and meta-level SMTs such as phrase-based SMT, hierarchical phrase-based SMT and syntax-based SMT. In this work, we utilize a phrase-based SMT for both base-level and meta-level. We use a phrase-based model for meta-level SMT, because we are supposed to improve a single SMT system. In addition, we train another phrase-based SMT based on full training set to produce target 1-best outputs and then use these outputs as input test set for meta-level SMT.

Figure 1 (left side) illustrates the cross-validation methodology, while Figure 1 (right

side) illustrates the stacking framework at runtime. Figure 2 also shows the algorithm in details.

### 3.1 Training base-level SMTs

After splitting the whole training corpus to separate training and test sets during cross-validation process, we train 5 phrase-based SMT systems on the training part and obtain the result of these systems on the corresponding test sets. We need these results for the next step.

### 3.2 Training meta-level SMTs

We gathered the  $n$ -best outputs of base-level SMTs on the corresponding test sets and built a meta-level corpus using these outputs along with correct human translations which was available from our original corpus. Then a meta-level SMT is trained on this corpus. We train our meta-SMT system on 10 meta-level corpus which is progressively created from  $n$ -best outputs of base-level systems,  $n = 1, \dots, 10$ ; i.e. each meta-level corpus that is created from  $n$ -best list also contains  $(1 \dots n - 1)$ -best list. In the results, we call these systems as meta-SMT (1-best) and meta-SMT (2-best) and so on.

### 3.3 Tuning meta-level SMTs

We must tune our meta-SMTs in a principled way. Similar to the training step, after splitting the whole tuning corpus to separate tuning and test sets during cross-validation process, we tune

---

**Input:** Training set  $D = \{(e_1, f_1), (e_2, f_2), \dots, (e_d, f_d)\}$ ;  
Tuning set  $T = \{(e'_1, f'_1), (e'_2, f'_2), \dots, (e'_t, f'_t)\}$ ;  
Test set  $S = \{(e''_1, f''_1), (e''_2, f''_2), \dots, (e''_s, f''_s)\}$ ;  
Base-level and Meta-Level SMT paradigms  $Bparadigm$  and  $Mparadigm$ , respectively.

**Process:**

- $baseline\_SMT = Bparadigm(D)$  % Train baseline SMT on the whole training set.
- $baseline\_SMT = baseline\_SMT(T)$  % Tune baseline SMT on the whole tuning set.
- $T_1 = baseline\_SMT(S)$  % Test baseline SMT on the original test set.
- $J$ -fold cross-validation: Divide the training and tuning sets into  $J$  roughly equal parts.
- $MD = \phi$ ; % Generate a new training set.
- $MT = \phi$ ; % Generate a new tuning set.

for  $j = 1, \dots, J$ :

$SMT_j = Bparadigm(D \setminus D^j)$  % Train base-level SMTs by their training parts  $D \setminus D^j$ .

$MD_n^j = SMT_j(D^j)$  % Test base-level SMTs on the corresponding test set to obtain  $n$ -best list.

$MD = MD \cup MD_n^j$  % Collect the outputs of base-level SMTs to create meta-level training corpus.

$SMT_j = SMT_j(T \setminus T^j)$  % Tune base-level SMTs by their tuning parts  $T \setminus T^j$ .

$MT^j = SMT_j(T^j)$  % Test base-level SMTs on the corresponding test set of tuning set.

$MT = MT \cup MT^j$  % Collect the outputs of base-level SMTs to create meta-level tuning corpus.

end;

$meta - SMT = Mparadigm(MD)$  % Train meta-level SMT by applying it to the new training corpus.

$meta - SMT = meta - SMT(MT)$  % Tune meta-level SMT by applying it to the new tuning corpus.

**Output:**  $T_2 = meta - SMT(T_1)$  % Test meta-SMT on the outputs of baseline SMT as test set.

---

Figure 2. Stacking algorithm adapted to SMT

5 base-level SMT systems on the tuning part and obtain the result of these systems on the corresponding test sets. Finally a meta-level development set is created by gathering these outputs paired with correct human translations to tune meta-level SMTs.

## 4 Experiments

### 4.1 Data

The corpus that is used for training and cross-validation process is Verbmobil project corpus which includes some tourists' conversations about time scheduling and appointment settings in German and English (Ney, 2000). Then a large part of English sentences are translated to Persian by human translators to build an English-Persian corpus (Bakhshaei et al., 2010). This dataset includes 23K lines in both sides, 249K and 216K words in Persian and English sides, respectively. We have chosen this corpus because it is small enough to perform cross-validation.

### 4.2 Experimental Setup

We use GIZA++ (Och and Ney, 2000) to perform the bi-directional word alignment between source and target side of each sentence pair. The final word alignment is generated using the *grow-diag-final-and* symmetrizing strategy. To speed up alignment, all the sentences with more than 80 words are removed. A 3-gram language model is trained on the target side of the bilingual data using the SRILM toolkit (Stolcke, 2002). The translation quality is evaluated in terms of case-insensitive BLEU metric.

We have run a phrase-based statistical machine translation with the Moses decoder (Koehn et al., 2007) to build baseline, base-level and meta-level SMTs.

We use MERT (Och, 2003) to tune the feature weights on the development data.

### 4.3 Evaluation

We investigate the effectiveness of our approach on improving a phrase-based SMT system. BLEU scores are computed on 250 test sentences

Type of SMT	Test set
<i>baseline SMT</i>	30.47
<i>meta-SMT (1-best)</i>	31.20
<i>meta-SMT (2-best)</i>	31.00
<i>meta-SMT (3-best)</i>	31.37
<b><i>meta-SMT (4-best)</i></b>	<b>31.49</b>
<b><i>meta-SMT (5-best)</i></b>	<b>31.41</b>
<i>meta-SMT (6-best)</i>	31.05
<i>meta-SMT (7-best)</i>	31.19
<b><i>meta-SMT (8-best)</i></b>	<b>31.40</b>
<i>meta-SMT (9-best)</i>	31.30
<b><i>meta-SMT (10-best)</i></b>	<b>31.54</b>

Table 1: BLEU (%) scores of baseline SMT and meta-SMTs on the Verbmobil test set.

with four reference translations. Table 1 shows the results of our approach against baseline SMT on the test set. We see that almost all meta-SMTs are achieved over 0.5 BLEU improvement on the test set. The biggest improvement is obtained by meta-SMT (10-best) by 1.07 BLEU improvement. Moreover, we see a similar behavior of our approach on the development set. Considering the results on the development set, meta-SMT (4-best) and meta-SMT (8-best) will be good choices for meta-level SMT.

While these results are very encouraging, we must investigate why this approach is helpful. We find that two factors possibly contribute to these results. first, performing cross-validation on the training set; second, and possibly more importantly, the re-optimization on the system. In order to verify whether the improvements are due to the cross-validation or re-optimizing, we perform two experiments. The first is to test this approach without any cross-validation process, but with the development set obtained from stacking. It means that all source side sentences of the training corpus are translated by using an SMT system that is trained on the bilingual same corpus. This experiment is referred to as Straight1 in the results. The second is to build meta-level SMTs tuned with a development set which is obtained directly from baseline SMT (i.e., without performing cross-validation on it). This experiment is referred to as Straight2 in the results.

A comparison between the results of the three settings (Stacking, Straight1 and Straight2) is shown in Figure 3. The figure shows BLEU curve on the test set, where the X-axis is the number of base-level outputs (n-best) that is used to create meta-level corpus for meta-SMT, and

Figure 3. Comparison of Stacking, Straight1 and Straight2.

the Y-axis is the BLEU scores of the final meta-SMT calculated from each approach. After analyzing the results, it can be concluded that both factors, i.e., cross-validation and re-optimizing the system with the stacking-based development set, are important to outperform the baseline SMT system. Since use of both factors, consistently lead to the best results.

In all of the experiments, the size of the n-best list varies from 1 up to 10. The main reason for the upper limit is just that the experiments are very time consuming.

We conducted statistical significance tests using *paired bootstrap resampling* proposed by Koehn (2004) to measure the reliability of the conclusion that meta-SMTs are really better than baseline SMT. It is observed that all stacking-based meta-SMTs are really better than the baseline SMT in 99% of the times.

## 5 Related Work

Stacking is a machine learning (ML) algorithm that is a well-studied topic in the ML community (Wolpert, 1992; Breiman, 1996a), and has been successfully adapted in natural language processing and information retrieval, such as named entity recognition (Wu et al., 2003) and Information extraction (Sigletos et al., 2005).

There are also some researches on applying ensemble learning algorithms into SMT. Xiao et al. (2010) presented a general solution for adaptation of bagging and boosting to SMT. The results of their work showed that ensemble learning algorithms are promising in SMT.

Most other researches are in the statistical post-editing (SPE) techniques which have been used successfully to improve the output of Rule-

Based MT (RBMT) systems. Simard et al. (2007a), trained a “mono-lingual” Phrase-based SMT system (the *Portage* system) on the output of an RBMT system for the source side of the training set of the Phrase-based SMT system and the corresponding human translated (manually post-edited) reference. More recently, Béchara et al. (2011) designed a full phrase-based SMT pipeline that included a translation step and a post-editing step. The authors report significant improvements of 2 BLEU points for a French to English translation task, using a novel context aware approach. This method takes into account the source sentences during the post-editing process through a word-to-word alignment between the source words and the target words generated by the translation system.

As far as we are aware, the research presented in this paper is the first attempt to apply stacking algorithm to SMT with the configuration presented.

## 6 Conclusion and Future Work

We have presented a simple and effective approach to translation error modification by building a meta-level SMT using a meta-level corpus that is created from original corpus by cross validation. Experimental results showed that such a meta-SMT can fix many translation errors that occur in the baseline translations. The proposed method outperforms the baseline SMT on the same test set. We also believe that stacked generalization can be used to combine multiple SMT systems. As a future work, we have planned to develop a technique for combining multiple SMT systems using stacked generalization algorithm.

Moreover, we are running more tests with different language-pairs and larger corpora. We also have planned to use the confusion network methods on the input of meta-level SMTs, so that the meta-SMT can translate a confusion network built based on the n-best output of baseline SMT. As another future work, we will apply our framework under different SMT paradigms such as hierarchical phrase-based SMT and syntax-based SMT.

## Acknowledgments

We would like to thank Somayeh Bakhshaei and Abbas Masoumzadeh for their helpful discussions.

## Abstract

We present a novel approach to learning phrasal inversion transduction grammars via Bayesian MAP (maximum *a posteriori*) or information-theoretic MDL (minimum description length) model optimization so as to incorporate simultaneously the choices of model structure as well as parameters. In comparison to most current SMT approaches, the model learns phrase translation lexicons that (a) do not require enormous amounts of run-time memory, (b) contain significantly less redundancy, and (c) provide an obvious basis for generalization to abstract translation schemas. Model structure choice is biased by a description length prior, while parameter choice is driven by data likelihood biased by a parameter prior. The search over possible model structures is made feasible by a novel top-down rule segmenting heuristic which efficiently incorporates estimates of the posterior probabilities. Since the priors reward model parsimony, the learned grammar is very concise and still performs significantly better than the maximum likelihood driven bottom-up rule chunking baseline.

## 1 Introduction

We introduce a minimalist, unsupervised learning model that induces relatively clean, compact phrasal translation lexicons by employing a novel Bayesian approach that attempts to find the maximum *a posteriori* (MAP) or minimum description length (MDL) model. The approach iteratively segments the rules in a top-down fashion which allows for efficient estimation of the model prior and the likelihood of the data given a limited change in the model—it is, in other words, possible to gener-

ate a set of possible rule segmentations and compare them using the model posteriors or description length.

Our new approach differs from most other SMT approaches to unsupervised learning of phrasal translations, which (a) require enormous amounts of run-time memory, (b) contain a high degree of redundancy, and (c) do not provide an obvious basis for generalization to abstract translation schemas. The current state-of-the-art in SMT (Koehn *et al.*, 2003; Chiang, 2005) relies on long pipelines of mismatched learning models and heuristics. There is no way for latter stages of the pipeline to recover a mistake of omission made in an earlier stage, which forces the individual steps to massively overgenerate hypotheses. This typically manifests as massive redundancy in the phrasal lexicon, which causes significant overhead at run-time. The fact that it is even possible to improve the performance of a phrase-based direct translation system by tossing away most of the learned segmental translations (Johnson *et al.*, 2007) illustrates these deficiencies well. By staying within a single framework throughout training and testing, we do not have to overgenerate hypotheses—instead, we are able to evaluate their effect on the posterior model probability at the time they are proposed during learning. This cuts down the size of the phrasal lexicon significantly, and consequently saves the decoder a lot of run-time resources. The fact that we learn a phrasal inversion transduction grammar, or ITG (Wu, 1997) also means that the power to generalize and abstract over categories is built into the formalism (although we will not make use of this feature in this work).

A word as to the bigger-picture motivation for this line of inquiry may be necessary. By insisting on the fundamental machine learning principle of matching the training model to the testing model, we accept forfeiting the short term boost

in BLEU that is typically seen when embedding a learned ITG in the midst of the common heuristics employed in statistical machine translation. For example, Cherry and Lin (2007); Zhang *et al.* (2008); Blunsom *et al.* (2008, 2009); Haghighi *et al.* (2009); Saers and Wu (2009, 2011); Blunsom and Cohn (2010); Burkett *et al.* (2010); Riesa and Marcu (2010); Saers *et al.* (2010); Neubig *et al.* (2011, 2012) all plug some aspect of the ITGs they learn into training pipelines for existing, mismatched decoders, typically in the form of the word alignment that an ITG imposes on a parallel corpus as it is biparsed. Although this allows us to tap into the vast engineering efforts that have gone into tweaking existing decoders, it also prevents us from understanding the quality of the learned transduction grammar, whose characteristics become obscured by the many unrelated variables in the subsequent processing pipeline. Our own past work has also taken similar approaches, but it is not necessary to do so—instead, any ITG can be used for decoding by directly parsing with the input sentence as a hard constraint, as we do in this paper. The motivation for our present series of experiments is that as a field we are well served by tackling the fundamental questions as well, and not exclusively focusing on engineering short term incremental BLEU score boosts where the quality of an induced ITG itself is obscured because it is embedded within many other heuristic algorithms.

Bayesian approaches to grammar induction have a long history in computation linguistics. Starting with monolingual grammar induction (Chen, 1995; Stolcke and Omohundro, 1994), and moving on to transduction grammar induction (Blunsom *et al.*, 2008, 2009; Blunsom and Cohn, 2010; Neubig *et al.*, 2011, 2012). So far, the induced transduction grammar have only been used to derive Viterbi-style word alignments to feed into existing translation system, and there has been no evaluation of the grammars actually learned. In contrast, we directly evaluate the grammars that we induce.

Our algorithm for learning the structure of an ITG relies on segmenting known bilingual segments, starting with the sentence pairs of the training data, and continuing with the segments learned in this way. This is similar to the Recursive Alignment Model, or MAR (Vilar, 2005; Vilar and Vidal, 2005). Our method is, however, learning a full ITG, where MAR only learns a translation lex-

icon; furthermore, MAR is a discriminative model, whereas ours is a generative.

Transduction grammars can also be induced from treebanks instead of unannotated corpora, which cuts down the vast search space by enforcing additional, external constraints—taking it from the realm of unsupervised induction into the realm of supervised induction. This approach was pioneered by Galley *et al.* (2006) with numerous variants in subsequent research, usually referred to as **tree-to-tree**, **tree-to-string** and **string-to-tree**, depending on where the analyses are found in the training data. Our view on this line of research is that it complicates the learning process by adding external constraints that are bound to match the translation model poorly; grammarians of English should not be expected to care about its relationship to Chinese. It does, however, constitute a way to borrow nonterminal categories that help the translation model.

The work presented in this paper is related to our preliminary work with description length as learning objective (Saers *et al.*, 2013b). A key difference lies in the added parameter training, which facilitates a completely Bayesian interpretation. The present paper aims to be self-contained, by explaining the relationships throughout.

## 2 Background

In this section we briefly survey essential foundations for inversion transduction grammars and description length together with its Bayesian interpretation—in other words, what we search for, and how.

### 2.1 Inversion transduction grammars

Inversion transduction grammars, or ITGs (Wu, 1997), are an expressive yet efficient way to model translation. Much like context-free grammars (CFGs), they allow for sentences to be explained through composition of smaller units into larger units, but where CFGs are restricted to generate monolingual sentences, ITGs generate *pairs of sentences*—**transductions** rather than languages. Naturally, the components of different languages may have to be ordered differently, which means that transduction grammars need to handle these differences in order. Rather than allowing arbitrary reordering and pay the price of exponential time complexity, ITGs allow the only monotonically straight or inverted order of the productions,

which cuts the time complexity down to a manageable polynomial.

Formally, an ITG is a tuple  $\langle N, \Sigma, \Delta, R, S \rangle$ , where  $N$  is a finite nonempty set of nonterminal symbols,  $\Sigma$  is a finite set of terminal symbols in  $L_0$ ,  $\Delta$  is a finite set of terminal symbols in  $L_1$ ,  $R$  is a finite nonempty set of inversion transduction rules and  $S \in N$  is a designated start symbol. An inversion transduction rule is restricted to take one of the following forms:

$$S \rightarrow [A], A \rightarrow [\Psi^+], A \rightarrow \langle \Psi^+ \rangle$$

where  $S \in N$  is the start symbol,  $A \in N$  is a nonterminal symbol, and  $\Psi^+$  is a nonempty sequence of nonterminals and biterminals. A **biterminal** is a pair of symbol strings:  $\Sigma^* \times \Delta^*$ , where at least one of the strings have to be nonempty. The square and angled brackets signal straight and inverted order respectively. With straight order, both the  $L_0$  and the  $L_1$  productions are generated left-to-right, but with inverted order, the  $L_1$  production is generated right-to-left. The brackets are frequently left out when there is only one element on the right-hand side, which means that  $S \rightarrow [A]$  is shortened to  $S \rightarrow A$ .

Like CFGs, ITGs also have a 2-normal form, analogous to the Chomsky normal form for CFGs, where the rules are further restricted to only the following four forms:

$$S \rightarrow A, A \rightarrow [BC], A \rightarrow \langle BC \rangle, A \rightarrow e/f$$

where  $S \in N$  is the start symbol,  $A, B, C \in N$  are nonterminal symbols and  $e/f$  is a biterminal string.

## 2.2 MAP and MDL

Our approach to transduction grammar induction can be equivalently interpreted either from a Bayesian perspective as finding the grammar model  $\Phi$  with maximum *a posteriori* probability (MAP) given training data corpus  $D$ , or from a compression perspective as finding the model  $\Phi$  with minimum description length (MDL) needed to encode data  $D$  so we can transmit both the encoded data and the model needed to decode it using as few bits as possible.

In the MAP case, the goal is to find the model  $\Phi$  with the maximum posterior probability, given the data  $D$  and assuming a prior  $P(\Phi)$  over the space of models:

$$P(\Phi|D) = \frac{P(\Phi)P(D|\Phi)}{P(D)}$$

which gives the following search problem:

$$\operatorname{argmax}_{\Phi} P(\Phi|D) = \operatorname{argmax}_{\Phi} P(\Phi)P(D|\Phi)$$

since the data is fixed.

In the MDL case, the minimum description length principle is about compressing a corpus by finding the optimal balance between the size of a model,  $DL(\Phi)$ , and the size of some data given the model,  $DL(D|\Phi)$  (Solomonoff, 1959; Rissanen, 1983). In information theoretic terms, we encode the data with a model, and then transmit both the encoded data *and* the information needed to decode the data (the model) over a channel; the minimum description length is the minimum number of bits we can get away with sending over the channel. The encoded data can be interpreted as carrying the information necessary to disambiguate the uncertainties that the model has about the data. The model can *grow in size* and become *more certain* about the data, or it can *shrink in size* and become *more uncertain* about the data. Formally, description length (DL) is:

$$DL(\Phi, D) = DL(\Phi) + DL(D|\Phi)$$

which gives the following search problem:

$$\operatorname{argmin}_{\Phi} DL(\Phi, D) = \operatorname{argmin}_{\Phi} DL(\Phi) + DL(D|\Phi)$$

which is equivalent to the MAP search problem if we follow the Shannon (1948) lower bound on the number of bits required to encode a specific outcome of a random variable such that  $DL(\cdot) = -\lg P(\cdot)$  and conversely  $P(\cdot) = 2^{-DL(\cdot)}$ , since in that case the description length of the model  $DL(\Phi) = -\lg P(\Phi)$  and the description length of the data given the model  $DL(D|\Phi) = -\lg P(D|\Phi)$ . These two interchangeable views of the problem are complimentary; in our previous work on minimizing description length (Saers *et al.*, 2013a,b), we have used this equality to model the description length of the data given the model in terms of the probability of biparsing a parallel corpus with an ITG.

In Bayesian modeling, it is frequently useful to break out different aspects of the prior. For transduction grammars, we will break the prior into three aspects: the type of transduction grammar ( $\Phi_G$ ), the structure of the grammar (the specific set of rules conforming to the type,  $\Phi_S$ ), and the parameters of the grammar ( $\theta_{\Phi}$ ). The prior is thus

broken down such that:

$$P(\Phi) = P(\Phi_G) P(\Phi_S|\Phi_G) P(\theta_\Phi|\Phi_S, \Phi_G)$$

The prior over grammar formalisms  $P(\Phi_G)$  will be kept fixed at *bracketing inversion transduction grammar* in this paper. In our previous work on minimizing description length, the model length depended purely on the grammar structure, which was what we were trying to induce. Reusing that in the Bayesian interpretation gives:

$$P(\Phi_S|\Phi_G) = 2^{-DL(\Phi_S|\Phi_G)}$$

The next section contains details about how the description length of ITGs is calculated. For the parameter prior  $P(\theta_\Phi|\Phi_S, \Phi_G)$ , we choose a symmetric Dirichlet distribution over rule right-hand sides given rule left-hand sides, with a concentration parameter of two ( $\alpha_0 = \alpha_1 = \dots = \alpha_{R_i-1} = 2$  for all  $i$ ).

The full search problem we are trying to solve is thus:

$$\begin{aligned} \operatorname{argmax}_{\Phi_G, \Phi_S, \theta_\Phi} & P(\Phi_G) \times P(\Phi_S|\Phi_G) \\ & \times P(\theta_\Phi|\Phi_S, \Phi_G) \times P(D|\Phi_G, \Phi_S, \theta_\Phi) \end{aligned}$$

or conversely:

$$\begin{aligned} \operatorname{argmin}_{\Phi_G, \Phi_S, \theta_\Phi} & DL(\Phi_G) + DL(\Phi_S|\Phi_G) \\ & + DL(\theta_\Phi|\Phi_S, \Phi_G) + DL(D|\theta_\Phi, \Phi_S, \Phi_G) \end{aligned}$$

As stated earlier, we will keep  $\Phi_G$  fixed so that we are only considering bracketing inversion transduction grammars.

### 2.3 Description length of ITGs

As mentioned, the structural prior of an ITG is based on its description length. To compute the description length of an ITG, we will turn to information theory, which can be used to compute the space requirements for encoding a sequence of symbols. This requires the serialization of ITGs into sequences of symbols. To serialize an ITG, we first need to determine the alphabet that the message will be written in. We need one symbol for every nonterminal,  $L_0$ -terminal and  $L_1$ -terminal. We will also make the assumption that all these symbols are used in at least one rule, so that it is sufficient to serialize the rules in order to express the entire grammar. To serialize the rules,

we need some kind of delimiter to know where one rule ends and the next starts; we will exploit the fact that we also need to specify whether the rule is straight or inverted (unary rules are assumed to be straight), and merge these two functions into one symbol. This gives the union of the symbols of the grammar and the set  $\{\langle \rangle, \langle \rangle\}$ , where  $\langle \rangle$  signals the beginning of a straight rule, and  $\langle \rangle$  signals the beginning of an inverted rule. The serialized format of a rule will be: rule type/start marker, followed by the left-hand side nonterminal, followed by all right-hand side symbols. The symbols on the right-hand sides are either nonterminals or biterminals. The serialized form of a grammar is the serialized form of all rules concatenated.

Consider the following toy grammar:

$$\begin{aligned} S &\rightarrow A & A &\rightarrow \langle AA \rangle & A &\rightarrow [AA] \\ A &\rightarrow \text{have/有} & A &\rightarrow \text{yes/有} & A &\rightarrow \text{yes/是} \end{aligned}$$

Its serialized form would be:

$$\langle \rangle SA \langle \rangle AAA \langle \rangle AAA \langle \rangle A \text{have} \text{有} \langle \rangle A \text{yes} \text{有} \langle \rangle A \text{yes} \text{是}$$

Now we can, again turn to information theory to arrive at an encoding for this message. Assuming a uniform distribution over the symbols, each symbol will require  $-\lg \frac{1}{N}$  bits to encode (where  $N$  is the number of different symbols—the type count). The above example has 8 symbols, meaning that each symbol requires 3 bits. The entire message is 23 symbols long, which means that we need 69 bits to encode it.

### 3 Initializing model structure: Initial ITG rules

To tackle the pitfalls of premature pruning in our earlier rule-chunking approaches of starting out with a fairly general transduction grammar and fitting it to the training data (Saers *et al.*, 2011, 2012), we do the exact opposite here: we start with a transduction grammar that fits the training data as well as possible, and generalize from there. The transduction grammar that fits the training data the best is the one where the start symbol rewrites to the full sentence pairs that it has to generate. It is also possible to add any number of nonterminal symbols in the layer between the start symbol and the bisentences without altering the probability of the training data. We take advantage of this by allowing for one intermediate symbol so that the ITG conforms to the normal form and always rewrites

the start symbol to precisely one nonterminal symbol. Our initial ITG thus contains long rules that look like this:

$$\begin{aligned}
S &\rightarrow A \\
A &\rightarrow e_{0..T_0}/f_{0..V_0} \\
A &\rightarrow e_{0..T_1}/f_{0..V_1} \\
&\dots \\
A &\rightarrow e_{0..T_N}/f_{0..V_N}
\end{aligned}$$

where  $S$  is the start symbol,  $A$  is the nonterminal,  $N$  is the number of sentence pairs in the training corpus,  $T_i$  is the length of the  $i^{\text{th}}$  output sentence,  $V_i$  is the length of the  $i^{\text{th}}$  input sentence,  $e_{0..T_i}$  is the sequence  $e_{0e_1} \dots e_{T_i-1}$  of output tokens (that is: the  $i^{\text{th}}$  output sentence), and  $f_{0..V_i}$  is the sequence  $f_0f_1 \dots f_{V_i-1}$  of input tokens (that is: the  $i^{\text{th}}$  input sentence).

#### 4 Generalizing model structure: Shortening long ITG rules

To generalize the initial inversion transduction grammar we need to identify parts of the existing biterminals that could be validly used in isolation, and allow them to combine with other segments. This is the very feature that allows a *finite* transduction grammar to generate an *infinite* set of sentence pairs; doing this, moves some of the probability mass which was concentrated in the training data out to other data that are still unseen—the very notion of generalizing beyond the training data.

In practice, we will segment the existing lexical rules into smaller lexical rules and the structural rules needed to compose them into the original, unsegmented, lexical unit. This preserves the capability to generate the original transduction, but also allows for novel combinations of the newly introduced lexical building blocks into novel sentence pairs, which extends the set of sentence pairs that the grammar can generate. Although it is possible to segment one rule at a time, as we did in Saers *et al.* (2013c), it is better to collect several rules with something in common and exploit this commonality, as we did in Saers *et al.* (2013a,b). Compared to these previous works, the objective criterion that we use to drive structural generalization, as defined in Section 2.2, is also a further improvement; our shift here from an MDL to a MAP interpretation naturally suggests the enhanced formulation of the Bayesian priors.

The general strategy is to propose a number of sets of biterminal rules and a place to segment them, estimate the posterior probability given these sets and commit to the best. That is: we do a greedy search over the power set of possible segmentations of the rule set. As we will see, this intractable problem can be reasonably efficiently approximated.

The key component in the approach is the ability to evaluate the change in a posteriori probability if a specific segmentation was made in the grammar. This can then be extended to a set of segmentations, which only leaves the problem of generating suitable sets of segmentations.

In this work, we are only considering segmentation of lexical rules, which keeps the ITG in normal form, greatly simplifying processing without altering the expressivity. A lexical ITG rule has the form  $A \rightarrow e_{0..T}/f_{0..V}$ , where  $A$  is the left-hand side nonterminal—the category,  $e_{0..T}$  is a sequence of  $T$  (from position 0 up to but not including position  $T$ )  $L_0$  tokens and  $f_{0..V}$  is a sequence of  $V$  (from position 0 up to but not including position  $V$ )  $L_1$  tokens. When segmenting this rule, three new rules are produced which take one of the following forms depending on whether the segmentation is inverted or not:

$$\begin{aligned}
A &\rightarrow [BC] & A &\rightarrow \langle BC \rangle \\
B &\rightarrow e_{0..S}/f_{0..U} & \text{or} & B \rightarrow e_{0..S}/f_{U..V} \\
C &\rightarrow e_{S..T}/f_{U..V} & C &\rightarrow e_{S..T}/f_{0..U}
\end{aligned}$$

All possible splits of the terminal rule can be accounted for by choosing the identities of  $B$ ,  $C$ ,  $S$  and  $U$ , as well as whether the split is straight or inverted.

The key to a successful segmentation is to maximize the potential for reuse. Any segment that can be reused maximizes the model prior. Consider the lexical rule:

$$\begin{aligned}
A &\rightarrow \text{five thousand yen is my limit/} \\
&\quad \text{我最多出五千日元}
\end{aligned}$$

(Chinese pinyin romanization: *wǒ zuì dōu chū wǔ qiān rì yuán*). This rule can be split into three rules:

$$\begin{aligned}
A &\rightarrow \langle AA \rangle, \\
A &\rightarrow \text{five thousand yen/五千日元}, \\
A &\rightarrow \text{is my limit/我最多出}
\end{aligned}$$

Note that the original rule consists of 16 symbols (in our encoding scheme), whereas the three new

rules consists of  $4 + 9 + 9 = 22$  symbols. Add to that that three rules are likely to be less probable than one rule when parsing, which makes the training data less likely as well. It is reasonable to believe that the bracketing inverted rule  $A \rightarrow \langle AA \rangle$  is present in the grammar already, but this still leaves 18 symbols, which is decidedly longer than 16 symbols—and we need to get the length to be shorter if we want to see a net gain. What we really need to do is find a way to reuse the lexical rules that came out of the segmentation. Now suppose the grammar also contained this lexical rule:

$A \rightarrow$  the total fare is five thousand yen/  
 总共的费用是五千日元

(Chinese pinyin romanization: *zōng gòng de fèi yòng shì wǔ qiān rì yuán*). This rule can also be split into three rules:

$A \rightarrow [AA]$ ,  
 $A \rightarrow$  the total fare is/总共的费用是,  
 $A \rightarrow$  five thousand yen/五千日元

Again, we will assume that the structural rule is already present in the grammar, the old rule was 19 symbols long, and the two new terminal rules are  $12 + 9 = 21$  symbols long. Again we are out of luck, as the new rules are longer than the old one. The way to make this work is to realize that the two existing rules share a bilingual affix—a **bi-affix**: five thousand dollars translating into 五千日元. If we make the two changes at the same time, we get rid of  $16 + 19 = 35$  symbols worth of rules, and introduce a mere  $9 + 9 + 12 = 30$  symbols worth of rules (assuming the structural rules are already in the grammar). Making these two changes at the same time is essential, as the length of the five saved symbols can be used to offset the likely decrease in the probability of the data given the grammar. And of course: the more rules we can find with shared biaffixes, the more likely we are to find a good set of segmentations.

Our algorithm takes advantage of the above observation by focusing on the biaffixes found in the training data. Each biaffix defines a set of lexical rules paired up with a possible segmentation. We evaluate the biaffixes by estimating the change in posterior probability associated with committing to all the segmentations defined by a biaffix. This allows us to find the best set of segmentations, but rather than committing only to the one best set of

segmentations, we will collect all sets which would improve the posterior probability, and try to commit to as many of them as possible. This minimizes the parsing efforts, which are very expensive.

The pseudocode for the search algorithm can be found in Algorithm 1. It uses the methods `collect_biaffixes`, `eval_map`, `sort_by_delta` and `make_segmentations`, which collects all biaffixes found in the rules of an ITG, evaluates the change in posterior probability caused by segmenting an ITG according to a biaffix, sorts biaffix–change-in-posterior pairs according to the latter, and commits to a set of segmentations, respectively.

To evaluate the change in posterior probability caused by a proposed set of candidate segmentations, we need to calculate the ratio between the posterior of the current model structure and the model structure that would result from committing to the candidate segmentations:

$$\frac{P(\Phi'|D)}{P(\Phi|D)} \propto \frac{P(\Phi'_S|\Phi_G) P(D|\Phi'_S, \Phi_G, \theta_{\Phi'})}{P(\Phi_S|\Phi_G) P(D|\Phi_S, \Phi_G, \theta_{\Phi})}$$

The proportionality holds because we are keeping the model formalism ( $\Phi_G$ ) and the model parameters ( $\theta_{\Phi}$  and  $\theta_{\Phi'}$ ) fixed. We arrive at the ratio between the structural priors by using description

length:

$$\frac{P(\Phi'_S|\Phi_G)}{P(\Phi_S|\Phi_G)} = 2^{-(\text{DL}(\Phi'_S) - \text{DL}(\Phi_S))}$$

Rather than biparsing the entire training data with the two models, we approximate the change as the ratio between the probabilities of the rules that differ. We thus assume that:

$$\frac{P(D|\Phi'_S, \Phi_G, \theta_{\Phi'})}{P(D|\Phi_S, \Phi_G, \theta_{\Phi})} = \frac{\hat{p}'(r_1)\hat{p}'(r_2)\hat{p}'(r_3)}{\hat{p}(r_0)}$$

where  $\hat{p}$  and  $\hat{p}'$  are the estimated rule probability functions within  $\theta_{\Phi}$  and  $\theta_{\Phi'}$  respectively. They differ only with respect to the changed rules, such that:

$$\begin{aligned}\hat{p}'(r_0) &= 0 \\ \hat{p}'(r_1) &= \hat{p}(r_1) + \frac{1}{3}\hat{p}(r_0) \\ \hat{p}'(r_2) &= \hat{p}(r_2) + \frac{1}{3}\hat{p}(r_0) \\ \hat{p}'(r_3) &= \hat{p}(r_3) + \frac{1}{3}\hat{p}(r_0)\end{aligned}$$

When more than one rule is segmented, we first aggregate the changes in rule probabilities for the entire set of rules, and then aggregate the changes in data probability.

We have now approximated the change in posterior probability to the point that we can efficiently calculate it in closed form for an arbitrary set of rule segmentations.

For practical purposes, we perform the search in two phases: one that focuses on the structure of the ITG, and one that focuses on the probabilities. The former performs top-down rule segmentation as described in Saers *et al.* (2013b), adjusting  $\Phi_S$  to optimize the posterior (thus affecting the prior over the structure of the ITG  $P(\Phi_S|\Phi_G)$  and the conditional probability of the data given the complete model  $P(D|\Phi_G, \Phi_S, \theta_{\Phi})$ ). The latter adjusts the model parameters  $\theta_{\Phi}$  to optimize the posterior (thus affecting the prior over the parameters  $P(\theta_{\Phi}|\Phi_S, \Phi_G)$  and again  $P(D|\Phi_G, \Phi_S, \theta_{\Phi})$ ), assuming the model structure  $\Phi_S$  to be fixed, as well as  $\Phi_G$  which remains fixed as bracketing inversion transduction grammars.

The prior is a symmetric Dirichlet distribution over rule right-hand sides given rule left-hand sides. To get the conditional, we have to biparse the training data, and to maximize it, we perform expectation maximization (Dempster *et al.*,

1977), as specified for ITGs by (Wu, 1995) with the caveat that we increase all the fractional counts by one before normalizing. The biparsing is done with our in-house implementation of the cubic time biparsing algorithm described in Saers *et al.* (2009), with a beam width of 100.

## 5 Experimental setup

To test the viability of the idea of starting with a very specific ITG consisting of long rules, and iteratively segmenting the rules to induce a more general ITG under a MAP or MDL objective, we have implemented the steps detailed in Sections 3 and 4; in this section we will describe in greater detail the exact experimental conditions of our empirical study.

The initial BITG is set to have the relative frequency of the unique sentences as the probability of the corresponding rules. This parametrization is identical to what we would have arrived at with any other initialization that was subsequently optimized with expectation maximization; in this case it is possible to jump straight to the optimum. The generalization step requires biparsing in order to estimate the posterior—we use the cubic time biparsing algorithm described in Saers *et al.* (2009), with a beam width of 100. In the parameter optimization step, we use the exact same biparser.

As training data, we use the IWSLT07 Chinese–English data set (Fordyce, 2007), which contains 46,867 sentence pairs of training data, and 489 Chinese sentences with 6 English reference translations each as test data; all the sentences are taken from the traveling domain. Since the Chinese is written without whitespace, we use a tool which tries to clump characters together into more “word-like” sequences (Wu, 1999).

After each induction iteration there is a fully-functional grammar that we can test as a translation system. For this, we use our in-house ITG decoder, which uses a CKY-style parsing algorithm (Cocke, 1969; Kasami, 1965; Younger, 1967) with cube pruning (Chiang, 2007) to integrate the language model scores. We use SRILM (Stolcke, 2002) to train a trigram language model on the English side of the training data.

To evaluate the resulting translations, we use BLEU (Papineni *et al.*, 2002), and NIST (Dodington, 2002), and compare the results against our bottom-up oriented chunking ITG induction approach (Saers *et al.*, 2012).

Figure 1: Number of rules (a), and the impact of changes in the model structure (b) during the structure induction phase. The change in model structure is broken down into the model prior (bottom) and data given model (top).

Figure 2: Variations in translation quality over different iterations. The dotted line represents the baseline (Saers *et al.*, 2012).

## 6 Results

We need to evaluate (a) how well the introduced induction works, and (b) how well the resulting model works. How well the induction works can be seen in Figure 1, which shows how the model changes over iterations. Although the number of rules rises, the model structure prior becomes more probable, indicating that smaller rules are being learned. The improvements in the prior fully makes up for the loss in the probability of the data given the model, which indicates that we are indeed generalizing successfully. The translation quality of the resulting model is found in Table 1 and Figure 2, which show how the translation quality changes as measured by two automatic quality metrics (Papineni *et al.*, 2002; Doddington, 2002). It is clear that the maximum *a posteriori* probability objective pushes the top-down learning approach far past the maximum likelihood objective of the bottom-up chunking learning approach, which is the baseline we are comparing against.

## 7 Conclusions

We have introduced a minimalist model for unsupervised Bayesian induction of parsimonious

Table 1: Translation results of the baseline, the initial model and the model after  $n$  iterations.

System	NIST	BLEU
baseline	0.8554	8.83
initial	0.0000	0.00
iteration 1	0.6686	9.38
iteration 2	3.9976	15.30
iteration 3	<b>4.3928</b>	<b>17.89</b>
iteration 4	4.3122	16.26
iteration 5	4.0981	16.10
iteration 6	3.9191	15.97
iteration 7	3.8338	15.06

phrasal ITGs, and shown that iteratively splitting existing rules into smaller rules driven by a maximum a posteriori probability objective is superior to iteratively chunking atomic rules into longer rules driven by a maximum likelihood objective. A novel top-down segmenting search strategy allows for efficient prediction of changes in posterior probability of the data given changes in the model—a key ingredient for MAP training. Decoding is done directly with induced transduction grammars, a more “pure” evaluation methodology than embedding them within many other heuristic components that obscure induction characteristics. This provides an obvious foundation for generalization to more general transduction grammars.

## Abstract

Previous research on quality estimation for machine translation has demonstrated the possibility of predicting the translation quality of well-formed data. We present a first study on estimating the translation quality of *user-generated content*. Our dataset contains English technical forum comments which were translated into French by three automatic systems. These translations were rated in terms of both comprehensibility and fidelity by human annotators. Our experiments show that tried-and-tested quality estimation features work well on this type of data but that extending this set can be beneficial. We also show that the performance of particular types of features depends on the type of system used to produce the translation.

## 1 Introduction

Quality Estimation (QE) involves judging the correctness of a system output given an input without any output reference. Substantial progress has been made on QE for Machine Translation (MT), but research has been mainly conducted on well-formed, edited text (Blatz et al., 2003; Ueffing et al., 2003; Raybaud et al., 2009; Specia et al., 2009). We turn our attention to estimating the quality of *user-generated content* (UGC) translation – a particularly relevant use of QE since the translation process is likely to be affected by the noisy nature of the input, particularly if the MT system is trained on well-formed text.

The source language content is collected from an IT Web forum in English and translated into French by three automatic systems. For each MT system, the produced translation is manually evaluated following two criteria: the translation

comprehensibility and fidelity. We evaluate several feature sets on the UGC dataset including the baseline suggested by the organisers of the WMT 2012 QE for MT shared task (Callison-Burch et al., 2012) and a feature set designed to model typical characteristics of forum text.

The novel contributions of the paper are: 1) testing the WMT QE for MT Shared Task baseline feature set on the UGC dataset and demonstrating its portability, 2) introducing new features which contribute to significant performance gains on both QE tasks, and 3) building three different QE systems using three different MT systems and showing that the usefulness of a feature type depends on the MT system although better performance can be achieved by training a QE system on the combined output of the three systems.

The paper is organised as follows. Related work on QE for MT is described in Section 2, followed in Section 3 by a description of the dataset. We describe the QE features in Section 4 and present the results of our experiments in Section 5. A discussion of the results, as well as a comparison with previous work, are presented in Section 6. Finally, we conclude and suggest future work in Section 7.

## 2 Background

The main approach for QE in MT is based on estimating how correct MT output is through characteristic elements extracted from the source and the target texts and the MT system involved in the translation process. These elements, or features, are seen as predictive parameters that can be combined with machine learning methods to estimate binary, multi-class, or continuous scores. First applied at the word level (Gandraber and Foster, 2003; Ueffing et al., 2003), QE for MT was then extended to the sentence level during a workshop in the same year (Blatz et al., 2003).

Many different feature sources have been used including surface features (segment length, punc-

tuation marks, etc.), language model features (perplexity, log-probability, etc.), word or phrase alignment features,  $n$ -best list features, internal MT system scores (Quirk, 2004; Ueffing and Ney, 2004), and linguistic features (Gamon et al., 2005; Specia and Gimenez, 2010). In a recent study, features based on the intra-language mutual information between words and backward language models were introduced (Raybaud et al., 2011). Other studies evaluate the gain brought by features extracted from MT output back-translation (Albrecht and Hwa, 2007), pseudo-references in the form of output from other MT systems for the same source sentence (Soricut et al., 2012), and topic models (Rubino et al., 2012).

Previous studies also differ on the labels to predict: binary scores (Quirk, 2004) or continuous scores such as those given by automatic metrics (Bojar et al., 2013) or averaged human evaluations (Specia et al., 2009; Callison-Burch et al., 2012). As regards the learning algorithms used, several have been tried, with support vector machine and decision tree learning proving popular (Callison-Burch et al., 2012).

### 3 Dataset

We use the dataset presented in Roturier and Bensadoun (2011), which was obtained by machine-translating 694 English segments, harvested from the Symantec English Norton forum<sup>1</sup>, into French using three different translators (MOSES (Koehn et al., 2007), MICROSOFT<sup>2</sup> (MS) and SYSTRAN). The translations were then evaluated in terms of comprehensibility (1 to 5 scale) and fidelity (binary scale) by human annotators. The source side of this data set represents user-generated content – see Banerjee et al. (2012) for a detailed description of the characteristics of this type of data and see Table 2 for some examples. For each of the three translators, we extract 500 segments from this dataset to build our training sets. The remaining 194 segments per translator are used as test sets. The distribution of the comprehensibility and fidelity classes over the three MT systems are shown in Table 1.

### 4 Quality Estimation Features

In this section, we describe the features which we added to the 17 baseline features provided by the

<sup>1</sup><http://community.norton.com>

<sup>2</sup><http://www.bing.com/translator/>

Class	Comprehensibility					Fidelity
	1	2	3	4	5	1
MOSES	6.1	55.0	12.7	11.2	15.0	37.2
MS	10.7	39.8	19.2	13.5	16.9	46.0
SYSTRAN	11.5	45.7	14.8	11.7	16.3	41.2

Table 1: Distribution (%) over the comprehensibility and fidelity classes for the 694 segments per MT system.

WMT12 QE shared task organisers to make our “extended” feature set. We then introduce a set of 37 features which relate specifically to the user-generated-content aspect of our data.

#### 4.1 Extended Feature Set

- **15 Surface Features** Average target word length, average source word occurrence, number of uppercased letters and the ratio of all source and target surface features.

- **180 Language Model Features** Source and target  $n$ -gram ( $n \in [1; 5]$ ) log-probabilities and perplexities on two LMs built on the seventh version of Europarl and the eighth version of News-Commentary (30 features). The same number of features are extracted from a backward version of these two LMs (Duchateau et al., 2002). We repeat this feature extraction process using four LMs built on the Symantec Translation Memories (TMs)<sup>3</sup> and four LMs built on the monolingual Symantec forum data<sup>4</sup>.

- **15 MT Output Language Model Features** A MOSES English-French PB-SMT system is trained on the Symantec TMs and the same target LM used to extract the baseline LM features. The English side of the Symantec Norton monolingual forum data is translated by this system and the output is used to build a 5-gram LM. Target features are then extracted in a similar way as the standard LM features.

- **4 Word Alignment Features** Using GIZA++ (Och and Ney, 2000) and the Symantec TMs, word alignment probabilities are extracted from the source and target segments.

- **78  $n$ -gram Frequency Features** The number of source and target segments unigrams seen in a reference corpus plus the percentage of  $n$ -grams in frequency quartiles ( $n \in [1; 5]$ ). The reference corpus is the same corpus used to extract the LM features.

<sup>3</sup>  $\sim 1.6M$  aligned segments in English and French.

<sup>4</sup>  $\sim 3M$  segments in English and  $\sim 40k$  segments in French.

---

*so loe and behold I get a Internet Worm Protection Signature File Version: 20090511.001. on 5/20/09 in the afternoon*  
*Start NIS 2009 > In the Internet pane, click Settings > Under Smart Firewall, click configure next to Advanced settings >*  
*In the Advanced Settings window, turn off Automatic Printer Sharing control.*

---

*ok then what should do am i safe as is meaning just leave it alone as long it get blocked it can get my info right i have*  
*no clew how get rid of it the only thing i could do that i know would work is to take everthing out my computer and format*  
*it with boo disk will this work?*

---

Table 2: Processing challenges associated with forum text: some examples.

- **9 Back-translation Features** We translate the target segments back into the source language using 3 different MT systems: MS, SYSTRAN and a MOSES PB-SMT system (trained on the Symantec TMs) and we measure the distance between the original source segments and the back-translated ones using BLEU, TER and Levenshtein.

- **23 Topic Features** Following Rubino et al. (2012; 2013), a bilingual topic model based on Latent Dirichlet Allocation (Blei et al., 2003) is built using the Symantec TMs. 20 features are the source and target segment distributions over the 10-dimensional topic space and 3 features are the distances between these distributions, using the cosine, euclidean distance and city-block metrics.

- **16 Pseudo-reference Features** Following Soricut et al. (2012), we compare each MT system output to the two others using sentence-level BLEU, error information provided by TER (no. of insertions, deletions, etc.) and Levenshtein.

- **3 Part-of-Speech Features** We count the number of POS tag types in the source and target segments, extracted from trees produced by the Stanford parser (Klein and Manning, 2003). The ratio of these two values is also included.

#### 4.2 UGC-related Features

We also experiment with features that capture the noisy nature of UGC. Some are related to the inconsistent use of character case, some to non-standard punctuation, some to spelling mistakes and some to the tendency of sentence splitters to underperform on this type of text. From each source-target pair, we extract the following information (in the form of one feature for the source segment, one for the target segment and, where appropriate, one for the ratio between the two):

- **11 Case Features** the number of upper and lowercased words, the number of fully uppercased words, the number of mixed-case words and whether or not the segment begins with an upper-case letter.

- **13 Punctuation Features** the ratio between punctuation characters and other characters, the

number of words containing a full stop, the number of sentences produced by an off-the-shelf sentence splitter for each segment (included in NLTK (Bird, 2006)), whether or not the segment contains a dash, an ellipsis, and whether or not the segment ends with a punctuation symbol.

- **9 Acronym and Emotion Features** the number of web and IT-domain acronyms and the number of emoticons.

- **4 Linguistic Features** the number of spelling mistakes flagged by the spellchecker LANGUAGE-TOOL<sup>5</sup> and whether or not the segment starts with a verb (indicating imperatives or questions).

## 5 Experiments

Classification models are built using the  $C$ -SVC implementation in LIBSVM (Chang and Lin, 2011) with a Radial Basis Function (RBF) kernel. Optimal hyper-parameters  $C$  and  $\gamma$  are found by grid-search with a 5-fold cross-validation on the training set (optimising for accuracy). For evaluation, we measure the accuracy, Mean Absolute Error (MAE) and Root Mean Square Error (RMSE). All the results are compared to the baseline for significance testing using bootstrap resampling. We present the results on the comprehensibility task first, followed by the results on the fidelity task. In order to remove noisy and redundant features we also experiment with feature selection. We try several approaches<sup>6</sup> and report results with the approach that performs best during cross-validation on the training set.

### 5.1 Translation Comprehensibility Results

The full set of comprehensibility estimation results are presented in Table 3. We see that a higher classification accuracy does not necessarily imply lower MAE and RMSE, e.g. the MOSES and

<sup>5</sup><http://www.language-tool.org/>

<sup>6</sup>These include information gain univariate filtering, correlation-based multivariate filtering, a naive Bayes wrapper approach and principal component analysis. All are implemented in the WEKA machine learning toolkit (Hall et al., 2009). Of the approaches tried, none stood out as clearly superior to the others and the choice seems to depend on the task and the MT system.

SYSTRAN experiments show that the extended set leads to a higher classification accuracy compared to the baseline, while the two error scores are lower on the baseline compared to the extended set. This discrepancy can happen because the accuracy measure is not sensitive to differences between comprehensibility scores whereas the error measures are – the error measures will prefer a system which gives a 5-scoring translation a score of 4 than one which gives it a score of 1. Statistical significance tests show that the extended feature set outperforms the baseline significantly only for the system trained on MS translations. The UGC feature set seems to add useful information only for the system trained on MOSES translations.

	MOSES	MS	SYSTRAN
<i>Baseline</i>			
Acc. (%)	67.0	39.7	55.2
MAE	0.48	0.96	0.64
RMSE	<b>0.94</b>	1.38	1.07
<i>Extended</i>

<i>Mixed-Translator: Extended+UGC</i>			
Acc. (%)	69.1	<b>44.3*</b>	54.6
MAE	0.48	<b>0.84*</b>	0.65
RMSE	0.98	1.27	1.09

Table 3: Translation comprehensibility estimation. Best results are in bold, statistically significant improvements over the baseline ( $p < 0.05$ ) are indicated with \*.

To evaluate the impact of different types of features, we conduct an evaluation by feature subset (see Figure 1). The results show that the best-performing features vary across the MT systems. The pseudo-reference and POS features are particularly useful for the system trained on MOSES translations. For the system trained on MS translations, the  $n$ -gram frequency features based on the Symantec TMs are clearly outperforming all the other feature types, with an accuracy of 42.8%. For the system trained on SYSTRAN translations, the pseudo-reference features yield an accuracy

Figure 1: Feature types for comprehensibility.

score of 56.7%, which outperforms the extended set. The system trained on MS translations does not benefit from the pseudo-reference features as much as the two other QE systems. Perhaps this is because these features provide a reliable indication of translation quality when the two MT systems being compared are trained on similar data – MOSES was trained using the domain- and genre-specific data and SYSTRAN is optimized using a domain-specific lexicon, which increases the proximity of the translations generated by these two systems. LM features appear to be very useful for the three MT systems: the backward LM built on the TMs leads to the best accuracy results amongst the LM-based features for MS, while SYSTRAN and MOSES benefit from features extracted using a backward LM built on forum data.

According to the results in Fig. 1, several feature types individually outperform the baseline and the extended sets, which indicates that unsuited features are included in these two sets and motivates the application of feature selection. The feature selection algorithms are applied in two ways: on the extended set and on each feature type individually. For this second approach, the reduced feature types are combined to form the final set. The results obtained with the first and second feature selection methods are presented in the fourth and fifth rows of Table 3 respectively. The systems trained on MS and SYSTRAN translations clearly benefit from the feature selection process with significant improvement over the baseline. For the system trained on the MOSES translations, only the accuracy scores are improved over the baseline. The choice of which of the two methods of applying feature selection to use also depends on MT system.

As the training set for each MT system is small (500 instances), we combine these training sets and build a mixed-translator classification model (last row in Table 3). Note that this means that each training source segment will appear three times (one for each of the MT systems). We use the *Extended+UGC* feature set to build the mixed-translator model. Comparing to the results in the third row (individual MT classification model), we observe that it is generally beneficial to combine the translations into one larger model.

## 5.2 Translation Fidelity Results

The fidelity results are presented in Table 4.<sup>7</sup>

	MOSES	MS	SYSTRAN
Baseline	81.4	62.9	68.0
Extended	81.4	63.4	<b>76.8</b>
Extended+UGC	80.4	65.5	73.7
Extended+sel.	77.3	64.4	72.2
Type+sel.	<b>82.0</b>	<b>69.1</b>	74.2
Mixed-Translator: Ext+UGC	<b>82.0</b>	66.5	76.3

Table 4: Accuracy for fidelity estimation, best results are in bold.

According to the results for the extended feature set, the baseline result for the system trained on MOSES translations appears to be very difficult to improve upon. For this system, adding the UGC features actually degraded the accuracy scores, while it helps the system trained on MS translations. The extended set reaches the best accuracy scores (76.8%) for the system trained on SYSTRAN translations with a 8.8pt absolute improvement over the baseline set. However, statistical significance testing show that none of the improvements over the baseline are statistically significant.

As with the comprehensibility results, the impact of the feature sets depends on the MT system (see Figure 2). Again, the pseudo-reference features lead to the highest accuracy score for the system trained on MOSES translations (+2.1pts absolute compared to the baseline and extended sets) and the system trained on SYSTRAN translations (equal to the extended set), while it is not the case for the system trained on MS translations. For this latter system, the  $n$ -gram frequency features based on the forum data reach 66.0% accuracy. The accuracy results per feature type show a larger divergence compared to the results obtained on the

<sup>7</sup>We do not measure the two error scores for the fidelity scores prediction because it is a binary classification task.

Figure 2: Feature types for fidelity.

comprehensibility task. Some feature types appear to be particularly noisy for the fidelity task, for instance the surface features for MOSES, the back-translation for MS and the word-alignment for SYSTRAN. To tackle this issue, the same feature selection methods previously used for the comprehensibility task are applied. The fourth and fifth rows in Table 4 show the results for the two methods of applying feature selection. We can see that selecting features within individual feature types leads to better results compared to applying feature selection to the full set.

As with the comprehensibility task, we build a mixed-translator fidelity estimator using the *Extended+UGC* feature set (last row in Table 4) and we observe here also that it is beneficial to combine the training data compared to training individual models.

## 6 Analysis

Adding features to the baseline set does not necessarily lead to better QE. Perhaps the baseline feature set is already diverse enough (surface, LM, word alignment, etc.). However, an error analysis shows that including the UGC features does bring useful information, especially when the source segments contain URLs, as shown in Table 5. In the case of untranslated elements, the spellchecker sometimes provides important information to the classifier about the MT output quality.

When we compare the QE results over the three MT systems, there is substantial variation. One possible explanation for this variation is the class distributions for the three sets of translations. The set whose quality is hardest to predict (MS) is the one with a more balanced distribution over the classes for both tasks (see Table 1). As classifiers

Table 5: Example of segments where the correct comprehensibility class is predicted using UGC features.

can be biased towards the majority class, the QE task appears to be more difficult with a balanced dataset with a high standard deviation.

The best-performing feature type varies amongst the MT systems. For instance, the features built on the domain-specific translation memories (LMs and  $n$ -gram counts) bring more useful information when estimating the translation comprehensibility of the MS translations. It is possible that this is happening because the MOSES and SYSTRAN systems were trained on domain-specific data while the MS system was not. Domain-specific features may be particularly helpful in estimating the quality of the output of a general-purpose, non-domain-tuned MT system.

Although the MS translations represent the most difficult set for the QE task, they are the best translations according to BLEU score (0.39 compared to 0.37 for MOSES and 0.35 for SYSTRAN). However it is not possible to conclude from this that there is a negative correlation between MT and QE performance since there are only three MT systems and the differences between them are small. Whether or not this points to a general trend requires further experimentation with other QE datasets, feature sets and MT systems.

	base.	win	full	+ full sel.	+ type sel.
MAE	0.69	0.61	0.67	0.67	0.67
RMSE	0.82	0.75	0.84	0.84	0.83

Table 6: Comparison between the baseline, the shared task winner and our approach on the WMT12 QE dataset.

To test the portability of our feature set and feature selection methods, we evaluate them on the WMT 2012 shared task dataset. The feature set contains the same features as the *Extended* set, apart from the ones which could not be extracted from the training data provided by the shared task organisers, such as forum and Symantec TM LMs and  $n$ -gram features. We report the results in Table 6. We do not outperform the baseline features in terms of RMSE but we do with MAE. Feature selection does not bring any improvement in MAE, but RMSE is slightly improved when selection is carried out at the level of individual feature type. Our system lags behind the top-ranked system (Soricut et al., 2012) – more feature selection experimentation is required in order to narrow this gap. It would also be interesting to see how the top-ranked system performs on our UGC dataset.

## 7 Conclusion

We have conducted a series of quality estimation experiments on English-French user-generated content, estimating both translation comprehensibility and fidelity, and training systems on the output of three individual MT systems. The experiments show that the information brought by a type of feature can be more or less useful depending on the MT system used. We show that the baseline suggested by the WMT12 QE shared task organisers leads to respectable results on user-generated content but we also show that there is sometimes some modest benefit to be found in extending this feature set. The features that are designed specifically to take into account that our data is user-generated content did not perform as well as other new features. However, we cannot conclude from this that modelling the forum characteristics of our data is unnecessary since the LM features trained on forum text perform well. In the future we plan to apply QE at the level of forum post rather than segment.

## Abstract

In this paper, we propose a selective combination approach of pivot and direct statistical machine translation (SMT) models to improve translation quality. We work with Persian-Arabic SMT as a case study. We show positive results (from 0.4 to 3.1 BLEU on different direct training corpus sizes) in addition to a large reduction of pivot translation model size.

## 1 Introduction

One of the main challenges in statistical machine translation (SMT) is the scarcity of parallel data for many language pairs especially when the source and target languages are morphologically rich. Morphological richness comes with many challenges and the severity of these challenges increases when the richness and morphological complexity are expressed differently in the source and target languages.

A common SMT solution to the lack of parallel data is to pivot the translation through a third language (called pivot or bridge language) for which there exist abundant parallel corpora with the source and target languages. The literature covers many pivoting techniques. One of the best performing techniques, phrase pivoting (Utiyama and Isahara, 2007), builds an induced new phrase table between the source and target. One of the problems of this technique is that the size of the newly created pivot phrase table is very large (Utiyama and Isahara, 2007).

Given a parallel corpus between the source and target language, combining a direct model based on this parallel corpus with a pivot model could lead to better coverage and overall translation quality. However, the combination approach needs

to be optimized in order to maximize the information gain.

In this paper, we propose a selective combination approach of pivot and direct SMT models. The main idea is to select the relevant portions of the pivot model that do not interfere with the more trusted direct model. We show positive results for Persian-Arabic SMT (from 0.4 to 3.1 BLEU on different direct training corpus sizes). As a positive side effect, we achieve a large reduction of pivot translation model size.

This paper is organized as follows. Section 2 briefly discusses some related work. Section 3 presents linguistic challenges and differences between Arabic and Persian. In Section 4, we discuss our pivoting strategies. Then Section 5 discusses our approach for selective combination. In Section 6, we present our experimental results.

## 2 Related Work

### 2.1 Pivoting

Many researchers have investigated the use of pivoting (or bridging) approaches to solve the data scarcity issue (Utiyama and Isahara, 2007; Wu and Wang, 2009; Khalilov et al., 2008; Bertoldi et al., 2008; Habash and Hu, 2009). The core idea is to introduce a pivot language, for which there exist large source-pivot and pivot-target bilingual corpora. Pivoting has been explored for closely related languages (Hajič et al., 2000) as well as unrelated languages (Koehn et al., 2009; Habash and Hu, 2009). Many different pivoting strategies have been presented in the literature. The following two are perhaps the most commonly used.<sup>1</sup>

<sup>1</sup>Another notable strategy is to create a synthetic source-target corpus by translating the pivot side of source-pivot corpus to the target language using an existing pivot-target model (Bertoldi et al., 2008). A new source-target model is built from the new corpus.

The first strategy is sentence pivoting in which we first translate the source sentence to the pivot language, and then translate the pivot language sentence to the target language (Khalilov et al., 2008).

The second strategy is phrase pivoting (Utiyama and Isahara, 2007; Cohn and Lapata, 2007; Wu and Wang, 2009). In phrase pivoting, a new source-target phrase table (translation model) is induced from source-pivot and pivot-target phrase tables. We compute the lexical weights and translation probabilities from the two phrase tables.

In this paper, we utilize the phrase pivoting strategy as our baseline, which is shown to be better in performance compared to sentence pivoting (El Kholy et al., 2013).

## 2.2 Domain Adaptation

We propose a selective combination approach of pivot and direct SMT models to improve the translation quality. Our approach is similar to domain adaptation techniques where training data from many diverse sources are combined to build a single translation model which is used to translate sentences in a new domain.

Domain adaptation has been explored in the field through different methods. Some methods involve information retrieval (IR) techniques to retrieve sentence pairs related to the target domain from a training corpus (Eck et al., 2004; Hildebrand et al., 2005). Other domain adaptation methods are based on distinguishing between general and domain specific examples (Daumé III and Marcu, 2006). In a similar approach, Koehn and Schroeder (2007) use multiple alternative decoding paths to combine different translation models and the weights are set with minimum error rate training (Och and Ney, 2003).

In contrast to domain adaptation, we generate a new source-target translation model by phrase pivoting technique from two models. We then use domain adaptation approach to select relevant portions of the pivot phrase table and combine them with a direct translation model to improve the overall translation quality.

## 2.3 Morphologically Rich Languages

Since both Persian and Arabic are morphologically rich, we should mention that there has been a lot of work on translation to and from morphologically rich languages (Yeniterzi and Oflazer, 2010; Elming and Habash, 2009; El Kholy and Habash, 2010a; Habash and Sadat, 2006; Kathol and Zheng, 2008; Shilon et al., 2010). Most of

these efforts are focused on syntactic and morphological processing.

There have been a growing number of publications that consider translation into Arabic. Sarikaya and Deng (2007) use joint morphological-lexical language models to re-rank the output of English-dialectal Arabic MT. Other efforts report results on the value of morphological tokenization of Arabic during training and describe different techniques for detokenizing Arabic output (Badr et al., 2008; El Kholy and Habash, 2010b).

On the other hand, work on Persian SMT is limited to few studies. For example, Kathol and Zheng (2008) use unsupervised morpheme segmentation for Persian. They show that hierarchical phrase-based models can improve Persian-English translation. There are also other attempts to improve Persian-English SMT by working on syntactic reordering (Gupta et al., 2012) and rule-based post editing (Mohaghegh et al., 2012). There is also some work done on showing the effect of different orthographic and morphological processing for Persian on Persian-English translation (Rasooli et al., 2013a).

To our knowledge, there hasn't been a lot of work on Persian and Arabic as a language pair. One example is an effort based on improving the reordering models for Persian-Arabic SMT (Matusov and Köprü, 2010). Another recent effort improved the quality of Persian-Arabic by pivoting through English and adding additional features to reflect the quality of projected alignments between the source and target phrases in the pivot phrase table (El Kholy et al., 2013).

## 3 Arabic and Persian Linguistic Issues

In this section we present our motivation and choice for preprocessing Arabic, Persian and English data. Both Arabic and Persian are morphologically complex languages but they belong to two different language families. They both express richness and linguistic complexities in different ways (El Kholy et al., 2013).

One aspect of Arabic's complexity is its various attachable clitics and numerous morphological features (Habash, 2010) which include conjunction proclitics, e.g.,  $+و$  *w+* 'and', particle proclitics, e.g.,  $+ل$  *l+* 'to/for', the definite article  $+ال$  *Al+* 'the', and the class of pronominal enclitics, e.g.,  $+هم$  *+hm* 'their/them'. Beyond these clitics, Arabic words inflect for person, gender, number,

aspect, mood, voice, state and case.<sup>2</sup> This morphological richness leads to thousands of inflected forms per lemma and a high degree of ambiguity: about 12 analyses per word, typically corresponding to two lemmas on average (Habash, 2010). We follow El Kholy and Habash (2010a) and use the PATB tokenization scheme (Maamouri et al., 2004) in our experiments which separates all clitics except for the determiner clitic *Al+*. We use MADA v3.1 (Habash and Rambow, 2005; Habash et al., 2009) to tokenize the Arabic text. We only evaluate on detokenized and orthographically correct (enriched) output following the work of El Kholy and Habash (2010b).

Persian on the other hand has a relatively simple nominal system. There is no case system and words do not inflect with gender except for a few animate Arabic loanwords. Unlike Arabic, Persian shows only two values for number, just singular and plural (no dual), which are usually marked by either the suffix *ها+ +hA* and sometimes *ان+ +An*, or one of the Arabic plural markers. Persian also possess a closed set of few broken plurals loaned from Arabic. Moreover, unlike Arabic which expresses definiteness, Persian expresses indefiniteness with an enclitic article *ی+ +y* ‘*a/an*’ which doesn’t have separate forms for singular and plural. When a noun is modified by one or more adjective, the indefinite article is attached to the last adjective. Persian adjectives are similar to English in expressing comparative and superlative constructions just by adding suffixes *تر+ +tar* ‘+er’ and *ترین+ +taryn* ‘+est’ respectively. Verbal morphology is very complex in Persian. Each verb has a past and present root and many verbs have attached prefix that is regarded part of the root. A verb in Persian inflects for 14 different tense, mood, aspect, person, number and voice combination values (Rasooli et al., 2013b).

We follow El Kholy et al. (2013) and tokenize Persian text using Perstem (Jadidinejad et al., 2010) which is a deterministic rule based approach for segmentation of Persian.

English, our pivot language, is quite different from both Arabic and Persian. English is poor in morphology and barely inflects for number and tense, and for person in a limited context. English preprocessing simply includes down-casing, separating punctuation and splitting off “’s”.

<sup>2</sup>We use the Habash-Soudi-Buckwalter Arabic transliteration (Habash et al., 2007) with extensions for Persian as suggested by Habash (2010).

## 4 Pivoting Strategies

In this section, we review the two pivoting strategies that are our baselines.

### 4.1 Sentence Pivoting

In sentence pivoting, English is used as an interface between two separate phrase-based MT systems; Persian-English direct system and English-Arabic direct system. Given a Persian sentence, we first translate the Persian sentence from Persian to English, and then from English to Arabic.

### 4.2 Phrase Pivoting

In phrase pivoting (sometimes called triangulation or phrase table multiplication), we train a Persian-to-Arabic and an English-Arabic translation models, such as those used in the sentence pivoting technique. Based on these two models, we induce a new Persian-Arabic translation model.

Since we build our models are based Moses phrase-based SMT (Koehn et al., 2007), we provide the basic set of phrase translation probability distributions.<sup>3</sup> We follow Utiyama and Isahara (2007) in computing the probability distributions. The following are the set of equations used to compute the lexical probabilities ( $\phi$ ) and the phrase translation probabilities ( $p_w$ )

$$\begin{aligned}\phi(f|a) &= \sum_e \phi(f|e)\phi(e|a) \\ \phi(a|f) &= \sum_e \phi(a|e)\phi(e|f) \\ p_w(f|a) &= \sum_e p_w(f|e)p_w(e|a) \\ p_w(a|f) &= \sum_e p_w(a|e)p_w(e|f)\end{aligned}$$

where  $f$  is the Persian source phrase.  $e$  is the English pivot phrase that is common in both Persian-English translation model and English-Arabic translation model.  $a$  is the Arabic target phrase.

We also build a Persian-Arabic reordering table using the same technique but we compute the reordering probabilities in a similar manner to Henriquez et al. (2010).

As discussed earlier, the induced Persian-Arabic phrase and reordering tables are very large. Table 1 shows the amount of parallel corpora used to train the Persian-English and the English-Arabic and the equivalent phrase table sizes compared to the induced Persian-Arabic phrase table.<sup>4</sup>

<sup>3</sup>Four different phrase translation scores are computed in Moses’ phrase tables: two lexical weighting scores and two phrase translation probabilities.

<sup>4</sup>The size of the induced phrase table size is computed but not created.

Translation Model	Training Corpora Size	Phrase Table	
		# Phrase Pairs	Size
Persian-English	≈4M words	96,04,103	1.1GB
English-Arabic	≈60M words	111,702,225	14GB
Pivot_Persian-Arabic	N/A	39,199,269,195	≈2.5TB

Table 1: Translation Models Phrase Table comparison in terms of number of line and sizes.

We follow the work of El Kholy et al. (2013) and filter the phrase pairs used in pivoting based on log-linear scores. We present some baseline results to show the effect of filtering on the translation quality in Section 6.2.

## 5 Approach

In this section, we discuss our selective combination approach. We explore how to effectively combine both a pivot and a direct model built from a given parallel corpora to achieve better coverage and overall translation quality. We maximize the information gain by selecting the relevant portions of the pivot model that do not interfere with the more trusted direct model.

To achieve this goal, we investigate the idea of classifying the pivot phrase pairs into five different classes based on the existence of source and/or target phrases in the direct model. The first class contains the phrase pairs where the source and target phrases are in the direct system together. The second class is the same as the first class except that the source and target phrases exist but not together as a phrase pair in the direct system. The third, fourth and fifth classes are for the existence of source phrase only, target phrase only and neither in the direct system. Table 2 shows the different classifications of the portions extracted from the pivot phrase table with their labels which are used later in our results tables.

We use one of Moses phrase table combination techniques (Koehn and Schroeder, 2007) to combine the direct model with the different pivot portions (explained in more details in section 6.1).

## 6 Experiments

In this section, we present our results for the selective combination approach between direct and pivoting models.

### 6.1 Experimental Setup

For the direct Persian-Arabic SMT model, we use an inhouse parallel corpus of about 165k sentences and 4 million words.

Pivot phrase-pairs classification	Src exists in direct	Tgt exists in direct	Src & Tgt exist in direct
SRC : TGT	✓	✓	✓
SRC , TGT	✓	✓	×
SRC ONLY	✓	×	×
TGT ONLY	×	✓	×
NEITHER	×	×	×

Table 2: Phrase pairs classification of the portions extracted from the pivot phrase table.

In our pivoting experiments, we build two SMT models. One model to translate from Persian to English and another model to translate from English to Arabic. The English-Arabic parallel corpus is about 2.8M sentences (≈60M words) available from LDC<sup>5</sup> and GALE<sup>6</sup> constrained data. We use an in-house Persian-English parallel corpus of about 170K sentences and 4M words.

Word alignment is done using GIZA++ (Och and Ney, 2003). For Arabic language modeling, we use 200M words from the Arabic Gigaword Corpus (Graff, 2007) together with the Arabic side of our training data. We use 5-grams for all language models (LMs) implemented using the SRILM toolkit (Stolcke, 2002). For English language modeling, we use the English Gigaword Corpus with 5-gram LM using the KenLM toolkit (Heafield, 2011).

All experiments are conducted using Moses phrase-based SMT system (Koehn et al., 2007). We use MERT (Och, 2003) for decoding weights optimization. For Persian-English translation model, weights are optimized using a set 1000 sentences randomly sampled from the parallel corpus while the English-Arabic translation model weights are optimized using a set of 500 sentences from the 2004 NIST MT evaluation test set

<sup>5</sup>LDC Catalog IDs: LDC2005E83, LDC2006E24, LDC2006E34, LDC2006E85, LDC2006E92, LDC2006G05, LDC2007E06, LDC2007E101, LDC2007E103, LDC2007E46, LDC2007E86, LDC2008E40, LDC2008E56, LDC2008G05, LDC2009E16, LDC2009G01.

<sup>6</sup>Global Autonomous Language Exploitation, or GALE, is a DARPA-funded research project.

(MT04).

We use a maximum phrase length of size 8 across all models. We report results on an in-house Persian-Arabic evaluation set of 536 sentences with three references. We evaluate using BLEU-4 (Papineni et al., 2002).

For the combination experiments, Moses allows the use of multiple translation tables (Koehn and Schroeder, 2007). Different combination techniques are available. We use the ‘‘Either’’ combination technique where the translation options are collected from one table, and additional options are collected from the other tables. If the same translation option (identical source and target phrases) is found in multiple tables, separate translation options are created for each occurrence, but with different scores.

## 6.2 Baseline Evaluation

We compare the performance of sentence pivoting against phrase pivoting with different filtering thresholds. The results are presented in Table 3. In general, the phrase pivoting outperforms the sentence pivoting even when we use a small filtering threshold of size 100. Moreover, the higher the threshold the better the performance but with a diminishing gain.

Pivot Scheme	BLEU
Sentence Pivoting	19.2
Phrase_Pivot_F100	19.4
Phrase_Pivot_F500	20.1
Phrase_Pivot_F1K	<b>20.5</b>

Table 3: Sentence pivoting versus phrase pivoting with different filtering thresholds (100/500/1000).

We use the best performing setup across the rest of the experiments which is filtering with a threshold of 1K.

## 6.3 System Combinations

In this section, we investigate the selective combination approach. We start by the basic combination approach and then explore the gain/loss achieved from dividing the pivot phrase table to five different classes as discussed in Section 5.

### 6.3.1 Baseline Combination

Table 4 shows the results of the basic combination in comparison to the best pivot translation model and the best direct model. The results shows that combining both models leads to a gain in performance. The question is how to improve the quality

by doing a smart selection of only relevant portion of the pivot phrase table which is discussed next.

Model	BLEU%
Phrase_Pivot_F1K	20.5
Direct	23.4
Direct+Phrase_Pivot_F1K	<b>23.7</b>

Table 4: Baseline combination experiments between best pivot baseline and best direct model.

### 6.3.2 Selective Combination

In this section, we explore the idea of dividing the pivot phrase pairs into five different classes based on the existence of source and/or target phrases in the direct system as discussed in Section 5. We discuss our results and show the trade off between the quality of translation and the size of the different classes extracted from the pivot phrase table.

Table 5 shows the results of the selective combination experiments on a learning curve of 100% (4M words), 25% (1M words) and 6.25% (250K words) of the parallel Persian-Arabic corpus.

Model	Parallel data set size		
	4M	1M	250K
Direct	23.4	21.0	16.8
Phrase_Pivot_F1K	20.5		
Base Combination	23.7 *	<b>22.1 *</b>	<b>21.7 *</b>
SRC : TGT	22.9	21.2	17.3 *
SRC , TGT	23.0	21.3	18.5 *
SRC ONLY	23.5	20.1	17.5 *
TGT ONLY	<b>23.8*</b>	21.4 *	18.3 *
NEITHER	23.4	21.6 *	19.9 *

Table 5: Selective Combination experiments results on a learning curve. The first row shows the results of the direct system. The second row shows the result of the best pivot system. The third row shows the results of the baseline combination experiments with the whole pivot phrase table. Then the next set of rows show the results of the selective combination experiments based on the different classifications. All scores are in BLEU. (\*) marks a statistically significant result against the direct baseline.

The results show that pivoting is a robust technique when there is no or small amount of parallel corpora. In our case study on Persian-Arabic SMT, the direct translation systems built from parallel corpora starts to be better than the pivot translation system when trained on 1M words or more.

The base combination between the direct translation models and the pivot translation model leads to a boost in the translation quality across the learning curve. As expected, the smaller the parallel corpus used in training the more gain we get from the combination.

The results also show that some of pivot the classes provides more information gain than others. In fact some of the classes hurt the overall quality; for example, (SRC : TGT) and (SRC , TGT) both hurt the quality of translation when combined with direct model trained on 100% of the parallel data (4M words).

An interesting observation from the results is that by building a translation system with only 6.25% of the parallel data ( $\approx$  250K words) combined with the pivot translation model, we can achieve a better performance (21.7 BLEU) than a model trained on four times the amount of data (Size: 1M words; Score: 21.0 BLEU).

It is also shown across the learning curve that the best gains are achieved when the source phrase in the pivot phrase table doesn't exist in the direct model. This is expected due to the fact that by adding unknown source phrases, we decrease the overall OOVs.

Model	Parallel data set size		
	4M	1M	250K
SRC : TGT	0.2%	0.1%	0.1%
SRC , TGT	35.2%	29.0%	16.0%
SRC ONLY	59.9%	63.3%	64.1%
TGT ONLY	2.3%	3.4%	6.1%
NEITHER	2.3%	4.3%	13.7%

Table 6: Percentage of phrase pairs extracted from the original pivot phrase table for each pivot class across the learning curve.

Pruning the pivot phrase table is an additional benefit from the selective combination approach. Table 6 shows that percentage of phrase pairs extracted from of the original pivot phrase table for each pivot class across the learning curve. The bulk of the phrase pairs are extracted in the classes where the source phrases exist in the direct model which add the least and sometimes hurt the overall combination performance.

For the large parallel data (4M words), selective combination with (TGT ONLY) class gives a slightly better result in BLEU while hugely reducing the size of the pivot phrase table used (2.3% of the original pivot phrase table). For smaller parallel data, the advantage is reduced but here comes

the trade off between the quality of the translation and the size of the model.

## 7 Conclusion and Future Work

We propose a selective combination approach between pivot and direct models to improve the translation quality. We showed that the selective combination can lead to a large reduction of the pivot model without affecting the performance if not improving it. In the future, we plan to investigate classifying the pivot model based on morphological patterns extracted from the direct model instead of just the exact surface form.

## Acknowledgments

The work presented in this paper was possible thanks to a generous research grant from Science Applications International Corporation (SAIC). The last author (Sawaf) contributed to the effort while he was at SAIC. We would like to thank M. Sadeqh Rasooli, Jon Dehdari and Nadi Tomeh for helpful discussions and insights into Persian.

## Abstract

Incorporating semantic information in the Statistical Machine Translation (SMT) framework is starting to gain some popularity in both the semantics and translation communities. In this paper, we present encouraging results obtained from experiments conducted on English to Arabic SMT system using static, dynamic, and hybrid integration of fine-grained Multiword Expression (MWE). We achieve an improvement up to 0.82 absolute BLEU score by integrating MWEs over a vanilla SMT system. We empirically show that different MWE types require different integration methods in the SMT framework.

## 1 Introduction

Multiword expressions (MWEs) are roughly defined by (Sag et al., 2002) as “idiosyncratic concepts that cross word boundaries (spaces).” MWEs are widely used, 41% of the entries in WordNet 1.7 (Fellbaum, 1998) are MWEs, but unfortunately they have proved to be hard to model in natural language processing applications. Typical statistical machine translation (SMT) systems, in particular, do not explicitly model MWEs. This might indicate that state of the art SMT systems are doing well without having any knowledge of whether a given phrase is a multiword expression or not. However, recent research (Carpuat and Diab 2010, Bouamor et al., 2012) show that explicitly modeling MWEs in the SMT framework yields non-negligible gains depending on the integration method.

In this paper we study explicit modeling of the diverse kinds of MWEs in a phrase-based SMT framework for the English-Arabic language pair. This paper is organized as follows: section 2 overviews the different types of MWEs, section

3 reviews the previous work related to MWEs and SMT. Section 4 details our approach followed by the results in section 5. Our discussion of the results is presented in section 6 and finally the conclusions are in section 7.

## 2 Multiword Expressions Classification

According to (Sag et al., 2002), MWEs are broadly classified into institutionalized phrases and lexicalized phrases based on the varying degree of lexical rigidity and semantic compositionality.

**Institutionalized phrases** are conventionalized phrases that are syntactically and semantically compositional, but statistically idiosyncratic (e.g. “traffic light”, “to kindle excitement”).

**Lexicalized phrases** have at least in part idiosyncratic syntax or semantics. They can be further broken down into:

(a) **Fixed expressions** which undergo neither morphosyntactic variation, nor internal modification (e.g. “by and large”, “every which way”) [AV, AJ],

(b) **Semi-fixed expressions** such as (1) non-decomposable idioms (e.g. “kick the bucket”) [VNC], (2) compound nominal (e.g. “car park”, “part of speech”) [NNC], and (3) proper names and named entities (e.g. “New York”) [NE].

(c) **Syntactically-flexible expressions** such as (1) verb particle construction (e.g. “write up”, “look up”) [VPC], (2) light verb constructions (e.g. “make a decision”) [LVC], and (3) decomposable idioms (e.g. “sweep under the rug”) [VNC].

## 3 Related Work

Previous work has focused on automatically learning and integrating translations of very specific MWE categories, such as, for instance, idiomatic Chinese four character expressions (Bai

et al., 2009.) MWEs have also been defined not from a lexical semantics perspective but from a SMT error reduction perspective, as phrases that are hard to align during SMT training (Lambert and Banchs, 2005). For each of these particular cases, translation quality improved by augmenting the SMT translation lexicon with the learned bilingual MWEs either directly or through improved word alignments.

Ren et al. (2009) described a method integrating an in-domain bilingual MWE to Moses by introducing an additional feature that identifies whether or not a bilingual phrase contains bilingual MWEs. This approach was generalized in Carpuat and Diab (2010) who replaced the binary feature by a count feature representing the number of MWEs in the source language phrase. They present results on a large data set of English to Arabic SMT. They introduce two ways of integrating MWE knowledge in the SMT framework: Static and Dynamic integration. For Static integration, MWE tokens in the source data are grouped together with an underscore. While in Dynamic integration, the MWEs are identified in the phrase table and an additional weighted feature, as a soft constraint, is added to the phrase translation table. Carpuat and Diab (2010) focus only on MWEs as identified in WordNet (Fellbaum, 1998) with no explicit distinction between the different types of MWEs. Accordingly, the MWEs are considered a single type with no attention to various POS information. Our work here is taking a much fine grained approach and deeper study and analysis.

## 4 Approach

We adopt a Phrase-based SMT framework, Moses (Koehn et al., 2007). In the following subsections, we address the issue of representation of MWE in our SMT pipeline and then we investigate the manner in which the MWE information is integrated in the SMT framework.

### 4.1 Data Sets

For training the translation models, we use LDC GALE newswire parallel Arabic-English corpus (LDC2007E103) (a total of 474299 sentence pairs / about 10M un-tokenized words / 12M tokenized words). The Log-Linear model features weights are tuned using the newswire part of NIST MT06 (765 sentence pairs) as the tuning dataset and BLEU (Papineni et al., 2002) as the objective function. For training the language model (LM), we use the LDC Arabic

GIGAWORD 4th edition (LDC2009T30) (about 850M un-tokenized words).

We use the newswire part of NIST-MT04 (707 sentences) as our development test-set to compare performance and select combinations of different conditions. We report results using two blind test-sets; NIST-MT05 (1056 sentences) and the newswire part of NIST-MT08 (813 sentences). These standard test sets are originally designed to test Arabic to English translation systems thus it consists of one Arabic source set and four English human reference translation sets. To use these test sets for testing English to Arabic translation systems, we created new test sets where the source set is constructed by concatenating the four English human translations of the original standard test set, and the reference set is constructed by duplicating the original standard test set Arabic source four times. This means that the new test sets have four times the number of sentences of the original standard test sets. Increasing the test set size enhances the reliability of the evaluation scores as reported by (Zhang and Vogel 2010).

### 4.2 MWEs lists

We need a mechanism by which to identify MWE in the source English text. We rely on two identification sources depending on the type of MWE: an MWE list extracted from a wide coverage lexical database and a named entity recognition tool. As mentioned earlier in section 2, we consider several types of MWEs for this study: Verb-based MWEs (VNC, VPC, and LVC), Noun-based MWEs (NNC, and NE), Adjective (AJ) and Adverb (AV) based MWE.

#### WordNet Extracted MWEs Lists:

For the VPC, VNC, LVC, NNC and AJ and AV categories of MWE, we extract an extensive list from the wide coverage English WordNet database 3.0. (Fellbaum,1998). Table 1 shows the number of MWEs extracted from WordNet 3.0 dictionaries. It is worth noting that the MWE.V list comprises all three types of verbal MWEs (VNC, VPC, LVC), moreover the MWE.N includes NNC and some NEs as listed in WordNet.

MWE list	# MWE types
MWE.V	3,089
MWE.N	62,244
MWE.AJ	3,358
MWE.AV	826

Table 1: WordNet 3.0 based MWE statistics

## Named Entities Tagging:

We consider Named Entities (NEs) as another type of MWE. To construct our NEs list, we exploit a named entity tagger, the Stanford NER [SNER] (Finkel et al., 2005). SNER tags named entities in a given English text into three categories: 1) Person 2) Organization and 3) Location. We are interested in Multiword NEs only and pay no attention to the different NE categories. The extracted NEs list consists of the 65616 Multiword NEs tagged by SNER in our training corpus.

There are some overlaps between the NEs list and the MWE lists extracted from WordNet as shown in table 2. The large overlap is between the NEs list and the MWE.N, which contains NEs as listed in WordNet 3.0.

	MWE.N	MWE.AJ	MWE.AV
# types	1216	24	5
Examples	abraham lincoln abu dhabi abu sayyaf adam smith addis ababa adriatic sea	african american anti american central american costa rican east african eastern orthodox	north east north northeast north west south east south west

Table 2: Overlaps between the WordNet MWEs lists and the NEs list

## Matching Algorithm:

In order to identify the MWE in the source English side of the parallel data, we use a Maximum Forward Matching algorithm that finds the longest matching MWE in the text. The algorithm matches over the tokenized version of the data and if no match, it backs-off to the lemmatized version to account for the different inflectional forms of the MWE (e.g. “take place” and “took place”). Our current matching algorithm doesn’t handle gap flexibility like in the phrasal verbs MWEs (i.e. “break up” is handled while “break it up” is not.)

## 4.3 SMT System

### Data preprocessing and models generation:

The Arabic side of the train, tune, development and test data sets and the language model training data sets are tokenized using AMIRA 2.1 toolkit (Diab 2009, Diab et al., 2007) into the Arabic TreeBank tokenization scheme. The Arabic side of the training data is further processed to generate a lemmatized version used in the alignment stage of the SMT pipeline. We use the undiacritized version (both tokenized and lemmatized) in all our experiments.

The English side is tokenized using Tree Tagger (Schmid, 1994). It is then tagged using the selected MWE list according to the condition under investigation. The English lemmatized version of the training data is also generated for use in alignment.

We used SRILM toolkit (Stolcke, 2002) to create a 5-gram Arabic LM modified using Kneser-Ney smoothing.

In all our experimental conditions, the parallel corpus is word-aligned using GIZA++ in both translation directions using the lemmatized version of both sides to decrease data sparseness, and phrase translations of up to 10 words are extracted from the tokenized version of both sides using the grow-diag-final-and heuristic (Koehn et al., 2007).

We optimized log-linear model feature weights using Minimum Error Rate Training (MERT) (Och, 2003). To account for the instability of MERT, we run the tuning step three times per condition with different random seeds and use the optimized weights that give the median score.

## Integration Methods:

### (a) Static Integration (S)

In Static integration of MWEs in SMT, MWEs in English training, tuning and testing data are underscored as a preprocessing step based on a pattern match to the WN list entries and NER results. Hence static integration is a manipulation on the data representation, the SMT system is kept intact.

### (b) Dynamic Integration (D)

Dynamic integration is a soft constraint strategy that adds a new feature into the log linear model of phrase-based SMT. It is a count feature indicating the number of MWEs in the English phrase in the phrase table, thereby biasing the system, at decoding time, towards using phrases that do not break MWEs. The training, tuning, development and test data do not undergo any MWEs annotation (no underscoring).

### (c) Zone Integration (Z)

We define constrained reordering zones for all MWEs found in the test data and the decoder is forced to respect these boundaries while constructing the translation hypothesis. This is easily represented using XML tags in the system input to Moses decoder (Koehn and Haddow, 2009). It is worth noting that words within a zone are not necessarily translated as a single phrase and can be reordered; input phrases that cross zone

boundaries can be used in translation hypotheses without breaking the reordering constraint.

#### (d) *Hybrid Integration*

Motivated by the development-set results of the previous integration methods and MWEs schemes, we carried out a set of experiments investigating combining the best performing conditions.

#### **MWEs Schemes:**

We created 7 MWEs schemes combining the various types of WordNet-based MWE lists and NEs list. They are listed in Table 3, along with the number of types and tokens of MWEs found in the training data according to each of the MWE Schemes.

We combine MWEs schemes and integration methods to get the different experimental conditions listed in Table 4. Here is some example input preprocessing for the same sentence according to different conditions:

-Baseline (and all dynamic integration):

invading iraqis kurdistan is no longer an easy task .

-S\_VAA<sup>1</sup>:

invading iraqis kurdistan is no\_longer an easy task .

-S\_NN:

invading iraqis\_kurdistan is no longer an easy task .

-Z\_VAA+NN:

invading <zone> iraqis kurdistan </zone> is <zone>  
no longer </zone> an easy task .

## **5 Evaluation Results**

We used four standard MT metrics<sup>2</sup>; BLEU (Papineni et al., 2002), NIST (Doddington, 2002), METEOR<sup>3</sup> (Banerjee and Lavie, 2005), and TER (Snover et al., 2006), to report and compare performance of different experimental conditions. Table 4, summarizes the results.

The results show that, for the three integration methods (S, D and Z), the only conditions that help across all test-sets are S\_VAA and D\_VAA. S\_VAA gives the best results except for METEOR where D\_NN and D\_NE are outperforming S\_VAA.

<sup>1</sup> We use the convention: IntegrationMethod\_MWEScheme [-IntegrationMethod\_MWEScheme]\* to label different conditions: e.g “S\_VAA-D\_NE+NN” refers to a hybrid integration where the “VAA” MWEs are statically integrated and the “NE+NN” MWEs are dynamically integrated.

<sup>2</sup> We report case-sensitive scores as our system output is in Buckwalter transliteration.

<sup>3</sup> For METEOR scores, we used “exact” module only.

We want to investigate which part of the SMT pipeline does S\_VAA condition help, so we carried another experiment (A\_VAA) where the VAA is used in the alignment stage of the pipeline only. We simply removed underscores from the input phrases in the phrase table and the lexical reordering table and used the new tables as A\_VAA tables. The tune and test data-sets are the same as the normal baseline (no underscoring). The results show that the major part of the S\_VAA configuration enhancement is actually coming from the alignment stage.

Motivated by the development set results of S\_VAA, A\_VAA and the enhancement of METEOR scores by D\_NN and D\_NE, we carried out a couple of experiments investigating hybrids of the integration methods.

**S\_VAA-\***: In these configurations we use static integration for VAA and dynamic integration for NE and/or NN. For example, for S\_VAA-D\_NE the input phrases in the phrase table have VAA MWEs underscored and the probabilities have the added extra feature counting NEs in the input phrase. The train, tune and test data for this configuration has VAA MWEs underscored.

**A\_VAA-\***: In these configurations we use the phrase tables of the S\_VAA and remove underscores from the input phrases. We then add the extra feature indicating the counts of the NE and/or NN MWEs found in the input phrase.

Table 4 shows that A\_VAA-D\_NE+NN gives the best overall consistent performance with absolute BLEU score improvement of 0.63 for MT04-NW, 0.82 for MT05 and 0.45 for MT08-NW.

## **6 Discussion**

Static integration mainly helps when the MWE is a fixed expression (AV, AJ) that needs to be translated as a whole non-compositionally. That’s why we see the VAA condition (more than half of its list is fixed MWEs) giving the best results. Static integration also helps for semi-fixed expressions (VNC, NNC and NEs) conditioned by having enough training samples otherwise we increase OOV. If we look at table 3, we can see that the average number of tokens per type for all NE conditions is very low. This is mainly due to the huge number of NE types. That’s why NEs schemes do not show any improvement using static integration. On the other hand, S\_NN shows some inconsistent improvements depending on the data sparsity. For example, in our sample test sentence, S\_NN condition

created the new token “iraqis\_kurdistan” which is not in the training data.

Dynamic integration helps solving this data sparsity issue by introducing a new feature that is weighted globally using all evidences belonging

to the same category to favor phrase pairs with unbroken MWE of that category. That’s why we see some improvements for NEs and NNs in addition to VAA.

MWE Scheme	MWE List	#Lemma Types	# Token Types	# Tokens	(Tokens/Types)
NN	MWE.N	8,075	10,503	329,116	31.33
VAA	MWE.V, MWE.AJ , MWE.AV	3,003	5,733	184,899	32.25

Table 4. BLEU,NIST, METEOR and TER scores of the different experimental conditions for NIST test sets MT04-NW, MT05 and MT08-NW\*<sup>4</sup>

<sup>4</sup> The gray highlighted cells indicate enhancement over Baseline. The Bold underlined score per column is the best score for that Testset/Metric. (Note: lower TER scores indicate better performance)

Zone integration is not helping (except non-significantly<sup>5</sup> for NEs on MT08-NW), this is due to the fact that marking MWEs as zones and enforcing decoder to respect these zones does not prevent the decoder from translating MWEs compositionally. While the decoder is not allowed to translate out of zone phrases unless it fully finishes translating the words in the zone, it is permissible to divide the zone into any combination of phrases and translate these phrases individually and in any order.

Following are the translation of our sample test sentence for selected conditions:

-Z VAA+NN:

gzw ErAqy krdstAn lm yEd shlA .

## 7 Conclusion

Our study indicates that, at least for our language pair, different MWE types require different integration methods in the SMT pipeline where the more flexible an MWE is, the more the dynamic the integration needs to be. Therefore, for NE and NN, dynamic integration yields the best results. While for VAA, which tend to be more rigid, we gain the most from static integration.

Our results strongly suggest that explicit modeling for MWE and their various types definitely impact SMT performance positively. This is important since the number of MWE (VAA+NN+NE) tokens in the text only amounts to a total of 5.3% of the data, even though in terms of type ratio, MWEs (VAA+NN+NE) account for 46% of the types (indicating that we see a lot of variability in type but with very low frequency), yet we see gains of up to 0.82 absolute BLEU points (for A\_VAA-D\_NE+NN MT05). We anticipate such effects to be even

more pronounced in other more nuanced data sets such as blogs and broadcast conversations where the use of MWEs is pervasive compared to Newswire.

For future work, we plan to extend our matching algorithm to account for syntactically flexible MWEs by allowing gaps within MWE. We also plan to enhance feature engineering of the dynamic integration by assigning each MWE type a dedicated feature in the model. Finally we plan to extend our study to different language pairs and for MWEs in both source and target languages.

## Abstract

In this paper we investigate the application of uncertainty detection to text watermarking, a problem where the aim is to produce individually identifiable copies of a source text via small manipulations to the text (e.g. synonym substitutions). As previous attempts showed, accurate paraphrasing is challenging in an open vocabulary setting, so we propose the use of the closed word class of uncertainty cues. We demonstrate that these words are promising for text watermarking as they can be accurately disambiguated (from the non-cue uses of the same words) and their substitution with other cues has marginal impact to the meaning of the text.

## 1 Introduction

The goal of digital watermarking is to hide digital information (a secret marker) in an audio stream, image or text file. These markers are by design not perceivable while listening, watching or reading the data, but can be read with a tailor-made algorithm and can be used to authenticate the data that carries it, or to identify its owner. We discuss the concept of a watermark and the process of embedding it in a media in more detail in Section 2. Text watermarking is a digital watermarking problem where the aim is to embed a secret message (a sequence of bits) in a *text* in order to make the actual text copy individually identifiable (Bergmair, 2007). That is, given a natural language source text (e.g. an ebook), the aim is to produce individual copies of the text by means of surface, syntactic or semantic manipulations. The individualized copies should preserve the readability and the meaning of the original text, i.e. the modifications should be undetectable to the readers.

The manipulation of the text can be performed

on the surface or the content level. Surface manipulation affects the visual appearance of the text, as in white space modulation. In contrast, syntactic reordering looks e.g. for conjunctions and reorders the connected words or phrases. Finally, semantic manipulation, such as *synonym substitution*, takes a target word and replaces it with a contextually plausible synonym. Consider the following examples:

He was *bright* and independent and proud.  
He was *bright* and independent and proud. (surface)  
He was independent and *bright* and proud. (syntactic)  
He was *clever* and independent and proud. (semantic)

In steganography, there is a natural tradeoff between capacity (the length of the secret message that can be embedded in a cover medium) and precision (how well the manipulations preserve readability and meaning). Text watermarking is a precision-oriented application as it requires very high transformation quality, and relatively low capacity (recall) is acceptable as the goal is to make a relatively small number of changes in a text. Surface manipulations are typically very easy to spot, so those are not realistic alternatives, while syntactic and semantic methods are equally viable. From a practical perspective, the most reliable method should be used to embed the secret information. E.g. enumeration reordering is a relatively robust method, provided we have a good parser at hand to detect the conjoined units. On the other hand, if there is a reference in the near context, it can be more reliable to employ synonym substitution:

He made offers to John and Mary. The latter *accepted*.  
He made offers to John and Mary. The latter *agreed*.

Here we investigate paraphrasing as a way to embed secret information in texts. An open vocabulary approach to synonym substitution could ensure rather high capacity. For example, Chang and Clark (2010b) suggest to identify one paraphrase position per sentence, thereby enabling the system to encode one bit per sentence, but they achieve

original bitmap	#	after embedding	#
1 1 1 0 0 0	1	1 1 1 0 0 0	1
1 1 1 1 0 1	1	1 1 1 0 0 1	0
1 0 1 0 0 1	1	1 0 1 1 0 1	0
1 1 0 0 0 1	1	1 1 0 0 0 1	1
1 0 0 0 0 1	0	1 0 0 0 0 1	0
0 0 0 0 1 1	0	0 0 0 0 1 1	0

Table 1: Example watermark.

this at the cost of relatively low precision (around 70% even when using the information about the correct word sense). In contrast, we propose to use a closed word class – i.e. uncertainty cues – for paraphrasing. Semantically uncertain propositions are common in natural language: they either directly express something as uncertain (epistemic modality); assert the speaker’s hypotheses, beliefs; express events that are unconfirmed or under investigation or conditional to other events, etc. These linguistic devices are lexical in nature, i.e. they are triggered by the use of specific keywords in the sentence, which we refer to as *uncertainty cues*. These words are good targets for paraphrasing since – when replaced by another uncertainty cue with similar properties (part of speech and meaning) – their substitution does not change the meaning of the sentence: the main proposition (“who does what, when and where”) remains the same and the proposition stays uncertain:

The legislative body *may* change.  
The legislative body *might* change.

That is, in our approach a classifier first detects uncertainty cues in a text. Then, those disambiguated cues that are both detected with high precision and have such paraphrases that are valid in all “uncertain” contexts can be replaced with their paraphrase. This manipulation affects the watermark bit contained in the passage and thus allows information encoding. The actual process is described in more detail in Section 2.1.

With this work, we show that a closed-class approach to generating paraphrases has desirable properties for watermarking: almost perfect substitution quality and acceptable embedding capacity. At the same time, we propose a novel application of uncertainty cue detection: paraphrasing of uncertainty cues for linguistic steganography.

## 2 Digital Watermarking

In this section we elaborate on what a watermark message is. In the simplest setup, we can define a watermark message as a sequence of  $k$  bits (0 or 1 values). Then the message then can take  $2^k$  different values, and can be used to identify the owner

of the medium, if each owner gets a copy of the data with a different digital message embedded in it. Take, for example, the problem of embedding a 6-bit message in a black-and-white bitmap image. In this case, we divide the bitmap to six equal-size parts and consider the parity of the sum of bits in a given part as the message bit. Table 1 shows a  $6 \times 6$  bitmap and the embedding of a 6-bit message (100100, one bit in each line). For a comprehensive overview of the different watermarking techniques, we refer the reader to Cox et al. (2008).

### 2.1 Natural Language Watermarking with Paraphrases

In order to encode a single bit in a larger block of text – like a paragraph or section – based on bit parity, we first assign a bit (0 or 1) to every word in the vocabulary, i.e. not just those that we plan to manipulate. Then, in each block of the source text, we sum the bits encoded by the original text and take its parity (*even* = 0, *odd* = 1) as the secret bit. In case our message should contain the other bit, we have to make exactly 1 synonym substitution, replacing a 0-word with a 1-word or vice versa to reverse the parity of the block, in order to embed the desired bit in the text. Reading the message only requires the same methodology to detect the blocks (sections) in the text and the initial word-to-bit mapping to calculate the parity of the blocks.

If we consider only a small set of words as candidates for substitution, this places a constraint on the system: it has to be ensured that the receiver can identify which blocks are used to actually encode information. This can be done, for example, if we use such blocks that contain at least one paraphrasable word after the potential manipulation: this way the reader can be sure the actual block encodes a bit (as there is capacity left in the block).

This simple parity-based message encoding approach offers straightforward ways to combine different embedding techniques, which is desirable: in order to combine conjunction reordering with the proposed paraphrasing method, one could use the (parity of the) number of changes in the conjoined list of items from their lexicographic order as the bit encoded in a conjunction, and can use that bit in the message encoding process. In our application scenario, we plan to implement several different text manipulation methods (and combine

them based on their confidence). Therefore the goal of this study is to propose an approach with high precision and coverage will be ensured by a range of syntactic methods and paraphrasing together.

### 3 Related Work

In this section we briefly introduce the previous work in *natural language watermarking* and in *uncertainty detection*.

The most prominent previous work in natural language watermarking (Atallah et al., 2003) focus on manipulating the sentence structure in order to realize meaning-preserving transformations of the text, which in turn can be used to embed information in the text. This approach either requires the presence of a robust syntactic (and semantic) parser to construct the representation which supports complex sentence-level transformations, or it has to be simplified to local transformations (e.g. conjunction modulation, as in the examples above) in order to ensure high precision without the requirement of deep linguistic analysis. Unfortunately, robust syntactic and semantic parsing of arbitrary texts is still challenging for natural language processing. This fact justifies the importance of more shallow models, such as synonym substitution, provided these approaches can ensure high precision and robust performance across domains. For a general and detailed overview of linguistic steganography, including methods other than paraphrasing, see for example Bennett (2004) and Topkara et al. (2005).

#### 3.1 Paraphrasing for Linguistic Steganography

As regards synonym substitution, the first studies made no use (Topkara et al., 2006) or just limited use (Bolshakov, 2005) of the context through collocation lists. While this approach offers a relatively high capacity, the transformations result in frequent semantic, or even grammatical, errors in the text, which is undesirable (Bennett, 2004).

Recently Chang and Clark (2010a,b) proposed the use of contextual paraphrases for linguistic steganography. This offers a higher perceived quality and is therefore more suited to text watermarking where quality is a crucial aspect. Chang and Clark (2010b) used the English Lexical Substitution data (McCarthy and Navigli, 2007) from SemEval 2007 for evaluation, WordNet as the

source of potential synonyms and n-gram frequencies for candidate ranking to experiment with paraphrasing for linguistic steganography. They introduced a graph coloring approach to embed information in a text through the substitution of words with their WordNet synonyms. They report an accuracy slightly above 70% for their paraphrasing technique and a potential capacity of around one bit per sentence.

Chang and Clark (2010a) used a paraphrase dictionary mined from parallel corpora using statistical machine translation (SMT) methods. The ranking of candidate paraphrases was also based on n-gram frequencies and for a set of 500 paraphrase examples they reported 100% precision (with very low, 4% recall) for substitution grammaticality. The possible change in meaning for otherwise grammatical replacements was not evaluated.

#### 3.2 Uncertainty Cue Detection

Another major field of work related to this study is the detection of uncertainty cues, which we propose to use for paraphrasing in Section 4. The first approaches to uncertainty detection were based on hand-crafted lexicons (Light et al., 2004; Saurí, 2008). In particular, ConText (Chapman et al., 2007) used lexicons and regular expressions not only to detect cues, but also to recognize contexts where a cue word does not imply uncertainty.

Supervised uncertainty cue detectors have also been developed using either token classification (Morante and Daelemans, 2009) or sequence labeling approaches (Tang et al., 2010). A good overview and comparison of different statistical approaches is given in Farkas et al. (2010). Szarvas et al. (2012) addressed uncertainty cue detection in a multi-domain setting, using surface-level, part-of-speech and chunk-level features and sequence labeling (CRF) models. They found that cue words can be accurately detected in texts with various topics and stylistic properties. We make use of the multidomain corpora presented in their study and evaluate a cross-domain cue detection model for text watermarking.

### 4 Uncertainty Cue Detection for Text Watermarking

In this section we experiment with uncertainty cue detection and paraphrasing, and study the potential of this approach for text watermarking.

## 4.1 Dataset, Experimental Setup and Evaluation Measures

We used here the dataset introduced by Szarvas et al. (2012). It consists of texts from three different domains (articles from Wikipedia, newspaper articles and biological scientific texts) and is annotated for uncertainty cues. The uncertainty cues in the corpora are marked only in contexts where they are used in an uncertain meaning, i.e. these texts can be used to train a shallow (*cue* vs. *non-cue* meaning) disambiguation model for these phrases. Here we aim to paraphrase the *cue* uses of the words to encode information via cue-to-cue paraphrasing. We train and test our models on separate parts of the corpora: for example, to assess the accuracy of cue detection in Wikipedia texts, we train the model only on newswire and scientific texts, and so on. This is a cross-domain evaluation setting and is therefore a good estimate of how the system would perform on further, yet different text types from our training datasets.

For evaluation, we use the overall precision of the recognized uncertainty cues, and we also measure the capacity that can be achieved by paraphrasing these words, i.e. how frequently one of these words that we use to encode information actually occurs in a text (the number of detected objects divided by the number of sentences processed). These two criteria – precision and capacity – measure how well the uncertainty detector would perform as a stego system. In addition, we also perform an error analysis of the top-ranked instances that received the highest posterior probability scores by the classifier. The highest-ranked instances are especially important as the underlying application would chose the highest-ranked instance in a larger block of text to actually implement a change to the text.

## 4.2 Uncertainty Detection Model

We implemented a cue recognition model similar to that described in Szarvas et al. (2012), using simple features that are robust across various text types. This is important, as we plan to use the model for text types that can be different from those in the training corpus, and for which NLP modules such as parsers might have questionable performance.

Conditional Random Fields were found to provide the best overall results in cue detection. However, the relative advantage of sequence taggers

corpus	# sent.	# cues	precision	capacity	F(cue)
Wiki	20756	3438	69.69%	16.56%	71.28%
news	3123	522	84.48%	16.71%	70.33%
sci	19473	3515	91.58%	18.05%	70.92%

Table 2: Summary of cue recognition results.

over simple token-based classifiers is more prominent for less frequent, long cue phrases<sup>1</sup>. Since in this study we concentrate on the more simple and frequent unigram cues (or fixed constructions, such as *not clear*), we use a Maximum Entropy (Maxent) classifier model (McCallum, 2002) in our experiments for cue detection and disambiguation.

In our classification setup, each token is a separate instance, described by a set of features collected from a window of size 2 around the token. That is, each feature can be present under 5 different names, according to their relative position, except for sentence beginning and ending tokens (out-of-sentence positions are discarded). We used the following features to describe each token: i) lexical features (word base forms and word bigrams); ii) 3 to 5 characters long word prefixes and suffixes; iii) word-surface-level features denoting whether the word is written in all uppercase, uppercase initial, or lowercase form, it is a punctuation mark or number; and iv) part of speech tags.

## 4.3 Results

The results of the cross-domain cue recognition experiments are summarized in Table 2. The columns indicate the total number number of sentences and recognized cues in the corpora, their precision and the capacity that can be achieved via cue paraphrasing. For comparison to previous works, we also provide the overall phrase-level F score for uncertainty cues. These numbers are slightly better than those reported by Szarvas et al. (2012) for cross-training with CRFs, probably due to the different settings (we used two domains for training, not just one).

As can be seen, the uncertainty cue recognizer is accurate even in a challenging cross-training setting: the precision is well above 80% for two out of three domains, and is around 70% for the most difficult Wikipedia dataset. This precision could realize a capacity of one bit per every six sentences, on average (capacity at or above 16%). In

<sup>1</sup>We performed an initial experiment using token-based and sequential models on our corpora and found no statistically significant difference in performance on unigram cues.

corpus	# sent.	# cues	precision	capacity
Wiki	20756	1869	89.46%	9.00%
news	3123	223	93.72%	7.14%
sci	19473	2688	98.95%	13.80%

Table 4: Summary of results with the 29 selected keywords.

order to use this cue recognizer as a watermarking method with the above-mentioned precision and capacity, we should provide a valid paraphrase for all of the 300 uncertainty cues found in the corpora. Doing that, a precision of 70% or more is promising in the light of the precision values below 50% for the first answers at SemEval 2007 for an all-words substitution task (Yuret, 2007), and of the fact that this precision stays around 70% even if the correct sense is picked in advance based on the human answers (Chang and Clark, 2010b).

On the other hand, as we argued in Section 2.1, it is desirable to improve precision at the cost of capacity. Thus, we filtered the uncertain vocabulary for such cues that are both frequent and accurate: we kept the cues that had a frequency of at least 10, with a precision above 80%. This left us 37 cues in total and this list was given to two annotators to provide paraphrases. The annotators were told to perform a web search for various contexts of the words and suggest paraphrases that are acceptable in all the words’ uncertainty-cue-uses and contexts. The two annotators agreed on a unique paraphrase which fits in all uncertain contexts of the target words for only 29 cues. These words with the proposed paraphrases and examples from the Wikipedia corpus are listed in Table 3. The columns indicate the selected cue words with their part of speech and the proposed paraphrase cue (or *XX* where we could not provide a suitable paraphrase). As can be seen, each cue is paraphrased with another cue with the same part of speech. Thus, their inflected forms can be generated based on the original words’ POS tags. For the remaining eight cues the annotators either did not find a proper substitute (e.g. *belief*) or found the word to have several uncertain readings which would require different paraphrases in different contexts (e.g. *expect* which can be rephrased as *wait*, *hope*, *count on*, ...).

Table 4 provides aggregate numbers for the selected 29 cue words. The columns indicate the total number of sentences in the corpora, the number of recognized instances of the 29 se-

lected cues and their precision and capacity. As can be seen, for these words the classifier yielded excellent precision scores, even with cross-domain training. In scientific and newswire texts, the model performs well above 90% precision, while in Wikipedia texts the precision is slightly lower.

As regards the capacity of the selected cues in the texts, on average we can find one instance of the selected cue words in every 7–14 sentences. The above precision and capacity scores can be realized in an actual watermarking method with the use of the paraphrases in Table 3. While this coverage seems lower than some other approaches (e.g. Chang and Clark (2010b) can achieve approximately one bit per sentence capacity), it is still acceptable for text watermarking of lengthy documents (such as ebooks), and as mentioned earlier, different methods can be combined to increase capacity. In the light of this, we consider our results especially promising, due to the remarkable precision scores, and the positive characteristic that these changes do not affect the main propositions in the sentences, i.e. meaning is well preserved.

Although direct comparisons are difficult to make, Chang and Clark (2010a) evaluated how accurately their model predicted a paraphrase to be grammatical, which is similar to our goal here. Their model achieved similar precision levels with similar or slightly lower potential capacity scores. Other previous approaches reported substantially lower precision (typically aiming to achieve high recall). These results suggest that our methodology, making a change in 7–14% of the sentences with a precision of 90–98% is a very competitive alternative for precision-oriented linguistic steganography.

#### 4.4 Error Analysis

The proposed method can embed information in a cover text with remarkably high precision, as the applied changes to the text are perfectly grammatical and do not affect the main aspects of the meaning of the text. Our error analysis also confirms this (see Appendix). We checked the 250 top-ranked classifications in the Wikipedia and scientific text corpora, and 223 classifications in the newswire texts (the total number of detected instances of the 29 selected cues). We checked the errors in the instances that obtained the highest posterior scores because in a larger block the sys-

WORD	POS	SUBST.	Example

view (that)	N	opinion (that)	... that undermined their capacity to accept the <b>view</b> that socialist incentives would not work
whether	IN	if	... or <b>whether</b> his paintings were purchased by Italians.

Table 3: Uncertain paraphrase dictionary with examples from the Wikipedia corpus.

tem would select the most confident position to perform a substitution, so precision at top ranks is the most important. We found 20 false positive classifications in these 723 sentences, attributed to eight different keywords. This is above 97% precision at top ranks, the errors are detailed in the appendix, together with example sentences. As can be seen, many of these misclassifications actually do not do any major harm to the meaning of the text: some of these high-ranked examples are actually replaceable with the proposed cover words even in a non-cue usage (this is the reason for their high posterior score).

## Conclusion and Future Work

In this paper we proposed uncertainty cue detection and the paraphrasing of uncertainty cues as a new approach to linguistic steganography. We experimented with texts from three different domains using cue detection models trained on out-of-domain texts in order to simulate a realistic application scenario. We found that uncertainty cues are capable of embedding a 1-bit message in a block of text of around 10–13 sentences on average. Although this capacity is limited, in turn the use of uncertainty cues offers nearly perfect

precision, i.e. the manipulated texts are grammatical and preserve the original text’s meaning. As in text watermarking the goal is to embed a relatively short message in potentially large texts, but with high precision (quality), the paraphrasing of uncertainty cues is a promising alternative.

Arguably, the ideal setting from an application perspective would be an open-vocabulary substitution system, but such an approach suffers from significant limitations stemming from the difficulty of paraphrasing in a general setting. An alternative could be to use a larger set of frequent words in a lexicalized approach for lexical substitution which might offer higher capacity with comparable precision Biemann and Nygaard (2010).

On the other hand, we think it is a viable approach to target the extra-propositional aspects of meaning (such as uncertainty proposed here) for lexical substitution in linguistic steganography. This – by definition – leaves the main proposition of the sentence (*who does what, when and where*) untouched, ensuring high transparency. To this end, we also plan to extend the capacity of this approach via paraphrasing other word classes such as opinion expressions (e.g. *great X* for *excellent X*, *awful X* for *terrible X*).

jia.zhongye@gmail.com, zhaohai@cs.sjtu.edu.cn

## Abstract

Chinese Input Method Engine (IME) plays an important role in Chinese language processing. However, it has been subjected to lacking a proper evaluation metric for a long time. The natural metric for IME is user experience, which is a rather vague goal for research purpose. We propose a novel approach of quantifying user experience by using keystroke count and then correspondingly develop a framework of IME evaluation, which is fast and accurate. With the underlying linguistic background, the proposed evaluation framework can properly model the user behavior as Chinese is input through English keyboard. It is helpful to point out a way to improve the current Chinese IME performance.<sup>1</sup>

## 1 Introduction

Chinese IME is a software solution that enables user to input Chinese into computer with a reasonable size keyboard, by mapping Chinese characters into English letter combinations. Nowadays the majority of Chinese IMEs are pinyin based. Pinyin is originally designed as the phonetic symbol of a Chinese character, using Latin letters as its syllable notation. For example, the pinyin of the Chinese character “爱”(love) is “ài”.<sup>2</sup> There are only less

than 500 pinyin syllables in standard modern Chinese, compared with over 6,000 commonly used Chinese characters, which leads to serious ambiguity for pinyin-to-character mapping. Other IMEs using various mapping scheme more or less share this same ambiguity problem, although some of them such as five-stroke IME<sup>3</sup>, may have lower ambiguity but they are very difficult to learn. So at present pinyin IMEs are the most popular, we focus on them in this paper. Modern IMEs are *sentence-based* (Chen and Lee, 2000) to reduce the ambiguity, which means that the IME generates a character sequence upon a sequence of English letter inputs, e.g. pinyin syllables. This is a non-typical sequence labeling task, as English alphabet input is the original sequence and Chinese characters are target labels. IMEs usually utilize beam search incorporated with language model initialized by (Chen and Lee, 2000), then later extended by (Liu and Wang, 2002), (Lee, 2003), and (Zhang, 2007). There are also various methods using conventional sequence labeling techniques such as: support vector machine (Jiang et al., 2007), maximum entropy model (Wang et al., 2006), conditional random field model (Li et al., 2009) and machine translation (Yang et al., 2012a), etc. IME also attracts attention from major software and internet corporations, Microsoft<sup>4</sup>, Google<sup>5</sup> and many others developed their own IME products.

Note that “sentence” from an IME’s viewpoint is not the linguistic “sentence”. It is actually the *Max Input Unit* (MIU), the longest consecutive Chinese character sequence inside a sentence. For example, the sentence “第51届ACL年会即将召开” (The 51st annual meeting of ACL will open soon)

\*This work was partially supported by the National Natural Science Foundation of China (Grant No.60903119, Grant No.61170114, and Grant No.61272248), and the National Basic Research Program of China (Grant No.2009CB320901 and Grant No.2013CB329401).

<sup>†</sup>Corresponding author

<sup>1</sup>KySS is the abbreviation for: **KeyStroke Score**

<sup>2</sup>Chinese is a language with tone, but for nearly all pinyin IMEs, tone marks are omitted since it is inconvenient to input.

<sup>3</sup><http://www.wangma.com.cn/>

<sup>4</sup><http://bing.msn.cn/pinyin/>

<sup>5</sup><http://www.google.com/intl/zh-CN/ime/pinyin/>

has 3 MIUs: “第”, “届” and “年会即将召开”. For more precise expression, we will use “MIU” or “character sequence” throughout this paper as far as possible, instead of “sentence”.

Chinese is used by the largest population in the world, and IME is necessary for all Chinese computer users. However according to our best knowledge there are no comprehensive and quantified metrics for evaluating its performance. The existing evaluation metrics for IME (Chen and Lee, 2000; Yang et al., 2012a) only focus on the character sequence generation, by adopting typical sequence labeling measurements such as character-wise precision and recall, sequence error rate and so on. However IME is an application deeply involving human-computer interaction, user behavior ought to be taken into account for IME evaluation (Zheng et al., 2011). Rather than merely judging the performance of character sequence generation, a good IME evaluation system should properly model the user behavior.

Compared with other typical evaluation systems for NLP tasks, such as the well known machine translation evaluation system BLEU (Papineni et al., 2002) and the summarization evaluation system ROUGE (Lin, 2004), they measure the closeness of machine translation/summarization and human results, using some  $n$ -gram co-occurrence statistics (Lin and Hovy, 2003), while our IME evaluation framework tries to quantify user experience during inputting Chinese. Existing keystroke based methods mostly focus on the keystroke duration and frequency pattern for biometric authenticate system security (Giot et al., 2009; El-Abed et al., 2012), instead of user experience modeling.

## 2 The Evaluation System

### 2.1 The User-IME Interaction

As introduced in Section 1, nearly all IMEs nowadays are “sentence based”. However, IME does not always succeed to exactly generate the entire expected character sequence for an input letter sequence. Thus IMEs output a list of all possible *candidate* character sequences corresponding to the input sequence.

Suppose that the input pinyin sequence is  $S_1S_2\dots S_n$  where  $S_i$  is a pinyin syllable with index  $i$  and  $n$  is number of pinyin syllables. The *best character sequence* has the same length as the input pinyin sequence, and is always in the first position of the list. Other output character sequences in

the candidate list is given according to  $S_1S_2\dots S_{n'}$  where  $n'$  is usually less than  $n$ . As  $n$  is usually large, it is unlikely that the best character sequence is completely correct, but for those shorter character sequences in the candidate list, user can always find that one of them may partially match his/her input target. If user has selected a candidate from the list to partially complete the input, for example, the character sequence for  $S_1S_2\dots S_j$  has been determined by this selection, then IME will dynamically output a new list of character sequences for the rest pinyin sequence  $S_{j+1}S_{j+2}\dots S_n$ . User can continue to make the selection from the list until the desired input is accomplished. For a candidate, we define its position in candidate list as its *rank*,  $r$ . The best character sequence has  $r = 0$ . The candidate at the  $j$ -th position in the list has  $r = j - 1$ .

There are often dozens of candidates for a pinyin sequence, as the space of input interface is limited, candidates have to be shown in multiple pages. A *page* is part of the candidate list. User can make the choice from the page by pressing candidate ID  $1, 2, \dots, m$  in the current page. If the expected word/character does not occur in the current page, user has to press a “next-page”<sup>6</sup> key to see more candidates.

Suppose that one wants to input the MIU “年会即将召开”(The annual meeting will open soon) by typing the pinyin sequence “nian hui ji jiang zhao kai”, a typical IME prompt window is like Figure 1a.

As shown in Figure 1a, the best character sequence is not completely correct for the input purpose. User has to pick up the 2nd candidate “年会”(annual meeting). Then the IME will update the window as Figure 1b. User can select the 3rd candidate “即将”(soon). The IME will update for the rest as shown in Figure 1c. The first candidate exactly completes the expected character sequence.

In the real world, user behavior is very difficult to predict. In order to alleviate the difficulty of user behavior modeling, an abstract assumption for user-IME interaction is proposed: all user input actions are only restricted to pinyin sequence input, candidate ID selection and page turning. In this manner, user inputs a sequence of pinyin then make a choice from the candidate list in the current page given by the IME, if the desired character se-

<sup>6</sup>Usually this “next-page” key is not the PageDown key, but mapped to some more convenient keys such as “+” or “.”.

nian hui ji jiang zhao kai	年会 ji jiang zhao kai	年会即将 zhao kai
1.年会激将召开	1.激将召开	1.召开
2.年会	2.激将	2.找
3.年	3.即将	3.赵
4.念	4.即	4.照
5.粘	5.及	5.招

Figure 1: IME windows for inputting an MIU

quence is not presented in the current page, then user has to press “next-page” and goes on until the target is met.

Under this proposed user behavior model, user input is divided in to two parts: 1. a sequence of alphabet keys for pinyin and 2. a selection action sequence of “next-page” and candidate ID keys. The first part of inputting alphabet keys for different IMEs will be always the same, thus it can be ignored for evaluation metric. The second part would be the essential difference among different IMEs. We define the sequence of ranks of candidates as *Rank Sequence*, For an ideal rank sequence, it is always just  $\{0\}$ . For our previous example in this section, the actual rank sequence is  $\{1, 2, 0\}$ .

## 2.2 Evaluating IME

To make use of the rank sequence, i.e. keystroke count, as the metric to evaluate an IME, we define a few terms as follows:

- $\mathcal{L}$ : It is the length of MIU in characters.
- $\mathcal{P}$ : It is the length of rank sequence. It measures how many parts the MIU is split into to accomplish the input. In the previous example,  $\mathcal{P} = 3$  for “年会”, “即将” and “召开”. In the ideal situation,  $\mathcal{P}$  for any MIU is 1 since the exactly expected character sequence is rank at the top.
- $\mathcal{R}$ : It is the sum of all the elements in the rank sequence, i.e. the sum of ranks of candidates for each part. In our previous example,  $\mathcal{R} = 1 + 2 + 0 = 3$ . For the ideal situation,  $\mathcal{R}$  is always 0.
- $\mathcal{R}_W$ : It is the total keystroke without alphabet keys, by using the weighted sum of rank sequence:

$$\mathcal{R}_W = \sum_{i=1}^{k-1} \omega(r_i) + 1. \quad (1)$$

The weight function  $\omega(\cdot)$  reflects the cost of pressing “next-page” and candidate ID keys.

In the rest of this paper we will assume there are 5 candidates on each page which is the default setting for most existing IMEs. We also assume the keystroke cost of pressing numeric keys for candidate ID is 1 and the keystroke cost of pressing “next-page” is also 1, then the weight function is

$$\omega(r) = \lfloor \frac{r}{5} \rfloor + 1.$$

For example the 1st candidate on 3rd page has  $\mathcal{R}_W = 1 \times 2 + 1 = 3$ .  $\mathcal{R}_W$  measures how many keys the user has to press i.e. how much effort the user has to make to accomplish inputting an MIU.

- **KySS**: It is the final evaluation score of an IME. Consider an evaluation corpus  $\mathbb{C}$  with MIUs  $\{m_1, m_2, \dots, m_c\}$ , for a certain IME, the  $i$ -th MIU  $m_i$  has  $\mathcal{R}_W(i)$ , then the KySS score for the actual IME on the corpus is defined as the ratio between the total  $\mathcal{R}_W$  for the ideal IME and the total  $\mathcal{R}_W$  given by the actual IME:

$$\text{KySS} = \frac{\sum_{m_i \in \mathbb{C}} \mathcal{R}_W^{\text{ideal}}(i)}{\sum_{m_i \in \mathbb{C}} \mathcal{R}_W(i)} \quad (2)$$

$$= \frac{\|\mathbb{C}\|}{\sum_{m_i \in \mathbb{C}} \mathcal{R}_W(i)}. \quad (3)$$

For an ideal IME, we have  $\text{KySS} = 1$ . For actual IMEs,  $0 < \text{KySS} < 1$ . An IME with higher KySS is supposed to perform better.

## 3 Analysis on IMEs

### 3.1 Corpus

To build a corpus for evaluation, we extract 100,000 sentences from *China Daily* corpus<sup>7</sup>. We annotate it with pinyin sequence using the method in (Yang et al., 2012b). The corpus contains over 4 million characters, 87.6% of which are Chinese

<sup>7</sup>[http://www.icl.pku.edu.cn/icl\\_res/default\\_en.asp](http://www.icl.pku.edu.cn/icl_res/default_en.asp)

characters, other 12.4% are foreign letters, digits and punctuation. At last, a corpus with over 420,000 MIUs is built.

The IME for evaluation is sunpinyin<sup>8</sup> which is the state-of-the-art open-source Chinese pinyin IME on Linux developed by the former *Sun Microsystems, Inc.*

The distribution of  $\mathcal{L}$  for the evaluation corpus is shown in Figure 2. It can be seen that the length of

Figure 2: Distribution of  $\mathcal{L}$

Figure 3: Linear fit on log-frequency over  $\mathcal{L}$

MIUs roughly follows an exponential function distribution in statistics. A linear regression on log-frequency is made and it fits the actual data well. The result is shown in Figure 3.

<sup>8</sup><http://code.google.com/p/sunpinyin/>

Figure 4: Cumulative distribution of  $\mathcal{L}$

Figure 5: Rate of successful MIU generation

Although there are very long MIUs in the corpus, it can be observed from the cumulative distribution of  $\mathcal{L}$  in Figure 4 that most MIUs are short ones.

Paying so much attention to the length statistics of MIUs is necessary, because the core task of IME, character sequence generation, is heavily affected by the sequence length. The rate of successful character sequence generation decays linearly with the increment of  $\mathcal{L}$  as shown in Figure 5.

It also can be seen from Figure 4 that nearly 50% of MIUs are between 7 and 26 characters long, but as shown in Figure 5 they suffer from the rate of successful character sequence generation less than 0.5, which will be our major concern later.

### 3.2 Position Matters: How Character Sequence Generation Fails

From our empirical observation over those cases in which IME fails to generate the completely correct MIU, we found something interesting. The histograms of  $\mathcal{P}$  and  $\mathcal{R}$  of MIUs with  $\mathcal{L} = 10$  are shown in Figure 6, note that only unsuccessful results are plotted in the figure.

The interesting point is that a peak appears at  $\mathcal{L}/2$  in the histograms, as is shown in dotted lines in Figure 6. All the cases that we observed with length ranging from 7 to 26 demonstrate this “error peak” property.

We extract MIUs, IME generated best character sequences and rank sequences of those cases. The underlying reason is discovered after a manual inspection: in those best character sequences, the last error is at the rear of MIU. In such cases user has to select candidate words one by one until the end of the MIU.

For example, while inputting the MIU “大理 航空是个年轻的航空”(Dali airport is a new airport), the best character sequence generated by IME is “大力航展是个年轻的航展”(STRONG air show is a new air show). Its  $\mathcal{L} = 11$ . The selected candidates are: “大理”(Dali), “航空”(airport), “是个”(is), “年轻”(new), “的”(meaningless function word), and “航空”; so  $\mathcal{P} = 6$ . And the rank sequence is  $\{2, 1, 1, 1, 1, 1\}$  so  $\mathcal{R} = 7$ . So when errors occur at the rear of MIU, we have  $\mathcal{P} \approx \mathcal{N}_W$ , where  $\mathcal{N}_W$  is the number of words in MIU. For most of the real circumstances, those correctly generated words in the front part of MIU achieve a very high rank  $r$ , often the highest among candidates, i.e.,  $r = 1$  so  $\mathcal{R} \approx \mathcal{P} \approx \mathcal{N}_W$ . In sunpinyin, candidates except for the best character sequence are words queried from an internal dictionary. An important linguistic issue is that average length of Chinese words is about 1.8 characters, nearly two character long (Zhao et al., 2006). At last we obtain  $\mathcal{N}_W \approx \mathcal{L}/2$ , which explains the “error peak” at the middle position.

### 3.3 Improving IMEs with Evaluation Results

We propose a method to make use of the “error peak” for better IME performance. Among all those MIUs with the “error peak” problem, we can see an annoying situation is that all words except for the last few ones are successfully generated. In order to correct one or two words, user has to select word by word all the way through the character se-

quence. To avoid unnecessary selection, the IME can cut the front part of the generated character sequence and make it an independent candidate so that user can accomplish inputting as many words in one selection as possible. We suggest five cutting policies as the following:

- **Weakest**: Cut at the position where the conditional probability is smallest.
- **Mean, LtoR**: Cut at the position where the probability is lower than the mean of conditional probabilities of the sequence, scanning from left to right.
- **Mean, RtoL**: Similar as previous but scanning from right to left.
- **Halfway**: Cut at exactly at the middle position.
- **Fixed**: Cut a fixed length sequence. We experiment on length from 1 to 10 and found the best length is 3.

The KySS for each policy is shown in Table 1. The baseline is the original algorithm used by sun-

Policy	KySS
Baseline	27.67%
Weakest	29.41%
Mean, LtoR	29.21%
Mean, RtoL	29.06%
Halfway	30.71%
Fixed-3	31.30%

Table 1: KySS of each policy

pinyin without any cutting. To our surprise, the dummy **Fixed-3** and **Halfway** cutting performs best with a more than 10% boost over the baseline due to its robustness. The **Fixed-3** and **Halfway** policy can always stably cut out a reasonable length of MIU. The problem with **Mean, RtoL** is that it is likely to cut at the end of MIU thus the head that it cuts out may still include errors. On the contrast, the **Mean, LtoR** policy tends to cut out too few words. And the **Weakest** policy is easy to fail because it often cuts a sequence with a low conditional probability but actually being correct.

## 4 Conclusion and Future Work

In this paper, a novel evaluation framework for Chinese IME, KySS, is proposed by effectively modeling user behavior during Chinese input. This evaluation framework aims to fast and accurately evaluate various IMEs from the view of user experience. It uses keystroke count as core metric.

(a) Histogram of  $\mathcal{P}$

(b) Histogram of  $\mathcal{R}$

Figure 6: Histogram of  $\mathcal{P}$  and  $\mathcal{R}$ , with  $\mathcal{L} = 10$

With the help of the framework we preliminarily propose a sequence cutting strategy to enhance the current IME.

The real world IME and user behavior can be very complicated. In this paper, we make a simplified assumption that all user input is correct. Unfortunately it may contain typos. And the IME may have prediction feature, i.e. generating character sequence longer than the input pinyin sequence. We may include those in our future work.

## Abstract

In this paper we present results for two tasks: *social event detection* and *social network extraction* from a literary text, *Alice in Wonderland*. For the first task, our system trained on a news corpus using tree kernels and support vector machines beats the baseline systems by a statistically significant margin. Using this system we extract a social network from *Alice in Wonderland*. We show that while we achieve an F-measure of about 61% on social event detection, our extracted un-weighted network is not statistically distinguishable from the un-weighted gold network according to popularly used network measures.

## 1 Introduction

Social network analysis affects a wide range of academic disciplines and practical applications: psychology (Seidman, 1985; Koehly and Shivy, 1998), anthropology (Sanjek, 1974; Johnson, 1994; Hage and Harary, 1983), political science (Knoke, 1990; Brandes et al., 2001), literary theory (Moretti, 2005), management (Tichy et al., 1979; Cross et al., 2001; Borgatti and Cross, 2003), and crime prevention and intelligence (Sparrow, 1991). In the past, social networks were constructed through interviews, surveys and experiments. With the advent of the internet and online social networks, researchers have started constructing networks using meta-data that reflects interactions, such as self-declared friendship linkages, sender-receiver email linkages, comments on a common blog-post, etc. However, these methodologies of creating social networks ignore a vastly rich network expressed in the unstructured text of such sources. Moreover, many rich sources of social networks remain

untouched simply because there is no meta-data associated with them (literary texts, news stories, historical texts). There have been recent efforts to extract social networks from text by mining interactions between people expressed linguistically in unstructured text (Elson et al., 2010; He et al., 2013). However, these approaches are restricted to extracting interactions signaled by quoted speech.

In this paper, we present results for extracting a social network from *Alice in Wonderland* that is not restricted to interactions signaled by quoted speech. We define a social network for a fictional text as follows: nodes are characters and links are *social events*. Two nodes in the network are connected if the characters engage in a social event. We introduced the notion of *social events* in our previous work (Agarwal et al., 2010), in which we presented our annotation scheme for annotating social events on the Automatic Content Extraction (ACE-2005) corpus. We presented a preliminary system for social event detection and classification in Agarwal and Rambow (2010). This system was trained and tested only on the ACE-2005 corpus. A priori, it is unclear if a system trained on a news corpus will be able to extract a high quality social network from a text from a very different genre (literary fiction). There are many syntactic and lexical differences between these genres. For example, news corpora have almost no questions, very little dialog presented as direct speech, and very little use of the first and second person pronouns. The vocabulary in literature can also be very different (relating to, say, whaling, passion, or teenage angst rather than current events). In this paper, we make two novel contributions. First, in an intrinsic evaluation, we show that our system without any domain (or genre) adaptation performs reasonably well on a new genre. Second, in an extrinsic evaluation, we show that the social network that our system extracts is not statistically distinguishable from the underlying gold network

in terms of various standard and popularly used network analysis metrics.

The paper is structured as follows: In section 2 we describe our notion of social events and the annotated data we use for training and testing in our experiments. In section 3, we briefly describe the tree kernel structures used by our system to detect social events in text. Section 4 presents the social network analysis metrics we use to evaluate the quality of the predicted network. In section 5, we present the experiments and results. We discuss some related work in section 6 and conclude in section 7 and mention future directions of research.

## 2 Social Events and Data

In Agarwal et al. (2010), we defined a **social event** as an event in which two people *interact* such that for at least one person, the interaction is **deliberate** or **conscious**. Put differently, at least one person must be aware of the interaction.

[Toujan Faisal], 54, {said} [she] was {informed} of the refusal by an [Interior Ministry committee] overseeing election preparations.

In the above example, the people (or groups of people) involved in social events are *Toujan Faisal* and the *Interior Ministry committee*. There are two social events in this example: one described by the word *said*, in which *Toujan Faisal* is *talking about* the committee, and the other described by the word *informed*, in which *Toujan Faisal* presumably has a mutual interaction with the committee.

We annotated two corpora for social events: 1) The Automatic Content Extraction (ACE) data-set<sup>1</sup> (Agarwal et al., 2010) and 2) the *Alice in Wonderland* data-set<sup>2</sup> (Agarwal et al., 2012).

For each pair of entity mentions in a sentence, if the annotators annotate a social event, we count this as a positive example for the task of social event detection. If no social event is annotated between a pair of entity mentions, we count this as a negative example. Note that we only consider pairs of entity mentions that correspond to different entities; our annotation scheme disregards self-interactions (talking to oneself).

<sup>1</sup>Version: 6.0, Catalog number: LDC2005E18

<sup>2</sup><http://www.gutenberg.org/ebooks/19551>

We use all of ACE data for training and refer to this data-set as **ACE-train**. We use all of *Alice in Wonderland* data for testing and refer to this data-set as **Alice-test**. The distribution of these data-sets is presented in Table 1.

Data-set	# of social events	# of No-event
ACE-train	396	1,101
Alice-test	81	128

Table 1: The distribution of social events in the training and test sets used for experiments

## 3 SINNET: Social Interaction Network Extractor from Text

In Agarwal and Rambow (2010), we presented a preliminary system that extracts social events from news articles. We used Support Vector Machines (SVM) in conjunction with tree kernels for detecting social events between pairs of entities, called target entities, that co-occur in a sentence. Following is a brief description of the tree structures that we used for building our models. We used the Stanford parser’s (Klein and Manning, 2003) phrase structure and dependency tree representations. Of the following tree structures, 1-3 have previously been proposed by Nguyen et al. (2009) for the relation extraction task, while we introduced the fourth structure in Agarwal and Rambow (2010) for social event detection task.

1. PET: This refers to the smallest phrase structure tree that contains the two target entities.
2. Grammatical Relation (GR) tree: This refers to the smallest dependency tree that contains the two target entities. We replace the words (in the nodes of the tree) with their corresponding grammatical roles. For example, in Figure 1, if we replace *Toujan Faisal* by *nsubj*, *54* by *appos*, *she* by *nsubjpass* and so on, we will get a GR tree.
3. Grammatical Relation Word (GRW) tree: We get this tree by adding the grammatical relations as separate nodes between a node and its parent. For example, in Figure 1, if we add *nsubj* as a node between *T1-Individual* and *Toujan Faisal*, add *appos* as a node between *54* and *Toujan Faisal*, and so on, we will get a GRW tree.

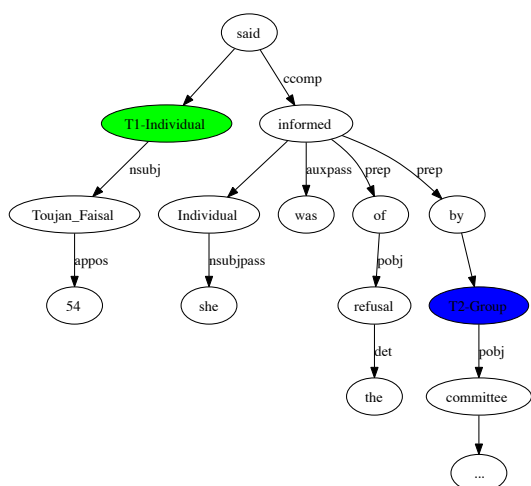

Figure 1: Dependency parse tree for the sentence (in the ACE corpus): *[Toujan Faisal], 54, said [she] was informed of the refusal by an [Interior Ministry committee] overseeing election preparations.*

4. Sequence in GRW tree (SqGRW): This is the sequence of nodes from one target to the other in the GRW tree. For example, in Figure 1, this would be *Toujan\_Faisal nsubj T1-Individual said ccomp informed prep by T2-Group pobj committee*.

We also use combinations of the aforementioned structures. For example, PET\_GR\_SqGRW refers to a kernel that considers a linear combination of three structures (PET, GR and SqGRW) for calculating similarities between examples. We use the Partial Tree kernel, first proposed by Moschitti (2006a), to calculate similarities between these tree structures.

In this paper, we use a Bag of Words Model (BOW) as a baseline. In the BOW model, each sentence is represented as a vector of three feature spaces. The first feature space encodes the presence and absence of words between the start of sentence and the start of the first target entity mention. The second feature space encodes the presence and absence of words between the end of the first target entity mention and the start of the second target entity mention. The third feature space encodes the presence and absence of words between the end of the second target entity mention and the end of the sentence. This feature space has previously been used by GuoDong et

al. (2005) for the relation extraction task on ACE. We use stemming and remove stop words from our feature space.

## 4 Social Network Analysis Metrics

In this section we briefly discuss some of the most popular social network analysis (SNA) metrics used by researchers to mine information from networks. We evaluate the social network extracted by our system with the gold network using these metrics. At a broad level, SNA researchers are interested in measuring importance of nodes in the network and in finding community structures in the network. To measure the importance of nodes, they use the notion of centrality. Following are the centrality measures that are often used in the literature (Freeman, 1979):

1. **Degree centrality** of a node in the network measures the number of incoming and outgoing links from the node. Degree centrality is viewed as an index of a node's *communication activity*.
2. **Betweenness centrality** of a node in the network measures the frequency with which a point falls between pairs of other nodes on the shortest paths connecting them. Nodes with high betweenness centrality are strategically located on the communication paths linking pairs of others, thus having the potential of influencing the group by withholding or distorting information (Bavelas, 1948; Shaw, 1954; Shimbel, 1953).

Another aspect of social networks that SNA researchers are interested in has to do with finding communities in the network and structural properties of networks. Following are some basic metrics used for this task:

1. **Graph density**: The density of a graph is the ratio of the number of edges to the number of possible edges. This measures how close the network is to being complete.
2. **Connected components**: a connected component of an undirected graph is a subgraph in which any two vertices are connected to each other by some path. The number of connected components is an indication of the overall connectivity of the network.

3. **Triads:** A triad is a set of three parties connected pair-wise to each other. In his seminal work, Simmel (1950) argued that triads are a fundamental unit of sociological analysis. He argued that three actors in a triad may allow qualitatively different social dynamics that cannot be reduced to individuals or dyads.

## 5 Experiments and Results

We present experiments and results for two tasks: social event detection and social network extraction. We use the same system for both tasks; the first task is an intrinsic evaluation of our system, while the second task presents an extrinsic evaluation of our system. In the following subsections, we describe the individual tasks, their experimental set-up followed by a discussion of results.

### 5.1 Social Event Detection

Task description: Given a pair of entity mentions in a sentence, we evaluate how well we identify the occurrence of a social event between these two entities. This is a binary task with two classes: presence/absence of a social event. We evaluate using F-measure on the presence of social events.

Tree structure	P	R	F
BOW	34.62	77.78	47.91
PET	58.54	59.26	58.90
GRW	49.14	70.37	57.87
SqGRW	49.59	74.07	59.41
PET_GR	56.32	60.49	58.33
PET_GR_SqGRW	56.82	61.73	59.17
GR_SqGRW	54.37	69.14	60.87
GRW_SqGRW	51.30	72.84	60.20
GR_GRW_SqGRW	50.47	66.67	57.45

Table 2: Results for training on ACE-train and testing on Alice-test. P refers to Precision, R refers to Recall, F refers to F1-measure. Terminology used for the tree structures is explained in detail in Section 3.

Experimental set-up: For all our experiments, we use the SVM-Light-TK package (Moschitti, 2006b) for training models. We use the default parameters of the package to avoid over-fitting. Since we are interested in knowing how well we do at finding the social events, we report Precision, Recall and F-measure of the class of interest (the minority class) instead of % accuracy. For

training, we set the  $-j$  parameter of the package to the ratio of the number of negative examples to the number of positive examples in the training data-set. The  $-j$  parameter assigns a weight to the minority class. Since the SVM optimizes for accuracy, if we do not set this parameter at the time of training, the learner may learn a trivial hyperplane classifying all the examples as negative (the majority class), thus achieving a high accuracy. By assigning a weight to the examples in the minority class, we increase the cost of mis-classifying these examples, thus forcing the learner to find a non-trivial hyperplane. We use the model trained just on bag-of-words (BOW) as a baseline.

Discussion of results: Table 2 presents the results for models trained on ACE-train and tested on Alice-test. We use the tree kernel structure combinations described in section 3. The results show that building a model using tree kernels outperforms the bag-of-words baseline model by an absolute 10% F1-measure. This difference is statistically significant with  $p < 0.05$ .

### 5.2 Social Network Extraction

In this section, we provide results to establish that the un-weighted network extracted using social event detection models is *close* to the true underlying network.

Task description and experimental set-up: Using our social event detection models, we build an un-weighted network of entities in *Alice in Wonderland*. For this task, we report the *distance* between the SNA metrics in the predicted and gold networks. Table 3 summarizes the metrics we use for our evaluation and elaborates on the meaning of *distance*. We use two baseline systems for our evaluation:

1. **B-Simple:** For this baseline, we create a network by linking all pairs of entity mentions (of different entities) that appear in the same sentence.
2. **B-BOW:** This is the network extracted by building a model that uses bag-of-words features for training.

Discussion of results: Table 4 shows results for the SNA metrics (Section 4) for the kernel combinations used to extract a network from *Alice in Wonderland*. The terminology used in Table 4 is explained in Table 3.

Symbol	Name and explanation
P, R, F, %A	Precision, Recall, F1-measure and Accuracy
p	McNemar’s two-sided p-value significance test. We linearize the adjacency matrix of the predicted and gold network and test if these two vectors are significantly different.
D, B	Degree and Betweenness centrality. For each of these centrality measures, we find the centrality of nodes in the network, represented by a vector $\vec{v}$ , where the $i^{th}$ component of the vector is the centrality of the $i^{th}$ node. We then calculate the Euclidean distance between the predicted and gold vectors, which measures the difference in degree centralities of the nodes in the two networks.
S, CC, T	Network density, number of connected components and number of triads respectively. For these measures, we calculate the difference between the gold and the predicted network. For example, a value of 6 in the column labeled CC and the row labeled Alice in Table 2 is the difference in number of connected components found in the predicted network and the gold network.

Table 3: Terminology used to present results in Table 4

System	Stats					Centrality		Community		
	P $\uparrow$	R $\uparrow$	F $\uparrow$	%A $\uparrow$	p $\uparrow$	D $\downarrow$	B $\downarrow$	S $\downarrow$	CC $\downarrow$	T $\downarrow$
B-Simple	0.40	1.00	0.57	97.58	0.0000	19.67	0.57	0.0245	23	439
B-BOW	0.47	0.87	0.61	98.15	0.0000	13.00	0.34	0.0145	14	165
PET	<b>0.77</b>	0.65	<b>0.71</b>	<b>99.12</b>	0.12	<b>6.93</b>	0.15	0.0026	2	<b>0</b>
GRW	0.61	0.68	0.65	98.78	0.38	8.31	0.10	0.0019	1	49
SqGRW	0.64	<b>0.81</b>	<b>0.71</b>	98.93	0.01	8.77	0.11	0.0045	6	34
PET_GR	0.72	0.60	0.66	98.96	0.15	7.75	0.12	0.0026	2	28
PET_GR _SqGRW	0.72	0.65	0.68	99.01	0.41	7.87	0.10	0.0016	3	18
GR_SqGRW	0.67	0.70	0.68	98.93	<b>0.75</b>	8.77	<b>0.06</b>	<b>0.0008</b>	1	23
GR_GRW _SqGRW	0.63	0.68	0.66	98.83	0.55	8.31	0.10	0.0013	<b>0</b>	6

Table 4: Results comparing the two baseline systems (B-Simple and B-BOW) with the models trained on the tree kernel structures discussed in Section 3.  $\uparrow$  means greater value is better.  $\downarrow$  means lesser value is better. Network density of the gold network is 0.0166. The number of connected components in the gold network are 34. The number of triads in the gold network are 103.

Table 4 shows that all the systems trained using tree kernels are better than the two baselines across all SNA metrics. In terms of F-measure, both the baselines perform significantly worse than the tree kernel based systems. In terms of p-value, both the baselines are significantly different from the gold network, whereas none of the tree kernel based systems are significantly different from the gold network. In terms of the distance between the vectors of centrality measures (D, B) for the predicted and gold network – the distance is larger for the baselines, which means that the difference in centrality measures of nodes in the baseline system and the gold network is larger than the differ-

ence in centrality measures of nodes in the other systems and the gold network. The difference in network densities of the baseline and gold network is also larger than the difference in network densities (S) of the other systems and the gold network. The same is the case with the number of connected components (CC) and the number of triads (T). Using these results, we conclude that the network predicted by our system that uses tree kernels performs well in terms of extracting an unweighted, undirected network from *Alice in Wonderland*. In particular, the tree structure derived from the phrase structure tree (PET) performs the best on most of the SNA metrics.

## 6 Literature Survey

With the advent of the internet and social media, researchers have got access to different forms of communication such as Email (Klimt and Yang, 2004; Rowe et al., 2007), online discussion threads (Hassan et al., 2012), Slashdot, Epinions, and Wikipedia (Jure Leskovec and Kleinberg, 2010). There have also been approaches of extracting networks based on Information Retrieval techniques – Jing et al. (2007) extract a network from conversational speech data. The events they are interested in are custody, death, hiding, liberation, marriage, migration, survival and violence. Tang et al. (2008) aim at extracting and mining academic social networks. Aron Culotta and McCallum (2004) extract social networks and contact information from email and the Web. Mori et al. (2006) mine networks based on the collective context in which entities appear.

Our notion of social network is different from the aforementioned work. We are interested in extracting *interaction* networks from unstructured text. In terms of our goals, our work is closest to the work by Elson et al. (2010) and He et al. (2013). Elson et al. (2010) and He et al. (2013) are also interested in extracting a social network from literary texts. However, they restrict their definition of *interaction* to interactions that are signaled by quotation marks. Our system does not have this limitation and is therefore able to extract interaction links appearing even in reported speech (non-dialogue text).

## 7 Conclusion and Future Work

In this paper, we have addressed the problem of extracting a social network from literary narrative text. We have used our previous system that detects social events to extract a network from *Alice in Wonderland*. This system was trained on news articles and has never been tested out of domain. Our evaluation on *Alice in Wonderland* has two components: a standard intrinsic evaluation in terms of the detection of social events, and an extrinsic evaluation which measures how well the un-weighted network formed by the extracted social events mirrors the gold social network. For the extrinsic evaluation, we use various network measures such as centrality or density. We show that while we achieve an F-measure of about 61% on the intrinsic evaluation, our extracted network is not statistically distinguishable from the gold net-

work according to the various network measures.

In the future, we will apply our system to more literary texts. We are currently acquiring annotations on 19th century novels such as *Emma* by Jane Austen. We will also apply our system to other genres such as historical documents.

# Using the Web to Train a Mobile Device Oriented Japanese Input Method Editor

Xianchao Wu, Rixin Xiao, Xiaoxin Chen

Baidu Inc.

wuxianchao@gmail.com, {xiaorixin, chenxiaoxin}@baidu.com

## Abstract

This paper describes the construction of a Japanese Input Method Editor (IME) system for mobile devices, using the large-scale Web pages. We provide the training process of our IME model, n-pos model for local Kana-Kanji conversion and n-gram model for online cloud service. Especially, we propose an online algorithm of mining new compound words, together with the detailed post-filtering process to prune the billion level entries to be used in mobile services. Experiments show that our IME system outperforms two state-of-the-art Japanese IME baselines. We have released our system in a completely free form<sup>1</sup> and the system is currently used by millions of users.

## 1 Introduction

Mobile devices such as smart phones and tablet PCs are used by billions of users. For example, Google's Android system has obtained more than 900 million<sup>2</sup> active devices till May 2013. In this paper, we use large-scale Web pages to train a Japanese IME system for mobile devices.

Languages such as Chinese and Japanese can not be typed directly using Latin keyboards. This is because there are only 26 English letters in a Latin keyboard, yet the number of Chinese characters are in tens thousands level. Furthermore, by connecting several Chinese characters together, the number of yielded words and frequently used phrases/idioms are in million level. Thus, language-dependent Input Method Editor (IME) systems are indispensable which maps from combinations of English letters to Chinese char-

acters/words/phrases and Japanese Kanji/Kana sequences.

For example, suppose we want to input a Japanese verb “炒める” (means “fry”, “炒” is a Japanese Kanji character, “める” are two Japanese Kana characters). We first need to know the Kana pronunciation of the Kanji character “炒”, which is “いた”. That is, the verb is pronounced as “いためる”. Then, we need to know the mapping from English letters to Japanese Kanas. Here, “い”, “た”, “め”, “る” respectively correspond to “i”, “ta”, “me”, “ru”, which can be directly typed by using the Latin keyboards. This mapping (e.g., from “i” to “い”) is unique and predefined already. Thus, the real challenge for constructing an IME system for Japanese is to provide the most reasonable Kanji sequence from a given Kana sequence:

- one Kanji character can have several correct Kana pronunciations (e.g., “炒” can be pronounced as “いた”, “しょう”, “そう”, etc.);
- one Kana sequence corresponds to numerous Kanji candidates (such as “いためる” for “炒める”, “痛める” (pain), etc.);

It is the context that determines the selection of the most reasonable Kanji sequence. For example, “心をいためる” (“心” = heart, “を” is a Japanese particle right follows an argument and before the argument's predicate) requires the Kanji to be “痛める” (heart pain) and “野菜をいためる” needs the Kanji to be “炒める” (fry vegetables). However, it is not a trivial work for modelling the context. That is, how to choice the context from large-scale Web pages such that the context is optimized to be used in a mobile device oriented Japanese IME?

To answer this question, we need to consider the following constraints:

- mobile devices need more strict controlling of CPU and memory usages than laptops;

<sup>1</sup><http://simeji.me/>

<sup>2</sup><http://www.android.com/>

- free wireless services are not supposed to be available anywhere, any time.

Consequently, we have to limit the number of Kana-Kanji entries to be loaded into memory and ensure a high precision of Kana-Kanji conversion even without on-line services (such as cloud input).

## 2 The Model

Our Japanese IME system is constructed based on the n-pos<sup>3</sup> model (Mori et al., 1999; Komachi et al., 2008; Kudo et al., 2011). For statistical Kana-Kanji conversion, we predicate the optimal mixed Kana-Kanji sequence  $\hat{y}$  ( $= w_1 \dots w_n$ ) from the input Hirakana sequence  $\mathbf{x}$ :

$$\hat{y} = \operatorname{argmax}_{\mathbf{y}} P(\mathbf{y})P(\mathbf{x}|\mathbf{y}) \quad (1)$$

$$P(\mathbf{y}) = \prod_{i=1}^n P(w_i|c_i)P(c_i|c_{i-1}) \quad (2)$$

$$P(\mathbf{x}|\mathbf{y}) = \prod_{i=1}^n P(r_i|w_i) \quad (3)$$

As shown in Figure 1, for training this model, we used 2.5TB Japanese Web pages as the training data. We run Mecab<sup>4</sup> with IPA dictionary<sup>5</sup> on Hadoop<sup>6</sup>, an open source software that implemented the Map-Reduce framework (Dean and Ghemawat, 2004), for parallel word segmenting, Part-of-Speech (POS) tagging, and Kana pronunciation annotating. Then, based on maximum likelihood estimation, we estimate:

- $P(c_i|c_{i-1})$ , bi-gram POS tag model;
- $P(w_i|c_i)$ , POS-to-word emission model, from  $c_i$  to a word  $w_i$ ; and,
- $P(r_i|w_i)$ , pronunciation model, from  $w_i$  to its Kana pronunciation  $r_i$ .

There are several lexicons/models to be used in the final IME system. The first is called the basic lexicon. An entry in this lexicon is alike  $\langle w_i^{i+m}, c_i^{i+m}, r_i^{i+m} \rangle$ . Here,  $w_i^{i+m}$  stands for  $m + 1$  words (of  $w_i \dots w_{i+m}$ ). One word  $w_i$  exactly corresponds to one POS tag  $c_i$  and one Kana

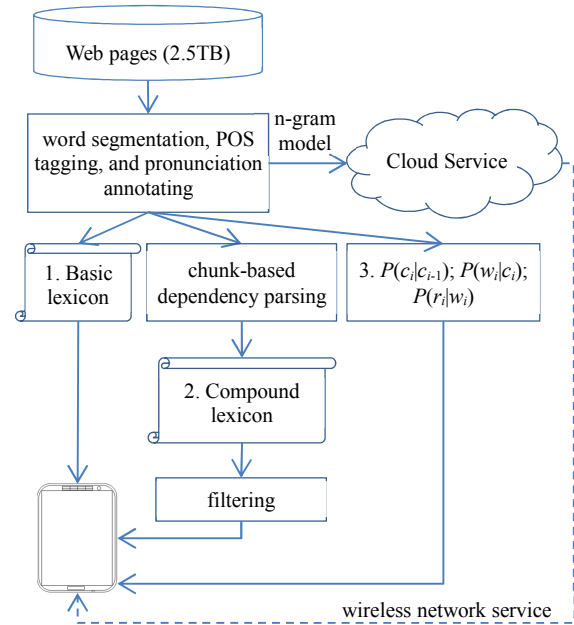

Figure 1: The main process of using the Web to train the IME system.

sequence  $r_i$  as its pronunciation. One word sequence with multiple reasonable POS sequences and/or Kana pronunciations will be stored separately as different entries. This lexicon contains: (1) Japanese words (such as particles, adjectives, adverbs, verbs, nouns, etc.) with the highest frequencies, and (2) the most frequently used idioms which are collected manually by our Japanese language experts.

The second is the compound lexicon which contains new words, collocations, and predicate-argument phrases. As drawn in Figure 1, dependency parsing is performed before mining. Web sentences were parsed by a state-of-the-art chunk-based Japanese dependency parser, Cabocha<sup>7</sup> (Kudo and Matsumoto, 2002a). The mining and filtering process will be introduced in the next section. The motivation of constructing this lexicon is to extract the most important context information, such as the strong constraints among predicates and their arguments. For example, as former mentioned, the pre-predicate arguments such as “心” (heart) or “野菜” (vegetables) with given Kana sequence “をいためる” will determine which predicate verb to choose, “痛める” or “炒める”.

The third is the n-pos model with three kinds of probabilities which are used during decoding, i.e., searching the n-best  $\mathbf{y}$ s from a given input Kana

<sup>3</sup>n-pos model is short for n-gram part-of-speech model

<sup>4</sup><https://code.google.com/p/mecab/>

<sup>5</sup><http://code.google.com/p/mecab/downloads/detail?name=mecab-ipadic-2.7.0-20070801.tar.gz>

<sup>6</sup><http://hadoop.apache.org/>

<sup>7</sup><http://code.google.com/p/cabocha/>

sequence  $\mathbf{x}$ .

Finally, we train a 4-gram language model on surface word level and construct a cloud Kana-Kanji conversion service through wireless network communication between a mobile device and the cloud. The only difference with former n-pos model is the factorization of  $P(\mathbf{y})$ :

$$P(\mathbf{y}) = \prod_{i=1}^n P(w_i | w_{i-1}, w_{i-2}, w_{i-3}) \quad (4)$$

The first three lexicons/models are stored in the mobile devices to be accessed during Kana-Kanji decoding using Equation 1. The final 4-gram language model is estimated in a different way from the n-pos model. Thus, we are forced to interpolate cloud's m-best Kanji candidates into local mobile device's n-best Kanji candidates. We perform duplicated candidate removing before interpolating. Possible methods includes:

- insert the cloud candidates into fixed positions, e.g., from the second position to the m+1 position of the local n-best list; or,
- upload the local n-best candidates to the cloud and then use the 4-gram language model to compute the candidates' language model scores; or,
- download POS tags of the m-best candidates from the cloud and locally compute their scores under the local n-pos model.

The first method is the simplest without a large usage of the wireless network. The later two methods make the direction comparison of cloud and local candidates yet possibly take a large usage of the network. For simplicity, we choose the first method (e.g., taking cloud result as the first candidate) in our IME system.

### 3 Compound Word Mining and Filtering

#### 3.1 Mining Process

The basic lexicon used in our Japanese IME system is short at capturing new words and phrases, which are appearing everyday in the latest Web pages. For example, person names, technical terms and organization names are newly created and used in Web pages such as news, blogs, question-answering systems. We argue it is essential for the IME system to regularly update

its compound lexicon to cover these new and hot words/phrases.

Alike the format of the basic lexicon, entries with  $m + 1$  ( $m$  differs among the entries) words in the compound lexicon is also triples of  $\langle w_i^{i+m}, c_i^{i+m}, r_i^{i+m} \rangle$ . In this paper, we mine three types of new compound words, together with their pronunciations from Japanese Web pages:

- words, which are combinations of single characters and shorter words (e.g., “副/ふく 垢/あか” = “secondary (twitter) account”);
- collocations, which are combinations of words (e.g., “ドバイ ショック” = “Dubai (debt) crisis”). Here, Japanese collocations are allowed to include Kanjis, Katakanas and Hirakanas. Different from many former researches (Manning and Schütze, 1999; Liu et al., 2009) which only mine collocations of two words, we do not limit the number of words in our “collocation” lexicon; and,
- predicate-argument phrases, which are combinations of chunks constrained by semantic dependency relations (e.g., “心 を 痛める” = heart pain).

New words and collocations are mined from single chunks in the dependency trees generated by Cabocha. This mining idea is based on the fact that an Japanese morphological analyser (e.g., Mecab) tends to split one out-of-vocabulary (OOV) word into a sequence of known Kanji characters, and most of these known Kanji characters are annotated to be notional words. Consequently, Cabocha, which takes words/characters and their POS tags as features for discriminative training using a SVM model (Kudo and Matsumoto, 2002b), can still *correctly* tend to include these single-Kanji-character words into one chunk. Thus, we can re-combine the wrongly separated pieces into one (compound) word.

Predicate-argument phrases are mined from adjacent chunks with dependency relations. Since Japanese is a Subject-Object-Verb (SOV) language, the predicate frequently follows its subject/object arguments.

Figure 2 and 3 give the distributions (number of words per compound word vs. the frequency of compound words in a similar number of words) of single/double chunk lexicons (without any filtering yet). For new words and collocations mined

Figure 2: The distributions of the number of words per compound in single chunk lexicon, mined from the 2.5TB web data.

Figure 3: The distributions of the number of words per predicate-argument phrases, mined from the 2.5TB web data.

from single chunks, we limit the number of words frequently ranges from 2 to 8. For predicate-argument phrases, most number (of words) is in the interval of [2, 11].

Frequency information is used for pruning the compound entries to be finally used in mobile devices. The mining algorithm can be performed in an online way. For one aspect, we can timely crawl the latest Web pages and execute the mining process. The frequencies of lastly mined entries can be simply accumulated to the existing entries. On the other hand, we allow the users to upload their input logs to the cloud and execute the mining process to extract single user oriented personally entries. Again, the frequencies of similar words/phrases are simply accumulated.

Recall the n-pos model and the n-gram language model. Since all the probabilities are estimated in a maximum likelihood way, we can simply update the probabilities in these models by accumu-

lating frequencies to similar words/phrases. Thus, we say that our IME system is self-growing as the Web becoming larger and users using it longer.

### 3.2 Filtering Process

After successful mining of the compound lexicon, it is still challenging to prune it to be used in mobile devices with limited computing ability and memory. The trade-off is that, we have to maintain a good enough local lexicon yet with extremely limited number of entries. We use the following algorithms step by step for filtering:

- use the likelihood ratio method as described in (Manning and Schütze, 1999);
- use the LH score as described in (Okazaki and Ananiadou, 2006);
- use the log file of the cloud service; and,
- use hand-made deep filtering rules.

We hereafter describe these filtering strategies. Likelihood ratio is an approach to hypothesis testing, which has been proved to be appropriate for sparse data (Manning and Schütze, 1999). That is, even for candidate phrases will relatively low frequencies, if they share a strong relation with each other, then they are still possibly kept. Likelihood ratio is simply a number that tells us how much more likely one hypothesis is than the other one:

- Hypothesis 1.  $P(w_2|w_1) = p = P(w_2 | -w_1)$ ;
- Hypothesis 2.  $P(w_2|w_1) = p \neq P(w_2 | -w_1)$ .

The first hypothesis judges if the occurrence of word  $w_2$  is *independence* with word  $w_1$ , and the second hypothesis is about *dependence* which is good evidence for an interesting collocation candidate. The computing of  $\log\lambda = \log(L(H_1)/L(H_2))$  exactly follows the definitions in (Manning and Schütze, 1999). Deal to short of space, we skip the detail here. Note that for phrases with more than two words (e.g., three words), we separately take the first/last two words as one unit, and the other word as another unit. Then, if and only if both  $w_1w_2, w_3$  and  $w_1, w_2w_3$  are collocation candidates, then  $w_1w_2w_3$  is taken as one reasonable collocation.

After likelihood ratio based filtering, we checked the remaining entities and found too

many nested entries. For example, even both  $w_1w_2w_3$  and  $w_1w_2$  were kept in the final compound lexicon, only one of them was judged manually to be the correct one. Dealing with this problem, we use the LH score formula as described in (Okazaki and Ananiadou, 2006). we reuse the heuristic LH formula to compute the collocation likelihood  $LH(c)$  for a candidate  $c$ :

$$LH(c) = \text{freq}(c) - \sum_{t \in T_c} \text{freq}(t) \times \frac{\text{freq}(t)}{\sum_{t \in T_c} \text{freq}(t)}.$$

Here,  $c$  is a Kanji (sub-)sequence candidate;  $\text{freq}(c)$  denotes the frequency of co-occurrence of  $c$  with the final/first word(s) of the phrases; and  $T_c$  is a set of nested Kanji sequence candidates, each of which consists of a preceding (or, succeeding) Kanji or Kana character followed by (or, follows) the candidate  $c$ . This LH score can be computed in left-to-right (i.e., taking the former one or more words as no-changing words and seek the word list that follows these former words) direction or right-to-left direction. For example, for left-to-right computing, we can collect all the phrases starts with the similar word  $w_1$  and then collect all the compound entries start with  $w_1$ . Then, after computing LH score, we can limit the number of entries start with  $w_1$ .

Even after these two automatic filtering algorithms, we still find there are too many entries remaining in the compound lexicon. The third step of filtering is the usage of the cloud log file which stores the entries that users uploads to the cloud. This filtering strategy is to only keep those entries whose Kana pronunciations were found in the log file. The consideration is to connect the Web to the real requirements of the users.

Finally, we manually check the remaining lexicon and construct deep filtering rules. For example, entries that starts with “ない”, “等” are pruned out; entries with POS tags of “particles”, “auxiliary verbs” are pruned out. Note that, this manual checking is performed before the final lexicon is generated. Filtering rules are constructed after this manual checking step and further used for filtering the test set as can be find in the next section (22 entries were filtered from the 5K entries in the test set).

## 4 Experimental Results

We have described in detail the training and filtering process for constructing lexicons and models.

Systems	top-1	top-6	top-12	Missing Words
Baseline1	84.91	89.11	89.31	532
Baseline2	82.64	94.23	94.80	112
IME-basic	81.36	85.82	85.82	705
+ compound	85.78	91.22	91.30	431
+ cloud (1st)	88.99	94.98	96.44	41

Table 1: The top-1/6/12 precisions (%) of the baselines and our IME system under several configurations. Here, IME-basic stands for our IME system with only the basic lexicon; + compound stands for the system together with the basic lexicon and the compound lexicon; + cloud stands for taking cloud’s best candidate as IME’s first candidate.

In terms of the decoding algorithm, we use beam searching for n-best Viterbi decoding (Huang and Chiang, 2005). The training data is a 2.5TB Japanese Web page set. Our basic lexicon contains around 100k entries, while the compound lexicon is limited to contain around 50k entries. No limitation is set to the 4-gram language model running in the cloud.

Our test set contains 4,978 Kana-Kanji entries of frequently used word, idioms, and phrases. The entries of this test set comes from the following three lexicons/corpora:

- (partial) “JDMWE” (Japanese Dictionary of Multi-Word Expressions) (Shudo et al., 2011) lexicon with 2,169 entries;
- “Nagoya” compound word lexicon<sup>8</sup> with 3,628 entries such as idioms;
- 16,611 long form words in the “BCCWJ” (Balanced Corpus of Contemporary Written Japanese) corpus (Maekawa, 2008).

We then retrieve each entry in these three lexicons using Google<sup>9</sup> and only keep the top 5K entries with higher frequencies. After obtaining the 5K entries, we perform manually constructed deep filtering rules (which have been used during training) and remove 22 entries which are judged to be not suitable to be taken as collocations with complete meaning.

We use top-n precisions  $P_n$  to evaluate the accuracy of the IME systems. We use  $\langle k_m, r_m \rangle$  to

<sup>8</sup><http://kotoba.nuee.nagoya-u.ac.jp/jc2/base/list>

<sup>9</sup><https://www.google.co.jp/>

express one entry in the test set, where  $m$  ranges from 1 to  $M$ ,  $k_m$  is the Kana input and  $r_m$  is the Kanji reference.

$$P_n = \frac{\sum_{m=1}^M \{\delta(r_m, \text{IME}_n(k_m))\}}{M} \quad (5)$$

Given one  $k_m$ ,  $\text{IME}_n(k_m)$  generates the  $n$ -best Kanji candidate for  $k_m$ . The  $\delta()$  function is defined as follows:

$$\delta(r_m, \text{IME}_n(k_m)) = \begin{cases} 1 & \text{if } r_m \in \text{IME}_n(k_m), \\ 0 & \text{otherwise.} \end{cases}$$

When  $n$  takes 1,  $P_1$  is equivalent to the traditional definition of precision.

Table 1 shows the top- $n$  precisions and the number of missing words of two state-of-the-art Japanese IME baseline systems and our IME system under several configurations of lexicons/models. Both the baseline systems and our IME systems are in mobile device versions.

Here, baseline1<sup>10</sup> is a commercial Japanese IME system whose lexicon contains around 200k entries. This baseline system is constructed by using statistical methods on relatively a small-scale training data and a lot of hand-made Kana-Kanji conversion rules. Deal to resource limitation, we could not obtain further detailed technical information of this system and can only buy one copy and test it in an open testing way.

The second baseline IME system (Kudo et al., 2011), baseline2<sup>11</sup>, is constructed in a statistical way by using the large-scale Japanese Web pages as the training data. N-pos model is also the major model supporting its training and decoding algorithms. This system can be freely obtained.

From the table, we have the following observations:

- when only using the basic lexicon, our IME system is worse than both of the baselines;
- when the compound lexicon is appended, the top-1 precision of our IME system is better than baselines, yet top-6/12 precisions are still not good (by checking the lexicon size of baseline2, we found that around 300k to 400k entries were contained. Yet there are only around 100k+50k entries in our basic/compound lexicons);

<sup>11</sup><https://play.google.com/store/apps/details?id=com.google.android.inputmethod.japanese>

Systems	top-1	top-6	top-12	Missing Words
IME	76.12	82.05	82.05	224
+ log	79.41	87.74	87.82	152
improves	3.29	5.69	5.77	-72

Table 2: The top-1/6/12 precisions (%) of our IME system under several configurations. Here, IME stands for the system using basic and compound lexicons; + log stands for appending compound entries mined from users' log.

- finally, by using cloud service, the top- $n$  precisions are significantly better than two baselines.

We did another experiment for testifying the “online” ability of our IME system. The training data is the users' logs. We used these logs (of during two months) to extract compound words and append them to existing compound lexicons. There are 6k entries appended. The testing data (which contains 1,248 entries) is a set of compound words using logs of the latest three days.

Table 2 shows the changes of top-1/6/12 precisions by appending the compound entries mined from users' log. We observe that the precisions are improved 3.29% to 5.77%. These improvements show evidence that the IME system can grow itself in an online way with more data and more users.

## 5 Conclusion

We have described the construction of a Japanese Input Method Editor (IME) system for mobile devices, using 2.5TB Web pages. We provided the training process of our IME model, n-pos model for local Kana-Kanji conversion and n-gram model for online cloud service. In particular, we described an online algorithm of mining new compound words, together with the detailed post-filtering process to prune the billion level entries to be used in mobile services. Experiments showed that our IME system outperforms two state-of-the-art Japanese IME baselines. We have released our system in a completely free form and the system has been downloaded by more than 5 million users and is currently used by users in million level<sup>12</sup>.

## Abstract

This paper presents a novel approach to categorize, model and identify contextual information in natural language interface to database (NLIDB) systems. The interactions between user and system are categorized and modeled based on the way in which the contextual information is utilized in the interactions. A relationship schema among the responses (user and system responses) is proposed. We present a novel method to identify contextual information in one specific type of user-system interaction. We report on results of experiments with the university related queries.

## 1 Introduction

Natural Language Interface to Database (NLIDB) systems allow the users to query databases in a natural language (Androustopoulos et al., 1995; Meng and Wang, 2001; Popescu et al., 2003; Stratica et al., 2005; Li et al., 2005; Giordani, 2008; Giordani and Moschitti, 2009; Gupta et al., 2012). Although NLIDB systems are able to answer a wide range of natural language queries (NL queries), they are not used much in commercial applications. One of the main reasons for the less acceptance of these systems in real-time applications is that they lack robust context processing capabilities (Bertomeu et al., 2006). Currently there is very little work which explicitly aims to investigate the role of context processing capabilities in NLIDB systems. However, the importance of context processing capabilities has been explored extensively in Question Answering systems (Chai and Jin, 2004; Kato et al., 2004; Kirschner and Bernardi, 2007; Negri and Kouylekov, 2007; Kirschner and Bernardi, 2010).

Users often fail to express their intention (information need) in a single NL query (user re-

sponse) (Bertomeu et al., 2006). Hence to answer a sequence of related NL queries, NLIDB systems should keep track of contextual information. NLIDB systems which do not use contextual information (non-contextual NLIDB) fail to completely capture the user's intention.

**U1:** How many third year students have registered for Robotics course in Monsoon 2011?

**S1:** 12

**U2:** How many got 'A' grade?

**S2:** 2

**U3:** Show the name of the professor who guides the student 'Newton'

**S3:** Prof. Einstein

**U4:** Did he teach any course?

**S4:** No

Figure 1: An example of context based user-system interaction

For example, let us consider a user-system interaction shown in Figure 1. User responses are represented as U1, U2, etc. and system responses are represented as S1, S2, etc. In this example, to interpret U2, information present in the preceding query U1 is needed. That means information present in U1 is the contextual information for U2. Query U3 does not depend on the information present in preceding queries. Semester name 'Monsoon 2011' present in U1 and the professor name 'Einstein' present in S3 are needed to interpret U4.

### 1.1 Background

In a semantic template based non-contextual NLIDB system (Gupta et al., 2012), the main stages involved in extracting answers (system's response) from the database are shown in Figure 2. At the syntactic analysis stage, the linguistic information is extracted from the NL query. At the semantic analysis stage, entities, attributes and the

values to these attributes are identified by using the output of the syntactic analysis module and semantic templates. At the query processing stage, entities identified in the semantic stage are mapped onto the domain conceptual model based on an entity relationship graph (ER graph) and a shortest path in the ER graph connecting them is computed. SQL (Structured Query Language) query is generated using the path obtained and the SQL query is later executed to produce results.

Figure 2: NLIDB system without context processing capabilities

In our approach, the context processing capabilities are incorporated into a non-contextual NLIDB system without disturbing the internal functioning of the existing modules of the system as shown in Figure 3.

Figure 3: Context based NLIDB system

## 2 Related Work

Chai and Jin (2004) and Sun and Chai (2007) investigate the role of discourse modeling to track contextual information in interactive Question Answering systems. They analyzed the relations between user’s responses and proposed models based on centering theory to identify the contextual information. However, the above mentioned models fail to utilize system’s responses. Kirschner and Bernardi (2007) and Bernardi and Kirschner (2008) proposed models which utilize both user’s responses and system’s responses. But, in all these approaches, no attempt was made to understand the structure of user-system interactions. *We believe that understanding the structure of user-system interactions is the key to identifying an effective model to track contextual information.*

Bertomeu et al. (2006) made an attempt to understand the structure of user-system interactions. Along the lines of their work, we aim to identify models which reflect the underlying structure of user-system interactions. We propose three models based on the way in which the contextual information is utilized in the user-system interactions. Contextual information can sometimes be found beyond the immediate preceding responses (antecedents) as discussed in (Bertomeu et al., 2006). The approach proposed in this paper was able to identify contextual information present in such responses. Further, it was also able to identify the contextual information present in more than one antecedent.

The remainder of this paper is organized as follows. In section 3, we more precisely define the problem and introduce our terminology and notation conventions. In section 4, we categorize the interactions between user and system. We model the user-system interactions in section 5. We propose a relationship schema among the responses (user and system responses) in section 6. In section 7, using these relations, we present a novel method to identify contextual information for one of the models proposed in section 5. Finally, we present our experimental results in section 8 and conclude in Section 9.

## 3 Problem

Responses by both user and system in a user-system interaction can be grouped into a set based on the information shared among them. Each individual group is called ‘local contextual group’ (LCG) and the corresponding information (i.e. information present in every user response of that group) maintained by it is called ‘local contextual information’ (LCI) or ‘contextual information’. Given a user response, first we need to identify the LCG to which it belongs and then use the corresponding LCI to interpret the user response.

The following notation is used throughout this paper:

$lc_i$  denotes the  $i^{\text{th}}$  LCG.

$u_{kl}$  denotes the  $k^{\text{th}}$  user response and there are  $l$  LCGs just before this response is given by the user.

$s_{kl}$  denotes the  $k^{\text{th}}$  system response and there are  $l$  LCGs just before this response is given by system.

For every user response  $u_{kl}$ , there will be a corresponding system response  $s_{kl}$ . We define the pair  $(u_{kl}, s_{kl})$  as a **dialogue unit**  $d_{kl}$ .

The user response  $u_{kl}$  can either belong to any of the previous LCGs  $lc_i = 1,2,3 \dots l$  or it can lead to the formation of new LCG  $lc_{l+1}$ . This is because the user can only either refer to the past information or can provide new information. User cannot refer to future local contexts (i.e.  $i > l+1$ ).

The system response  $s_{kl}$  can only belong to any of the previous local contexts  $lc_i = 1,2,3 \dots l$ . It cannot belong to  $lc_{l+1}$  or any of the other future local contexts. This is because the system can only provide output for the past ( $i \leq l$ ) user responses. Hence, only a user response can create a new LCG.

So there are two primary steps to identify contextual information of a user response  $u_{kl}$ : (a) To identify all the LCGs present in the interaction and (b) To find the corresponding LCG to which  $u_{kl}$  belongs.

#### 4 User-System Interactions

Kato et al. (2004) categorized the interactions between user and system into two types: Browsing type and Gathering type. In our experiments, we found a similar and more finer categorization to be helpful for analyzing the interactions:

**1) Strongly Coherent interaction:** In this kind of interaction, the user interacts with the system with a topic in mind and a goal to achieve. In our experiments, we found that most of the responses in such an interaction are closely related with each other (section 8).

**2) Coherent interaction:** In this kind of interaction, the user only knows about the topic and he does not have any specific goal. Here, the responses may not be as closely related as in strongly coherent interactions.

**3) Weakly Coherent interaction:** In this kind of interaction, the user neither has a topic nor a goal. Most of the responses in this type of interaction may not be related with each other.

#### 5 Modeling User-System Interaction

Depending on the way in which the contextual information can be utilized in the user-system interactions, we propose the following three models:

**1) Linear Disjoint Model:** In this model, the following three conditions hold true:

**condition 1:**  $u_{kl}$  can belong to only one LCG.

**condition 2:**  $u_{kl} \in lc_i$  or  $u_{kl} \in lc_{i+1}$ , where  $i = l$ .

This implies that user response can only either belong to the immediate previous LCG or it can form

a new LCG.

**condition 3:** All LCGs are disjoint.

This implies that responses belonging to a LCG can be interpreted without depending on the information present in responses belonging to any of the other LCGs.

For example, let us consider a Linear Disjoint interaction (i.e. user-system interaction which can be modeled by Linear Disjoint Model) shown in Figure 4. In this example,  $d_{10}$ ,  $d_{20}$  belong to first LCG and  $d_{31}$ ,  $d_{41}$  belong to second LCG. We can interpret the responses belonging to second LCG without depending on the information present in responses belonging to first LCG.

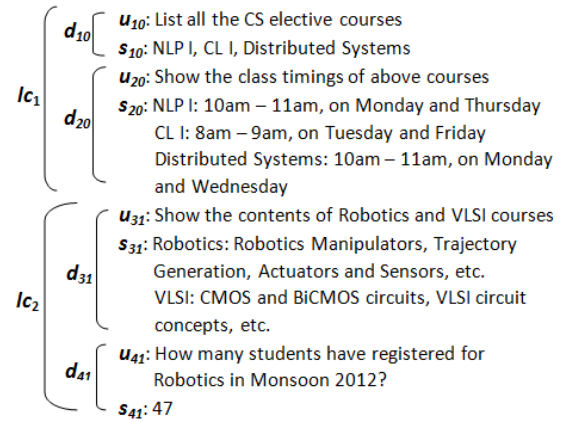

Figure 4: An example of Linear Disjoint interaction

**2) Linear Coincident Model:** In this model, condition 1 and condition 2 hold true. Condition 3 does not hold true if  $lc_i$  and  $lc_j$  are adjacent (i.e.  $|j-i| = 1$ ). This implies that interpreting responses belonging to a LCG may need the information present in the responses belonging to its adjacent LCG.

Figure 5: An example of Linear Coincident interaction

For example, let us consider an example of Linear Coincident interaction shown in Figure 5. In this example,  $d_{10}$  belong to first LCG and  $d_{21}$  belong to second LCG.  $u_{21}$  corefer the student name 'Newton' present in  $u_{10}$ . Hence interpreting the

responses belonging to second LCG needs the information present in responses belonging to first LCG.

It may also be noted that  $d_{10}$  and  $d_{21}$  may appear to belong to the same LCG but this is not so. If we assign both  $d_{10}$  and  $d_{21}$  to same LCG, then the information present in  $d_{10}$  would be used to interpret  $u_{21}$ . In this case  $u_{21}$  would be interpreted as ‘Did Newton complete Physical Activity credits in Monsoon 2009 and Spring 2011’. But the user’s intention is to know whether Newton completed Physical Activity credits or not (in any of the semesters). Hence both  $d_{10}$  and  $d_{21}$  cannot belong to same LCG.

**3) Non-Linear Model:** In this model, all the three conditions may or may not hold true. This implies that user response can belong to more than one LCG. Also interpreting responses belonging to a LCG may need the information present in the responses belonging to any of the other LCGs. Identification of contextual information in such interactions is very difficult compared to Linear Disjoint and Linear Coincident interactions. Complexity of contextual information present in various models is as follows:

*Linear Disjoint Model < Linear Coincident Model < Non-Linear Model*

## 6 Relationships between User Response and Dialogue Units

In a semantic template based non-contextual NLIDB system (Gupta et al., 2012), entities identified in semantic stage (explicit entities) are mapped onto the domain conceptual model based on an entity relationship graph (ER graph). A shortest path (sub-graph) in the ER graph connecting the explicit entities is computed. Implicit entities are the entities in the sub-graph which connect the explicit entities. For every user response, a sub-graph is generated. So for every dialogue unit, there exists a sub-graph.

Between user response ( $u_{kl}$ ) and dialogue units ( $d_{ij}$  where  $i < k$  and  $j < l$ ), we define the following relationships based on their corresponding sub-graphs:

(1) **Strong Link:**  $u_{kl}$  and  $d_{ij}$  are said to be strongly linked if their sub-graphs satisfy the following three properties.

*property 1:* there is at least one explicit entity ( $e_f$ ) in common.

*property 2:* there is at least one attribute ( $a_f$ ) of the

entity  $e_f$  in common.

*property 3:* there is at least one value ( $v_f$ ) to the attribute ( $a_f$ ) in common.

(2) **Link:**  $u_{kl}$  and  $d_{ij}$  are said to be linked if property 1, property 2 are satisfied and property 3 is not satisfied.

(3) **Weak Link:**  $u_{kl}$  and  $d_{ij}$  are said to be weakly linked if none of the properties are satisfied i.e. they either have implicit entities in common or no entity in common.

For example, let us consider the user-system interaction shown in Figure 6. Here  $u_{20}$  and  $d_{10}$  are strongly linked because they both have common explicit entity ‘course’, common attribute ‘course name’ and common value ‘Database Systems’ to that attribute. Similarly,  $u_{41}$  and  $d_{31}$  are strongly linked.  $u_{52}$  and  $d_{41}$  are linked because they only have the entity ‘professor’ in common.  $u_{31}$  and  $d_{20}$  are weakly linked because they don’t have any explicit entity in common.

## 7 Identifying contextual information in Linear Disjoint Model

To use contextual information in a user-system interaction, we need to perform two primary steps. First, we need to identify all the LCGs present in the interaction. Then, given a user response, we need to find the corresponding LCG to which it belongs. In our approach, we perform these two steps simultaneously.

In Linear Disjoint Model, a user response can either belong to the immediate previous LCG or it can form a new LCG. Let the user response be  $u_{kl}$ . That means there are already  $l$  LCGs before user has given this response. Now we need to find whether  $u_{kl}$  belongs to  $lc_l$  or not.

Suppose if  $u_{kl}$  is assigned to the LCG  $lc_l$ , the corresponding contextual information is used to interpret  $u_{kl}$ . Otherwise, a new LCG  $lc_{l+1}$  is created and  $u_{kl}$  is assigned to  $lc_{l+1}$ .

We use the relationships between user responses and dialogue units to determine whether  $u_{kl}$  belongs to  $lc_l$  or not. The intuition behind using these relationships is given below:

1) If  $u_{kl}$  is *strongly linked* to **any** dialogue unit belonging to  $lc_l$ , then it indicates that the user might be referring to the information present in  $lc_l$  and hence  $u_{kl}$  is assigned to  $lc_l$ .

2) If  $u_{kl}$  is *linked* to **any** dialogue unit belonging to  $lc_l$ , then it indicates that user might be reducing focus on the information present in  $lc_l$  and hence

the system creates a new LCG  $lc_{l+1}$  and assigns  $u_{kl}$  to  $lc_{l+1}$ . Since reducing focus may not always lead to formation of new LCG, system confirms with user by asking some questions.

3) If  $u_{kl}$  is *weakly linked* to **any** dialogue unit belonging to  $lc_l$ , then it indicates that user might not be referring to the information present in  $lc_l$  and hence the information present in  $lc_l$  is not used as contextual information. A new LCG  $lc_{l+1}$  is created and  $u_{kl}$  is assigned to  $lc_{l+1}$ .

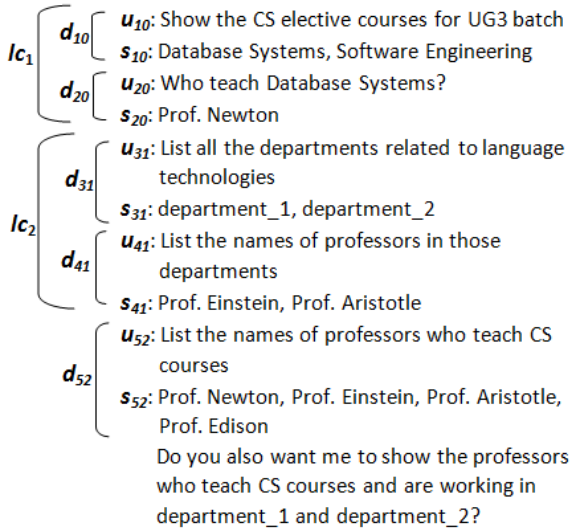

Figure 6: An example of Linear Disjoint model

For example, let us consider a Linear Disjoint interaction shown in Figure 6. Since  $u_{20}$  and  $d_{10}$  are strongly linked, we use the information present in  $d_{10}$  as the contextual information for  $u_{20}$ . Hence the output will be the names of professors who teach the course ‘Database Systems’ for UG3 batch.

As  $u_{31}$  and  $d_{20}$  are weakly linked, information present in  $d_{10}$  and  $d_{20}$  are not used as contextual information for  $u_{31}$ . Also a new LCG  $lc_2$  is created and  $u_{31}$  is assigned to  $lc_2$ . Similarly  $u_{41}$  uses information present in  $d_{31}$  as contextual information because they are strongly linked.

As  $u_{52}$  and  $d_{41}$  are linked, the user might be reducing focus on the information present in  $lc_2$ . Hence,  $u_{52}$  is interpreted without using the information present in  $lc_2$  as contextual information and later system confirms with user by asking some questions.

## 8 Experiments and Discussions

We carried out experiments on university related queries. Using the existing non-contextual NLIDB

system (Gupta et al., 2012), we have developed 110 dialogues which cover a wide range of topics such as course registration, seminar talks, credit requirements and cultural events. Each dialogue contains a sequence of user and system responses (or turns). On an average, each dialogue contains about 12 responses, corresponding to a total of 1320 responses.

Out of these 110 dialogues, 40 dialogues are of strongly coherent type, 40 dialogues are of coherent type and 30 dialogues are of weakly coherent type. We found that 96.6% of these dialogues belong to Linear Disjoint Model and 3.4% of the dialogues belong to Linear Coincident Model. We did not find any dialogues belonging to Non-Linear Model. This indicates that the method proposed in this paper is sufficient to identify contextual information in most of the real-time interactions.

	Strong Links	Links	Weak Links
Strongly Coherent interaction	72.84%	22.89%	4.29%
Coherent interaction	46.25%	43.75%	10%
Weakly Coherent interaction	34.34%	41.34%	24.34%

Table 1: Average percentage of relationships observed in different types of interactions

Table 1 shows the average percentage of various relationships (proposed in section 6) observed in different types of interactions. In a strongly coherent interaction type, higher percentage of strong links are observed. This is consistent with the definition of strongly coherent interaction. In such an interaction, user interacts with the system with a topic in mind and a goal to achieve. At each stage of the interaction, the user tries to move closer to the goal. Hence, we can expect the user to construct a query (or response) using the information obtained from the previous queries. This also explains the presence of a very small percentage of weak links.

From the definition of coherent interaction type, one would expect a higher percentage of links than strong links. On the contrary, we found almost equal percentage of strong links and links. This is because in a coherent interaction, the user can ask about various details regarding a topic. We can call these details as short term goals (or temporary

goals). In contrast to strongly coherent interaction where user has a single goal (long term goal) to achieve, coherent interaction contains many short term goals.

User may not get an answer for every short term goal in a single query. Hence, we can expect the user to ask multiple queries (but these are much less than the total number of queries used to achieve long term goal) to achieve short term goals. The interaction corresponding to every short term goal have high percentage of strong links than links. Interactions corresponding to every two short term goals are expected to connect with either links or weak links. But since we have a fixed topic, we can expect higher probability for links to connect those short term goals. As there can be many short term goals, percentage of links will be also high.

In a weakly coherent interaction, higher percentage of weak links are observed compared to other two types of interactions. This is because the user neither has topic nor a goal to achieve. Hence, while interacting with the system, the user may randomly pick topics and ask various details related to those topics. Once a topic is chosen, the interaction can be viewed as a coherent interaction. Hence, we can see almost the same percentage of strong links and weak links. Notice that there is a higher probability for interactions with different topics to be weakly linked with each other. As a user may frequently change the topics, we can see the increase in the percentage of weak links.

Table 2 shows the average number of local contexts, average length of local context (i.e. total number of responses in each local context) observed in different types of interactions. As discussed earlier, in a strongly coherent interaction, the user has a fixed and a single goal to achieve. So, we can expect most of the queries to be related to each other. Hence, this type of interactions contain less number of local contexts and each local context has more responses.

Coherent interactions contain many short term goals and each short term goal is expected to contain less number of responses compared to the long term goals present in strongly coherent interactions. So this type of interactions contain comparatively more number of local contexts and smaller average length than strongly coherent interactions.

In weakly coherent interactions, user can change the topics very often and hence contain higher number of local contexts and least average length.

	Number	Length
Strongly Coherent interaction	2.2	4.67
Coherent interaction	3	1.88
Weakly Coherent interaction	3.83	1.43

Table 2: Average number and average length of local contexts observed in different types of interactions

We applied the method proposed in section 7 to 106 Linear Disjoint dialogues (which constitute 96.6% of the total dialogues). The results obtained are impressive. For each dialogue, we evaluated the percentage of the queries for which the corresponding contextual information has been identified correctly. The contextual information is identified with 100% accuracy for 78 dialogues i.e. our method successfully identified the appropriate context for every user response of those dialogues. The contextual information for 13 dialogues has been identified with 10 to 20% error. 9 dialogues are found with error greater than 40%.

## 9 Conclusion

In this paper we categorized user-system interactions and then proposed three models (Linear Disjoint Model, Linear Coincident Model and Non-Linear Model) depending on the way in which the contextual information can be utilized in the interactions. We proposed a new relationship schema among the responses. Central in our approach is the use of these relationships to identify contextual information in Linear Disjoint interactions. Furthermore, we evaluated our approach on university related queries and the results confirm the viability of the proposed approach. In our corpus, we found that 96.6% of the total interactions are Linear Disjoint interactions. Hence the method proposed in this paper is sufficient to identify contextual information in most of the real-time interactions.

In the future, we plan to investigate how to identify the model of an interaction. We also intend to identify contextual information in Linear Coincident interactions and Non-Linear interactions.

# Iterative Development and Evaluation of a Social Conversational Agent

Annika Silvervarg, Arne Jönsson

Department of Computer and Information Science

Linköping University, Linköping, Sweden

annika.silvervarg@liu.se, arne.jonsson@liu.se

## Abstract

We show that an agent with fairly good social conversational abilities can be built based on a limited number of topics and dialogue strategies if it is tailored to its intended users through a high degree of user involvement during an iterative development process. The technology used is pattern matching of question-answer pairs, coupled with strategies to handle: follow-up questions, utterances not understood, abusive utterances, repetitive utterances, and initiation of new topics.

## Introduction

Social aspects of conversations with agents, such as small talk and narrative storytelling, can have a positive effect on peoples general interest in interacting with it and help build rapport (Bickmore, 2003). It can also be utilised to develop a relationship and establishing trust or the expertise of the agent (Bickmore and Cassell, 1999). We are interested in exploring if and how these and other effects transfer to an educational setting where children and teenagers interact with pedagogical agents in virtual learning environments. We see several reasons to incorporate social conversation with such agents, for example, it allows for cognitive rest, it can increase overall engagement and receptivity and it can make students feel more at ease with a learning task or topic (Silvervarg et al., 2010). There has, however, been few attempts to understand the users' behaviour in social conversations with pedagogical agents (Veletsianos and Russell, 2013) and embodied conversational agents (Robinson et al., 2008).

In this paper we report on how we iteratively have worked with addressing the questions of 1) what do users talk about during social conversation with a pedagogical agent, 2) how do users

talk during social conversation with a pedagogical agent, 3) how does the answers to 1) and 2) affect the dialogue functions needed to implement social conversation with a pedagogical agent.

## A social conversational pedagogical agent

Our work extends a virtual learning environment with an educational math game named "The Squares Family" (Pareto et al., 2009). A crucial part of the environment is a pedagogical agent, or more specifically a teachable agent (Biswas et al., 2001). While the student is playing the game, the agent "learns" the rules of the game in two ways, by observation or through on-task multiple choice questions answered by the user. A teachable agent is independent and can act on its own, yet is dependent on the student to learn rules and strategies. The intended users are 12-14-year-old students, and the teachable agent is designed as having the same age or slightly younger.

The conversational module for off-task conversations has been developed as a rather independent module of the learning environment. Off-task conversation is based on a character description of the teachable agent that is consistent with the overall role of the agent as a peer in the environment.

The challenge can be seen as a question of managing the students' expectations on the agent's abilities. Our approach was to frame and guide the interaction with the student in such a way that, ideally, the shortcomings and knowledge gaps of the agent never become a critical issue for achieving a satisfying communication. We have therefore chosen to work with user-centred agile system development methods to be able to capture the users' behaviour and tailor the agent's conversational capabilities to meet their expectations. This includes combining focus group interviews and Wizard-of-Oz role-play (Dahlbäck et al., 1993) with development and evaluation of prototypes, surveys and analyses of natural language interaction logs.

The off-task conversation is implemented using a slightly extended version of AIML, Artificial Intelligence Markup Language (Wallace, 2010). AIML works on the surface level and map user utterances to system responses. User utterances can consist of words, which in turn consist of letters, numerals, and the wildcards `_` and `*`, which function like words. Synonyms are handled using substitutions and grammatical variants through several different patterns for the same type of question and topic.

Responses consist in their simplest form of only plain text. It is also possible to set or get data in variables and predicates, give conditional responses, choose a random response from a set of responses, and combinations of these. AIML also allows for handling a limited context by either referring to the systems last utterance or a topic that span multiple exchanges.

### Prototype 1

In the first iteration an agent persona was developed through focus groups with 20 target users. The persona sketch formed the basis for WOZ-style role play, in which students simulated off-task conversations in the game. Three students played the part of the agent, and four students played the role of the user. The resulting 12 dialogues were analysed according to topics, linguistic style and dialogue phenomenon. A number of new topics emerged that had not been brought up in the focus groups. The linguistic style of the utterances could be characterised as grammatical, short sentences, with the use of smileys and "chat-expressions". The dialogue mostly consisted of unconnected question and answer pairs, but some instances of connected dialogue with 3-4 turns occurred. The initiative was evenly distributed between user and system. There were frequent use of elliptical expressions, mostly questions of the type "what about you", but no anaphora.

Based on these findings the first prototype implemented basic question-answer pairs, a strategy for follow-up questions from the agent and user, a topic model with 6 topics that could be initiated by the agent (to allow for mixed-initiative dialogue), and a very simple strategy to handle utterances that the agent could not understand. To handle variations in user input (choice of words and grammatical variations) the system used substitutions where, for example, synonyms and hyponyms

were substituted for a "normalised" word, and variations of patterns that used the "normalised" keywords. The agent's replies were sometimes randomly chosen from a set of 3-5 variants to get some variation if the user asked the same question several times. Follow-up questions were randomly attached to half of the answers the agent gave to questions from the user. When the agent did not understand a user utterance it said so three out of four times, but in one out of four it instead initiated a new topic and posed a question to the user. The agent also initiated a new topic when the user gave an acknowledgement, such as ok, after an answer from the agent.

To evaluate the system a total of 27 students tested the prototype. After a short introduction to the project and the system they played the game for 10 minutes, chatted with the agent for 5 minutes, then played the game for 5 minutes and chatted for 5 minutes again. Analysis of the corpus showed that failed interpretations had to be dealt with. Many of the failed interpretations were due to linguistic variations on known topics, and most of all acknowledgments, but also greetings and follow-up questions. Topics also needed to be expanded, both new topics, for example age, food, pets, favourite colour and cars, but also more sub-topics related to, for example, computer games, school subjects, and TV. Topics initiated by the agent were proved to be a good strategy and implied that the model should be expanded with new topics and more sub-topics. If the agent could initiate more topics it would both make the dialogue more fun but also help the user to know what type of topics the agent could talk about. A recovery strategy to deal with utterances that the system still were not able to interpret correctly, for example utterances out of scope, was also needed to help the user understand what they could talk about and avoid losing track of the conversation. The recovery strategy should also include ways of breaking long sequences of utterances that included, for example, random letters and "Ok" sub-dialogues, and steer the dialogue back to a topic.

Evaluation of the prototype also showed that hazing, testing and flaming occurred rather frequently, for example comments and questions regarding the agent's appearance, intellectual capacities, and sexual orientation and activities. To fend this off, the agent also needed to recognise such utterances and have a strategy to direct the dialogue

in a more productive direction.

## Prototype 2

The second prototype expanded the agent's dialogue functionality with a recovery strategy for utterances not understood by the agent, a strategy to handle abusive utterances, a strategy for delayed follow-up questions by the user (e.g. Agent: How are u? User: Fine. Agent: Ok. User: wbu?), an extended topic model, a better model for agent initiative and flow of the dialogue, and extended vocabulary.

The recovery strategy for utterances not understood by the agent was implemented similar to the one used by SGT Star (Artstein et al., 2009); first a simple "clarification", utterance 2 in Figure 1, then, a "stall", followed by a "move on", and finally a "prompt" that directs the user to a new topic. In our system the agent stall is a general prompt for the user to initiate a new topic, utterance 4 in Figure 1, if this fails the agent proposes a topic, utterance 6 in Figure 1, and as a last resort takes the initiative and asks a question, utterance 8 in Figure 1.

- 1 User: fgd
- 2 Agent: I did not understand that
- 3 User: cb
- 4 Agent: I did not catch that, can we talk about something else?
- 5 User: s
- 6 Agent: Let's talk about school
- 7 User: s
- 8 Agent: My school is okay, a little too much homework, wbu?

Figure 1: Example of how the agent handles utterances that are not understood.

The strategy to handle abusive utterances are similar in that the first response is general, such as "eh, let's talk about something else", followed by two attempts to change the topic, randomly done either by a general request for the user to suggest a topic or by the agent to introduce a new topic, followed by a remark that further abuse will result in a report to the teacher. If the user continued with abusive utterances the loop starts again

To avoid repetitive utterance sequences such as many greetings, laughs or acknowledgements in a row, the agent initiated new topics when those types of utterances were repeated. The AIML parameter topic was used to handle delayed follow-up questions from the user. The topic model used for this purpose was extended to include a total of

15 topics, where some were related, for example music and favourite artist.

Evaluation of the prototype was conducted in the same way as for prototype 1. This time with 42 users, 22 girls and 20 boys. Analysis of the chat logs revealed that the model for follow-up questions needed to be revised. Since follow-up questions were initiated randomly by the agent it sometimes asked for information the user already had provided, which seemed to irritate the user. The model for topic initiation by the agent could also be refined to provide more coherence in the dialogue. Another problem detected was that the strategy to use the current topic as context to interpret generic follow-up questions sometimes was overused and led to misunderstandings when the user tried to introduce a new topic. The agent thus needed a more sophisticated strategy to handle topics and topic shifts.

## Prototype 3

The main improvements of prototype 3 was the introduction of mini narratives, an improved strategy for follow-up questions and an improved strategy to introduce and continue a topic. For three main topics, free time, music and school, sub-topics were added, and when the agent took the initiative it tried to stay within topic and either tell a mini-narrative or introduce a sub-topic. Follow-up questions were now only posed if the user had not already provided answers to the question earlier in the conversation.

The conversational agent was evaluated at a Swedish School, where 19 students, from three classes, 12-14 years old, used the learning environment with the conversational agent during three lectures. The students played the game for about a total of 120 minutes and after every second game session a break was offered. During the first three breaks the students had to chat with the agent until the break ended, after that chatting was optional.

Table 1 shows the proportion of different types of user utterances in the logged conversations. The coding scheme is based on the coding schemes used by Robinson et al. (2010) to evaluate virtual humans. As can be seen in Table 1 most user utterances are "appropriate" in that they are either Information requests (Q), Answers (A), General dialogue functions (D) or Statements (S), but a total of 22% are "inappropriate", i.e. Incomprehensible

(G) or Abusive (H).

Table 1: Dialogue action codes and proportion of different agent utterances.

Code	Description	Prop
D	General dialogue functions, e.g. Greeting, Closing, Politeness	14%
H	Hazing, Testing, Flaming, e.g. Abusive comments and questions	11%
Q	Information Request, e.g. Questions to the agent	31%
R	Requests, e.g. Comments or questions that express that the user wants help or clarification	0%
A	Answer to agent utterances	18%
S	Statements	16%
G	Incomprehensible, e.g. Random key strokes or empty utterances	11%

As for the agent's responses it seems that the system handles most utterances appropriately although many of these are examples of requests for repair, see Table 2. The highest value 3, i.e. appropriate response, means that the agent understood the user and responded correctly. Request Repair, is when the system does not understand and asks for a clarification or request that the user changes topic. Partially appropriate, code 2, is typically used when the user's utterance is not understood by the agent, and the agent's response is to initiate a new topic. Inappropriate response, code 1, is when the system responds erroneously, typically because it has misinterpreted the user's utterance.

Table 2: Agent response codes and proportion of different agent responses.

Code	Description	Prop
3	Appropriate response	51%
2	Partially appropriate	15%
RR	Request Repair	30%
1	Inappropriate response	4%

Given a definition of Correct Response as any response that is not inappropriate, code 1 in Table 2, we see that prototype 3 handles 96% of the user's utterances appropriately or partly appropriate. The proportion of responses where the system correctly interprets the user's utterance is, however, only 54%, and there are still 11% Flaming/Hazing which also affects the number of repetitions, which is very high. Most of the not correctly interpreted utterances and the repetitions, occurs when the student is hazing/flaming or testing the system, e.g. none of the user's utterances

in Figure 1 is correctly interpreted (code 3) but all are correctly responded to (code 2).

## Prototype 4

The evaluation of prototype 3 did not indicate any need for more sophisticated dialogue functions but rather that the number of correctly interpreted utterances needed to increase. Therefore the focus of prototype 4 was to add and refine patterns used for interpretation of user utterances, for example adding more synonyms and expressions. It also included adding answers to some questions related to the already present topics, for example, questions on the agent's last name and questions and comments about game play. Since prototype 3 still had problems with a lot of abusive comments prototype 4 also included a revised strategy to handle abusive utterances, where the agent gradually tries to change the topic and finally stops responding if the abuse continues to long. If and when the user changes topic the strategy is reset.

The evaluation of prototype 4 comprise conversations with 44 students, 12-14 years old. The students used the system more than once which gives us 149 conversations with a total of 4007 utterances of which 2003 are from the agent. Each utterance was tagged with information about, dialogue function, topic, initiative, agent interpretation, agent appropriate response, and abuse.

Many of the utterances that the agent could not correctly interpret in prototype 3 were due to the fact that users did not engage in the conversation and did not cooperate, rather they were testing the agent, abusing it or just writing nonsense. We believe that the strategies we have developed to handle such utterances are more or less as good as a human. For the evaluation of prototype 4 we therefore modified the criteria for tagging an utterance as appropriate. An utterance was only appropriate if the agent responded as good as a human, taking into account that if a user utterance is very strange, a human cannot provide a very good answer either, see Table 3. In this new coding scheme we also removed the previous category RR where utterance that request repairs falls into R3 (if a human could not interpret the user utterance neither) or R2 depending on how appropriate they are in the context.

There are also cases when the agent's response may have been better if it was a human, but where it is not obvious how, or even that a human could

Table 3: Agent response values.

Code	Value
R3	Agent responses that a human could not have done better
R2	Agent responses that are ok but a human may have responded better
R1	Agent responses that are erroneous because the agent did not understand the student or misunderstood

do better. We tag these R2 as well not to give credit to the agent for such responses.

Table 4 shows topics with information on how many utterances in total belonged to each topic, and how well the agent responded to utterances within each topic (R1, R2 or R3), as well as the proportion of not appropriate or only partially appropriate responses in percentage. NO TOPIC is for utterances like greetings, requests for repair, random letters or words, and abuse. As can be seen in Table 4 the agent gives appropriate responses (R3) to 1399, i.e. 70%, of the users' utterances. Table 4 lists all the topics present in the corpus and shows that although given the opportunity to talk about anything, users tend to stick to a small number of topics.

Table 4: Topics present in the corpus and the number of appropriate responses (R3), partially appropriate response (R2), and non-appropriate responses (R1).

TOPIC	Tot	R3	R2	R1	Prop R1 + R2

TV	2	1	1	0	50%
<b>Total</b>	<b>2003</b>	<b>1399</b>	<b>494</b>	<b>110</b>	<b>30%</b>

To further investigate the utterances causing problems we looked at the responses tagged as R1

and R2 and classified them as caused by greetings (GREETING), questions (QUESTION), statements (STATEMENT) or utterances where correct interpretation depends on the dialogue history (HISTORY). The proportions of problematic utterances and the dialogue functions of these utterances are shown in Table 5.

Over half of the problematic utterances are questions. Of these the majority are regular questions, while 30% of them are specific follow up questions on a previously introduced topic. A small number are generic follow up questions either directly following an answer to a question posed by the agent (Agent: Do you like school?, User: yes, wbu?), or a free standing delayed question (Agent: Do you like school? User: Yes. Agent: ok, User: wbu?). Statements are causing 29% of the not appropriate answers, mainly statements and answers to questions. There are also some abusive comments and random utterances. Problems related to the dialogue history is comparatively small. It includes both answers, statements and different kinds of questions. Examples of utterances the agent cannot handle well are follow up questions on topics previously introduced by the agent or the user, statements that comment on previous answers, use of anaphora referring to previous questions or answers, users' attempt to repair when the agent does not understand, and delayed answers to questions asked more than one utterance before.

From Table 6 we see that most of the problems relate to a small number of topics. PERSINFO, FREETIME and MATHGAME have mainly problems with statements and questions. The agent has for example insufficient knowledge and ability to talk about the math game itself. It also lacks knowledge about personal information such as hair colour, eye colour and other personal attributes. MUSIC and SCHOOL are common topics where the user often tries to make follow up topics that the agent cannot handle.

## Conclusions

We have worked iteratively with user centred methods and rather straightforward natural language processing techniques to develop a social conversational module for a pedagogical agent aimed at students aged 12-14 years. The importance of involving students in the development process cannot be underestimated. Initially they

gave us valuable insights on the capabilities of an agent capable of social conversation. In the iterations to follow they provided feedback on how to refine the conversation to handle both "normal" conversation as well as not so conventional conversation. Using questionnaires to measure system performance or as an instrument for further development is not fruitful (Silvervarg and Jönsson, 2011). We have instead relied on analysis of the

logs to find bugs, and detect patterns that suggest lack or sophistication of dialogue capabilities that should be added or refined.

The strategy has been fairly successful. We seems to have captured what users talk about very well. The number of topics is surprisingly small given that the user can introduce any topic they want. A possible improvement could be to include a more elaborate model for topics and subtopics for some topics. There are also still knowledge gaps concerning some questions within topics, such as personal attributes and traits of the agent.

How they talk about the topics are also fairly well understood, in that the dialogue capabilities needed have been discovered and implemented. It may be that addition of anaphora resolution could improve the agents responses, but that would probably be a marginal improvement, since problems related to anaphora are very rare. Some of the problems are related to the large variation of how the same question or statement can be expressed, and the limited power of interpretation based on keywords, but this does not seem to be a big problem. The same can be said for spelling mistakes. Inclusion of an automatic spellchecker may increase the successful interpretations, but probably only to a small degree.

A remaining problem that is hard to address is the fact that some users are very uncooperative. They deliberately test the system or are just not engaging in the dialogue but rather write nonsense or abuse. Previous studies have shown that there seem to be three types of users (Silvervarg and Jönsson, 2011): 1) those that really try to use the system and often also like it, 2) users that do not use the system as intended, but instead tries to find its borders, or are bored and never tries to achieve an interesting dialogue, but rather resorts to flaming/testing/hazing, and 3) those that are in between. Users of type 1 are rather unproblematic, as long as the agent has enough topics and sub-topics they will have a meaningful conversation. Users of type 2 will probably never be engaged in a meaningful conversation with the agent no matter how sophisticated it is. Focus must instead be to avoid users of type 3 to adhere to type 2 behaviour, which could be achieved by having a variety of techniques to handle abusive and testing behaviour and enough topics and sub-topics to allow for a varied enough conversation, as presented in this paper.

## Abstract

In this paper, we propose a morphological disambiguation method for Turkish, which is an agglutinative language. We use a hybrid method, which combines statistical information with handcrafted rules and learned rules. Five different steps are applied for disambiguation. In the first step, the most likely tags of words are selected. In the second step, we use handcrafted rules to constrain possible parses or select the correct parse. Next, the most likely tags are selected for still ambiguous words according to the suffixes of the words that are unseen in the training corpus. Then, we use transformation-based rules that are learned by a variation of Brill tagger. If the word is still ambiguous, we use some heuristics for the disambiguation. We constructed a hand-tagged dataset for training and applied a ten-fold cross validation with this dataset. We obtained 93.4% accuracy on the average when whole morphological parses are considered in calculation. The accuracy increased to 94.1% when only part-of-speech tags and inflections of last derivations are considered. Our accuracy is 96.9% in terms of part-of-speech tagging.

## 1 Introduction

Digital text sources increase every day and people can reach digital sources via Internet. The automatic processing of these sources becomes crucial in order to use and manage them effectively. Many NLP researchers work on different topics like summarization of texts, translation between natural languages, information extraction, etc. However, working on natural languages has difficulties due to their ambiguous natures. Since constraining possible morphological parses of words with disambiguation methods reduces the ambiguity problem, morphological disambiguation is crucial for performing better operations on texts.

In this paper, we propose a method for morphological disambiguation of Turkish texts.

Turkish is an agglutinative language. Agglutinative languages generate words by joining affixes together and each affix represents one unit of meaning. This property loads many meanings to a single word. Since suffixes can increase the ambiguity by generating totally different words, the morphological analysis of words with many suffixes is much harder.

Our hybrid system uses statistical knowledge, learned transformation-based rules, handcrafted rules and some heuristics in the disambiguation process. In our system, we first obtain the statistical information about words and suffixes like frequencies of their corresponding morphological parses and learn transformation-based rules. In disambiguation, we use an iterative approach that applies techniques from the most reliable technique to the less reliable technique. First, if the word exists in our training set, we select the morphological parse with the highest frequency. Then, we consider handcrafted rules of SupervisedTagger software (Daybelge and Cicekli, 2007) for disambiguation. Next, we use statistical information about suffixes and select the morphological parse with the highest frequency in the corpus for that suffix. Then, we apply the disambiguation rules learned from the corpus. Finally, we use some heuristics, which depend on some statistical information to select morphological parses for still ambiguous words.

The major contribution of this study is our hybrid morphological system, which combines the statistical, and rule based approaches for disambiguation. The accuracy of our hybrid disambiguation system is quite good when examined with the Turkish language which has a very flexible set of grammar rules and very ambiguous words. Our combined approach works very well even with less statistical language sources such as a small hand-tagged corpus. Although the size of our hand-tagged corpus is relatively small, the performance of our hybrid system is very good. The performance of the presented hybrid system

can be improved further when a bigger hand-tagged corpus is available.

The rest of the paper consists of four sections. Section 2 describes the related work in morphological disambiguation. Section 3 explains the proposed system. Section 4 describes the corpus and presents the performance results of the system. Section 5 concludes the paper by summarizing the study and discusses some future work.

## 2 Related Work

The related work about morphological disambiguation can be divided into three categories: statistical, rule based and hybrid which is the combination of the two approaches. Statistical approaches select the morphological parses using a probabilistic model that is built with the training set consisting of unambiguously tagged texts. There are various models used in the literature, such as, maximum entropy models (Ratnaparkhi, 1996; Toutanova and Manning, 2000), Markov Model (Church, 1988) and hidden Markov Model (Cutting et. al., 1992). In rule based methods, hand crafted rules are applied in order to eliminate some incorrect morphological parses or select correct parses (Daybelge and Cicekli, 2007; Oflazer and Tür, 1997; Voutilainen, 1995). These rules can also be learned from a training set using a transformation based (Brill, 1995) or memory based (Daelemans, 1996) learning approaches. There are also studies that combine statistical knowledge and rule based approaches (Leech et al., 1994; Tapanainen and Voutilainen, 1994; Oflazer and Tür, 1996).

The disambiguation studies can also be divided according to the languages they are applied. Levinger et al. (1995) used morpho-lexical probabilities learned from an untagged corpus for morphological disambiguation of Hebrew texts. Hajic and Hladká (1998) used maximum entropy modeling for Czech, which is an inflectional language. Morphological disambiguation of agglutinative languages, such as Turkish, Hungarian, Basque, etc., is harder than others because they have more morphological parses per words. Megyesi (1999) has used Brill's POS tagger with extended lexical templates to Hungarian. Hajic (2000) extended his work for Czech to five other languages including Hungarian. Ezeiza et al. (1998) combined statistical and rule based disambiguation methods for Basque. Rule based methods (Oflazer and Tür, 1997; Daybelge and Cicekli, 2007) and trigram-based statistical model (Tür et al., 2002) are used for the disambigua-

tion of Turkish words. Yüret and Türe (2006) propose a decision list induction algorithm for learning morphological disambiguation rules for Turkish. Sak et al. (2007) apply perception algorithm in disambiguation of Turkish Texts.

## 3 Disambiguation System

A Turkish word can have many morphological parses containing many morphemes that give us morphological information about the word. For example, the word "çiçekçi" (florist) has the following *morphological parse* (MP)<sup>1</sup>:

$$\begin{aligned} & \text{çiçek+Noun+A3sg+Pnon+Nom} \\ & \quad \wedge \text{DB+Noun+Agt+A3sg+Pnon+Nom.} \end{aligned} \quad (1)$$

The first part gives us the stem, which is "çiçek" (flower). We define the rest of the parse as the *whole tag* of the word. In parse, " $\wedge$ DB" shows that the word is derived from one type to another and its meaning has changed rather than its inflection. We define the final morphemes after the last derivation as the *final tag* of the word. For this example, the whole tag is:

$$\begin{aligned} & \text{Noun+A3sg+Pnon+Nom} \\ & \quad \wedge \text{DB+Noun+Agt+A3sg+Pnon+Nom,} \end{aligned} \quad (2)$$

and the final tag is:

$$\text{Noun+A3sg+Pnon+Nom}$$

where the type of derivation "Agt" is ignored. The rules that are learned by our system depend on morphological parses, whole tags or final tags of words.

Our disambiguation system consists of two main parts: *training* and *disambiguation*. The training corpus is used for the induction of disambiguation rules and the generation of the tables *Most Likely Tag of Word Table* (WordTbl) and *Most Likely Tag of Suffix Table* (SuffixTbl). WordTbl is used to retag the corpus by our Brill tagger in order to learn rules. WordTbl, SuffixTbl and the learned rules are used in the disambiguation process.

The first table (WordTbl) holds frequencies of all morphological parses of words, and the second one (SuffixTbl) holds the frequencies of all possible morphological parses for suffixes. Of course, WordTbl also indicates most likely morphological parses of words since the highest frequency morphological parse is the most likely parse. Since all possible Turkish words cannot be seen in a training corpus, WordTbl will not hold most likely parses for all words. In order to make

<sup>1</sup> Noun is a major word category; A3sg is a noun agreement marker; Pnon is a noun possessive marker; Nom is a noun case marker; derivational boundaries are marked with  $\wedge$ DB.

an intelligent guess for the most likely parse of an unseen word, we use its suffix. For this purpose, we create SuffixTbl. In order to create SuffixTbl, we find suffixes of words according to their correct morphological parse and calculate the frequencies for tags corresponding to suffixes. For example, the suffix of the word “çiçekçi” (florist) whose morphological parse is given in (1) is “çi” and its corresponding whole tag is given in (2). We find frequencies of all corresponding whole tags for suffixes to store them in SuffixTbl.

### 3.1 Learning disambiguation rules

In order to learn disambiguation rules, we use a variation of Brill tagger. After all words in the training corpus are initially tagged with their most likely parses using WordTbl, disambiguation rules are learned. The learned disambiguation rules are based on morphological parses, whole tags, or final tags. The general format of a disambiguation rule is as follows:

*if* conditions *then*  
*select* MPs containing TAG for  $word_i$

The conditions of a rule depend on the possible MPs of the target word  $word_i$  and the current selected MPs of the previous (or following) one or two words. Thus, the conditions of a rule can be one of the following:

- $wordC_i$  **and**  $wordC_{i-1}$
- $wordC_i$  **and**  $wordC_{i-1}$  **and**  $wordC_{i-2}$
- $wordC_i$  **and**  $wordC_{i+1}$
- $wordC_i$  **and**  $wordC_{i+1}$  **and**  $wordC_{i+2}$

Each condition  $wordC_k$  is in the following form:

TAG of  $word_k = TAG_a$

TAGs appearing in the conditions or the MP selection part of a rule can be MPs, whole tags, or final tags.

In the learning of disambiguation rules, a variation of Brill tagger (Brill, 1995) is used. All possible rules are tried in order to select the rule that gives the best improvement. After applying the selected rule, we repeat the process in order to infer the other rules. These iterations end if there is no progress or the improvement is below a threshold. In the selection of the best rule, our method differs from the original Brill tagger. We select the rule with the highest precision as the best rule in iterations. For example, if rule A causes 100 correct tags and 1 wrong tag and rule B causes only 10 correct tags without any wrong tags, the original Brill tagger may choose the rule A for that iteration. However, we select rule B

because it causes no mistakes. The reason for this approach is that we want to increase the correctness of the condition words in the rule applications for later steps of the algorithm, and mistakes in early stages can cause more mistakes in further steps.

The rules are learned using the dataset of 25098 hand-tagged words. After tagging all words in the training set with their most likely tags, we infer the best rule at each iteration step of the algorithm. We generate all possible rules from all the words in the dataset. After generating all rules, we select the rule with the highest precision as the best rule. If there is more than one rule with the highest precision, we select the one, which affects more words. When there is more than one rule with the highest precision and they affect the same number of words, we select any one of them. We applied ten-fold cross-validation for experiments. In the training part of the experiments, we have learned 395.2 rules on average.

### 3.2 Morphological Disambiguation

In the morphological disambiguation of Turkish words, we have used a hybrid disambiguation system, which uses statistical techniques, rule based techniques and some heuristics. After the given Turkish text is morphologically analyzed by a Turkish morphological analyzer, the hybrid disambiguation steps are applied.

In the morphological analysis of a given Turkish text, SupervisedTagger software (Daybelge and Cicekli, 2007) which uses a PC-Kimmo based morphological analyzer (Istek and Cicekli, 2007) is used. SupervisedTagger contains a morphological analyzer and a rule-based morphological disambiguation tool. The morphological parsing capability of SupervisedTagger is improved by using an updated unknown word recognizer and new heuristics for proper nouns and foreign words. If a word begins with a capital letter and it is not the first word of the sentence, it is assumed that it has also a proper name morphological parse even though it is not in the proper name list. In addition, the words that are not correct according to the Turkish grammatical rules are assumed to be foreign words that have proper name morphological parse. By these extensions, the average number of morphological parse per word is increased from 1.8 to 2.0.

In our hybrid disambiguation tool, we use the statistical information in tables WordTbl and SuffixTbl, hand-crafted rules of SupervisedTagger, rules learned by our Brill tagger and

some fall-back heuristics. The disambiguation algorithm consists of five major components:

- *Selection of the Most Likely Tag of Word*
- *SupervisedTagger Disambiguation*
- *Selection of the Most Likely Tag of Suffix*
- *Application of the Learned Rules*
- *Selection with Fall-Back Heuristics.*

The system tries to find the correct morphological parses step by step using the components in the given order. Correct parses of words can be selected or ambiguity levels of words can be reduced by eliminating some illegal parses. But words can be still ambiguous after intermediate steps. After the last step *Selection with Fall-Back Heuristics*, a single morphological parse will be definitely selected for each word.

#### ***Selection of the Most Likely Tag of Word (MW)***

- The statistical information in WordTbl helps us to find the most likely parses of words appearing in the training set. If the word exists in WordTbl, the most frequent parse is selected for that word. Since not all words appear in the training set, some words will be still ambiguous at the end of this step. WordTbl may not contain all words because our training data set is small, and the number of unique Turkish words is huge. In one of our experiments, we determined that the number of unique words is 870,000 in a 6 billion word Turkish corpus. In fact, this is one of the reasons that we decided to use a hybrid approach for the morphological disambiguation.

***SupervisedTagger Disambiguation (ST)*** – In this step, the words are tried to be disambiguated by SupervisedTagger software. Supervised-Tagger uses 342 hand-coded disambiguation rules of two types: *selection* and *elimination* rules. The selection rules select a morphological parse directly. The elimination rules eliminate the wrong ones as much as it can. In other words the selection rules completely disambiguate words, and the elimination rules reduce the ambiguity levels of words. SupervisedTagger is applied only to ambiguous words. At the end of this step, there can still be ambiguous words but the ambiguity level can be reduced by the rules of SupervisedTagger.

#### ***Selection of the Most Likely Tag of Suffix (MS)***

– If the word is not disambiguated by the first two steps, we try to disambiguate using the statistical information in SuffixTbl. The possible suffixes of a word are determined according to its morphological parses, and the most likely morphological parse corresponding to those suf-

fixes is selected if the suffixes appear in SuffixTbl. The word may not be disambiguated at this step because of the huge number of possible suffixes. In one of our experiments, we also determined that the number of unique suffixes is 40,000 in a 6 billion word Turkish corpus.

***Application of the Learned Rules (LR)*** – It can be considered that tagging words according to their frequency is not correct. In this step, we are trying to correct our mistakes and handle special cases by applying the rules that are learned by our Brill tagger. The order of rule application is the order of learning. The condition part of a rule contains a condition depending on the target word of the rule, and one or two more conditions depending on other condition words. A rule can be applicable to a target word if all of the following conditions are satisfied:

- Its condition words are completely disambiguated and satisfy their conditions.
- The target word is disambiguated and satisfies its condition, or the target word is ambiguous and one of its still possible parses satisfies its condition.
- At least one of the parses of the target word contains the correct tag given in the selection part of the rule.

When a rule is applied, the target word can be completely disambiguated, or some of its parses are selected as its possible parses. If the target word contains only one morphological parse satisfying the correct tag, it is disambiguated; otherwise its parses satisfying the correct tag are selected as possible parses for the next step and others are eliminated. For example, the following rule is applicable under the given conditions:

***if*** (final TAG of word<sub>i</sub> = *Adverb* **and**  
whole TAG of word<sub>i-1</sub> = *Noun+A3sg+P3sg+Nom*)  
***then select*** MPs with whole tag *Adjective* for word<sub>i</sub>

If the whole tag of the selected MP of word<sub>i-1</sub> is *Noun+A3sg+P3sg+Nom*, the final tag of at least one of possible MPs for word<sub>i</sub> is *Adverb*, and word<sub>i</sub> contains at least one MP having the whole tag *Adjective*, then MPs containing *Adjective* tag are selected for word<sub>i</sub>.

***Selection with Fall-Back Heuristics (SH)*** - At this last step, a small number of words can still be ambiguous. In this step, we perform the selection with fall-back heuristics in order to disambiguate the remaining ambiguous words. We have determined the following four heuristics and applied them in the given order. The application order is determined empirically.

a) *Selection of Non-Derived (SND)* – SND heuristic selects the parses containing no derivation suffixes since non-derived words are more common than derived words.

b) *Selection of Proper Noun (SP)* - SP heuristic selects the proper noun senses of the words if their possible parses contain proper noun senses.

c) *Selection of Noun (SN)* - SN heuristic selects the parses that their part of speech tags are noun.

d) *Selection of Shortest (SS)* - After applying all techniques and heuristics, if the word is still not disambiguated, we select the shortest parse in terms of the character length.

Number of words	25098
Number of distinct words	8493
Average number of parses per word	1.982
Number of words with single parse	12260
Maximum number of parses in one word	16
Number of distinct parses	17934
Number of distinct whole tags	2052
Number of distinct final tags	343
Number of proper nouns	3305
Number of non-proper nouns	9670
Number of derived words	4772

Table 1. Statistics of Data Corpus

## 4 Evaluation

We have constructed a data corpus consisting of 25098 hand-tagged words. In the preparation of the corpus, we used Turkish texts from different news portals. Ten graduate students tagged words with correct morphological parses using SupervisedTagger software. The statistical information about our dataset is given in Table 1. There are 12 different part of speech tags which are noun, proper noun, conjunction, pronoun, adjective, question, interjection, verb, adverb, post-position, number and punctuation. The 48.8% of the corpus is unambiguous. The most ambiguous word has 16 different parses. There are 2052 distinct whole tags, which show the ambiguity problem of Turkish.

Our disambiguation system uses five different techniques (MW, ST, MS, LR, and SH) step by step. It is obvious that the order of the techniques is crucial for the performance of the system. In order to see which order gives the best accuracy, we have applied each technique separately and obtained the average accuracies by using 10 fold cross validation. In Table 2, the second column shows the average number of words having more than one parse and they are processed by the corresponding technique. The accuracy of the

technique for the applied words is given in the third column. The fourth column shows the accuracy for disambiguated words so far (disambiguated words by the technique plus unambiguous words (UW)).

Technique	# of words applied	Acc. of Tech.	Acc. of (UW+Tech.)
MW	822.8	0.916	0.966
ST	802.4	0.798	0.919
MS	872.4	0.700	0.873
LR	26.6	0.744	0.994

Table 2. Results of techniques for the first step

Since MW gives the highest accuracy, it is reasonable to choose MW for the first step. Applying the learned rules at the first step is not reasonable since there are not enough disambiguated words yet. The reason for having high accuracy so far is that we have few words that are disambiguated in the first step, and unambiguous words in the corpus increase the accuracy.

Technique	# of words applied	Acc. of Tech.	Acc. of (UW+MW+Tech)
LR	18.9	0.741	0.967
ST	260.5	0.873	0.955
MS	369.4	0.761	0.934

Table 3. Results of techniques for the second step

For the second step, we tried MS, ST, and LR. The results are given in Table 3. When we compare Table 2 and Table 3, we can see that the accuracy of techniques increased, meaning that using more reliable techniques in the early steps causes an increase in the accuracy of other techniques by eliminating words that they cannot disambiguate correctly. Applying the learned rules (LR) at this step is again the worst technique. Using ST in the second step gives a higher accuracy than using MS. It is better to disambiguate more words in earlier steps with higher accuracy since the ambiguous words will be disambiguated with less reliable heuristics unless we disambiguate them at earlier steps. Thus, we select ST as the second, and MS as the third. Since ST and MS are better than LR, LR is chosen as the 4th component. The accuracy at the end of the 4th step is 0.942.

After the applications of the first four components, there are still some ambiguous words, and the number of ambiguous words after applying MW, ST, MS and LR is 71.4 on average (2.8%).

In order to disambiguate the remaining ambiguous words, we use fall-back heuristics. Since SND-SP-SN-SS order for the fall-back heuristics produced the best accuracy, we use that order. Finally, we disambiguated all words having the accuracy of 0.934 by using the order of MW-ST-MS-LR-SH.

SupervisedTagger uses handcrafted disambiguation rules. In order to measure the performance of the statistical components of our system, SupervisedTagger component is removed. The accuracy of the overall system is dropped from 0.934 to 0.924. This means that handcrafted rules help to improve the performance of the system. We believe that the importance of handcrafted rules will reduce significantly if we train our system with a huge tagged corpus.

In the calculation of the accuracy, we consider the whole morphological parse. However, in some words, all parses have same inflections after their last derivations so that they have the same grammatical function in the sentence. In other words, they have same final tags. In the calculation of the accuracy, if we consider only the final inflections (the final tags), the accuracy of the overall system becomes 0.941. When only the final part of speech tags are considered, the accuracy becomes 0.969.

Selection						
True	Prop	Adj	Adv	Noun	Verb	
Prop	6.6	5.7	1.2	12.3	2.4	
Adj	1.3	4.2	2.0	6.0	1.5	
Adverb	0.2	3.4	1.3	2.4	0.1	
Noun	18.0	9.7	1.4	57.8	4.3	
Verb	0.9	1.5	0.0	2.2	5.1	

Table 4. The distribution of confusions

When we examined the errors of our system, we observed that most of the mistakes are in nouns, proper nouns, adjectives, verbs and adverbs. In Table 4, the distribution of wrong disambiguation is given. In the calculation, the average number of mistakes in every fold is used. We can see that adjectives are mostly confused with nouns. This is reasonable, since every adjective can also be used as noun in Turkish. Adverbs are also mostly confused with adjectives. Nouns are mostly confused with other nouns. This is an expected result since Turkish is an agglutinative language and there can be many different inflections from a stem. Verbs are most confused with verbs with different inflections. In addition, we can say that nouns are the POS tags mostly confused while adverbs are the least.

In our version of Brill Tagger we prefer the rules with minimum number of errors first instead of preferring the rules with most accuracy increase which the original Brill tagger uses. In order to see whether learning transformation based rules that cause no errors is useful or not, we defined a base method to apply our data set. In this base method, we select the most likely MP for a word from WordTbl if the word is in WordTbl. If it is not in WordTbl, the first MP for the word is selected. That is to say, the most likely MP for a word is selected randomly if it does not appear in the training corpus. Then we applied our learned rules and rules learned according to original Brill Tagger separately in order to see the difference between them. We again applied ten-fold cross validation and our variation had much higher accuracy than the original Brill Tagger.

## 5 Conclusion and Future Work

In this paper, we propose a hybrid disambiguation method that combines the statistical approaches with rule based approaches for Turkish. The first step is the selection of the most likely tags of words. If word is not disambiguated yet, we use hand-crafted rules. Then we use the most likely tags of suffixes for disambiguation. The learned transformation rules are applied in the fourth step.

For training and testing, we have constructed a relatively small corpus, which consists of highly ambiguous words. We applied ten-fold cross validation and obtained 93.4% accuracy on average when we considered whole morphological parses of words. The accuracy increases to 94.1% when final tags are considered. In addition, our accuracy is 96.9% for POS tags. When we use a huge corpus, we believe that our results will improve further.

We have used our components in different orders to see their effects. We observed that MW performs best. MS is better than ST for handling harder words. Considering ST together with the statistical approaches increases the performance of the system. The learned rules have also increased the accuracy.

Our system gives promising results in the disambiguation of Turkish words. Enlarging the corpus which will be useful for the statistical parts is left as a future work. In addition, examining different rule types and learning methodologies are also left for future work.

# A Dynamic Confusion Score for Dependency Arc Labels

Sambhav Jain and Bhasha Agrawal  
Language Technologies Research Center  
IIIT-Hyderabad, India

{sambhav.jain, bhasha.agrawal}@research.iiit.ac.in

## Abstract

In this paper we propose an approach to dynamically compute a *confusion score* for dependency arc labels, in typed dependency parsing framework. This score accompanies the parsed output and aims to administer an informed account of *parse correctness*, detailed down to each edge of the parse. The methodology explores the confusion encountered by the oracle of a data driven parser, in predicting an arc label. We support our hypothesis by empirically illustrating, for 20 languages, that the labels with a high confusion score are notably the predominant parsing errors.

## 1 Introduction

Recently, a major research drive has been towards building data driven dependency parsers for various languages. Shared tasks like CoNLL-X and CoNLL 2007 have acted as development and testing grounds for various efforts in the field. The majority of the emerged systems follow either *graph based paradigm* (McDonald et al., 2005; McDonald and Pereira, 2006) eg. MST Parser (McDonald et al., 2005) or *transition based paradigm* (Yamada and Matsumoto, 2003; Nivre and Scholz, 2004) eg. MaltParser (Nivre et al., 2007).

A time complexity relatively lower than their earlier counterparts makes the above parsers apt for use by real time NLP applications like Machine Translation (Galley and Manning, 2009). However, Popel et al. (2011) in the context of MT pointed out that an incorrect parse can hurt the accuracy of output. Thus, correctness of individual parses becomes a key factor in such a setup.

This calls for measures which can indicate upfront the quality of each individual output. A relevant work in this direction is by Mejer and Crammer (2012). They proposed methods to estimate

*confidence of correctness* of predicted parse in a graph based parsing scenario using MSTParser. Graph-based and transition-based parsers exhibit two very distinctive approaches towards parsing, each having its own strengths and limitations (McDonald and Nivre, 2007; Zhang and Clark, 2008). The diversity in the two techniques motivated us to explore and formulate a similar measure in transition based paradigm. We choose MaltParser<sup>1</sup> (Nivre et al., 2007), which produces a parse tree using a *shift-reduce* based transition algorithm, to work with. It uses *SVM* to train an oracle to predict parsing action. The measures proposed by Mejer and Crammer (2012) can not be straight off applied in transition based parsers, as unlike the graph based approach they commit local operations and thus can not directly produce globally optimum k-best parses.

We propose computing an entropy based label confusion score, dynamically computed and assigned while parsing (the computational details are presented in section 2 of this paper). Since entropy measures the uncertainty in a random variable, we prefer to call the measure, in our approach, *confusion score*. This measure aims to give a more informed picture of the parsed output.

We integrated our approach on top of the current functionality of MaltParser, adjusting it to accredit a confusion score with each arc label predicted in the output. Figure 1 depicts a typical parse from our proposed system where each arc label has been designated a confusion score.

The measure can also be utilized to flag potential *incorrectly parsed edges* which later, can either be manually corrected or altogether discarded (to fall back on lower level but more accurate features). We empirically illustrate in section 4, that such a score can be effectively used for automatic error detection in parsed outputs and guide manual

<sup>1</sup>MaltParser version 1.7 from <http://www.maltparser.org>

Figure 1: A dependency parse tree with edge confusion score. '#' represents incorrect arc label.

correction.

## 2 Dynamic Confusion Score

MaltParser outputs a single best parse by greedily choosing parsing actions advocated by an oracle trained on the training data. In a typed dependency framework, the parser performs two distinct kinds of actions; attachment of vertices and assigning arc labels to edges. MaltParser provides a choice<sup>2</sup> to train separate oracles for these two kinds or a single oracle that jointly predicts attachment and arc label.

In case of separate oracles for attachment and label prediction, the parser queries the attachment oracle until a *Left Arc* or *Right Arc* action is predicted. The label oracle is then queried for an arc label in the given context. There is further a provision for having a separate oracle for *Left Arc* and *Right Arc* label prediction. Nevertheless, an oracle is always queried for a parsing action against a given context.

### 2.1 Uncertainty in Label Prediction

The problem of predicting arc label correctness can mathematically be posed as follows: For random variables  $X$  and  $Y$  representing context and parsing-actions respectively; an oracle  $\phi$  is defined such that  $\phi : X \rightarrow Y$ . Here,  $Y$  is always a closed set, comprising permissible parser actions. The uncertainty in predicting  $Y$  to one of its possible values  $y_1, \dots, y_n$  can be attributed as the confusion, the oracle has in prediction. It is known that entropy is a measure of the uncertainty in a random variable (Ihara, 1993). Thus, this uncertainty can be quantitatively determined by  $entropy(H)$  calculated by the following formula

$$H(Y/X) = - \sum_{i=1}^n p(y_i/X) \log p(y_i/X) \quad (1)$$

<sup>2</sup><http://www.maltparser.org/userguide.html#predstrate>

were  $p(y_i/X)$  is the posterior probability of  $y_i$  being predicted as the parsing action in the given context  $X$ . The higher the entropy, the more uncertain the oracle is about the prediction.

However, there is no readily available provision indicating the magnitude of confusion the oracle encounters during prediction. The rest of this section presents a sequential account of our approach.

### 2.2 SVM based Oracle

The oracle discussed earlier, is a multiclass classifier which predicts a transition action based on the context. MaltParser employs Support Vector Machine (Cortes and Vapnik, 1995) for classification and provides an option between LIBSVM (Chang and Lin, 2011) and LIBLINEAR (Fan et al., 2008) to build the classifier(s). Both implement “*one-vs-one multi-class classification*” method which incorporates  ${}^nC_2$  binary models ( $n$  denotes number of classes), one for each distinct pair of classes. Prediction is done by voting among these binary classifiers and the class with maximum votes is emitted as decision class. This method does not exert any sort of probabilities and in our scenario we seek posterior probability estimates of the classes.

### 2.3 Posterior Probabilities

Platt et al. (1999) showed that posterior probabilities can be estimated in SVM by training the parameters of an additional sigmoid function to map the SVM output into probabilities. Later, Wu et al. (2004) extended the idea for multiclass probability estimates by combining pairwise class probabilities. In our work, we utilize the second method (proposed in Wu et al. (2004)), which suggests the following optimization formula:-

$$\min_p \sum_{i=1}^k \sum_{j:j \neq i} (r_{ji}p_i - r_{ij}p_j)^2$$

$$\text{subject to } \sum_{i=1}^k p_i = 1, p_i \geq 0, \forall i$$

where,

$k$  = total classes,

$r_{ij}$  = probability of  $i$  in binary classifier with classes  $i$  &  $j$ ,

$p_i$  = probability of  $i$  in multiclass estimation

The solution to above optimization, furnishes multiclass estimation of probability for each class.

## 2.4 Entropy as Confusion Measure

Now, with the available class posterior probabilities, entropy based confusion measure is computed using equation 1. The base of the  $\log$  is the number of label classes which ensures the entropy to be in the range of 0 to 1. Confusion score for arc label would require querying the arc label oracle, and thus MaltParser must be configured to deliver separate oracles for attachment and arc label in the training phase.

## 3 Extendibility of the Confusion Score

This section presents the possible extensions and constraints of the proposed score.

### 3.1 Extension to Full Parse Confusion

The confusion score in the proposed approach is calculated separately for each arc label. Calculation of a confusion score for a full parse can be done by taking an average over the edges in the parse. Other measures like average of worst  $k$  labels, score of worst label itself, etc. can also be adopted. This enables visualization of the confusion for the complete parse tree. This can be apt in the scenario of a large collection of parse trees, such as treebanks and also for applications like Active Learning (Tang et al., 2002; Hwa, 2004).

### 3.2 Extendibility to Other Algorithms

Since our method executes at the oracle level, it is independent of the algorithmic choice used in the parser. Also, pseudo projective transformation (Nivre and Nilsson, 2005) too is an extrinsic process, so non-projectivity does not perturb our approach.

### 3.3 Extendibility for Attachments

The approach, at first, may seem extendable to attachments also since it would require querying the attachment oracle for attachment confusion. However it is not extendable to edge correctness prediction. The restricting factor being the presence of non-labeling parser action i.e. *Shift* and *Reduce*. Since these transitions are not decomposed over the tree edges, the oracle confusion associated with them can not be delineated to any edges. For example, at a given point in the parsing process, assuming the arc-standard system (but the same holds for other algorithms also), the oracle will need to decide if it should perform a *Left*,

Figure 2: Precision, recall and  $f$ -score for various values of confusion score on ‘Hungarian’ development set.

*Right* or *Shift* action. This decision will influence not only the single edges added by the left or right operation, but also other, future edges. It should be noticed that the Shift action will not add any edge, but will have a very complex effect on the set of edges that could or could not be added in the future. Thus, the entropy of this particular decision cannot be attached to any specific final edge and hence the methodology can not be extended to arc-attachments.

## 4 Error Detection in Parser Output

In this section, we empirically illustrate the efficacy of our proposed measure in automatic error detection and guiding manual error correction.

### 4.1 Automatic Error Detection

Automatic error detection aims to efficiently determine and flag incorrectly predicted edges. The edges exhibiting a high confusion score are also highly probable to be incorrect, as the oracle is uncertain in its decision. Using this insight, an edge-label is flagged as potential error if its confusion score is above a pre-calculated threshold( $\theta$ ).

In this task we have focused on the arc label correctness, i.e. we flag the edges which have a high probability for an incorrect arc label.

### 4.2 Data and Experimental Setup

We conducted experiments on 20 languages, using data from CoNLL-X (Buchholz and Marsi, 2006), CoNLL 2007 (Nilsson et al., 2007) and MTPIL COLING 2012 (Sharma et al., 2012) shared tasks on dependency parsing. We carried out experiments on the systems proposed in Nivre et al.

Language	Threshold ( $\theta$ )	F-score (%)	Precision (%)	Recall (%)	EDI

Table 1: Language wise results for automatic error detection task. EDI x% edges= Error detected on inspecting top x% of total edges. Data Source:- ¶:CoNLL-X, #:CoNLL 2007, ♠:MTPIL COLING 2012

(2006), Hall et al. (2007) and Singla et al. (2012), which are individually, the best performing Malt-Parser based systems, in the respective shared tasks. All the results reported here are on the official test sets.

### 4.3 Identifying Optimum Threshold( $\theta$ )

Threshold( $\theta$ ) is a crucial parameter in the experimental setup. An optimum  $\theta$  is chosen by making use of the development set. We iteratively increase candidate values for  $\theta$ , from minimum to maximum possible value of confusion score, with an adequate interval. Corresponding to each of these values, the incorrect edges are flagged and *precision*, *recall* & *F-score* (Manning et al., 2008) are calculated. The value asserting the maximum *F-score* is chosen as the final  $\theta$ . Here for simplicity, we have used balanced *F-score*, i.e.  $F_1$ -score. However, as per the application and available resources, a relevant  $F_\beta$  can be chosen to maximize the yield on the input effort.

$$F_\beta = (1 + \beta^2) \times \frac{\text{precision} \times \text{recall}}{(\beta^2 \times \text{precision}) + \text{recall}}$$

Figure 2 depicts *precision*, *recall* and  $F_1$ -score corresponding to each candidate value

of  $\theta$  for Hungarian development data. The maximum  $F_1$ -score is attained at 0.36 which is thus taken as the final  $\theta$  for Hungarian.

Since, CoNLL-X and CoNLL 2007 datasets do not provide development sets, we hold out random 10% sentences of a training set as development data. The remaining training data is utilized to train a parser and identify an optimum threshold on the development set, as explained earlier. However, the final training is performed on the entire training data and evaluated on the test set.

### 4.4 Results and Discussion

Table 1 exhibits the results obtained for automatic error identification. An average  $F_1$ -score of 48.96%, *precision* of 44.19% and *recall* of 57.23% is obtained over 20 languages in the task.

To efficiently capture the efficacy of our approach, another metric is presented (columns 6-8) which corresponds to the percentage of errors detected by inspecting top 1%, 5% and 10% of total edges. The metric gives a more precise picture of the effort required to correct errors.

Our experiments indicate that on average 42.44% errors can be detected by just inspecting top 10% of total edges. This portrays that the

effort required here is one fourth as compared to that in conventional sequential correction. On inspecting top 5% and 1% of all edges, 24.00% and 5.51% errors can be detected. Best results are obtained for Japanese and Portuguese where 57.59% of errors are detected by merely inspecting 10% of total edges for Japanese, while 35.23% and 10.43% errors are detected on inspecting 5% and 1% edges respectively for Portuguese.

A comparison with Mejer and Crammer (2012) is not possible as they only give confidence scores for parent-child attachments while our approach gives confusion scores for parent-child edge's dependency label. In a typed dependency framework both attachments and labels are significant and hence our approach is complementing Mejer and Crammer (2012).

## 5 Conclusion and Future Work

This paper presents our effort towards computing a confusion score that can estimate, upfront, the correctness of the dependency parsed tree. The confusion score, accredited with each edge of the output, is targeted to give an informed picture of the parsed tree quality. We supported our hypothesis by experimentally illustrating that the edges with a higher confusion score are the predominant parsing errors.

Not only parsed output, manual treebank validation too can benefit from such a score. An n-fold cross validation scheme can be adopted, in this case, to compute and assign confusion scores and detect annotation errors. Also, this score has scope in active learning where unannotated instances exhibiting high confusion can be prioritized for manual annotation.

## Abstract

Bilingual corpora offer a promising bridge between resource-rich and resource-poor languages, enabling the development of natural language processing systems for the latter. English is often selected as the resource-rich language, but another choice might give better performance. In this paper, we consider the task of unsupervised cross-lingual POS tagging, and construct a model that predicts the best source language for a given target language. In experiments on 9 languages, this model improves on using a single fixed source language. We then show that further improvements can be made by combining information from multiple source languages.

## 1 Introduction

Supervised part-of-speech (POS) taggers perform very well in cases where substantial manually-annotated data is available, as is the case for languages such as English, Portuguese, German, French and Arabic. For example, Petrov et al. (2012) built supervised POS taggers for 22 European languages using the TNT tagger (Brants, 2000), with an average accuracy of 95.2%. However, creating annotated linguistic resources is expensive and time-consuming. Many widely-spoken languages, such as Vietnamese, Javanese, and Lahnda have little or no manually annotated data, making a supervised approach impossible.

However, parallel texts are becoming increasingly available through sources such as multilingual websites and documents, and large archives of translation memory from books, news, etc. Moreover, the number of languages with parallel data is increasing. The era of English dominating one side of parallel texts is shifting to a far wider range of languages. Parallel data can

be exploited to bridge languages, and to transfer annotated information from a highly-resourced *source* language to a lesser-resourced *target* language, to build unsupervised POS taggers (e.g., Das and Petrov, 2011; Duong et al., 2013).

One issue in building such a tagger is choosing the source language. English is commonly used, because parallel data which has English on one side is often most readily available. However, the appropriate source language might depend on the target language. For example, Snyder et al. (2008) found that a better tagger for Slovene could be built by using data from Serbian – a closely related language – than from English. Moreover, if parallel data for a target language with more than one source language is available, it might be possible to exploit this additional information; however, this issue has not been explored to date.

In this paper we build unsupervised POS taggers for 72 language pairs. We identify features based on monolingual and parallel corpora that we use to predict the best source language to build a tagger for a given target language. We show that choosing an appropriate source language can improve the accuracy of a state-of-the-art unsupervised POS tagging methodology, compared to using a single fixed source language. This prediction can be done based on features of the source and target language derived from monolingual corpora – important if parallel data is not available for our target language, and we need to choose which data to collect – although further improvements can be obtained using features based on parallel corpora. We then show that if multiple source languages are available, even better accuracy can be obtained by combining information from them.

## 2 Related work

One approach to build an unsupervised POS tagger is to *project* tag information from a resource-rich source language to a resource-poor target lan-

guage. Das and Petrov (2011) and Duong et al. (2013) both achieve state-of-the-art performance on eight European languages using this cross-lingual approach. The two approaches are similar in the following respects. First, both project tag information from source to target language, applying some kind of noise reduction along the way: Das and Petrov use high confidence alignments, while Duong et al. use high confidence sentences. Second, both use a semi-supervised method to obtain more labeled data: Das and Petrov use graph based label propagation, while Duong et al. use self-training. Finally, both apply noise reduction/filtering on the (automatically) labeled data: Das and Petrov only extract the tag dictionary from labeled data, while Duong et al. heuristically revise tags after each self-training step. Crucially, in both of these approaches, once a tagger is built from parallel data, it can be used to tag monolingual text. The method of Duong et al. is less computationally intensive than that of Das and Petrov, as the graph-based propagation algorithm used by the latter requires convex optimisation. Because of its relative simplicity, yet comparable accuracy, in this paper we extend the method of Duong et al.

Both Das and Petrov and Duong et al. exploit the Europarl Corpus with English as the source language (Koehn, 2005).<sup>1</sup> However, as recent work has shown, it is worth considering other choices of source language. For example, Snyder et al. (2008) found that the accuracy of a Slovene tagger improved by 7.7% when paired with Serbian, a closely related language, but only 1.3 percentage points when paired with English. Reddy and Sharoff (2011) and Hana et al. (2004) showed that for closely related languages, transition probabilities for an HMM tagger can be used interchangeably. This suggests that the source language might have a drastic effect on tagger performance. In this paper we investigate the problem of making a good choice of source language(s).

### 3 Parallel data

We would like to conduct experiments on a resource-poor target language, however, it would be much harder to evaluate. We instead experiment with nine languages: English, Danish, Dutch, Portuguese, Swedish, Greek, Italian, Spanish, and German. We use the JRC-Acquis corpus which provides parallel data for every pair of 22

<sup>1</sup>Das and Petrov also use the ODS United Nations dataset.

Table 2: Corpus size (number of tokens) for each language, with English as the source language. The vocabulary size for a 1M word sample from JRC-Acquis for each language is also shown.

European languages (Steinberger et al., 2006). We thus, extract a subset of 72 language pairs. It’s worth nothing that we consider  $(x-y)$  and  $(y-x)$  to be distinct language pairs. To the best of our knowledge, JRC-Acquis is the biggest corpus providing parallel data for all language pairs we consider. Table 1 shows some statistics about the data.

## 4 Features

In this section, we consider factors that influence the choice of source language. We divide the features into two categories: *monolingual features* which exploit only monolingual data, and *bilingual features* which exploit parallel data.

### 4.1 Monolingual features

**Morphological complexity.** Morphologically rich languages introduce complexity when aligning parallel data because there is much greater ambiguity in alignment. Given the reliance of our approach on alignments, morphological complexity is an important factor to consider. We can estimate morphological complexity by counting the number of types, i.e. the vocabulary size, in a fixed amount of text. Table 2 shows the vocabulary size for each language, based on a one

million word sample from JRC-Acquis (although any monolingual corpus could be used).

**Language relatedness.** Our nine languages belong to three language families: Germanic (English, Danish, Dutch, Swedish, German); Romance (Portuguese, Italian, Spanish), and Baltic (Greek). Duong et al. (2013) note that their tagger performs better on Germanic languages than that of Das and Petrov (2011), which might be because this is the same family as the source language used (English). Thus, language relatedness is an important factor to consider.

We quantify language relatedness using lexicostatistics on the Swadesh 200 Wordlist (Dyen et al., 1992). Lexicostatistics involves the judgment of a linguist about whether a given pair of words are cognates. The relatedness of two languages is just the percentage of cognates in the wordlist. Dyen et al. provides a table showing this number for all 84 Indo-European languages. We thus, extract a subset of 36 language pairs from this list.<sup>2</sup> Note that this measure is symmetric.

## 4.2 Bilingual features

**Corpus size.** The most obvious factor is corpus size. The more data we have, the better. We count the number of parallel sentences in the corpus. Table 2 shows the corpus size for each language pair with English as the source side.

**One-to-One alignment proportion.** We believe that one-to-one mappings are more meaningful for this task than many-to-one mappings. The intuition is that, if there is only one possible way to copy a tag from the source language to the target language, we can be more confident about the mapping. The proportion of 1–1 mappings is calculated using a fixed number of parallel sentences (800k sentences) for all language pairs.

**Sentence alignment score.** Sentence alignment scores are provided by the aligner for IBM Model 3. Duong et al. (2013) used these scores to rank sentences in building their tagger, showing this to be effective in choosing high quality sentences. Higher alignment scores might therefore correspond to a more accurate tagger. We use the average sentence alignment score for each language pair as a feature.

**Lexical translation entropy.** We adopt the idea of translation model entropy from Koehn et al.

<sup>2</sup>This estimate of language relatedness is not based on parallel text, and is therefore considered a monolingual feature.

(2009). However, instead of scanning all possible sentence segmentations and calculating the phrase-based entropy, we use a simpler method based on the lexical translation table. That is, the entropy for each lexical entry is calculated as

$$H(s) = - \sum_{t \in T} p(t|s) \times \log_2 p(t|s)$$

where  $T$  is the set of possible translations of word  $s$ , and  $t$  is a translation. For each language, we pick a fixed amount of text (1 million words) and calculate the average entropy for all words.

## 5 Build taggers

In this section we construct 72 taggers, using parallel data for 72 language pairs, and then evaluate the performance of each pair. We use an open source unsupervised cross-lingual POS tagger (UMPOS) from Duong et al. (2013), a state-of-the-art system. UMPOS employs the consensus 12 Universal Tagset (Petrov et al., 2012),<sup>3</sup> to avoid the problem of transliterating between different tagsets for different languages, and to enable comparison across languages.

The input for UMPOS is a tagger for the source language,  $Tagger(s)$ , along with parallel data ( $s-t$ ). The source language  $s$  is tagged using  $Tagger(s)$ , and then the tagged labels are projected to the target language  $t$ . Sentences are then ranked, and a seed model tagger  $T_0$  is built on just the high scoring sentences. By applying self-training with revision, a series of new models  $T_1, T_2, \dots, T_m$  is constructed where  $T_i$  is the tagger after  $i$  iterations. The target language tagger,  $Tagger(t)$ , is then the last model,  $T_m$ .

$Tagger(s)$  is trained from manually annotated data  $Data(s)$  which is mainly derived from the CoNLL 2006 and CoNLL 2007 Shared Tasks. Using the matching provided by Petrov et al., we map the individual tagsets to the Universal Tagset. We train a supervised POS tagger  $Tagger(s)$  on the annotated data using the TNT tagger (Brants, 2000). Table 3 shows the source and size of annotated data, and the 5 fold cross-validation accuracy of  $Tagger(s)$ , for each language.

We evaluate each  $Tagger(t)$  using  $Data(t)$ ; results are shown in Table 4. The average tagger per-

<sup>3</sup>NOUN, VERB, ADJ, ADV, PRON (pronouns), DET (determiners and articles), ADP (prepositions and postpositions), NUM (numerals), CONJ (conjunctions), PRT (particles), “.” (punctuation), and X (all other categories, e.g., foreign words, abbreviations).

Table 3: Source and size of annotated data for each language. The accuracy of each source language tagger is also shown.

formance for each source language is also given. It turns out that choosing Dutch instead of English as the source language gives the best average accuracy. The tagger performance on each target language is much better than the baseline that always picks the most frequent tag for each word.

The Greek tagger performs poorly. From Table 2, Greek is the most morphologically complex language in this set, and has the smallest corpus size, two factors which partially explain why tagger performance for Greek is low whether Greek occupies either the source or target language role.

From Table 4, it seems that taggers perform better if the source and target language are in the same language family. For example, the top four source languages for Danish are Dutch, English, Swedish, and German, and the top two source languages for Portuguese are Italian and Spanish. This confirms the intuition in adding language relatedness features in section 4.

Duong et al. (2013) used English as the source language to build taggers for the same eight other languages. The only difference between these two experiments is that Duong et al. used Europarl (Koehn, 2005) data instead of JRC-Acquis. Table 2 also compares the size of parallel data with

Language	JRC-Acquis	Europarl

de	74.0	85.4
Average	71.8	83.4

Table 5: Accuracy on JRC-Acquis and Europarl using English as the source language.

English as the source language for JRC-Acquis and Europarl. Given that Europarl is larger, higher performance is expected. Table 5 compares the tagger accuracy for each target language using English as the source language, for the two datasets. As expected, the accuracies are higher for Europarl. However, there is a strong correlation between the results for the two experiments (Pearson’s  $r = 0.7$ ). This suggests that, if we had as much data as Europarl for every language pair (not just English), we would expect all numbers in Table 4 to improve substantially (not only the first row where English is the source language).

## 6 Source language selection

In this section, using features defined in section 4 and tagger performance in Table 4, we build a model that can predict the performance of the target language tagger given a source language.

### 6.1 Individual feature correlation

Table 6 shows the Pearson’s correlation ( $r$ ) and coefficient of determination ( $r^2$ ) of each feature with tagger accuracy.

Surprisingly, the one-to-one alignment proportion is very strongly correlated with tagger performance ( $r = 0.745$ ). Lexical translation entropy

Features	$r$	$r^2$
Source vocabulary size	-0.613	0.376
Target vocabulary size	-0.202	0.041
Language relatedness	0.497	0.247
Corpus size	0.620	0.385
One-to-one alignment proportion	0.745	0.556
Sentence alignment score	0.492	0.242
Lexical translation entropy	-0.590	0.348

Table 6: Pearson’s  $r$  and  $r^2$  for each feature.

has a negative correlation, as expected, because lower entropy leads to a better alignment and therefore better tagger performance. The source language vocabulary size is highly negatively correlated, but that strong relationship is not found for the target language. This suggests that the model is not affected much by the target language, but prefers a morphologically simple source language.

Corpus size also has a high positive correlation, confirming the intuition that more data is better. This strong relationship, together with the negative correlation for morphological complexity, consolidates the explanation above about the poor performance of the tagger for Greek, where the availability of data is very limited, and where Greek has the richest morphology of any language considered.

## 6.2 Building a predictive model

In this experiment we build a model to predict the performance of a target language tagger given a source language. We fit all features into a multiple linear regression model. The  $r^2$  value improved greatly to 0.74, compared to 0.556 for one-to-one alignment proportion, the best individual feature.

We evaluate our model in a leave-one-out cross validation experiment. To build a predictive model for language  $t$ , we remove data in Table 4 associated with  $t$  and train the multiple linear regression model  $model(t)$  on the remaining data. So, given source language  $s$  and  $(s-t)$  parallel data,  $model(t)$  outputs the predicted performance of the tagger trained on  $(s-t)$  parallel data. The correlation of the predicted value with the original value (Table 4) is very high ( $r = 0.81$ ).

We also build another predictive model based solely on monolingual features (morphology complexity and language relatedness). The intuition here is that, if we want to build a tagger for a target language, but only have monolingual data for that language, what parallel data would we want to collect first? This monolingual model also shows a high correlation with the original table ( $r = 0.74$ ). If we only use language relatedness, the correla-

Figure 1: Combining multiple source languages to produce a single file.

tion is very weak ( $r = 0.13$ ), showing that language relatedness on its own is not effective at predicting the best source language.

The predicted best source language for each target language is the language predicted to produce the highest accuracy tagger. Table 7 shows the source language prediction from models exploiting all features, and only monolingual features. The Fixed model always chooses Dutch (nl) as the source language, because Dutch gives the highest average accuracy (Table 4). The Oracle model always picks the best language, and gives the upperbound for the predictive model as a point of comparison. As expected, the model exploiting all features achieves a higher average accuracy than the monolingual model, which nevertheless still outperforms Fixed (although there is some variation for individual languages). With respect to the Oracle upperbound, and Fixed baseline, the error rate reduction for the monolingual and all features models is 10.9% and 52.3%, respectively, showing the effectiveness of using a predictive model.

## 7 Multiple Source Languages

In this section, we combine information from multiple source languages to build a single target language tagger. We take a simple approach to doing so, as shown in Figure 1. Each  $s_i$  is a tagged corpus for source language  $i$ . POS tags are then projected to the target language side  $t$  for each corpus. We merge all of these partially-tagged target language corpora (in which unaligned words are untagged) to form  $T$ .<sup>4</sup> We build the target lan-

<sup>4</sup>Because the JRC-Acquis corpus consists of translations of documents into multiple languages, in some cases the same target language sentence occurs in the parallel corpus for multiple source languages. In this preliminary approach to combining information from multiple source languages, we simply treat these as different target language sentences. Because the sentences are aligned with different source languages, they might contain different partial tag information.

Table 8: Tagger accuracy when combining the 1-, 3-, 5-, and 7-best source languages. The best system for each target language is shown in bold.

guage tagger from  $T$  by adapting the method from Section 5. The typical steps for this method are (1) tag the source language, (2) project labels from the source to target language, (3) build the seed model, and (4) apply self-training with revision to produce the final model. Here we simply start from step (3) and build the seed model from  $T$ .

In these experiments we assume that when building a tagger for a target language we have access to all other source languages. Table 8 shows accuracy when combining information from the 1-, 3-, 5-, and 7-best source languages, as determined by an oracle. As more source languages are added, average accuracy increases, demonstrating that the method of Duong et al. (2013) can be substantially improved by combining information from multiple source languages. Having established this, in future work we will consider using the best languages as identified by the various feature sets. Moreover, for individual target languages, the best accuracy is not always achieved using the most source languages, suggesting that further work could be done to identify the best set of source languages. There is also a trade-off be-

tween accuracy and efficiency; taggers built from more source languages are generally slower.

## 8 Conclusions

In this paper, we have investigated the problem of choosing the best source language(s) to use in unsupervised cross-lingual POS tagging based on tag projection in parallel corpora. We have shown that our predictive model can select a source language – based on only monolingual features of the source and target languages – that improves tagger accuracy compared to choosing the single, best-overall source language. However, if parallel data is available, our predictive model is able to leverage this to select a more appropriate source language and obtain further improvements in accuracy. Finally, we showed that if multiple source languages are available, even better accuracy can be obtained by combining information from them.

Based on these findings, a synopsis for building a tagger for a resource-poor target language  $t$  is as follows: (1) if parallel data for  $t$  is unavailable, use monolingual features to predict the best source language  $s$  and collect  $(s-t)$  parallel data; (2) if there are multiple parallel corpora for  $t$ , and there is sufficient time, combine all the corpora to produce a tagger with the best expected accuracy; (3) if time is limited, use all features to identify the  $n$ -best source languages.

In future work, we would like to apply the methods described in this paper for identifying “good” source languages for other cross-lingual NLP tasks which exploit parallel data to transfer annotations between languages, including grammar induction, parsing, and morphological analysis. We further intend to expand our experiments to consider more source and target languages.

## Abstract

Information Structure (IS) determines the “communicative” segmentation of the meaning of an utterance, which makes it central to the semantics–syntax–intonation interface and therefore also to NLP. Despite this relevance, IS has not received much attention in the context of the majority of the reference treebanks for data-driven NLP that already contain a semantic and syntactic layers of annotation. We present our work in progress on the annotation of the Penn TreeBank with the thematicity dimension of the IS as defined in the Meaning-Text Theory. We experiment with tagging and transition-based parsing techniques. Especially the latter achieve acceptable accuracy with even very small training samples, which is promising for languages with scarce resources.

## 1 Introduction

The *Information Structure* (IS) (aka *Topic-Focus Articulation*, TFA (Sgall, 1967) in the Prague School and *Communicative Structure*, CommStr (Mel’čuk, 2001) in the Meaning-Text Theory) determines the “communicative” segmentation of the meaning of an utterance. This makes it central to the semantics–syntax–intonation interface (Lambrech, 1994; Hajičová et al., 1998; Steedman, 2000; Mel’čuk, 2001; Erteschik-Shir, 2007) and therefore also to NLP. However, despite its prominence, IS has been largely ignored so far in the context of the reference treebanks for data-driven NLP: Penn Treebank (Marcus et al., 1993) and its semantic counterpart PropBank (Palmer et al., 2005) for English, Tiger (Thielen et al., 1999) for German, Ancora (Taulé et al., 2008) for Spanish, etc. To the best of our knowledge, only the Prague

Dependency Treebank (PDT) (Hajič et al., 2006) is annotated with IS in terms of TFA. This is not to say that no proposals have been made for the annotation of IS in general; see, e.g., (Calhoun et al., 2005) for English, (Dipper et al., 2004) for German, (Paggio, 2006) for Danish, etc. However, in the light of the above mentioned interface, it is crucial to have the same corpus annotated with semantic, syntactic and IS structures.

In this paper, we present our work in progress on the annotation of the ConLL ’09 variant of the Penn TreeBank (PTB) (Hajič et al., 2009) with the *thematicity* dimension of Mel’čuk’s CommStr.<sup>1</sup> We have chosen thematicity because (i) it distinguishes, apart from the traditional Theme and Rheme, a Specifier element, and (ii) it is hierarchical in that a thematicity partition can be embedded into another thematicity partition. Both of these features facilitate a fine-grained communicative partition of complex utterances with subordinations and thus a more accurate and detailed projection between the different layers of the semantics–syntax–intonation interface.

Unlike most other proposals, we aim to automate the annotation procedure and experiment with tagging and transition-based parsing techniques. In this respect, our goal is similar to that of Postolache et al. (2005), who explore different classifier models for automatic labeling of tectogrammatical nodes in the PDT with Topic / Focus. But while Postolache et al. use for training 78.3% (38,737 sentences or 494,759 tectogrammatical nodes) of the TFA+tectogrammatical layer of the PDT, our training sample is infinitely smaller: we train on 360 manually annotated sentences. The purpose of the small training sample is

<sup>1</sup>It is important to note that thematicity does not intend to capture the IS in its entirety—as, e.g., Vallduví (1992)’s or Erteschik-Shir (2007)’s proposals do. It is just one of the eight dimensions of the CommStr, although the most central one.

twofold. First, to minimize the manual annotation effort, and, second, to assess whether automatic IS annotation can be bootstrapped starting from minimal resources.

In the next section, we introduce the theoretical notion of thematicity in the sense of the Meaning-Text Theory and present the criteria for the determination of its individual elements. Section 3 describes our tagging and parsing approaches to automatic annotation of thematicity. Section 4 outlines the experiments we carried out in order to assess the quality of both approaches, and Section 5, finally, discusses the outcome of these experiments and sketches some directions of future work we plan to undertake in this area.

## 2 Theoretical Background

Since its introduction by the Prague School of Linguistics (Mathesius, 1929; Firbas, 1966; Daneš, 1970), a great number of models that define and determine the IS of an utterance have been proposed; for an overview, see, e.g., (Vallduví, 1992; Mel'čuk, 2001; Kruijff-Korbayová and Steedman, 2003; Zimmermann and Féry, 2009). In our work, we draw upon Mel'čuk (2001)'s model, which foresees a tripartite communicative segmentation of the meaning of an utterance: Theme–Rheme–Specifier. The Specifier (SP) sets up the context of the utterance *U*; Rheme (R) denotes the part of *U* that the speaker presents as stated by *U*; and Theme (T) denotes that part of *U* that the speaker presents as something about which R is stated.<sup>2</sup> T and R (also referred to in the literature as *topic/focus* and *topic/comment*) constitute the *Communicative Core* (CC) of a sentence.

The basic unit that we annotate with SP/T/R tags is a *proposition*. A proposition (P) is either a *full clause*, i.e., a clause that contains a finite verb, or a *reduced clause*, i.e., a clause with elision of the corresponding finite verb (as *up 150 in Mitsubishi Estate ended the day at 2680, up 150*). The following assumptions hold: (i) each P possesses a CC; (ii) if a sentence is composed by a coordination of Ps (each with its own subject), no global CC is assigned: each of the Ps has its own CC, with the coordinative conjunction as the SP of the second P; (iii) two non-coordinated Ps (each holding an independent CC, with the subordinated

conjunction as SP) form a global CC such that the one that comes first is T and the other one is R; if their linear order is altered, the T/R assignment switches although the meaning remains the same; (iv) if a sentence contains a main P and a relative subordinate P, one main CC is assigned (without taking into account the presence of the relative clause), and at the same time an embedded CC is assigned to the subordinate proposition. That is, as already mentioned in Section 1, thematicity in the Meaning-Text Theory is *per se* hierarchical in that each thematicity element (SP/T/R) can in itself be again assigned a thematicity structure.<sup>3</sup>

Consider (1) for illustration of the thematicity segmentation of a sample sentence (for clear and unambiguous notation, propositions are enclosed in “{...}”):

(1) {[Years ago]SP, [he]T [collaborated with the new music gurus Peter Serkin and Fred Sherry in the very countercultural chamber group Tashi, {[which]T [won audiences over to dreaded contemporary scores like Messiaen's Quartet for the End of Time]R}.]R }

For the communicative segmentation of a fragment of the PTB as gold standard, we used the following empirically determined criteria:

**Criteria for determining the Specifier:** Given that Specifiers do not express a separate message, but, rather, the context of the message to which they belong, we mark as Specifiers:

- fronted temporal, locative and manner circumstantials: {[Apparently]SP [he]T [did so]R};
- fronted AdjPs with a sentential scope: {[Tired of the same]SP, [he]T [gave up]R};
- fronted discourse markers: {[But]SP [it]T [was neither deep]R};
- circumstantials of the type *according to ...* (independently of their position): {[About 25 % of the insiders]T, [according to SEC figures]SP, [file their reports late]R};
- phrases that introduce direct speech (independently of their position): {[It]T [is done]R, [he said]SP};
- NPs in vocative case (independently of their position): {[Anna]SP, [he]T [did it]R}.

<sup>2</sup>Strictly speaking, Theme and Rheme are defined over the meaning of an utterance, rather than the utterance itself. It is for brevity that we speak of an IS of an utterance.

<sup>3</sup>The hierarchical relations in a given thematicity segmentation are in practice controlled by indices. Thus, ‘T(T1)’ will stand for “theme within the theme element marked as ‘T1’ ” and ‘R(T1)’ for “rheme within T1”. To distinguish between elements of the same type at the same level of the hierarchy, numbers are used: ‘T1’ vs. ‘T2’ ‘R1’ vs. ‘R2’, etc.

**Criteria for determining the Theme:** *Theme* is the part of the sentence that expresses what the Speaker is talking about. Therefore, it tends to be located in the initial part of the sentence (after the Specifiers, if there are any). In an SVO language as English, the Theme therefore coincides most of the times with the subject. Apart from this *ad hoc* criterion, a number of “hard” criteria to identify the Theme are available; among them:

- it can be identified by the question “And what about X” (then, X is Theme): {[John]T [answered the question]R}: *And what about John?* (\**And what about question?*);
- it is not accessible for general negation/questioning: {[He]T [did it]R}: \**Not he did it*;
- a relative clause is treated as an independent proposition, and therefore the relative pronoun is the Theme only if it is subject (otherwise, it is a focalized part of the Rheme): *the boy* {[who]T [cooked]R} vs. *the boy* {[whom]R1-1,Foc [I]T [met]R1-2};
- indefinite pronouns such as *nobody*, *somebody*, *nothing*, etc. and negative noun phrases cannot be Themes: e.g., in *None of the boys did it*, it is not *none of the boys*, which is the Theme, but rather *it*;
- sentences of the form *It + is + Adjective + Infinitive verb* reverse the typical position of the theme, with the infinitive verb being the theme: {[It's necessary]R [to talk]T};
- headings or titles are all-thematic.

Occasionally, a split of Theme can be observed: {[Considered as a whole]T1-1, [[Mr. Lane]T1(SP) [said]R1(SP)]SP, [the filings required under the proposed rules]T1-2 “[will be at least as effective, if not more so , for investors following transactions]R.”}

**Criteria for determining the Rheme:** The easiest way to recognize Rheme is through exclusion: if an element is not Theme nor Specifier, then it is part of the Rheme. A few explicit criteria can also be introduced:

- Rheme can be negated and/or questioned: {[I]T [think so]R}: *I don't think so / Do I think so?*;
- existential sentences (those that begin with *There is/are*) are all rhematic: {[There are apples on the table]R};
- non-fronted temporal, locative and manner circumstantials form part of the Rheme: {[I]T [met John some months ago in the park, in a very unexpected way]R.}

In addition, it is to be noted that if the Rheme

contains a ditransitive verb that allows arguments to exchange syntactic positions, we assume that this exchange is motivated by different ISs; cf. {[John]T [[gave me]T(R1) [money]R(R1)]R1} vs. {[John]T [[gave money]T(R1) [to me]R(R1)]R1} (the tag ‘R’ is supplied with a number for unambiguous notation). Furthermore, within NPs that start with *wh*-words that do not belong to pseudo-clefting constructions, split Rhemes are observed: {[[What]R1-1(T1) [he]T(T1) [said]R1-2(T1)]T1 [was hilarious]R1}.

### 3 Annotating PTB with Thematicity

Given that the thematicity structure as used in this paper is of a hierarchical nature, its automatic annotation can be viewed not only as a tagging but also as a (constituency) parsing task. We carried out experiments with both approaches, taking the tagger variant as baseline (the idea is to apply a simple and well researched technique in order to compare it with a more elaborated one). For both, we use the CoNLL '09 format; cf. Figure 1. A line in this format consists of an id, a word form, a lemma, a pos tag, and the dependency annotation with the head node and the edge label (all retrieved from the CoNLL Shared Task 2009 data set). The last two columns contain the gold communicative tag and the tag predicted in the course of the automatic annotation, respectively.

id	form	lemma	pos	head	edge	com.	p-com.
1	He	he	PRP	2	SBJ	[]T	-
2	believes	believe	VBZ	0	ROOT	[	-
3	in	in	IN	2	ADV	-	-
4	what	what	WP	6	OBJ	[]T	-
5	he	he	PRP	6	SBJ	[	-
6	plays	play	VBZ	3	PMOD	]R]R	-
7	.	.	.	2	P	-	-

Figure 1: Example of a sentence annotated with its thematicity structure in CoNLL format.

In the case of tagging, we aim to assign to each element of a sentence a T, R or a SP tag. For this purpose, we use classifier-based sequence tagging. The tagger assigns one of the three tags to each word by going from left to right through the sentence. For the selection of the appropriate tag, the tagger considers features from a window of two words before and after the word in question.; cf. Table 1 for the features used by the tagger.

For training the classifier of the sequence tagger, we use the perceptron algorithm. Following Collins and Duffy (2002), averaging of the param-

Features based on PoS tags
$\pi(i), \pi(i-1)\pi(i), \pi(i)\pi(i+1), \pi(i+1)\pi(i+2)$
$\pi(i-1)\pi(i-2), \pi(i-2)\pi(i-1)\pi(i),$
$\pi(i-1)\pi(i)\pi(i+1), \pi(i)\pi(i+1)\pi(i+2)$
Features involving PoS tags and word forms
$w(i), \pi(i-1)w(i), w(i)\pi(i+1), w(i+1)\pi(i+2)$
$\pi(i+1)w(i+2), w(i-1)\pi(i-2), \pi(i-1)w(i-2)$
$w(i-1)w(i), w(i)w(i+1)$
$w(i+1)w(i+2), w(i-1)w(i-2)$

Table 1: Features for the sequence tagger.  $i$  ( $i = 0, 1, \dots$ ) denotes the  $i$ th word in the input sentence;  $\pi$  and  $w$  are functors to extract the PoS tags respectively word forms of the tokens.

eters obtained in the training algorithm is applied for classifying the test examples.

In the case of parsing, we aim to derive the hierarchical IS (or *communicative tree*) of a given sentence. The communicative tree  $T_c$  of a sentence  $x = w_1 \dots w_n$  is a quintuple  $T_c = (V, E, L, \delta, 0')$ , such that  $V = V_t \cup V_c$  is a set of nodes, with  $V_t = 0, \dots, n$  as a set of terminal nodes and  $V_c = o', 1', \dots, m'$  as a set of non-terminal communicative (label) nodes;  $E \subseteq V \times V$  is a set of edges;  $L$  is the set of communicative labels (in the case of thematicity: SP, T, R and P);  $\delta : E \rightarrow L$  is a labeling function for nodes;  $0'$  is the root node. That is, we interpret the  $T_c$  as a kind of constituency tree.

For the implementation of the parser, we use the idea of transition-based parsing (Yamada and Matsumoto, 2003; Nivre et al., 2004), which uses a classifier to predict the shift/reduce actions. We draw upon the transition set of the *arc-eager parser* Nivre (2004), but with a slightly different semantics in that we define a transition system for the derivation of the  $T_c$  as a quadruple  $C = (S, Y, c_0, S_y)$ , where  $S$  is a set of parsing states;  $Y$  is a set of transitions, each of which is a (partial) function  $t: S \rightarrow S$ ;  $s_0$  is an initialization function that maps a sentence  $x$  to a configuration  $s \in S$ ; and  $S_y \subseteq S$  is a set of terminal states. A transition sequence for a sentence  $x$  in  $C$  is a sequence of pairs of states and transitions. As set  $S$  of states, we use the tuple  $s = (\Sigma, B, V_c, Z, E, \delta, o)$ , where the stack  $\Sigma$  and the input buffer  $B$  are disjoint sublists of the terminal nodes  $V_t$ ,  $V_c$  is the set of communicative (label) nodes,  $Z$  is the stack of communicative nodes,  $E$  is the set of edges,  $\delta$  is a labeling function for communicative label nodes  $n \in V_c$ , and  $o$  is a counter for the number of pairs of delimitation brackets. The initial state for a sentence  $x$  is  $s_0 = ([0], [1, \dots, n], \{0'\}, [0'], \{\}, \delta, 0)$ . Terminal configurations have an empty buffer and

only the root node  $n$  is contained in the stack  $\Sigma$ :  $s = ([0], [], V_c, Z, E, \delta, x)$ . Figure 2 shows the possible transitions.

As features of the transition-based system, we use a rich feature set based on the dependency structure drawn from (Zhang and Nivre, 2011) (since we use as input a dependency structure these features are available). In addition, we use the path from the top stack element to the word of the last open bracket (as sequence of pos tags). For the training of the transition-based system, we use the perception algorithm with averaging, a beam-search with 10 elements and early update (Collins and Roark, 2004). The oracle for training of the system follows the bottom-up parsing strategy. As soon as the communicative part is completed, we remove (reduce) the nodes that belong to it from the stack. Figure 3 shows a sequence of transitions that the analyser performs to create the  $T_c$  of the example sentence in Figure 1.

## 4 Experiments

Following the criteria in Section 2, four annotators in teams of two manually annotated a fragment of 435 sentences of the PTB with the thematicity structure, in a series of blocks of about 40–50 sentences. To ensure high mutual agreement, the annotation procedure went as follows. First, one of the teams provided a first round annotation of a block of sentences. This annotation was revised by the other team and the two annotations were discussed in plenum to achieve a consensus and to refine the annotation guidelines. The refined guidelines were used by the first team to annotate the next block of sentences—to be again revised by the other team and discussed in plenum. And so on.<sup>4</sup>

For training, we use the first 360 sentences, the next 40 sentences as development set, and the remaining 35 sentences as test set. Table 2 presents the results on the test set for the sequence tagger and the transition-based analyser. The Accuracy Score (AS) measures the correctly assigned thematicity tags on a token basis in the same way as PoS tagging is evaluated. That is, given, e.g., the sequence  $[, -, []T, [, ]R$  and the predicted sequence  $-, -, []T, [, ]R$ , we see 3 correct to-

<sup>4</sup>At this stage, we did not measure the initial agreement between the annotators since our goal was to achieve a high level of agreement in the course of the discussion. However, to follow the common practice in corpus annotation, we will provide in the near future the inter-annotator figures.

Transition		Condition
LEFT-BRACKET	$([\sigma i], B, V_c, [\zeta u'], E, \delta, o) \Rightarrow ([\sigma i], B, V_c, \cup\{o' \leftarrow (o + 1)'\}, [\zeta u' o'], E \cup \{(i, o'), (u', o')\}, o + 1)$	$i \neq 0$

19 REDUCE <sub>.....</sub> REDUCE $\Rightarrow$	$([0], [], \{0', 1', 2', 3', 4'\}, [0'], \{\dots, (\text{he}, 4'), (2', 4'), (0', 2')\}, \{\dots, (4' \rightarrow R), (2' \rightarrow R)\}, 4)$

Figure 3: Transition sequence for the sentence: *He believes in what he plays.*

kens out of 5, i.e., an accuracy score of 60%. Note that the assignment  $] ] R$  instead of  $] R$  is considered as wrong. In contrast to this simple score, the labeled bracket score (LBS) and the unlabeled bracket score (UBS) consider the bracketing; the scores are calculated with the `evalb`-script as used for the evaluation of phrase structure parsers.

System	AS	LBS	UBS
sequence tagger	71.74	51.78	53.29
transition-based	88.67	68.95	74.33

## 5 Discussion and future work

The results of our experiments show that the interpretation of the annotation of PTB with IS as a transition-based parsing task is promising. Acceptable accuracy scores are achieved already with a very small training set. A direct comparison with other works on automatic annotation with IS, as e.g., (Postolache et al., 2005) with TFA, is not possible since the data sets and the annotation

schemata are different; see, e.g., (Hajičová, 2007) for a precise outline of the criteria for the annotation of TFA in the Prague school and a juxtaposition of TFA and the CommStr. However, it is instructive to observe that the AS we achieve with the transition parser is about the same as Postolache et al.’s accuracy with RIPPER and MAXENT models and only slightly below their performance with C4.5. This means that parsing is a valid alternative to token-oriented classification. However, we must be aware that parsing can only be applied if we assume the IS structure to be hierarchical (more precisely, a tree). The parser performance in terms of LBS and UBS, which capture the “bracketing” of the transitivity elements within the structure, are somewhat lower and can still be improved with a larger training sample (see below).

To have a clearer idea what the most recurrent mistakes of our IS parser are and whether they can be avoided (e.g., by a larger training sample) we carried out an error analysis of the resulting automatic annotation. This analysis has shown that sentences with clear (lexical, syntactic,

and/or punctuation) thematicity markers are analyzed correctly. Cf., e.g., (2) and (3):

(2) [*Indeed*]SP, [*the government*]T [*is taking a calculated risk*]R

(3) [*At the same time*]SP, [*the government*]T [*didn't want to appear to favor GM by allowing a minority stake [that]T [might preclude a full bid by Ford]*]R

In more complex sentences, the algorithm does not accurately detect the propositions involved, triggering the following errors: (a) consecutive themes (even if the second one begins with a verb) (4); (b) consecutive rhemes (even if there is no theme and there is no verb in the first rheme) (5); (c) reduced clauses are not labelled as embedded rhemes (6).

(4) [*In a prepared statement*]SP, [*GM*]T [*suggested its plans for Jaguar*]T [*would be more valuable in the long run than the initial windfalls investors*]T [*migh reap from a hostile Ford bid*]R.

(5) [*Erwin Tomash, the 67-year-old founder of this maker of data communications products and a former chairman and chief executive*]R, [*resigned as a director*]R.

(6) [*In national over-the-counter trading*]R, [*SFE technologies shares*]T [*closed yesterday at 31.25 cents a share, up 6.25 cents*]R.

Another detected error is that just the verb is labelled as rheme, which also brings embeddedness problems (7).

(7) “ [*Our intensive discussions with Jaguar , at their invitation*]R , ” [*GM said*]R , “ [*have as their objectives to create a cooperative business relationship with Jaguar [that]T [would]R provide for the continued independence of this great British car company...*]R.

Apart from these major errors, a number of minor errors can be detected—e.g., subordinate conjunctions are assumed as part of the theme if they are initial (8); initial locative or temporal specifiers are always labelled as part of the rheme (9); initial specifiers are confused with themes (10); etc.

(8) [*Although GM*]T [*has U.S. approval to buy up to 15% of Jaguar's stock*]SP, [*it*]T [*[hasn't yet disclosed how many shares it now owns]*]R.

(9) [*After a stronger - than - expected pace early this year*]R , [*analysts*]T [*say the market , after a series of sharp swings in recent months, now shows signs of retreating*]R.

(10) [*Under the circumstances*]T , [*Dataproducts said* , [*[Mr. Tomash]*]T [*said*]R]SP [*he*]T [*was un-*

*able to devote the time required because of other commitments*]R.

Finally, we found some few cases of non-annotated parts (*Dataproducts said* in (10)) or over-generated levels of embeddedness.

All these errors are likely to be straightened out with a larger training sample. The dependency curve between the accuracy ( $y$ -axis) and the size of the training set ( $x$ -axis) in Figure 4 shows that an increase of the size of the training set (e.g., to 1000 sentences) will further improve the scores. We are about to do this and apply the retrained transition-based analyser to the entire PTB. The information about how the resulting IS-bank can be accessed will be posted at <http://www.taln.upf.edu/resources>.

Our future work involves the extension of the annotation by other dimensions of the CommStr and a study of the correlation between the various dimensions of the IS and prosody. We assume that in particular the hierarchical structure of thematicity will correlate well with the prosodic structure of both simple and parenthetical or subordinate constructions, and thus contribute to a better quality in speech synthesis. Our positive experience with it in natural language text generation, where it guides syntactic realization, confirms this assumption.

Figure 4: Dependency between the size of the training set and accuracy.

## Abstract

This paper gives an Abstract Categorical Grammar (ACG) account of (Kallmeyer and Kuhlmann, 2012)’s process of transformation of the derivation trees of Tree Adjoining Grammar (TAG) into dependency trees. We make explicit how the requirement of keeping a direct interpretation of dependency trees into strings results into lexical ambiguity. Since the ACG framework has already been used to provide a logical semantics from TAG derivation trees, we have a unified picture where derivation trees and dependency trees are related but independent equivalent ways to account for the same surface–meaning relation.

## 1 Introduction

Tree Adjoining Grammars (TAG) (Joshi et al., 1975; Joshi and Schabes, 1997) is a tree grammar formalism relying on two operations between trees: *substitution* and *adjunction*. In addition to the tree generated by a sequence of such operations, there is a *derivation tree* which records this sequence. Derivation trees soon appeared as good candidates to encode semantic-like relations between the elementary trees they glue together. However, some mismatch between these trees and the relative scoping of logical connectives and relational symbols, or between these trees and the dependency relations, have been observed. Solving these problems often leads to modifications of derivation tree structures (Schabes and Shieber, 1994; Kallmeyer, 2002; Joshi et al., 2003; Rambow et al., 2001; Chen-Main and Joshi, To appear).

While alternative proposals have succeeded in linking derivation trees to semantic representations using unification (Kallmeyer and Romero,

2004; Kallmeyer and Romero, 2007) or using an encoding (Pogodalla, 2004; Pogodalla, 2009) of TAG into the ACG framework (de Groote, 2001), only recently (Kallmeyer and Kuhlmann, 2012) has proposed a transformation from standard derivation trees to dependency trees.

This paper provides an ACG perspective on this transformation. The goal is twofold. First, it exhibits the underlying lexical blow up of the yield functions associated with the elementary trees in (Kallmeyer and Kuhlmann, 2012). Second, using the same framework as (Pogodalla, 2004; Pogodalla, 2009) allows us to have a shared perspective on a phrase-structure architecture and a dependency one and an equivalence on the surface-meaning relation they define.

## 2 Abstract Categorical Grammars

ACGs provide a framework in which several grammatical formalisms may be encoded (de Groote and Pogodalla, 2004). They generate languages of linear  $\lambda$ -terms, which generalize both string and tree languages. A key feature is to provide the user direct control over the parse structures of the grammar, the *abstract language*, which allows several grammatical formalisms to be defined in terms of ACG, in particular TAG (de Groote, 2002). We refer the reader to (de Groote, 2001; Pogodalla, 2009) for the details and introduce here only few relevant definitions and notations.

**Definition.** A higher-order linear signature is defined to be a triple  $\Sigma = \langle A, C, \tau \rangle$ , where:

- $A$  is a finite set of atomic types (also noted  $A_\Sigma$ ),
- $C$  is a finite set of constants (also noted  $C_\Sigma$ ),
- and  $\tau$  is a mapping from  $C$  to  $\mathcal{T}_A$  the set of types built on  $A$ :  $\mathcal{T}_A ::= A | \mathcal{T}_A \multimap \mathcal{T}_A$  (also noted  $\mathcal{T}_\Sigma$ ).

A higher-order linear signature will also be called

a vocabulary.  $\Lambda(\Sigma)$  is the set of  $\lambda$ -terms built on  $\Sigma$ , and for  $t \in \Lambda(\Sigma)$  and  $\alpha \in \mathcal{T}_\Sigma$  such that  $t$  has type  $\alpha$ , we note  $t :_\Sigma \alpha$  (the  $\Sigma$  subscript is omitted when it is obvious from the context).

**Definition.** An abstract categorial grammar is a quadruple  $\mathcal{G} = \langle \Sigma, \Xi, \mathcal{L}, s \rangle$  where:

1.  $\Sigma$  and  $\Xi$  are two higher-order linear signatures, which are called the abstract vocabulary and the object vocabulary, respectively;
2.  $\mathcal{L} : \Sigma \longrightarrow \Xi$  is a lexicon from the abstract vocabulary to the object vocabulary. It is a homomorphism<sup>1</sup> that maps types and terms built on  $\Sigma$  to types and terms built on  $\Xi$ . We note  $t :=_{\mathcal{G}} u$  if  $\mathcal{L}(t) = u$  and omit the  $\mathcal{G}$  subscript if obvious from the context.
3.  $s \in \mathcal{T}_\Sigma$  is a type of the abstract vocabulary, which is called the distinguished type of the grammar.

**Definition.** The abstract language of an ACG  $\mathcal{G} = \langle \Sigma, \Xi, \mathcal{L}, s \rangle$  is  $\mathcal{A}(\mathcal{G}) = \{t \in \Lambda(\Sigma) \mid t :_\Sigma s\}$

The object language of the grammar  $\mathcal{O}(\mathcal{G}) = \{t \in \Lambda(\Xi) \mid \exists u \in \mathcal{A}(\mathcal{G}). t = \mathcal{L}_G(u)\}$

Since there is no structural difference between the abstract and the object vocabulary as they both are higher-order signatures, ACGs can be combined in different ways. Either by having a same abstract vocabulary shared by several ACGs in order to make two object terms (for instance a string and a logical formula) share the same underlying structure as  $\mathcal{G}_{d-ed\ trees}$  and  $\mathcal{G}_{Log}$  in Fig. 1. Or by making the abstract vocabulary of an ACG the object vocabulary of another ACG, allowing the latter to control the admissible structures of the former, as  $\mathcal{G}_{yield}$  and  $\mathcal{G}_{d-ed\ trees}$  in Fig. 1.

### 3 TAG as ACG

As Fig. 1 shows, the encoding of TAG into ACG uses two ACGs  $\mathcal{G}_{d-ed\ trees} = \langle \Sigma_{der\theta}, \Sigma_{trees}, \mathcal{L}_{d-ed\ trees}, \mathbf{s} \rangle$  and  $\mathcal{G}_{yield} = \langle \Sigma_{trees}, \Sigma_{string}, \mathcal{L}_{yield}, \tau \rangle$ . We exemplify the encoding<sup>2</sup> of a TAG analyzing (1)<sup>3</sup>

<sup>1</sup>In addition to defining  $\mathcal{L}$  on the atomic types and on the constants of  $\Sigma$ , we have:

- If  $\alpha \multimap \beta \in \mathcal{T}_\Sigma$  then  $\mathcal{L}(\alpha \multimap \beta) = \mathcal{L}(\alpha) \multimap \mathcal{L}(\beta)$ .
- If  $x \in \Lambda(\Sigma)$  (resp.  $\lambda x.t \in \Lambda(\Sigma)$  and  $t u \in \Lambda(\Sigma)$ ) then  $\mathcal{L}(x) = x$  (resp.  $\mathcal{L}(\lambda x.t) = \lambda x.\mathcal{L}(t)$  and  $\mathcal{L}(t u) = \mathcal{L}(t)\mathcal{L}(u)$ )

with the proviso that for any constant  $c :_\Sigma \alpha$  of  $\Sigma$  we have  $\mathcal{L}(c) :=_\Xi \mathcal{L}(\alpha)$ .

<sup>2</sup>We refer the reader to (Pogodalla, 2009) for the details.

<sup>3</sup>The TAG literature typically uses this example, and (Kallmeyer and Kuhlmann, 2012) as well, to show the mismatch between the derivation trees and the expected se-

Figure 1: ACG architecture for TAG

- (1) John Bill claims Mary seems to love
- This sentence is usually analyzed in TAG with a derivation tree where the *to love* component scopes over all the other arguments, and where *claims* and *seems* are unrelated, as Fig. 2(a) shows.

The three higher-order signatures are:

$\Sigma_{der\theta}$ : Its atomic types include  $\mathbf{s}$ ,  $\mathbf{vp}$ ,  $\mathbf{np}$ ,  $\mathbf{s}_A$ ,  $\mathbf{vp}_A \dots$  where the  $X$  types stand for the categories  $X$  of the nodes where a substitution can occur while the  $X_A$  types stand for the categories  $X$  of the nodes where an adjunction can occur. For each elementary tree  $\gamma_{lex.\ entry}$  it contains a constant  $C_{lex.\ entry}$  whose type is based on the adjunction and substitution sites as Table 1 shows. It additionally contains constants  $I_X : X_A$  that are meant to provide a fake auxiliary tree on adjunction sites where no adjunction actually takes place in a TAG derivation.

$\Sigma_{trees}$ : Its unique atomic type is  $\tau$  the type of trees. Then, for any  $X$  of arity  $n$  belonging to the ranked alphabet describing the elementary trees of the TAG, we have a constant

$$X_n : \overbrace{\tau \multimap \dots \multimap \tau}^{n \text{ times}} \multimap \tau$$

$\Sigma_{string}$ : Its unique atomic type is  $\sigma$  the type of strings. The constants are the terminal symbols of the TAG (with type  $\sigma$ ), the concatenation  $+$  :  $\sigma \multimap \sigma \multimap \sigma$  and the empty string  $\varepsilon$  :  $\sigma$ .

Table 1 illustrates  $\mathcal{L}_{d-ed\ trees}$ .<sup>4</sup>  $\mathcal{L}_{yield}$  is defined as follows:

- $\mathcal{L}_{yield}(\tau) = \sigma$ ;
- for  $n > 0$ ,  $\mathcal{L}_{yield}(X_n) = \lambda x_1 \dots x_n. x_1 + \dots + x_n$ ;
- for  $n = 0$ ,  $X_0 : \tau$  represents a terminal sym-

mantics and the relative scopes of the predicates.

<sup>4</sup>With  $\mathcal{L}_{d-ed\ trees}(X_A) = \tau \multimap \tau$  and for any other type  $X$ ,  $\mathcal{L}_{d-ed\ trees}(X_A) = \tau$ .

$\text{bol}$  and  $\mathcal{L}_{\text{yield}}(X_0) = X$ .

Then, the derivation tree, the derived tree, and the yield of Fig. 2 are represented by:

$$\begin{aligned} t_0 &= C_{\text{to love}} (C_{\text{claims}} I_{\mathbf{s}} C_{\text{Bill}}) (C_{\text{seems}} I_{\mathbf{vp}}) C_{\text{Mary}} C_{\text{John}} \\ \mathcal{L}_{\text{d-ed trees}}(t_0) &= \mathbf{s}_2 (\text{np}_1 \text{ John}) (\mathbf{s}_2 (\text{np}_1 \text{ Bill}) (\mathbf{vp}_2 \text{ claims} (\mathbf{s}_2 \\ &\quad (\text{np}_1 \text{ Mary}) (\mathbf{vp}_2 \text{ seems} (\mathbf{vp}_1 \text{ to love})))) \\ \mathcal{L}_{\text{yield}}(\mathcal{L}_{\text{d-ed trees}}(t_0)) &= \text{John} + \text{Bill} + \text{claims} \\ &\quad + \text{Mary} + \text{seems} + \text{to love} \end{aligned}$$

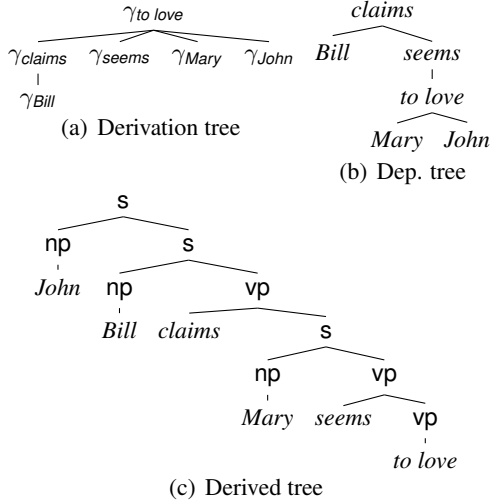

Figure 2: *John Bill claims Mary seems to love*

## 4 From Derivation Trees to Dependency Trees

(Kallmeyer and Kuhlmann, 2012)’s process to translate derivation trees into dependency trees is a two-step process. The first one does the actual transformation, using macro-tree transduction, while the second one modifies the way to get the yield from the dependency trees rather than from the derivation ones.

### 4.1 From Derivation To Dependency Trees

This transformation aims at modeling the differences in scope of the argument between the derivation tree for (1) shown in Fig. 2(a) and the corresponding dependency tree shown in Fig. 2(b). For instance, in the derivation trees, *claims* and *seems* are under the scope of *to love* while in the dependency tree this order is reversed. According to (Kallmeyer and Kuhlmann, 2012), such edge reversal is due to the fact that an edge between a *complement taking adjunction* (CTA) and an initial tree has to be reversed, while the other edges remain unchanged.

Moreover, in case an initial tree accepts several adjunction of CTAs, (Kallmeyer and Kuhlmann, 2012) hypothesizes that the farther from the head a CTA is, the higher it is in the dependency tree. In the case of *to love*, the  $\mathbf{s}$  node is farther from the head than the  $\mathbf{vp}$  node. Therefore any adjunction on the  $\mathbf{s}$  node (e.g. *claims*) should be higher than the one on the  $\mathbf{vp}$  node (e.g. *seems*) in the dependency tree. We represent the dependency tree for (1) as  $t'_0 = d_{\text{claims}} d_{\text{Bill}} (d_{\text{seems}} (d_{\text{to love}} d_{\text{John}} d_{\text{Mary}}))$ .

In order to do such reversing operations, (Kallmeyer and Kuhlmann, 2012) uses Macro Tree Transducers (MTTs) (Engelfriet and Vogler, 1985). Note that the MTTs they use are *linear*, i.e. non-copying. It means that any node of an input tree cannot be translated more than once. (Yoshinaka, 2006) has shown how to encode such MTTs as the composition  $\mathcal{G}' \circ \mathcal{G}^{-1}$  of two ACGs, and we will use a very similar construct.

### 4.2 The Yield Functions

(Kallmeyer and Kuhlmann, 2012) adds to the transformation from derivation trees to dependency trees the additional constraint that the string associated with a dependency structure is computed directly from the latter, without any reference to the derivation tree. To achieve this, they use two distinct yield functions:  $\text{yield}_{\text{TAG}}$  from derivation trees to strings, and  $\text{yield}_{\text{dep}}$  from dependency trees to strings.

Let us imagine an initial tree  $\gamma_i$  and an auxiliary tree  $\gamma_a$  with no substitution nodes. The yield of the derived tree resulting from the operations of the derivation tree  $\gamma$  of Fig. 3 defined in (Kallmeyer and Kuhlmann, 2012) is such that

$$\begin{aligned} \text{yield}_{\text{TAG}}(\gamma) &= a_1 + w_1 + a_2 + w_2 + a_3 \\ &= (\text{yield}_{\text{TAG}}(\gamma_i))(\text{yield}_{\text{TAG}}(\gamma_a)) \\ &= (\lambda \langle x_1, x_2 \rangle. a_1 + x_1 + a_2 + x_2 \\ &\quad + a_3) \langle w_1, w_2 \rangle \end{aligned}$$

where  $\langle x, y \rangle$  denotes a tuple of strings.

Because of the adjunction, the corresponding dependency structure has a reverse order ( $\gamma' = \gamma'_a(\gamma'_i)$ ), the requirement on  $\text{yield}_{\text{dep}}$  imposes that

$$\begin{aligned} \text{yield}_{\text{dep}}(\gamma') &= a_1 + w_1 + a_2 + w_2 + a_3 \\ &= (\text{yield}_{\text{dep}}(\gamma'_a))(\text{yield}_{\text{dep}}(\gamma'_i)) \\ &= (\lambda \langle x_1, x_2, x_3 \rangle. x_1 + w_1 + x_2 + w_2 \\ &\quad + x_3) \langle a_1, a_2, a_3 \rangle \end{aligned}$$

In the interpretation of derivation trees as strings, initial trees (with no substitution nodes)

Abstract constants of $\Sigma_{der\theta}$	Their images by $\Sigma_{der\theta}$	The corresponding TAG trees
$C_{John} : np$	$c_{John} : \tau$ $= np_1 John$	$\gamma_{John} =$ 
$C_{seems} : vp_A \multimap vp_A$	$c_{seems} : (\tau \multimap \tau) \multimap (\tau \multimap \tau)$ $= \lambda^0 vx.v (vp_2 seems x)$	$\gamma_{seems} =$ 
$C_{to\ love} : s_A \multimap vp_A \multimap np$ $\multimap np \multimap s$	$c_{to\ love} : (\tau \multimap \tau) \multimap (\tau \multimap \tau) \multimap \tau \multimap \tau \multimap \tau$ $= \lambda^0 avso.s_2 o$ $(a (s_2 s (v (vp_1 to\ love))))$	$\gamma_{to\ love} =$ 
$C_{claims} : s_A \multimap vp_A$ $\multimap np \multimap s_A$	$c_{claims} : (\tau \multimap \tau) \multimap (\tau \multimap \tau) \multimap \tau \multimap \tau \multimap \tau$ $= \lambda^0 avsc.a (s_2 s (a (vp_2 claims c)))$	$\gamma_{claims} =$ 
$I_X : X_A$	$\lambda x.x : \tau \multimap \tau$	

Table 1: TAG as ACG: the  $\mathcal{L}_{d-ed\ trees}$  lexicon

are interpreted as functions from tuples of strings into strings, and auxiliary trees as tuples of strings. The interpretation of dependency trees as strings leads us to interpret initial trees as tuples of strings and auxiliary trees as function from tuples of strings to strings.

Figure 3: Yield from derivation trees

Indeed, an initial tree can have several adjunction sites. In this case, to be ready for another adjunction after a first one, the first result itself should be a tuple of strings. So an initial tree (with no substitution nodes) with  $n$  adjunction sites is interpreted as a  $(2n + 1)$ -tuple of strings. Accordingly, depending on the location where it can adjoint, an auxiliary tree is interpreted as a function from  $(2k + 1)$ -tuple of strings to  $(2k - 1)$ -tuple of strings.

Taking into account that to model trees having the substitution nodes is then just a matter of adding  $k$  string parameters where  $k$  is the number of substitution nodes in a tree. Then using the interpretation:

$$\begin{aligned}
 yield_{dep}(d_{to\ love}) &= \lambda x_{11} x_{21}. \langle x_{11}, x_{21}, to\ love, \varepsilon, \varepsilon \rangle \\
 yield_{dep}(d_{seems}) &= \lambda \langle x_{11}, x_{12}, x_{13}, x_{14}, x_{15} \rangle. \\
 &\quad \langle x_{11}, x_{12} + seems + x_{13}x_{14}, x_{15} \rangle \\
 yield_{dep}(d_{claims}) &= \lambda x_{21} \langle x_{11}, x_{13}, x_{14} \rangle. \\
 &\quad \langle x_{11} + x_{21} + claims + x_{14} + x_{13} \rangle
 \end{aligned}$$

we can check that

$$yield_{dep}(d_{claims} d_{Bill} (d_{seems}(d_{to\ love} d_{Mary} d_{John}))) = \langle John + Bill + claims + Mary + seems + to\ love \rangle$$

**Remark.** The given interpretation of  $d_{to\ love}$  is only valid for structures reflecting adjunctions both on the  $s$  node and on the  $vp$  node of  $\gamma_{to\ love}$ . So actually, an initial tree such as  $\gamma_{to\ love}$  yields four interpretations: one with the two adjunctions (5-tuple), two with one adjunction either on the  $vp$  node or on the  $s$  node (3-tuple), and one with no adjunction (1-tuple). The two first cases correspond to the sentences (2a) and (2b).<sup>5</sup> Accordingly, we need multiple interpretations for the auxiliary trees, for instance for the two occurrences of *seems* in (3) where the yield of the last one  $yield_{dep}(d_{seems})$  maps a 5-tuple to a 3-tuple, and the yield of the first one maps a 3-tuple to a 3-tuple. And  $yield_{dep}(d_{claims})$  maps a 3-tuple to a 1-tuple of strings. We will mimic this behavior by introducing as many different non-terminal symbols for the dependency structures in our ACG setting.

- (2) a. John Bill claims Mary seems to love  
b. John Mary seems to love
- (3) John Bill seems to claim Mary seems to love

**Remark.** Were we not interested in the yields but only in the dependency structures, we wouldn't have to manage this ambiguity. This is true both for (Kallmeyer and Kuhlmann, 2012)'s approach and ours. But as we have here a unified framework for the two-step process they propose, this lexical blow up will result in a multiplicity of types as Section 5 shows.

<sup>5</sup>As the two other ones are not correct English sentences, we can rule them out. However, from a general perspective, we should take such cases into account.

## 5 Disambiguated Derivation Trees

In order to encode the MTT acting on derivation trees, we introduce a new *abstract* vocabulary  $\Sigma'_{der\theta}$  for *disambiguated derivation trees* as in (Yoshinaka, 2006). Instead of having only one constant for each initial tree as in  $\Sigma_{der\theta}$ , we have as many of them as adjunction combinations. For instance,  $\gamma_{to\ love}$  gives rise to the several constants in  $\Sigma'_{der\theta}$ :

$$\begin{aligned} C_{to\ love}^{11} &: \mathbf{s}_A^{31} \multimap \mathbf{vp}_A^{53} \multimap \mathbf{np} \multimap \mathbf{np} \multimap \mathbf{s} \\ C_{to\ love}^{10} &: \mathbf{s}_A^{31} \multimap \mathbf{np} \multimap \mathbf{np} \multimap \mathbf{s} \\ C_{to\ love}^{01} &: \mathbf{vp}_A^{31} \multimap \mathbf{np} \multimap \mathbf{np} \multimap \mathbf{s} \\ C_{to\ love}^{00} &: \mathbf{np} \multimap \mathbf{np} \multimap \mathbf{s} \end{aligned}$$

Here,  $C_{to\ love}^{11}$  is used to model sentences where both adjunctions are performed into  $\gamma_{to\ love}$ .  $C_{to\ love}^{10}$  and  $C_{to\ love}^{01}$  are used for sentences where only one adjunction at the **s** or at the **vp** node occurs respectively.  $C_{to\ love}^{00} : \mathbf{np} \multimap \mathbf{np} \multimap \mathbf{s}$  is used when no adjunction occurs.<sup>6</sup> This really mimics (Yoshinaka, 2006)'s encoding of (Kallmeyer and Kuhlmann, 2012) MTT rules:

$$\begin{aligned} \langle q_0, C_{to\ love}(x_1, x_2, x_3, x_4) \rangle &\rightarrow \\ \langle q_2, x_2 \rangle (\langle q_4, x_4 \rangle (d_{to\ love}(\langle q_1, x_1 \rangle, \langle q_3, x_3 \rangle))) & \\ \langle q_0, C_{to\ love}(x_1, x_2, x_3) \rangle &\rightarrow \\ \langle q_2, x_2 \rangle (d_{to\ love}(\langle q_1, x_1 \rangle, \langle q_3, x_3 \rangle)) & \\ \langle q_0, C_{to\ love}(x_1, x_2, x_3) \rangle &\rightarrow \\ \langle q_4, x_4 \rangle (d_{to\ love}(\langle q_1, x_1 \rangle, \langle q_3, x_3 \rangle)) & \\ \langle q_0, C_{to\ love}(x_1, x_2) \rangle &\rightarrow \\ d_{to\ love}(\langle q_1, x_1 \rangle, \langle q_3, x_3 \rangle) & \end{aligned}$$

where the states  $q_0, q_1, q_2, q_3$  and  $q_4$  are given the names **s**, **np**,  $\mathbf{s}_A^{31}$ , **np**, and  $\mathbf{vp}_A^{53}$  resp.

Moreover,  $\mathbf{s}_A^{31}, \mathbf{vp}_A^{31}, \dots, \mathbf{vp}_A^{2(n+1)2(n-1)}$  ... are designed in order to indicate that a given adjunction has  $n$  adjunctions above it (i.e. which scope over it). The superscripts  $(2(n+1))(2(n-1))$  express that an adjunction that has  $n$  adjunctions above it is translated as a function that takes a  $2(n+1)$ -tuple as argument and returns a  $2(n-1)$ -tuple.

To model auxiliary trees which are CTAs we need a different strategy. For each such adjunction tree  $T$  we have two sets in  $\Sigma'_{der\theta}$ :  $\mathcal{S}_T^1$  the set of constants which can be adjoined into **initial** trees and  $\mathcal{S}_T^2$  the set of constants which can be adjoined into **auxiliary** trees.

For instance,  $\gamma_{seems}$  would generate  $\mathcal{S}_{seems}^1$  that includes  $C_{seems31}^{11}, C_{seems31}^{10}, C_{seems31}^{01}, C_{seems31}^{00}, C_{seems53}^{11}$  etc.  $C_{seems31}^{00}$  is of type  $\mathbf{vp}_A^{31}$ , which means that it can be adjoined into initial trees which contain  $\mathbf{vp}_A^{31}$  as its argument type (e.g.  $C_{to\ love}^{01}$ ).

<sup>6</sup>See note 5.

$C_{seems31}^{11}$  is of type  $\mathbf{s}_A^{3-3} \multimap \mathbf{vp}_A^{3-3} \multimap \mathbf{vp}_A^{31}$ . It means it expects two adjunctions at its **s** and **vp** nodes respectively and returns back a term of type  $\mathbf{vp}_A^{31}$  (as in *John claims to appear to seem to love Mary*). Here,  $\mathbf{s}_A^{3-3}$  and  $\mathbf{vp}_A^{3-3}$  are types used for modeling *adjunction on adjunctions*.

When an auxiliary tree is adjoined into another auxiliary tree as in (3), we do not allow the former to modify the tupleness of the latter. For instance  $\gamma_{seems}$  would generate  $\mathcal{S}_{seems}^2$  that includes  $C_{seems3-3}^{11}, C_{seems3-3}^{10}, C_{seems3-3}^{01}, C_{seems3-3}^{00}, C_{seems5-5}^{11}$  etc.  $C_{seems3-3}^{00}$  has a subscript  $(k-k)$  that correspond to adjunctions into adjunction trees. The type of  $C_{seems3-3}^{00}$  is  $\mathbf{vp}_A^{3-3}$ , meaning that it can directly adjoin into auxiliary trees which have arguments of type  $\mathbf{vp}_A^{3-3}$ .  $C_{seems3-3}^{01}$  is of type  $\mathbf{vp}_A^{3-3} \multimap \mathbf{vp}_A^{3-3}$ , which means that it itself expects an adjunction and the result can be adjoined into another adjunction tree.

Now it is easy to define  $\mathcal{L}_{der}$  from  $\Sigma'_{der\theta}$  to  $\Sigma_{der\theta}$ . It maps every type  $X \in \Sigma'_{der\theta}$  to  $X \in \Sigma_{der\theta}$  and every  $X_A^N$  to  $X_A$ ; types without numbers are mapped to themselves, i.e. **s** to **s**, **np** to **np**, etc. Moreover, the different *versions* of some constant, that were introduced in order to extract the yield, are translated using only one constant and *fake* adjunctions. For instance:

$$\begin{aligned} \mathcal{L}_{der}(C_{to\ love}^{11}) &= C_{to\ love} \\ \mathcal{L}_{der}(C_{to\ love}^{10}) &= \lambda x s o. C_{to\ love} x I_{vp} s o \\ \mathcal{L}_{der}(C_{to\ love}^{00}) &= C_{to\ love} I_s I_{vp} \end{aligned}$$

## 6 Encoding a Dependency Grammar

The ACG of (Pogodalla, 2009) mapping TAG derivation trees to logical formulas already encoded some reversal of the predicate-argument structure. Here we map the disambiguated derivation trees to dependency structures. The vocabulary that define these *dependency trees* is  $\Sigma_{dep}$ . It is also designed to allow us to build two lexicons from it to  $\Sigma_{string}$  (to provide a direct yield function) and to  $\Sigma_{Log}$  (to provide a logical semantic representation).

In  $\Sigma_{dep}$  constants are typed as follows:  $d_{to\ love}^5 : \tau_{np}^1 \multimap \tau_{np}^1 \multimap \tau^5$ . Here,  $\tau_{np}^1$  is the type into which the **np** type is translated from *disambiguated derivation tree*. The superscript 1 indicates that  $\tau_{np}^1$  will be translated into 1-tuple into  $\Sigma_{string}$ . Now, it is easy to see that in order to translate  $C_{to\ love}^{10} : \mathbf{s}_a^{31} \multimap \mathbf{np} \multimap \mathbf{np} \multimap \mathbf{s}$  and  $C_{to\ love}^{01} : \mathbf{vp}_a^{31} \multimap \mathbf{np} \multimap \mathbf{np} \multimap \mathbf{s}$ , we need to

have constants like:  $d_{to\ love}^3 \mathbf{S} : \tau_{np}^1 \multimap \tau_{np}^1 \multimap \tau^3$  and  $d_{to\ love}^3 \mathbf{V} : \tau_{np}^1 \multimap \tau_{np}^1 \multimap \tau^3$ .

Moreover, we have constants for adjunction trees, like  $d_{seems}^5 : \tau^5 \multimap \tau^3$  that will be used in the translation of  $C_{seems53}^{01}$ , and  $d_{seems}^{5-5} : \tau^5 \multimap \tau^5$  for  $C_{seems5-5}^{00}$ . Furthermore, additional constants are needed to have things *correctly* typed. For this reason, the constants  $d_3^1, d_5^3$  etc. are introduced. Each  $d_{2n+1}^{2n-1}$  has type  $\tau^{2n+1} \multimap \tau^{2n-1}$ .

Finally, non-CTAs like  $n_A, n_A^d, vp_A$  and  $s_A$  are translated as  $\tau_{n_A}^2, \tau_{n_A^d}^2, \tau_{vp}^2$ , and  $\tau_s^2$  respectively. A superscript 2 indicates that they are modeled as 2-tuples in  $\Sigma_{string}$ .

Now we can define  $\mathcal{L}_{dep}$ , the lexicon from  $\Sigma'_{der\theta}$  to  $\Sigma_{dep}$  translating disambiguated derivation trees into dependency trees:

$$\begin{aligned} \mathcal{L}_{dep}(\mathbf{s}) &= \tau^1 \\ \mathcal{L}_{dep}(\mathbf{np}) &= \tau_{np}^1 \\ \mathcal{L}_{dep}(X_A^{(2n+1)(2n-1)}) &= \tau^{2n+1} \multimap \tau^{2n-1} \\ \mathcal{L}_{dep}(X_A^{(2n+1)(2n+1)}) &= \tau^{2n+1} \multimap \tau^{2n+1} \\ &\text{for } X \in \mathbf{s}_A^{31}, \mathbf{vp}_A^{53} \dots \end{aligned}$$

$$\begin{aligned} \mathcal{L}_{dep}(C_{to\ love}^{11}) &= \lambda S V s o. S(V(d_{to\ love}^5 s o)) \\ \mathcal{L}_{dep}(C_{to\ love}^{10}) &= \lambda S s o. S(d_{to\ love}^3 s o) \\ \mathcal{L}_{dep}(C_{to\ love}^{01}) &= \lambda S V s o. V(d_{to\ love}^3 s o) \\ \mathcal{L}_{dep}(C_{seems53}^{00}) &= \lambda x. d_{seems}^5 x \\ \mathcal{L}_{dep}(C_{seems53}^{01}) &= \lambda V x. d_{53}^5(V(d_{seems}^5 x)) \\ \mathcal{L}_{dep}(C_{seems53}^{11}) &= \lambda S V x. d_{53}^5(S(V(d_{seems}^5 x))) \\ \mathcal{L}_{dep}(C_{seems5-5}^{01}) &= \lambda V x. V(d_{seems}^{5-5} x) \\ \mathcal{L}_{dep}(C_{seems5-5}^{00}) &= \lambda x. d_{seems}^{5-5} x \end{aligned}$$

Furthermore, we describe  $\Sigma_{Log}$ <sup>7</sup> and define two lexicons:  $\mathcal{L}_{dep. yield} : \Sigma_{dep} \longrightarrow \Sigma_{string}$  and  $\mathcal{L}_{dep. log} : \Sigma_{dep} \longrightarrow \Sigma_{Log}$ . Table 2 provides examples of these two translations.

$\mathcal{L}_{dep. yield}$ : It translates any atomic type  $\tau^n$  or  $\tau_X^n$  with  $X \in \{n_A, n_A^d \dots\}$  as a  $n$ -tuple of string  $(\underbrace{\sigma \multimap \sigma \dots \multimap \sigma}_{n+1\text{-times}}) \multimap \sigma$ .<sup>8</sup>

$\Sigma_{Log}$ : Its atomic types are  $e$  and  $t$  and we have the constants: **john**, **mary**, **bill** of type  $e$ , the constant **love** of type  $e \multimap e \multimap t$ , the constant **claim** of type  $e \multimap t \multimap t$  and the constant **seem** of type  $t \multimap t$ .

$\mathcal{L}_{dep. log}$ : Each  $\tau^{2(n+1)}$  is mapped to  $t$ ,  $\tau_{np}^1$  is mapped to  $(e \multimap t) \multimap t$ ,  $\tau_{n_A^d}^2$  is mapped to  $(e \multimap t) \multimap (e \multimap t) \multimap t$ . The types

<sup>7</sup>We refer the reader to (Pogodalla, 2009) for the details.

<sup>8</sup>We encode a  $n$ -tuple  $\langle M_1, \dots, M_n \rangle$  as  $\lambda f. f M_1 M_2 \dots M_n$  where each  $M_i$  has type  $\sigma$ .

of non-complement-taking verbal or sentential adjuncts  $\tau_{vp}^2$  and  $\tau_s^2$  are translated as  $t \multimap t$ .

Let us show for the sentence (1) how the ACGs defined above work with the data provided in Table 2. Its representation in  $\Sigma'_{der\theta}$  is:  $T_0 = C_{to\ love}^{11} (C_{claims31} C_{Bill}) C_{seems53} C_{Mary} C_{John}$ . Then

$$\mathcal{L}_{der}(T_0) = t_0$$

and

$$\mathcal{L}_{dep}(T_0) = d_{claims}^1 d_{Bill} (d_{seems}^{53} (d_{to\ love}^5 d_{Mary} d_{John})) = t'_0$$

and finally

$$\begin{aligned} \mathcal{L}_{dep. yield}(t'_0) &= \mathcal{L}_{yield}(\mathcal{L}_{d-ed\ trees}(t_0)) \\ &= \lambda f. f(\mathbf{John} + (\mathbf{Bill} + (\mathbf{claims} \\ &\quad + ((\mathbf{Mary} + ((\mathbf{seems} + \mathbf{to\ love}) + \epsilon)) + \epsilon)))) \end{aligned}$$

and

$$\mathcal{L}_{dep. log}(t'_0) = \mathbf{claim\ bill\ (seem\ (love\ john\ mary))}$$

## 7 Conclusion

In this paper, we have given an ACG perspective on the transformation of the derivation trees of TAG to the dependency trees proposed in (Kallmeyer and Kuhlmann, 2012). Figure 4 illustrates the architecture we propose. This transformation is a two-step process using first a macro-tree transduction then an interpretation of dependency trees as (tuples of) strings. It was known from (Yoshinaka, 2006) how to encode a macro-tree transducer into a  $\mathcal{L}_{dep} \circ \mathcal{L}_{der}^{-1}$  ACG composition. Dealing with typed trees to represent derivation trees allows us to provide a meaningful (wrt. the TAG formalism) abstract vocabulary  $\Sigma'_{der\theta}$  encoding this macro-tree transducer. The encoding of the second step then made explicit the lexical blow up for the interpretation of the functional symbols of the dependency trees in (Kallmeyer and Kuhlmann, 2012)'s construct. It also provides a push out (in the categorical sense) of the two morphisms from the disambiguated derivation trees to the derived trees and to the dependency trees. The diagram is completed with the yield function from the derived trees and from the dependency trees to the string vocabulary.

Finally, under the assumption of (Kallmeyer and Kuhlmann, 2012) of plausible dependency structures, we get two possible grammatical approaches to the surface-semantics relation that are related but independent: it can be equivalently modeled using either a phrase structure or a dependency model.

Abstract constants of $\Sigma_{dep}$	Their images by $\mathcal{L}_{dep. yield}$	Their images by $\mathcal{L}_{dep. log}$

## Abstract

Named entities (NE) are important information carrying units within documents. *Named Entity extraction (NEX)* task consists of automatic construction of a list of phrases belonging to each NE of interest. NEX is important for domains which lack a corpus with tagged NEs. We present an enhanced version and improved results of our unsupervised (bootstrapping) NEX technique (Patil et al., 2013) and establish its domain independence using experimental results on corpora from two different domains: agriculture and mechanical engineering (IC engine<sup>1</sup> parts). We use a new variant of Multiword Expression Distance (MED) (Bu et al., 2010) to quantify proximity of a candidate phrase with a given NE type. MED itself is an approximation of the information distance (Bennett et al., 1998). Efficacy of our method is shown using experimental comparison with pointwise mutual information (PMI), BASILISK and KNOWITALL. Our method discovered 8 new plant diseases which are not found in Wikipedia. To the best of our knowledge, this is the first use of NEX techniques for agriculture and mechanical engineering (engine parts) domains.

## 1 Introduction

Agriculture is an activity of fundamental importance in all societies. For example, agriculture plays a vital role in the economy of India: generating second largest farm output in the world,

\*Preliminary version of this paper was presented as a poster at NLDB 2013.

<sup>1</sup> Internal Combustion engine

providing 52% of rural employment ( $\approx$  250 million people) and contributing  $\approx$  15% to the GDP<sup>2</sup>. Hence timely and widespread dissemination of agriculture-related information is important. Such information - extracted, collated and summarized from a variety of document sources such as news, reports, web-sites and scientific literature - can be used to improve various aspects of services provided to large population dependent on agriculture. Problem of information extraction for domains such as agriculture is particularly challenging due to non-availability of any tagged corpus.

Several domain-specific *named entities (NE)* occur in the documents (such as news) related to the agriculture domain- CROP: names of the crops including varieties; DISEASE: names of the crop diseases and disease causing agents such as pathogen (bacteria, viruses, fungi), insects etc.; CHEMICAL\_TREATMENT: names of pesticides, insecticides, fungicides etc. used in the treatment of a crop disease. Consider an example of NEs tagged for agricultural information extraction:

We usually spray [soybeans]<sub>CROP</sub> with a [strobilurin fungicide]<sub>CHEM\_TREATMENT</sub> because of the potential for [soybean rust]<sub>DISEASE</sub> and other diseases.

As there are few, if any, tagged corpora of agriculture-related documents, we consider an unsupervised approach for extracting these NEs. *NE extraction (NEX)* problem consists of automatically constructing a gazette containing example instances for each NE of interest. A *NE recognition (NER)* algorithm basically matches the given gazette  $G$  (for a particular NE, say DISEASE) with the given document  $D$  to identify occurrences of the instances from  $G$  in  $D$ . While gazette-based NER is fast, the accuracy depends on the quality and completeness of the gazette.

In this paper, we present an enhanced version

<sup>2</sup>[http://en.wikipedia.org/wiki/Economy\\_of\\_India](http://en.wikipedia.org/wiki/Economy_of_India) (access date 31-Jan-2013)

and improved results of our bootstrapping approach to NEX (Patil et al., 2013) and establish its domain independence. We demonstrate the use of this NEX technique for creating gazettes of NE in the agriculture and mechanical engineering domains. Apart from the new application domains for NE extraction, other specific contributions of this paper are as follows: We propose a new variant of the well-known information distance (Bennett et al., 1998; Li et al., 2004; Bu et al., 2010) measure, to decide whether a candidate phrase is a valid instance of the NE or not. We use additional tools and show their effectiveness on improving the gazette quality: (i) a candidate generation algorithm based on maximum entropy classifier; and (ii) a post processing algorithm in the spirit of the assessor module in (Etzioni et al., 2005), but we use statistical hypothesis-testing. Utility and effectiveness of our method is evident from its ability to discover new named entities. For instance, using a limited news corpus, we discovered 8 new crop diseases which are not mentioned in Wikipedia.

The rest of the paper is organized as follows. Section 2 contains a brief overview of related work. In Section 3, we summarize information distance and multiword expression distance, along with new extensions. In Section 4, we discuss our unsupervised algorithm for gazette creation. In Section 5, we present experimental results. Finally we conclude with an outline of future work.

## 2 Related Work

Thelen and Riloff (2002) propose a bootstrapping algorithm called BASILISK for NEX. Etzioni et al. (2005) present a system called KNOWITALL, which implements an unsupervised domain-independent, bootstrapping approach to generate large facts of a specified NE (such as CITY or FILM) from the Web. Many other unsupervised approaches have been proposed for both NEX and NER: (Collins and Singer, 1999; Kim et al., 2002; Meulder and Daelemans, 2003; Talukdar et al., 2006; Jimeno et al., 2008; Liao and Veeramachaneni, 2009; Palshikar, 2012). The basic structure of the bootstrapping approach to NEX is well-known: starting with a seed list of examples of a particular NE type, iteratively identify other phrases which are “similar” to them and add them to the seed list. The algorithm terminates either after a specified number of iterations, or on reaching

a specified gazette size, or when no new entries get added or when the new entities show a “drift”.

## 3 Information Distance for NE

Information distance (Bennett et al., 1998) is an abstract and universal domain-independent, statistically motivated distance measure based on the concept of *Kolmogorov complexity*. Given a Universal Turing Machine (UTM)  $U$ , *Kolmogorov complexity*  $K_U(x|y)$  of a binary string  $x$ , given another binary string  $y$ , is the length of the shortest program for  $U$  that computes  $x$  when given  $y$  as input. Bennett et al. (1998) showed that the quantity (which they called the *information distance*)  $D_{max}(x, y) = \max\{K(x|y), K(y|x)\}$  measures the distance between objects (such as binary strings)  $x$  and  $y$ .

Bu et al. (2010) presented a variant of the information distance, which measures the distance between an  $n$ -gram and its semantics. They define the *context*  $\phi(g)$  of an  $n$ -gram  $g$  as the set of all web-pages containing  $g$  while the *semantics*  $\mu(g)$  of  $g$  is the set of all web-pages that contain all words in  $g$  but not necessarily as a contiguous  $n$ -gram. For example, for  $g = \text{Bill Gates}$ ,  $\phi(g)$  consist of all pages containing `Bill Gates` as the bigram while  $\mu(g)$  consists of all web-pages that contain both `Bill` and `Gates` but not necessarily as a bigram. Clearly,  $\phi(g) \subseteq \mu(g)$ . The *Multiword Expression Distance (MED)*  $MED(g)$  measures the distance of  $g$  from an “intended” (non-compositional) semantics:

$$MED(g) = D_{max}(\phi(g), \mu(g))$$

$$MED(g) \approx \log|\mu(g)| - \log|\phi(g)|$$

Bu et al. (2010) demonstrated the use of MED to perform NER. In this paper, we use a variant of MED to perform NEX. Unlike (Bu et al., 2010), we are constrained to use a corpus rather than the entire Web. Let  $\mathbf{D}$  be a given untagged corpus of sentences. Let  $K$  be a given constant indicating the window size (e.g.,  $K = 3$ ). Let  $g$  be a given candidate phrase. The *context* of  $g$  and a given word  $w$ , denoted  $\phi_K(g, w)$ , is the set of all sentences in  $\mathbf{D}$  which contain both  $g$  (as a  $n$ -gram) as well as  $w$  and further,  $w$  occurs within a window of size  $K$  around  $g$  in that sentence. The *semantics* of  $g$  and a given word  $w$ , denoted  $\mu(g, w)$ , is the set of all sentences in  $\mathbf{D}$  which contain both  $g$  (as an  $n$ -gram) and  $w$ , though  $g$  and  $w$  need

not be within a window of size  $K$  in the sentence. Clearly,  $\phi_K(g, w) \subseteq \mu(g, w)$ . Then we define the *distance* between  $g$  (a given candidate phrase) and a given word  $w$  as follows:

$$MED0_{D,K}(g, w) = \log|\mu(g, w)| - \log|\phi_K(g, w)|$$

Let  $W = \{w_1, w_2, \dots, w_m\}$  be a given finite, non-empty set of  $m$  words. The definition of  $MED0$  is extended to use a given set  $W$  (rather than a single word  $w$ ) by taking the average of the  $MED0$  distance between  $g$  and each word in  $W$ :

$$MED_{D,K}(g, W) = \frac{MED0_{D,K}(g, w_1) + \dots + MED0_{D,K}(g, w_m)}{m}$$

We assume that a subroutine  $MED(\mathbf{D}, K, W, g)$  returns the MED distance  $MED_{D,K}(g, W)$ , as defined above.

## 4 NEX Using MED

In NEX task, we are given (i) an untagged corpus  $\mathbf{D}$  of documents; and (ii) a seed list  $L$  containing known examples of a particular NE type  $T$ . The goal is to create a gazette containing other instances of the NE type  $T$  that occur in  $\mathbf{D}$ . We first look at some sub-problems and then give the complete algorithm for NEX in Section 4.4.

### 4.1 Pre-processing step

The first task is to identify all phrases in  $\mathbf{D}$  that are likely to be instances of the NE type  $T$ . In the simplest case, all phrases in  $\mathbf{D}$  that have the same syntactic structure as the instances in  $L$  could be considered as candidates. For example, for DISEASE, one could look for all NPs that may begin with at most one adjective (e.g., `gray mold`), followed by one or more nouns and whose head word is a singular common noun (as in `crown rot` or `tissue blight`). We assume such simple logic is implemented in a subroutine *GenCandidates* (not shown in this paper). However, even with such syntactic restrictions, the number of candidate instances is usually very large. For instance, for agricultural domain corpus described in Section 5, around 350,000 candidates were output by *GenCandidates*. It also contains many phrases which are obviously not the instances of  $T$  (e.g., `moderate field tolerance`).

Algorithm *Prune* (Fig. 1) *pre-processes* the list  $C$  of candidates from *GenCandidates* using a

```

function Prune( $\mathbf{D}, C, n_0, L_1, L_2$ )
 $G_1 := \emptyset; G_2 := \emptyset;$ 
for  $i := 0; i < MaxIter; i++$  do
   $H_1 := \emptyset; H_2 := \emptyset;$ 
  Build maximum entropy classifier  $M$  using
  instances in  $L_1 \cup G_1$  and  $L_2 \cup G_2$  as positive and
  negative examples for class  $T$  respectively;
  foreach phrase  $g \in C$  &&  $g \notin G_1 \cup G_2$  do
     $(c, pc) :=$  predicted class of  $g$  using  $M$  along
    with predicted probability for class  $c$ 
    if  $c == T$  then  $H_1 := H_1 \cup \{(c, pc)\}$ 
    else  $H_2 := H_2 \cup \{(c, pc)\}$  endif
  end foreach
  Retain only top  $n_0$  elements in  $H_1$  and in  $H_2$  in
  descending order of  $pc$  values
   $G_1 = G_1 \cup H_1$  // add only the phrases from  $H_1$  to  $G_1$ 
   $G_2 = G_2 \cup H_2$  // add only the phrases from  $H_2$  to  $G_2$ 
end for
return ( $G_1$ )

```

Figure 1: Algorithm *Prune*

self-trained, iterative maximum entropy (MaxEnt) classifier. Some of the major features used by MaxEnt classifier are: words in the phrase, words in context and their POS tags, next and previous verbs, binary features to capture presence of adjective, capitalization, proper nouns within phrase.

### 4.2 Backdrop of a Gazette

The key problem in unsupervised NEX is to decide, using  $\mathbf{D}$ , whether a candidate phrase  $g$  has the same NE type  $T$  as the examples in  $L$ . For example, given  $L = \{\text{gray mold, crown rot, tissue blight}\}$  as a seed list for  $T = \text{DISEASE}$  and  $g = \text{corn rust}$  as a candidate phrase, we need to decide whether  $g$  is a DISEASE or not. The idea is to use the  $MED_{D,K}$  as defined above to accept only those  $g$  which have “low” distance (“high” similarity) between  $g$  and the backdrop of the gazette  $L$ , which is defined as a set  $W$  of words “characteristic” (or strongly indicative) of  $T$ .

Function *GetBackdrop*( $\mathbf{D}, L, K, m_0$ ) (Fig. 2) computes, using  $\mathbf{D}$ , the set  $W$  for a given gazette  $L$ . Essentially, it computes how many times each word  $w$  occurs in the context window of given size  $K$  around every entry in  $L$ . Then it computes a *relevance score* for each word. The *relevance score* is computed as a product of following factors: the entropy  $H$  of the word; the number  $b$  of entries in  $L$  for which it is a context word; and ratio of the total number  $f_L$  of times the word occurs in the context of all entries in  $L$  to its frequency  $f$  in the entire corpus  $\mathbf{D}$ . Finally, it returns the top  $m_0$  words in terms of the highest relevance score values as the backdrop for

```

function GetBackdrop(D, L, K, m0)
W = ∅ // initially empty
h = ∅ // hash table key=word value=count
foreach word w in D do
  foreach entry ui ∈ L do
    compute the frequency f(w,ui) of how many
      times w occurs in the context window of
      size K for ui
  end foreach
  // f(w) = total no. of occurrences of w in D
  // fL(w) = f(w,u1) + f(w,u2) + ... + f(w,uL) = total no. of
  // occurrences of w in the context of all entries in L
  compute the entropy of w as
  
$$H(w) = - \sum_{i=1}^{|L|} \frac{f(w, u_i)}{f_L(w)} \log \left( \frac{f(w, u_i)}{f_L(w)} \right)$$

  b(w) := no. of entries ui ∈ L for which f(w,ui) > 0
  Define score(w) := fL(w) / f(w) × b(w) × H(w)
end foreach
W := select top m0 words in terms of their scores
return(W)

```

Figure 2: Algorithm *GetBackDrop*

*L*. For example, suppose *L* consists of 6 DISEASE instances. For the word `causes`,  $b(\text{causes}) = 6$ ,  $H(\text{causes}) = 1.51$  and  $f(\text{causes}) = 75$ , leading to  $\text{score}(\text{causes}) = 16.9895$ . For the word `technology`,  $b(\text{technology}) = 2$ ,  $H(\text{technology}) = 0.0646$  and  $f(\text{technology}) = 84$ , leading to  $\text{score}(\text{technology}) = 0.2485$ . Clearly, `causes` is much more relevant as a cue word for DISEASE than `technology`. The score gives more importance to words that appear more frequently as well as in the context of more entries in the given gazette. Higher entropy value indicates that the word is used more uniformly in the context of many entries in *L*. Words with a more skewed usage (lower entropy) may be good indicator words for specific entries rather than for all entries in *L*. Such words are not preferred.

### 4.3 Assessing the Gazette

We propose a *post-processing* step to assess and improve the quality of the candidate gazette created, by identifying (and removing) those entries in the candidate gazette which are very unlikely to be true instances of NE type *T*.

Suppose the candidate gazette includes the two phrases  $g_1 = \text{late blight}$  and  $g_2 = \text{wet weather}$ . Suppose we had also been given a small set *Q* of *cue words* for the NE type *T*; e.g., for DISEASE, *Q* could be {`disease`, `cause`, `symptom`}. For a given phrase *g*, we compute two counts:  $c(g) = \text{count of sentences in } \mathbf{D} \text{ which contain the } n\text{-}$

gram *g* and  $cq(g) = \text{count of sentences in } \mathbf{D} \text{ which contain (in any order) both the } n\text{-gram } g \text{ and at least one word in } Q$ . Clearly,  $cq(g) \leq c(g)$ . Let  $\hat{f}(g) = \frac{cq(g)}{c(g)}$ . Clearly,  $0 \leq \hat{f}(g) \leq 1$ . For example,  $\hat{f}(g_1) = 38/90 = 0.422$  and  $\hat{f}(g_2) = 104/642 = 0.162$ .

Let  $0 < f_0 < 1$  be a fixed value; e.g.,  $f_0 = 0.2$  (we shall shortly discuss how to obtain  $f_0$ ). Essentially,  $\hat{f}(g)$  indicates how well the phrase *g* “co-occurs” with words in *Q*. “Low” values of  $\hat{f}(g)$  (e.g., those below  $f_0$ ) indicate that the number of occurrences of *g* drops drastically when you restrict to only those sentences that contain at least one word in *Q*. Such phrases are unlikely to be true instances of *T*. We perform a statistical hypothesis test (called *proportion test*) that the fraction  $\hat{f}(g)$  is greater than the given constant  $f_0$ . The null hypothesis is  $H_0 : f(g) \geq f_0$ , where  $f(g)$  is the “true” proportion for *g*, since the observed proportion varies depending on **D**. The test statistic is

$$\frac{\hat{f}(g) - f_0}{\sqrt{\frac{f_0(1-f_0)}{c(g)}}}$$

which follows the Standard Normal distribution. Hence the probability (*p*-value) of observing a particular value of the test statistic can be computed using standard tables. The null hypothesis is rejected if *p* is less than the given significance level  $\alpha$  (we use  $\alpha = 0.05$ ).

For  $g_1, g_2$ , the test statistic values are 5.270 and  $-2.407$ ; and the *p*-values are 0.999 and 0.008. Thus  $g_2$  is correctly rejected as an unlikely instance for the NE type DISEASE. Note that this step requires the user to provide the set *Q* of cue words for NE type *T*; we found that generally only a few words ( $\leq 10$ ) are enough. We set  $f_0$  to just below the minimum among the values for the current gazette *L*. We assume that this logic is implemented as a function *Assessor*(**D**, *Q*, *L*), where *L* is the gazette containing phrases to be assessed.

### 4.4 Unsupervised Gazette Creation

Algorithm *CreateGazetteMED* (Fig. 3) coordinates various modules described so far in this section. It starts with an initial seed list *L* of instances of a particular NE type *T*. It first calls the algorithm *GenCandidates* to create a list *C* of candidate phrases for *T* using **D** and prunes *C* using the algorithm *Prune*. Then in each iteration, it calls the algorithm *GetBackdrop* to cre-

```

algorithm CreateGazetteMED
input  $\mathbf{D}$  // set of all sentences from the corpus
input  $L = \{g_1, \dots, g_n\}$  // seed list of NE instances
input  $L_2$  // seed list of entity non-instances
input  $Q$  // set of cue words for NE type  $T$ 
input  $K$  // context window size; default = 3
input  $n_0$  // no. of candidate instances; default 50000
input  $h_0$  // threshold for MED; default = 0.2
input  $m_0$  // no. of backdrop words; default = 150
input  $maxIter$  // maximum no. of iterations; default = 15
output  $L$  // gazette with new entries added
 $C := GenCandidates(\mathbf{D})$ 
 $C := Prune(\mathbf{D}, C, n_0, L, L_2)$ 
for  $i = 1; i < maxIter; i++$  do
   $A := \emptyset$  // initially empty
   $W := GetBackdrop(\mathbf{D}, L, K, m_0)$ 
  foreach candidate phrase  $g \in C$  &&  $g \notin L$  do
    if  $MED(\mathbf{D}, K, W, g) \leq h_0$  then
       $A := A \cup \{g\}$ 
    endif
  end foreach
   $L := L \cup A$  // add entries in  $A$  to  $L$ 
end while
 $L := Assessor(\mathbf{D}, Q, L)$  // remove unlikely entries

```

Figure 3: Algorithm *CreateGazetteMED*

ate the set  $W$  of backdrop words for  $T$  using  $L$ . Then it uses the modified MED to measure the similarity of each candidate phrase  $g \in C$  with  $W$  and adds  $g$  to a temporary set  $A$  only if it has a “high” similarity with  $W$  (above a threshold). A configurable number (default 10) of top candidates from set  $A$  are added to  $L$  in each iteration. At the end of  $maxIter$ , final set of candidates in  $L$  is then pruned using the *Assessor* algorithm. We have enhanced the earlier version (Patil et al., 2013) by using weighted backdrop to compute  $MED_{D,K}(g, W)$ . Note that the algorithm contains four independent ways of assessing whether a sequence of words is an instance of  $T$  or not, as implemented in *GenCandidates*, *Prune*,  $MED_{D,K}$  and *Assessor*.

## 5 Experimental Evaluation

**Experimental Setup:** In addition to the agricultural news corpus described in (Patil et al., 2013), we also evaluated the proposed technique on a corpus of 7500 engine repair records from mechanical engineering domain. Goal is to create a gazette of engine part names from the engine repair records. The agriculture corpus consists of 30533 documents in English containing 999168 sentences and approximately 19 million words. It was collected using crawler4j (Ganjisaffar, 2013) by crawling the agriculture news web-

	Crop	Disease	Chem. Treatment	Engine Part
$MED_{D,K}$ with assessor	352 (0.662)	237 (0.928)	332 (0.886)	88 (0.818)
PMI with assessor	419 (0.625)	315 (0.911)	341 (0.883)	92 (0.793)
$MED_{D,K}$ no assessor	372 (0.637)	267 (0.831)	502 (0.671)	91 (0.802)
PMI no assessor	441 (0.603)	361 (0.801)	512 (0.670)	95 (0.779)
BASILISK	352 (0.278)	237 (0.924)	332 (0.386)	100 (0.67)

Figure 4: Number of entries (& precision) in the final gazette for each NE type. (To use the same baseline for comparing precision of the proposed algorithm and BASILISK, we use the gazette size of BASILISK comparable to that of  $MED_{D,K}$  with Assessor.)

sites (websites, 2012)<sup>3</sup>. A sample of seeds used to bootstrap the NEX for each category are as following - CROP: {wheat, cotton, corn, soybean, banana}; DISEASE: {wilt, leaf spot, rust, weevil}; CHEM.TREATMENT: {di-syston, evito, tilt, headline}; ENGINE.PARTS: {piston, gaskets, bearings, crankshaft, cylinder}.

**Results:** Fig. 4 summarizes the gazette sizes along with precision for NE types from both agriculture and mechanical engineering (IC engine parts) corpora. Detection rate for agriculture NE type are shown in Fig. 5. To calculate the precision, all the gazettes created by all the algorithms were manually and independently verified by at least three different human annotators. From these results, we conclude that the proposed technique performs well in *domain independent* manner. Assessor module improves precision for all NE types for both measures  $MED_{D,K}$  and PMI. Post-processing using assessor has positive impact on gazette quality. In this experiment, we used top 1000 candidates produced by algorithm *Prune*, instead of top 5000 used in the earlier version (Patil et al., 2013). We observe significant improvement in precision for all NE types. It is clear that the gazette quality is dependent on the output of algorithm *Prune*. We are investigating their inter-relationship as part of this on-going work.

A sample entries from gazette created for each NE type  $T$  are as follows: CROP: {rr alfalfa, sugarcane, biofuel crops, winter canola};

<sup>3</sup>Permission awaited from the content-owners for public release of the corpus for research purpose.

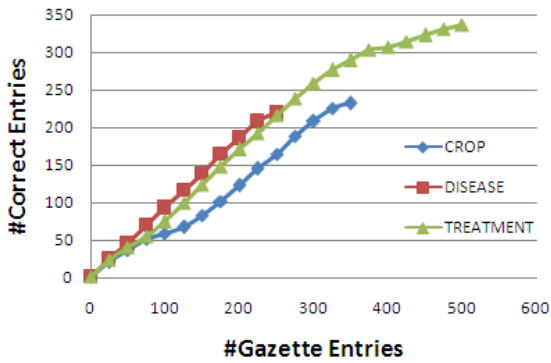

Figure 5: Detection rate of *CreateGazetteMED* with Assessor

DISEASE: { asian soybean rust, alternaria, downy mildew, citrus greening, fusarium wilt}; CHEM.TREATMENT: { ultra blazer, strobilurin, telone II, gaucho grande, spartan}; ENGINE.PARTS:{ piston pin, conn rod, cam gear, cyl head, piston skirt}.

To highlight effectiveness of the gazettes created, we compared our DISEASE gazette with wikipedia. We listed all the page titles on wikipedia falling under categories *Plant pathogens and diseases* (1935) and *Agricultural pest insects* (203). It was quite encouraging to find that, our gazette, though created on a limited size corpus, contained diseases/pathogens not present in wikipedia.<sup>4</sup> Some of these are - limb rot, grape colaspis, black shank, glume blotch, seed corn maggot, mexican rice borer, green bean syndrome, hard lock.

**Comparison with BASILISK:** Our implementation of BASILISK (Pawar et al., 2012) has comparable precision with the proposed *CreateGazetteMED* algorithm for DISEASE category. However, *CreateGazetteMED* clearly outperforms BASILISK for all other categories. Major reason behind worse performance of BASILISK is that it scores each occurrence of the phrase in the corpus independently and the decision to add that phrase to the gazette depends on the highest among all of these scores. *CreateGazetteMED* computes a single score for each phrase by combining evidences from all of its occurrences in the corpus.

**Comparison with KNOWITALL:** KNOWITALL (Etzioni et al., 2005) is a leading, web-scale unsupervised information extraction engine. We implemented basic version of KNOWITALL

algorithm and executed it on above mentioned corpus of agricultural news items. For agriculture domain, KNOWITALL extracted gazettes of following sizes for the three NE types - CROP : 36 entries (20 correct); DISEASE : 55 entries (49 correct); CHEM.TREATMENT : 13 entries (12 correct).

We believe that reason for KNOWITALL's limited gazette size lies in inherent difference between a web-scale search vis-a-vis searching a given corpus. This results in skewed search query statistics and affects the size of gazettes created.

**Comparison with PMI:** To gauge the effectiveness of  $MED_{D,K}$  as a proximity measure, we compare it with PMI (Bouma, 2009). We follow exactly the same steps as described in our *CreateGazetteMED* algorithm with the only difference being use of PMI, instead of  $MED_{D,K}$ . For the results with top 1000 candidates from Prune (Fig. 4),  $MED_{D,K}$  compares favorably with PMI as a proximity measure for all the NE types. Comparing with results with top 5000 candidates from Prune (in (Patil et al., 2013)), we observe that  $MED_{D,K}$  is a more robust proximity measure than PMI. Sensitivity of these measures to output of pre-processing step is part of future work.

## 6 Conclusions and Further Work

We presented improved results of our unsupervised NEX technique, *CreateGazetteMED*. A new variant of MED is used to quantify the proximity (similarity) of a candidate phrase with a given NE type. We established its domain independence using corpora from agriculture and mechanical engineering domains. Effectiveness of *CreateGazetteMED* was validated using experimental comparison with PMI, BASILISK and KNOWITALL. Our method incorporated a pre-processing step (based on MaxEnt classifier). We also proved efficacy of statistical hypothesis testing as a post-processing step to improve gazette quality. As part of further work, developing a robust stopping criterion for automatically stopping the gazette creation process needs attention. Unsupervised relation extraction (such as relations between CROP, DISEASE, CHEMICAL.TREATMENT and many other NEs) is a natural extension. Establishing language independence of the proposed technique, exploring effect of number and quality of initial seeds are also promising avenues.

## Abstract

In this paper we introduce a feature-based neural language model, which is trained to estimate the probability of an element given its previous context features. In this way our feature-based language model can learn representation for more sophisticated features. We introduced the deep neural architecture into the Chinese Word Segmentation task. We got a significant improvement on segmenting performance by sharing the pre-learned representation of character features. The experimental result shows that, while using the same feature sets, our neural segmentation model has a better segmenting performance than CRF-based segmentation model.

## 1 Introduction

Nowadays, as a distributed representation learning framework, Deep Learning Architecture has received a lot of attention in the NLP literature.

As Hinton introduced the idea of distributed representation for symbolic data in (Hinton, 1986), this idea has been a research hot spot for more than twenty years.

Bengio (2003) applied Hinton's idea in the context of language modeling, and developed a neural language model. Mikolov (2011) improved Bengio's neural language model by adding recurrence to the hidden layers, allowing it to beat the state-of-the-art  $n$ -gram model not only in terms of perplexity but also in terms of word error rate in speech recognition. Schwenk (2012) applied similar models in statistical machine translation and improved the BLEU score by almost 2 points.

Different from the traditional  $n$ -gram model, a distributed representation of word can be learned by neural language model from unlabeled raw data. As the most important philosophy of Deep

Learning architecture, the property of learning distributed word representation of neural language model have been proved very useful in NLP tasks.

Colobert et al. (2011) developed the SENNA system that shares word representations across the tasks of language modeling, part-of-speech tagging, chunking, named entity recognition, semantic role labeling and syntactic parsing, which approaches or surpasses the state-of-the-art on these tasks. More interestingly, their experimental result shows that, sharing the word representations that are learned by the neural language model on massive raw data can significantly improve the overall performance of the other tasks.

All these research have showed us the very good capability of the neural language model in learning word representation. However, for many NLP tasks, not only the distributed representation of word, but also the representation of features is important. Since the neural language model can learn the representation of words, can we use it to learn representation of features?

In this paper, we introduce a more generalized feature-based neural language model, which can learn distributed representation of features, which is very useful for many NLP tasks.

Traditional neural language model aims to estimate the probability of a word given words in its previous context, our feature-based neural language model is a generalization of the traditional neural language model, which views the language modeling problem as feature-based prediction problem. The features used to predict an element can be words or characters as well as other sophisticated features extracted from the previous context. After training, our feature-based neural language model can learn a distributed representation of those sophisticated features.

To test the usefulness of the feature representation learned by our feature-based neural language model, we introduce a deep neural archi-

ture into the Chinese Word Segmentation task. We conducted a series of experiments on the SIGHAN-2005 datasets, and got a positive result.

By sharing the feature representation learned by our feature-based neural language model with our neural segmentation model, we got a significant improvement on the segmentation performance.

We also made comparison between our neural segmentation model and the classical segmentation method based on Conditional Random Fields(CRF). The experimental result shows that, while using the same feature sets, the neural segmentation model have a better performance than that of CRF-based method, especially when sharing the pre-learned feature representations.

The rest of the paper is organized as follows. Section 2 overviews the task of Chinese Word Segmentation. Section 3 introduce our feature-based neural language model. The deep neural architecture used for segmentation is described in Section 4. Section 5 gives the experimental result. The last section concludes this paper.

## 2 Chinese Word Segmentation

Unlike English and other western languages, Chinese do not delimit words by white-space. Therefore word segmentation is a very basic and important pre-process for Chinese language processing.

Traditional word segmentation approaches are lexicon-driven (Liang, 1987). Lexicon-driven methods assume that predefined Chinese word lexicon is available, hence the segmentation performance strongly depends on the predefined lexicon.

Xue (2003) proposed a novel way of segmenting Chinese texts, and views the Chinese word segmentation task as a character tagging task. According to Xue’s approach, a tagging model is learned from manually segmented training texts, and then used to assign each character a tag indicating the position of this character within a word it belongs to. Xue’s approach, which did not require any predefined lexicon and have a high performance, became the most popular approach to Chinese word segmentation in recent years.

In Sighan Bakeoff-2005, two participants (Low, 2005) and (Tseng, 2005) have given the best results in almost all word segmentation tracks. Both of their systems use sequence tagging methods based on Conditional Random Field (CRF).

CRF is a statistical sequence modeling framework first introduced into natural language pro-

cessing in (Lafferty et al., 2001). Peng et al. (2004) first used this framework for Chinese word segmentation by treating it as a binary decision task, such that each character is labeled either as the beginning of a word or the continuation of one.

In this paper, we use a CRF-based segmentation system to do a series of comparative experiments.

As in most other work did on segmentation, we use a 4-tag schema, such that each Chinese character is labeled by a tag in the tag set “B,M,E,S”. In which, “B”, “E” and “M” stands for the character in the beginning, ending or middle of a word, “S” means that the character is a word by itself.

We use the following feature templates, which are widely used in most segmentation work:

(a)  $C_n(n = -2, -1, 0, 1, 2)$

(b)  $C_n C_{n+1}(n = -2, -1, 0, 1)$

(c)  $C_{-1} C_1$

Here  $C$  refers to a character;  $n$  refers to the position index relative to the current character. By setting the above feature templates, we actually set a 5-character window to extract features, the current character, 2 characters to its left and 2 to its right.

Other work on segmentation used much more sophisticated feature templates other than the one introduced above. However, defeating the state-of-the-art segmentation work is not the main purpose of this paper. Here, we just want to test whether our model can use the same feature set more efficiently than the CRF-based model. Since it is practicable but not necessary to use other sophisticated feature templates to do the model comparison, we just use the aforementioned feature template as the standard feature set for the Chinese word segmentation task.

## 3 Feature-based Neural Language Model

In this section, we first overview the widely used traditional neural language model. Then we introduce our feature-based neural language model, which is a generalization of the traditional one and can learn representation of features from unlabeled raw data through unsupervised training.

### 3.1 Traditional Neural Language Model

Language models are widely used in many NLP applications to compute “scores” describing how likely a piece of text is. The classical  $n$ -gram language model is a direct application of Markov

models, estimating the probability of a word given its previous words in a sentence.

Neural language models were proposed by Bengio and Ducharme (2003) and Schwenk and Gauvain (2004). These neural language models were designed to estimate the conditional probability of a word given its previous context in a sentence.

Different from the traditional  $n$ -gram language model, neural language model can learn a distributed representation of words from unlabeled raw data. As an application of the deep learning architecture, what we value most is the representation learning ability of the neural language model.

For many NLP tasks, the distributed representation of features is important as well as the one of words. However, the traditional neural language model have this shortcoming that it is designed to learn representation of words only.

To overcome this shortcoming of the traditional neural language model, we propose a much more generalized neural language model that can learn distributed representation of features. To distinguish from the traditional one, we call it the feature-based neural language model.

### 3.2 Feature-based Neural Language Model

Unlike the traditional neural language model, which aims to estimate the probability of a word given its previous context words, our feature-based neural language model views the language modeling problem as feature-based prediction problem. Our feature-based neural language model estimate the probability of an element given its history context feature set. The predicted element could be a word or a character in a sentence.

The architecture of our feature-based neural language model is summarized in Figure 1.

More formally, the probability estimated by our feature-based neural language model is:

$$p(E|F_{history}, \theta)$$

where  $\theta$  is the set of parameters of our model. We denote the feature set extracted from the history context of an element  $E$  as  $F_{history}$ :

$$F_{history} = \{f_1, f_2, \dots, f_k\}$$

The first layer of our feature-based neural language model is called lookup table layer, which maps each  $f \in F_{history}$  into a  $d_f$ -dimensional feature vector  $W_{.f} \in \mathbb{R}^{d_f}$ :

$$LT_W(f) = W_{.f}$$

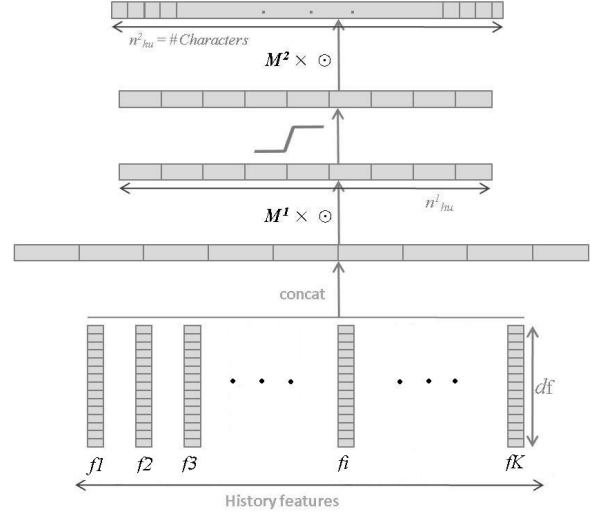

Figure 1: Feature-based Neural Language Model

where  $W$  is called the lookup table, which contains the distributed representation of features, and it is the most important parameter of our feature-based neural language model.

Given a set of features  $F_{history} = [f]_1^k$ , the lookup table layer applies the same operation for each feature in  $F_{history}$ , producing the following  $d_f \times k$  matrix:

$$LT_W([f]_1^k) = (W_{.[f]_1} \quad W_{.[f]_2} \quad \dots \quad W_{.[f]_k})$$

This matrix can be viewed as a  $d_f k$ -dimensional vector  $z^1$  by concatenating its column vectors. Then  $z^1$  can be fed to further neural network layers which perform affine transformations as below:

$$z^l = M^l z^{l-1} + b^l$$

where  $M^l \in \mathbb{R}^{n_{hu}^l \times n_{hu}^{l-1}}$  and  $b^l \in \mathbb{R}^{n_{hu}^l}$  are the parameters to be trained. The hyper-parameter  $n_{hu}^l$  indicates the number of hidden units of the  $l^{th}$  layer. If the  $l^{th}$  layer is not the last layer, to extract highly non-linear features, a non-linearity function must follow. We use  $Tanh()$  to be our non-linearity function.

$$Tanh(a) = \frac{e^a - e^{-a}}{e^a + e^{-a}}$$

Finally, the output size of the last layer  $L$  of the network is equal to the number of possible elements. Each output can be then interpreted as the corresponding probability of an element given the history context feature set.

### 3.3 Model Training

All the parameters of our feature-based neural language model are trained by maximizing a likelihood over the unlabeled training data, using stochastic gradient ascent method (Bottou, 1991).

If we denote  $\theta$  to be all the trainable parameters of the network, which are trained using a training set  $\mathcal{T}$  we want to maximize:

$$\theta \mapsto \sum_{(f_h, e) \in \mathcal{T}} \log p(e | f_h, \theta) \quad (1)$$

where  $e$  is an element and  $f_h$  is the corresponding history context feature set of  $e$ .

We maximize equation (1) with stochastic gradient method, by iteratively selecting a random example  $(f_h, e)$  and making a gradient step:

$$\theta \leftarrow \theta + \lambda \frac{\partial \log p(e | \mathbf{f}_h, \theta)}{\partial \theta}$$

where  $\lambda$  is a chosen learning rate, which is also one of the hyper-parameters of our model.

Since our feature-based neural language model is trained on the unlabeled raw data, so its training process is an unsupervised learning procedure.

## 4 Deep Neural Architecture For Chinese Word Segmentation

In this section, we introduce the deep neural architecture into the Chinese word segmentation task.

### 4.1 Neural Network Segmentation Model

Figure 2: Neural Network Architecture for CWS

The architecture of our neural segmentation model is summarized in Figure 2. We can see that

this architecture is almost the same as our feature-based neural language model, only have slightly difference at the output layer.

As input, character features (unigram or bigram features) are fed as indices taken from a finite dictionary  $\mathcal{D}$ . This dictionary  $\mathcal{D}$  contains all the character features which appeared in the training data.

The first layer of the network maps each of these character feature  $c_f \in \mathcal{D}$  into a  $d_f$ -dimensional feature vector  $W_{\cdot c} \in \mathbb{R}^{d_f}$ , where  $W$  contains distributed representations of the character features. Given a set of character features  $[c_f]_1^T$  in  $\mathcal{D}$ , the lookup table layer applies the same operation for each character feature in the sequence, producing a  $d_f \times T$  matrix.

Given a character to tag, we consider a fixed-size  $k_{sz}$  window of characters around this character to collect the character features. If we only use the unigram features, then there will be  $k_{sz}$  ( $T = k_{sz}$ ) character features that are first passed through the lookup table layer, producing a matrix of fixed size  $d_f \times k_{sz}$ . If we use both the unigram and bigram features, then there will be  $2k_{sz} - 1$  ( $T = k_{sz} + k_{sz} - 1$ ) character features that will produce a matrix in shape of  $d_f \times (2k_{sz} - 1)$ .

And this matrix can be viewed as a  $d_f T$ -dimensional vector by concatenating its column vectors. Then this concatenated vector  $z^1$  can be fed to further neural network layers which perform affine transformations over their inputs.

To extract highly non-linear features at hidden layers, we also use  $Tanh()$  to be our non-linearity function here.

Finally, the output size of the last layer  $L$  of the segmentation model is equal to the number of possible tags, which is 4 (B,M,E,S) in our case. Each output can be then interpreted as probability of tagging the current Chinese character with the corresponding tag.

### 4.2 Model training

All the parameters of our neural segmentation model are trained by maximizing a likelihood over the training data, using stochastic gradient ascent, like we did in previous section.

Since the lookup table of feature vectors is the most important parameter in this neural segmentation model, sharing a well trained lookup table must have a positive impact on the segmentation performance.

We will use our feature-based neural language

model to pre-train a lookup table on a larger raw text data, and then use this pre-trained lookup table to initialize the corresponding lookup table parameter of the neural segmentation model.

Since the pre-training process is unsupervised, so the whole training process of our segmentation model is actually a semi-supervised procedure.

## 5 Experiments

### 5.1 Experimental Setup

To make a comprehensive comparison between our neural segmentation model and the CRF-based model, we conduct a closed test on the PKU dataset from the Sighan-2005 Chinese word segmentation bake-off competition.

We remove the the white-spaces between words in the training and testing data sets of PKU and MSRA datasets and make it all a raw text training data for our feature-based neural language model. Some statistical information of the data sets are given in Table 1.

	PKU	MSRA
Word Types	55,303	88,119
Words	1,109,947	2,368,391
Character Types	4,698	5,167
Characters	1,826,448	4,050,469

Table 1: Statistics of Sighan-2005 data sets.

For evaluation, we use the standard bake-off scoring program to calculate precision, recall, F1, OOV and IV word recall.

To make a performance comparison between our neural segmentation model and the CRF-based model under the same feature sets, we did experiments under three different scenarios.

In each scenario, both our neural segmentation model and CRF-based model are trained using the same feature sets described in Table 2.

As shown in Table 2, in scenario 1, both two models use unigram character features only, in scenario 2 the unigram and bigram character features are used, and in scenario 3 the standard feature set for the CRF-based model.

In each scenario, a feature-based neural language model is trained to learn the distributed representation (lookup table) of the features that is used by the neural segmentation model.

For each experimental setup, we provide the results of our neural segmentation model with

	Feature Sets
Scenario 1	$C_{-2}, C_{-1}, C_0, C_1, C_2$
Scenario 2	$C_{-2}, C_{-1}, C_0, C_1, C_2$ $C_{-2}C_{-1}, C_{-1}C_0, C_0C_1, C_1C_2$
Scenario 3	$C_{-2}, C_{-1}, C_0, C_1, C_2$ $C_{-2}C_{-1}, C_{-1}C_0, C_0C_1, C_1C_2$ $C_{-1}C_1$

Table 2: Feature Sets used in 3 scenarios.

or without sharing the look up table parameters learned by our feature-based language model.

In this paper, we use an open source toolkit “CRF++”<sup>1</sup> to train the CRF models. While training the CRF models, we set the parameter cutoff threshold for the features to be 3 and other parameters are set by default. The hyper-parameters of our feature-based neural language model and neural segmentation model are set as in Table 3.

Window size	$k_{sz} = 5$
Feature dim	$d_f = 30$
Hidden units	$n_{hu} = 300$
learning rate	$\lambda = 0.001$

Table 3: Hyper-Parameters of our neural segmentation model and feature-based neural language model.

### 5.2 Scenario 1: Only Unigram Features

In Table 4 are given the results of experiments on scenario 1, in which only unigram character features are used by both segmentation models.

As the result shows, while using the same feature set, our neural segmentation model have a better performance than that of the CRF-based model, which means our model makes use of the features more efficiently than the CRF-based model.

From the result we can see that sharing the lookup table parameters with the pre-trained feature-based neural language model can significantly improve the performance of our neural segmentation model. The OOV recall is boosted from 48.9% to 68.8%, this means pre-trained lookup table can help neural segmentation model to deal with OOV problem more smoothly.

### 5.3 Scenario 2: Unigram & Bigram Features

The results in Table 5 shows the performance of our neural segmentation model and the CRF-

<sup>1</sup>crfpp.sourceforge.net

	P	R	F1	$R_{OOV}$	$R_{IV}$
CRF	0.846	0.863	0.855	0.533	0.866
NN	0.871	0.879	0.875	0.489	0.895
NN+LM	0.912	0.927	0.920	0.688	0.926

Table 4: Results of our Neural Segmentation Model (NN) and CRF-based Segmentation Model, using only unigram features, “+LM” means sharing pre-trained lookup table parameters.

based model when unigram and bigram features are used. The experimental result again shows that the performance of our neural segmentation model surpasses that of the CRF-based model, while using the same feature set.

We can see that using our feature-based neural language model to pre-train the lookup table parameters can significantly boost the system performance, which means our feature-based neural language model can learn a better lookup table that contains task-useful information.

	P	R	F1	$R_{OOV}$	$R_{IV}$
CRF	0.918	0.934	0.926	0.566	0.940
NN	0.927	0.933	0.930	0.566	0.949
NN+LM	0.932	0.940	0.936	0.628	0.950

Table 5: Results of our Neural Segmentation Model (NN) and CRF-based Segmentation Model, using unigram and bigram features, “+LM” means sharing pre-trained lookup table parameters.

#### 5.4 Scenario 3: All Standard Features

The results in Table 6 shows the performance of our neural segmentation model and the CRF-based model when the standard feature set are used.

The  $+LM_1$  in Table 6 means that neural segmentation model only share unigram feature representations, which are learned by our feature-based language model in scenario 1. The  $+LM_2$  means neural segmentation model share the representations of the standard feature set learned by our feature-based language model.

We can see that our neural segmentation model have almost the same but still better performance than that of CRF-based model. The result also shows that, only sharing pre-learned unigram feature representation is not helpful to boost the performance of our neural segmentation model. When sharing the pre-learned representations of the same features used by neural segmentation model, a significant improvement on the system performance can be achieved.

From Table 4, 5 and 6 we can see that, sharing pre-learned feature representations can always boost the performance of our neural segmentation model. This means that our feature-based neural language model is effective in learning feature representations, even if the features are more sophisticated. The performance boost mainly come from the improvement on OOV recall, means that the pre-learned feature representations is helpful while dealing with the OOV problem in Chinese Word Segmentation task.

	P	R	F1	$R_{OOV}$	$R_{IV}$
CRF	0.924	0.939	0.931	0.609	0.943
NN	0.936	0.928	0.932	0.579	0.958
$NN+LM_1$	0.935	0.929	0.932	0.569	0.958
$NN+LM_2$	0.940	0.939	0.940	0.695	0.955

Table 6: Results of our Neural Segmentation Model (NN) and CRF-based Segmentation Model using standard features, “+LM” means sharing pre-trained lookup table parameters.

## 6 Conclusion

In this paper we introduced a generalized feature-based neural language model, which is trained to estimate the probability of an element given its previous context features, thus making it possible to learn distributed representation of more sophisticated features, which is useful for NLP tasks.

To test the efficiency of the feature representation learned by our feature-based neural language model, we introduced the deep neural architecture into the Chinese Word Segmentation task. We conducted a series of experiments on the Sighan-2005 PKU-dataset.

Experimental result shows that our neural segmentation model have a better performance than that of CRF-based model, while these two models are using the same feature sets.

By sharing the representation learned by our feature-based neural language model with the neural segmentation model, we got a significant improvement on system performance. This proved that useful feature representation can be learned by our feature-based neural language model.

## Abstract

Previous research shows that Kalman filter based human-computer interactive Chinese word segmentation achieves an encouraging effect in reducing user interventions, but suffers from the drawback of incompetence in distinguishing segmentation ambiguities. This paper proposes a novel approach to handle this problem by using an adaptive Dirichlet process mixture model. By adjusting the hyperparameters of the model, ideal classifiers can be generated to conform to the interventions provided by the users. Experiments reveal that our approach achieves a notable improvement in handling segmentation ambiguities. With knowledge learnt from users, our model outperforms the baseline Kalman filter model by about 0.5% in segmenting homogeneous texts.

## 1 Introduction

As Chinese text is written without natural delimiters such as whitespaces, word segmentation is often the essential first step in Chinese language processing (Liang, 1987). Over the past two decades, various methods have been developed to address this issue (Nie et al., 1994; Sun et al., 1998; Luo et al., 2002; Zhang et al., 2003; Peng et al., 2004; Goldwater et al., 2006). Generally, supervised statistical learning methods are more adaptive and robust in processing unrestricted texts than the traditional dictionary-based methods.

However, in some domain-specific applications, for example ancient Chinese text processing, there is neither enough homogeneous corpora for training a reliable statistical model, nor a well-defined dictionary. In these tasks, unsupervised word segmentation is preferred to utilize the linguistic knowledge derived from the raw corpus itself. Many researches also enable users to take part in the segmentation process, adding expert knowledge to the system (Wang et al., 2002; Li and Chen, 2007). This is quite reasonable since the criteria of word segmentation are dependent on a user or the destination of use in many applications (Sproat et al., 1996).

Zhu et al. (2013) proposed a Kalman filter based human-computer interactive learning model for segmenting Chinese texts depending upon neither lexicon nor any annotated corpus. This approach enables experts to observe and intervene with the segmentation results, while the segmenter learns and adapts to these knowledge iteratively. At the end of this procedure, a segmentation result that fully matches the demand of the user is returned. However, in some complicated cases where segmentation ambiguities exist, the Kalman filter will not converge and keep swapping in two or more states.

To overcome this drawback, we established an adaptive Dirichlet process mixture model (ADPMM) for human-computer interactive word segmentation. ADPMM gradually adapts itself to the knowledge supplied by users through the process of human-computer interaction, notably reducing human interventions by classifying each occurrence of a bigram into its corresponding class. Each generated class bears a tag *separated* or *combined* derived from user interventions; bigrams classified to a class later is judged as *separated* or *combined* according to the class tag. Knowledge learnt from the user can further

---

\* To whom all correspondence should be addressed.

be used to aid the segmentation of homogeneous corpus.

The rest of this paper is organized as follows. The next section reviews related work. The details of our model are elaborated in Section 3. In Section 4, experiments are presented to illustrate the performance of our model. The final section concludes the proposed model and discusses possible future work.

## 2 Related Work

Unsupervised word segmentation is generally based on some predefined criteria, for example *mutual information* ( $mi$ ), to recognize a substring as a word. Sproat and Shih (1990) studied comprehensively in this direction using mutual information. Many successive researches applied different ensemble methods to mutual information (Chien, 1997; Yamamoto and Kenneth, 2001). Sun et al. (2004) designed an algorithm based on the linear combination of  $mi$  and *difference of t-score* ( $dts$ ). Other criteria like *description length gain* (Kit and Wilks, 1999), *assessor variety* (Feng et al., 2004) and *branch entropy* (Jin and Tanaka-Ishii, 2006) were also explored.

Any automatic segmentation has limitations in some way and is far from fully matching the particular need of users. Thus, human-computer interactive strategies are explored to allow users to pass their linguistic knowledge to the segmenter by directly intervening the segmentation process. Wang et al. (2002) developed a sentence-based human-computer interaction inductive learning method. Feng et al. (2006) proposed a certainty-based active learning segmentation algorithm to train an  $n$ -gram language model in an unsupervised learning framework. Li and Chen (2007) further explored a candidate word based human-computer interactive segmentation strategy.

Kalman filters (Kalman, 1960) are based on linear dynamic systems discretized in the time domain. Given parameters, Kalman filters estimates the unobserved state. Zhu et al. (2013) applied Kalman filter model to learn and estimate user intentions in their human-computer interactive word segmentation framework.

A Dirichlet process is a stochastic process that is a distribution whose domain is itself a distribution (Ferguson, 1973). It can also be viewed as an infinite-dimensional generalization of the Dirichlet distribution. It can be used to construct a mixture model with an unknown number of components (West et al., 1993). Dirichlet processes have been used to handle Chinese word

segmentation. Goldwater et al. (2006) explored a bigram model built upon a Dirichlet process to discover contextual dependencies.

## 3 Model

### 3.1 Baseline Model

Sun et al. (1998) proposed *difference of t-score* ( $dts$ ) as a useful complement to *mutual information* ( $mi$ ). They further designed a compound statistical measurement based on the linear combination of  $mi$  and  $dts$ , named  $md$  (Sun et al., 2004). Given any bigram  $xy$ , in terms of  $md(x,y)$  and a threshold  $\Theta$ , whether the bigram should be combined or separated can be determined—when  $md(x,y)$  is greater than  $\Theta$ , the bigram  $xy$  has more chance to be in a word. This model is a reference to our basic model before the human-computer interaction process. The formulae for calculating  $md$  are as follows:

$$mi^*(x, y) = \frac{mi(x, y) - \mu_{mi}}{\sigma_{mi}},$$

$$dts^*(x, y) = \frac{dts(x, y) - \mu_{dts}}{\sigma_{dts}}, \quad (1)$$

$$md(x, y) = mi^*(x, y) + \lambda \times dts^*(x, y),$$

where  $\mu_{mi}$  and  $\mu_{dts}$  are means of  $mi$  and  $dts$  in the corpus;  $\sigma_{mi}$  and  $\sigma_{dts}$  are standard deviations.  $mi^*$  and  $dts^*$  are normalized versions of measure  $mi$  and  $dts$ ;  $\lambda$  is an empirical value.

Meanwhile, there is an optimization where local maxima and minima of  $md$  appear (Sun et al., 2004). Consider a character string  $abcd$ . If  $md(b,c) > md(a,b)$  and  $md(b,c) > md(c,d)$ , then  $bc$  is considered a *local maximum*. *Local minimum* follows a similar definition. Obviously, local maxima are more likely to form words, while local minima are more likely to be separated. To reflect this kind of tendency, we increase the  $md$  values at local maxima by a constant  $s$ , and decrease the  $md$  values at local minima by  $s$ .

Based on the compound statistical measure  $md$ , Zhu et al. (2013) further developed a human-computer interactive word segmentation framework. In their model, the human interaction process is mapped to a time series process, and user judgments are treated as measurements of the true  $md$  value of bigrams. Each bigram is modeled by a Kalman filter independently to learn and estimate user intentions from user interventions (which may contain noise). Linguistic knowledge is gradually accumulated from the interactions, and eventually, a segmentation that fully matches the specific use is returned.

Both baseline models above use a threshold value  $\Theta$  to classify each bigram into two classes, namely *combined* and *separated*. Both approaches are inherently binary classifiers which seek to classify occurrences of bigrams into classes.

### 3.2 Problem of Segmentation Ambiguity

In the scenario of human-computer interactive Chinese word segmentation, the Kalman filter approach proposed by Zhu et al. (2013) encounters the problem of segmentation ambiguity, rendering it unsuccessful in converging in some special cases. If segmentation ambiguity exists, human interventions would be swapping, which in turn results in swapping states of the Kalman filter.

Take the bigram 及其 used in Zhu et al. (2013) as an example. It exhibits at least two types of segmentation in the corpus (e.g., *separated* in 以及/其他 ‘and others’, and *combined* in 及其/浮动 ‘and its fluctuations’). The Kalman filter approach will not converge, and will keep swapping between two or more states as shown in Figure 1.

**Figure 1.** Problem encountered in Kalman Filter model on the bigram 及其. The vertical axis denotes the *md* value, and the horizontal axis denotes the occurrence of 及其 in the text. An increase in the value denotes that there exist interventions tagged by the user as *combined*; whereas a decrease in the value indicates the presence of interventions tagged as *separated*.

To address this problem, we adopt the *md* measure described by Sun et al. (2004) to construct a Dirichlet process mixture model to classify each occurrence of a bigram into its corresponding class. Each class bears a tag *separated*

or *combined* derived from user interventions. This model gradually adapts itself to the knowledge supplied by the user’s interventions through human-computer interaction, making it more robust in distinguishing segmentation ambiguities through the process of classifying them into different classes.

### 3.3 Adaptive Dirichlet Process Mixture Model

To address the problem mentioned above, classification of each occurrence of a bigram into its corresponding class is required. Since we cannot predict the exact number of classes, a Dirichlet process mixture model (West et al., 1993) would suffice. Similar to the Kalman filter based approach, we also assume that each bigram is independent, i.e., if the model for one bigram changes, other bigrams is not affected. To simplify our discussion, we focus on only one bigram in this section. Notations used in this paper are listed in Table 1.

Symbol	Definition
$\Theta$	Threshold <i>md</i> value
$x_i$	The <i>md</i> value of the <i>i</i> th occurrence of the specific bigram
$\mu_k$	The expectation of the <i>k</i> th class
$\sigma_k^2$	The variance of the <i>k</i> th class
$z_i$	The class indicator of sample $x_i$ , i.e., $x_i$ belongs to class $z_i$
$\alpha$	Concentration parameter of the Dirichlet process mixture model
$H$	Prior base distribution of the Dirichlet process mixture model
$N(x   \mu, \sigma^2)$	Probability density of $N(\mu, \sigma^2)$ at $x$
$H(\mu, \sigma^2)$	Probability density of $H$ at $(\mu, \sigma^2)$
$N\text{-}\Gamma^{-1}$	Normal-inverse-gamma distribution
$\psi$	Prior sum of squared deviations of the mixture model

**Table 1.** Notations used in this paper.

We consider the *md* value of each occurrence of a bigram as a *sample* of the bigram. Initially, samples are classified into class *separated* or *combined* according to threshold value  $\Theta$ . During the interaction process, more classes should be

generated to handle complex situations when binary classifiers are unable to produce correct segmentation result. As the exact number of classes cannot be predicted, the model used for the generation of multiple classes can be formulated as an infinite Gaussian mixture model, in which each sample belongs to a class that follows a Gaussian distribution, and each distribution is specified by a mean and a variance.

Infinite Gaussian mixture models can be formulated by a Dirichlet process with concentration parameter  $\alpha$  and base distribution  $H$  (West et al., 1993):

$$\begin{aligned} G &\sim \text{DP}(\alpha, H), \\ (\mu_k, \sigma_k^2) &\sim G, \\ x_{i, \dots, N} &\sim N(\mu_k, \sigma_k^2). \end{aligned} \quad (2)$$

For simplicity, we choose the prior base distribution  $H$  to be the conjugate prior of  $N(\mu, \sigma^2)$ . The conjugate prior of a Gaussian distribution with unknown expectation and variance is the normal-inverse-gamma distribution:

$$(\mu, \sigma^2) \sim H = \text{N-}\Gamma^{-1}(\mu_0, \kappa, \nu, \psi), \quad (3)$$

where  $\mu_0$  is the prior expectation of  $\mu$  estimated from  $\kappa$  observations, and  $\psi$  is the prior sum of squared deviations estimated from  $\nu$  observations (O’Hagan et al., 2004).

The prior parameter  $\alpha$  and  $\psi$  are of special interest here. Parameter  $\alpha$  is the concentration of the Dirichlet process. The greater  $\alpha$  is, the probability of producing more classes increases. Parameter  $\psi$  represents the prior sum of squared deviations of each class. The lesser  $\psi$  is, the higher precision a class is, and the range the class covers becomes smaller.

To produce more classes that covers smaller ranges, we increase  $\alpha$  and decrease  $\psi$ . We define this step as ADJUSTPARAMETER, which is implemented by multiplying a constant value to  $\alpha$  and  $\psi$  respectively.

In the scenario of human-computer interactive word segmentation, humans can judge whether the segmentation result produced by the segmenter is correct or not. These judgments act as constraints over samples. Classes produced shall conform to these judgments, i.e., samples within each class are uniformly judged as *separated* or uniformly judged as *combined*. If the initial result does not conform to human judgments, more classes with smaller ranges should be generated. Thus ADJUSTPARAMETER should be performed.

Our adaptive Dirichlet process mixture model works as follows: In the initial state of a bigram, we construct a classifier such that all samples

below the threshold  $\Theta$  are marked *separated*, while all samples above  $\Theta$  are marked *combined*. Whenever a user intervention occurred, implying that the current classifier cannot distinguish certain segmentation ambiguities, we increase the concentration parameter  $\alpha$ , i.e. increase the probability to generate more classes, and decrease the prior class sum of squared deviations  $\psi$ , i.e. increase the precision of a class. With these parameters adjusted, re-cluster all the samples to date. Since the prior parameters  $\alpha$  and  $\psi$  are adjusted, the segmenter tends to produce more classes. Iterate this process until all classes conform to human judgments, i.e., samples within each produced class share the same human judgment. Then tag each class with *separated* or *combined* according to the human judgments of the samples in that class. In this way, the Dirichlet process mixture model will adapt itself to conform to human judgments upon samples. This algorithm is illustrated in Algorithm 1.

In Algorithm 1, Line 5 and 6 implements ADJUSTPARAMETER. Empirical values 2.0 and 0.9 are assigned to coefficients  $p_\alpha$  and  $p_\psi$ . The algorithm CLUSTERBYDPM will be elaborated in Section 3.4.

---

#### Algorithm 1. ADAPTIVEDPMM

---

**Input:** Sample set  $X$ , human judgments  $J$

**Output:** Clustering result  $C$

```

1: begin
2:   do
3:      $C \leftarrow \text{CLUSTERBYDPM}(X, \alpha, \psi)$ 
4:     if  $C$  conforms to human judgments  $J$  break
5:      $\alpha \leftarrow \alpha \times p_\alpha$ 
6:      $\psi \leftarrow \psi \times p_\psi$ 
7:   while maximum iteration count not reached
8:   Tag each class in  $C$  according to judgments  $J$ 
9: end

```

---

Whenever a user intervention occurred, the algorithm above is run once, and it returns the expectation and variance of each class, along with the class tag. Use the expectation and variance to construct a naïve Bayes classifier from these data, namely

$$z = \arg \max_k P(k)N(x | \mu_k, \sigma_k^2), \quad (4)$$

where  $x$  is a new sample,  $z$  is the class which  $x$  belongs to, and  $\mu_k, \sigma_k^2$  are the expectation and variance of class  $k$ .  $P(k)$  is the class-prior, i.e. the proportion class  $k$  takes in the whole set of samples. Bigram with  $md$  value  $x$  is judged *separated* or *combined* according the tag associated with class  $z$ . This naïve Bayes classifier is used to classify new occurrences of the bigram until the user intervenes again.

### 3.4 Inference of the Dirichlet Process Mixture Model

Each time a user intervenes in the segmentation process, implying that the samples should be re-clustered, we use a Gibbs sampler to perform the clustering task (MacEachern, 1994; Neal, 2000; Rasmussen, 2000). The algorithm below adopts Algorithm 3 described by Neal (2000).

Set up a Markov chain whose state consists of  $\mathbf{z} = (z_1, \dots, z_n)$ , i.e., the class indicator of current samples. Repeatedly sample as follows:

For  $i = 1, \dots, n$ : Draw a new value for  $z_i$  from:

$$P(z_i = z | z_{-i}, x_i) \propto \begin{cases} \frac{n_{-i,z}}{n-1+\alpha} \int N(x_i | \varphi) H_{-i,z}(\varphi) d\varphi & \text{if } z = z_j \text{ for some } j \neq i \\ \frac{\alpha}{n-1+\alpha} \int N(x_i | \varphi) H(\varphi) d\varphi & \text{if } z_i \neq z_j \text{ for all } j \neq i \end{cases}, \quad (5)$$

where  $\varphi$  indicates the parameter pair  $(\mu, \sigma^2)$ ;  $n_{-i,z}$  is the number of samples in class  $z$  except  $x_i$ ; and  $H_{-i,z}$  is the posterior distribution of  $\varphi$  based on the prior  $H$  and all observations  $x_j$  for which  $j \neq i$  and  $z_j = z$ .

Since  $H$  is chosen to be the conjugate prior of Gaussian distribution, i.e. the normal-inverse-gamma distribution mentioned in Section 3.3, the integral term in Equation (5) is analytically feasible, thus the sampling method presented here is feasible.

## 4 Experiments

In this section, we conducted several experiments to evaluate the performance of our segmentation model. Firstly, we analyzed the performance of segmentation ambiguity handling through a case study. Secondly, we verified the improvement in reducing human intervention after introducing our model. Thirdly, we tested the reusability of knowledge learnt from human interaction. The experiments are based on the *People's Daily* corpus from Jan. 1998 to Jun. 1998 provided by the Institute of Computational Linguistics, Peking University.

Several baseline models are used in this section. One is the approach proposed by Sun et al. (2004) (abbreviated as *Sun's Appr.*) mentioned in Section 3.1, and the other is the Kalman Filter based approach proposed by Zhu et al. (2013) (abbreviated as *Zhu's Appr.*). In addition, the memory approach (abbreviated as *Memory Appr.*), a bigram based human interactive model

whose initial segmentation is exactly the same as Sun's Approach but its prediction of the bigram is taken from the latest human intervention (i.e., the latest correct segmentation result judged by human), is also compared in Sections 4.2 and 4.3. Our adaptive Dirichlet process mixture model is abbreviated as ADPMM.

### 4.1 Case Study

In this part, we took the aforementioned bigram 及其 as an example, and examined the exact number of interventions by users during the human-computer interaction process. Models used for comparison are Memory Appr., Zhu's Appr. and ADPMM. The simulation of the segmentation process was performed by using the correct segmentation text as input to the model. We define an *intervention rate* (IR) of a specific bigram to measure the human effort in a corpus. The IR of bigram  $xy$  is defined as

$$\text{IR}[\%] = \frac{\# \text{ of interventions of } xy}{\# \text{ of occurrences of } xy} \times 100\%. \quad (6)$$

Table 2 shows the number of interventions (denoted by NI) and the IR of bigram 及其 under each model with *People's Daily* Jan. 1998 to Mar. 1998 as test text. It can be seen from the table that ADPMM significantly reduced the number of interventions of bigram 及其 under all three corpora. In Feb. 1998, ADPMM reduced the NI from 36 in Zhu's Appr. to 16 (about 55.56% reduction in percentage), while in Mar. 1998, from 36 to 10 (about 72.22% reduction in percentage). This experiment shows that our model greatly reduced the number of interventions in the case of the segmentation-ambiguous word 及其.

Corpus		Memory Appr.	Zhu's Appr.	ADPMM
Jan.	NI	63	43	<b>17</b>
	IR	39.38	26.88	<b>10.63</b>
Feb.	NI	63	36	<b>16</b>
	IR	42.00	24.00	<b>10.67</b>
Mar.	NI	56	36	<b>10</b>
	IR	25.00	16.07	<b>4.46</b>

**Table 2.** Number of interventions (NI) and IR[%] of bigram 及其 under different corpora.

### 4.2 Simulating the Human-Computer Interactive Segmentation Process

In this part, we simulated the human-computer interaction by using the correct segmentation text as input to the model. We adopted the binary

prediction rate (BPR) described by Zhu et al. (2013) to quantify the conformity of the prediction of the model to user intention. BPR is defined as

$$\text{BPR}[\%] = \frac{\text{\#of correct predictions}}{\text{\#of all predictions}} \times 100\% . \quad (7)$$

The result of the experiment is shown in Table 3. It can be seen that our model gained a slightly higher BPR than both Zhu’s Appr. and Memory Appr. (this is because segmentation ambiguities are relatively rare in corpora), which indicates that our model can reduce user interventions more effectively than Zhu’s Appr.

Corpus	Sun’s Appr.	Memory Appr.	Zhu’s Appr.	ADPMM
Jan.	84.22	94.55	94.66	<b>94.95</b>
Feb.	84.58	94.74	94.83	<b>95.14</b>
Mar.	84.59	95.04	95.17	<b>95.46</b>

**Table 3.** BPR[%] of different approaches under different corpora.

### 4.3 Knowledge Reusability Test

After the experiment in Section 4.1, we obtained the classification information for each bigram, and we assumed that this information can be viewed as a kind of learnt knowledge that could be used to aid further word segmentation on homogeneous corpus.

In this part, we performed an incremental test on knowledge reusability. This is done by applying the model with knowledge learnt from text of previous months to segment the text of the current month, from Jan. to Jun., respectively. For example, we took the model with knowledge learnt from Jan. to segment the text of Feb.; the model with knowledge learnt from both Jan. and Feb. to segment text of Mar.; and so on. The BPRs of Memory Appr., Zhu’s Appr. and ADPMM are recorded using the testing scheme described above. As is shown in Figure 2, with the knowledge accumulating, the advantage of our model increases significantly: on Jan. (no previous knowledge exists), the advantage of our model is 0.29% and 0.40% over Zhu’s Appr. and Memory Appr. respectively; on Jun. this advantage is enlarged to 0.47% and 0.68%; on May., this advantage reached 0.56% and 0.80%. This experiments shows that when a large training corpus is present, knowledge of segmentation ambiguities will be stored in our model through the form of different classes of a bigram, making it more robust in handling future segmentation ambiguities.

**Figure 2.** BPR[%] of different word segmentation approaches using an incremental testing scheme.

## 5 Conclusions and Future Work

Research shows that Kalman filter based human-computer interactive Chinese word segmentation framework suffers from the drawback of ineptitude in handling segmentation ambiguities. This paper proposes an adaptive Dirichlet process mixture model (ADPMM). ADPMM adjusts the hyperparameters so that ideal classifiers can be generated to conform to the interventions provided by the users. Experiments showed that our approach achieves a notable improvement (more than 55.56% in a case study) in handling segmentation ambiguities, therefore effective in reducing human effort. In the knowledge reusability test, our model outperforms the baseline Kalman filter model by about 0.5% in segmenting homogeneous texts with knowledge learnt from users.

Our future work will concentrate on improving statistics criteria that would reflect contexts more precisely. As in the experiments, we found that the number of classes may grow rapidly. This is caused by the ineffectiveness of the *md* measure to distinguish different contexts.

## Abstract

If we compare the widely used Conditional Random Fields (CRF) with newly proposed “deep architecture” sequence models (Collobert et al., 2011), there are two things changing: from linear architecture to non-linear, and from discrete feature representation to distributional. It is unclear, however, what utility non-linearity offers in conventional feature-based models. In this study, we show the close connection between CRF and “sequence model” neural nets, and present an empirical investigation to compare their performance on two sequence labeling tasks – Named Entity Recognition and Syntactic Chunking. Our results suggest that non-linear models are highly effective in low-dimensional distributional spaces. Somewhat surprisingly, we find that a non-linear architecture offers no benefits in a high-dimensional discrete feature space.

## 1 Introduction

Sequence labeling encompasses an important class of NLP problems that aim at annotating natural language texts with various syntactic and semantic information, such as part-of-speech tags and named-entity labels. Output from such systems can facilitate downstream applications such as Question Answering and Relation Extraction. Most methods developed so far for sequence labeling employ generalized linear statistical models, meaning methods that describe the data as a combination of linear basis functions, either directly in the input variables space (e.g., SVM) or through some transformation of the probability distributions (e.g., “log-linear” models).

Recently, Collobert et al. (2011) proposed

“deep architecture” models for sequence labeling (named Sentence-level Likelihood Neural Nets, abbreviated as SLNN henceforth), and showed promising results on a range of tasks (POS tagging, NER, Chunking, and SRL). Two new changes were suggested: extending the model from a linear to non-linear architecture; and replacing discrete feature representations with distributional feature representations in a continuous space. It has generally been argued that non-linearity between layers is vital to the power of neural models (Bengio, 2009). The relative contribution of these changes, however, is unclear, as is the question of whether gains can be made by introducing non-linearity to conventional feature-based models.

In this paper, we illustrate the close relationship between CRF and SLNN models, and conduct an empirical investigation of the effect of nonlinearity with different feature representations. Experiments on Named Entity Recognition (NER) and Syntactic Chunking tasks suggest that non-linear models are highly effective in low-dimensional distributed feature space, but offer no benefits in high-dimensional discrete space. Furthermore, both linear and non-linear models improve when we combine the discrete and continuous feature spaces, but a linear model still outperforms the non-linear one.

## 2 From CRFs To SLNNs

A CRF models the conditional probability of structured output variables  $\mathbf{y}$  given observations  $\mathbf{x}$ . In sequence modeling, the observations are typically words in a sentence, and the output variables are some syntactic or semantic tags we are trying to predict for each word (e.g., POS, named-entity tags, etc.). The most commonly used CRF model has a linear chain structure, where prediction  $y_i$

at position  $i$  is independent of other predictions, given its neighbors  $y_{i-1}$  and  $y_{i+1}$ . It is customary to describe the model as an undirected graphical model, with the following probability definition:

$$P(\mathbf{y}|\mathbf{x}) = \frac{\prod_{i=1}^{|\mathbf{x}|} \Psi(\mathbf{x}, y_i; \Theta) \prod_{j=1}^{|\mathbf{x}|} \Phi(\mathbf{x}, y_j, y_{j-1}; \Lambda)}{Z(\mathbf{x})}$$

$$\Psi(\mathbf{x}, y_i; \Theta) = \exp \left\{ \sum_{k=1}^m \theta_{(k, y_i)} f_k(\mathbf{x}) \right\}$$

$$\Phi(\mathbf{x}, y_i, y_{i-1}; \Lambda) = \exp \left\{ \sum_{k=1}^{m'} \lambda_{(k, y_i, y_{i-1})} g_k(\mathbf{x}) \right\}$$

$$Z(\mathbf{x}) = \sum_{\mathbf{y}'} \left( \prod_{i=1}^{|\mathbf{x}|} \Psi(\mathbf{x}, y'_i) \prod_{j=1}^{|\mathbf{x}|} \Phi(\mathbf{x}, y'_j, y'_{j-1}) \right)$$

$\Psi(\mathbf{x}, y_i)$  denotes node clique potentials in this graph, and  $\Phi(\mathbf{x}, y_i, y_{i-1})$  denotes edge clique potentials.  $f_k(\mathbf{x})$  is the set of node-level feature functions,  $m$  is the number of node features, and  $\theta_{(k, y_i)}$  is a weight parameter of feature  $k$  associated with a particular output  $y_i$ ; similarly for edges we have  $g_k(\mathbf{x})$ ,  $m'$ , and  $\lambda_{(k, y_i, y_{i-1})}$ .  $Z(\mathbf{x})$  is the partition function that sums over all possible assignments of output variables in the entire sequence.

Let us focus our discussion on the node clique potentials  $\Psi$  for now. We call the operand of the exponentiation operator in  $\Psi$  a *potential function*  $\psi$ . In a CRF, this can be expressed in matrix notation as:

$$\psi(\mathbf{x}, y_i; \Theta) = |\Theta^\top \mathbf{f}(\mathbf{x})|_{\hat{y}_i 1}$$

We use the notation  $\hat{y}_i$  to denote the ordinal index of the value assigned to  $y_i$ . This linear potential function  $\psi$  can be visualized using a neural network diagram, shown in the left plot in Figure 1. Each edge in the graph represents a parameter weight  $\theta_{(k, \hat{y}_i)}$ , for feature  $f_k(\mathbf{x})$  and a variable assignment of  $y_i$ . In neural network terminology, this architecture is called a single-layer Input-Output Neural Network (IONN).<sup>1</sup> Normalizing locally in a logistic regression is equivalent to adding a *softmax* layer to the output layer of the IONN, which was commonly done in neural networks, such as in Collobert et al. (2011).

We can add a hidden linear layer to this architecture to formulate a two-layer Linear Neural

<sup>1</sup>The bias parameter “ $b$ ” commonly seen in Neural Network convention can be encoded as an “always on” feature in the input layer.

Network (LNN), as shown in the middle diagram of Figure 1. The value of the node  $z_j$  in the hidden layer is computed as  $z_j = \sum_k \omega_{(k, j)} f_k(\mathbf{x})$ . The

value  $y_i$  for nodes in the output layer is computed as:  $y_i = \sum_j \delta_{(j, i)} z_j = \sum_j \delta_{(j, i)} \sum_k \omega_{(k, j)} f_k(\mathbf{x})$ .

where  $\omega_{(k, j)}$  and  $\delta_{(j, i)}$  are new parameters introduced in the model. In matrix form, it can be written as  $\mathbf{y} = \Delta^\top \mathbf{z} = \Delta^\top \Omega^\top \mathbf{f}(\mathbf{x})$ . The node potential function now becomes:

$$\psi'(\mathbf{x}, y_i; \Omega, \Delta) = |\Delta^\top \Omega^\top \mathbf{f}(\mathbf{x})|_{\hat{y}_i 1}$$

This two-layer network is actually no more powerful than the previous model, since we can always compile it down to a single-layer IONN by making  $\Theta = \Omega \Delta$ . In the next step, we take the output of the hidden layer in the LNN, and send it through a non-linear activation function, such as a *sigmoid* or *tanh*, then we arrive at a two-layer Deep Neural Network (DNN) model. Unlike the previous two models, the DNN is non-linear, and thus capable of representing a more complex decision surface.

So far we have extended the potential function used in node cliques of a CRF to a non-linear DNN. And if we keep the potential function for edge cliques the same as before, then in fact we have arrived at an identical model to the SLNN in Collobert et al. (Collobert et al., 2011). The difference between a SLNN and an ordinary DNN model is that we need to take into consideration the influence of edge cliques, and therefore we can no longer normalize the clique factors at each position to calculate the local marginals, as we would do in a logistic regression. The cardinality of the output variable vector  $\mathbf{y}$  grows exponentially with respect to input sequence length. Fortunately, we can use *forward-backward* style dynamic programming to compute the marginal probabilities efficiently.

It is also worth pointing out that this model has in fact been introduced a few times in prior literature. It was termed *Conditional Neural Fields* by Peng et al. (2009), and later *Neural Conditional Random Fields* by Do and Artieres (2010). Unfortunately, the connection to Collobert and Weston (2008) was not recognized in either of these two studies; vice versa, neither of the above were referenced in Collobert et al. (2011). This model also appeared previously in the speech recognition literature in Prabhavalkar and Fosler-Lussier (2010).

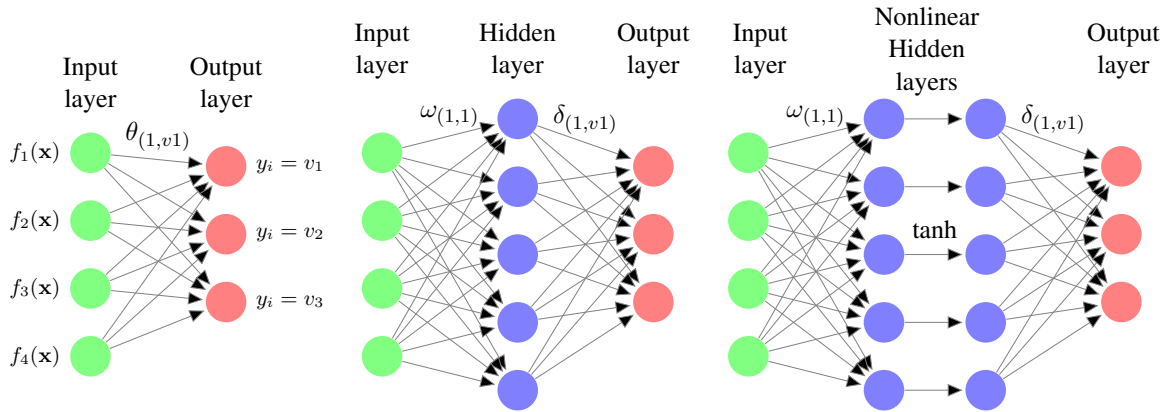

Figure 1: In this diagram, we assume the random variable  $y_i$  has three possible value assignments ( $v_1, v_2, v_3$ ). On the left side is the linear potential function  $\psi$  in CRF, illustrated as a single-layer Input-Output Neural Network. In the middle is a potential function as a two-layer Linear Neural Network; on the right side is a two-layer Deep Neural Network.

### 3 Parameter Learning

Supervised conditional training of the SLNN model amounts to maximizing the objective function  $\mathcal{L}$ , which is given by the sum of log-probabilities over training examples:

$$\mathcal{L}(\mathbf{Y}^*|\mathbf{X}) = \sum_{l=1}^{|\mathbf{X}|} \left( \sum_{i=1}^{|\mathbf{x}^l|} \psi'(\mathbf{x}^l, \mathbf{y}_i^{l*}) + \sum_{j=1}^{|\mathbf{x}^l|} \phi(\mathbf{x}^l, \mathbf{y}_j^{l*}, \mathbf{y}_{j-1}^{l*}) \right) - \sum_{l=1}^{|\mathbf{X}|} \log Z(\mathbf{x})$$

The change in node potential function from  $\psi$  to  $\psi'$  does not affect the inference procedure, and thus we can employ the same dynamic programming algorithm as in a CRF to calculate the log sum over  $Z(\mathbf{x})$  and the expectation of feature parameters.

We adopted the simple L-BFGS algorithm for training weights in this model (Liu and Nocedal, 1989). Although L-BFGS is in general slower than mini-batch SGD – another common optimization algorithm used to train neural networks (Bengio et al., 2006, *inter alia*), it has been found to be quite stable and suitable for learning neural networks (Socher et al., 2011). The gradient of a parameter  $\omega_{(k,j)}$  is calculated as the following:

$$\frac{\partial \mathcal{L}}{\partial \omega_{(k,j)}} = \sum_{l=1}^{|\mathbf{X}|} \sum_{i=1}^{|\mathbf{x}^l|} \left( \frac{\partial \psi'(\mathbf{x}^l, \mathbf{y}_i^l)}{\partial \omega_{(k,j)}} - \mathbb{E}_{P(\mathbf{y}^l|\mathbf{x}^l)} \left[ \frac{\partial \psi'(\mathbf{x}^l, \mathbf{y}_i^l)}{\partial \omega_{(k,j)}} \right] \right)$$

The partial derivative of the potential function  $\frac{\partial \psi'(\mathbf{x}^l, \mathbf{y}_i^l)}{\partial \omega_{(k,j)}}$  can be calculated using the back-propagation procedure, identical to how gradients of a standard Multilayer Perceptron are calculated. The gradient calculation for output layer parameters  $\Delta$  and edge parameters  $\Lambda$  follow the same form. We apply  $\ell_2$ -regularization to prevent overfitting.

### 4 Empirical Evaluation

We evaluate the CRF and SLNN models on two standard sequence labeling tasks: Syntactic Chunking and Named Entity Recognition (NER). In both experiments, we use the publicly available Stanford CRF Toolkit (Finkel et al., 2005).

#### 4.1 Named Entity Recognition

We train all models on the standard CoNLL-2003 shared task benchmark dataset (Sang and Meulder, 2003), which is a collection of documents from Reuters newswire articles, annotated with four entity types: *Person*, *Location*, *Organization*, and *Miscellaneous*. We adopt the BIOES-style annotation standard. Beginning and intermediate positions of an entity are marked with *B*- and *I*- tags, and non-entities with *O* tag. The training set contains 204K words (14K sentences), the development set contains 51K words (3.3K sentences), and the test set contains 46K words (3.5K sentences).

To evaluate out-of-domain performance, we run the models trained on CoNLL-03 training data on two additional test datasets. The first dataset

(ACE) is taken from the ACE Phase 2 (2001-02) and ACE-2003 data. Although the ACE dataset also consists of newswire text and thus is not strictly out-of-domain, there is a genre or dialect difference in that it is drawn from mostly American news sources, whereas CoNLL is mostly English. The test portion of this dataset contains 63K words, and is annotated with 5 original entity types: *Person*, *Location*, *Organization*, *Fact*, and *GPE*. We remove all entities of type *Fact* and *GPE* by relabeling them as *O* during preprocessing, and discard entities tags of type *Miscellaneous* in the output of the models. The second dataset is the MUC7 Formal Run test set, which contains 59K words. It is also missing the *Miscellaneous* entity type, but includes 4 additional entity types that do not occur in CoNLL-2003: *Date*, *Time*, *Money*, and *Percent*. We converted the data to CoNLL-2003 type format using the same method applied to the ACE data.

We used a comprehensive set of features that comes with the standard distribution of Stanford NER model (Finkel et al., 2005). A total number of 437,905 features were generated for the CoNLL-2003 training dataset.

## 4.2 Syntactic Chunking

In Syntactic Chunking, we tag each word with its phrase type. For example, tag *B-NP* indicates a word starts a noun phrase, and *I-PP* marks an intermediate word of a prepositional phrase. We test the models on the standard CoNLL-2000 shared task evaluation set (Sang and Buchholz, 2000). This dataset comes from the Penn Treebank. The training set contains 211K words (8.9K sentences), and the test set contains 47K words (2K sentences). The set of features used for this task is:

- Current word and tag
- Word pairs:  $w_i \wedge w_{i+1}$  for  $i \in \{-1, 0\}$
- Tags:  $(t_i \wedge t_{i+1})$  for  $i \in \{-1, 0\}$ ;  $(t_{-1}, t_0, t_{i+1})$ ;
- The Disjunctive word set of the previous and next 4 positions

A total number of 317794 features were generated on this dataset.

## 4.3 Experimental Setup

In all experiments, we used the development portion of the CoNLL-2003 data to tune the  $\ell_2$ -regularization parameter  $\sigma$  (variance in Gaussian prior), and found 20 to be a stable value. Overall tuning  $\sigma$  does not affect the qualitative results

in our experiments. We terminate L-BFGS training when the average improvement is less than  $1e-3$ . All model parameters are initialized to a random value in  $[-0.1, 0.1]$  in order to break symmetry. We did not explicitly tune the features used in CRF to optimize for performance, since feature engineering is not the focus of this study. However, overall we found that the feature set we used is competitive with CRF results from earlier literature (Turian et al., 2010; Collobert et al., 2011). For models that embed hidden layers, we set the number of hidden nodes to 300.<sup>2</sup> Results are reported on the standard evaluation metrics of entity/chunk precision, recall and F1 measure.

For experiments with continuous space feature representations (a.k.a., word embeddings), we took the word embeddings (130K words, 50 dimensions) used in Collobert et al. (2011), which were trained for 2 months over Wikipedia text.<sup>3</sup> All sequences of numbers are replaced with num (e.g., “PS1” would become “PSnum”), sentence boundaries are padded with token PAD, and unknown words are grouped into UNKNOWN. We attempt to replicate the model described in Collobert et al. (2011) without task-specific fine-tuning, with a few exceptions: 1) we used the *soft tanh* activation function instead of *hard tanh*; 2) we use the BIO2 tagging scheme instead of BIOES; 3) we use L-BFGS optimization algorithm instead of stochastic gradient descent; 4) we did not use Gazetteer features; 5) Collobert et al. (2011) mentioned 5 binary features that look at the capitalization pattern of words to append to the embedding as additional dimensions, but only 4 were described in the paper, which we implemented accordingly.

## 5 Results and Discussion

For both the CRF and SLNN models, we experiment with both the discrete binary valued feature representation used in a regular CRF, and the word embeddings described. Unless otherwise stated, the set of edge features is limited to pairs of predicted labels at the current and previous positions, i.e.,  $(y_i, y_{i-1})$ . The same edge features were used in Collobert et al. (2011) and were called “transition scores” ( $[A]_{i,j}$ ).

<sup>2</sup>We tried varying the number of hidden units in the range from 50 to 500, and the main qualitative results remain the same.

## 5.1 Results of Discrete Representation

The first question we address is the following: in the high-dimensional discrete feature space, would the non-linear architecture in SLNN model help it to outperform CRF?

Results from Table 1 suggest that SLNN does not seem to benefit from the non-linear architecture on either the NER or Syntactic Chunking tasks. In particular, on the CoNLL and MUC dataset, SLNN resulted in a 1% performance drop, which is significant for NER. The specific statistical properties of this dataset that lead to the performance drop are hard to determine, but we believe it is partially because the SLNN has a much harder non-convex optimization problem to solve – on this small dataset, the SLNN with 300 hidden units generates a shocking number of 100 million parameters (437905 features times 300 hidden dimensions), due to the high dimensionality of the input feature space.

To further illustrate this point, we also compared the CRF model with its Linear Neural Network (LNN) extension, which has exactly the same number of parameters as the SLNN but does not include the non-linear activation layer. Although this model is identical in representational power to the CRF as we discussed in Section 2, the optimization problem here is no longer convex (Ando and Zhang, 2005). To see why, consider applying a linear scaling transformation to the input layer parameter matrix  $\Omega$ , and apply the inverse scaling to output layer  $\Delta$  matrix. The resulting model has exactly the same function values. We can see from Table 2 that there is indeed a performance drop with the LNN model as well, likely due to difficulty with optimization. By comparing the results of LNN and SLNN, we see that the addition of a non-linear activation layer in SLNN does not seem to help, but in fact further decreases

	CRF			LLN

ACE	81.0	74.2	<b>77.4</b>	80.7	74.3	77.3
MUC	72.5	74.5	73.5	72.3	75.2	<b>73.7</b>
Chunk	93.7	93.5	<b>93.6</b>	93.1	93.2	93.2

Table 2: Results of CRF versus LNN, over discrete feature space.

performance in all cases except Syntactic Chunking.

A distinct characteristic of NLP data is its high dimensionality. The vocabulary size of a decent sized text corpus is already in the tens of thousands, and bigram statistics are usually an order of magnitude larger. These basic information units are typically very informative, and there is not much structure in them to be explored. Although some studies argue that non-linear neural nets suffer less from the curse of dimensionality (Attali and Pagés, 1997; Bengio and Bengio, 2000; Pitkow, 2012), counter arguments have been offered (Camastra, 2003; Verleysen et al., 2003). The empirical results from our experiment seems to support the latter. Similar results have also been found in other NLP applications such as Text Classification. Joachims concluded in his seminal work: “non-linear SVMs do not provide any advantage for text classification using the standard kernels” (Joachims, 2004, p. 115). If we compare the learning curve of CRF and SLNN (Figure 2), where we vary the amount of binary features available in the model by random sub-sampling, we can further observe that SLNNs enjoy a small performance advantage in lower dimensional space (when less than 30% of features are used), but are quickly outpaced by CRFs in higher dimensional space as more features become available.

Another point of consideration is whether there is actually much non-linearity to be captured in sequence labeling. While in some NLP applications like grammar induction and semantic parsing, the data is complex and rich in statistical structures, the structure of data in sequence labeling is considerably simpler. This contrast is more salient if we compare with data in Computer Vision tasks such as object recognition and image segmentation. The interactions among local variables there are much stronger and more likely to be non-linear. Lastly, models like CRF actually already capture some of the non-linearity in the

Figure 2: The learning curve of SLNN vs. CRF on CoNLL-03 dev set, with respect to the percentage of discrete features used (i.e., size of input dimension). Y-axis is the F1 score (out of 100), and X-axis is the percentage of features used.

Table 3: Results of CRF versus SLNN, over continuous space feature representations.

input space through the interactions of latent variables (Liang et al., 2008), and it is unclear how much additional gain we would get by explicitly modeling the non-linearity in local inputs.

## 5.2 Results of Distributional Representation

For the next experiment, we replace the discrete input features with a continuous space representation by looking up the embedding of each word, and concatenate the embeddings of a five word window centered around the current position. Four binary features are also appended to each word embedding to capture capitalization patterns, as described in Collobert et al. (2011). Results of the CRF and SLNN under this setting for the NER task is show in Table 3.

With a continuous space representation, the SLNN model works significantly better than a CRF, by as much as 7% on the CoNLL development set, and 3.7% on ACE dataset. This suggests that there exist statistical dependencies within this low-dimensional (300) data that cannot be effectively captured by linear transformations, but can be modeled in the non-linear neural nets. This perhaps coincides with the large performance im-

	CoNLL <sub>d</sub>	CoNLL <sub>t</sub>	ACE	MUC

SLNN <sub>continuous</sub>	86.6	80.7	75.0	70.8
SLNN <sub>join</sub>	91.9	87.1	81.2	79.7

Table 4: Results of CRF and SLNN when word embeddings are appended to the discrete features. Numbers shown are F1 scores.

provements observed from neural nets in handwritten digit recognition datasets as well (Peng et al., 2009; Do and Artieres, 2010), where dimensionality is also relatively low.

## 5.3 Combine Discrete and Distributional Features

When we join word embeddings with discrete features, we see further performance improvements, especially in the out-of-domain datasets. The results are shown in Table 4.

A similar effect was also observed in Turian et al. (2010). The performance of both the CRF and SLNN increases by similar relative amounts, but the CRF model maintains a lead in overall absolute performance.

## 6 Conclusion

We carefully compared and analyzed the non-linear neural networks used in Collobert et al. (2011) and the widely adopted CRF, and revealed their close relationship. Through extensive experiments on NER and Syntactic Chunking, we have shown that non-linear architectures are effective in low dimensional continuous input spaces, but that they are not better suited for conventional high-dimensional discrete input spaces. Furthermore, both linear and non-linear models benefit greatly from the combination of continuous and discrete features, especially for out-of-domain datasets. This finding confirms earlier results that distributional representations can be used to achieve better generalization.

## Abstract

Many NLP tools are released as programs that include statistical models. Unfortunately, the models do not always match the documents that the tool user is interested in, which forces the user to update the models.

In this paper, we investigate model adaptation under the condition that users cannot access the data used in creating the original model. Transfer learning and online learning are investigated as adaptation strategies. We test them on the category classification of Japanese newspaper articles. Experiments show that both transfer and online learning can appropriately adapt the original model if the dataset for adaptation contains all data, not just the data that cannot be well handled by the original model. In contrast, we confirmed that the adaptation fails if the dataset contains only erroneous data as indicated by the original model.

## 1 Introduction

Recent natural language processing (NLP) systems are built using machine learning (supervised learning). The developers of these systems basically create annotated corpora from which statistical models are generated. However, if the documents that users want to apply the systems to do not belong to the domain of the annotated corpora, the resulting accuracy tends to be unsatisfactory.

For instance, Figure 1 shows the typical drop in accuracy in the category classification task of newspaper articles over time; the statistical model was trained using supervised data from 1995 (details are described later). Even though the test data were obtained from newspaper articles (i.e., the same domain data), the accuracy against 2007

Figure 1: Accuracy of Category Classification with training by 1995 Dataset

articles fell by about 10% from the 1996 articles. The reasons for this include the emergence of new words and changes in word distribution. In order to recover this degradation, we have to re-train the models.

To overcome this problem, transfer learning methods have been proposed (Pan and Yang, 2010). Many transfer learning methods assume that the users can obtain both the original data and additional data for adaptation. However, in most practical cases, the users sometimes are unable to access the original data. For example, only the developers are licensed to handle the original data, not the users.

NLP tools, such as taggers, parsers, and classifiers, are commonly released as programs that include the original models. Since many users cannot update the original models, they continue to use them even if the user's documents do not match the models (Figure 2).

The objective of this paper is to investigate methods that, given an additional dataset, permit adaptation of original models under the constraint that the original dataset is unavailable.

The target task of this paper is category classification of newspaper articles. Because NLP tools such as taggers or parsers are founded on struc-

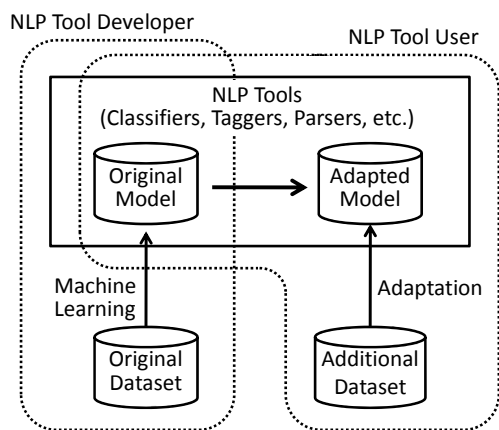

Figure 2: Relationship between Developers and Users of NLP Tools

tured learning, which extends the classification, we select the linear classification task.

In this paper, we investigate the combination of the following learning methods and additional datasets.

- We test two learning methods, batch and online learning. In batch learning, we use a maximum entropy classifier (Berger et al., 1996; Chen and Rosenfeld, 2000) and adapt the model using transfer learning. In online learning, we select soft confidence-weighted learning (Wang et al., 2012).
- We test two kinds of additional datasets. One is that all data are used for adaptation. The other is that only the data that failed to predict correct categories by the original model are used. We consider the active learning strategy for the second dataset.

The remainder of this paper is organized as follows. In Section 2, we detail the task, datasets, and learning methods (batch and online learning). Section 3 describes the experiments conducted and their results, and Section 4 summarizes the findings of this study.

## 2 Settings and Adaptation Methods

### 2.1 Task and Data

The task of this study is category classification of Japanese newspaper articles. We selected articles from Mainichi Shinbun newspapers for the years of 1995, 1996, 2005, and 2006. A part of the 1995 data is widely used in the Japanese

Set Name	Period	# of Data
Original Dataset	Jan.,1995 - Nov.,1995	102,454
Additional Dataset	Jan.,2005 - Nov.,2005	88,202
Development set	Dec.,1995	9,043
Test set 1	Jan.,1996 - Dec.,1996	114,116
Test set 2	Jan.,2006 - Dec.,2006	95,761

Table 1: Statistics of Data Used

NLP community because its dependency structures and predicate-argument structures have been annotated<sup>1</sup>.

One of 16 categories is assigned to each article. The category denotes type of the article, such as ‘Economics’, ‘International’, ‘Sports’, ‘Top page’, and so on. The task of this study is to predict the category of each article from its content (text).

Figure 3 shows the relationships among datasets (for learning and testing) and models. We took articles from Jan. to Nov. in 1995 as the original dataset, and used them to train the original model. The original dataset was not used thereafter. Articles from Dec. 1995 were used to tune the model’s hyperparameters. The additional dataset for adaptation was created from articles from Jan. to Nov. 2005. We prepared two test sets. The first consisted of 1996 articles (Test set 1), and the second consisted of 2006 articles (Test set 2). Our objective is to improve the accuracy against Test set 2. The statistics of the datasets are shown in Table 1.

Features for classification are ‘bag-of-words’ of the title and the first paragraph of the article. Only content words (nouns, verbs, adverbs, adjectives, and interjections) that appear more than once are used as features.

### 2.2 Transfer Learning from Batch Learning

#### 2.2.1 Regularized Adaptation

The problem setting of this paper is a sort of transfer learning (domain adaptation). Because we cannot access the original data, this problem is regarded as “model-based domain adaptation” according to the taxonomy of transfer learning by Sha and Kingsbury (2012). Regularized adaptation (Evgeniou and Pontil, 2004; Xiao and Bilmes, 2006) is a variant of model-based domain adaptation. As the regularizer, it uses the differences

<sup>1</sup>Dependency structures are published as Kyoto University Text Corpus ([http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?Kyoto University Text Corpus](http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?Kyoto%20University%20Text%20Corpus)). Predicate-argument structures are published as NAIST Text Corpus (Iida et al., 2007) (<http://cl.naist.jp/nldata/corpus/>). Note that the texts of the articles must be purchased from the newspaper company.

Figure 3: Datasets and Models

in parameters between the adapted model and the original model, not adapted parameters. This is done to minimize the differences between the original model and the adapted model.

Although Evgeniou and Pontil (2004) proposed regularized adaptation for SVMs, and Xiao and Bilmes (2006) proposed the same for neural networks, they can also be applied to maximum entropy classifiers<sup>2</sup>. The loss function,  $\ell$ , is represented as follows.

$$\ell = - \sum_i \log P(y_{AD_i} | \mathbf{x}_{AD_i}; \mathbf{w}_{AD}) + \frac{1}{2C} \sum_{k=1}^d (w_{AD_k} - w_{OR_k})^2, \quad (1)$$

where  $P(y|\mathbf{x}; \mathbf{w})$  denotes the posterior probability of a sample computed with the weight parameters of the model  $\mathbf{w}$ ;  $y_{AD_i}$  and  $\mathbf{x}_{AD_i}$  are the input and output of the  $i$ th sample in the additional dataset, respectively,  $w_{AD_k}$  and  $w_{OR_k}$  denote weight parameters of the adapted and the original model, respectively; both have dimensions of  $d$ , and  $C$  is a hyperparameter.

The maximum entropy classifier used in this paper estimates the weight parameters to minimize the above loss function. The first term in Equation (1) suppresses discriminative errors of the additional data at minimum, and the second term suppresses differences between the original model and the adapted model.

### 2.2.2 Regularization with Two Hyperparameters

The output classes of the adapted model are identical to those of the original model in this task. In contrast, features for classification are not identical because new words appear over time.

<sup>2</sup>Regularized adaptation is used as a re-training function of the Japanese morphological analyzer MeCab (Kudo et al., 2004), which is based on conditional random fields (CRFs). <http://mecab.googlecode.com/svn/trunk/mecab/doc/index.html>

In Equation (1), all features, which include features from the original data and the additional data, are treated equally. However, if we significantly change weight parameters of the original model features, the original model can correctly classify less data due to errors. In contrast, with regard to the new features from the additional data, we can change the parameters without limitation. Therefore, it is natural to distinguish new features from those of the original model.

Here, assuming that the number of dimensions of the parameters in the original model is  $d_{OR}$ , and that in the adapted model (i.e., the features include the original and additional data) is  $d_{AD}$ , the loss function becomes,

$$\ell = - \sum_i \log P(y_{AD_i} | \mathbf{x}_{AD_i}; \mathbf{w}_{AD}) + \frac{1}{2C_{AD}} \sum_{k=1}^{d_{OR}} (w_{AD_k} - w_{OR_k})^2 + \frac{1}{2C_{OR}} \sum_{k=d_{OR}+1}^{d_{AD}} w_{AD_k}^2, \quad (2)$$

where  $C_{OR}$  denotes the hyperparameter that was used while learning the original model, and  $C_{AD}$  denotes the hyperparameter for the additional data. If we set them as  $C_{OR} \geq C_{AD}$ , only the new features from the additional data can change significantly; changes to the existing features of the original model are suppressed.

### 2.3 Online Learning

Online learning is a strategy that updates current parameters in order to correctly classify training samples one-by-one. It matches the problem setting in this paper because it can train a new model by altering the original model to suit the additional data. However, it usually loses information about old samples (in our case, the original data). Therefore, we need to iterate the learning process on the entire dataset several times.

The recent proposal Confidence-weighted learning (CW) generates each weight parameter from a Gaussian distribution whose mean is  $\mu$  and standard deviation is  $\sigma$  (Dredze et al., 2008; Crammer et al., 2009a). This method expresses confidence in frequently updated parameters, and accepts only small changes to them. Rarely updated parameters can be greatly changed. Confidence is expressed by a covariance matrix. CW is known to offer faster convergence than the conventional online learning algorithms such as perceptrons and passive-aggressive methods. In other words, CW makes learned samples hard to forget. The CW algorithm offers the possibility of adapting to the additional data without referring to the original data.

It is known that the training performance of the original CW algorithm suffers if the training samples contain significant noise components that are linearly-inseparable. The adaptive regularization of weight algorithm (AROW; (Crammer et al., 2009b)) and the soft confidence-weighted learning algorithm (SCW; (Wang et al., 2012)) were proposed to overcome this weakness. In this paper, we employ the SCW algorithm.

In SCW-I, which uses a linear penalty, parameter updating is represented as follows.

$$\begin{aligned}
 (\boldsymbol{\mu}_{t+1}, \Sigma_{t+1}) = & \\
 \arg \min_{\boldsymbol{\mu}, \Sigma} \{ & D_{KL}(\mathcal{N}(\boldsymbol{\mu}, \Sigma) \| \mathcal{N}(\boldsymbol{\mu}_t, \Sigma_t)) + \\
 C \ell^\phi(\mathcal{N}(\boldsymbol{\mu}, \Sigma), & (\boldsymbol{x}_t, y_t)) \}, \quad (3)
 \end{aligned}$$

where  $\boldsymbol{\mu}$  denotes a mean vector and  $\Sigma$  denotes a covariance matrix of the parameters,  $D_{KL}(\cdot \| \cdot)$  denotes Kullback-Leibler divergence,  $\mathcal{N}(\boldsymbol{\mu}, \Sigma)$  denotes a multivariate normal distribution with mean of  $\boldsymbol{\mu}_k$  and standard deviation of  $\sigma_k$ ,  $\ell^\phi(\cdot)$  is a loss function based on the hinge loss, and  $C$  is a hyperparameter that restricts the maximum change permitted in the update. Following Equation (3), the loss of the correct class  $y_t$  predicted from input feature vector  $\boldsymbol{x}_t$  becomes minimum by the second term, and simultaneously the change in parameters is suppressed by the first term. (Final update formulae are provided in (Wang et al., 2012)).

However, there are some problems in implementing Equation (3) directly. The following approximations are applied in general.

- Weight parameters  $w$  should be generated from Gaussian distribution  $\mathcal{N}(\boldsymbol{\mu}, \Sigma)$ , but the mean vector  $\boldsymbol{\mu}$  is directly used as weight parameters.

- The size of the covariance matrix is  $d \times d$ , where  $d$  denotes the number of dimensions of the parameters, and so memory consumption is high. To avoid this problem, only diagonal elements are considered (the matrix is degenerated to a vector).

In addition, the hyperparameters that control the maximum change and the confidence value,  $C$  and  $\phi$ , must be set manually.

To apply the SCW algorithm, we first construct the original model from the original data using Equation (3) until classification errors become minimum on the development set. Note that the original model retains not only the mean vector but also the covariance matrix. In adaptation, we regard the original model as  $(\boldsymbol{\mu}_0, \Sigma_0)$  and similarly update it using the additional data, one-by-one.

### 3 Experiments

#### 3.1 Experimental Settings

**Methods** We test the methods described in Sections 2.2 and 2.3 (represented as ‘Transfer’ and ‘Online,’ respectively). The following baselines are also tested.

- (a) Original Model. This case yields the upper bound of Test set 1.
- (b) The model is trained using only the additional dataset. If there is enough data, this yields the upper bound of Test set 2.
- (c) The model is trained by the feature augmentation method (Daumé, 2007) using the original data and the additional data, which is one of the domain adaptation techniques. This case yields the upper bound if we can access the original data.
- (d) The case in which the models of (a) and (b) are interpolated at the ratio of 1:1. This provides a baseline for the lack of access to the original data.

**Additional Datasets** We used two types of additional datasets. One is (e) all data in 2005 newspapers are used for adaptation (Normal Case). The other is (f) only the data unknown to the original model are used (Active Learning). In practical cases, we want to adapt the model when we find a failure of the original model. Therefore, case (f) is a practical setting. The additional datasets of the original models have different numbers of

Type	Method/Dataset	Transfer		Online	
		Test1	Test2	Test1	Test2
Baselines	(a) Original Model	<b>70.90%</b>	61.49%	<b>71.41%</b>	62.60%
	(b) Additional Only	56.73%	<b>75.66%</b>	57.07%	<b>76.36%</b>
	(c) Original + Additional Data	<b>70.99%</b>	<b>75.77%</b>	<b>72.00%</b>	<b>76.58%</b>
	(d) Interpolation	68.70%	72.28%	68.49%	72.98%
Model Adaptation	(e) Normal Case	64.26%	<b>75.78%</b>	66.87%	<b>75.78%</b>
	(f) Active Learning	50.32%	63.29%	57.28%	65.81%

Table 2: Test Set Accuracies of Methods and Datasets

entities, 34,950 and 33,633 for the Transfer and Online cases, respectively.

**Tuning** The hyperparameters are optimized against the development set when the original models are trained and the same values are used in all experiments.

### 3.2 Results of the Methods

The results are shown in Table 2.

First of all, focusing on baselines (a) and (b), Test set 1 yielded basically the highest accuracies for case (a), while for (b) it was Test set 2. Using datasets that are near to the test sets yields better model training in this task.

Focusing on case (c), in which training uses both the original and the additional datasets, the advantages of cases (a) and (b) are secured. However, although we applied domain adaptation, the improvements from cases (a) and (b) were little. This result indicates that the size of the additional dataset was sufficient and that the model matched the upper bound by using just the additional dataset. In addition, we confirmed that the accuracies of interpolation (d) were intermediate between those of (a) and (b).

While accuracy slightly differed with the learning method, the Transfer and Online cases exhibited the same tendency.

Next, for normal case (e) in model adaptation, both Transfer and Online achieved basically the highest accuracies against Test set 2. This result shows that model adaptation worked effectively. On the other hand, focusing on the accuracies of Test set 1, Online learning exhibited a smaller degradation from the original model (a) than Transfer. We suppose that this difference is due to the difference between maximum entropy and SCW-I, rather than that between the transfer/online learning. The maximum entropy method optimizes parameters based on the maximum a posteriori (MAP), and it is sensitive to probability distribution. In contrast, SCW-I used

in Online is based on margin criteria, and ignores data outside the margin. Therefore, Online yielded smaller degradation.

In the case of active learning (f), the effects of model adaptation were little compared to the other cases. Namely, improvements against Test set 2 were slight and the accuracies of Test set 1 were degraded from the original model (a). Because transfer learning assumes that the target domain should be similar to the source domain, the dataset difference impacts performance significantly. We can conclude that we should collect (and use) all data for model adaptation regardless of whether or not the original model can correctly classify it.

### 3.3 Accuracies according to Additional Data Size

Figure 4 plots accuracy versus the size of the additional datasets. In the normal case (e), the accuracies of Test set 2 improved with both the Transfer and the Online cases along with dataset size. In contrast, the accuracy of Test set 1 with Transfer degraded faster than Online, as described in Section 3.2. The degradation with Online started when over 2,000 data points were added. This result shows that the SCW-I algorithm of Online is relatively robust and remembers the previously learnt data.

Focusing on active learning (f), the accuracies of Test set 2 were degraded with both Transfer and Online when all additional data was used. The addition of huge amounts of erroneous data causes a harmful effect regardless of the learning method used.

### 3.4 Hyperparameters in Transfer Learning

Finally, Table 3 shows the accuracies when the hyperparameters for the existing features in the original model and the new features that appear only in the additional data were distinguished by the method described in Section 2.2.2. Here, hyperparameter  $C_{OR}$  was set when the original model

(e) Model Adaptation (Normal Case)

(f) Model Adaptation (Active Learning)

Figure 4: Test Set Accuracy versus Size of Additional Data

Method	$C_{OR}$	$C_{AD}$	Test 1	Test 2
(e) Normal Case	0.1	0.001	70.33%	67.26%
	0.1	0.01	68.09%	72.71%
	0.1	0.1	64.26%	75.78%
(f) Active Learning	0.1	0.001	67.70%	65.15%
	0.1	0.01	61.28%	66.87%
	0.1	0.1	50.32%	63.29%

Table 3: Accuracies of Different Hyperparameters

was trained, and only  $C_{AD}$  was changed.

In the normal case, while the changes to the existing parameters were suppressed (small  $C_{AD}$ ), the accuracy of Test set 2 decreased. However, it was higher than that of the original model (61.49%  $\rightarrow$  67.26%), and the accuracy on Test set 1 was almost constant (70.90%  $\rightarrow$  70.33%). If we have to adapt the model under the condition that the original performance is to be maintained, the two hyperparameter approach is effective.

In the active learning case, although we distinguished the hyperparameters, the results were not improved from the normal case.

## 4 Conclusions

We investigated the characteristics of model adaptation wherein the original training data cannot be accessed. We tested transfer learning (regularized adaptation) on the maximum entropy classifier and online learning (soft confidence-weighted learning). Our results are summarized as follows.

- If the additional dataset contains all data, regardless of whether it can be correctly classified by the original model or not, both transfer learning and online learning basically achieved the highest accuracy.

- However, the maximum entropy classifier with regularized adaptation changed more data, which the original model correctly classified, yielding more errors than online learning by SCW-I.

- Restricting the additional data to the data that the original model could not classify correctly had negative effects in our problem setting (i.e., the original dataset cannot be accessed).

- We could slightly adapt the model while retaining previous classification performance by distinguishing the hyperparameters for the existing features and those for the new features.

In natural language processing, structured learning is frequently used for sequential labeling, parsing, and so on. Our future work is to apply model adaptation to structured learning.

## Abstract

Recently, translation scholars have made some general claims about translation properties. Some of these are source language independent while others are not. Koppel and Ordan (2011) performed empirical studies to validate both types of properties using English source texts and other texts translated into English. Obviously, corpora of this sort, which focus on a single language, are not adequate for claiming universality of translation properties. In this paper, we are validating both types of translation properties using original and translated texts from six European languages.

## 1 Introduction

Even though it is content words that are semantically rich, function words also play an important role in a text. Function words are more frequent and predictable than content words. Generally, function words carry grammatical information about content words. High frequency function words are relatively shorter than mid/low frequency function words (Bell et al., 2008). Due to their high frequency in texts and their grammatical role, function words also indicate authorial style (Argamon and Levitan, 2005). These words could play an important role in translated text and in the translation process.

Source and translation classification is useful for some Natural Language Processing (NLP) applications. Lembersky et al. (2011) have shown that a language model from translated text improves the performance of a Machine Translation (MT) system. A source and translation classifier

can be used to identify translated text. This application also can be used to detect plagiarism where the plagiarised text is translated from another language.

From the early stage of translation studies research, translation scholars proposed different kinds of properties of source text and translated text. Recently, scholars in this area identified several properties of the translation process with the aid of corpora (Baker, 1993; Baker, 1996; Olohan, 2001; Laviosa, 2002; Hansen, 2003; Pym, 2005). These properties are subsumed under four keywords: *explicitation*, *simplification*, *normalization* and *levelling out*. They focus on the general effects of the translation process.

Toury (1995) has a different theory from these. He stated that some *interference* effects will be observable in the translated text. That is, a translated text will carry some fingerprints of its source language. Specific properties of the English language are visible in user manuals that have been translated to other languages from English (for instance, word order) (Lzwaini, 2003). Recently, Pastor et al. (2008) and Ilisei et al. (2009; 2010) have provided empirical evidence of simplification translation properties using a comparable corpus of Spanish.

Koppel and Ordan (2011) perform empirical studies to validate both theories, using a sub-corpus extracted from the *Europarl* (Koehn, 2005) and IHT corpora (Koppel and Ordan, 2011). They used a comparable corpus of original English and English translated from five other European languages. In addition, original English and English translated from Greek and Korean was also used in their experiment. They have found that a translated text contains both source language dependent and independent features.

Obviously, corpora of this sort, which focus on a single language (e.g., English), are not adequate for claiming the universal validity of translation properties. Different languages (and language families) have different linguistic properties. A corpus that contains original and translated texts from different source languages will be ideal for this kind of study. In this paper, we are validating both types of translation properties using original and translated texts from six European languages. As features, we used frequencies of the 100 most frequent words of each target language.

The paper is organized as follows: Section 2 discusses related work, followed by an introduction of our corpus in Section 3. The experiment and evaluation in Section 4 are followed by a discussion in Section 5. Finally, we present conclusions and future work in Section 6.

## 2 Related Work

Corpus-based translation studies is a recent field of research with a growing interest within the field of computational linguistics. Baroni and Bernardini (2006) started corpus-based translation studies empirically, where they work on a corpus of geo-political journal articles. A Support Vector Machine (SVM) was used to distinguish original and translated Italian text using n-gram based features. According to their results, word bigrams play an important role in the classification task.

Van Halteren (2008) uses the *Europarl* corpus for the first time to identify the source language of text for which the source language marker was missing. Support vector regression was the best performing method.

Pastor et al. (2008) and Ilisei et al. (2009; 2010) perform classification of Spanish original and translated text. The focus of their works is to investigate the *simplification* relation that was proposed by (Baker, 1996). In total, 21 quantitative features (e.g. a number of different POS, average sentence length, the parse-tree depth etc.) were used where, nine (9) of them are able to grasp the simplification translation property.

Koppel and Ordan (2011) have built a classifier that can identify the correct source of the translated text (given different possible source languages). They have built another classifier which can identify source text and translated text. Furthermore, they have shown that the degree of difference between two translated texts, translated

from two different languages into the same target language reflects, the degree of difference of the source languages. They have gained impressive results for both of the tasks. However, the limitation of this study is that they only used a corpus of English original text and English text translated from various European languages. A list of 300 function words (Pennebaker et al., 2001) was used as feature vector for these classifications.

Popescu (2011) uses *string kernels* (Lodhi et al., 2002) to study translation properties. A classifier was built to classify English original texts and English translated texts from French and German books that were written in the nineteenth century. The *p-spectrum* normalized kernel was used for the experiment. The system works on a character level rather than on a word level. The system performs poorly when the source language of the training corpus is different from the one of the test corpus.

We can not compare our findings directly with Koppel and Ordan (2011) even though we use text from the same corpus and similar techniques. The English language is not considered for this study due to unavailability of English translations for some languages included in this work. Furthermore, instead of the list of 300 function words used by Koppel and Ordan (2011), we used the 100 most frequent words for each candidate language.

## 3 Data

The field of translation studies lacks a multilingual corpus that can be used to validate translation properties proposed by translation scholars. There are many multilingual corpora available used for different NLP applications. A customized version of the *Europarl* corpus (Islam and Mehler, 2012) is freely available for corpus-based translation studies. However, this corpus is not suitable for the experiment we are performing here. We extract a suitable corpus from the *Europarl* corpus in a way similar to Lembersky et al. (2011) and Koppel and Ordan (2011). Our target is to extract texts that are translated from and to the languages considered here. We trust the source language marker that has been put by the respective translator, as did Lembersky et al. (2011) and Koppel and Ordan (2011).

To experiment with stylistic differences in translated text, a list of function words and their

	German	Dutch	French	Spanish	Polish	Czech

Table 1: The customized corpus for source language identification (number of words per language)

respective native frequencies is necessary. Since for many languages such a list does not exist, we pursue an alternative strategy. A list of the 100 most frequent words is available for many languages and since at the same time the majority of these first 100 most frequent words of any language are function words, we use these lists. The 100 most frequent German words are taken from the *Deutscher Wortschatz*.<sup>1</sup> The most frequent Czech word list is taken from the freely available Czech national corpus.<sup>2</sup> The 100 most frequent Spanish words are taken from the book *A Frequency Dictionary of Spanish: Core Vocabulary for Learners* (Davies, 2006). The French most frequent words are taken from the *A Frequency Dictionary of French: Core Vocabulary for Learners* (Lonsdale and Bras, 2009). The 100 most frequent Dutch words are taken from snowball.<sup>3</sup> The most frequent Polish word list are collected from the Polish scientific publisher PWN.<sup>4</sup>

## 4 Experiment

In order to validate two different kinds of translation properties mentioned in Section 1, two different experiments will be performed. For the first experiment, our hypothesis is that texts translated into the same language from different source languages have different properties, a trained classifier will be able to classify texts based on different sources. Our second hypothesis is that translated texts are distinguishable from source texts; a classifier can be trained to identify translated and original texts. Note that we use the Naive Bayes multinomial classifier (Mccallum and Nigam, 1998) in WEKA (Hall et al., 2009) for classification. To overcome the data over-fitting problem, we randomly generate training and test set  $N$  times and calculate the weighted average of  $F$ -Score and  $Ac$ -

*curacy*. In this experiment the value of  $N$  is 100. The randomly generated training sets contain 80% of the data while the remaining data is used as a test set. To evaluate the classification results, we use standard  $F$ -Score and  $Accuracy$  measures.

### 4.1 Source Language Identification

In this experiment, our goal is to validate the translation properties postulated by Toury (1995). He stated that a translated text inherits some fingerprints from the source language. The experimental result of Koppel and Ordan (2011) shows that text translated into English holds this property. If this characteristic also holds for text translated into other languages, then it will corroborate the claim by Toury (1995). If it does not hold for a single language then it might be claimed that this translation property is not universal. In order to train a classifier, we use texts translated into the same language from different source languages. Table 1 shows the statistics of the corpus used for source language identification experiments. Later, each corpus is divided into a number of chunks (see Table 2). Each chunk contains at least seven sentences. Our hypothesis is again similar to Koppel and Ordan (2011), that is, if the classifier’s accuracy is close to 20%, then we cannot say that there is an *interference* effect in translated text. If the classifier’s accuracy is close to 100% then our conclusion will be that *interference* effects exist in translated text. Table 3 and Table 4 show the evaluation results. Table 3 shows the  $F$ -Scores for translated text from different source languages. Rows represent translated texts and columns represent source languages.

A first minor observation can be made, in that the consistency of the results increases when analyzing them with respect to the concept of *language family*. The term *language family* is broadly used in linguistics as a denomination of groups of languages that have descended from a common

	German	Dutch	French	Spanish	Polish	Czech

Spanish	84.7%
Polish	51.3%
Czech	50.5%

Table 4: Source language identification evaluation (Accuracy)

ancestor. In the vast majority of cases, members of the same language family share a considerable number of words and grammatical structures. In the experiment, we consider three language families: Romance languages (French and Spanish), Germanic languages (German and Dutch), and Slavic languages (Polish and Czech).

With a Romance target language,<sup>5</sup> the identification of other Romance and of Germanic languages as translation sources performs high, with an F-Score of between 0.86 and 0.95. However, a noticeable drop in performance concerns the identification of the Slavic languages.

When we take a look at the confusion matrices for the respective classifications, we find that, for instance, most misclassifications in the French target language data are between the sources of Polish and Czech. For Germanic target languages, the pattern repeats: when translated into German or Dutch, Polish and Czech texts are hardest to identify as the correct source.

The Slavic target languages show a different pattern. Even in another Slavic target language, a Slavic source language cannot reliably be identified in our setting. In addition to this, translations into Slavic are harder to distinguish from each other. Misclassifications in this case show language family specific patterns: German is, for instance, most often misclassified as Dutch in both the Czech and the Polish data.

<sup>5</sup>Target language refers to text translated into the language

## 4.2 Source Translation Classification

Translated texts have distinctive features that make them different from original or non translated text. According to Baker (1993; 1996), Olohan (2001), Lavisoa (2002), Hansen (2003), and Pym (2005) there are some general properties of translations that are responsible for the difference between these two text types. Some of these properties are source and target language independent. According to their findings, a translated text will be similar to another translated text but will be different from a source text. In the past, researchers have used comparable corpora to validate these translation properties (Baroni and Bernardini, 2006; Pastor et al., 2008; Ilisei et al., 2009; Ilisei et al., 2010; Koppel and Ordan, 2011). Most of them used comparable corpora for two-class classification, distinguishing translated texts from the original texts. Only Koppel and Ordan (Koppel and Ordan, 2011) used English texts translated from multiple source languages. We perform similar experiments only for six European languages as shown in Table 1. In this experiment, the translated text in our training and test set will be a combination of all languages other than the target language. For example: when the original class contains original texts (source) in German, then the translation class contains texts that are translated German texts, translated from French, Dutch, Spanish, Polish, and Czech texts. Each class contains 200 chunks of texts, where as the translated class has 40 chunks from each of the source languages. The source language texts are extracted for the corresponding languages in a similar way from the Europarl corpus. Koppel and Ordan (2011) received the highest accuracy (96.7%) among all works noted above. The training and test data are generated in similar ways as in our previous experiment. That is, 80% of the data is randomly extracted for training and the rest of the data is used for testing. Expected F-Scores are calculated from 100 samples. Table 5 shows the evaluation results. Even though the classifier for German achieves around 99% accuracy, we cannot compare the result with Koppel and Ordan (Koppel and Ordan, 2011) as the amount of chunks for the classes are different. The classifiers for other languages also display very high accuracy.

The result of Table 5 shows that general translation properties exist for all languages used in this experiment.

Language	Accuracy	F-Score
German	99.9%	0.99
Dutch	95.1%	0.95
French	81.9%	0.81
Spanish	94.4%	0.94
Polish	93.3%	0.93
Czech	81.1%	0.81

Table 5: Source translation classification

## 5 Discussion

The results show that training a classifier based on the 100 most frequent words of a language is sufficient to obtain interpretable results. We find our results to be compatible with Koppel and Ordan (2011) who used 300 function words. A list of the 100 most frequent words is easily obtainable for a vast number of languages, while lists consisting strictly of function words are rare and cannot be produced without considerable additional effort.

While the 100 most frequent words of a language are sufficient to train a classifier for Germanic or Romance languages, it fails to perform equally well for Slavic languages. Koppel and Ordan (2011) claim that Toury’s (1995) findings of *interference* of a translation hold true; we find the assumption to be too simplistic, since for Slavic text either as a source or target language this statement cannot be supported.

Although function words do exist in all the languages we examined, the language families differ in the degree to which it is necessary to use them. For instance, French lacks a case system (Dryer and Haspelmath, 2011), and makes instead use of prepositions. On the other hand, Polish and Czech most extensively use (inflectional) affixes (Kulikov et al., 2006). Regarding the distribution of word frequencies, for both Polish and Czech, the use of affixes causes a flatter Zipf curve. Kwapien et al. (2010) put it so :“...typical Polish texts have smaller  $\alpha$  [as exponent of the formula  $f(r) \sim r^{-\alpha}$ ] than typical English texts (on average: 0.95 vs. 1.05).” This means that on average a more frequent word does not differ as much in its frequency from a word 10 ranks further down in Polish as it does in English. Consequently, there will be fewer instances of the 100 most frequent words in the same portion of text. This is an obvious reason why a classifier’s training must remain weaker in comparison to languages with a steeper Zipf curve. There is a positive correlation to language family when considering the probabil-

ity of finding the same strategy (e.g. prepositions vs. affixes). In summary, the fact that Slavic uses more affixes, or is more inflectional in linguistic terms, explains to some extent why the classifier performs worst for Slavic target text.

However, for Slavic source texts, the classification results are equally unsatisfactory, which has to be explained differently. One phenomenon contributing here could be that Romance and Germanic have a recent history of mutual loans and calques, which increases the probability of finding synonyms where one has a Romance origin and one a Germanic origin. In the case of a translation, the translator, when confronted with such a synonym, might choose the item similar to the source language within the target language, as this minimizes the translation effort, complies thus to an economy principle and has virtually no effect on the translation.<sup>6</sup> Making this choice, the translator unintentionally distorts the native frequency patterns for the target language. This could be one of the processes generating an imprint of translated text in the frequency spectrum, since function words are also subject to loaning and synonymy.

If the translator has a choice for translating a preposition/affix and neither of the possibilities is similar to the source language, nor a loanword or structurally similar, he/she will go for the predominant word or structure of the target language (since he/she is a native of the target language by translation industry standard), making the translation less different from native text. The data can be influenced by many additional variables such as differing translation paradigms influencing the choice of structures (free translation vs. faithful translation), different industry standards, the size of the chunks,<sup>7</sup> the quality of the translation source marking, the native tongue of the translator(s), the time pressure for delivery, the payment, the membership of all sample languages to the European subbranch of Indo-European languages, the qualities of the lists of the most frequent 100 words, the genre of the Europarl corpus, and possibly many more.

This said, we believe the best hypothesis for the

<sup>6</sup>For French to English translations an example would be the translator’s choice of “intelligent” as a translation for French “intelligent” in a place where “smart” would have been slightly more natural.

<sup>7</sup>Since a short text contains fewer anaphora and thus personal pronouns.

interpretation of the data is that a good classification result is reached firstly for languages with a more isolating structure, since they make less use of affixes and therefore more of function words, and should display steeper Zipf curves. Secondly, the classification result should be better, the more instances the text contains, where the translator for one token (or for one structure) of the source language has the choice between at least two words or structures in the target language with one of those being similar to the source language, the other being different. The number of such instances most probably correlates positively with the degree and quality of language relationship and language contact since the number of cognates, loans and calques does. However, this number can also be “accidentally high” for two unrelated languages when they overlap in grammatical structure. As has been postulated for instance by Croft (2003), languages undergo a cyclic development from structurally more isolating towards agglutinative to inflectional and then back to isolating. When a language is in a state of transition, which practically all languages are, they offer two structural encoding possibilities for one specific grammatical property, e.g., a genitive (for instance, inflectional (an affix) as in *Peter’s house* and isolating (a preposition) as in *the house of Peter*). All languages should share structural properties, since there are only three types and each language has practically at least two.

Corroborating this rather complex hypothesis, we examine data on Bulgarian and Romanian. We take Bulgarian as the target language. The data showed that the classifier classifies Czech text no worse than Dutch or German and only slightly worse than French. When we replace Czech with Bulgarian and Spanish with Romanian in the German target language, the language family dependent pattern gets blurred and the identification of Polish performs quite well, that of Romanian relatively poor, while French is identified reliably. This together with the observation that Romanian is misclassified either as Polish or Bulgarian and Bulgarian is mostly misclassified as Romanian seems to be a strong hint towards the impact of the language specific usage of function words, linguistic structure, and the importance of language contact. Bulgarian and Romanian constitute the core of the most prominent linguistic contact zone or *sprachbund* ever written on the Balkans. This

suggests that Romanian and Bulgarian translators may, due to grammatical convergence of their languages make, given two equivalent structures in any target language, the same (structurally motivated) choices and hence leave a very similar imprint. That is, sprachbund membership as well as language family could be decisive factors for a classifiers performance.

## 6 Conclusion

We have shown that *interference* as originally proposed by Toury (1995) is not supported by the data without making further assumptions. Language family and language contact should be considered separately for each language pair as sources for possible weak results of a classifier even when operating with function words as should be general structural similarity. As for the properties of translated text being universal, we found support for this in our data in a real n-ary validation setting. We have also shown that the much more easily obtainable lists of the 100 most frequent words work almost as well for classification as do longer lists that contain only function words.

## 7 Acknowledgments

We would like to thank Prof. Moshe Koppel and Dr. Noam Ordan for providing their data, and Prof. Dr. Alexander Mehler for suggestions and comments. We also thank Dr. Timothy Price for checking English and three anonymous reviewers. This work is funded by the LOEWE Digital-Humanities project at the Goethe-Universität Frankfurt.

## Abstract

This paper describes a new method, based on information theory, for measuring sentence similarity. The method first computes the information content (IC) of dependency triples using corpus statistics generated by processing the Open American National Corpus (OANC) with the Stanford Parser. We define the similarity of two sentences as a function of (1) the similarity of their constituent dependency triples, and (2) the position of the triples in their respective dependency trees. We apply the algorithm to 15 pairs of sentences that were also given to human subjects to assign a similarity score. The human- and computer-generated scores are compared; the results are promising, but point to the need for further refinement.

## 1 Introduction

This project seeks to develop an algorithm that measures the extent to which the meanings of two given sentences overlap. Our plan is to use such an algorithm in a clustering application (Lang and Mersch, 2012).

The technique described in this paper extends previous work applying an information-theoretic definition of similarity to a number of different domains (Lin, 1998). Lin's information-theoretic definition of similarity performs as well as or better than other information-theoretic similarity metrics that leverage domain specifics (Resnik, 1995; Wu and Palmer, 1994).

The metric being proposed in this paper shares characteristics of word co-occurrence methods and descriptive feature-based methods (Li et al., 2006), in addition to using structural information provided by the Stanford Parser (Klein and Manning, 2003). We test this metric on 15 pairs of sen-

tences, each of which was assessed for similarity by 40 fluent English speakers.

## 2 Background & Related Work

Methods that detect similarity of long documents often utilize co-occurring words (Salton, 1988), since similar texts share a high number of words. But this does not transfer well to short, sentence-length texts, since language allows similar meanings to be expressed using different vocabularies.

Existing text similarity measures suffer from drawbacks. Vector-based methods employ high-dimensional, sparse representations that are computationally inefficient (Landauer et al., 1998; Salton, 1988; Burgess et al., 1998). Some methods rely on extensive manual preprocessing (McClelland and Kawamoto, 1986), making them impractical for large-scale use. Still other methods suffer from domain dependency (Li et al., 2006).

Related work on text similarity may be grouped into three categories:

1. Methods based on word co-occurrence (i.e. "bag of words" methods) disregard the impact of word order on meaning (Meadow et al., 1999); thus, the two sentences:

$T_1$ : The cat killed the mouse.

$T_2$ : The mouse killed the cat.

are regarded as identical, since they use the same words. Documents are represented as vectors in an  $n$ -dimensional space, where  $n$  is the length of a pre-compiled word list, typically in the tens or hundreds of thousands. The resulting representations are sparse and computationally inefficient (Li et al., 2006). Also, these methods often exclude function words (e.g. the, of, an, etc.) that have low relevance for similarity of long documents but convey information important for sentence similarity. These methods will not detect similarity of sentences that use different

words to convey the same meaning. However, they achieve improved results by examining word pairs instead of single words (Okazaki et al., 2003).

2. Corpus-based methods. Latent semantic analysis (LSA) constructs an occurrence count matrix where the rows represent words and the columns text units, usually paragraphs or documents. It is more suitable for longer texts than for sentences (Landauer et al., 1998). Hyperspace Analogues to Language (HAL) (Burgess et al., 1998) constructs a word co-occurrence matrix based on a moving window of a predefined width, typically 10. HAL is also more effective for longer texts than for sentences (Li et al., 2006).
3. Descriptive feature-vector methods. These methods employ pre-defined thematic features to represent a sentence as a vector of feature values, then obtain a similarity measurement through a trained classifier (Taraban and McClelland, 1988). Choosing a suitable set of features and automatically obtaining values for features pose obstacles for these methods (Islam and Inkpen, 2008).

In contrast to the above approaches, Lin (1998) proposes an information-theoretic measure of similarity. This measure is derived from assumptions about similarity rather than from a domain-specific formula. The metric can be applied to any domain with a probabilistic model. From a set of assumptions grounded in information theory, Lin proves a Similarity Theorem:

the similarity between  $A$  and  $B$  is measured by the ratio between the amount of information needed to state the commonality of  $A$  and  $B$  and the information needed to fully describe what  $A$  and  $B$  are:

$$\text{sim}(A, B) = \frac{\log P(\text{common}(A, B))}{\log P(\text{description}(A, B))}$$

[...] If we know the commonality of the two objects, their similarity tells us how much more information is needed to determine what these two objects are. (Lin, 1998)

Lin applies the definition to four different domains; one of these is similarity between words according to the distribution of dependency triples extracted from a text corpus. Lin's test uses a database of 14 million dependency triples extracted from a corpus consisting of items from the *Wall Street Journal* and from the *San Jose Mercury*. He also applies it to semantic similarity in a taxonomy. Lin achieves better results than distance-based definitions of similarity; his results correlate slightly better with human judgment than measures proposed by Resnik (1995) and by Wu and Palmer (1994). To illustrate the domain independence of his measure, Lin also applies it to the domain of ordinal values.

### 3 Approach

The Stanford Parser (de Marneffe et al., 2006) was applied to the Open American National Corpus (Ide and Suderman, 2004) to produce a database containing the counts of occurrences of all the dependency triples, which are of the form  $\langle \text{role}, \text{governor}, \text{dependent} \rangle$ , appearing in the corpus. Cover and Thomas (2006) define the information content of a proposition as the negative logarithm of its probability. We use this definition to compute the information content of the triples occurring in the corpus. Given a dependency triple, we define two predicates:

- A governor-position predicate substitutes a variable for the governor in the triple.
- A dependent-position predicate substitutes a variable for the dependent in the triple.

For example,

$t_1$ :  $\langle \text{dobj}, \text{grow}, \text{tomato} \rangle$

is one of the dependency triples occurring in the sentence:

$s_1$ : The gardener has grown tomatoes.

The governor-position predicate corresponding to  $t_1$  is:

$p_1$ :  $\langle \text{dobj}, \_G, \text{tomato} \rangle$

which binds to all occurrences of "tomato" as a direct object; the dependent-position predicate is:

$p_2$ :  $\langle \text{dobj}, \text{grow}, \_D \rangle$

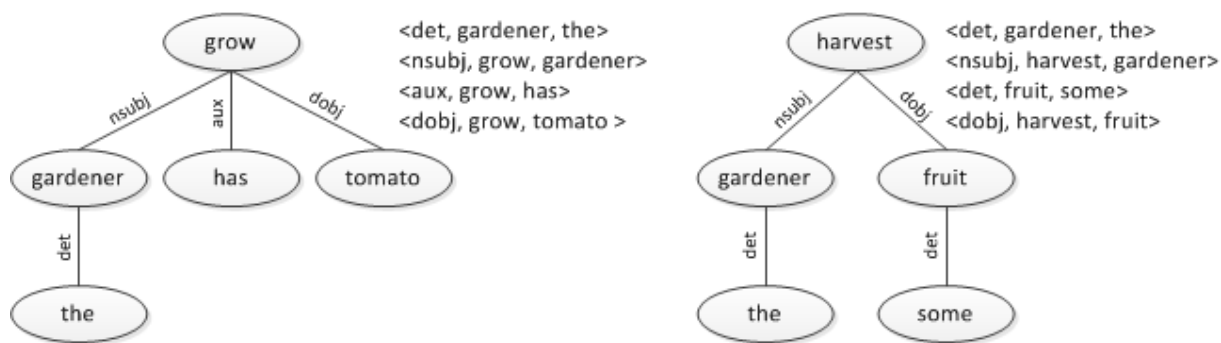

Figure 1: Dependency trees and dependency triples for  $s_1$  and  $s_2$

which binds to all occurrences of “grow” as a transitive verb. The information content of  $t_1$  is computed from the number of occurrences of instantiations of its dependent-position predicate. In general, let  $A$  be the number of occurrences of  $\langle r, g, d \rangle$  and let  $B$  be the number of occurrences of instantiations of  $\langle r, g, \_D \rangle$ . The information content of  $\langle r, g, d \rangle$  is defined by:

$$IC(\langle r, g, d \rangle) = -\log \frac{A}{B}$$

Next, we define similarity of two dependency triples using Lin’s information-theoretic definition of similarity. The definition is explained by an example computing the similarity between the following:

- $t_1$ :  $\langle \text{dobj}, \text{grow}, \text{tomato} \rangle$   
 $t_2$ :  $\langle \text{dobj}, \text{harvest}, \text{fruit} \rangle$

where  $t_2$  is a triple from the sentence:

$s_2$ : The gardener harvested some fruit.

The predicates  $p_1$  and  $p_2$  (above) are formed from  $t_1$ ; from  $t_2$ , we form the predicates:

- $p_3$ :  $\langle \text{dobj}, \_G, \text{fruit} \rangle$   
 $p_4$ :  $\langle \text{dobj}, \text{harvest}, \_D \rangle$

For each of these of these predicates, we form the set of all instantiations,  $M(p_n)$ . The numbers following the triples are hypothetical values for  $IC(t_n)$ :

- $M(p_1)$ :  $\{ \langle \text{dobj}, \text{grow}, \text{tomato} \rangle 1.7, \langle \text{dobj}, \text{raise}, \text{tomato} \rangle 3.8, \langle \text{dobj}, \text{eat}, \text{tomato} \rangle 2.4 \}$   
 $M(p_2)$ :  $\{ \langle \text{dobj}, \text{grow}, \text{tomato} \rangle 1.7, \langle \text{dobj}, \text{grow}, \text{strawberry} \rangle 2.7, \langle \text{dobj}, \text{grow}, \text{beard} \rangle 5.6 \}$

- $M(p_3)$ :  $\{ \langle \text{dobj}, \text{grow}, \text{fruit} \rangle 3.9, \langle \text{dobj}, \text{harvest}, \text{fruit} \rangle 7.2, \langle \text{dobj}, \text{eat}, \text{fruit} \rangle 1.2 \}$

- $M(p_4)$ :  $\{ \langle \text{dobj}, \text{harvest}, \text{tomato} \rangle 8.7, \langle \text{dobj}, \text{harvest}, \text{strawberry} \rangle 9.7, \langle \text{dobj}, \text{harvest}, \text{fruit} \rangle 7.2 \}$

For the two governor-position predicates,  $p_1$  and  $p_3$ , we compute the quotient of (1) the sum of the ICs of triples in  $M(p_1)$  and  $M(p_3)$  that have the same word in the governor position and (2) the sum of the ICs of all the triples in  $M(p_1)$  and  $M(p_3)$ . Triples that appear in both models are counted both times. Call this quotient  $S_g$ .

$$S_g = \frac{1.7 + 2.4 + 3.9 + 1.2}{1.7 + 3.8 + 2.4 + 3.9 + 7.2 + 1.2}$$

We form the quotient  $S_d$  similarly, using the dependent-position predicates. Finally, we define

$$\text{sim}(t_1, t_2) = \alpha \cdot S_g + (1 - \alpha) \cdot S_d$$

where  $\alpha$  is a real value between zero and one.

We extend this definition of similarity between triples to define similarity between sentences. Given two sentences, the nodes of their respective dependency trees are words and the tree edges are dependency relations. For example, the triple  $\langle \text{dobj}, \text{grow}, \text{tomato} \rangle$  indicates that *grow* and *tomato* are two nodes in the dependency tree and that there is a directed edge from *grow* to *tomato* labeled *dobj*.

Given two dependency trees and two nodes, one from each of the given trees, we form a collection of pairs where the first component is a branch that has the first node in the governor position and the second component is a branch that has the second node in the governor position. The process for forming this collection is as follows:

	$s_1$	$s_2$	Survey Average	Tree Similarity
1	The cat killed the mouse.	The mouse killed the cat.	0.5	0.633
2	The man walked to the store.	The person went to the store.	3.625	0.512
3	The student killed time.	The student killed the roach.	0.35	0.134
4	The janitor cleaned the desk.	The desk was cleaned by the janitor.	4.85	0.001
5	The locksmith went to the movies.	The window was stuck shut.	0.075	0.108
6	The dog went missing for three days.	The squirrel avoided the trap.	0.075	0.131
7	The student ran out of notebook paper.	The printer ran out of paper.	1.2	0.632
8	The door is open.	The door is closed.	0.5	0.330
9	Traffic downtown is heavy.	The downtown area is crowded.	2.4	0.075
10	The secretary stopped for coffee on the way to the office.	The office worker went out for dinner after work.	0.675	0.030
11	Biologists discovered a new species of ant.	Physicists verified the existence of black holes.	0.45	0.060
12	The artist drew a picture of the landscape.	The artist sketched a picture of the landscape.	4.375	0.675
13	The bear searched for food at the picnic grounds.	The bear scavenged the park for food.	3.525	0.500
14	A college degree allows one to have a rewarding career.	A bachelor's degree is necessary to get a high paying job.	2.125	0.294
15	The train arrives at half past three.	The visitor will be in the station this afternoon.	1.125	0.093

Table 1: Sentence Pairs with human subject survey averages and tree similarity measures. Survey averages range from 0 to 5; tree similarity measures range from 0 to 1.

- The triple with the highest information content from the collection of triples that have one of the given nodes in the governor position is identified. This triple may come from either tree.
- A search is done for the most similar triple from the other dependency tree.
- The two triples just identified are matched and removed from consideration. The process repeats until all of the branches exiting from one of the nodes have been matched.

Matching triples enables the recursive comparison of nodes from different dependency trees. We define the similarity of two nodes as the weighted average of:

- the similarity of the triples matched as described above;
- the result of recursively computing similarity of matched dependents (nodes one level

deeper in the dependency tree); and

- unmatched branches, defined as having a similarity of zero (The two nodes may have unequal numbers of children).

The similarity of two sentences is the similarity of their root nodes.

#### 4 Results

We applied the algorithm to 15 pairs of sentences written for the purpose of testing the approach. We asked 40 native English speakers to rank the similarity of each pair on a scale of 0 to 5, where 0 indicates “no overlap in meaning” and 5 indicates “complete overlap in meaning.” The tree similarity algorithm was applied to the sentence pairs. Table 1 shows the results (survey averages range from 0 to 5; tree similarity measures range from 0 to 1).

The two similarity measures have a correlation coefficient of 0.279; however, inter-annotator

agreement was low (Fleiss's kappa = 0.313). Pairs 7, 10, 14, and 15 had the lowest inter-annotator agreement. Without these pairs, the 11 pairs that remaine (1, 2, 3, 4, 5, 6, 8, 9, 11, 12, and 13) have kappa = 0.399 and have a correlation coefficient of 0.291 with the tree similarity algorithm. Pair 4, the active/passive switch, is incorrectly scored 0 by the algorithm, whereas the annotators were in strong agreement of a rating close to 5. Removing pair 4 from the analysis (which lowers kappa) gives a correlation coefficient of 0.618 between annotator averages and the algorithm results. These results suggest that, once the algorithm is refined to properly handle the active/passive switch, it will provide results that correlate to the judgment of native speakers.

## 5 Contributions & Future Work

Our approach is grounded in information theory. The representation avoids high-dimensional, sparse vectors; this allows the use of the trained database without having to condense it.

Previously Lang (2010) proposed implementing Lévi-Strauss's procedure for finding the structure of a myth (Lévi-Strauss, 1955). We plan to apply the tree similarity metric in a clustering algorithm for grouping sentences into categories corresponding to the constituent terms of his canonical formula.

# Effective Selectional Restrictions for Unsupervised Relation Extraction

Alan Akbik   Larysa Visengeriyeva   Johannes Kirschnick   Alexander Löser

Einsteinufer 17, 10587 Berlin, Germany

firstname.lastname@tu-berlin.de

## Abstract

Unsupervised Relation Extraction (URE) methods automatically discover semantic relations in text corpora of unknown content and extract for each discovered relation a set of relation instances. Due to the sparsity of the feature space, URE is vulnerable to ambiguities and underspecification in patterns. In this paper, we propose to increase the discriminative power of patterns in URE using selectional restrictions (SR). We propose a method that utilizes a Web-derived soft clustering of  $n$ -grams to model selectional restrictions in the open domain. We comparatively evaluate our method against a baseline without SR, a setup in which standard 7-class Named Entity types are used as SR and a setup that models SR using a fine-grained entity type system. Our results indicate that modeling SR into patterns significantly improves the ability of URE to discover relations and enables the discovery of more fine-granular relations.

## 1 Introduction

In traditional approaches for Relation Extraction (RE), all target relations (such as BORNIN or HASWONPRIZE) need to be specified in advance. For each relation, an extractor is trained or manually created that finds relation instances in text (Jiang and Zhai, 2007). This process is expensive and usually involves manually labeling large amounts of training data, making it difficult to scale RE to large sets of relations. Worse, because target relations must be manually defined in advance, the usefulness of RE in corpora of unknown content is limited (Akbik et al., 2012). This limits their applicability to the open domain where a potentially unbounded number of relations may be expressed in text.

In contrast, Unsupervised Relation Extraction (URE) approaches do not require target relations to be pre-specified, and require no labeled training data (Rosenfeld and Feldman, 2007). Instead, they automatically *discover* prominent relations in a given text corpus and *extract* for each identified relation a list of relation instances. Current methods (Akbik et al., 2012; Yao et al., 2012) utilize a vector space model of semantics in which they group co-occurring pairs of entities (referred to as *entity pairs*) into clusters based on distributional evidence over observed patterns. Each cluster is interpreted as one discovered semantic relation and the entity pairs in each cluster as the instances of this relation.

**Pattern ambiguities.** However, a problem for such approaches is that patterns may be ambiguous in the sense that they point to more than one relation. The pattern “[X] GET [Y]”<sup>1</sup> for example may be observed for a person and a product (“*Jim got a new VW Beetle.*”), a person and a disease (“*Jim got H1N1.*”) or (colloquially) between a person and a difficult-to-understand topic (“*Jim finally got Game Theory.*”). Such ambiguous patterns can cause entity pairs that belong to different relations (such as <Jim, VW Beetle> and <Jim, H1N1>) to be falsely grouped into the same semantic relation. See Table 1 for a structured illustration of this example.

This is especially problematic because the number of observed patterns for each individual entity pair is usually disproportionately small compared to the space of all possible patterns. In such a sparse feature space, false evidence caused by ambiguities can potentially have a negative impact on

---

<sup>1</sup>Patterns are denoted with the placeholders [X] for the *subject* entity, and [Y] for the *object* entity of the entity pair they are observed with. In this paper, we use lexico-syntactic patterns extracted from dependency trees. For readability reasons, we omit information on dependency links. [X] in this pattern is either a subject or an apposition to the word GET. Likewise, [Y] is its object.

Sentence	Entity pair	Pattern	Restricted Pattern
<i>Yesterday, Jim got a new VW Beetle.</i>	<Jim, VW Beetle>	[X] GET [Y]	[X:PERSON] GET [Y:PRODUCT]
<i>Jim got H1N1.</i>	<Jim, H1N1>	[X] GET [Y]	[X:PERSON] GET [Y:DISEASE]
<i>Jim finally got Game Theory.</i>	<Jim, Game Theory>	[X] GET [Y]	[X:PERSON] GET [Y:THEORY]

Table 1: Example of pattern generation from three sentences. Three entity pairs are observed that belong to different relations. For example <Jim, VW Beetle> may belong to a PERSONACQUIREPRODUCT relation and <Jim, H1N1> to a PERSONINFECTEDWITHDISEASE relation. Without selectional restrictions, however, the same pattern is observed for all entity pairs, giving false evidence that they share the same relation. With selectional restrictions, different patterns are correctly observed.

the overall relation extraction quality of a URE approach.

**Selectional restrictions in patterns.** One approach to this problem is to include information on selectional restrictions (SR) to the patterns to increase their discriminative power (Resnik, 1996). We could restrict the patterns to apply only to entities of certain semantic classes or types. So, instead of the pattern “[X] GET [Y]” for the above mentioned examples we might generate “[X:PERSON] GET [Y:PRODUCT]” for “*Jim got a new VW Beetle.*”, “[X:PERSON] GET [Y:DISEASE]” for “*Jim got H1N1.*” and so forth (see Table 1).

However, modeling selectional restrictions in URE is not trivial, as it is unclear what type system and what *granularity* of types are required. For example, the types of a standard NER tagger (PERSON, LOCATION, ORGANIZATION etc.) may be too coarse grained for the above example, not being able to distinguish between DISEASE and PRODUCT.

While more fine-grained NER taggers have recently been researched (Ling and Weld, 2012), it is unclear whether they can be applied to the open domain. Here, we may encounter a potentially unrestricted set of entities of arbitrary types and granularity that varies from corpus to corpus. Also, each entity may have different types depending on how the type hierarchy is modeled; the string “*VW Beetle*” for instance may refer to a car, a product or a brand.

**Contributions.** In this paper, we address these challenges and study effective and viable methods for modeling selectional restrictions for URE in the open domain. We evaluate and discuss modeling SR using Named Entity types from the Stanford NER tagger (Finkel et al., 2005) as well as fine-grained Named Entity classes derived from the YAGO knowledge base (Hoffart et al., 2011). In addition, we propose a novel method that over-

comes shortcomings of existing methods by leveraging a Web-derived clustering of  $n$ -grams to model restrictions in an unsupervised fashion. We evaluate all setups against an informed baseline (based on previous work by (Akbik et al., 2012; Rosenfeld and Feldman, 2007)) in which patterns are not restricted.

We observe in all experiments that selectional restrictions significantly improve URE. The best performing setups use fine-grained Named Entity classes and our proposed open domain method, yielding  $f$ -measure improvements of 28% and 15% respectively over the baseline. We inspect the clustering results and find that the choice of SR influences the granularity of discovered relations. Based on our findings, we identify limitations of SR and outline challenges for URE.

## 2 Previous Work

We review previous work in URE with regards to selectional restrictions, and introduce the phrasal clustering dataset we use in our proposed method.

**URE.** There are a number of canonical works that relate to URE; (Lin and Pantel, 2001) first used distributional evidence to measure the similarity of patterns to find paraphrases of patterns. (Turney, 2006) instead computed the similarity of pairs of nouns using patterns as features. Their goal was finding analogies in text. (Rosenfeld and Feldman, 2007) then used a clustering method on a similar vector space model to group pairs of entities into clusters that represent semantic relations.

More recent work has addressed the problem of ambiguous patterns in URE in different ways. Notably, (Akbik et al., 2012) have evaluated pattern generation methods using lexical, shallow and deep syntactic features. They found that the use of deep syntactic features reduces pattern ambiguity and dramatically increases overall relation extraction  $f$ -measure by 65%. However, they do not model selectional restrictions in their pattern gen-

eration step.

**Selectional Restrictions.** Other recent work has incorporated information from NER taggers into their feature set. (Mesquita et al., 2010) use a standard 4-class NER tagger, but do not individually evaluate its impact. (Yao et al., 2012) use a very rich feature set, including fine-grained Named Entity types and document topics, to first disambiguate each pattern individually and in a second step perform URE using disambiguated patterns. This approach is problematic for many corpora because it requires a massive redundancy of pattern observations for disambiguation. In their experiments, they handled only patterns that are seen more than 200 times in their corpus. For comparison, in the large data set that we use in this paper, only 9 out of over 36.000 patterns are observed more than 200 times.

**Phrasal Clustering.** Contrary to previous work we do not propose using a manually established type system for selectional restrictions. Rather, we use a clustering of more than 10 million distinct one-to-five-word-grams from the Google  $n$ -gram data set (Lin and Wu, 2009) computed by (Lin et al., 2010). Previous work has leveraged the latent semantic information given by phrasal cluster memberships of  $n$ -grams to solve tasks other than URE. For example, (Zhou et al., 2011) increase the performance of deep syntactic parsers with regard to long-range dependencies, and (Täckström et al., 2012) transfer linguistic structure using cross-lingual word clusters.

In this work, we interpret each phrasal cluster as an entity type and all  $n$ -grams assigned to a cluster as belonging to this type. We incorporate this into the pattern generation step of our URE method and use this information to model selectional restrictions. Thus, the type system is not manually specified, but rather induced without supervision from a large Web corpus, making it a natural fit for the open domain and URE.

### 3 Pattern Generation

Pattern generation is the phase in URE in which patterns are generated for each co-occurring entity pair in the observed corpus. Current techniques go through each sentence in the corpus individually and generate <entity pair, pattern, count> tuples. In the following, we present the architecture of our URE system (Section 3.1) and illustrate how we integrate different options for modeling SR into

the pattern generation process. We present options that use types from an NER tagger (Section 3.2), fine-grained entity types from the YAGO knowledge base (Section 3.3), as well as the proposed phrasal clustering method (Section 3.4).

#### 3.1 Baseline System

In our system, we use a pattern generation method that makes use of dependency parses. We implement the algorithm described in (Akbik et al., 2012). Here, patterns are generated as a sequence of typed dependencies and lemmas of tokens on the shortest path between two entities in a parse. In addition to the tokens on the shortest path (referred to as *core tokens*), additional tokens are collected from their vicinity in the dependency tree. The position of the entities are denoted by the placeholders “[X]” and “[Y]”. We further prune patterns using linguistically-informed filters, e.g. removing patterns that consist only of direct dependencies between subject and object. We give an example of pattern generation applied to a sentence in Figure 1.

**Similarity of entity pairs.** Using this technique, we generate a list of pattern-entity pair observation tuples, which we use to construct a pair pattern frequency matrix. Each row vector represents one distinct entity pair  $e_i$  and each column one distinct pattern  $p_j$ . The value of the matrix cell  $c_{ij}$  is the number of times that  $e_i$  occurs in the pattern  $p_j$ . This representation allows us to compute the similarity of two entity pairs by computing the cosine distance between their corresponding rows in the pair pattern matrix (Bullinaria and Levy, 2007). We compute the pairwise similarity for all entity pairs to generate a dissimilarity matrix and execute a clustering method on this matrix.

**Clustering.** In line with most previous work in URE (Rosenfeld and Feldman, 2007; Wang et al., 2011), we use a Hierarchical Agglomerative Clustering (HAC) approach with the *average linkage* scheme (Han et al., 2011). This approach iteratively merges the two closest entity pairs to compute a dendrogram of cluster merges.

The dendrogram is cut at a point given by the *cutting threshold* parameter, yielding a set of clusters. This parameter is usually estimated or determined through experimentation. A common method is to execute an exhaustive search over a subset of the parameter space (referred to as

Figure 1: Illustration of the pattern generation process for one example sentence with the entities “Jim” and “VW Beetle”. Part-of-speech and Named Entity class tags are given below the tokens in the sentence. The shortest path between the two entities is highlighted bold in the dependency tree. The word “got” lies along this path, which is lemmatized to produce the pattern [X] GET [Y]. As an option, the Named Entity classes of the entities are included as selectional restrictions into the pattern, yielding the pattern [X:PERSON] GET [Y:MISC].

grid search), guided by cross-validation on a training set (Bergstra and Bengio, 2012). Through such experimentation, we determine that the cutting threshold must be set at a high value (for example around 0.999) to produce good clustering results<sup>2</sup>.

**Clustering result.** The clustering produces a set of clusters, which each consist of a set of entity pairs. Each resulting cluster is interpreted as one discovered relation, and all entity pairs in the cluster as the instances of this relation. The clustering result is then passed to an evaluation step discussed in detail in Section 4.

### 3.2 Named Entity Type Restrictions

We first extend the system with an option to use standard Named Entity types as selectional restrictions, in a similar fashion as a previous URE system (Mesquita et al., 2010). We incorporate the Stanford NER 7-class tagger into the sentence parsing pipeline and determine the type of each entity. These types are used to restrict the generic placeholders [X] and [Y] in generated patterns with the types of the subject and object entities.

For the example sentence illustrated in Figure 1, the tagger determines the class PERSON for “Jim”, and MISC for “VW Beetle”. The latter class is used for all entities that cannot be assigned any of the named classes. We therefore generate the pattern “[X:PERSON] GET [Y:MISC]” in this example. Because we model entity type restrictions directly into the patterns, we increase the space of all possible patterns and make individual patterns

<sup>2</sup>We determine different values for other linkage schemes. For example, when using the *single-link* linkage scheme in HAC, we find a good estimation for the cutting threshold to be 0.9.

more discriminative.

However, as shown in the example in Section 1, the Named Entity classes given by a 7-class tagger are coarse grained and may not include the types necessary to disambiguate all patterns. Also, there is a risk that Named Entity taggers may determine the wrong type for an entity<sup>3</sup>. This could lead to false evidence that negatively impacts URE.

### 3.3 Fine-grained Entity Type Restrictions

Because classes from a standard 7-class NER tagger may be too coarse grained for URE, we next extend the system with the option of modeling fine-grained Named Entity classes. We choose an approach that requires entities to be disambiguated and linked to Wikipedia URIs. The YAGO knowledge base then enables us to retrieve fine-grained entity classes for disambiguated entities, such as their Wikipedia categories (of which we use only the head nouns as restrictions). Because many YAGO entities belong to more than one class, this method returns a set of classes for each entity. For example, the Wikipedia categories for “VW Beetle” are “TAXICAB VEHICLES”, “AUSTRIAN INVENTIONS”, “INDUSTRIAL DESIGNS”, “SUBCOMPACT CARS” and others.

For each entity pair, we retrieve two sets of entity classes (one for the subject and one for the object). We determine the Cartesian product over these two sets and create one distinct pattern with selectional restrictions for each combination. For the example sentence, this means that we generate a list of patterns, including “[X:PERSON] GET [Y:CAR]”, “[X:PERSON] GET [Y:VEHICLE]” and “[X:PERSON] GET [Y:INVENTION]”, each of

<sup>3</sup>(Finkel et al., 2005) report an overall *f*-measure of 87% on the CoNLL 2003 Named Entity Recognition dataset.

1) Lookup phrasal clusters for subject and object entity

Pattern	Entity pair
[X] get [Y]	<Jim, VW Beetle>

<i>N</i> -gram lookup	Cluster	Weight	Other <i>n</i> -grams in cluster
VW Beetle	825	0.3	Chrysler Voyager, Toyota Highlander
VW Beetle	805	0.17	Computer Parts, Office Supplies
⋮	⋮	⋮	⋮
Jim	269	0.4	Becky, Doug, Eileen, Frances
⋮	⋮	⋮	⋮

2) Add cluster IDs as selectional restrictions to patterns.

Pattern	Entity pair	Weight
[X:269] get [Y:825]	<Jim, VW Beetle>	0.12
[X:269] get [Y:805]	<Jim, VW Beetle>	0.04
[X:283] get [Y:269]	<Jim, VW Beetle>	0.18
⋮	⋮	⋮

Figure 2: Illustration of the proposed pattern generation process that uses phrasal cluster memberships as selectional restrictions. In 1), phrasal clusters are retrieved for the subject and object of the entity pair. “VW Beetle” for example is in cluster 825, which contains many other car names. In 2) the Cartesian product over the phrasal clusters for subject and object is built and used as selectional restrictions for the pattern generated with the baseline method. This yields a set of patterns with different selectional restrictions.

which is used as a feature. While this method increases the overall number of observed patterns by about one order of magnitude, individual patterns are much more discriminative than without selectional restrictions.

**Limitations.** Two things must be noted regarding this method of determining fine-grained Named Entity classes. Firstly, it does not necessarily produce patterns at the desired granularity. In Section 1 we discussed the pattern “[X:PERSON] GET [Y:PRODUCT]” to be most appropriate, which is not generated by this method. More importantly though, the method is limited to entities that can be disambiguated to the appropriate Wikipedia page. While this is possible on the dataset we use for the evaluation, it is much more difficult to determine fine-grained Named Entity classes in the open domain with this method. We therefore implement this option mainly for evaluation purposes, in order to determine URE capabilities given a fine-grained, high quality type system for selectional restrictions.

### 3.4 Phrasal Clusters as Restrictions

To address the limitations of the methods described in 3.3, we propose a method for modeling SR that does not require an existing type system or the disambiguation of entities.

We extend the system with the option of using selectional restrictions derived from a phrasal

clustering computed by (Lin and Wu, 2009) over a dataset of more than 10 million distinct one-to-five-word-grams from the Google *n*-gram data set (Lin and Wu, 2009). In this dataset, each *n*-gram is assigned to ten different phrasal clusters with different association values, also referred to as *weights*. Weights are between 0 and 1, with a higher value indicating a stronger assignment confidence. Because the clustering is based on lexical context, *n*-grams in a cluster often share semantic properties. For example, the dataset contains clusters of entities like cities, cars, movies, etc (Lin and Wu, 2009).

During pattern generation, we look up the phrasal cluster IDs for the lexical representation of an entity and use this ID as selectional restriction. For example, the string “VW Beetle” belongs to phrasal cluster number 825 with weight 0.3. Semantically similar strings, such as “Chrysler Voyager” and “Toyota Highlander” are also part of this cluster. We can use this information to restrict the subject of the pattern only to strings that belong to cluster 825. Another phrasal cluster for “VW Beetle” is cluster 805 (with a lower weight of 0.17), which consists of more general product terms such as “Computer Parts” and “Office Supplies”. “Jim” is found in cluster 269, which contains many person first names. See Figure 2 for an illustration of this example.

We build the Cartesian product over the two

sets of phrasal clusters retrieved for the subject and object of an entity pair. Because each entity (e.g. its lexical representation) has 10 soft cluster memberships, the Cartesian product of phrasal clusters for both entities of an entity pair yields a total of 100 distinct weighted phrasal cluster ID combinations, hereafter referred to as *restriction pairs*. The weight of each restriction pair is computed by building the product of the confidence weights of the respective entity-phrasal cluster assignments. Each restriction pair is encoded into its pattern by adding to the entity placeholders “[X]” and “[Y]” a qualifier indicating the phrasal cluster ID. For each observation and restriction pair, a distinct pattern is generated.

This option increases the overall number of distinct patterns by two orders of magnitude. Patterns are also less humanly readable than their counterparts that use coarse- or fine-grained Named Entity types. We use this feature space to evaluate the assumption that we can leverage distributional evidence over a large Web corpus to model selectional restrictions in URE without an existing type system.

## 4 Evaluation

In this section, we perform experiments to measure the impact of different options of modeling selectional restrictions in patterns for URE. We also qualitatively inspect clusters and patterns.

### 4.1 Experimental Setup

Our experiments are performed on a silver standard dataset of 200.000 sentences crawled from the Web and labeled using distant supervision (Mintz et al., 2009). The sentences contain 4500 distinct entity pairs that are part of the YAGO knowledge base<sup>4</sup>. This allows us to compare the results of URE against the YAGO knowledge base. We compute BCubed (Amigó et al., 2009) precision, recall and  $f$ -measure values, which are commonly used to extrinsically evaluate clustering results. We perform this evaluation on the following setups:

**BASELINE** In this setup, we establish the URE quality of the baseline system (see Section 3.1) without modeling selectional restrictions. The baseline is based on the system described in (Akbik et al., 2012).

<sup>4</sup>In (Akbik et al., 2012) we illustrate and evaluate the labeling procedure in detail.

**NER-7CLASS** This scenario simulates previous work by (Mesquita et al., 2010). We evaluate the impact of using a standard NER tagger to model selectional restrictions (see Section 3.2).

**NER-YAGO** In this setup, we evaluate the use of a high quality, fine-grained type system to model selectional restrictions. We retrieve fine-grained entity classes from Wikipedia categories as described in Section 3.3.

**PROPOSED-OPEN-1** This setup is a modification of the proposed method that makes use of phrasal clusters to model selectional restrictions in the open domain. Here, we only use the cluster with the top weight (instead of all 10) as restriction for an entity.

**PROPOSED-OPEN-5** Like PROPOSED-OPEN-1 this is a modification of the proposed method. Here, the top 5 clusters for each string are used as restrictions. We use this setup to assess the impact of using only the most likely portion of the full phrasal clusters data set.

**PROPOSED-OPEN-FULL** The proposed method making use of the full phrasal clusters data set.

In addition to varying the pattern generation method we also experiment with different cutting thresholds in the Hierarchical Agglomerative Clustering method. We use two cutting threshold parameters that were determined through experimentation (see Section 3.1), namely 0.9995 and 0.9999 (referred to as  $C_{0.9995}$  and  $C_{0.9999}$  respectively). We also perform a grid search over the parameter space to determine the best cutting threshold for each setup, which we refer to as  $C_{best}$ .

### 4.2 Quantitative Evaluation

Table 2 shows the results of the quantitative evaluation. At all cutting thresholds, we observe improvements in overall  $f$ -measure with all setups (except PROPOSED-OPEN-1) over the baseline. These results indicate the value of including selectional restrictions in the pattern generation step of a URE method. When comparing the different methods, we note that NER-YAGO and PROPOSED-OPEN-FULL perform best, outperforming the baseline at peak setting by 15% and 28% respectively. PROPOSED-OPEN-1 performs much worse than the baseline, especially

	$C_{0.9995}$			$C_{0.9999}$			$C_{best}$		
	P	R	F1	P	R	F1	P	R	F1
BASELINE	0.34	0.59	0.43	0.21	0.74	0.33	0.46	0.45	0.46
NER-7CLASS	0.39	0.55	0.46	0.52	0.45	0.48	0.51	0.47	0.49
NER-YAGO	0.74	0.39	<b>0.52</b>	0.65	0.50	<b>0.57</b>	0.65	0.53	<b>0.59</b>
PROPOSED-OPEN-1	0.95	0.02	0.04	0.95	0.02	0.04	0.95	0.02	0.04
PROPOSED-OPEN-5	0.70	0.31	0.43	0.59	0.45	<b>0.51</b>	0.57	0.49	0.53
PROPOSED-OPEN-FULL	0.58	0.45	<b>0.51</b>	0.49	0.54	<b>0.51</b>	0.57	0.49	<b>0.53</b>

Table 2: Overview of the results of the comparative evaluation. At all cutting threshold settings, setups NER-YAGO and PROPOSED-OPEN-FULL achieve significantly higher  $f$ -measure scores than the baseline. We find that at peak performance, the PROPOSED-OPEN-5 setup reaches a similar quality as PROPOSED-OPEN-FULL.

BASELINE		
ID	Example patterns	Example entity pairs
1	[Y] OWNED BY [X], [Y] PART OF [X],	[X] BUY [Y], [Y] ACQUIRED BY [X] <SNCF, Systra> <Eskom, Arnet Power Station>

10	[X:18] [Y:452] CANDIDATE, [X:793] [Y:284] CANDIDATE,	[X:233] [Y:441] POLITICIAN, [X:259] [Y:441] POLITICIAN <Bob Allen, Republican Party> <Fob James, Democratic Party>

Table 3: 10 sample clusters found with setups BASELINE, NER-YAGO and PROPOSED-OPEN. Each cluster is characterized by the top patterns in its centroid and represents one discovered relation. The entity pairs that make up the cluster are instances of discovered relations. Cluster 3, for example, represents the CHILDOF relation which holds between two persons.

with regards to recall. This is because this method produces highly overspecified patterns that do not allow for efficient grouping of entity pairs.

We also note that the cutting threshold setting has a significant impact on recall, precision and  $f$ -measure. At the PROPOSED-OPEN-5 setup, for example, minor variations in the parameter (from  $C_{0.9995}$  to  $C_{0.9999}$ ) cause an absolute  $f$ -measure difference of 0.8 points. This observation strongly indicates the importance of finding methods to ef-

fectively parameterize URE.

### 4.3 Qualitative Evaluation

We manually inspect a sample of the discovered relations and patterns to gain insight into how the different setups affect the relation discovery capabilities of our URE method. We illustrate our observations with a number of clusters shown in Table 3. We give examples of clusters for three setups: BASELINE, NER-YAGO and PROPOSED.

For each cluster, which represents one discovered relation, we list a small set of representative patterns and entity pairs.

Cluster 1, for example, is a cluster that represents company acquisitions, as is indicated by top patterns such as “[Y] ACQUIRED BY [X]” and “[Y] PART OF [X]”. Entity pairs in this cluster are relation instances. This means that <Eskom, Arnet Power Station> is an instance of the COMPANYACQUISITION relation. We find that this cluster corresponds most closely to the OWNS relation from the YAGO knowledge base.

**Readability.** Generally, we note that using named classes for selectional restrictions (NER-7CLASS and especially NER-YAGO) result in more human readable patterns than their counterparts in the baseline and proposed methods. Consider clusters 6 and 9. Cluster 6 is easy to evaluate, as the top patterns are human readable. It represents the INFLUENCEDBY relation that holds between a person and a philosopher. Cluster 9, on the other hand, is characterized by patterns that consist only of prepositions and phrasal cluster IDs. We must consult the entity pairs to determine that this cluster represents the ACTEDIN relation that holds between an actor and a film.

**Granularity.** In many cases, we find that selectional restrictions lead to the discovery of more fine-grained relations. An example of this is cluster 7, which denotes a relationship between a singer and the music album she created. All 46 instances in this cluster belong to the more general CREATED relation from YAGO that holds between a person and something she created (such as films, novels, albums etc.). This observation has implications for the use of selectional restrictions in URE, namely that the granularity of discovered relations can be influenced by the choice of type system. This also points to difficulties for the method of evaluating URE against an existing knowledge base as discovered relations might differ in granularity from the KB schema. Both these observations merit further investigation in future work.

**Ambiguities.** We look into errors made by the URE method and find that many errors are due to pattern ambiguities. Cluster 2, for example, mostly corresponds to the YAGO relation HASWONPRIZE. However, the patterns “[X] WIN [Y]” and “[Y] WINNING [X]” that hold between correct instances such as <Cher, Emmy Award>

also hold between false positives such as <Chile, Chilean War for Independence>. In more discriminative setups, this error is not made. For example, cluster 5 contains the more differentiated pattern “[X:ORGANIZATIONS] WIN [Y:WARS]”.

## 5 Conclusion and Outlook

In this paper, we addressed the problem of pattern ambiguities in URE by evaluating different methods of modeling selectional restrictions. We find that SR generally have a positive impact on relation discovery capabilities of our URE method. Significantly, we find a fine-grained type system to be the best setting, especially if URE is applied to a closed domain where most types of interest can be detected. For the open domain, we have presented a method that makes use of a Web-derived phrasal clustering of  $n$ -grams. We find our proposed method to be effective in reducing pattern ambiguities, with the advantage of being independent of a manually determined type system. Based on our results, we believe that correctly restricted deep syntactic patterns are the best features for URE.

In a qualitative evaluation of clustering results, we have determined two main issues that merit being addressed in future work in URE. First, automatic evaluation of URE remains problematic, as relations might be discovered that differ in granularity or semantics from the knowledge base that is evaluated against. Current evaluation methods penalize such divergence, even though discovered relations might still be correct. Second, we found that the parameterization of the clustering approach used in URE greatly influences the result quality and granularity. We find that even minor variations on the cutting threshold parameter for Hierarchical Agglomerative Clustering greatly impact overall  $f$ -measure.

Future work will focus on closely investigating clustering techniques and methods for effective parametrization. In addition, we intend to investigate Active Learning (Sun and Grishman, 2012) as a method to include minimal amounts of human feedback to guide the relation discovery process and improve overall URE results.

## Abstract

We address the task of bootstrapping a semantic lexicon from a list of seed terms and a large corpus. By restricting to a small subset of semantically strong patterns, i.e., coordinations, we improve results significantly. We show that the restriction to coordinations has several additional benefits, such as improved extraction of multiword expressions, and the possibility to scale up previous efforts.

## 1 Introduction

High-quality semantic lexicons are needed for many natural language processing (NLP) tasks like information extraction and discourse processing (Riloff and Shepherd, 1997). Building such lexicons manually is costly and time-consuming. Automatic lexicon construction is therefore an important task and much prior work has addressed it.

This paper adopts *Basilisk* (Thelen and Riloff, 2002) as its basic approach, a system that uses lexico-syntactic patterns for bootstrapping. We have adapted *Basilisk* to our setting in several ways. Whereas the original *Basilisk* covers a wide variety of lexico-syntactic patterns, we restrict ourselves to a specific type of patterns, i.e., coordinations. Coordinations have been exploited in lexical acquisition before (e.g., Roark and Charniak (1998); Caraballo (1999); Goyal et al. (2010)). Most of this previous work uses a pairwise perspective (i.e., a focus on whether two words co-occur in a coordination). However, we use coordinations in a *Basilisk* approach, for which patterns contain several terms in general. We therefore do not split up coordinations in pairs but keep the complete coordination intact. Coordinations in technical domains frequently contain more than 2 elements.

We argue that bootstrapping methods, known to be particularly sensitive to the ambiguity of terms

and contexts and prone to semantic drift, benefit from the strong semantic coherence found in coordinations. The elements of a coordination often have a common hypernym; i.e., they are co-hyponyms or members of a common semantic class.

Furthermore, the high arity of coordinations, the fact that coordinations have two or more arguments (e.g., “platinum, nickel, palladium, copper, silver, or gold”) further constrains the semantics. For example, if two out of three elements in a coordination have already been identified as substances, this makes it likely that the third is also a substance. General or lexico-syntactic patterns in lexical bootstrapping have arity 1, i.e., they have a single argument. These patterns are too often not restrictive enough to prevent false terms infecting the semantic lexicon, which can lead to semantic drift. For example, given a corpus in which the semantic class DISEASE is not predominant, after some iterations the weak pattern “treatment of <X>” is selected, which also provides many off-class candidates (e.g., treatment of *prisoners*). In coordinations, the semantic coherence among terms leads to more selective patterns. For example, the coordination “congenital heart defect, atherosclerosis, <X>, scleroderma or tuberos sclerososis” can only hold a slot for diseases.

We will show that the restriction to coordination patterns has several additional benefits. The focus on simple coordination patterns circumvents the need for identifying various syntactic relations (e.g., subject), that are part of the extraction patterns of the original *Basilisk*. Therefore, it circumvents the need for parsing. Syntax in the patent domain, we address in this paper, is complex and characterized by long clauses (cf. average number of tokens per sentence: BNC: 19.7; Brown: 21.3; WSJ: 22.4; Wikipedia: 24.3; EPO: 32.4). The shallow parser used by Thelen and Riloff (2002) would need several months to parse our corpus.

Furthermore, the restriction to a subset of very strong bootstrapping patterns limits the overproduction of patterns radically. We can therefore apply our method to the largest domain-specific corpus that has been used for semantic bootstrapping so far.

Lastly, we benefit from the increased precision in extracting multiword expressions (MWEs) when using coordination patterns. In contrast to original Basilisk and most prior work, we learn terms of any length, because, as we will see later, in the technical domain under consideration MWEs are predominant (e.g., “alkyl trimethyl ammonium methosulfate”).

The paper is structured as follows. In Section 2, we describe our data set, the task we address and our evaluation methodology. Section 3 describes Basilisk and our adaptations, in particular, the context patterns we use. Experimental setup and results are presented in Section 4. In Section 5, we discuss and analyze these results. The last two sections describe related work and conclusions, respectively.

## 2 Data, task description and evaluation methodology

**Data.** We use the patent data distributed by the European Patent Office<sup>1</sup> (EPO) as our corpus. We extract the description (the main part of a patent) from 561,676 English patents filed between 1998 and 2008 and perform sentence splitting and tokenization using Treetagger (Schmid, 1994) and lemmatization and part-of-speech (POS) tagging using MATE (Bohnet, 2010). Sentences up to a size of 100 tokens extracted from a sample of 25,000 patents are parsed by MATE. The resulting EPO corpus consists of roughly 4.6 billion tokens.

**Task description.** The task we address is semantic tagging of patents. The research reported here was conducted as part of a project on computational linguistics analysis of patent text. We want to be able to support functionalities like color-coding entities of a particular semantic class for quick perusal; or searching for entities in a particular semantic class. Our longterm goal is to support semantic tagging for a large variety of semantic classes. In this paper, we focus on the semantic classes SUBSTANCE and DISEASE. A substance is a particular kind of physical matter with uniform properties. Substances are of obvious relevance

for the patent domain and a large proportion of patents contain substances. A disease is an abnormal condition that affects the body of an organism. We selected disease as a clearly nontechnical category to be able to investigate potential differences of lexical bootstrapping algorithms for categories with very different properties.

Gazetteers are crucial for good performance in machine-learning-based semantic tagging (Ratinov and Roth, 2009), e.g., the best performing systems for recognition of person, location and organization named entities all use gazetteer features (e.g., Florian et al. (2003)). It is in this context that we address the task of bootstrapping lexicons from corpora: for most semantic classes of interest in the patent domain high-coverage lexicons are not available.

**Evaluation methodology.** Since our primary task is semantic tagging, we evaluate the quality of the bootstrapped lexicon directly on this task, i.e., on the task of tagging members of the semantic class in text – rather than evaluating the lexicon in a type-based evaluation as a set of terms without context as most previous work has done. A tagging-based evaluation directly measures what we need for our application, e.g., frequent terms have a higher impact on tagging accuracy than rare terms, and ambiguous terms with a rare class sense depress tagging accuracy.

**Terminology.** From now on, we use the term *MWE* for a noun phrase that we identify as a candidate class instance; we include one-word noun phrases in the definition of MWE in this paper. We call an MWE in a particular context in our gold standard a *gold-standard MWE* if it was annotated as a member of the semantic class in question. We call an MWE a *lexicon MWE* if our bootstrapping algorithm has added it to the induced lexicon as a class instance.

**Gold standard creation.** Asking human annotators to mark all instances of SUBSTANCE/DISEASE in a randomly selected set of patents is very inefficient because this would result in annotators spending a lot of time reading patent text that contains (almost) no class instance. Moreover, annotation quality is higher in patents that contain at least a moderate number of class instances since annotators will remain alert as they go through the document.

To address this problem, for the two classes we stratify the EPO corpus into three strata according

<sup>1</sup>www.epo.org

to density  $\rho$ : high, medium and low.  $\rho$  is computed as the proportion of class instances per token. Since the low-density stratum contains virtually no class instances, we exclude it from our experiments.

We randomly select 1000 patents from each of the medium-density and high-density strata and then one sentence from each patent. One annotator labeled 200 sentences using the GATE<sup>2</sup> annotation tool. Then problematic annotation examples were discussed. Afterwards, the annotator labeled the remaining 1800 sentences. For assessing the quality of the gold standard, a second trained annotator labeled 200 sentences of our evaluation set. Inter-annotator agreement for both classes was  $\kappa = .712$  (macro kappa) and  $\kappa = .818$  (micro kappa) (Cohen, 1960), which indicates substantial to excellent agreement (Landis and Koch, 1977).

### 3 Bootstrapping algorithms

```

1: lexicon ← seed
2: for int  $i = 0; i < m; i++$  do
3:   patterns ← patternsOf(lexicon)
4:   score(patterns)
5:   patterns ← return-top-k(patterns, 20 +  $i$ )
6:   terms ← termsOf(patterns) – lexicon
7:   score(terms)
8:   lexicon ← lexicon  $\cup$  return-top-k(terms, 5)
9: end for
10: return lexicon

```

Figure 1: Basilisk algorithm. The original version of Basilisk defines terms as head nouns.

The basic bootstrapping algorithm we use is Basilisk as shown in Figure 1 (Thelen and Riloff, 2002). Basilisk first initializes the lexicon as the seed set (line 1). The basic idea of the algorithm is to identify context patterns that reliably identify lexicon terms (lines 3–4), e.g., *made of*  $\langle X \rangle$ . Line 5 selects a subset of patterns<sup>3</sup> based on the scoring function  $R\log F$ :

$$R\log F(\text{pattern}_i) = F_i/N_i \log_2(F_i)$$

where  $F_i$  is the number of learned lexicon terms that occur in  $\text{pattern}_i$  and  $N_i$  is the total number of terms occurring in  $\text{pattern}_i$ . Lines 6–7 select the terms associated with the patterns selected on line 5 and score them. Terms are scored using  $\text{AvgLog}$ , the average log frequency, (line 7):

<sup>2</sup>gate.ac.uk

<sup>3</sup>We discard patterns that only occur with already learned terms, guaranteeing that each of the selected  $20 + i$  patterns on line 5 can potentially contribute new terms

$\text{AvgLog}(\text{term}_i) = 1/P_i \sum_{j=1}^{F_i} \log_2(F_j + 1)$  where  $P_i$  is the number of patterns in which  $\text{term}_i$  occurs and  $F_j$  is the number of learned lexicon terms that occur in  $\text{pattern}_j$ . The 5 highest scoring terms are then added to the lexicon (line 8).

#### 3.1 Basilisk-G

To process the large-scale patent corpus efficiently, we implemented a simple chunker that identifies noun phrases (NPs) using regular expressions (REs) on POS tags. We refer to this RE/POS-based algorithm as *Basilisk-G* – for “Basilisk General Patterns”. Basilisk-G is an instantiation of the basic Basilisk algorithm in Figure 1 that uses a more general definition of patterns that only requires POS tagging and no parsing. We use all patterns of the form  $w_{-i} \dots w_{-1} \langle \text{np} \rangle w_1 \dots w_j$  where  $0 \leq i, j \leq 3$  and  $i + j \geq 2$ ; i.e., context extends up to three tokens out to the left and right from  $\langle \text{np} \rangle$  and must consist of at least two tokens. We discard patterns whose context does not contain a verb or a noun. The standard version of Basilisk uses pattern templates like  $\langle \text{subj} \rangle$  *verb* and *noun prep*  $\langle \text{np} \rangle$ . Our more general definition covers most instantiations of these templates, but it extends the patterns considered to a much larger variety of lexical contexts. For example, fragments of a coordination like *, silver, <np>* or *platinum* are also instantiations of the general Basilisk-G pattern template. As we will see later, these types of patterns (which original Basilisk does not use) turn out to be very effective.

Similar to patterns, we define MWEs in Basilisk-G (Figure 1, line 6) as part of an NP extracted using REs: an MWE is a (possibly zero-length) sequence of prehead modifiers (adjectives and nouns) terminated by the head.

#### 3.2 Basilisk-C

In this section we introduce *Basilisk-C* – for “Basilisk Coordination Patterns”, a Basilisk instantiation that uses only coordinations.

We allow two different types of coordinations: *and/or* coordinations and punctuation coordinations.

An *and/or* coordination is a list of NPs consisting of two parts. In the first part of the list, NPs are separated by commas or semicolons. In the second part, NPs are separated by “and”, “or” or “and/or”. The second part has minimum length 2:

$$((\text{NP}, )*(\text{NP}; )*) \text{NP} ((\text{and}/\text{or})?|\text{or}) \text{NP} +$$

A punctuation coordination is defined as a list of at least three NPs separated by commas or semicolons:  $((NP, )+ NP, NP) \mid ((NP; )+ NP; NP)$ <sup>4</sup>

Because we detect the coordinations and the NPs based on POS REs without performing a full syntactic analysis and because the assumption of co-hyponymy is incorrect in certain cases, there are several incorrect matches. We automatically removed border elements of a coordination if they indicate an extraneousness to the coordination. One indicator of extraneousness was the unique presence of a determiner for example “this description” in “as concrete examples of [this description, methyl alcohol and benzyl alcohol] may be cited”, where [...] matches the coordination pattern. Moreover, we removed conjuncts that indicate a hypernym relation such as “other products” in “copolymers, polyisobutene and other products”.

We treat the conjuncts that survive filtering as an unordered set, i.e., we ignore their order in the text. The set is discarded and not used by Basilisk-C if it only contains one element.

## 4 Experimental setup and results

**Experimental setup.** We evaluate performance of the two algorithms Basilisk-G and Basilisk-C introduced above. We run experiments on EPO (Section 2) with the goal of learning the classes SUBSTANCE and DISEASE. Our seed set (Figure 1, line 1) consists of the 4223 substances distributed by Ciaramita and Johnson (2003) as part of SuperSenseTagger and 239 diseases extracted from Simple English Wikipedia<sup>5</sup>.

For Basilisk-C, we extracted 9.7 million unique coordinations, out of a total of 25 million.

For Basilisk-G, we found 1.6 billion unique context patterns. In order to be able to run experiments quickly, we introduce frequency thresholds for MWEs, patterns and MWE-pattern combinations. We only consider MWEs and patterns that occur at least  $\theta_1 = 10$  times and MWE-pattern combinations that occur at least  $\theta_2 = 3$  times in EPO. These thresholds are unlikely to diminish lexicon quality since many rare instances of MWEs are due to OCR errors or failures of our RE-based recognition of NPs (see also (Qadir and Riloff, 2012)). Using the thresholds  $\theta_1$  and  $\theta_2$ ,

<sup>4</sup>This version of Basilisk uses the same RE to detect NPs as Basilisk-G.

<sup>5</sup>[simple.wikipedia.org/wiki/List\\_of\\_diseases](http://simple.wikipedia.org/wiki/List_of_diseases)

there were 3.2 million unique MWEs, 56 million unique patterns and 121 million unique MWE-pattern combinations. This is the raw data we run Basilisk-G on.

As discussed in Section 2, our evaluation methodology directly evaluates the semantic lexicon on the task of interest: semantic tagging of patents. The tagging method we use is simple lexicon lookup. While tagging MWEs we exploit the compositional structure of entities by merging adjacent or overlapping token-based labels (e.g., *fatty acid* and *acid amide* are merged to *fatty acid amide*). In our decision to use lexicon lookup for tagging, we follow Qadir and Riloff (2012), who argue convincingly that for a specialized class and domain, ambiguity of terms (which would be the main reason for using a context-dependent method like a CRF) is a limited phenomenon and ignoring it does not greatly affect performance. Even so, it is important to keep in mind that tagging precision does not directly reflect lexicon accuracy.

We use the measures precision, recall and  $F_1$ . Tagging results are evaluated using the evaluation module of GATE. The scores give half credits for partial matches and full credits for exact matches.

### Performance of Basilisk-G and Basilisk-C.

Table 1 shows the performance of the baseline and of Basilisk-G and Basilisk-C for different lexicon sizes. The baseline uses the seed set (SUBSTANCE: 4223; DISEASE: 239) for tagging. We first run iterations until the size of the induced lexicon is 5000 and then double the lexicon three times – to 10,000, 20,000 and 40,000 – to investigate the relationship between lexicon size and tagging performance.

Both Basilisk-G and Basilisk-C consistently beat the baseline in recall and  $F_1$  for DISEASE and in all three measures for SUBSTANCE. We mark each performance number with a star if it is significantly higher than the number above it.<sup>6</sup> For example, Basilisk-G’s and Basilisk-C’s  $F_1$  of .549 for 10,000 substances is significantly better than the baseline (.539).

Basilisk-C outperforms Basilisk-G in most cases. We mark each Basilisk-C performance number with † if it is significantly higher than the Basilisk-G number to the left of it. The largest differences between Basilisk-C and Basilisk-G can be found for the smaller semantic class of diseases and at larger lexicon sizes. This is to be expected

<sup>6</sup>Approximate randomization test (Yeh, 2000),  $p < .05$

size	SUBSTANCE						DISEASE					
	P		R		$F_1$		P		R		$F_1$	
	B-G	B-C	B-G	B-C	B-G	B-C	B-G	B-C	B-G	B-C	B-G	B-C
seed	.597		.491		.539		.793		.233		.360	
5000	.599*	.598	.494*	.492*	.542*	.540*	.790	.724	.455*	.556*†	.578*	.629*†
10,000	.605*	.604*	.502*	.504*	.549*	.549*	.476	.643†	.645*	.602*	.548	.622†
20,000	.610*	.614*	.509*	.529*†	.555*	.568*†	.392	.530†	.642	.701*†	.487	.604†
40,000	.612*	.619*	.515*	.549*†	.559*	.582*†	.300	.473†	.642	.720†	.409	.571†

Table 1: Tagging performance measured by precision (P), recall (R) and  $F_1$  of seed baseline and for different lexicon sizes of Basilisk-G (B-G) and Basilisk-C (B-C); \* indicates significantly higher than the number above it; † indicates significantly higher than the number to the left of it.

because we would expect semantic drift to be more prominent for smaller classes and to grow with the size of the induced lexicon. Closer inspection reveals that Basilisk-G indeed drifts to any kind of technical properties. For substances, Basilisk-C outperforms Basilisk-G mainly in recall. This large class is less sensitive to semantic drift but, as we will discuss in detail in the error analysis, still benefits from the MWE extraction of Basilisk-C. These results support the argument we have made for restricting to coordinations in Basilisk for both predominant classes such as SUBSTANCE and minor semantic classes such as DISEASE.

Note that the best performance for the small class of diseases is found at a lexicon size of 5000:  $F_1 = .629$ . It outperforms the seed baseline (+.269) and Basilisk-G (+.051). Precision drops rapidly when doubling the lexicon size and introducing more and more semantic drift. For the large semantic class of substances we find that increasing the lexicon size generally improves performance. The overall best result achieved,  $F_1 = .582$ , is achieved by Basilisk-C and the largest lexicon size (40,000).

Figure 2: Performance of Basilisk-C as a function of lexicon size for substances

Our comparisons between Basilisk-G and Basilisk-C are limited to a lexicon size of 40,000 because running Basilisk-G for larger lexicons be-

comes infeasible in our current setup. However, one of the additional advantages of restricting to coordinations is scalability. Figure 2 shows the performance of Basilisk-C as a function of lexicon size for very large substance lexicons. The figure suggests that there is an upward trend for  $F_1$  and recall up to very large lexicon sizes. The curves do not increase monotonically, partly due to the fact that once the lexicon has reached a size of more than 100,000, only a few additional MWEs found in the evaluation corpus are responsible for the changes. Thus, the curves do not directly reflect actual expected performance. Basilisk-C achieves the highest performance at the right edge of the graph at lexicon size 400,000:  $F_1 = .611$ ,  $P = .608$ ,  $R = .615$ . To our knowledge, Basilisk-type algorithms have not been run for lexicons of this size before.

The tagging performance seems low for practical purposes. However, this reflects the lexicon quality (i.e., the bootstrapping performance) only partially. Since we are using a large domain-specific patent corpus, we are faced with many high-specific and infrequent terms. Many false positives arise because of class instances missed by the annotators. An optimal gold standard for this domain would require domain specialists.

**Comparison with original Basilisk.** We already explained that running original Basilisk on the whole EPO corpus is not feasible due to its size and the length of the sentences. However, for a comparison of Basilisk-G and Basilisk-C with the original Basilisk, we parsed sentences up to a size of 100 tokens from 25,000 sample patents. We define *Basilisk-LS* – for “Basilisk Lexico-Syntactic patterns” and extract all lexico-syntactic patterns described in (Riloff and Phillips, 2004). We introduce two versions of Basilisk-LS: the originally head-based *Basilisk-LS<sub>head</sub>* and a variant, *Basilisk-LS<sub>MWE</sub>*, that extracts MWEs defined as basic noun phrases without determiner or post-

nominal phrases such as PPs or relative clauses. From all parsed sentences, we extract POS-based coordinations and all general patterns for our systems. The tagging results for a substance lexicon of size 20K is shown in Table 2.

System	P	R	$F_1$
Basilisk-LS <sub>head</sub>	.437	.502	.467
Basilisk-LS <sub>MWE</sub>	.582	.506	.541
Basilisk-G	.560	.524	.542
Basilisk-C	.620	.567	.592

Table 2: Comparison of B-LS, B-G and B-C

The results for Basilisk-LS<sub>head</sub> show that precision is a severe problem in tagging substance head nouns on patents. When inducing and tagging MWEs as it has been done by the other systems, precision is much higher. Both Basilisk-LS<sub>MWE</sub> and Basilisk-G only slightly outperform the seed baseline in  $F_1$  (Table 1). Once more Basilisk-C outperforms all other systems by far.<sup>7</sup>

**Extension on other classes and domains.** To show that Basilisk-C can be applied to other classes and domains, we ran an additional experiment. We applied Basilisk-C to the class FIXED-LOCATION as defined by Qadir and Riloff (2012) and used Wikipedia coordinations. As there was no annotated data available for this class, we ran a type-based evaluation. A human judge rates accuracy of 100 samples of the lexicon. As seed set, we selected five US states, five European countries and ten national capitals. We induced 5000 fixed locations with an accuracy of 80%. We conclude that depending on corpus size lexical bootstrapping based on coordinations is applicable to any domain for several classes.

## 5 Analysis and discussion

**High arity.** In previous sections we explained that the high arity of the coordination relation constrains the semantics of its arguments and remedies problems related to ambiguity that can give rise to semantic drift. We have seen this in the results. The relatively small class (for our domain) of diseases is prone to semantic drift especially

<sup>7</sup>Recall of Basilisk-C for the subcorpus is even better than on the full EPO corpus shown in Table 1. The reason for this is that sentences up to 100 tokens contain shorter coordinations. MWEs in short coordinations tend to be less specific and thus more frequent in a test set. This explains why recall of semantic tagging is better when using shorter coordinations.

when larger lexicon sizes are induced. Basilisk-C is able to remedy this problem and leads to higher performances than Basilisk-G and the differences are largest for larger lexicon sizes.

On the other hand, we discussed the phenomenon that MWEs in short coordinations tend to be less specific. Despite the fact that shorter coordinations provide a smaller pool of term candidates, we expect recall in the semantic tagging task to be higher when using shorter coordinations because the available term candidates are less specific and thus have a higher frequency, i.e., a higher chance to occur in the test set. Table 3 shows the tagging performance of a lexicon with 20,000 substances and one with 10,000 diseases induced by Basilisk-C applied to different ranges of coordination lengths. It shows that Basilisk-C using only coordinations up to a size of 5 terms (“2 to 5”) outperforms Basilisk-C using all coordinations (“2 to  $\infty$ ”) in recall. In predominant classes such as SUBSTANCE, shorter coordinations do not harm precision. However, for classes like DISEASE, precision decreases when shorter coordinations are used, as illustrated in Table 3.

Coordination length	P	R	$F_1$
20,000 substances			
2 to $\infty$	.614	.529	.568
2 to 5	.615	.568	.591
10,000 diseases			
2 to $\infty$	.643	.602	.622
2 to 5	.470	.645	.544

Table 3: Comparison of coordination lengths

**High-confidence pattern.** We argued in subsection 3.2 that coordinations impose a stronger semantic coherence on MWEs than general context patterns or lexico-syntactic patterns do. Table 4 shows that coordinations are indeed high-confidence patterns for learning substances. High-confidence Basilisk-G patterns after 1000 and 6000 iterations are listed. Each of the top 20 patterns after 1000 iterations is a coordination. Apparently, the patterns that are selected in the beginning of learning as the ones best suited for identifying substances are all fragments of coordinations. Thus, performance of Basilisk-G and Basilisk-C for a lexicon of 10,000 MWEs (cf. Table 1) is fairly equal.

In contrast, after 6000 iterations only three of the highest-confidence patterns still are coordinations (not shown) – the other 17 are other types of

	type of pattern	example
$i = 1000$	NN , <np> ,	nitrate , <np> ,
	, <np> , NN	, <np> , magnesium
$i = 6000$	NN , <np> CC	oxide , <np> , and
	, <np> , NN	, <np> , sodium
	NN of <np> (	weight of <np> (
	of <np> verb	of <np> was added

Table 4: Highest-confidence Basilisk-G patterns after  $i$  iterations (examples from top 20)

patterns (Table 4,  $i = 6000$ ). As Basilisk-G’s performance improves more slowly than performance of Basilisk-C after the initial iterations (cf. Table 1, 20,000 to 40,000), we conclude that coordinations are the most effective patterns and the addition of other pattern types contribute little to learning new substances.

**Scalability.** Besides the scalability upgrade in preprocessing by avoiding parsing, Basilisk-C, in particular ranking of coordinations and MWEs, runs quicker as the input of term-pattern combinations is about 80% smaller than for original Basilisk. This means a crucial scalability benefit for corpora even larger than EPO.

**MWE extraction.** The results in Table 2 show that inducing and tagging only head nouns rather than MWEs leads to poor precision. This result is to be expected as our set of gold-standard MWEs comprises 45.4% true MWEs and tagging only the head nouns thereof leads to partial credits.

By restricting patterns to coordinations, Basilisk-C avoids MWE recognition problems. Coordinated noun phrases tend to be less modified, less complex and the context of an NP within the coordination makes it easier to determine its boundaries; the internal boundaries are always connectors. Table 5 shows some MWEs induced by Basilisk-G and the subparts thereof induced by Basilisk-C.

<p>high-molecular weight <u>vinylidene fluoride resin</u>  above <u>metal chelate compound</u>  unsaturated <u>fatty acid ester</u>  heat-fusible <u>polymer fine particle</u></p>
--

Table 5: Examples of MWEs in B-G; underlined tokens match MWEs induced by B-C

**Coordination abundance.** Basilisk-C works best for a text type in which large coordinations are abundant since this is the only context pattern it considers. In an analysis of the prevalence

of coordinations in different corpora, we observed that long coordinations (those with at least three conjuncts) are more prevalent in patents than in other genres (average length of 4.6 in EPO vs 3.6 in other corpora). Thus, coordinations seem to be a particularly promising resource for lexical bootstrapping in technical domains like patents. However, as exemplified by our experiments with Wikipedia, Basilisk-C shows similar performance on other domains, given that the members of the semantic class appear often in coordinations.

## 6 Related work

We have chosen a semisupervised approach to lexical bootstrapping here since it is reasonable to expect that in the type of application scenario we have in mind resources are available to create a seed set. There are also completely unsupervised approaches to lexical bootstrapping (e.g., Lin and Pantel (2002); Davidov et al. (2007); Van Durme and Paşca (2008); Dalvi et al. (2012)), but they usually cannot match the quality of approaches like ours that use human input such as a seed set.

The bootstrapping approach we have adopted here starts with a seed set and then iteratively extends the lexicon by adding the highest-confidence MWEs in each iteration. Basilisk (Thelen and Riloff, 2002) is perhaps the best known bootstrapping method of this type, but there exists a large literature on similar methods, some of which exploit lexical co-occurrence statistics (e.g., Riloff and Shepherd (1997)) and some of which use syntactic analysis (e.g., Roark and Charniak (1998); Riloff and Jones (1999); Phillips and Riloff (2002)). Our approach does not make use of syntactic analysis but relies on POS patterns.

Some recent work attempts to improve Basilisk’s accuracy. Igo and Riloff (2009) enhance precision by checking candidate terms using web queries. Qadir and Riloff (2012) combine Basilisk in an ensemble with an SVM tagger and a coreference resolution system. Our focus is learning technical terminology from very large corpora using coordinations, but any work that improves the accuracy of basic Basilisk could also be beneficial in our setting.

Gazetteers are crucial for good performance in named entity recognition (NER). Work on automatic extraction of gazetteers for NER includes (Toral and Muñoz, 2006; Kazama and Torisawa, 2007). Most of this work is complementary to

our approach because it uses knowledge bases like Wikipedia or is only applicable to traditional named entities (NEs). Traditional NEs like person are capitalized. Substances are not. Our work also differs in its focus on coordinations and technical text.

Coordinations have been frequently used in work on lexical acquisition. Caraballo (1999) builds a hierarchy of coordinated nouns and their hypernyms. Cederberg and Widdows (2003) use coordinations to estimate the semantic relatedness of nouns. Widdows and Dorow (2002) and Qiu et al. (2011) cluster nouns and evaluate the semantic homogeneity of the clusters. Etzioni et al. (2005) use Hearst patterns to bootstrap lexicons. They also consider coordinations when selecting candidates. This previous work on coordinations is unsupervised and not focused on learning a particular semantic class that is defined by a seed set.

Roark and Charniak (1998) use a variety of syntactic constructions, including coordinations, for bootstrapping. Our approach is different in that we do not require parsing and that we cover MWEs in general, not just heads or compounds with a common head. However, some of the other syntactic constructions presented by Roark and Charniak (1998) could also be amenable to reliable detection by REs. We plan to investigate this in future work. Goyal et al. (2010) create a plot unit representation creator. Therefore, they induce a lexicon of *patient polarity verbs* (i.e., verbs that impart positive or negative states on their patients) based on Basilisk, that learns from coordinated verbs. This work is focused on verbs with the same patient polarity in binary coordinations extracted from a web corpus. Our approach is based on coordinations of any size from a large patent corpus and focuses on semantic lexicon induction.

One distinguishing characteristic of our work is the patent domain. Other work on technical or scientific domains includes press releases of pharmaceutical companies (Phillips and Riloff, 2002), medline abstracts (McIntosh and Curran, 2009), message board posts from the Veterinary Information Network (Huang and Riloff, 2010) and texts from ProMed and PubMed (Igo and Riloff, 2009; Qadir and Riloff, 2012).

Patents can be argued to be particularly difficult technical text due to long sentences, legalese and complex NP syntax. To the best of our knowledge, our experiments are also the largest seman-

tic bootstrapping experiments on technical text to date. While there has been much work on experiments on large web corpora and other general text (e.g., Kozareva et al. (2008); Carlson et al. (2009); Bakalov et al. (2011)), the corpora in other lexical bootstrapping work on technical domains have been an order of magnitude smaller than ours.

We showed that using only coordinations remedies the problem of semantic drift. Other work on semantic drift includes Yangarber et al. (2002); Curran et al. (2007); McIntosh and Curran (2008); McIntosh and Curran (2009).

## 7 Conclusion

In this paper, we presented Basilisk-C. The method is inspired by original Basilisk but adapts it to large corpora of technical text by restricting it to one type of patterns: coordinations.

This restriction to coordinations, a relation that is known to impose strong semantic coherence upon its members and as such a possible remedy for semantic drift, leads to significant improvements for the task of semantic tagging, compared to an unrestricted version of Basilisk.

We further extended original Basilisk to include MWEs, as these are predominant in technical text and showed that coordination patterns yield higher precision in MWE extraction.

The proposed method avoids the need for parsing, which is cumbersome for large corpora with long sentences, typical for the technical domain. In general, we upgrade scalability because the coordination patterns represent a fraction of the patterns original Basilisk utilized.

Apart from using linguistics patterns such as coordinations, we plan to use structured data, such as table columns and rows to extract co-hyponyms in future work.

We will make our gold-standard and the induced lexicons publicly available<sup>8</sup>.

## Abstract

This paper proposes state-of-the-art models for time-event relation extraction (TERE). The models are specifically designed to work effectively with relations that span multiple sentences and paragraphs, i.e., inter-sentence TERE. Our main idea is: (i) to build a computational representation of the context of the two target relation arguments, and (ii) to encode it as structural features in Support Vector Machines using tree kernels. Results on two data sets – Machine Reading and TimeBank – with 3-fold cross-validation show that the combination of traditional feature vectors and the new structural features improves on the state of the art for inter-sentence TERE by about 20%, achieving a 30.2 F1 score on inter-sentence TERE alone, and 47.2 F1 for all TERE (inter and intra sentence combined).

## 1 Introduction

Time-Event Relation Extraction (TERE) is the task of linking event mentions and relation mentions to occurrences of “time stamps” in text. We define it as follows: given a set of textual expressions denoting events and relations, and a set of time expressions in the same text document, find all instances of temporal relations between elements of the two input sets. A relation between an event and a time expression indicates that the event occurs within the temporal context specified by the time expression, for example, the following sentence:

*He succeeded James A. Taylor, who stepped down as chairman, president and chief executive in March for health reasons; the appointment took effect Nov. 13.*

conveys two different events, *succession* and *stepping down*, linked to the time stamps, *Nov. 13* and *March*, respectively.

In this paper, we focus on the task of linking time expressions to events, i.e., we carry out a classification task, where, for each possible pair of (event/relation, time) in a document, the classifier decides whether there exists a link between the two. In particular, we assume that the event mentions, relation mentions and time expressions are given to us by an external process. There is a large body of work on the above topics and they remain difficult problems, but we use human annotated mentions and expressions as input to our models since TERE itself is a relatively new problem in this context. Previous work in TempEval-2 (Verhagen et al., 2010) and our work (Hovy et al., 2012) have shown that accurate relation classifiers can be modeled with supervised approaches, provided that the expressions are limited to be in the same sentence. In contrast, there is almost no previous work on inter-sentence TERE (ISTERE), for three main reasons:

- Across a document, the number of time-event pairs to consider is large, as they are quadratic in the number of time and event expressions.
- There are almost no practically useful linguistic models that can be applied for capturing inter-sentence relations.
- Defining inter-sentence features is complex: their non-optimal definition in a task such as TERE – where there is a rather high imbalance between positive and negative examples – results in underperforming machine learning models.

In this paper, we design novel supervised models for ISTERE based on a structural representation of the pairs of sentences that contain the target rela-

tion arguments. We define methods to deal with time-event relations, where the text fragment indicating the time expression, e.g., *the appointment took effect Nov. 13* of the example above, is separated from the main event, e.g., *succession and stepping down*. In particular, our representation is constituted by a pair of shallow syntactic trees (one for each sentence containing the relation arguments), where their nodes are enriched with semantic labels, i.e., EVENT and TIME. We rely on automatic feature engineering with structural kernels (see e.g., (Moschitti, 2008; Moschitti, 2009)) to feed the learning algorithm with meaningful patterns implicitly described by such a representation. Kernels are applied to our shallow syntactic representations of text resulting in a model robust to noise and easily adaptable to new domains and tasks, such as ISTERE.

We tested our models on Machine Reading and TimeBank datasets over three different configurations: (i) relation arguments both within the same sentence, (ii) relation arguments in different sentences and (iii) relation arguments both, within and across, sentences. Our experiments demonstrate that such approach is very promising, as it improves over the state of the art for ISTERE by up to 20% in F1.

In the remainder of the paper, Sec. 2 surveys the related work, Sec. 3 presents the previous state-of-the-art models for intra-sentence TERE also using structural kernels, Sec. 4 describes our new models for intra/inter TERE, Sec. 5 lays out the experiments and, finally, Sec. 6 discusses the results deriving our conclusions.

## 2 Related Work

The extraction of relations between entities has been a long-standing topic of research, with work spanning more than a couple of decades, e.g., ACE (Doddington et al., 2004) and MUC (Grishman and Sundheim, 1996).

In particular, sentence-level Relation Extraction (RE) has been typically modeled with supervised approaches, using manually annotated data, such as ACE (Kambhatla, 2004). Most work has focused on kernel methods, i.e., string and tree kernels (Bunescu and Mooney, 2005; Culotta and Sorensen, 2004; Zhang et al., 2005; Zhang et al., 2006) or their combinations (Nguyen et al., 2009). From the kernel perspective, our approach to TERE is another variant of the general RE work using kernel: we use PTK applied to two-level

shallow syntactic trees, which extracts a sort of hierarchical subsequences. This follows up our rather long research, e.g., tree kernels for modeling the relations between syntactic constituents embedded in pairs of text (i.e., question and answer passage) for answer re-ranking (Moschitti et al., 2007; Moschitti, 2008; Moschitti, 2009; Moschitti and Quarteroni, 2008; Moschitti and Quarteroni, 2010). A more computationally expensive solution based on enumerating relational links between constituents was given in (Zanzotto and Moschitti, 2006; Zanzotto et al., 2009) for the textual entailment task. Some faster versions were provided in (Moschitti and Zanzotto, 2007; Zanzotto et al., 2010). More efficient solutions based on a shallow tree and relational tags were recently proposed in (Severyn and Moschitti, 2012; Severyn et al., 2013).

Regarding the more specific task of extraction of temporal relations, the typical approaches follow similar principles of the above RE methods. Early work was devoted to ordering events with respect to one another, e.g., (Chambers and Jurafsky, 2008), and detecting their typical durations, e.g., (Pan et al., 2006). The TempEval workshops (Verhagen et al., 2007) defined the task of (i) extracting temporal relations between events and time expressions and (ii) naming relations like BEFORE, AFTER or OVERLAP. We focus on the first part of the TempEval task, following (Filatova and Hovy, 2001; Boguraev and Ando, 2005; Hovy et al., 2012), where we used the the system and results associated with the latter paper as a baseline of this paper. (Mirroshandel et al., 2011) used syntactic tree kernels for event-time links in the same sentence. As we aim at exploring long-distance RE, we consider more robust representations than syntactic trees, i.e., shallow syntactic trees, which we have successfully used in other research, e.g., (Severyn and Moschitti, 2012).

A recent challenge, i2b2<sup>1</sup> 2012, also dealing with ISTERE was carried out in the biomedical domain. We could not directly compare with the challenge's systems as their results were not available to us during the writing of this paper. Thus, we can only report on work targeting similar tasks, e.g., (Mani et al., 2006) used time relations between events to build a classifier that marks each pair of events with a temporal relation, exploiting temporal closure properties; and (ii) (Kolomiyets

<sup>1</sup><https://www.i2b2.org/pubs/index.html>

Figure 1: A kernel representations of the baseline model constituted by a bag-of-words (BOW) tree

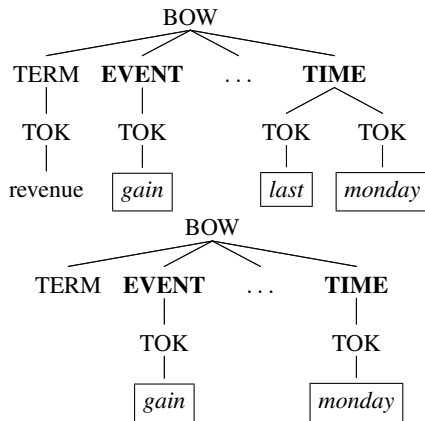

Figure 2: E.g. features from STK with BOW tree

et al., 2012) proposed to link events via partial ordering relations like BEFORE, AFTER, OVERLAP and IDENTITY.

Finally, a recent work explicitly tackling the ISTERE task is described in (Do et al., 2012). Their system was based on three classifiers: (i) a local classifier, which processes all pairs of events and time expressions in a document and decides which pairs are linked together; (ii) a classifier between pairs of events, which determines their relations: BEFORE, AFTER, OVERLAP and NO RELATION; and (iii) a joint model which, exploiting global constraints, can highly improve the overall ISTERE accuracy. We will further comment on this work in Sec. 6.

### 3 Baseline Models for TERE

The analysis of previous work has shown that there is almost no models for ISTERE. Therefore to align with prior work, we compare with previous models on *standard* TERE (extraction within a sentence). For this purpose, after formally defining the task, we describe the system we used as our baseline, which includes two types of features: (i) those manually designed also called linear features and (ii) structural features generated by tree kernels.

**Task Definition.** TERE is formally defined as follows: given the sets of expressions  $E$  denoting events or relation mentions, and  $T$  describing

time expressions in the same document: (i) build all pairs  $\langle e, t \rangle$  where  $e \in E$  and  $t \in T$ ; and (ii) classify  $\langle e, t \rangle$  to determine if a time-event relation is held, i.e., if  $e$  occurs or holds within the temporal context specified by  $t$ . In our study, we assume that: (i) a timestamp must be explicitly stated for each event/relation that we consider to be in a temporal relation; and (ii) every event/relation is associated with only one time expression whereas a temporal expression can be linked to one or more events or relations.

**Feature Vectors.** We used system and features defined in our previous work (Hovy et al., 2012), which in turn are based on the work by (Boguraev and Ando, 2005). The feature set can be divided in three different classes: (i) Features associated with events or relations. These are very similar to features typically used to represent the context of entities in traditional relation extraction tasks, which are primarily syntactic features drawn from the parser and for reporting verbs. (ii) Features specific to the temporal expressions. These are primarily designed to capture various properties of the temporal expressions. For instance, whether it is a duration, time or date, or whether its premodifiers are among those that indicate the type of expression. We include also surface features, such as numeric or non-numeric tokens in the phrase. (iii) Features describing context around both the arguments. These are primarily drawn from the work by Boguraev and Ando, and include features such as n-grams and syntactic/structural patterns. The latter also cover syntactic relations between an event and a temporal expression, ordering of the two in the sentence, etc.

**Tree Kernels.** Convolution tree kernels (TK) compute the number of common substructures between two trees without explicitly considering the whole fragment space. TKs are equivalent to a scalar product between vectors of tree fragments. Therefore using TK in SVMs is equivalent to use subtrees as features. Different TKs exist, here we consider the partial tree kernel (PTK) defined in

Figure 3: New sentence tree representation (STR)

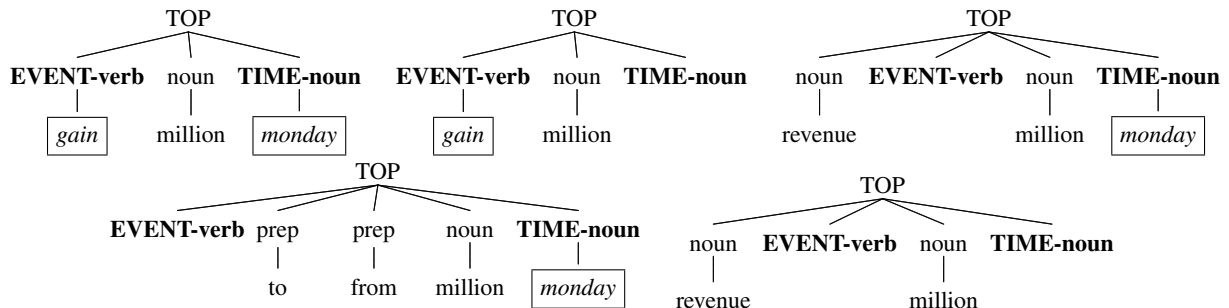

Figure 4: Some of the structural features generated by PTK when applied to the STR of Fig. 3

(Moschitti, 2006), which can count any tree fragments constituted by connected nodes.

**Computational Structures.** In (Hovy et al., 2012), we showed that combining manually engineered features with tree kernels produces a better model. We also show that exploiting syntactic information of the sentence containing the relational expressions is not trivial. Thus, we developed a bag-of-words (BOW) tree representation capturing the context of the target time/event expressions. The latter were marked-up with labels such as EVENT (or equivalently RELATION) and TIME. Figure 1 illustrates an example of the tree representations for the sentence:

*Revenue gained 13% to \$77.3 million from \$68.5 million last Monday.*

Such BOW tree is constituted by: (i) a root node; (ii) a conceptual level, which specifies the semantic type in the sentence, i.e., TERM, TIME or EVENT expressions; (iii) a token node level (TOK); and the lexical level, listing the words of the constituents. PTK applied to such trees generates features, such as [TIME [last][monday]] and [TIME [[monday]]] or more interesting features like those shown in Figure 2. For example, such features can learn the pattern: *revenue, EVENT\_gain, \*, last, TIME.*

It should be noted that such a tree represents only one relation. In case a sentence contains more than one event/relation, separate trees for each must be generated (each will be a separate training/test instance). Such trees differ in the position of the EVENT/RELATION nodes (at level

1 of the tree).

Finally, in (Hovy et al., 2012) we showed that this model significantly improves over manually engineered features. However, to exploit syntactic information, we defined another separate tree with POS-tag nodes in place of words causing the features coming from different trees to be disjoint. This model cannot be applied for ISTERE as the large number of identical nodes, TERM and TOK would cause the PTK computational complexity to degenerate to  $O(n^2)$  (see (Moschitti, 2009)).

#### 4 Models for Inter-Sentence TERE

We describe here our new representation, which is an improvement over our previous models on intra-sentence TERE and, more importantly, can be used for ISTERE.

**Intra-Sentence Representation.** We improve on the previous work by reformulating the BOW tree as follows:

1. We remove the TERM and TOK levels and we propose only two levels — the POS-tag and the word sequences.
2. The annotation of the target time or event expression is directly performed on the POS-tag node.

For example, Fig. 3 shows the transformation of the trees in Fig. 1 to the new representation. The event *gain* and the time expression *last monday* are marked at POS-tag level<sup>2</sup>. This also compacts the segmentation of time expressions. As a result, the application of PTK to the new sentence tree

<sup>2</sup>The POS tagset is the one used in the IBM Watson system (Ferrucci et al., 2010).

Figure 5: A second STR containing a time expression. Together with the one of Fig. 3 containing the event, it forms the representation pair, input to the kernel used for ISTERE.

representation (STR) generates very powerful and compact features, e.g., those described in Fig. 4. The last fragment of the figure suggests that if, in a sentence, there is the noun *revenue* followed by (i) any word tagged as EVENT, (ii) the noun *million* and (iii) any TIME expression, the EVENT is probably associated with such TIME expression. Note that this is not a rule but just a feature receiving a weight from SVMs based on training data.

Finally, it should be noted that the average running time of PTK will be  $O(n)$ , because the new tree does not contain many repeated node labels. This is far more efficient than the PTK applied to BOW trees (see (Moschitti, 2009)).

**Inter-Sentence Representation.** STR still cannot encode relations whose arguments are located in different sentences. Our approach for this problem is to design two STRs for the sentences containing the two potential arguments of a relation. For example, let us suppose that a time expression of the *gain*-EVENT in Fig. 3, e.g., *late period*, is expressed in the following sentence: *The late period has profit from continuing operations of \$4 million*.

We produce another STR associated with it, as shown in Fig. 5. This way, we model  $\langle e, t \rangle$  with a pair of trees  $\langle E, T \rangle$ , where  $e \in E$  and  $t \in T$  (see Sec. 3). Accordingly, we define the kernel  $K(p_1, p_2)$  over two pairs  $p_1 = \langle E_1, T_1 \rangle$  and  $p_2 = \langle E_2, T_2 \rangle$  as:  $TK(p_1, p_2) = \text{PTK}(E_1, E_2) + \text{PTK}(T_1, T_2)$ .

It should be noted that: (i) the additive combination of kernels is still a valid kernel and it corresponds to the merged fragment space of E and T trees; (ii) the kernel product can also be applied but it has shown poor results in previous work (Moschitti, 2004); and (iii) PTK allows for modeling structural features in two sentences located in different part of the document. Thus, the features will be pairs of tree fragments from E and T. It is worth noting that the pairs of BOW and POS trees used in (Hovy et al., 2012) cause PTK to be too slow for this setting (although they may achieve comparable accuracy).

Additionally, the PTK can be combined with a linear kernel of manually engineered features using an additive operation. If  $\vec{x}_i$  is the vector representation of the manually engineered features of  $p_i$ , the kernel combination of PTK and the linear kernel is  $\text{PTK}(p_i, p_j) + \vec{x}_i \cdot \vec{x}_j$ . The linear features extracted for the EVENT expression in one sentence and the TIME expression in the other sentence can reconstruct their shared context thanks to the pairs of tree fragments generated by PTK. The next section will empirically verify this hypothesis.

## 5 Experiments

In this section, (i) we compare our model against the state of the art for intra-sentence TERE; and (ii) we test its validity for ISTERE.

### 5.1 Setup

We used two corpora: Machine Reading Program (MRP) corpus to compare with our previous system (Hovy et al., 2012) (our baseline) and Time-Bank data (Pustejovsky et al., 2003), which in contrast to MRP data, enables us to train and test our system with inter-sentence gold standard (GS) annotation. During testing, we used GS annotations for the timestamps and events, i.e., we only classify which events and time expressions are linked together.

**MRP data.** Following our work in (Hovy et al., 2012), we used the data made available in MRP related to linking timestamps and events in the intelligence community (IC) domain (Strassel et al., 2010). It is based on news reports about terrorism taken from the Gigaword corpus. It includes 169 documents containing 2,046 pairs of event and temporal expressions (505 positive, 1,541 negative instances) within the same sentence. We increased the original number of event instances by means of gold event-coreference annotations, i.e., two events that co-refer will share their annotated time expressions; thus we can merge them and increase the size of our gold annotation. As before, 41% of all correct event-time pairs are not in the same sentence (for relations this ratio is more than 80% of the correct fluent-time links).

	Training Set			Validation Set			Test Set		
	Pos.	Neg.	Total	Pos.	Neg.	Total	Pos.	Neg.	Total
DIST=0	1,125	2,754	3,879	155	405	560	162	463	625
DIST>0	900	65,221	66,121	129	9,311	9,440	182	16,600	16,782
DIST≥0	2,025	67,975	70,000	284	9,716	10,000	344	17,063	17,407

Table 1: Distribution of data in the three TimeBank subsets.

While it allows us to compare with previous work, the MRP data is not very well suited for training and testing new systems modeling ISTERE. Indeed, almost all inter-sentence pairs of time/event contain members that (i) are coreference of either the time or the event and (ii) are typically located in the same sentence. This means that, given an accurate system for intra-sentence TERE and a good coreference resolution system, ISTERE described in the MRP corpus can be easily solved. The combined system is still very complex and interesting, but it inevitably falls in the class of coreference resolution problems. Here we aim at studying linguistic phenomena directly connected to inter-sentence relations, which go beyond coreference resolution. For this reason, we also ran experiments on a second corpus described below, which is more suitable to our study.

**TimeBank corpus.** Distributed by the Linguistic Data Consortium<sup>3</sup>, it consists of 183 documents – news articles from several news sources that have been annotated with event and time expressions compliant with the TimeML specification<sup>4</sup>. We divided the corpus in three subsets containing relations whose arguments are located in: (i) the same sentence (DIST=0), (ii) more than one sentence (DIST>0) and (iii) both previous cases (DIST≥0). The distribution of positive and negative examples in the training, validation and test sets are reported in Table 1. It is interesting to note that the distribution of positive examples in DIST=0, i.e., the intra-sentence relations, is 30% of all possible pairs. In contrast, such distribution in DIST>0, i.e., inter-sentence relations, drastically reduces to 1.4% of the pairs occurring in a document. This imbalance immediately gives the feeling of the complexity of the ISTERE task.

**Learning Model.** we used SVM-Light-TK (Moschitti, 2006; Joachims, 1999), which enables the use of the Partial Tree Kernel (PTK) (Moschitti, 2006). We used the default kernel hyperparameters and the margin/error trade-off param-

<sup>3</sup>LDC2006T08 at <http://www.timeml.org/site/timebank/documentation-1.2.html>

<sup>4</sup>The inter-annotator agreement numbers are specified in the referring website

ter to favor replicability of our results, and study instead the cost-factor parameter as it tunes the balance between Precision and Recall, which is very critical for our task (highly skewed datasets). **Measures.** We estimated Precision, Recall and F1 with 10-fold cross-validation for MRP experiments for comparing with (Hovy et al., 2012). For TimeBank, we drew F1 plots using the random test set described in Table 1. To estimate the final F1 of our models, we used 3-fold cross-validation<sup>5</sup> applied to the merged train and test set in the table. In this case the cost-factors were estimated from the validation set (see the table above), which is not part of the merged data used for the 3-fold cross-validation. It should be noted that to create the folds and the other subsets, we took care to not mix RE pairs between the folds or between training, validation and test set.

## 5.2 Intra-Sentence TERE: MRP Results

We trained SVMs using PTK applied to STR of single sentences and also combined with linear features. We tested a few parameter values of the Precision/Recall trade-off (cost-factor) on a validation set then, following (Hovy et al., 2012), we ran 10-fold cross-validation. The average F1 was 76.84, which is directly comparable with the outcome we reported in (Hovy et al., 2012), i.e., an F1 of 76.5 (when linear features are used in combination with tree kernels). It should be noted that: (i) in (Hovy et al., 2012) we showed that our system achieved the same accuracy than the best system of TempEval-2; and (ii) our STR provides the same results of the combination of the two structures we used in the model above.

Additionally, we tested PTK alone and attained an F1 of 74.45. This basically suggests that if we only use tree kernels, we can trade-off several months of work for manual feature engineering for a little bit less accurate system. Those unfamiliar with structural kernels may think that the time spent for engineering tree representations is comparable to the one spent for engineering features.

<sup>5</sup>It is more suitable than a 10-fold setting for deriving the final accuracy, given the very low number of positive examples in DIST>0.

However, the abstraction provided by the tree kernels suggests that the effort required in engineering trees is orders of magnitudes lower. The baseline system using the manually engineered features was designed at IBM and required several months of manual effort to engineer, code and tune features. Our expert on kernel methods (who is not an expert on TERE) modeled STR in 20 minutes and the implementation only concerned the construction of strings representing trees like those in fig. 3 and 5. While this is anecdotal evidence, it is a good indicator of the power of tree kernels.

Furthermore, our experiments show that the combination of tree kernels and feature vectors is much more adaptable to variations of the TERE task and data. This can be observed, for instance, when considering RE from TimeBank.

### 5.3 Cost-factor role in ISTERE: TimeBank

We performed the first experiment using DIST=0 data and three different models, Linear (i.e., only using the manual features), PTK (which in this case only uses one tree) and their additive combination, i.e., Linear + PTK. In these experiments, the only critical parameter is the one tuning the Precision/Recall trade off (cost-factor parameter) as the high data imbalance between negative and positive examples can result in imbalanced Precision and Recall. Thus, we plotted the F1 of the above models (derived on the test set) according to a reasonable set of values of such parameter. The result is shown in Fig. 6. We note that (i) PTK produces a better F1 than linear features for any parameter value; (ii) the combination Linear + PTK highly improves on both achieving an interesting F1 of 64.35; (iii) in comparison with MRP, where the best model achieves an F1 of 76.84, the TimeBank task appears to be more difficult.

We ran an experiment for DIST>0, which considers only inter-sentence relations. Fig. 7 shows a similar curve as before, except that manual features have a higher accuracy than PTK. The F1, however, is rather low, indicating the complexity of the task and the inadequacy of manual features.

As predicted in Sec. 4, the combination of inter-sentence structural and manual features highly improves on the system F1 achieving a state-of-the-art value of 38.82 for ISTERE. Although, the result does not still guarantee a successful use of the proposed model for real-world applications, it clearly shows a promising research direction.

Finally, we tested DIST $\geq$ 0, i.e., the complete

Figure 6: TERE cost-factor impact on DIST=0

Figure 7: TERE cost-factor impact on DIST>0

Figure 8: TERE cost-factor impact on DIST $\geq$  0

TERE task on entire documents. Fig. 8 shows comparable performance between PTK and Linear but again when combined together the improvement is rather high, i.e., up to 10 absolute percent points (25% of relative improvement on manual features). It should be noted that the above results do not indicate the final system accuracy: for this purpose, the next section shows the 3-fold cross-validation results using cost-fact values that are (i) derived from the validation set (not included in the cross-validation data) and (ii) slightly different from those optimizing the plot in the figures.

	DIST=0			DIST>0			DIST≥0		
	Linear	PTK	Lin.+PTK	Linear	PTK	Lin.+PTK	Linear	PTK	Lin.+PTK
Prec.	36.7±1.3	57.2±0.7	60.9±3.0	18.5±2.5	29.1±5.5	29.2±4.4	33.8±1.1	34.2±2.5	39.8±2.3
Rec.	89.4±3.2	42.4±1.9	64.0±2.9	55.5±5.0	20.6±8.2	32.3±7.9	57.7±1.1	46.7±1.5	58.4±4.0
F1	52.0±0.9	48.7±1.0	62.3±1.7	27.7±3.4	23.1±5.4	30.2±4.5	42.6±1.0	39.4±1.2	47.2±1.8

Table 2: 3-fold cross-validation results for DIST=0, DIST>0 and DIST≥0 tasks.

#### 5.4 Cross-Validation Results

The previous section demonstrates the superiority of the combined Linear + PTK model over manual features for any value of the cost-factor parameter. To assess the significance of this, we carried out 3-cross-fold cross validation. Table 2 shows the average Precision, Recall and F1 over the 3-folds along with the associated standard deviation (preceded by  $\pm$ ). We note that (i) the relative improvement over the Linear model derived on DIST=0, about 20%, confirms the results showed by the plots; and (ii) the relative improvement derived on DIST>0 and DIST≥0 is lower, although still remarkable, i.e., up to 9% and 12%, respectively. This is probably due to the fact that 2 folds constitute a training set of 58K instances (for DIST≥0), whereas in the plot experiments the training data contained 70K examples. Evidently the more complex patterns needed for long-distance TERE require more training data to express their entire potential. Finally, feature vectors perform better than structural kernels alone but this does not contradict the fact that kernels save potentially large engineering work since: (i) even if the features had been engineered for MRP and used for TimeBank, the effort would have been done in any case whereas kernels almost completely avoid it; and (ii) the combination largely improve on the feature vectors: this may avoid the need of additional work for feature refining.

## 6 Discussion and Conclusions

Previous work has proposed intra-sentence TERE models based on manually designed features and tree kernels. In this paper, we propose new models for inter-and intra-sentence TERE. We provided a flexible kernel, which improves efficiency and capacity of generating meaningful features. It can be applied to the pairs of all document sentences for modeling ISTERE. This enables the use of all possible pairs of tree fragments from the time and event sentences as features, which improve on the features manually designed in (Hovy et al., 2012). For example, the latter cannot capture the relation with the “document date”, when the time expressions occur in the titles. This kind of features can

be added but a study of the problem and engineering effort are required. In contrast, our models can automatically generate such features.

Our experiments on MRP and TimeBank show that our approach provides high accuracy, up to 20% of relative improvement over state of the art. The reason for such impressive results is the adaptability and automatic feature engineering properties of tree kernels. Indeed, new data and settings pose new challenges to the RE systems, which require effort in engineering both features and methods. Our approach alleviates such effort as we can use a more general-purpose technology.

In this work, our model has been applied to establish the link between time expressions and events. However, in general, our model could be applied to the complete TERE task, thus also determining the relation types. Interestingly, the model proposed in (Do et al., 2012) is based on the pairwise classifiers we study in this paper. Although, the authors used a different dataset<sup>6</sup>, which makes an exact comparison with their systems difficult, we note that their local pair classifiers achieved an F1 of 42.13 (no global model, so the same setting as ours) and an F1 of 46.01 using their global model based on ILP. Our local pairwise classifier attained an F1 of 47.2, which can be used as input to the global model to further boost the overall system accuracy.

Finally, the pairwise approach may be considered computationally expensive. However, with modern technology,  $O(n^2)$  complexity (where  $n$  is the number of sentences in a document) is feasible. PTK is efficient and can be made faster with recent reverse kernel engineering work (Pighin and Moschitti, 2010; Pighin and Moschitti, 2009).

In summary, the main message of this paper is that ISTERE is complex, requiring a significant engineering effort. We have shown that tree kernels are adaptable, requiring less effort and improving on the state of the art in the full TERE task – relations spanning more than one sentence.

<sup>6</sup>They annotated a portion of the ACE corpus with (i) event mention and time interval association, and (ii) the temporal relations between event mentions.

# Unsupervised Extraction of Attributes and Their Values from Product Description

Keiji Shinzato

Satoshi Sekine

Rakuten Institute of Technology

{keiji.shinzato, satoshi.b.sekine}@mail.rakuten.com

## Abstract

This paper describes an unsupervised method for extracting product attributes and their values from an e-commerce product page. Previously, distant supervision has been applied for this task, but it is not applicable in domains where no reliable knowledge base (KB) is available. Instead, the proposed method automatically creates a KB from tables and itemizations embedded in the product's pages. This KB is applied to annotate the pages automatically and the annotated corpus is used to train a model for the extraction. Because of the incompleteness of the KB, the annotated corpus is not as accurate as a manually annotated one. Our method tries to filter out sentences that are likely to include problematic annotations based on statistical measures and morpheme patterns induced from the entries in the KB. The experimental results show that the performance of our method achieves an average F score of approximately 58.2 points and that filters can improve the performance.

## 1 Introduction

E-commerce enables consumers to purchase a large number of products from a variety of categories such as books, electronics, clothing and foods. In recent years, this market has grown rapidly around the world. Online shopping is regarded as a very important part of our daily lives.

Structured product data are most important for online shopping malls. In particular, product attributes and their values (PAVs) are crucial for many applications such as faceted navigation and recommendation. However, since structured information is not always provided by the merchants, it is important to build technologies to create this

structured information (such as PAVs) from unstructured data (such as a product description). Because of the wide variety of product types, such technology should not rely on a manually annotated corpus. One of the promising methods for information extraction (IE) without a manually annotated corpus is *distant supervision* (Mintz et al., 2009), which leverages an existing knowledge base (KB) such as Wikipedia or Freebase to annotate texts using the KB instances. These popular KBs, however, are not very helpful for distant supervision in an e-commerce domain for the following reasons. (1) An infobox in a Wikipedia article is not always tailored towards e-commerce. For instance, as of May 2013, the infobox attributes of wine in English Wikipedia included energy, carbohydrates, fat, protein and alcohol<sup>1</sup>. These are not particularly useful for users seeking their favorite wines through online shopping. Instead, the grape variety, production area, and vintage of the wine would be of greater interest. (2) On the other hand, Freebase contains PAVs for limited types of products such as digital cameras<sup>2</sup>. However, since Freebase is currently only available in English, we cannot use Freebase in a distant supervision method for other languages. Moreover, the number of categories whose PAVs are available in Freebase is limited even in English.

In this paper, we propose a technique to extract PAVs using an automatically induced KB. For the induction, the method uses structured data such as tables and itemizations embedded in the unstructured data. An annotated corpus is then automatically constructed from the KB and unstructured data, i.e. product pages. Since these texts are in HTML format, we can extract the attribute candidates and their values using pattern matching with tags and symbols. We can expect the KB to

<sup>1</sup><http://en.wikipedia.org/wiki/Wine>

<sup>2</sup>[http://www.freebase.com/view/digicams/digital\\_camera](http://www.freebase.com/view/digicams/digital_camera)

have a certain level of accuracy because the tables and itemizations are created by merchants who are product experts. However, there may be a need to group synonymous attribute names. We propose a method for grouping synonymous attribute names by observing the commonality of the attribute values and their co-occurrence statistics. The model for extracting attribute values is then trained using the annotated corpus to find PAVs of the products. Because the KB is incomplete, the annotated corpus may contain annotation mistakes; *false-positive* and *false-negative*. Thus, our method tries to filter out sentences that are likely to include those problematic annotations based on statistical measures and morpheme patterns induced from the entries in the KB.

The contributions of our work are as follows:

1. Unsupervised and scalable methods for inducing a KB consisting of PAVs, and for discovering attribute synonyms.
2. Unsupervised method for improving the quality of an automatically annotated corpus by discarding false-positive and false-negative annotations. These problematic annotations are always included in automatically annotated corpora although such corpora can be constructed without requiring expensive human effort.
3. Comprehensive evaluation of each component: Automatically induced KBs, annotation methodology, and the performance of IE models based on the automatically constructed corpora. In particular, the annotation methodology and the IE models are evaluated by using a dataset comprising 1,776 manually annotated product pages gathered from eight product categories.

To summarize, as far as we know, this is a first work to extract product attributes and their values relying solely on product data, and completing all the steps of this task, including KB induction, in a purely unsupervised manner.

## 2 Related Work

### 2.1 Product Information Extraction

Bing et al. (2012) proposed an unsupervised methodology for extracting product attribute-values from product pages. Their method first generates word classes from product review data re-

lated to a category using Latent Dirichlet Allocation (LDA) (Blei et al., 2003). The method then automatically constructs training data by matching words in classes and those in product pages for the category. After that, extraction models are built using the training data. Their method does not deal with attribute synonymy and problematic annotations in their training data. They evaluated the result of their extraction model only, while this paper reports on evaluation results of not only extraction models but also induced KBs and annotation methodology. In addition, their method employs LDA for generating word classes. This may involve the issue of *scalability* when running the method on large size real-world data. On the other hand, we employ a simple rule-based approach to induce the KBs. We can then straightforwardly apply the method on the large-scale data.

Mauge et al. (2012) also proposed methods to extract product attribute-values using hand-crafted patterns, and to group synonymous attributes in a supervised manner. They, however, only evaluated a part of the extracted attribute names, and aggregated synonymous attribute names. They did not evaluate the extracted attribute values.

Our work is also similar to Ghani et al. (2006), who construct an annotated corpus using a *manually tailored* KB and then train models using the corpus to extract attribute values. Probst et al. (2007) and Putthividhya and Hu (2011) also proposed a similar approach with the work of Ghani. The main difference between these works and ours is that our method does not require manually tailored KBs. Instead, our method automatically induces a KB of PAVs from structured data embedded in product pages.

In addition to the above, many wrapper based approaches have been proposed (Wong et al., 2008; Dalvi et al., 2009; Gulhane et al., 2010; Ferrez et al., 2013). The goal of these approaches is to extract information from documents semi-structured by any mark up language such as HTML. On the other hand, our method aims at extracting (product) information from full texts although the method leverages semi-structured documents to induce KBs.

### 2.2 Knowledge Base Induction

There are many works for automatically inducing KBs using syntactic parsing results (Rooth et al., 1999; Pantel and Lin, 2002; Torisawa, 2001; Kazama and Torisawa, 2008), and semi-

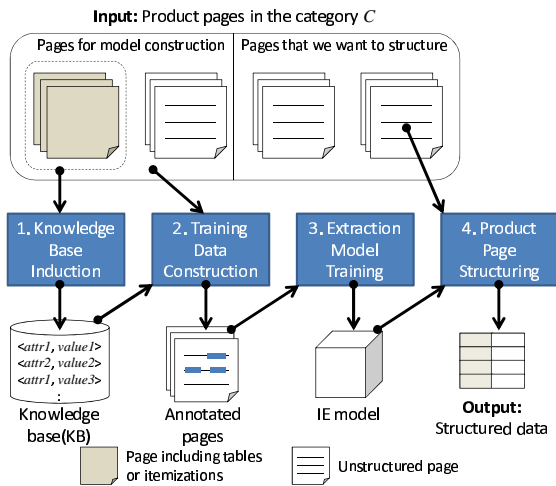

Figure 1: Overview of our approach.

structured data (Shinzato and Torisawa, 2004; Wong et al., 2008; Yoshinaga and Torisawa, 2006; Mauge et al., 2012). As clues for the induction of attribute-value KBs, previous works employ lexico-syntactic patterns such as *<attribute>:<value>* and *<value> of <attribute>*, and layout patterns in semi-structured data such as tables and itemizations marked up by HTML tags.

We employ similar clues as Yoshinaga and Torisawa (2006) for KB induction. In addition to the induction, our method tries to find synonymous attributes in the induced KB. This is the difference between Yoshinaga’s work and ours. The method of Mauge et al. (2012) also finds attribute synonyms, but it requires supervision to find these.

### 3 Data

We used Rakuten’s product pages comprising over 100 million products in 40,000 categories<sup>3</sup>. Each product is assigned to one category by merchants offering it on the Rakuten site. In contrast to Amazon, Rakuten’s product pages are not well-structured, because the product pages are designed by the merchants. Although some pages include tables for describing product information, majority of pages describe product information in full texts. That’s why we need to extract product information from the texts.

### 4 Approach

An overview of our approach is shown in Figure 1. The input for the approach is a set of product pages belonging to a single category like wine or shampoo. From the given pages, a value extraction model for the category is generated, and then the

The [ATTR] tag denotes a collected attribute, the [ANY] tag denotes a string, the [P] tag denotes the prefix and *open*-braces, and the [S] tag denotes the suffix and *close*-braces. The prefix, suffix and brace are defined in (Yoshinaga and Torisawa, 2006). Attributes of HTML tags are removed before running **P1**.

model is used to structure unstructured pages in the category.

A detailed explanation of steps 1, 2 and 3 in Figure 1 is given in the remaining sections. Explanation of step 4 is omitted because the extraction model is simply applied to a given page.

#### 4.1 Knowledge Base Induction

##### 4.1.1 Extraction of Attribute-Values

A KB is induced from the tables and itemizations embedded in the given product pages. We first collected product attributes based on the assumption that *expressions that are often located in table headers can be considered as attributes*. The regular expression `<TH.*?>.+?</TH>` is run on the given pages, and expressions enclosed by the tags are collected as attributes. (The `<TH>` tag is used for a table header.) The collected candidate set includes expressions that can not be regarded as attributes. We excluded these using a small set of stop words given in Figure 2.

To extract values corresponding to the collected attributes, the regular expressions listed in Figure 3 are run on the given product pages. An expression that matches the position of [ANY] is extracted as a value of the attribute corresponding to [ATTR]. The first appearance of [ATTR] is selected as the attribute in **P4**. The extracted value and its attribute are stored in the KB along with the number of merchants that use these in the table and itemization data. Henceforth, we refer to this number as the *merchant frequency* (MF).

##### 4.1.2 Attribute Synonym Discovery

The KBs constructed in the previous section still contains numerous synonyms; that is, attributes

with the same meaning, but different spellings, are included. This is because merchants do not have a standard method for describing products on their own pages. For example, “Bordeaux” and “Tuscany” can be regarded as production areas of wine. However, some merchants refer to “Bordeaux” as the *production area*, while others consider “Tuscany” to be the *region*. If we use KBs that include the incoherence as an annotation resource, corpora containing annotation incoherence are constructed. To avoid this problem, we set out to identify synonymous attributes in the KBs.

We attempt to discover attribute synonyms according to the assumption that *attributes can be seen as synonyms of one another if they have never been included in the same structured data, and they share an identical popular value*. We regard the MF of a value as a measure of *popularity*. Based on this assumption, for all combinations of attribute pairs with an identical attribute value whose MF exceeds  $N$ , we verify whether they appear simultaneously in structured data (i.e., table and itemization data). Attribute pairs satisfying the condition are regarded as synonyms. The value of  $N$  is defined by the equation  $N = \max(2, M_S/100)$  where  $M_S$  is the number of merchants providing structured data in the category. As a result, we obtain a vector of attributes that can be regarded as synonyms, such as (*region, country*), and (*grape, grape variety*) for the wine category. We refer to this set of synonym vectors as  $S_{attr}$ .

Next, synonym vectors with high similarity are iteratively aggregated. For example, the vector (*region, country, location*) is generated from the vectors (*region, country*) and (*location, country*). The similarity between vectors  $v_a$  and  $v_b$  is computed by the cosine measure:  $sim(v_a, v_b) = v_a \cdot v_b / |v_a| |v_b|$ . We iteratively aggregate the two vectors with the highest similarity in set  $S_{attr}$ . The aggregation process continues until the highest similarity is below the threshold  $th_{sim}$ , which we set to 0.5. The threshold value was determined empirically.

Table 1 shows an example of the KB for the wine category. We can see that the “variety” attribute includes three Japanese variants.

## 4.2 Training Data Construction

An annotated corpus for training a model for attribute value extraction is constructed from the given product pages and the KB built from those

Table 1: Example of the KB for the wine category. The top three attributes are listed with their top four values. (*number*] denotes the MF of a value.)

Attribute	容量 (volume)	品種 (variety)	タイプ (type)
Attribute synonyms	内容量 (content)	ぶどう品種 (grape variety) ブドウ品種 (grape variety) 使用品種 (usage variety)	—
Attribute values	750ML[147] 720ML[64] 375ML[49] 500ML[41]	シャルドネ [59] (Chardonnay) メルロー [36] (Merlot) シラー [29] (Syrah) リースリング [29] (Riesling)	辛口 [34] (dry) 赤 [24] (red) 白 [23] (white) フルボディ [23] (full body)
# values	159	1,578	153

pages. Values in the KB are simply annotated for the pages. Then, sentences possibly including incorrect annotations or sentences where annotation are missing are automatically filtered out from the annotated pages to improve annotation quality.

### 4.2.1 Attribute Value Annotation

All given product pages are split into sentences following block-type HTML tags, punctuation, and brackets. Each sentence is then tokenized by a morphological analyzer<sup>4</sup>. The longest attribute value matching a sub-sequence of the token sequence is annotated. We employed the Start/End tag model (Sekine et al., 1998) as chunk tags for the matched sequence. If the matched value corresponds to more than one attribute, the entry with the largest MF is selected for annotation. Note that if other attribute values are contained in the matched sub-sequence, they are not annotated.

### 4.2.2 Incorrect Annotation Filtering

Some attribute values with *low* MFs are likely to be *incorrect*. The quality of the corpus, and the performance of extraction models based on the corpus deteriorate if such values are frequently annotated. We detect incorrect value annotation in the corpus according to the assumption that *attribute values with low MFs in structured data (i.e., tables and itemizations) and high MFs in unstructured data (i.e., product descriptions) are likely to be incorrect*. Thus, we designed the following score:

$$Score(v) = \frac{MF_D(v)/N_M}{MF_S(v)/M_S}$$

<sup>4</sup>We used the Japanese morphological analyzer MeCab. (<http://mecab.googlecode.com/svn/trunk/mecab/doc/index.html>)

<b>T:</b>	Chateau	Talbot	is	a	famous	winery	in	France	.
<b>A:</b>	O	O	O	O	O	O	O	S-PA	O
<b>G:</b>	B-PR	E-PR	O	O	O	O	O	S-PA	O

Figure 4: Example of a sentence with missing annotations. The row **T** shows the tokens of the sentence, the row **A** shows automatic annotations, and the row **G** shows golden annotations. The ‘PR’ and ‘PA’ are abbreviations of *Producer* and *Production Area*, respectively. Label ‘O’ means that a token is not annotated with any label.

[NUMBER] [ML (milliliter)]
[シヤトー (Chateau)] [ANY]
[LOCATION] [ANY] [LOCATION] [市 (city)]

Figure 5: Examples of morpheme patterns induced from the KB for the wine category. The token [ANY] matches a sequence consisting of 1 - 3 arbitrary tokens. Tokens [LOCATION] and [NUMBER] are matched tokens whose part-of-speech is location and number, respectively.

where  $MF_D(v)$  and  $MF_S(v)$  are the MFs of value  $v$  in the product descriptions and structured data, respectively, and  $N_M$  is the number of merchants offering products in the category, and  $M_S$  is the number of merchants providing structured data in the category. The scoring function is designed so that values with a low MF for structured data and a high MF for item descriptions obtain high scores. We regard attribute values with scores greater than 30 as incorrect, and remove sentences that include annotation based on incorrect values from corpora. The threshold value was decided empirically.

#### 4.2.3 Missing Annotation Filtering

Because of the small coverage of the KB, sentences with missing annotations are contained in the corpus. For example, although the tokens *Chateau* and *Talbot* in Figure 4 should be annotated as B-PRODUCER and E-PRODUCER<sup>5</sup> respectively, they are not annotated. These missing annotations result in reduced performance (especially *recall*) of models based on the corpus since they are considered to be *other* examples when training the models. One of the possible way to reduce the influence of the missing annotations is to discard sentences with missing annotations. Thus, we removed such sentences from the corpus.

To detect missing annotations, we generate morpheme patterns from values in the KB. Ex-

<sup>5</sup>The beginning and the end of a value for the attribute called “Producer.”

Table 2: Features for training extraction models.

Basic features (BFs)	
Feature	Description
Token	Surface form of the token.
Base	Base form of the token.
PoS	Part-of-speech tag of the token.
Char. types	Types of characters contained in the token. We defined <i>Hiragana</i> , <i>Katakana</i> , <i>Kanji</i> , <i>Alphabet</i> , <i>Number</i> , and <i>Other</i> .
Prefix	Double character prefix of the token.
Suffix	Double character suffix of the token.
Context features	
Feature	Description
Context	BFs of $\pm 3$ tokens surrounding the token.

amples of the patterns for the wine category are given in Figure 5. First, attribute values are tokenized using a morphological analyzer, and then the PrefixSpan algorithm (Pei et al., 2001) is executed on the tokenized result to induce morpheme patterns<sup>6</sup>. We employed patterns that do not start and end with the [ANY] token, and which match attribute values in the KB and the total number of merchants corresponding to the matched values is greater than one.

### 4.3 Extraction Model Training

Models for attribute value extraction are trained using the corpus. We employed Conditional Random Fields (CRFs), and used CRFsuite<sup>7</sup> with default parameter settings as the implementation thereof. The features we used are listed in Table 2.

We built a single model for each category. In other words, we did not build a separate model for each attribute of each category.

## 5 Experiments

This section reports the experimental results. We carried out the experiments on eight categories, and evaluated them using the dataset discussed in Section 5.1. An evaluation was conducted for each component, that is, evaluation of the KB (Section 5.2), evaluation of the automatically annotated corpora (Section 5.3), and evaluation of the extraction models (Section 5.4).

### 5.1 Construction of Evaluation Dataset

We created an evaluation dataset comprising 1,776 product pages gathered from the eight categories in Table 3. In constructing the dataset, for each category, we first listed top 300 merchants according to the number of products offered by the mer-

<sup>6</sup>We used PrefixSpan-rel as the implementation of PrefixSpan. (<http://prefixspan-rel.sourceforge.jp/>)

<sup>7</sup><http://www.chokkan.org/software/crfsuite/>

Table 3: Categories and their selected attributes. The symbol # denotes incorrect attributes. The symbol \* is attached to the attributes that are not aggregated into their synonyms. For example, “country of origin” for wine is marked because it is not aggregated with “production area”.

Category	Attributes (Each attribute is represented by one of its synonyms.)
Wine	容量 (volume), 品種 (grape variety), タイプ (type), 産地 (production area), アルコール度数 (alcohol), 原産国 (country of origin)*, 生産者 (producer), 原材料 (material)
T-shirt(men)	サイズ (size), 素材 (material), 色 (color), 着丈 (length)*, 身幅 (body width)*, M(M size)#, 肩幅 (shoulder width)*, L(L size)#
Printer ink	容量 (volume), サイズ (size), カラー (color), 重量 (weight), 色 (color)*, 適応機種 (compatible model), 材質 (material), 製造国 (production area)
Shampoo	容量 (volume), メーカー (manufacturer), 製造国 (production area), 成分 (constituent), 商品名 (product name), 区分 (category), サイズ (size), 重量 (weight)
Golf ball	コア (core), サイズ (size), カバー (cover), 材質 (material), 重さ (weight), 原産国 (country of origin), デインプル形状 (shape of dimple), 色 (color)
Video game	サイズ (size), 重さ (weight), 材質 (material), 付属品 (accessory), 製造国 (production country), 色 (color), 対応機種 (compatible model), ケーブル長 (length of cable)
Car spotlight	サイズ (size), 色温度 (color temperature), 色 (color), 材質 (material), 重量 (weight), 適合車種 (compatible model), 製造国 (production country), 品番 (part number)
Cat food	内容量 (volume), 原産国 (production country), 粗繊維 (crude fiber), 粗脂肪 (crude fat), 粗灰分 (crude ash), 水分 (wet), 粗タンパク質 (crude protein), 重量 (weight)*

Table 4: Statistics of the corpora.  $p^{\#}$ ,  $s^{\#}$ , and  $v^{\#}$  denote the number of annotated pages, the number of annotated sentences, and the number of values, respectively.

Category	Test data (manually annotated)			Training data (automatically annotated)		
	$p^{\#}$	$s^{\#}$	$v^{\#}$	$p^{\#}$	$s^{\#}$	$v^{\#}$
Wine	282	1,863	3,040	25,358	28,952	48,645
T-shirt(men)	259	2,580	5,534	14,978	18,018	41,954
Printer ink	273	1,230	4,029	8,473	13,562	42,969
Shampoo	233	1,518	4,352	18,669	30,263	53,294
Golf ball	160	555	719	1,114	2,109	2,760
Video game	212	807	1,088	19,292	29,356	35,230
Car spotlight	271	1,401	2,282	8,124	12,910	18,937
Cat food	86	276	452	4,915	7,375	8,843
Total	1,776	10,230	19,496	100,923	142,545	252,632

chant in the category. Then, we randomly picked one from the product pages of each merchant. We extracted titles and sentences from the pages based on HTML tags. These texts were passed to the annotation process.

In selecting the attributes to be used for annotation, we selected the top eight attributes in each category according to the MFs of the attributes. Then, we manually discarded incorrect attributes and aggregated synonymous attributes that were not automatically discovered. These attributes are marked up with the symbols # and \* in Table 3, and are not considered in the evaluation in Sections 5.3 and 5.4.

An annotator was asked to annotate expressions in the text data, which could be considered as values of the selected attributes. The annotator was also asked to discard pages that offered multiple products and miscategorized products.

In this way, the evaluation dataset was constructed by one annotator. After the construction,

we checked the accuracy of the annotation. We picked up 400 annotated pages, and then checked them by another annotator whether annotations in the pages were correct. The agreement of annotations between the two annotators was about 88.4%. Statistics of the dataset are given in the *Test data* column in Table 4.

## 5.2 Evaluation of Knowledge Base

### 5.2.1 Evaluation of Extracted Attributes

We checked whether attributes extracted using our method could be regarded as *correct*. We asked two subjects to judge 411 expressions, all extracted attributes for the eight categories. The ratio of attributes that were judged as *correct* by both annotators was 0.776. The kappa statistics between the annotators was 0.581. This value is defined as *moderate agreement* in (Landis and Koch, 1977). Majority of the attributes judged as *incorrect* were extracted from complex tables and tables on miscategorized pages.

### 5.2.2 Evaluation of Attribute Synonyms

Next, we assessed the performance of our synonym discovery. We asked the subjects to aggregate synonymous attributes in KBs, and then computed *purity* and *inverse purity* scores (Artiles et al., 2007) using the data. We discarded attributes judged as incorrect when computing these scores. We computed macro-averaged scores for each subject, and then averaged them.

As a result, the averaged purity and inverse purity were 0.920 and 0.813, respectively. The purity score is close to perfect, which means that the merged expressions are mostly regarded as synonyms. On the other hand, the score for in-

Table 5: Accuracy of KBs. # shows the total number of KB entries with each MF.

MF of pairs	Wine		Shampoo	
	#	Acc. [%]	#	Acc. [%]
≥ 1 (All)	3,940	75.3 (301/400)	6,798	67.5 (270/400)
≥ 2	751	97.2 (69/71)	2,307	90.8 (118/130)
≥ 3	384	97.1 (33/34)	1,543	97.3 (73/75)
≥ 5	215	95.5 (21/22)	931	98.1 (52/53)

Table 6: Accuracy of our annotation method.

Annotation method	Prec. (%)	Recall (%)	F <sub>1</sub> score
(1) Naive annotation	47.46	<b>45.48</b>	<b>46.19</b>
(2) (1) + incorrect	51.39	39.14	43.00
(3) (2) + missing	<b>57.14</b>	29.29	37.21

verse purity is less than 0.82. Improvement of the methodology in terms of coverage is left for future work.

### 5.2.3 Evaluation of Attribute Values

We evaluated the quality of the KBs for the wine and shampoo categories only, because the evaluation for all categories requires enormous human effort. We randomly selected 400 values of attributes listed in Table 3, and then asked the subjects to judge whether the values could be regarded as *correct* for the attributes. To judge the pair  $\langle attr., value \rangle$  in the KB for category  $C$ , we automatically generated the sentence: “ $value$  is an expression that represents ( $attr.$  or  $S_{attr}^1$  or ... or  $S_{attr}^n$ ) of  $C$ .” Here,  $S_{attr}^n$  denotes the  $n$ th synonym of  $attr.$  The subjects judged a pair to be *correct* if the sentence generated from the pair was naturally acceptable. For example, the pair  $\langle variety, onion \rangle$  in the KB for the wine category is deemed incorrect because the sentence “*onion* is an expression that represents (*variety* or *grape variety* or *usage variety*) of *wine*.” is not acceptable.

The evaluation results are given in Table 5. The kappa statistics between the annotators were 0.632 for the wine category, and 0.678 for the shampoo category, respectively. These values indicate *good agreement*. We regarded a pair as correct if the pair was judged as correct by both annotators. We can see that the accuracy of each category is promising. In particular, the accuracy of pairs with MF greater than one is 90% or more. This means that merchant frequency plays a crucial role in constructing KBs from structured data that are embedded in product pages by different merchants.

### 5.3 Evaluation of the Annotated Corpora

We also checked the effectiveness of the proposed annotation method by annotating the same product

<b>KB match:</b> Naive KB matching for corpora (same as (3) in Table 6).
<b>Model w/o filters:</b> Training models based on corpora naively annotated using KBs. That is, filters for incorrect and missing annotations are not applied.
<b>Model with incorrect annotation filter (Model with incorrect only):</b> Training models based on corpora where only the filter for incorrect annotations is applied.
<b>Model with missing annotation filter (Model with miss only):</b> Training models based on corpora where only the filter for missing annotations is applied.

Figure 6: Alternative methods.

Table 7: Micro-averaged precision, recall and F score of the models for proposed method and alternatives.

Method	Prec.(%)	Recall (%)	F <sub>1</sub> score
Supervised Model	88.28	58.15	68.66
KB match	57.14	29.29	37.21
Model w/o filters	52.60	54.49	53.14
Model with incorrect only	<b>60.46</b>	54.23	56.84
Model with miss only	50.47	<b>59.71</b>	54.43
Model for proposed method	57.05	59.66	<b>58.15</b>

pages as those in the evaluation dataset, and then checking overlaps between the manual and automatic annotations. The experimental results are given in Table 6. We judged an extracted value to be *correct* if the value exactly matched the manually annotated one. The results are given as micro-averaged precision, recall, and F<sub>1</sub> scores for each attribute in each category. We can see that the proposed filtering methods improve the precision (annotation quality) at the expense of recall.

### 5.4 Evaluation of Extraction Model

We compared the performance of the extraction models trained for each category with the alternative methods shown in Figure 6. We naively matched entries in the KB for unlabeled product pages, and then randomly picked 100,000 unique sentences from the annotated pages. We refer to the picked sentences as the *Raw Corpus* (RC). Then, we ran the filters and training process on the RC since we were limited by the RAM required by CRFSuite. Some statistics of the corpora after applying the filters are shown in the column *Training data* in Table 4.

The evaluation results are shown in Table 7. **Model w/o filters** outperformed **KB match** by as much as 15.9 points in F<sub>1</sub> score. These improvements are caused by improving the recall of the method. This shows that contexts surrounding a value and patterns of tokens in a value are successfully captured. **Model with incorrect only** also achieved higher performance than **Model w/o**

Table 8: Types of errors.

Type		# err.
Automatic annotation	Context dependent role	15
	Part of a compound word	12
	Polysemous word	9
Incorrect KB entry		23
Over generation by	learned patterns	15
Extraction from	unrelated regions	12
Others		14

**filters.** Especially, the precision of the extraction models is improved by 7.9%. This means that the incorrect annotation filter successfully removed annotation based on incorrect KB entries from the annotated corpora. In addition, **Model with miss only** achieved higher performance than **Model w/o filters**. In particular, the recall of the method improved by 5.2%. This shows that the missing annotation filter effectively works for precisely training extraction models. As a result, the precision and recall of the proposed method are enhanced by employing both filters simultaneously, and the method achieved 58.15 points in F<sub>1</sub> scores.

By comparison, the performance of the extraction models based on manually annotated corpora is shown in Table 7. The supervised method was evaluated with 10-fold cross validation. From the table, we can see that the recall of our method outperforms that of the supervised method while the precision and F<sub>1</sub> score of our method are lower those of the supervised method.

## 6 Discussion

For the wine and shampoo categories, we randomly picked up 50 attribute values that were judged as incorrect. Then we classified them according to their error types. The classification result is shown in Table 8. Ratios of errors based on automatic annotation, and incorrect KB entities, over generation by learned patterns, and extraction from unrelated region with products are 36%, 23%, 15% and 12%, respectively.

The errors stemming from automatic annotation can be classified into three sub-types. Errors that require understanding of the context when annotating attribute values are the most common sub-type. For example, in the wine domain, the attribute-value pair <Production area, Bordeaux> was extracted from the following sentence:

- 土壌が ボルドー<Productionarea> のポムロールと非常に似ている。  
(Soil is very similar with ones in Pomerol region of Bordeaux<Productionarea>.)

Although the extracted pair can be regarded as a correct KB entity for the wine categories, it is not *production areas* of wine in the above sentence. This type of error can be reduced if we can successfully leverage the above sentence as a negative example in the model training step. To generate such negative examples is future work.

The second type of errors left for future work occurs in annotation of compound words. For example, automatically annotated corpora for the shampoo category has the following sentence:

- ヒアルロン酸<Constituent> 以上の保水力がある。  
(It has a higher water-holding ability than hyaluronan<Constituent> has.)

This sort of annotation errors may decrease if we omit the annotation of parts of compound words.

The third type of errors is annotation based on polysemous words. For instance, although <Alcohol, 10%> for the wine category is a correct KB entry, the word “10%” is used for describing various types of ratios. The following sentence is one of the examples where the word 10% is used with a meaning other than alcohol content in the wine domain:

- 輸出は全体の 10%<Alcohol> 程度。  
(The amount of exports is approximately 10%<Alcohol> of the total.)

A wrong extraction model for the alcohol attribute is trained through the above sentence. Disambiguation of attribute values is required in the annotation step in order to train precise models. On the task of extracting person names, a method for disambiguation of names is proposed by Bollegala et al. (2012). To employ similar disambiguation methodology is one of our plans for future work.

## 7 Conclusion

We proposed a purely unsupervised methodology for extracting attributes and their values from e-commerce product pages. We showed that the performance of our method attained an average F score of approximately 58.2 points using manually annotated corpora.

We believe the most important task for future work is to improve annotation quality. Disambiguation of attribute values and construction of wide coverage KBs are crucial to boost the quality. Another important future task concerns synonymy. We only tackled attribute synonymy. Discovery of attribute value synonyms is also an important future direction.

## Abstract

Determining the stance expressed in a post written for a two-sided debate in an online debate forum is a relatively new and challenging problem in opinion mining. We seek to gain a better understanding of how to improve machine learning approaches to stance classification of ideological debates, specifically by examining how the performance of a learning-based stance classification system varies with the amount and quality of the training data, the complexity of the underlying model, the richness of the feature set, as well as the application of extra-linguistic constraints.

## 1 Introduction

Determining the stance expressed in a post written for a two-sided debate in an online debate forum is a relatively new task in opinion mining. Given a post written for a *two-sided* topic discussed in an online debate forum (e.g., “*Should abortion be banned?*”), the goal of *debate stance classification* is to determine which of the two sides (i.e., *for* and *against*) its author is taking.

Previous approaches to debate stance classification have focused on three debate settings, namely congressional floor debates (e.g., Thomas et al. (2006), Bansal et al. (2008), Balahur et al. (2009), Yessenalina et al. (2010), Burfoot et al. (2011)), company-internal discussions (e.g., Agrawal et al. (2003), Murakami and Raymond (2010)), and online social, political, and ideological debates in public forums (e.g., Somasundaran and Wiebe (2010), Wang and Rosé (2010), Anand et al. (2011), Biran and Rambow (2011), Hasan and Ng (2012)). As Walker et al. (2012) point out, debates in public forums differ from congressional debates and company-internal discussions in terms of language use. Specifically, online debaters use colorful and emotional language to express their points,

which may involve sarcasm, insults, and questioning another debater’s assumptions and evidence. These properties could make stance classification of online debates more challenging than that of the other two types of debates.

Our goal in this paper is to gain a better understanding of how to improve machine learning approaches to stance classification of online debates by examining the following questions, which can be broadly categorized along four dimensions:

**Data.** Can we improve the performance of a stance classification system simply by increasing the number of stance-annotated debate posts available for training? Note, however, that the number of stance-annotated posts that can be downloaded from debate forums for a given debate domain (e.g., Abortion) is fairly limited. A natural question is: given a debate domain, can we identify from different data sources a large number of documents where authors express viewpoints relevant to the domain (e.g., blog posts, news articles) and then stance-label them heuristically, with the goal of employing these noisily labeled documents as additional data for training a stance classifier?

**Features.** The simplest kind of features one can think of is probably n-grams. Nevertheless, a stance classifier trained on unigrams is a relatively strong baseline (Somasundaran and Wiebe, 2010). Anand et al. (2011) augment an n-gram feature set with four types of features: document statistics, punctuations, syntactic dependencies, and, if applicable, the set of features computed for the immediately preceding post in the discussion thread (see Section 3 for details). How effective are Anand et al.’s features in improving an n-gram-based stance classifier? Will adding semantic features improve performance further?

**Models.** The simplest stance classification model is probably one that assigns a stance label to each debate post independently of the other posts. Can we get better performance by

exploiting the linear structure inherent in a post sequence? Since a post may contain materials irrelevant to stance classification, can we train a better model by learning only from the stance-related sentences without relying on sentences manually annotated with stance labels?

**Constraints.** Extra-linguistic inter-post constraints, such as *author constraints* (see Section 3), have been shown to be effective in improving stance classification performance by postprocessing the output of a stance classifier. Will the effectiveness of these constraints be dependent on the underlying debate domain? Will it be dependent on the accuracy of the stance classifier to which they are applied?

By examining these questions, we can potentially determine how the performance of a stance classification system varies with the amount and quality of the training data, the complexity of the underlying model, the richness of the feature set, as well as the application of extra-linguistic constraints. In our evaluation, we focus on stance classification of *ideological debates*.

## 2 Datasets

For our experiments, we collect debate posts from four popular *domains*, Abortion (ABO), Gay Rights (GAY), Obama (OBA), and Marijuana (MAR). Each post should receive one of two *domain labels*, *for* and *against*, depending on whether the author of the post *supports* or *opposes* abortion, gay rights, Obama, and the legalization of marijuana, respectively. To see how we obtain these domain labels, let us first describe the data collection process in more detail.

We collect our debate posts for the four domains from an online debate forum<sup>1</sup>. In each domain, there are several two-sided debates. Each debate has a subject (e.g., “Abortion should be banned”) for which a number of posts were written by different authors. Each post is manually tagged with its author’s stance (i.e., *yes* or *no*) on the debate subject. Since the label of each post represents the subject stance but not the domain stance, we need to automatically convert the former to the latter. For example, for the subject “Abortion should be banned”, the subject stance *yes* implies that the author opposes to abortion, and hence the domain label for the corresponding label should be *against*.

<sup>1</sup><http://www.createdebate.com/>

Domain	Posts	% of “for” posts	% posts in a thread	Average thread length
ABO	1741	54.9	75.1	4.1

OBA	985	53.9	57.1	2.6
MAR	626	69.5	58.0	2.5

Table 1: Statistics of the four datasets.

We construct one dataset for each domain. Statistics of these datasets are shown in Table 1.

## 3 Experimental Setup

In this section, we describe the experimental setup behind our investigation of the issues along the four dimensions of learning-based stance classification: models, features, data, and constraints.

### 3.1 Models

We seek to examine how model *complexity* impacts stance classification performance. We consider three types of models.

The first type of models is a binary classifier that assigns a stance label to each debate post independently of the other posts. We employ a generative model (Naive Bayes (NB) with add-one smoothing) and a discriminative model (Support Vector Machines (SVMs), as implemented in SVM<sup>light</sup> (Joachims, 1999)) in our investigation. This enables us to determine whether the relative performance of generative models and discriminative models changes with the amount of training data (Ng and Jordan, 2002), and whether generative models can handle complex, possibly overlapping features as well as discriminative models.

The second type of models, sequence models, is motivated by an observation: since a post in a post sequence is a reply to its parent post, its label should be determined in dependent relation to that of its parent. Consequently, these models assume as input a post sequence and output a sequence of stance labels, one for each post in the input sequence. As before, we employ two sequence labelers, one generative (first-order Hidden Markov Models (HMMs) with add-one smoothing) and one discriminative (linear-chain Conditional Random Fields (CRFs) (Lafferty et al., 2001), as implemented in Mallet (McCallum, 2002)).

The last type of models is *fine-grained* models. These models jointly determine the stance label of a debate post and the stance label of each of its sentences. We hypothesize that modeling sentence

stances could improve document stance classification performance: for example, features computed from sentences with a neutral stance should not play any role in determining the document stance. To avoid the cost of hand-annotating sentences with stance labels for training a sentence-stance classifier, we determine sentence stances in our model in an unsupervised manner. Moreover, while it is possible to implement fine-grained models based on NB, SVM, HMM, and CRF, we will focus exclusively on those based on NB and HMM. The reason is that they are easier to implement because we employ our own implementation of NB and HMM in these experiments.

**The generative story.** To generate a document  $d_i$ , we first pick a document stance  $c$  with probability  $P(c)$ . Given  $c$ , we generate each sentence in  $d_i$  independently of each other. To generate a sentence  $e_m$ , we first pick a sentence stance  $s$  with probability  $P(s|c)$ , and then generate  $f_n$ , the value of the  $n$ th feature representing  $e_m$ , with probability  $P(f_n|s, c)$ .

A few points deserve mention. First, fine-grained NB and fine-grained HMM both employ this document generative story, differing only in terms of whether the document stance is generated independently (NB) or in dependent relation to that of the preceding post (HMM). Second, while a document stance can have one of two possible values (*for* and *against*), a sentence stance can have one of three possible values (*for*, *against*, and *neutral*). Note that the stance of a sentence can be expressed by someone other than the author of the post; for example, a sentence may restate an opposing opinion by a different author.

**Training the fine-grained models.** As noted above, we need to estimate  $P(c)$ ,  $P(s|c)$ , and  $P(f_n|s, c)$ .  $P(c)$  can be estimated from the stance-labeled training documents.<sup>2</sup> However, since sentence stances are hidden, we estimate  $P(s|c)$  and  $P(f_n|s, c)$  using the Expectation-Maximization (EM) algorithm (Dempster et al., 1977).

To employ EM, we begin by heuristically labeling each sentence with a stance as follows. First, for each document stance  $c$ , we identify the list of informative unigrams, which consists of the open-class words that appear at least 10 times in the training data and is associated with  $c$  at least 70%

<sup>2</sup>In the case of HMMs, we need to additionally estimate the document transition probabilities, which can be done in a supervised manner.

of the times. Then, given a sentence  $e_m$ , its stance label is determined by taking a simple majority vote using the stance labels associated with the informative unigrams appearing in  $e_m$ . In case of a tie,  $e_m$  is labeled as *neutral*.<sup>3</sup>

After heuristic labeling, we begin with the M-step, where we estimate model parameters  $P(s|c)$  and  $P(f_n|c, s)$  from the training data. Since the data is now stance-labeled at both the document and sentence level, we can estimate these parameters using maximum likelihood estimation.

Next, we proceed to the E-step, where the goal is to estimate  $P(s|e_m, d_i, c)$ , the probability that a sentence expresses a sentence stance given the document stance. From the above generative story,

$$\begin{aligned} P(s|e_m, d_i, c) &\propto P(s|c)P(e_m, d_i|s, c) \\ &= P(s|c) \prod_{n=1}^{|F|} P(f_n|s, c) \end{aligned} \quad (1)$$

where  $F$  is the set of features in sentence  $e_m$ . We run EM until convergence.

**Applying the fine-grained models.** After training, we can apply the fine-grained models to classify each test post  $d_i$ . For fine-grained NB, we employ the following equation:

$$\begin{aligned} P(c|d_i) &\propto P(c)P(d_i|c) \\ &= P(c) \prod_{m=1}^{|S(d_i)|} P(s_{max}|e_m, d_i, c) \end{aligned} \quad (2)$$

where  $S(d_i)$  is the set of sentences in test post  $d_i$ , and  $s_{max}$  is the sentence stance with the maximum conditional probability (obtained using Equation 1) for sentence  $e_m$  in  $d_i$ .

For fine-grained HMM, we employ Viterbi to decode a post sequence, using  $P(d_i|c)$  as the “output probability” of a test post given stance  $c$ .

### 3.2 Features

We seek to examine how the features used to train the stance classification system impact its performance. We consider three feature sets.

**N-gram features.** The first feature set consists of unigrams and bigrams collected from the training posts. We encode them as binary features that indicate their presence or absence in a given post.

<sup>3</sup>Intuitively, sentences containing an equal number of *for* and *against* cues are not neutral. We label them as neutral simply because there is no reason to prefer one non-neutral stance to another.

Sentence: Every woman has the right to choose abortion.		
Frame	Target/Semantic Role of Element	Text
People	Target	woman
Possession	Target	has
	Owner	Every woman
	Possession	the right to choose abortion
Correctness	Target	right
Choosing	Target	choose
	Chosen	abortion

Table 2: Sample frame-semantic parse.

**Anand et al.’s (2011) features.** The second feature set, proposed by Anand et al., consists of five types of features: n-grams, document statistics, punctuations, syntactic dependencies, and, if applicable, the set of features computed for the immediately preceding post in its thread. Their n-gram features include both the unigrams and bigrams in a post, as well as its first unigram, first bigram, and first trigram. The features based on document statistics include the post length, the number of words per sentence, the percentage of words with more than six letters, and the percentage of words as pronouns and sentiment words. The punctuation features are composed of the repeated punctuation symbols in a post. The dependency-based features have three variants. In the first variant, the pair of arguments involved in each dependency relation extracted by a dependency parser is used as a feature. The second variant is the same as the first except that the head (i.e., the first argument in a relation) is replaced by its part-of-speech (POS) tag. The features in the third variant, the topic-opinion features, are created by replacing each feature from the first two types that contains a sentiment word with the corresponding polarity label (i.e., + or -).

**Adding frame-semantic features.** To provide semantic generalizations, we create features computed using FrameNet semantic frames (Baker et al., 1998). More specifically, we first apply SEMAFOR (Das et al., 2010) to create a frame-semantic parse for each sentence in a given debate post. Then, for each frame that a sentence contains, we create three types of frame-semantic features, as described below.

A *frame-word interaction feature* is a binary feature composed of (1) the name of the frame  $f$  from which it is created, and (2) an unordered word pair in which the words are taken from two frame elements of  $f$ . Specifically, for each pair of frame elements  $fe_1$  and  $fe_2$  of a frame  $f$ , we cre-

ate one frame-word interaction feature from each unordered word pair composed of one word from  $fe_1$  and one word from  $fe_2$ . Consider the frame-semantic parse of the sentence *Every woman has the right to choose abortion* shown in Table 2. Given the frame *Possession* and its frame elements *Every woman* and *the right to choose abortion*, we can generate frame-word interaction features such as *Possession-right-woman*, *Possession-choose-woman*, *Possession-abortion-woman*.

A *frame-pair feature* is a binary feature composed of a word pair corresponding to the names of two frames, in which the target of the first is present in a frame element of the second. Specifically, for each frame element  $fe$  of a frame  $f$ , if a substring of  $fe$  is the target of a frame  $f_2$ , we create a frame-pair feature composed of the ordered pair  $(f_2, f)$ . Consider the example in Table 2 again. Given the frame *Possession* and its frame elements *Every woman* and *the right to choose abortion*, we can create three frame-pair features, *People:Possession*, *Choosing:Possession*, and *Correctness:Possession*, since *woman*, *choose*, and *right* are the targets of frames *People*, *Choosing*, and *Correctness*, respectively.

A *frame n-gram feature* is the frame-based version of a word n-gram feature. Given a word unigram or bigram in which each word is an open-class word, we create all possible frame n-gram features from it by replacing one or more of its words with its frame name (if the word is a frame target) or its frame semantic role (if the word is present in a frame element). For instance, in the word bigram *woman+has* from the sentence in Table 2, both *woman* and *has* are open-class words and are targets of *People* and *Possession*, respectively. Hence, we create for *woman+has* three frame n-gram features: *woman+Possession*, *People+has*, and *People+Possession*. In addition, since *woman* plays the role of *Owner* in *Possession*, we create two more frame n-gram features, *Owner+Possession* and *Owner+has*.

**Using the frame-semantic features.** One way to use the frame-semantic features is to incorporate them into Anand et al.’s (2011) feature set and train a stance classifier on the augmented feature set.<sup>4</sup> We employ a different way of using the frame-semantic features, however. We train two

<sup>4</sup>Preliminary results indicate that training a stance classifier on the augmented feature set does not yield good performance, presumably because the frame-semantic features are significantly outnumbered by Anand et al.’s features.

Abortion		Gay Rights

Table 3: Sample search queries.

stance classifiers,  $C_A$  and  $C_{FS}$ .  $C_A$  is trained using Anand et al.’s (2011) features, whereas  $C_{FS}$  is trained using only the frame-semantic features. After training, we use the classifiers to predict the stance for a post  $x$  in the test set as follows. We first apply them independently to classify  $x$ , and then predict the stance for  $x$  by linearly interpolating the resulting classification values. The value of the interpolation constant is tuned to maximize performance on development data.<sup>5</sup>

### 3.3 Data

We seek to examine how the *amount* and *quality* of the training data impact stance classification performance.

To determine how classification performance varies with the amount of training data, we will plot learning curves in our evaluation.

As far as training data quality is concerned, our goal is to collect documents discussing viewpoints relevant to the debate domain of interest from different sources (e.g., blogs, news websites), stance-label them heuristically, and determine how these noisily labeled documents can be used in combination with the stance-annotated debate posts to train a stance classification system. Below we describe how we collect and utilize these documents.

**Collecting noisily labeled documents.** To collect noisily labeled documents, we employ a two-step procedure. We (1) create using commonsense knowledge a list of phrases that are reliable indicators of both stances for each domain; and then (2) use each phrase as an *exact* search query to retrieve noisily labeled documents from the Web.

Sample phrases that we create for each stance of each domain are shown in Table 3.<sup>6</sup> For instance, for the Abortion domain, the phrase *I support abortion* indicates the author’s support for

abortion. In contrast, *I think abortion should be banned* is indicative of the author’s stance against abortion. Since we use each phrase as a search query in the second step, we manually paraphrase each of them in hope to increase the number of retrieved documents. For instance, we create for *abortion should be banned* paraphrases such as *abortion should be prohibited*, *abortion should be illegal*, and *abortion should not be allowed*. Some paraphrases are created simply by employing different forms of a proper noun (e.g., *Obama*, *Barack Obama*, and *President Obama*). Table 4 shows the statistics of the noisily labeled documents. It took us less than two person-days to create the phrases and their paraphrases for each domain. Roughly the same number of phrases were created for the two stances in a domain.

As noted above, we use each phrase created in the first step as an exact search query to retrieve documents from the Web using Bing’s Search API.<sup>7</sup> A closer inspection of the retrieved documents reveals that many of them contain materials irrelevant to the search query. One of them, for instance, is a blog article discussing different facets of women rights, followed by comments from several readers. The search query that retrieved the document appeared in one of the readers’ comments. In this case, it makes sense to delete everything but this reader’s comment from the document before using it as noisily labeled data. For this reason, we heuristically extract the portion of each retrieved document that is relevant to the search query. More specifically, we define the relevant portion of a document as the smallest string that contains the search query string and is delimited by HTML tags. Note that we discard documents that contain less than 10 words (in order to avoid documents with no useful content) or are retrieved from `www.createdebate.com` (in or-

<sup>5</sup>We tried values from 0.0 to 1.0 in steps of 0.001.

<sup>6</sup>The complete set of phrases is available at <http://www.hlt.utdallas.edu/~saidul/stance.html>.

<sup>7</sup><https://datamarket.azure.com/dataset/bing/search>

ABO	125	10187	43.6
GAY	438	8148	62.5
OBA	205	9687	54.1
MAR	376	3333	57.7

Table 4: Noisy data statistics.

der to avoid overlaps with our evaluation datasets).

**Training with noisily labeled documents.** Given these noisily labeled documents, how can they be used in combination with the (cleanly labeled) debate posts in the training set for training stance classifiers? Motivated by Nguyen and Moschitti (2011), we train two stance classifiers,  $C_c$  and  $C_{c+n}$ .  $C_c$  is trained on only the debate posts in the training set.  $C_{c+n}$ , on the other hand, is trained on both the debate posts and the noisily labeled documents.<sup>8</sup> Both of them use the same set of features.

After training, we use these classifiers to predict the stance for a post  $x$  in the test set as follows. We first apply them independently to classify  $x$ , and then predict the stance for  $x$  by linearly interpolating the resulting classification values. The value of the interpolation constant is tuned to maximize performance on development data.<sup>9</sup>

### 3.4 Constraints

Previous work on stance classification of congressional debates has found that enforcing author constraints (ACs) can improve classification performance (e.g., Thomas et al. (2006)). ACs are a type of inter-post constraints that specify that two posts written by the same author for the same debate domain should have the same stance, and are typically used to postprocess the output of a stance classifier. We seek to determine how ACs impact the performance of a system for stance-classifying ideological debate posts, and whether their effectiveness depends on the debate domain.

In our experiments, we enforce ACs as follows. We first use a stance classifier to classify the test posts. Note that the classification value of a post can be thought of as a probabilistic vote that a post can cast on the stance labels. Then, given a set of

<sup>8</sup>We treat the noisily labeled documents as sequences of length one when using them to train HMMs and CRFs.

<sup>9</sup>We tried values from 0.0 to 1.0 in steps of 0.001. Note that when both frame-semantic features and noisily labeled documents are used, there are two interpolation constants to be tuned. In that case, we tune the constant associated with the frame-semantic features before tuning the one associated with the noisily labeled documents.

test posts written by the same author for the same debate domain, we sum up the probabilistic votes cast by these posts, and assign to each of them the stance that receives the larger number of votes.

## 4 Evaluation

In the previous section, we described the experimental setup for investigating the issues pertaining to the four dimensions of learning-based stance classification. In this section, we begin by describing the general experimental setup and then report on and discuss the evaluation results.

### 4.1 General Experimental Setup

Results are expressed in terms of *accuracy* obtained via 5-fold cross validation, where accuracy is the percentage of test instances correctly classified. Since all experiments require the use of development data for parameter tuning, we use three folds for model training, one fold for development, and one fold for testing in each fold experiment. All SVM and CRF learning parameters are set to their default values in SVM<sup>light</sup> and Mallet, respectively.

Learning curves are generated for all the experiments. Each point on a learning curve is computed by averaging the results of five independent runs corresponding to five different randomly selected training sets of the required size. To ensure a fair comparison of different learning models, the same five randomly selected training sets of the required size are used to train the models. Since the models based on HMMs and CRFs need to be trained on post sequences, we assemble a training set of a given size as follows: whenever a post is sampled for inclusion into the training set, we incorporate all the posts in the same post sequence into the training set.

### 4.2 Results

Results for the four domains are shown as four sub-tables in Table 5. Owing to space limitations, we do not show the learning curves. Rather, we show results for three selected points on each learning curve, which correspond to the three major columns in each sub-table. For instance, for Abortion, the three selected points correspond to training set sizes of 300, 600, and 1000. Within each major column there are six columns corresponding to the six learning models, among which the two fine-grained models are marked with the

Table 5: Five-fold cross-validation accuracies for the four domains.

superscript ‘F’. There are five rows in each sub-table. The ‘W’ row shows the results when only n-gram features are used. The ‘A’ row shows the results when Anand et al.’s (2011) features are used. The ‘A+FS’ row shows the results when both Anand et al.’s features and frame-semantic features are used. The last two rows show the results when noisily labeled documents and author constraints are added incrementally to A+FS.

To determine statistical significance, we conduct paired  $t$ -tests ( $p < 0.05$ ). These significance tests can be divided into three groups. The first group aims to determine whether the performance difference between the two systems shown in consecutive rows in a given column is statistically significant. If a number is marked with a dagger (†), it means that the performance difference between the corresponding system and the one in the previous row is statistically significant. The second group aims to determine whether the performance difference between two learning models are significant. We tested significance for three pairs of learning models: (1) SVM and NB; (2) NB and HMM; and (3) HMM<sup>F</sup> and CRF. If a number is marked with an asterisk (\*), it means

that the performance difference between the corresponding learning model and the one in the same pair is statistically significant.<sup>10</sup> The third group aims to determine whether the performance difference between NB/HMM and the corresponding fine-grained version of the model is statistically significant. If a number for a fine-grained model (NB<sup>F</sup>, HMM<sup>F</sup>) is marked with a double dagger (‡), it means that the performance difference between the model and its corresponding coarse-grained version (NB, HMM) is significant.

### 4.3 Discussion

**Q:** Can we improve performance by increasing the number of stance-labeled posts in the training set?

**A:** Yes. Keeping other factors constant, as we increase the number of (cleanly labeled) training posts from 100 to 500, we see significant improvements on all four domains: accuracies increase by 1.5, 2.4, 2.0, and 3.1 points for ABO, GAY, OBA, and MAR, respectively. As we further increase the number of training posts from 500 to 1000, we see

<sup>10</sup>If a number under the NB column is marked with an asterisk, it means that the performance difference between NB and SVM is significant.

another significant rise in performance: accuracies improve by 2.7 and 1.3 points for ABO and GAY, respectively. For ABO, GAY, and OBA, increasing the training set size seems to have a more positive impact on systems employing a simple feature set (W) than on those employing richer feature sets. Other than that, the degree of improvement does not seem to be dependent on the complexity of the model and the richness of the feature set.

**Q:** Which model is better, NB or SVM?

**A:** There is no clear winner. Other factors being equal, SVM beats NB significantly in 17% of the cases, NB beats SVM significantly in 27% of the cases, and the two are statistically indistinguishable in the remaining cases. Neither generative models nor discriminative models seem to have an advantage over the other for this task.

**Q:** Are the sequence models better than their non-sequence counterparts?

**A:** Yes. Comparing NB and HMM, we see that HMM consistently outperforms NB significantly, with improvements ranging from 1.6 to 2.2 points for the four domains. Now, comparing HMM and CRF, we see that while CRF does not always perform significantly better than HMM, in no case does it perform significantly worse.<sup>11</sup> Taken together, both sequence learners perform significantly better than NB. Since NB and SVM perform at the same level, we can conclude that sequence models indeed offer better performance.

**Q:** Are the fine-grained models better than their coarse-grained counterparts?

**A:** Considering HMM and HMM<sup>F</sup>, the answer is yes: HMM<sup>F</sup> beats HMM significantly by 1.1 to 2.1 points for the four domains. Considering NB and NB<sup>F</sup>, the answer is mostly yes: NB<sup>F</sup> beats NB significantly by 1.2 to 2.3 points for GAY and OBA respectively. For the remaining domains, NB<sup>F</sup> performs significantly better than NB in most cases, especially when the n-gram feature set and the Anand et al.'s feature set are used.

**Q:** Which is the best model?

**A:** HMM<sup>F</sup> and CRF achieve the best results, but there is no clear winner between them. Other factors being equal, CRF beats HMM<sup>F</sup> significantly in 26% of the cases, HMM<sup>F</sup> beats CRF significantly in 21% of the cases, and the two are statistically indistinguishable in the remaining cases.

<sup>11</sup>Significance test results between HMM and CRF are not shown in Table 5 due to space limitations.

**Q:** Is Anand et al.'s feature set (A) stronger than the n-gram feature set (W)?

**A:** Although the A systems generally yield small improvements (<1%) over the corresponding W systems, only 42% of those cases represent significant improvements. On the other hand, the W systems beat the corresponding A systems less than 15% of the times, and less than 10% of those cases represent significant improvements.

**Q:** Are frame-semantic features (FS) useful?

**A:** Yes. Apart from a few cases in ABO, the A+FS systems significantly outperform the corresponding A systems by 1.5–2.2 accuracy points for the four domains.

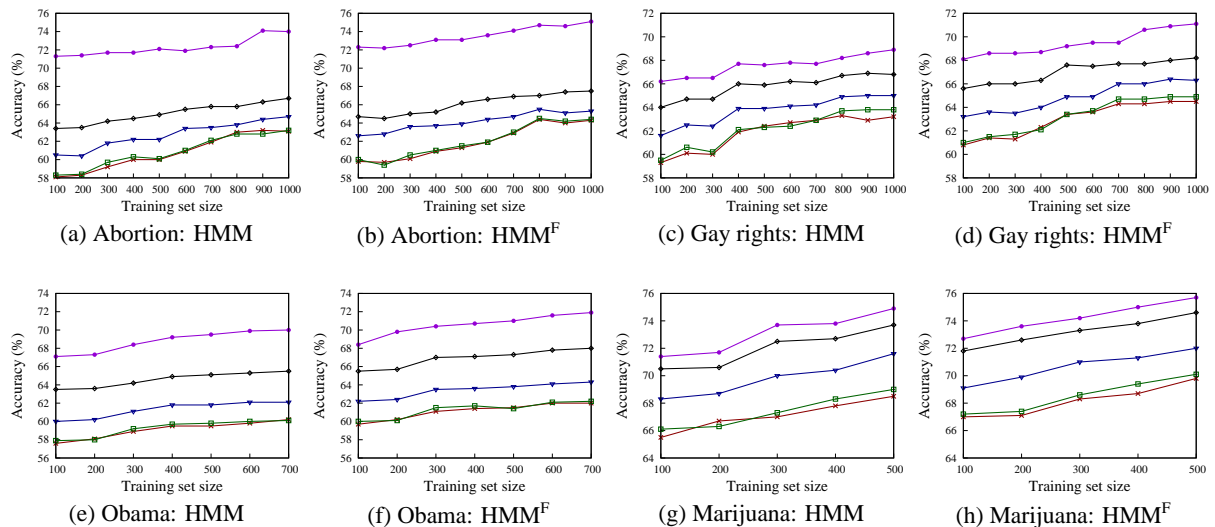

**Q:** Does using noisily labeled documents help improve performance?

**A:** Yes. Comparing A+FS and A+FS+N, we see that employing noisily labeled documents consistently yields a significant improvement of 1.8 to 3.3 points for the four domains, regardless of which learning model is used. For ABO and GAY, the improvement that we obtain out of the noisy data decreases as we increase the number of (cleanly labeled) debate posts. However, for OBA and MAR, we do not see such diminishing returns. This could be explained by the difference in the quality of the noisily labeled documents acquired for the different domains, but additional experiments are needed to determine the reason.

**Q:** Do ACs have different degrees of impact in different domains? If so, why?

**A:** Yes, ACs do seem to have different degrees of impact in different domains: on average, the addition of ACs yields a 7% improvement in ABO, a 2-3% improvement in GAY, a 4% improvement in OBA, and a <1% improvement on MAR. We hypothesize that this difference has to do with the percentage of test posts to which ACs can be applied successfully (i.e., an incorrect stance prediction will be turned into a correct one after applying ACs). To test this hypothesis, we take a closer look at two runs, an ABO run where HMM<sup>F</sup> is trained on 1000 posts and a MAR run where HMM<sup>F</sup> is trained on 500 posts. If our hypothesis is correct, then a larger fraction of the test posts in ABO should become correctly classified after the application of ACs. Indeed, the results are consistent with our hypothesis: we find that more than 8% of the test posts in ABO become correctly classified after applying ACs, while the corresponding number for MAR is less than 2%.

## Appendix: Learning Curves

The eight graphs above are the learning curves for HMM and HMM<sup>F</sup> for the four domains. The five curves in each graph correspond to the configurations in the five rows of each sub-table in Table 5. In each graph, the best-performing configuration is A+FS+N+AC, which is followed by A+FS+N and then A+FS. There is no clear winner between W and A, but the latter tends to outperform the former as the amount of training data increases.

## Abstract

This paper describes a corpus comprised of university entrance examinations, which is aimed to promote research on NLP-based problem solving. Since entrance examinations are created for quantifying human ability of problem solving, they are a desirable resource for benchmarking NLP-based problem solving systems. However, as entrance examinations involve a variety of subjects and types of questions, in order to pursue focused research on specific NLP technologies, it is necessary to break down entire examinations into individual NLP subtasks. For this purpose, we provide annotations of question classifications in terms of answer types and knowledge types. In this paper, we also describe research issues by referring to results of question classification, and introduce two international shared tasks that employed our resource for developing their evaluation data sets.

## 1 Introduction

This paper introduces natural language corpora whose source texts are taken from university entrance examinations. This resource has been developed aiming at benchmarking NLP systems for problem solving. In general, entrance examinations are mostly described in natural language, and the goal of reading the text is clear, viz., to solve questions. Therefore, this is an ideal resource for evaluating end-to-end NLP systems that read natural language text, perform some information processing, and output answers.

University entrance examinations have several desirable features to be used for benchmarking NLP-based problem solving. They are carefully designed for empirically quantifying a certain

ability of high-school-level students. Therefore, it is not a trivial task for NLP systems to solve university entrance examinations. On the other hand, it is guaranteed that required knowledge is fairly restricted, and legitimate solutions always exist. Despite such artificial restrictions, investigating the entire process of solving entrance examinations is meaningful, because it is expected to reveal true contributions of current NLP technologies to human-like problem solving tasks. In addition, evaluation results are intuitively understandable, and can be compared directly with human performance. This provides us with empirical evidence for analyzing the relationships between human intelligence and artificial intelligence.

While it is now clear that university entrance examinations are a useful resource for NLP benchmarking, it is also true that they will not be appropriate for focusing on individual NLP tasks, because they involve a variety of subjects and types of questions. It is almost hopeless to invent a single clever algorithm that can solve all types of questions. Therefore, it is necessary to break down entire examinations into NLP subtasks that can be investigated solely. For this aim, we annotate classifications of questions, which allow us to isolate specific NLP subtasks for focused research. An important point here is that, question classification allows us to extract individual NLP tasks, but, at the same time, their contributions to entire performance are always accessible. Therefore, our resource is inherently different from NLP resources that focus on monolithic NLP tasks/applications in nature, such as parallel corpora for machine translation research and evaluation data sets for question answering. Owing to question classifications, subsets of our resources have been adopted in international shared tasks for recognizing textual entailment and reading comprehension, which will also be mentioned in this paper.

Standardized tests for high-school-level stu-

dents are widely accepted in the world; examples include SAT (U.S.), Baccalauréat (France), Suneung (Korea), Gao Kao (China), and Center Test (Japan). In this work, we collect source texts from examinations of Center Test in Japan. Center Test has additional advantages as a NLP resource, because texts are free from copyright issues, and questions are given in a multiple-choice style, which allows for automatic evaluation.

The contributions of this paper are summarized as below:

- Describes details of the design of resources developed from university entrance examinations.
- Classifies questions from the NLP point of view, and discusses research issues involved.
- Introduces present use cases of our resources to show their effectiveness.

The resources introduced in this paper are made available for research purposes. As we will see below, this resource involves a variety of research issues in NLP and related AI technologies, and thus collaborative research based on such open resources is indispensable.

## 2 Motivation

Current NLP corpora can be classified into two types. One is to focus on specific fundamental NLP technologies, such as Penn Treebank (Marcus et al., 1993) developed for parsing research. The other is application-oriented data sets, meaning that corpora are used for evaluating specific NLP applications, such as machine translation and question answering (Voorhees and Buckland, 2012; Kando et al., 2011). However, despite significant advancement achieved by these resources, it is still unclear how far current NLP technologies have approached human intelligence, in particular, about the ability of generic problem solving. In the current NLP, research topics are inherently determined when corpora are developed, and there is no room for investigating performances of NLP technologies from a holistic view.

Our primary motivation to develop a corpus of university entrance examinations is to provide an open data set that encourages research on end-to-end NLP systems for problem solving. By investigating the entire process of solving various types

of examinations, we expect to recognize contributions of current NLP technologies and methodologies for integrating them from a holistic view.

For this purpose, university entrance examinations have several advantages as a benchmark, as explained below.

**Open but restricted real-world task** Since university entrance examinations are developed for empirically quantifying a certain ability of humans, solving them is not a toy task. However, because questions must be solvable by high-school students, this task requires much smaller knowledge space than contemporary NLP applications such as Web-scale question answering. Therefore, we can focus on algorithms of problem solving rather than relying on huge data.

**Fair and clear evaluation criteria** Intrinsically, standardized tests of university entrance examinations are carefully designed to guarantee fairness. To be more concrete, it is guaranteed that correct answers always exist, and everybody agrees with correct answers. This means that gold standard data is given at almost perfect agreement, which is an ideal feature as a benchmark. In addition, questions of Center Test are given in a multiple-choice style, which allows for automatic evaluation.

**Necessity of heterogeneous NLP tasks** Since university entrance examinations are aimed at quantifying various aspects of human intelligence, various forms of questions are developed in a variety of subjects. Therefore, to develop an end-to-end system to solve questions, multiple NLP components have to work in a collaborative manner. In some cases, they have to be connected to non-NLP components, such as mathematical solvers and ontology-based inference engines. Thus, investigating entrance examinations promotes interdisciplinary research within NLP, as well as with outside of NLP.

This also indicates the difficulty of focused research on individual NLP technologies. Therefore, we provide annotations for question classification, which enables us to extract a subset of examinations that is relevant to focused NLP tasks (see Section 3 and 4).

**Comparison to human performance** In our framework, overall performance of NLP systems is quantified as *scores*, which are directly comparable with human performance. We can therefore

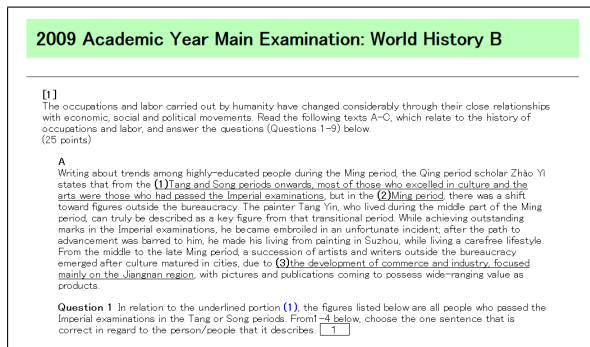

Figure 1: A screenshot of university entrance examination (2009 Center Test World History B)

recognize advantages and disadvantages of current NLP technologies compared to human problem solving. We can also empirically investigate relationships between NLP technologies and human ability of language understanding. Although NLP systems do not necessarily imitate human language processing, it is scientifically interesting to explore such relationships.

A possible criticism to our resource would be on its practical value. It is obvious that solving entrance examinations by NLP systems does not have any practical value. However, our intention is on the investigation of the whole process of problem solving. We believe that such holistic analysis of problem solving contributes to better understanding of current NLP technologies.

Another criticism would be on the reason why we focus on *university* entrance examinations, rather than easier questions, such as elementary school tests and TOEFL-like English tests. In this respect, we argue that university entrance examinations are most appropriate as a NLP benchmark. In preliminary investigation, we found that easy tests like elementary school tests rely more on generic knowledge and common sense, probably because the knowledge space and the vocabulary that can be used are too restricted. On the other hand, examinations in more expertized areas, such as medical license tests, are more uniformly developed and involve a less variety of NLP subtasks.

### 3 Resources

This section describes details of the resources we have developed. As we stated in Section 2, our primary aim is to investigate the entire process of problem solving related to natural language understanding. Therefore, we prepare data sets in which

Table 2: Summary of annotated resources

sion in Japan (a.k.a. Center Test).<sup>1</sup> Center Test is a nation-wide standardized test for university admission in Japan, and almost all high-school students who aim to enter a university in Japan take this exam. Therefore, questions are carefully designed in order to accurately quantify achievement levels of high-school students.

Table 1 shows a summary of source texts. The Center Test corpus includes examination texts from eleven subjects, namely, *World History*, *Japanese History*, *Modern Society*, *Politics & Economics*, *Ethics*, *Physics*, *Chemistry*, *Biology*, *Mathematics*, *Japanese (native language)*, and *English (foreign language)*, used in the years from 1990 to 2011.<sup>2</sup> In each year, a single main examination and a couple of additional examinations are available. In total, we have obtained 571 examinations, each of which contains 30-50 questions. The numbers of questions and sentences are also shown in the table, indicating a comprehensive amount as a corpus for NLP research.

While original texts are in Japanese (except for English tests), a part of examinations of World History, Politics & Economics, Physics, Chemistry, and Biology, are translated into English, in order to allow researchers to work on English NLP as well as cross-lingual NLP.

In addition to examinations, we collected textbooks of World History, Japanese History, Modern Society, Politics & Economics, Ethics, and Biology. Questions in these subjects often ask to recognize *facts*, such as historical facts and biological processes. Because textbooks describe such facts, we can use textbooks as knowledge sources for solving such questions. In fact, these textbooks were adopted as knowledge sources in a shared task on recognizing textual entailment (Section 5).

For these text data, we annotated document structures, question types, technical terms, dependency trees, and coreferences (see Table 2), which are explained in the consecutive sections.

<sup>1</sup><http://www.dnc.ac.jp/>

<sup>2</sup>Examination corpora of Geography, Geology, and General Science are under construction.

question	A question region including outermost question areas and minimal areas. An ID is assigned to each element. Question regions that do not include other question regions are given the attribute <code>minimal="yes"</code> , indicating smallest units of questions.
instruction	A statement or an instruction for a question.
data	Data provided to test-takers of reference, including not only texts but also images, tables, graphs, etc.
label	A label such as section numbers, question numbers, identifiers of text fragments, etc.
ansColumn	An identifier of an answer column. Each answer column is given a unique ID, which is referred to in answer data.
choices	A set of choices.
choice	An individual choice. The attribute <code>ra="yes"</code> denotes correct choices.
cNum	An identifier of a choice.
ref	A symbol that refers to another text fragment, such as underlined texts. A referred text fragment is denoted by the attribute <code>target</code> .
uText	An underlined text fragment. A unique ID is assigned when the text fragment is referred to by <code>ref</code> .

Table 3: Document structure tags

### 3.2 Document Structure Annotation

Examination texts are highly structured, while the automatic recognition of document structures is still a challenging task (Schäfer and Weitz, 2012). Therefore, our resource is provided with human-annotated document structures in the form of XML, as shown in Figure 2. Table 3 shows an excerpt of XML tags used for the annotation.<sup>3</sup> In addition to document structures, texts are also annotated with extra-linguistic markups, such as underlines (`uText`) and references (`ref`).

Owing to the document structure annotations, users can easily extract questions and relevant text regions. For example, a complete list of individual questions can be obtained by extracting elements `<question minimal="yes">`, and their corresponding answer columns and choices can also be extracted easily. Furthermore, text fragments referred to by a label like “(1)” can be obtained by following the attribute `target` of `ref` (see the example in Figure 2).

Formulas play crucial roles in examinations of Science and Mathematics. Although understanding of semantics of formulas is indispensable, the

<sup>3</sup>The complete list and the definitions of tags are provided together with annotated corpora.

<i>Answer types</i>	
sentence	Choices are described by sentences.
term	Choices are described by terms (e.g. person names).
image	Choices are represented by images or parts of an image.
formula	Choices are represented by formulas.
combination	Choices are described by a combination of sentences, terms, etc.
<i>Knowledge types</i>	
KS	An external knowledge source (e.g. textbooks) is required.
RT	Reading comprehension of a text given within a question is required.
IC	Image comprehension is necessary.
GK	General knowledge is required.
DM	Domain-specific inference (e.g. laws of dynamics) is required.

Table 4: Top-level categories for question classification

From 1-4 below, choose the one sentence that is correct in regard to the person/people that it describes.  
(1) Ouyang Xiu and Su Shi are writers representative of the Tang period.  
(2) Yan Zhenqing is a calligrapher representative of the Song period.  
(3) Wang Anshi, who lived during the Song period, carried out reforms called the New Policies (xin fa).  
(4) Qin Hui came into conflict with the party in favor of war, concerning the relationship with the Yuan.

Figure 3: A true-or-false question

semantic analysis of formulas is not trivial and is beyond the scope of NLP research. Therefore, we marked up all formulas that appear in examination texts with MathML.

### 3.3 Question Type Annotation

As mentioned in Section 2, university entrance examinations involve a variety of NLP subtasks, which prevents us from focusing on individual NLP tasks. In order to extract questions of interest, we annotate each question with classification categories. By extracting questions assigned specific categories, we can obtain a subset of examinations on which isolated NLP tasks can be studied.

Table 4 shows a subset of top-level categories for question classification. Questions are classified according to two perspectives. The *answer type* specifies the format of answers. For example, if choices are presented with a sentence, it is assigned the category *sentence*, which typically indicates *true-or-false questions* as exemplified in Figure 3. If *term* is assigned, the question is likely to be a *factoid-style question*. These categories are further classified into sub categories; for example,

*term* is divided by term categories (e.g. *person names*), while *combination* is further classified with elements of combinations. In total, 25 answer type categories are annotated.

The *knowledge type* describes the types of knowledge that are necessary to solve the question. While Table 4 shows representative top-level categories, they are further divided into fine-grained categories, and, in total, 90 knowledge type categories are annotated. For example, *KS* indicates that to answer the question requires referring to an external knowledge source like textbooks (e.g. Figure 3). This type of questions typically appear in examinations of Social Studies. *RT* indicates a similar type of questions, but necessary information is given as a text within an examination. Therefore, reading comprehension is necessary. *DM* means domain-specific inference is necessary depending on a subject. Individual domains are annotated with finer-grained categories, like *physical mechanics* and *electromagnetics*. For example, to solve questions of physical dynamics, calculation of formulas based on laws of dynamics is required. *GK* indicates any other type of knowledge, such as *typical situations and reactions in a restaurant*. Since the knowledge space is not strictly restricted, we suppose this is the most difficult type of questions for NLP systems.

In Section 4, we will discuss research issues involved in our resource, by observing results of question classification described here.

### 3.4 Linguistic Annotation

In addition to document structures and question classifications, we have developed resources annotated with technical terms, dependency trees, and coreference relations, in order to support research on fundamental NLP tools.

Technical terms are annotated to examinations and textbooks of World History, Japanese History, Modern Society, Politics & Economics, Ethics, and Biology. These subjects are selected because, as we will see in Section 4, a majority of questions in these subjects are either true-or-false or factoid-style questions, which can be approached by searching textbooks for relevant evidences. In such a scenario, technical terms are crucial keys for accurate search. For example, to solve the question shown in Figure 3, it is necessary to correctly recognize relationships among named entities like *Ouyang Xiu* and *the Tang period*.

	W. Hist.	J. Hist.	M. S.	P. & E.	Ethics	Bio.
instance	8864 (52.1)	5876 (35.5)	2558 (24.3)	2279 (22.6)	2556 (28.8)	90 (0.6)
class	5592 (32.9)	7808 (47.2)	5084 (48.4)	4779 (47.3)	1237 (14.0)	2382 (15.6)
both	2557 (15.0)	2848 (17.2)	2867 (27.3)	3039 (30.1)	5072 (57.2)	12790 (83.8)
# terms	17013 (100.0)	16532 (100.0)	10509 (100.0)	10097 (100.0)	8865 (100.0)	15262 (100.0)
# sentences	5797	5571	3674	3352	3245	4215

Table 5: Statistics of technical term annotations

	W. Hist.	J. Hist.	M. S.	P. & E.	Ethics
True-or-false question	1854 (73.6)	1308 (55.6)	1102 (79.5)	805 (88.6)	656 (81.8)
Factoid question	464 (18.4)	557 (23.7)	192 (13.9)	62 (6.8)	128 (16.0)
Reading comprehension	102 (4.0)	146 (6.2)	43 (3.1)	3 (0.3)	88 (11.0)
General knowledge	1 (0.0)	0 (0.0)	92 (6.6)	8 (0.9)	114 (14.2)
Image comprehension	222 (8.8)	198 (8.4)	111 (8.0)	101 (11.1)	17 (2.1)
# questions	2519 (100.0)	2351 (100.0)	1386 (100.0)	909 (100.0)	802 (100.0)

Table 6: Classification of questions (Social Studies)

We analyzed our corpus of examinations and textbooks, and developed an ontology of technical terms, which involves 72 categories. Their occurrences in examinations and textbooks are annotated manually. Table 5 shows statistics of technical term annotations on examinations.<sup>4</sup> Annotated terms not only include typical named entities (i.e. *instances*) like *person names*, but also include *class concepts* that describe domain-specific abstract terms, such as *genetic trait*. Several categories may include both instance terms and class terms (denoted as “both” in the table); for example, the category *artwork* includes *Isenheim Altarpiece* (instance) and *miniature* (class). Interestingly, the distributions of terms imply characteristics of each subject; for example, World History concerns named entities, while Biology is more focused on abstract concepts.

Dependency trees and coreferences are annotated in order to assess the performance of fundamental NLP tools including dependency parsers and coreference resolution systems. It is expected that these NLP tools work reasonably well on texts of examinations and textbooks, because in general texts in these domains are written in an unambiguous and easy-to-understand way. Currently, we have annotated a subset of a textbook of World History, and will extend the data as necessary.

#### 4 Analysis of Questions

This section discusses research issues involved in solving the university entrance examinations, by analyzing question classification results. Table 6, Table 7, and Table 8 show the number of

questions and its ratio (shown in brackets) classified into each category, for examinations of Social Studies, Science, and English/Japanese, respectively.<sup>5</sup> These classifications are obtained from answer type and knowledge type annotations introduced in Section 3, while classification categories are summarized and reinterpreted for readability.

For Social Studies (Table 6), it is obvious that most of the questions can be classified into *true-or-false* and *factoid-style questions*. Low ratios of *reading comprehension* and *general knowledge* indicate that most of the questions can be solved only by referring to external knowledge sources. This is promising, because current question answering methods and/or search-based methods would suffice. As we will see in Section 5, these types of questions have already been tackled in international shared tasks.

For Science subjects (Table 7), Biology looks similar to Social Studies, while results on Physics and Chemistry reveal different characteristics. Almost all questions in these subjects are annotated as *domain-specific inference*, indicating that simply referring to knowledge sources does not suffice, and inference engines, such as formula processing modules and ontology-based reasoning, will be required. In particular, nearly half of the questions in Physics are answered in *formulas*, indicating necessity of formula processing. The integration of NLP components with formula processing should be an interesting frontier.

Results on English and Japanese are totally different. They contain questions at different levels of difficulty. Questions that ask *lexi-*

<sup>4</sup>The statistics for textbooks is omitted for space limitation, but the tendency of the distribution is similar.

<sup>5</sup>The sum of ratios exceeds 100%, because a question might be classified into multiple categories.

	Physics	Chemistry	Biology
True-or-false question	390 (24.4)	578 (32.5)	938 (52.5)
Factoid question	239 (15.0)	367 (20.7)	564 (31.6)
Formula	683 (42.8)	399 (22.5)	136 (7.6)
Domain-specific inference	1594 (99.9)	1764 (99.3)	522 (29.2)
Reading comprehension	0 (0.0)	3 (0.2)	31 (1.7)
General knowledge	64 (4.0)	0 (0.0)	2 (0.1)
Image comprehension	1105 (69.3)	291 (16.4)	420 (23.8)
# questions	1595 (100.0)	1776 (100.0)	1767 (100.0)

Table 7: Classification of questions (Science)

	English	Japanese
Lexical knowledge	1085 (44.8)	778 (36.4)
Grammatical knowledge	703 (29.0)	126 (5.9)
Literature knowledge	0 (0.0)	36 (1.7)
Reading comprehension	892 (36.8)	872 (40.8)
Situation comprehension	1213 (50.1)	232 (10.8)
Rhetorical structure	0 (0.0)	173 (8.1)
Translation	0 (0.0)	465 (21.7)
Image comprehension	402 (16.6)	0 (0.0)
# questions	2423 (100.0)	2139 (100.0)

Table 8: Classification of questions (English and Japanese)

*cal/grammatical/literature knowledge* should be tractable for current NLP systems. However, a significant portion of questions involves *reading comprehension*, which is an outstanding problem in NLP. Research on reading comprehension is recently emerging (Peñas et al., 2011a; Peñas et al., 2011b), while the achievements are still far from satisfactory. Furthermore, English examinations involve a large portion of *situation comprehension* (e.g. selecting an appropriate conversation in a restaurant) and *image comprehension* (e.g. choosing an appropriate description of a given image), which are enormously difficult research issues. In this respect, achieving high scores in English tests can be an ultimate goal of the present effort.

While Mathematics is not shown in the tables, it is totally different from the subjects discussed above. Solving mathematics questions essentially consists of two components. One is natural language understanding, which converts text expressions into mathematical formulas, and the other is mathematical formula processing. Therefore, the primary research issues are to design an interface between the two components, and to increase the accuracy of the two components.

## 5 Use Cases

In addition to individual studies, two international shared tasks have adopted subsets of our resources for creating their evaluation data sets. Here we

<i>t</i> : In the period of Emperor Shenzong in the Baisong dynasty, Wang Anshi introduced and promulgated his reform policy (xin fa).
<i>h</i> : Wang Anshi, who lived during the Song period, carried out reforms called the New Policies (xin fa).

Figure 4: A text pair for recognizing textual entailment created from a World History examination.

briefly introduce these works, which prove the effectiveness of our resources for NLP research.

### 5.1 Recognizing Textual Entailment

The RITE task at the NTCIR conference is a shared task on recognizing textual entailment (Watanabe et al., 2013). RITE consisted of several subtasks, one of which adopted a subset of our resource as an evaluation data set. As described in Section 4, a significant portion of Social Studies consists of true-or-false questions, which can be solved by recognizing textual entailment relations. For example, Figure 3 shows a typical true-or-false question. Test-takers are required to find relevant facts from their knowledge, and judge whether each sentence is true or false. For NLP systems, this corresponds to finding an evidential text from a knowledge source like a textbook or Wikipedia, and judge whether a text fragment in the knowledge source *entails* each sentence. In fact, by extracting a relevant text from Wikipedia, we can create a text pair as shown in Figure 4, which can be used as evaluation data for recognizing textual entailment.

In the RITE task, true-of-false questions are extracted from four subjects, namely, World History, Japanese History, Modern Society, and Politics & Economies, while evidential texts are provided from Wikipedia and textbooks. In total, 510 text pairs are provided as a training set, and 448 pairs as a test set.

While the RITE task reveals that recognizing textual entailment can be applied directly to true-or-false questions, this is not the only solution

for this type of questions. Actually, Kanayama et al. (2012) demonstrated a method for applying a factoid-style question answering system to solve true-or-false questions, and evaluated their system using a World History portion of our resource. This reveals that a variety of approaches can be attempted to achieve the same goal, i.e., solving examinations.

## 5.2 Reading Comprehension

Shared tasks called Question Answering for Machine Reading Evaluation (QA4MRE) at the CLEF conferences (Peñas et al., 2011a; Peñas et al., 2011b) have been focusing on NLP technologies for reading comprehension tasks. In the task setting of QA4MRE, a short document is given, and systems are required to answer multiple-choice questions by reading the given document. Because given texts are small, methods that rely on huge texts as in typical question answering systems cannot be applied, while accurate and deep analysis of given texts is necessary. Original evaluation data sets for QA4MRE have been developed from scratch, focused on several topics like “Aids” and “Climate Change.”

In QA4MRE at CLEF 2013,<sup>6</sup> a pilot task that uses reading comprehension questions from English tests of our resource has been organized. The novelty of this pilot task is that questions are originally developed for assessing human English ability, rather than specifically developed for NLP system evaluation. Therefore, it is expected that various aspects of human natural language understanding appear in solving such questions.

## 6 Related Work

Recent advancement of empirical NLP owes much to language resources, such as annotated corpora and lexicons. Language resources to date have been developed specifically for focused NLP tasks, such as syntactic/semantic parsing, coreference resolution, and word sense disambiguation (Marcus et al., 1993; Kingsbury and Palmer, 2002; Hovy et al., 2006; Ide et al., 2010; Tateisi et al., 2005; Kawahara et al., 2002; Iida et al., 2007). Another type of corpora has been developed for evaluating NLP applications, such as machine translation and question answering, which are often provided in application-oriented evaluation campaigns (Voorhees and Buckland, 2012; Kando

<sup>6</sup><http://celct.fbk.eu/QA4MRE/>

et al., 2011; Catarci et al., 2012). In other words, the development of language resources is initiated by the demand for NLP tasks/applications. However, the resources presented in this paper are motivated in an opposite way. We start from texts that involve problem solving by humans, i.e., university entrance examinations, and by analyzing them we can identify NLP tasks that we have to tackle with. It can be said that the framework and the resources described in this paper provide another direction of NLP research.

NLP research that develops benchmark data from questions originally designed for evaluating human performance has also been emerging. For example, the Halo project (Angele et al., 2003) targeted Chemical tests, while IBM’s Deep QA (Ferrucci, 2012) employed factoid-style quizzes. However, their benchmark data sets are not open, and therefore collaborative research based on shared standard data cannot be pursued. Collaborative research is indispensable for our purpose, because entrance examinations involve a variety of NLP subtasks, and a single research group cannot solve the entire problem. Therefore, it is necessary to develop open resources as described in this paper.

## 7 Conclusion

We have introduced an NLP resource that is developed from university entrance examinations, aiming at the development and the evaluation of end-to-end NLP systems for problem solving. In total 571 examinations are collected from 11 subjects, involving 17260 individual questions, revealing a comprehensive resource for NLP benchmarking.

While the ultimate goal is to develop an integrated NLP system that can solve a wide range of questions, this also means it is difficult to focus on individual NLP subtasks. Therefore, we annotated question classifications so that users can extract fragments of the resource that are relevant to a focused NLP subtask. In fact, subsets of our resources have already been adopted by two international shared tasks, namely, NTCIR RITE for recognizing textual entailment, and CLEF 2013 QA4MRE, for reading comprehension.

In order to encourage collaborative and interdisciplinary research, the resources described in this paper are made available for research purposes.<sup>7</sup>

<sup>7</sup>The resource is available at <http://21robot.org/>.

# Linguistically Aware Coreference Evaluation Metrics

Chen Chen and Vincent Ng

Human Language Technology Research Institute

University of Texas at Dallas

Richardson, TX 75083-0688

{yzcchen, vince}@hlt.utdallas.edu

## Abstract

Virtually all the commonly-used evaluation metrics for entity coreference resolution are linguistically agnostic, treating the mentions to be clustered as generic rather than linguistic objects. We argue that the performance of an entity coreference resolver cannot be accurately reflected when it is evaluated using linguistically agnostic metrics. Consequently, we propose a framework for incorporating linguistic awareness into commonly-used coreference evaluation metrics.

## 1 Introduction

Coreference resolution is the task of determining which mentions in a text or dialogue refer to the same real-world entity. Designing appropriate evaluation metrics for coreference resolution is an important and challenging task. Since there is no consensus on which existing coreference evaluation metric is the best, the organizers of the CoNLL-2011 and CoNLL-2012 shared tasks on unrestricted coreference (Pradhan et al., 2011, 2012) decided to take the average of the scores computed by three coreference evaluation metrics, MUC (Vilain et al., 1995), B<sup>3</sup> (Bagga and Baldwin, 1998), and CEAF<sub>e</sub> (Luo, 2005), as the official score of a participating coreference resolver.

One weakness shared by virtually all existing coreference evaluation metrics is that they are *linguistically agnostic*, treating the mentions to be clustered as generic rather than linguistic objects. In other words, while MUC, B<sup>3</sup>, and CEAF were designed for evaluating coreference resolvers, their linguistic agnosticity implies that they can be used to evaluate *any* clustering task, including those that are not linguistic in nature.<sup>1</sup>

<sup>1</sup>This statement is also true for BLANC (Recasens and Hovy, 2011), a Rand Index-based coreference evaluation metric we will not focus on in this paper.

To understand why linguistic agnosticity is a potential weakness of existing scoring metrics, consider a document in which there are three coreferent mentions, *Hillary Clinton*, *she*, and *she*, appearing in this order in the document. Assume that two coreference resolvers,  $R_1$  and  $R_2$ , are applied to these three mentions, where  $R_1$  only posits *Hillary Clinton* and *she* as coreferent, and  $R_2$  only posits the two occurrences of *she* as coreferent. Being linguistically agnostic, existing scoring metrics will assign the *same* score to both resolvers after seeing that both of them correctly assign two of the three objects to the same cluster. Intuitively, however,  $R_1$  should receive a higher score than  $R_2$ :  $R_1$  has facilitated automated text understanding by successfully finding the referent of one of the pronouns, whereas from  $R_2$ 's output we know nothing about the referent of the two pronouns. Failure to rank  $R_1$  higher than  $R_2$  implies that existing scoring metrics fail to adequately reflect the performance of a resolver.<sup>2</sup>

Our goal in this paper is to address the aforementioned weakness by proposing a framework for incorporating linguistic awareness into the most commonly-used coreference scoring metrics, including MUC, B<sup>3</sup>, and CEAF. Rather than making different modifications to different metrics, one of the contributions of our work lies in the proposal of a *unified* framework that enables us to employ the *same* set of modifications to create linguistically aware versions of all these metrics.

## 2 Existing Evaluation Metrics

In this section, we review four scoring metrics, MUC, B<sup>3</sup>, and the two versions of CEAF, namely,

<sup>2</sup>One may disagree that  $R_1$  should be ranked higher than  $R_2$  by arguing that successful identification of two coreferent pronouns is not necessarily easier than resolving an anaphoric pronoun to a non-pronominal antecedent. Our argument, however, is based on the view traditionally adopted in pronoun resolution research that resolving an anaphoric pronoun entails finding a non-pronominal antecedent for it.

CEAF<sub>m</sub> and CEAF<sub>e</sub>. As F-score is always computed as the unweighted harmonic mean of recall and precision, we will only show how recall and precision are computed. Note that unlike previous discussion of these metrics, we present them in a way that reveals their common elements.

## 2.1 Notation and Terminology

In the rest of this paper, we use the terms *coreference chains* and *coreference clusters* interchangeably. For a coreference chain  $C$ , we define  $|C|$  as the number of mentions in  $C$ . *Key chains* and *system chains* refer to gold coreference chains and system-generated coreference chains, respectively. In addition,  $\mathcal{K}(d)$  and  $\mathcal{S}(d)$  refer to the set of gold chains and the set of system-generated chains in document  $d$ , respectively. Specifically,

$$\mathcal{K}(d) = \{K_i : i = 1, 2, \dots, |\mathcal{K}(d)|\},$$

$$\mathcal{S}(d) = \{S_j : j = 1, 2, \dots, |\mathcal{S}(d)|\},$$

where  $K_i$  is a chain in  $\mathcal{K}(d)$  and  $S_j$  is a chain in  $\mathcal{S}(d)$ .  $|\mathcal{K}(d)|$  and  $|\mathcal{S}(d)|$  are the number of chains in  $\mathcal{K}(d)$  and  $\mathcal{S}(d)$ , respectively.

## 2.2 MUC (Vilain et al., 1995)

MUC is a link-based metric. Given a document  $d$ , recall is computed as the number of common links between the key chains and the system chains in  $d$  divided by the number of links in the key chains. Precision is computed as the number of common links divided by the number of links in the system chains. Below we show how to compute (1) the number of common links, (2) the number of key links, and (3) the number of system links.

To compute the number of common links, a partition  $P(S_j)$  is created for each system chain  $S_j$  using the key chains. Specifically,

$$P(S_j) = \{C_j^i : i = 1, 2, \dots, |\mathcal{K}(d)|\} \quad (1)$$

Each subset  $C_j^i$  in  $P(S_j)$  is formed by intersecting  $S_j$  with  $K_i$ . Note that  $|C_j^i| = 0$  if  $S_j$  and  $K_i$  have no mentions in common. Since there are  $|\mathcal{K}(d)| * |\mathcal{S}(d)|$  subsets in total, the number of common links is

$$c(\mathcal{K}(d), \mathcal{S}(d)) = \sum_{j=1}^{|\mathcal{S}(d)|} \sum_{i=1}^{|\mathcal{K}(d)|} w_c(C_j^i), \quad (2)$$

$$\text{where } w_c(C_j^i) = \begin{cases} 0 & \text{if } |C_j^i| = 0; \\ |C_j^i| - 1 & \text{if } |C_j^i| > 0. \end{cases}$$

Intuitively,  $w_c(C_j^i)$  can be interpreted as the “weight” of  $C_j^i$ . In MUC, the weight of a cluster is defined as the *minimum* number of *links* needed to create the cluster, so  $w_c(C_j^i) = |C_j^i| - 1$  if  $|C_j^i| > 0$ .

The number of links in the key chains,  $\mathcal{K}(d)$ , is calculated as:

$$k(\mathcal{K}(d)) = \sum_{i=1}^{|\mathcal{K}(d)|} w_k(K_i), \quad (3)$$

where  $w_k(K_i) = |K_i| - 1$ . The number of links in the system chains,  $s(\mathcal{S}(d))$ , is calculated as:

$$s(\mathcal{S}(d)) = \sum_{j=1}^{|\mathcal{S}(d)|} w_s(S_j), \quad (4)$$

where  $w_s(S_j) = |S_j| - 1$ .

## 2.3 B<sup>3</sup> (Bagga and Baldwin, 1998)

One of MUC’s shortcoming is that it fails to reward successful identification of singleton clusters. To address this weakness,  $B^3$  first computes the recall and precision for each mention, and then averages these per-mention values to obtain the overall recall and precision.

Let  $m_n$  be the  $n$ th mention in document  $d$ . Its recall,  $R(m_n)$ , and precision,  $P(m_n)$ , are computed as follows. Let  $K_i$  and  $S_j$  be the key chain and the system chain that contain  $m_n$ , respectively, and let  $C_j^i$  be the set of mentions appearing in both  $S_j$  and  $K_i$ .

$$R(m_n) = \frac{w_c(C_j^i)}{w_k(K_i)}, P(m_n) = \frac{w_c(C_j^i)}{w_s(S_j)}, \quad (5)$$

where  $w_c(C_j^i) = |C_j^i|$ ,  $w_k(K_i) = |K_i|$ , and  $w_s(S_j) = |S_j|$ .

## 2.4 CEAF (Luo, 2005)

While  $B^3$  addresses the shortcoming of MUC, Luo presents counter-intuitive results produced by  $B^3$ , which it attributes to the fact that  $B^3$  may use a key/system chain more than once when computing recall and precision. To ensure that each key/system chain will be used at most once in the scoring process, his CEAF scoring metric scores a coreference partition by finding an optimal *one-to-one mapping* (or *alignment*) between the chains in  $\mathcal{K}(d)$  and those in  $\mathcal{S}(d)$ .

Since the mapping is one-to-one, not all key chains and system chains will be involved in it. Let

$\mathcal{K}_{min}(d)$  and  $\mathcal{S}_{min}(d)$  be the set of key chains and the set of system chains involved in the alignment, respectively. The alignment can be represented as a one-to-one mapping function  $g$ , where

$$g(K_i) = S_j, K_i \in \mathcal{K}_{min}(d) \text{ and } S_j \in \mathcal{S}_{min}(d).$$

The score of  $g$ ,  $\Phi(g)$ , is defined as

$$\Phi(g) = \sum_{K_i \in \mathcal{K}_{min}(D)} \phi(K_i, g(K_i)),$$

where  $\phi$  is a function that computes the *similarity* between a gold chain and a system chain. The optimal alignment,  $g^*$ , is the alignment whose  $\Phi$  value is the largest among all possible alignments, and can be computed efficiently using the Kuhn-Munkres algorithm (Kuhn, 1955).

Given  $g^*$ , the recall (R) and precision (P) of a system partition can be computed as follows:

$$R = \frac{\Phi(g^*)}{\sum_{i=1}^{|\mathcal{K}(d)|} \phi(K_i, K_i)}, P = \frac{\Phi(g^*)}{\sum_{j=1}^{|\mathcal{S}(d)|} \phi(S_j, S_j)}.$$

As we can see, at the core of CEAF is the similarity function  $\phi$ . Luo defines two different  $\phi$  functions,  $\phi_3$  and  $\phi_4$ :

$$\phi_3(K_i, S_j) = |K_i \cap S_j| = w_c(C_j^i) \quad (6)$$

$$\phi_4(K_i, S_j) = \frac{2|K_i \cap S_j|}{|K_i| + |S_j|} = \frac{2 * w_c(C_j^i)}{w_k(K_i) + w_s(S_j)} \quad (7)$$

$\phi_3$  and  $\phi_4$  result in mention-based CEAF (a.k.a. CEAF<sub>m</sub>) and entity-based CEAF (a.k.a. CEAF<sub>e</sub>), respectively.

## 2.5 Common functions

Recall that the three weight functions,  $w_c$ ,  $w_k$ , and  $w_s$ , are involved in all the scoring metrics we have discussed so far. To summarize:

- $w_c(C_j^i)$  is the weight of the common subset between  $K_i$  and  $S_j$ . For MUC, its value is 0 if  $C_j^i$  is empty and  $|C_j^i| - 1$  otherwise; for B<sup>3</sup>, CEAF<sub>m</sub> and CEAF<sub>e</sub>, its value is  $|C_j^i|$ .
- $w_k(K_i)$  is the weight of key chain  $K_i$ . For MUC, its value is  $|K_i| - 1$ , while for B<sup>3</sup>, CEAF<sub>m</sub> and CEAF<sub>e</sub>, its value is  $|K_i|$ .
- $w_s(S_j)$  is the weight of system chain  $S_j$ . For MUC, its value is  $|S_j| - 1$ , while for B<sup>3</sup>, CEAF<sub>m</sub> and CEAF<sub>e</sub>, its value is  $|S_j|$ .

Next, we will show that simply by redefining these three functions appropriately, we can create linguistically aware versions of MUC, B<sup>3</sup>, CEAF<sub>m</sub>, and CEAF<sub>e</sub>.<sup>3</sup> For convenience, we will refer to their linguistically aware counterparts as LMUC, LB<sup>3</sup>, LCEAF<sub>m</sub>, and LCEAF<sub>e</sub>.<sup>4</sup>

## 3 Incorporating Linguistic Awareness

As mentioned in the introduction, one of the contributions of our work lies in identifying the three weight functions that are common to MUC, B<sup>3</sup>, CEAF<sub>m</sub>, and CEAF<sub>e</sub> (see Section 2.5). To see why these weight functions are important, note that *any interaction between a scoring metric and a coreference chain is mediated by one of these weight functions*. In other words, if these weight functions are linguistically agnostic (i.e., they treat the mentions as generic rather than linguistic objects when assigning weights), the scoring metric that employs them will be linguistically agnostic. On the other hand, if these weight functions are linguistically aware, the scoring metric that employs them will be linguistically aware.

This observation makes it possible for us to design a *unified* framework for incorporating linguistic awareness into existing coreference scoring metrics. Specifically, rather than making different modifications to different scoring metrics to incorporate linguistic awareness, we can simply incorporate linguistic awareness into these three weight functions. So when they are being used in different scoring metrics, we can handily obtain the linguistically aware versions of these metrics.

In the rest of this section, we will suggest one way of implementing linguistic awareness. This is by no means the only way to implement linguistic awareness, but we believe that this is a good starting point, which hopefully will initiate further discussions in the coreference community.

### 3.1 Formalizing Linguistic Awareness

Other than illustrating the notion of linguistic awareness via a simple example in the introduction, we have thus far been vague about what ex-

<sup>3</sup>Note that for a given scoring metric,  $w_c(C) = w_k(C) = w_s(C)$  for any non-empty chain  $C$ . The reason why we define three weight functions as opposed to one is that they are defined differently in the linguistically aware scoring metrics, as we will see.

<sup>4</sup>Our implementation of the linguistically aware evaluation metrics is available from <http://www.hlt.utdallas.edu/~yzcchen/coreference>.

actly it is. In this section, we will make this notion more concrete.

Recall that the goal of (co)reference resolution is to facilitate automated text understanding by finding the referent for each referring expression in a text. Hence, when resolving a mention, a resolver should be rewarded more if the selected antecedent allows the underlying *entity* to be inferred than if it doesn't, because the former contributes more to understanding the corresponding text than the latter. Note that the more *informative* the selected antecedent is, the easier it will be for the reader to infer the underlying entity. Here, we adopt a simple notion of linguistic informativeness based on the mention type: a name is more informative than a nominal, which in turn is more informative than a pronoun.<sup>5</sup> Hence, a coreference link involving a name should be given a higher weight than one that doesn't, and a coreference link involving a nominal should be given a higher weight than one that involves only pronouns.

We implement this observation by assigning to each link  $e_l$  a weight of  $w_l(e_l)$ , where  $w_l(e_l)$  is defined using the first rule applicable to  $e_l$  below:

**Rule 1:** If  $e_l$  involves a name,  $w_l(e_l) = w_{nam}$ .

**Rule 2:** If  $e_l$  involves a nominal,  $w_l(e_l) = w_{nom}$ .

**Rule 3:**  $w_l(e_l) = w_{pro}$ .

There is a caveat, however. By assigning weights to coreference *links* rather than mentions, we will be unable to reward successful identification of singleton clusters, since they contain *no* links (and hence they carry no weights). To address this problem, we introduce a singleton weight  $w_{sing}$ , which will be assigned to any chain that contains exactly one mention.

So far, we have introduced four weights,  $W = (w_{nam}, w_{nom}, w_{pro}, w_{sing})$ , which encode our (somewhat simplistic) notion of linguistic awareness. Below we show how these four weights are incorporated into the three weight functions,  $w_c$ ,  $w_k$ , and  $w_s$ , to create their linguistically aware counterparts,  $w_c^L$ ,  $w_k^L$ , and  $w_s^L$ .

### 3.2 Defining $w_c^L$

Recall that  $C_j^i$  represents the set of mentions common to key chain  $K_i$  and system chain  $S_j$ . To define the linguistically aware weight function  $w_c^L(C_j^i)$ , there are three cases to consider:

<sup>5</sup>Different notions of linguistic informativeness might be appropriate for different natural language applications. In our framework, a different notion of linguistic informativeness can be implemented simply by altering the weight functions.

#### Case 1: $|C_j^i| \geq 2$

Recall that the linguistically agnostic  $w_c$  function returns a weight of  $|C_j^i| - 1$ . This makes sense, because in a linguistically agnostic situation, all the links have the same weight, and hence the weight assigned to  $C_j^i$  will be the same regardless of which  $|C_j^i| - 1$  links in  $C_j^i$  are chosen. However, the same is no longer true in a linguistically aware setting: since the links may not necessarily have the same weight, the weight assigned to  $C_j^i$  depends on which  $|C_j^i| - 1$  links are chosen. In this case, it makes sense for our linguistically aware  $w_c^L$  function to find the  $|C_j^i| - 1$  links that have the largest weights and assign to  $w_c^L$  the sum of these weights, since they reflect how well a resolver managed to find informative antecedents for the mentions. Note that the sum of the  $|C_j^i| - 1$  links that have the largest weights is equal the weight of the maximum spanning tree defined over the mentions in  $C_j^i$ .

#### Case 2: $|C_j^i| = 0$

In this case  $C_j^i$  is empty, meaning that  $K_i$  and  $S_j$  do not have any mention in common.  $w_c^L$  simply returns a weight of 0 when applied to  $C_j^i$ .

#### Case 3: $|C_j^i| = 1$

In this case,  $K_i$  and  $S_j$  have one mention in common. The question, then, is: can we simply return  $w_{sing}$ , the weight associated with a singleton cluster? The answer is no: since  $w_{sing}$  was created to reward *successful* identification of singleton clusters, a resolver should be rewarded by  $w_{sing}$  only if it correctly identifies a singleton cluster. In other words,  $w_c^L$  returns  $w_{sing}$  if all of  $C_j^i$ ,  $K_i$  and  $S_j$  contain exactly one mention (which implies that the singleton cluster  $C_j^i$  is correctly identified); otherwise,  $w_c^L$  returns 0.

The definition of  $w_c^L$  is summarized as follows, where  $E$  is the set of edges in the maximum spanning tree defined over the mentions in  $C_j^i$ .

$$w_c^L(C_j^i) = \begin{cases} \sum_{e_l \in E} w_l(e_l) & \text{if } |C_j^i| > 1; \\ w_{sing} & \text{if } |C_j^i|, |K_i|, |S_j| = 1; \\ 0 & \text{otherwise.} \end{cases} \quad (8)$$

### 3.3 Defining $w_k^L$

Recall that  $w_k^L$  aims to compute the weight of key chain  $K_i$ . Given the definition of  $w_c^L$ , in order to ensure that the maximum recall is 1, it is natural to define  $w_k^L$  as follows, where  $E$  is the set of edges

appearing in the maximum spanning tree defined over the mentions in  $K_i$ .

$$w_k^L(K_i) = \begin{cases} \sum_{e_l \in E} w_l(e_l) & \text{if } |K_i| > 1; \\ w_{sing} & \text{if } |K_i| = 1. \end{cases} \quad (9)$$

### 3.4 Defining $w_s^L$

Finally, we define  $w_s^L$ , the function for computing the weight of system chain  $S_j$ . To better understand how we might want to define  $w_s^L$ , recall that in MUC, B<sup>3</sup>, and both versions of CEAF, precision and recall play a symmetric role. In other words, precision is computed by reversing the roles of the key partition  $\mathcal{K}(d)$  and the system partition  $\mathcal{S}(d)$  used to compute recall for document  $d$ . If we wanted precision and recall to also play a symmetric role in the linguistically aware versions of these scoring metrics, it would be natural to define  $w_s^L$  in the same way as  $w_k^L$ , where  $E$  is the set of edges appearing in the maximum spanning tree defined over the mentions in  $S_j$ .

$$w_s^L(S_j) = \begin{cases} \sum_{e_l \in E} w_l(e_l) & \text{if } |S_j| > 1; \\ w_{sing} & \text{if } |S_j| = 1. \end{cases} \quad (10)$$

However, there is a reason why it is undesirable for us to define  $w_s^L$  in this manner. Consider the special case in which a system partition  $\mathcal{S}(d)$  contains only correct links, some of which are suboptimal.<sup>6</sup> Although  $\mathcal{S}(d)$  contains only correct links, the precision computed by any scoring metric that employs  $w_s^L$  with the above definition will be less than one simply because it contains suboptimal links. In other words, if a scoring metric employs  $w_s^L$  with the above definition, it will penalize a resolver for choosing suboptimal links twice, once in recall and once in precision.

To avoid penalizing a resolver for the same mistake twice,  $w_s^L$  cannot be defined in the same way as  $w_k^L$ .<sup>7</sup> In particular, only spurious links (i.e., links between two non-coreferent mentions), not suboptimal links, should be counted as precision errors. To avoid this problem, recall that  $P(S_j)$  is defined as a partition of system chain  $S_j$  created by intersecting  $S_j$  with all key chains in  $\mathcal{K}(d)$ .

$$P(S_j) = \{C_j^i : i = 1, 2, \dots, |\mathcal{K}(d)|\}$$

<sup>6</sup>Suboptimal links are links that are correct but do not appear in a maximum spanning tree for any of its chains.

<sup>7</sup>This implies that precision and recall will no longer play a symmetric role in our linguistically aware scoring metrics.

Note that a link is spurious if it links a mention in  $C_j^{i_1}$  with a mention in  $C_j^{i_2}$ , where  $1 \leq i_1 \neq i_2 \leq \mathcal{K}(d)$ . Without loss of generality, assume that there are  $ne_j$  non-empty clusters in  $P(S_j)$ . Note that we need  $ne_j - 1$  spurious links in order to connect the  $ne_j$  non-empty clusters. To adequately reflect the damage created by these spurious links, among the different sets of  $ne_j - 1$  spurious links that connect the  $ne_j$  non-empty clusters in  $P(S_j)$ , we choose the set where the sum of the weights of the links is the largest and count the edges in it as precision errors. We denote this set as  $E_t(S_j)$ .

Now we are ready to define  $w_s^L$ . There are two cases to consider.

**Case 1:**  $|S_j| > 1$

In this case,  $w_s^L(S_j)$  is computed as follows:

$$w_s^L(S_j) = \sum_{C_j^i \in P(S_j)} w_c^L(C_j^i) + \sum_{e \in E_t(S_j)} w_l(e). \quad (11)$$

Note that the second term corresponds to the precision errors discussed in the previous paragraph, whereas the first term corresponds to the sum of the values returned by  $w_c^L$  when applied to each cluster in  $P(S_j)$ . The first term guarantees that a resolver is penalized for precision errors because of spurious links, not suboptimal links.

**Case 2:**  $|S_j| = 1$

In this case,  $S_j$  only contains one mention. We set  $w_s^L(S_j)$  to  $w_{sing}$ .

## 4 Evaluation

In this section, we design experiments to better understand our linguistically aware metrics (henceforth *LMetrics*). Specifically, our evaluation is driven by two questions. First, given that the *LMetrics* are parameterized by a vector of four weights  $W$ , how do their behaviors change as we alter  $W$ ? Second, how do the *LMetrics* differ from the existing metrics (henceforth *OMetrics*)?

### 4.1 Experimental Setup

We use as our running example the paragraph shown in Figure 1, which is adapted from the Bible domain of the English portion of the OntoNotes v5.0 corpus. There are 19 mentions in the paragraph, each of which is enclosed in parentheses and annotated as  $m_x^y$ , where  $y$  is the ID of the chain to which this mention belongs, and  $x$  is the mention ID.

Figure 2 shows five system responses (a–e) for our running example along with the key chains.

(Jesus)<sub>a</sub><sup>1</sup> came near (Jerusalem)<sub>d</sub><sup>2</sup>. Looking at (the city)<sub>e</sub><sup>2</sup>, (he)<sub>b</sub><sup>1</sup> began to cry for (it)<sub>f</sub><sup>2</sup> and said, (I)<sub>c</sub><sup>1</sup> wish (you)<sub>g</sub><sup>2</sup> knew what would bring (you)<sub>h</sub><sup>2</sup> (peace)<sub>p</sub><sup>4</sup>. But it is hidden from (you)<sub>i</sub><sup>2</sup> (now)<sub>q</sub><sup>5</sup>. (A time)<sub>r</sub><sup>6</sup> is coming when ((your)<sub>j</sub><sup>2</sup> enemies)<sub>n</sub><sup>3</sup> will hold (you)<sub>k</sub><sup>2</sup> in on (all sides)<sub>s</sub><sup>7</sup>. (They)<sub>o</sub><sup>3</sup> will destroy (you)<sub>l</sub><sup>2</sup> and (all (your)<sub>m</sub><sup>2</sup> people)<sub>t</sub><sup>8</sup>.

Figure 1: A paragraph adapted from the Bible domain of the OntoNotes 5.0 corpus.

For conciseness, a mention is denoted by its mention ID, and each connected sub-graph forms one coreference chain. Moreover, the type of a mention is denoted by its shape: a *square* denotes a NAME mention; a *triangle* denotes a NOMINAL mention, and a *circle* denotes a PRONOUN mention. Note that  $S_{you}$ , the set of coreferent “you” mentions consisting of  $\{m_g^2, m_h^2, \dots, m_m^2\}$ , appears in all system responses.

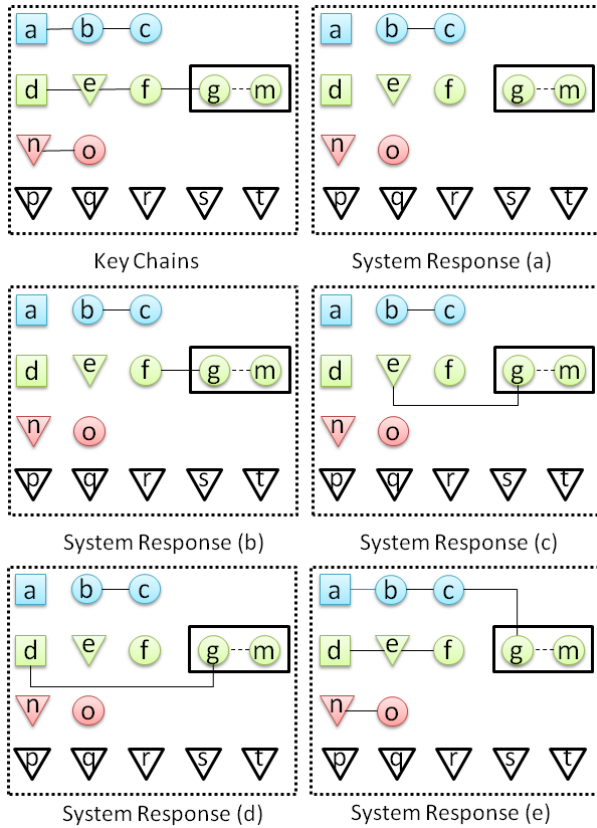

Figure 2: Key and system coreference chains.

Let us begin by describing the five system responses. Response (a) is produced by a simple and conservative resolver. Besides forming  $S_{you}$ , this resolver also correctly links  $m_b^1$  with  $m_c^1$ . Responses (b), (c) and (d) each improves upon response (a) by linking  $S_{you}$  to one of three preceding mentions, namely, one PRONOUN mention, one NOMINAL mention, and one NAME mention respectively. Response (e) is produced by an aggressive resolver that tries to resolve all the pro-

nouns to a non-pronominal antecedent, but unfortunately, it wrongly connects  $S_{you}$  to  $m_a^1$ ,  $m_b^1$  and  $m_c^1$ .

Next, we investigate the two questions posed at the beginning of Section 4.1. To determine how the *LMetrics* behave when used in combination with different weight vectors  $W = (w_{nam}, w_{nom}, w_{pro}, w_{sing})$ , we experiment with:

$$W_1 = (1.0, 1.0, 1.0, 10^{-20});^8$$

$$W_2 = (1.0, 1.0, 1.0, 0.5);$$

$$W_3 = (1.0, 1.0, 1.0, 1.0);$$

$$W_4 = (1.0, 0.75, 0.5, 1.0);$$

$$W_5 = (1.0, 0.5, 0.25, 1.0).$$

Note that  $W_1$ ,  $W_2$ , and  $W_3$  differ only with respect to  $w_{sing}$ , so comparing the results obtained using these weight vectors will reveal the impact of  $w_{sing}$  on the *LMetrics*. On the other hand,  $W_4$  and  $W_5$  differ with respect to the gap of the weights associated with the three types of mentions. Examining the *LMetrics* when they are used in combination with  $W_4$  and  $W_5$  will reveal the difference between having “relatively similar” weights versus having “relatively different” weights on the three mention types.

Figure 3 shows four graphs, one for each of the four *LMetrics*. Each graph contains six curves, five of which correspond to curves generated by using the aforementioned five weight vectors, and the remaining one corresponds to the *OMetric* curve that we include for comparison purposes. Each curve is plotted using five points that correspond to the five system responses.

## 4.2 Impact of $w_{sing}$

We first investigate the impact of  $w_{sing}$ . We will determine how the *LMetrics* behave in response to  $W_1$ ,  $W_2$  and  $W_3$ .

The first graph in Figure 3 shows the LMUC and MUC F-scores. As we can see, the scores of MUC and LMUC( $W_1$ ) are almost the same. This is understandable: the uniform edge weights and a very small  $w_{sing}$  in  $W_1$  imply that LMUC will

<sup>8</sup>We set  $w_{sing}$  to a very small value other than 0, because setting  $w_{sing}$  to 0 may cause the denominator of the expressions in (5) and (7) to be 0.

Figure 3: Comparison of the *LMetrics* scores under different weight settings and the *OMetrics* scores.

essentially ignore correct identification of single clusters and consider all errors to be equal, just like MUC. When we replace  $W_1$  with  $W_2$  and  $W_3$ , the two weight vectors with a larger  $w_{sing}$  value, and rescore the five responses, we see that the LMUC scores for responses (a), (b), (c) and (d) decrease. This is because LMUC uses  $w_{sing}$  to penalize these four responses for identifying wrong singleton clusters. On the other hand, the LMUC score for response (e) is higher than the corresponding MUC score, because LMUC additionally rewards response (e) for correctly classifying all singleton clusters without introducing erroneous singleton clusters.

The second graph in Figure 3 shows the  $LB^3$  and  $B^3$  F-scores. Here, we see that the scores for  $LB^3(W_1)$ ,  $LB^3(W_2)$  and  $LB^3(W_3)$  are identical. These results suggest that the value of  $w_{sing}$  does not affect the  $LB^3$  score, despite the fact that  $LB^3$  does take into account singleton clusters when scoring, a property that it inherits from  $B^3$ . The reason is that regardless of what  $w_{sing}$  is, if a mention  $m$  is correctly classified as a singleton mention, both of  $R(m)$  and  $P(m)$  will be 1, otherwise, both will be 0 (see formula (5)). Note, however, that there is a difference between  $LB^3$  and  $B^3$ : for an erroneously identified singleton cluster containing mention  $m$ ,  $LB^3$  sets  $P(m)$  to 0 while  $B^3$  sets  $P(m)$  to 1. In other words,  $LB^3$  puts a higher penalty on precision given erroneous singleton clusters. This difference causes  $LB^3$  and  $B^3$  to evaluate responses (a) and (e) differently. Recall that responses (a) and (e) are quite different: response (e) correctly finds informative antecedents for  $m_b^1, m_c^1, m_e^2, m_f^2$  and  $m_o^3$ , whereas response (a)

contains many erroneous singleton clusters. Despite the large differences in these responses,  $B^3$  only gives 0.7% more points to response (e) than response (a). On the other hand,  $LB^3$  assigns a much lower score to response (a) owing to the numerous erroneous singleton clusters it contains.

The third graph of Figure 3 shows the  $LCEAF_m$  and  $CEAF_m$  F-scores. Since  $LCEAF_m$  uses both singleton and non-singleton clusters when computing the optimal alignment, it should not be surprising that as we increase  $w_{sing}$ , the singleton clusters will play a more important role in the  $LCEAF_m$  score. Consider, for example,  $LCEAF_m(W_1)$ . Since  $w_{sing} = 0$ ,  $LCEAF_m(W_1)$  ignores the correct identification of singleton clusters. From the graph, we see that  $LCEAF_m(W_1)$  gives a higher score to response (a) than response (e). This is understandable: response (a) is not penalized for the many erroneous singleton clusters it contains; on the other hand, response (e) is penalized for the erroneous coreference links it introduces. Now, consider  $LCEAF_m(W_3)$ , where  $w_{sing} = 1$ . Here, response (e) is assigned a higher score by  $LCEAF_m(W_3)$  than response (a): response (a) is heavily penalized because of the many erroneous clusters it contains.

The rightmost graph of Figure 3 shows the  $LCEAF_e$  and  $CEAF_e$  F-scores. Like  $LB^3$ ,  $LCEAF_e$  returns the same score when it is used in combination with  $W_1, W_2$  and  $W_3$ , because the  $\phi_4$  similarity function returns 0 or 1 when the key cluster or the system cluster it is applied to is a singleton cluster, regardless of the value of  $w_{sing}$ . In addition, we can see that  $LCEAF_e$  penalizes erroneous singleton clusters more than  $CEAF_e$  does

Table 1: Comparison of the  $LMetrics(W_4)$  scores and the  $OMetrics$  scores.

for the same reason that  $LB^3$  penalizes erroneous singleton clusters more than  $B^3$  does.

In sum, the value of  $w_{sing}$  does not impact  $LB^3$  and  $LCEAF_e$ . On the other hand,  $LMUC$  and  $LCEAF_m$  pay more attention to singleton clusters as  $w_{sing}$  increases.

### 4.3 Impact of $w_{nam}$ , $w_{nom}$ and $w_{pro}$

When we were analyzing the  $LMetrics$  in the previous subsection, by setting  $w_{nam}$ ,  $w_{nom}$ , and  $w_{pro}$  to the same value, we were not exploiting their capability to be linguistically aware. In this subsection, we investigate the impact of linguistic awareness using  $W_4$  and  $W_5$ , which employ different values for the three weights.<sup>9</sup> To better understand the differences in recall and precision scores for each of the five system responses, we show these scores as computed by the  $LMetrics$  when they are used in combination with  $W_4$ .

First, consider response (a). As we can see from Figure 3 and the first row of Table 1, the  $OMetrics$  give decent scores to this output. Linguistically speaking, however, the system should be penalized more. The reason is that its output contributes little to understanding the document: in response (a), only the links between the PRONOUN mentions are established, and none of the PRONOUN or NOMINAL mentions is linked to a more informative mention that would enable the underlying entity to be inferred.

As expected,  $LMetrics(W_4)$  and  $LMetrics(W_5)$  assign much lower scores to response (a) than the  $OMetrics$ , owing to a relatively small value of  $w_{pro}$ . Also, we see that the  $LMetrics(W_5)$  scores are even lower than the  $LMetrics(W_4)$  scores. This suggests that the smaller the values of  $w_{pro}$  and  $w_{nom}$  are, the more heavily a resolver will be penalized for its failure to link a mention to a more informative coreferent mention.

Next, consider responses (b), (c) and (d). As the

<sup>9</sup>Like  $W_3$ , we set  $w_{sing}$  to 1 in  $W_4$  and  $W_5$ , because this assignment makes  $CEAF_m(W_3)$  rank response (e) above response (a), which we think is reasonable.

$OMetrics$  ignore the type of mentions while scoring, they are unable to distinguish the differences among these three system responses: the  $OMetrics$  results in Figure 3 and their results in rows 2, 3 and 4 of Table 1 show that the scores for responses (b), (c) and (d) are identical. Linguistically speaking, however, they should not be. Response (d) contributes the most to document understanding, because the presence of NAME mention  $m_d^2$  in its output enables one to infer the entity (*Jerusalem*) to which the mentions in  $S_{you}$  refer. In contrast, although response (b) correctly links  $S_{you}$  to PRONOUN mention  $m_f^2$ , one cannot infer the entity to which the mentions in  $S_{you}$  refer. The contribution of response (c) is in-between, because via  $m_e^2$ , we at least know that the mentions in  $S_{you}$  point to one *city*, although we do not know which *city* it is. Such differences in responses (b), (c) and (d) are captured by  $LMetrics(W_4)$  and  $LMetrics(W_5)$ . Specifically, the  $LMetrics$  scores for response (d) are higher than those for response (c), which in turn are higher than those for response (b).

It is worth noting that the performance gaps between responses (b) and (c) and between responses (c) and (d) are larger under  $LMetrics(W_5)$  than under  $LMetrics(W_4)$ . This is because  $w_{nom}$  and  $w_{pro}$  in  $W_5$  are comparatively smaller. These results enable us to conclude that as the difference in the three edge weights becomes larger, the performance gap between a less informative resolver and a more informative resolver according to the  $LMetrics$  widens.

## 5 Conclusion

We addressed the problem of linguistic agnosticity in existing coreference evaluation metrics by proposing a framework that enables linguistic awareness to be incorporated into these metrics. While our experiments were performed on gold mentions, it is important to note that our linguistically aware metrics can be readily combined with, for example, Cai and Strube’s (2010) method, so that they can be applied to system mentions.

## Abstract

Social networking sites such as Facebook and Twitter have become favorite portals for users to discuss and express opinions. Research shows that topical discussions around events tend to evolve socially on microblogs. However, sources like Twitter have no explicit discussion thread which will link semantically similar posts. Moreover, the discussion may be evolving in multiple different threads (like Facebook). Researchers have proposed the use of online contemporary documents to act as external corpus to connect pairs of contextually related semantic topics. This motivates the question: *given a significant social event, what is a good choice of external corpus to identify evolution of discussion topics around the event's context?* In this work, we compare the effectiveness of contemporary blog posts, online news media and forum discussions in creating ad-hoc external corpus. Using social propensity of evolution of topical discussions on Twitter to assess the goodness of the creation, we find online news media as most effective. We evaluate on three large real-life Twitter datasets to affirm our findings.

## 1 Introduction

Social media has become a hotbed of user generated content. Multiple online platforms have emerged for users to participate, interact and discuss. Social contact and activity networks like Facebook, video sharing networks like Youtube, photo/image sharing platforms like Pinterest, social bookmarking platforms like Digg, and mi-

croblogging platforms like Twitter have become prominent online social media platforms.

Research suggests that social microblogging platforms, like Twitter, diffuse information in a manner similar to news media (Kwak and Lee, 2010). In a world of millions of people (Twitter subscribers) with inherent entropy, in absence of explicit discussion threads (unlike online forums, for example), conversations around any event are expected to move towards different directions over time. Contradictory to this apparent expectation, research suggests that these discussions tend to temporally grow and evolve along social relationships of people engaging in these discussions, much more strongly, compared to random evolution (Narang and Nagar, 2013).

Interestingly, trending events on unstructured microblogs often get built around non-traditional, temporary and contemporary factors, entities and relationships. Because of the sheer number of diverse contemporary events, event types and associated documents, it is impossible to prepare well-defined, validated and clean corpus for each and every event. For instance, political turmoils have existed for ages; however, one may not expect a dedicated corpus to preexist for the Libya 2011 turmoil associating its places and locations, contemporary leaders, and all the other global political factors. Hence, there is a strong need of using contemporary online media for ad-hoc corpus creation in such a setting.

The use of external corpus has been shown to improve performance in language tasks such as question-answering, machine translation, and information retrieval (Kilgarriff, 2003; Clarke and Cormack, 2002; Dumaisl and Banko, 2002; Metzler and Diaz, 2005; Xu and Croft, 2000; Diaz and Metzler, 2006). But questions relating to the rele-

vance of the corpus have not been studied as much.

The finding of (Narang and Nagar, 2013) that topical discussions on microblogs tend to evolve socially is interesting. However, it simply uses contemporary online news media as the only source of external corpus, to establish *extended semantic relationships* across topic clusters. It does not attempt to use any other source of relevant semantic data for creating external corpus; nor does it assess the goodness of contemporary online news portals for this purpose.

In this study, we propose evaluating the goodness of different sources of external data for constructing ad-hoc corpus to connect topic clusters using extended semantic edges. In addition to the contemporary online news media corpus, we use two other independent external corpus for constructing extended semantic edges, namely contemporary online forum discussions and contemporary blog posts. To the best of our knowledge, ours is the first study of its kind.

We use three large scale real-life Twitter datasets, namely Libya 2011 political turmoil, Egypt 2011 political turmoil and London 2012 Olympics, having thousands of users and up to millions of tweets, to conduct experiments. For all datasets, we find online news media to best capture the evolution of discussion topics along social relationships, measured by the normalized mutual information or *NMI* (Coombs and Dawes, 1970) of the social discussion threads to discussion sequences. We believe this insight to be both novel and interesting. We further observe that, for most cases, online discussion forums perform better compared to blogs.

In summary, the main contributions of our work are the following.

- We empirically evaluate different contemporary relevant external documents, to establish extended semantic relationships across topical clusters formed around events.
- We assess the goodness of contemporary online discussion forums, blogs, online news media and Random search results, in forming extended semantic relationships, and find online news media to be most effective in creating ad-hoc corpus around given events.
- We demonstrate our findings on microblogging data using three real events.

## 2 Problem settings and our approach

### Problem settings

We observe the following:

1. There exist several concepts that are connected in a given context, but are not connected by any widely accepted relationship such as synonyms, antonyms, hypernymns, hyponymns *etc.* when taken in isolation. As an example, *damage* and *relief* are intuitively connected concepts in semantic clusters containing  $\{damage, fire, death, toll\}$  and  $\{fire, relief, spray, water\}$ . Yet, none of the traditional semantic relationships will connect these when considered in absence of the larger context, namely an event of fire. Practically, discussions on microblogs about damage caused by fire stands a realistic chance to evolve towards discussions about relief.

2. Events on microblog networks form around non-traditional, temporary and contemporary factors, entities and relationships. It is impractical to expect well-defined corpus to exist a priori.

Clearly, creating corpus applicable for a given event, to be able to connect concepts that are related in context of the event, is a research problem to solve. It is also important to assess the quality of the corpus created in the process.

### Algorithm

In absence of traditional a priori corpus, we attempt to construct ad-hoc corpus applicable to the context of the event. We follow the approach of (Narang and Nagar, 2013) to construct our graphs, conducting our experiments and measuring the goodness of our results. We use Twitter as our testbed. We attempt to use four independent types of contemporary external documents to be able to connect concepts related contextually, namely online forum discussions, blog posts, news media and Random search documents, to derive the *extended semantic relationships*. Our approach consists of the following steps.

#### 2.1 Topic-based cluster creation

We collect tweets belonging to an event from Twitter for our experiments. The whole tweet corpus is divided into clusters of tweets which are semantically related. Event topic cluster detection not being the focus of our work, we use an existing online clustering algorithm (Weng and Lee, 2011) to create clusters of topics related semantically. A semantic event cluster  $E^i$  is represented

as  $\{K^i, [T_s^i, T_e^i]\}$ , where  $K^i$  denotes the set of keywords extracted from the tweets which form the event  $E^i$  and  $T^i$  is time period of the event. We use existing established methods for computing K and T. K contains *idf* vector and proper nouns (extracted by PoS tagging) from the tweets, and uses Stanford's NLP Toolkit and the associated Named Entity Recognizer. T is simply the time of first and last tweet in the event cluster.

## 2.2 Extracting the relationships

Essentially, we generate an event topic graph  $\mathcal{G} = \{\mathcal{E}, \{R\}\}$ , in which  $\mathcal{E}$  represents the event topics (topical clusters), and act as the vertices of the graph. The set  $\{R\}$  represents the relationship edges between the clusters, and are formed from each of contextual semantic, temporal and social perspectives. We, hereby, elaborate on the algorithm used for extracting these relationships.

**Extended Semantic Relationships:** This relationship is extremely useful but challenging to establish. Lets us motivate the need for such relationship by a simple example. Consider two events with associated keywords  $E_1 = \{\text{damage, earthquake, dead, toll}\}$  and  $E_2 = \{\text{earthquake, relief, shelter}\}$ . Now, lets pick one work from each set *damage* and *relief*. One cannot establish any of the widely accepted relationships like synonym, antonyms, hypernyms, hyposynms etc when the words are taken in isolation. However, coupled with prior knowledge about the larger event *earthquake*, the words can be semantically related. In essence (with abuse of notation and terminology), damage and relief are independent variables without extra information, however, they are related given *earthquake*. Therefore, we would like to add the semantic edge between these events. We use external corpus to extract and quantify such semantic relationships. (Narang and Nagar, 2013) used only Google News for creation of the external corpus. But, due to the increased presence of users on Internet, these global and prominent topics are bound to be discussed in blogs and online discussions forums. The natural question which arise is then, which corpus is deemed to be best for the purpose. In this paper, we use different data sources as ad-hoc corpus, namely contemporary online discussions, blogs, online news and Random Search documents, to form four different graphs extended semantic per event. The novelty of our work lies in empirically determining

the goodness of each of these four different data source types in forming ad-hoc corpus.

### Extended semantic relationship extraction

We establish weighted extended semantic relationships across event clusters by the following steps. The input to the extended semantic relationship extraction algorithm for two events  $E^i$  and  $E^j$  is keyword list  $K^i$  and  $K^j$ .

#### Step 1: Generating Pairs and Pruning

**Mechanism-** We generate  $|K^i| \times |K^j|$  pairs of keywords which need to be evaluated for extended semantic relationship. Such large number of pairs would pose computational issues. To handle this, we prune pairs which are related semantically (synonyms, antonyms, hypernyms and hyponyms). We look at the similarity scores of  $K^i$  and  $K^j$  in Wordnet. We use the well-established Lin's method (Lin, 1998) to compute similarity scores of  $K^i$  and  $K^j$  using the feature vector built into the Wordnet lexical database. For sake of completeness, please note that Lin's measure of similarity between pair of words w1 and w2 is defined as:

$$sim(w1; w2) = \frac{2I(F(w1) \cap F(w2))}{I(F(w1)) + I(F(w2))}$$

, where  $F(w)$  is the set of features of a word w, and  $I(S)$  is the amount of information contained in a set of features S. Assuming that features are independent of one another,  $I(S) = -\sum_{f \in S} P \log(P(f))$ , where  $P(f)$  is the probability of feature f.

We retain a pair of words if the similarity score  $S_{ij}$  is lesser than a desirable similarity threshold  $S$ , and discard the pair otherwise. Since POS tagging is done on the tweets in the event, we also remove pairs where one of the word is Proper Noun or Active Verbs.

#### Step 2: Document Corpus Generation and Searching-

We use the keywords used for filtering Twitter Public API to search for news stories for the same time period on contemporary external documents. The retrieved documents act as our external corpus. We create an inverted index for this corpus, where for each word we store the document ids as well as the frequency of the word in the documents. Given the pair of words  $(K_l^i, K_m^j)$  (we will omit subscript l and m, when there is no ambiguity), we find the intersection of corresponding document lists. Therefore, at the end of this step we have list of documents (denoted by  $D_{lm}$ ) in which both the

words co-occur along with their frequency in the documents.

**Step 3: Pairwise Score Computation** - For each of the selected document, we compute the coupling of the pair of words. Assume,  $C(K_l^i, D_t)$  gives the *tf-idf* score of word  $K^i$  in document  $D_t$ . The pairwise coupling can be computed as minimum  $(C(K_l^i, D_t), C(K_m^j, D_t))$ . The overall coupling is calculated as average of coupling over all documents.

**Step 4: Overall Score Computation** - This process is repeated for all pair of words in  $E^i$  and  $E^j$ . Finally, for a given pair of event clusters  $E^i$  and  $E^j$ , if  $w_{ij}$  words were discarded and the rest were retained, then

$$overall\_score = \frac{\sum_{K^i, K^j} Coupling}{(|K^i| \times |K^j| - w_{ij})}.$$

The final scores are ranked in descending order and top K% are selected based on user preference or can be pruned based on threshold.

**Social Relationships:** Direct social connections are the core constituent elements of social relationships. Higher order social relationships can be established by exploring the social network structure. Well-defined structures such as communities with maximum modularity (Girvan and Newman, 2002; Clauset and Newman, 2004) can be extracted using efficient modularity maximization algorithms such as BGLL (Blondel and Guillaume, 2008).

#### Social relationship extraction

We construct social linkage graphs between pairs of events using social connections of event cluster members to construct edges. Each event associates a number of microblog posts (tweets) from a set of members of the microblog network (Twitter).

A person  $P$  is said to belong to an event cluster  $E^i$  iff  $(\exists M)$ , a microblog post, made by  $P$ , such that  $M \in E^i$ . Please note that with this definition, a person can potentially belong to multiple event clusters at the same time.

These connections are established by participation of direct social neighbors of individuals across multiple events. We draw an edge across a given pair of events if there is at least one direct (one-hop) neighbor in each event belonging to the pair of events. The weight of an edge between event cluster  $E^i$  and  $E^j$  is determined by the total number of one-hop neighbors existing between

these two clusters. So if  $E^i$  has  $P^i$  memberships,  $E^j$  has  $P^j$  memberships, the average number of neighbors in  $E^j$  of a member belonging to  $E^i$  is  $a_{ij}$  and the average number of neighbors in  $E^i$  of a member belonging to  $E^j$  is  $a_{ji}$  then the strength of the social edge between  $E^i$  and  $E^j$  is  $(P^i.a_{ij} + P^j.a_{ji})$ .

**Temporal relationship** The third kind of relationship we extracted is temporal relationship. We look at two kinds of temporal relationships. (a) We draw a temporal edge from event  $E^i$  to event  $E^j$  if  $E^i$  ended before  $E^j$  started and the timespan between the two events has to be less than or equal to 2 days. This follows from the assumption that on microblogging services like Twitter, a discussion thread will not last longer than this. This thresholding also prevents the occurrence of spurious edges across different clusters. It captures the *meets* and *disjoint* relationships described by (Allen and J.F., 1983). We call this a  $T_1$  temporal relationship. (b) We draw a temporal edge from event  $E^i$  to event  $E^j$  if  $E^i$  started before  $E^j$  started, and ended after the start but before the end of  $E^j$ . This captures the *overlaps* relationship described by (Allen and J.F., 1983). We call this a  $T_2$  temporal relationship. Please note that unlike the undirected semantic and social relationship edges, a temporal relationship edge is always directed. The source of a temporal relationship edge is the event with the earlier starting time, and the sink is the one with the later starting time.

### 2.3 Identifying and characterizing discussions

Finally, after establishing the relationships, we identify Discussion and Social discussion sequences in the same manner as described by (Narang and Nagar, 2013).

**Identifying discussion sequences:** A discussion sequence graph is defined as, a directed acyclic graph (DAG) of topics that are related using the semantic edges obtained by our earlier semantic relationship extraction process, where the relationships are established over time. Intuitively, a discussion sequence captures the topical evolution of discussions over time. We identify discussion sequences using the logical intersection (AND) of the relationship set of the undirected semantic and the directed temporal graphs, with the directions of the latter preserved in the output.

So, the discussion sequence DAG  $\mathcal{G}_{DS}$  is formed as:  $\mathcal{G}_{DS} = \{\mathcal{E}, \{\{R_T\} \cap \{R_S\}\}\}$ , where the set  $\{R_T\}$  represents the edge set of the directed temporal graph and the set  $\{R_S\}$  represents the edge set of the undirected semantic graph.

**Identifying Social discussion sequences:** We take the above graph, and take an edge set intersection with the social graph. This results in retaining the discussion sequences that are socially connected and eliminating the discussion sequences that are socially disconnected. The retained discussion sequences show the social evolution of discussion topics around events on microblogs. Hence, these socially connected discussion sequences are identified as social discussion threads.

## 2.4 Evaluation

In order to measure the goodness of the approach, we find the BGLL (Blondel and Guillaume, 2008) communities for the discussion sequence graphs and social discussion threads, and compute the normalized mutual information (NMI) (Coombs and Dawes, 1970) for each of these intersections. Please note that NMI values range between 0 and 1, and higher NMI values indicate higher overlaps of the two inputs.

(Narang and Nagar, 2013) showed that Discussion threads tend to evolve socially and as a result, the NMI values between communities formed on Discussion Sequences and Social Discussion thread is higher than in between BGLL communities formed on purely Social and Semantic Graph. In this paper, we will compare the NMI values between Discussion threads and Social Discussion threads with taking different extended semantic graphs for their construction. The corpus which results in highest NMI value between the two graphs has most relevant retrieved documents for the event.

## 3 Results

We collect Twitter data from three events that had created significant impact on social media - Libya 2011 political turmoil (collected 4 - 24 Mar'11), Egypt 2011 political turmoil (collected 1 - 4 Mar'11) and the London 2012 Olympics (collected 27 Jun - 13 Aug'12). We use Google News (<http://news.google.com>) with custom date ranges to collect the contemporary online news

data, and Google blog and discussions search options on Google's portal (<http://w.google.com>) with custom date ranges to collect the blog and forum discussions data respectively. We also used Google Search (<http://google.com>) to collect random search results for the same events which will be a mixture of all the data sources to act as a baseline. We gave the same keywords over the same time range while collecting documents from Google which were used for collection of tweets in the Twitter. Table 1 shows the basic statistics of the datasets.

Following the approach outlined in Section 2, we form semantic topic clusters from the tweets following the algorithm of (Weng and Lee, 2011). We now establish extended semantic, social and temporal relationships. For extended semantic relationships, we form four graphs, one each for online news media, discussions, blog and Random documents. For temporal relationships, we form two graphs, one each for the *follows* and *overlaps* relationships. Thus overall, for each dataset (Libya, Egypt and London), we construct 8 different graphs, constructing a total of 24 graphs for experimentation.

We now identify the discussion sequences by taking a logical intersection of the extended semantic and temporal graphs, and the social discussion threads by taking a logical intersection of the discussion sequences with the social relationship graph. We find the NMI (Coombs and Dawes, 1970) across these two graphs using the BGLL (Blondel and Guillaume, 2008) communities formed around these two graphs. We retain the top 10%, 20%, 30%, 40% and 50% of the graph edges and repeat our experiments to observe the overall trend. Figure 1 captures our findings for the temporal *follows* relationships.

The results clearly indicate that in each case, contemporary online news yields the best results (maximum NMI values). In most cases (except Egypt), online discussion forums give better results compared to blogs. This trend becomes more yet prominent as we retain higher fraction of the relationships. Random search results generally behave the worst, except in London which is a little surprising and interesting.

Table 2 shows the corresponding results for the temporal *overlaps* relationship for Libya, which also prominently shows a similar trend. We observe similar trends for other temporal *over-*

Table 1: Keywords used to collect the Twitter datasets, dates of data collection, number of users, tweets collected and clusters, and number of contemporary external news, forum and blogs documents collected

Dataset	Keywords	NumUsers	Tweets	Clusters	#News	#Forum	#Blogs
Libya	Libya, Gaddafi	83,177	1,011,716	1,344	3,266	280	263
Olympics	London, Olympic	1,313,578	2,319,519	299	1,186	516	307
Egypt	Egypt, Protest	37,961	60,948	141	1,753	513	285

Table 2: NMI values for temporal *overlaps* based graphs of Libya

Source	10%	20%	30%	40%	50%
Blogs	0.01	0.04	0.09	0.09	0.13
Forums	0.01	0.06	0.06	0.11	0.16
News	0.02	0.09	0.14	0.09	0.17
Random	0.02	0.04	0.00	0.08	0.11

*laps* graphs also, with the London Olympics data shows a few exceptions (omitted for space constraints).

To eliminate the possible bias due to the number of documents received for each type of corpus, we also repeated the experiment with taking top 200 documents from each sources namely, Online news, blogs, discussions and Random documents. We, then evaluated the performance of these corpora on the Libya dataset.

The figure 2 shows the NMI graph for the Libya dataset with taking only top 200 articles from each of the data sources. The contemporary news article consistently give best results even in this case which corresponds to the finding in the above experiment. Although, Random results also give an equivalent performance but this can be attributed to the fact that the initial results in Google search mostly contains Google News results which will be in prominence because of the low number of documents selected in this experiment.

## 4 Related Work

Significant research has been conducted on content analysis of information discussed on social media sites (Kwak and Lee, 2010). Grinev et al. (Grinev and Grineva, 2009) demonstrate Tweet-Sieve, a system that obtains news on any given subject by sifting through the Twitter stream. Along similar lines, Twinner by Abrol et al. Abrol and Khan (Abrol and Khan, 2010) identify news content of a query by taking into account the geographic location and the time of query. Nagar et al.

(Nagar and Seth, 2013) demonstrate how content flow occurs during natural disasters.

Several ways to cluster social content have been studied. There has been work on clustering based on links between the users by doing agglomerative clustering, min-cut based graph partitioning, centrality based and Clique percolation methods ((Porter and Onnela, 2009), (Fortunato, 2007)). Other approaches consider only the semantic content of the social interactions for the clustering (Zhou, 2006). More recently there has been work on combining both the links and the content for doing the clustering ((Pathak and Delong, 2008), (Sachan and Contractor, 2012)). In (Narang and Nagar, 2013) relationships between clusters are determined based on semantic, social and temporal information but did not study the impact of different corpus on their results.

External corpora have been used by researchers to create knowledge base in various fields like for question-answering (Clarke and Cormack, 2002; Dumaisl and Banko, 2002) models such as Chatbots etc, helping machine to translate documents like expanding queries (Kilgarriff, 2003; Metzler and Diaz, 2005) and also for improving Information retrieval using external information (Xu and Croft, 2000; Diaz and Metzler, 2006). They use generic corpora and to the best of our knowledge, there is no study which analyses the relevance of different corpora for the given problem.

## 5 Conclusions

In this work, we studied different contemporary online external data sources for constructing ad-hoc corpus to connect event topic clusters. We explored the content of contemporary online discussion forums, blogs, online news media and Mixture of different corpus, and evaluated their effectiveness in establishing semantic relationships across topical clusters. Exploiting the social propensity of evolution of such discussions, we assessed the goodness of these diverse data sources

(a) NMI for Libya turmoil

(b) NMI for London Olympics

(c) NMI for Egypt turmoil

Figure 1: NMI of social discussion threads (SDT) with respect to discussion sequences (DS): temporal *follows* relationship

using Twitter as a microblogging platform, and eventual NMI values as a qualitative indicator of the goodness of the extended semantic relationships established.

We found contemporary online news media to be the most effective type of external data source for creating ad-hoc corpus, using three large real-life Twitter datasets collected around major events. Further, we found contemporary online discussion forums to be usually, but not always, more effective compared to contemporary blogs. We also found using Mixture of all documents to be mostly give the worst performance.

Our work will be useful to studies and applications that require capturing the evolution of topical discussions on microblogs like Twitter. As future work, we propose evaluating other external

Figure 2: NMI of social discussion threads (SDT) with respect to discussion sequences (DS): temporal *follows* relationship with retaining only top 200 articles

sources of semantic data, and also apply on other microblogging platforms and data sets, for a more comprehensive and complete study.

## Abstract

There is a need of matching text difficulty to the expected reading skill of the audience. Readability measures were developed with this objective in mind, first by psycholinguists, and more recently, by practitioners of natural language processing. A common strategy was to extract linguistic features that are good predictors of readability, and then train discriminative classification or regression models that correlate well with human judgment. But correlation does not imply causality, which is a necessary property to explain why documents are not readable. Our objective is to provide mechanisms for text producers to adjust the readability of their content. We propose the use of generative models to diagnose causes of reading difficulty, and bring closer the realization of automatic readability optimization.

## 1 Introduction

Educational institutions, government agencies and some private companies have a special interest in authoring documents for a certain audience, but it is expensive to involve expert linguists to assess the readability of every document they produce. The first psycholinguistic studies developed readability formulas for grading purposes, based on surface linguistic features. Those formulas, despite of their simplicity, performed well and were widely used by editors to grade reading material for young readers. However, content producers might be tempted to adapt their manuscripts by tweaking the text features present in readability formulas, without gaining (or even degrading) real readability (Davison and Kantor, 1982).

Recently, the application of statistical models to linguistic problems proved successful, and am-

bitious tasks in automatic document transformation such as text summarization or machine translation became a hot topic in computational linguistics. Readability optimization is one of such document transformation problems. Recent studies on readability embrace machine learning techniques to recognize readability with an even higher accuracy. The common approach consists in extracting as many features as possible, and then training a classifier or a regression model using human annotated texts to predict a readability score given the observation of the linguistic features.

Those discriminative models correlate well with human judgment, but fail at explaining why a document is not readable. We call *readability diagnosis* the automatic discovery of the causes that lead to (un)readability, and we believe it is an essential step for readability optimization.

We propose the use of Bayesian causal networks to perform readability diagnosis. That is, given a document, the objective of our Bayesian network is to recognize the specific parts of the document that are difficult to read. Bayesian networks are a type of generative model, where the joint probability distribution is constructed by making certain independence assumptions. Their main advantage is that they allow to query the model regarding any linguistic variable, generalizing the functionality of traditional models.

In the next section we briefly introduce former work by psycholinguists and recent work by practitioners on natural language processing. We describe our application of Bayesian networks to readability diagnosis in Section 3 and summarize the capabilities of the model. Corpora, baseline system description and results are presented in Section 4, where we assess to what extent our generative model predicts cognitive evidence. Pointers to future work and applications that would benefit from our results can be found in Section 5, followed by our conclusions in Section 6.

## 2 Related Work

Readability formulas have been the subject of investigation long before the existence of current natural language processing techniques. Although sophisticated methods could have been developed, there was an emphasis on easy-to-compute formulas, where the readability score of a text is computed as a function of its linguistic features.

The Flesch-Kincaid formula (Flesch, 1948; Kincaid et al., 1975) was probably the first in gaining wide recognition among publishers. This formula is a linear combination of two variables<sup>1</sup>, as:

$$r_{\text{score}} = 0.39 \times \text{ASL} + 11.8 \times \text{ASW} - 15.59 \quad (1)$$

where ASL is the average number of words per sentence, and ASW is the average number of syllables per word. Despite of its simplicity, ASL and ASW are very discriminative linguistic features when assessing readability and this formula correlates surprisingly well with human judgment.

The search for more discriminative linguistic features continued, and Mc Laughlin (1969) found that the number of polysyllabic words in a certain amount of text is also a good predictor of reading difficulty. The rationale behind such a linguistic feature could be that the required lexical processing is higher when the word is longer, or that long words tend to be more infrequent and difficult to read (Rayner and Duffy, 1986). This work was followed by others (Fry, 1990) that counted the number of words in the text that were contained in the vocabulary of specific word lists. The use of word lists introduced a new dimension in readability, since it was possible to design hand-crafted lists that could not only account for lexical frequency, but also for semantic complexity.

Building on the idea of lexical frequency and counting on large amounts of text data, the use of word lists was generalized into unigram language models (Si and Callan, 2001), which increased the correlation with human judgment on readability.

Linguistic features of different nature were also explored, and grammatical features are an example of them (Heilman et al., 2007). Those features alone were found not to be as discriminant as the lexical ones, but performed well in combination with them. However, the effects were not additive, which suggests that variables correlated with each

---

<sup>1</sup>We will use the term *variables* interchangeably with *linguistic features*.

other to a certain extent. This was also noted in some other works (Petersen and Ostendorf, 2009), where syntactic features were also used, in combination with higher order n-gram language models.

Automatic text transformation for readability optimization is a task that naturally follows former readability studies and the large scale need of producing content for specific audiences. Authors in (Carroll et al., 1999; Devlin et al., 1999; Siddharthan, 2003) approached the problem using rules for syntactic transformation, anaphora substitutions and vocabulary simplifications, but those rules were not experimentally tested for their target readers. Williams and Reiter (2005) did test their transformation rules, but they were limited to assess the effects of their set of rules, which had a low coverage. Other authors (Aluísio et al., 2010; François and Fairon, 2012) integrated readability scores in authoring systems, to assist text simplification rather than fully automating it.

Previous work has concentrated on finding linguistic features that are good predictors of readability, and building discriminative models that best correlate with human judgment. But those models can only indicate whether a piece of text is readable or not, and fail in explaining the causes. In view of (semi-)automatic text simplification and readability optimization, we propose Bayesian causal networks as a generative model for readability. In this approach, readability is modeled as a factored joint probability distribution over lexical, part of speech, syntactic, semantic and discourse features. This provides an interpretable model to gain linguistic insight about what features impact most on readability in a *specific document* and to understand how that text should be transformed to increase readability even under human-imposed constraints.

## 3 Methodology

### 3.1 Discriminative and Generative Models

Previous work on readability assessment has focused on the development of discriminative models. Those discriminative models are functions  $\phi$  that map instantiations  $\ell$  of a set of linguistic features  $\mathcal{L}$  to a readability score  $r \in \mathbb{R}$ ,  $\phi : \mathcal{L} \rightarrow \mathbb{R}$ . In this work, examples of linguistic features are “proportion of verbs to words”, or “maximum number of active lexical chains” in a given text, and their instantiations are their actual values for that text. If we normalize the readability measure

so that it assigns 1 to the whole space of possible feature instantiations, we can regard the readability score as a probabilistic measure, and without loss of generalization, reformulate the problem as:

$$\hat{r} = \underset{r}{\operatorname{argmax}} \operatorname{Pr}(r \mid \ell), \quad (2)$$

where we have to find the readability score  $r$  with maximum probability, given the instantiation  $\ell$  of the set of linguistic features  $\mathcal{L}$ .

In this approach, the probability on all possible reading score assignments is well defined, but there is no attempt to model the probability of the instantiations  $\ell$  of linguistic features  $\mathcal{L}$ . As it has been reported in related work, most explanatory effects on readability do not add up across all linguistic features. This suggests that linguistic features interact with each other and have mixed effects on readability prediction. There have been ablation and correlation studies to bring light on those feature interactions (Kate et al., 2010), but they were limited to a few feature combinations and no attempts were done to study causal relationships or other conditional independencies.

To attain diagnosis capabilities, we propose the use of Bayesian causal networks as an example of generative models  $\operatorname{Pr}(r, \ell)$ , where the readability score and the linguistic features are modeled *together* using a joint probability distribution. There are, however, some challenges associated to this model that are described below.

### 3.2 Independence Assumptions

To preserve generality, we will regard joint probability distributions as tables, where every row defines the probability of a discrete value assignment to all linguistic features and the readability score. The number of parameters to be estimated in the model is proportional to the number of possible assignments, which is exponential with the number of linguistic features. A simple approach is to consider the readability to be dependent on all features, but all features independent from each other. The joint probability distribution can be consequently defined as:

$$\begin{aligned} \operatorname{Pr}(r, \mathcal{L}) &= \operatorname{Pr}(r, l_1, \dots, l_m) \\ &\approx p(r \mid l_1, \dots, l_m) \cdot p(l_1) \cdots p(l_m), \end{aligned} \quad (3)$$

where  $p(l_i)$  are the priors for every linguistic feature  $l_i$ , and the conditional probability distribution

$p(r \mid l_1, \dots, l_m)$  models the non-linear relationship between linguistic features and the readability score. The graphical representation of this model can be found in Figure 1a, where the gray circles are observed linguistic features, and edges encode probabilistic influence (or dependency). Due to the simplicity of this network, the number of dependencies in  $p(r \mid l_1, \dots, l_m)$  is large, which requires to estimate millions of parameters if there are more than twenty linguistic features.

In order to reduce the number of parameters without reducing the number of linguistic features, we will introduce language constructs in the form of hidden variables and set structural dependencies between the linguistic features and these language constructs. Guided by basic linguistic knowledge, we will detect sets of inter-dependent linguistic features and group them to a language construct consistent with the linguistic theory.

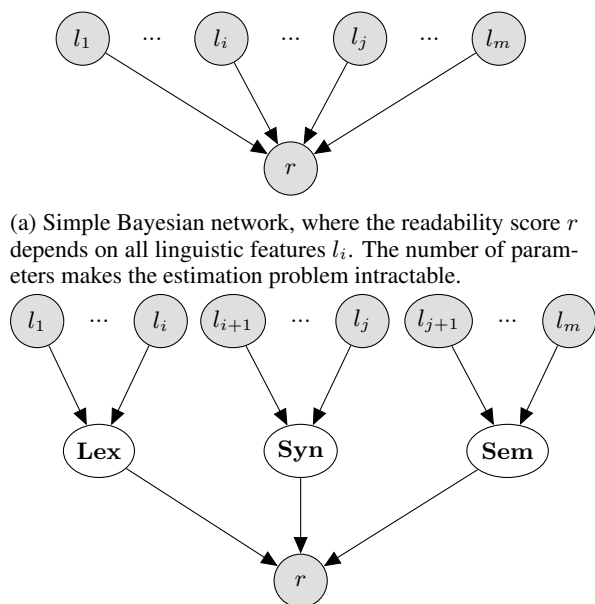

Examples of language constructs are the lexical difficulty **Lex**, the syntactic difficulty **Syn**, or the semantic difficulty **Sem**. Those variables cannot be directly measured in a text (because they are not well defined), but are rather unknown functions of some other linguistic features, such as the length of a word (in characters or syllables), the amount of uppercase letters (e.g. in acronyms) or the presence of digits (e.g. protein names in biology). The graphical representation that introduces language constructs as hidden variables can be found in Figure 1b. Those hidden variables are typically introduced in joint probabilistic models as:

$$\begin{aligned} \operatorname{Pr}(r, \mathcal{L}) &= \operatorname{Pr}(r, l_1, \dots, l_m) \\ &= \sum_{\mathbf{Lex}} \sum_{\mathbf{Syn}} \sum_{\mathbf{Sem}} \operatorname{Pr}(r, \mathbf{Lex}, \mathbf{Syn}, \mathbf{Sem}, l_1, \dots, l_m) \end{aligned} \quad (4)$$

By inspecting Figure 1b, we can observe that readability score  $r$  is independent from observable linguistic features  $l_i$  given the language constructs **Lex**, **Syn** and **Sem**. Thus, we can rewrite Equation 4 to factorize over the graph in Figure 1b as:

$$\begin{aligned} \operatorname{Pr}(r, l_1, \dots, l_m) &\approx \sum_{\mathbf{Lex}} \sum_{\mathbf{Syn}} \sum_{\mathbf{Sem}} p(r \mid \mathbf{Lex}, \mathbf{Syn}, \mathbf{Sem}) \\ &\quad \cdot p(\mathbf{Lex} \mid l_1, \dots, l_i) \cdot p(\mathbf{Syn} \mid l_{i+1}, \dots, l_j) \\ &\quad \cdot p(\mathbf{Sem} \mid l_{j+1}, \dots, l_m) \cdot p(l_1) \cdots p(l_m) \end{aligned} \quad (5)$$

where  $l_1, \dots, l_i$  are inter-dependent lexical features that somehow influence the lexical difficulty,

(a) Simple Bayesian network, where the readability score  $r$  depends on all linguistic features  $l_i$ . The number of parameters makes the estimation problem intractable.

(b) Structured Bayesian network that introduces language constructs (**Lex**, **Syn** and **Sem**) as hidden variables (white ellipses), with the purpose of reducing the dependencies of the readability score  $r$  from the rest of the linguistic features.

Figure 1: Graphical representations of causal networks. Arrows denote probabilistic influence.

$l_{i+1}, \dots, l_j$  are syntactic features that influence syntactic difficulty, and the remaining are semantic features. Now the readability score  $r$  depends only on a small set of language constructs, which dramatically reduces the amount of parameters.

### 3.3 Estimating Parameter Values

Hidden variables and independency assumptions are often necessary to reduce the number of parameters that need to be estimated, specially when there are many variables or there is a limited amount of training data. In the factor graph of Figure 2, there is a conditional probability distribution (CPD)  $\Pr(v \mid Pa_v)$  modeling the probability of every linguistic feature  $v$  given its parents  $Pa_v$  in the graph<sup>2</sup>. In this work, we make no assumptions on how a variable is related to its parents and we model this unknown relationship using non-parametric CPDs. The drawback is that we need to discretize the values of the linguistic variables and that the number of parameters<sup>3</sup> increases exponentially with the number of parent variables.

The estimation of the parameter values can be carried out using standard techniques that aim at optimizing the likelihood over the training data in presence of hidden variables. In this work,

<sup>2</sup>If a variable  $v$  has no parents, then its CPD is  $p(v)$ .

<sup>3</sup>The term “non-parametric” might be misleading, since this type of CPDs have many parameters.

we used the Expectation-Maximization (EM) algorithm (Dempster et al., 1977) for that purpose.

### 3.4 Querying the Model

Estimating the joint probability distribution  $\Pr(r, \ell)$  has its advantages, since it gives us complete knowledge about the problem. In order to interpret the model, we can perform some insightful queries involving any variable.

**Marginal Maximum a Posteriori** is used to find the most probable value assignment to some linguistic features given some evidence. This query can mimic the functionality of discriminative models, where the objective is to find the most probable readability score  $\hat{r}$  given the linguistic evidence  $\ell^0$ , in presence of language constructs  $\mathbf{L}$ :

$$\text{MAP}(\hat{r} \mid \ell^0) = \underset{r}{\text{argmax}} \sum_{\mathbf{L}} p(r, \mathbf{L} \mid \ell^0) \quad (6)$$

where the conditional probability distribution  $p(r, \mathbf{L} \mid \ell^0)$  can be found by using the Bayes rule:

$$p(r, \mathbf{L} \mid \ell^0) = \frac{p(r, \mathbf{L}, \ell^0)}{p(\ell^0)} \quad (7)$$

Another application of marginal MAP queries is to gain linguistic insight about what characterizes unreadable texts. This insight could be obtained by querying the model in the opposite direction, i.e.  $\text{MAP}(\hat{\ell} \mid r^0)$ , where we want to obtain the most plausible linguistic instantiation  $\hat{\ell}$  given a certain readability level  $r^0$ . More complex queries can be similarly performed by conditioning the marginal MAP. For instance, the query  $\text{MAP}(\hat{\ell} \mid \text{Lex}^{\text{high}}, r^{\text{good}})$  would result in the most plausible values of linguistic features that have a high lexical difficulty but a good readability.

**Sensitivity analysis** allows us to understand how sensitive a certain variable is to some observed linguistic features. In our study, we are interested in understanding what individual or combination of observable linguistic features influence most in the readability of a particular text. A common approach (Kjærulff and Madsen, 2007) is to compute the distance  $d$  between the joint probability distribution with different instantiations of the linguistic features under study.

## 4 Experiments

We first describe the data that we used to train our systems, and the data grounded on cognitive

effort that we used for validation. Then, we describe the full set of linguistic features and our baseline systems. Finally, we assess to what extent our Bayesian causal network is able to predict the specific parts of the documents that are difficult to read, and compare it to other systems.

#### 4.1 Corpora

To estimate the parameters of the Bayesian causal network and our baseline systems, we opted to use texts from three corpora, namely Wikipedia Simple<sup>4</sup>, Wikipedia English<sup>5</sup>, and PubMed<sup>6</sup>.

Wikipedia has been a valuable resource for the development of text transformation methods, such as summarization (Biadys et al., 2008), or machine translation (Smith et al., 2010), among others. Wikipedia Simple is a relatively new version of the Wikipedia English, where articles are written in simple English<sup>7</sup>. Wikipedia English does not require any specific writing style other than clarity, precision and completeness. Finally, PubMed corpus is a large collection of academic biomedical articles, where readability is often sacrificed for precision and completeness. We assume that these three corpora have different expected readabilities (high, intermediate and low, respectively), and we use them as readability annotations at document level. Some linguistic features considered in our work are sensitive to text length (i.e. number of active lexical chains or average coreference distance). For this reason, we collected only abstracts from Wikipedia Simple that contain 10, 11 or 12 sentences, and randomly sampled from Wikipedia English and PubMed the same amount of long abstracts with the same text length distribution as Wikipedia Simple, totaling in 8, 856 abstracts.

Our hypothesis is that Bayesian causal networks are capable of recognizing specific parts of documents that make texts difficult to read. To test our hypothesis, we need documents with readability annotations at sub-document level. But such fine-grained annotations are difficult to obtain even for expert linguists because there are many linguistic variables involved in the annotation decisions.

In this work, we indirectly annotate the reading difficulty of every part of the text using an estimation of the expected cognitive effort required

to understand that part of the text. There are several methods that have been proposed to measure moment-to-moment cognitive effort, such as functional magnetic resonance imaging (fMRI) to quantify activations of certain brain areas, or measurements in pupil size changes. However, those methods have difficulties in aligning cognitive effort spatially and temporally to segments in a text, and we opted to measure fixation time on individual words due to its relative simplicity. Thus, we work under the assumption that higher cognitive effort is reflected as longer fixation durations, since parts of the text that are difficult to read require longer cognitive processing time.

On the text side, we characterize a part of a text by a quantification of its linguistic features at word level. Let  $f_{i,j}$  be the quantification of linguistic feature  $i$  at word  $w_j$ . As an example, linguistic feature “is noun”,  $f_{\text{noun},j} = 1$  if  $w_j$  is a noun. Non-binary linguistic features can be similarly quantified in the range  $[0, 1]$  dividing their value by the maximum possible value. For features not defined at word level (e.g. “sentence length”), the feature quantification of words in the span are all equal to the quantification of the span.

In order to estimate fixation time  $T_i$  induced by every linguistic feature  $i$ , we accumulate fixation durations on words scaled by the quantification of every linguistic feature at those words, and normalize it by the total amount of fixation durations and total amount of feature quantification. Formally, let  $t_j$  be the total amount of fixation duration on word  $w_j$ . Then, fixation time  $T_i$  caused by linguistic feature  $i$  can be computed as:

$$T_i = \frac{\sum_j t_j \cdot f_{i,j}}{(\sum_j t_j) \cdot (\sum_j f_{i,j})} \quad (8)$$

We collected fixation durations on every word using the eye-tracker Tobii TX300, and used a text-gaze aligner (Martínez-Gómez et al., 2012) to correct the systematic errors introduced by the eye-tracker. There were 40 subjects participating in our study, and only the 20% of eye-tracking sessions with highest signal quality were selected for this study. Most subjects were non-native English speakers linked to academia, with varying language skills and background knowledge. They were asked to carefully read 2 documents on 3 topics (6 documents in total), about economics, nutrition and astronomy, and answer detailed questionnaires to assess their understanding. The average

<sup>4</sup><http://simple.wikipedia.org/>

<sup>6</sup><http://www.ncbi.nlm.nih.gov/pubmed/>

<sup>7</sup>Guidelines to write in simple English are proposed in Wikipedia Simple, but are not strictly enforced.

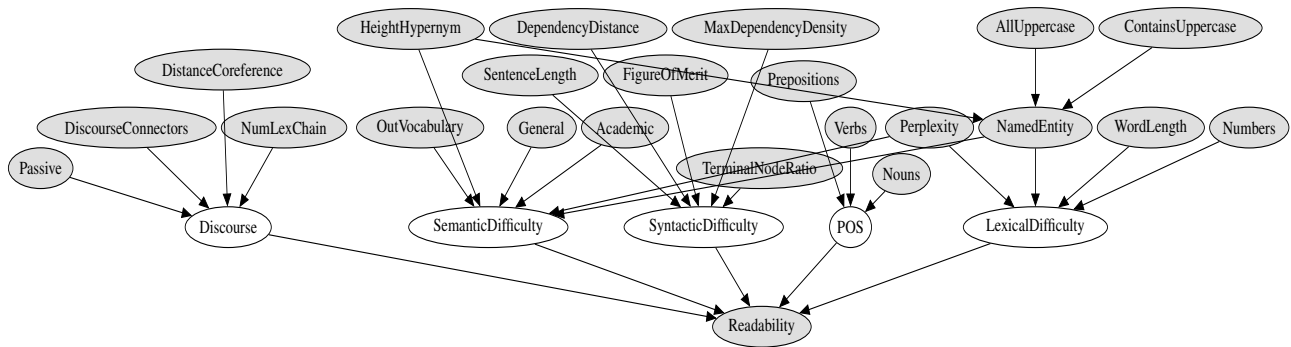

Figure 2: Graphical representation of our Bayesian causal network. Observable linguistic features are represented by white ellipses. Language constructs introduced as hidden variables are represented by gray ellipses. Directed edges indicate the direction of causality, and encode probabilistic influence.

duration of the reading and question-answering session was 1 hour, and every subject was compensated with the equivalent to 20 US dollars in cash at the end of the session. Documents contained 22.5 sentences and 469 words on average.

The objective of the Bayesian causal network will be to predict cognitive effort caused by each linguistic feature, and it will be compared to the results obtained by using discriminative methods.

#### 4.2 Feature Set

Figure 2 shows the 22 linguistic features (gray ellipses) that were used in this work, the 5 language constructs that were introduced as hidden variables (white ellipses), and their probabilistic relationships (directed edges). The linguistic features that appear as ancestors of lexical difficulty and Part of Speech (POS) correspond to their average at token level (i.e. in the case of “Numbers”, the percentage of tokens that are numbers).

Named entities were extracted using the NLTK toolkit (Bird et al., 2009), word lengths (in syllables) were computed by averaging the number of stresses in the CMU pronunciation dictionary (Weide, 1998). The perplexity was computed using Google 5-grams (Brants and Franz, 2006) with deleted interpolation tuned on a tokenized and non-lowercased separate subset of representative sentences from all three corpora. The percentage of prepositions, nouns and verbs was computed using the NLTK POS tagger.

Following the work in (Hudson, 1995) we considered the maximum dependency density and average distance between dependents as linguistic features that influence syntactic difficulty, computed using a dependency parser (Klein and Manning, 2003). Terminal node to non-terminal node

ratio is another typical phrase-based measure of syntactic difficulty, and it was computed using an HPSG parser (Miyao and Tsujii, 2008). The figure of merit, as given by the same parser, is a function of the lexical probability rules that are triggered during the automatic parsing, and somehow represents the parsing surprise.

Height of hypernyms were computed as the average distance between token lemmas to the most abstract term in WordNet (Fellbaum, 2010) and measures how specific terms are. “General”, “Academic” and “OutVocabulary” features denote the average number of words appearing in the General Word Service List (West and Jeffery, 1953), in the Academic Word List (Coxhead, 1998), or in none of them.

The average distance between mentions and their referents, and the maximum number of active lexical chains were computed using a coreference resolution system (Raghunathan et al., 2010) in a similar fashion to how the average dependency distance and maximum dependency density were computed to measure syntactic difficulty. Finally, the average number of passive clauses was computed using the output of the HPSG parser, and the percentage of tokens that are discourse connectors was measured checking the occurrence of every token in a hand-crafted list of 279 connectors.

#### 4.3 Baseline

Using our Bayesian network, we computed the importance of each linguistic feature for every document as the sensitivity of the network conditioned on the observation of the rest of the variables. We compared our system to two baselines. The first baseline, *raw features*, measures the importance of linguistic features (across the cor-

Figure 3: Correlations between predictions of feature impact on reading difficulty and the expected cognitive effort introduced by such features. Confidence intervals are computed at 95%.

pora) as the correlation between each linguistic feature and the readability score. As a second baseline, we chose SVM models due to their success in readability studies (François and Fairon, 2012). We measured their sensitivity to each linguistic feature, by observing the variations on the SVM response due to variations in each linguistic feature (Cortez, 2010), while holding the rest of linguistic variables to their average values. This baseline was built by training and tuning an SVM with a gaussian kernel in a cross-validation setup. Both baselines obtain quantifications of feature influence on readability independent of the document instantiation. For SVM sensitivity analysis, we also computed variability of SVM categorical response to changes in the linguistic feature under study while setting the rest of linguistic features to the instantiations on each document. However, there was a negligible variance in SVM response, and results are not reported for that experiment.

Confidence intervals for all systems were obtained by measuring prediction variability in 10 runs of random sampling with 90% of the data. All linguistic features were discretized in two intervals for the Bayesian network, except the readability score, which had three states (one for each class). This is an important loss of information for the Bayesian network, but it was necessary for computational reasons. SVM and raw features baselines, however, used continuous values.

#### 4.4 Results

Figure 3 shows correlations between predictions of feature impact on reading difficulty and the

expected cognitive effort introduced by such features. The  $x$ -axis corresponds to the identifier of each document for which we have estimated cognitive effort using the eye-tracker and the  $y$ -axis corresponds to correlations with the systems. Intervals for every prediction at a 95% confidence are displayed above and below each bar.

As it can be observed, raw features do not capture meaningfully cognitive effort and their correlations are close to zero, with a high confidence (narrow confidence intervals). The quantification on linguistic feature importance given by the SVM sensitivity analysis is slightly negative with large confidence intervals, which suggests that this type of analysis is not useful to predict reading difficulties in specific parts of the documents. The Bayesian causal network obtains mild, but consistent and positive correlations with the expected cognitive effort and its confidence intervals show strong significance.

Table 1 shows the most influential linguistic features on reading difficulty for documents 4 and 6. According to the cognitively-grounded reading difficulty, lexical perplexity (surprise), the occurrence of named entities, out of vocabulary words, passive clauses, academic words, nouns and abstraction (hypernyms) are the linguistic features that required longer fixation times in order to understand those documents. The Bayesian network ranked, on top 5, two and three of the most influential linguistic features for document 4 and 6.

## 5 Applications and Future Work

Bayesian causal networks for readability diagnosis have an immediate application to authoring systems, where the inference engine automatically detects text segments that make the text difficult to read. For that purpose, the average quantification of every linguistic feature has to be computed at document level. Then, causal reasoning (Bayesian sensitivity analysis) would be performed to find linguistic features with highest impact on reading difficulty for that specific document. Finally, instantiations of such linguistic features at segment level whose quantifications are above document average would be flagged for edition. Authors can then proceed to amend the text, or assert constraints. These constraints can take the form of “I want to increase readability without sacrificing the current lexical difficulty”. Such constraints can be introduced using marginal MAPs as described

Document 4	Cognitive effort	Bayesian	SVM	raw features
feature 1	<b>Nouns</b>	General	Dependency density	General
feature 2	<b>Out Vocabulary</b>	<b>Out Vocabulary</b>	General	<b>Out Vocabulary</b>
feature 3	<b>Passive</b>	<b>Academic</b>	Contains uppercase	<b>Academic</b>

feature 5	<b>Academic</b>	Figure of Merit	Verbs	Figure of Merit

Table 1: List of 5 most influential linguistic features for documents 4 and 6, sorted in descending order. The first column corresponds to the order given by cognitive effort. The rest of the columns correspond to predictions of systems. The Bayesian network finds 2 and 3 out of the 5 most influential features in documents 4 and 6. SVM and raw features provide constant estimations for all documents.

in Section 3.4. There are, however, features that cannot be tweaked individually and would require very complex user actions. Others are simply very difficult to handle by humans, as in the case of the terminal node to non-terminal node ratio.

In an automatic readability optimization setup, a set of transformation actions could be applied on a text, but discerning the most appropriate action can be challenging. Bayesian networks could be a solution to it, since they can infer the desirable configuration of linguistic values for a certain readability level in a given document, and what actions would lead to the largest readability gain.

The remaining challenges when working with non-parametric Bayesian networks are two. The first one is the necessary loss of information that occurs when discretizing features, and parametric models are possible solutions. Finding better network topologies is also an interesting challenge that brings linguistic insights into readability studies and increases the predictive power of the model. One approach is to refine the network using more thoughtful linguistic knowledge. Another possibility is to automatically estimate the optimal network topology driven by data, but causal properties could be difficult to preserve.

We used indirect measurements of cognitive effort that rely on the computation of a normalized fixation time on every linguistic feature. Fixation durations were recorded using a precise eye-tracker, but data collection is rarely exempt of systematic errors and new methods to estimate cognitive effort should account for this degraded calibration. Moreover, certain aspects of cognitive ef-

fort might not be reflected by fixation times, and other features of eye movements, such as regressions or changes in pupil diameter can be valuable.

Since estimations of feature impact on readability depends on each document, it was difficult to compare our findings to prior work. Future investigations in readability diagnosis would benefit from a combination of indirect measurements of cognitive effort and readability annotations by linguistic experts at sub-document level, that could be shared within the research community.

## 6 Conclusions

Discriminative models are built to predict readability and correlate well with human judgment. Those models are good readability predictors, but fail at explaining the causes of unreadability. With the intention of assisting humans to optimize readability or to fully automate it, we need methods able to infer the causes of readability.

We have presented the application of Bayesian causal networks to build generative readability models. To reduce the number of dependencies between linguistic features, we introduced language constructs as hidden variables and estimated the parameter values using the EM algorithm.

Using our proposed Bayesian causal network, we measured the impact of every linguistic feature in presence of all other variables, and compared the prediction accuracy to grounded cognitive effort. Our method showed significant and positive correlations with cognitive effort, suggesting that it is able to capture linguistic features that cause difficulties in reading for specific documents.

# Word Co-occurrence Counts Prediction for Bilingual Terminology Extraction from Comparable Corpora

Amir Hazem and Emmanuel Morin

Laboratoire d'Informatique de Nantes-Atlantique (LINA)

Université de Nantes, 44322 Nantes Cedex 3, France

{Amir.Hazem, Emmanuel.Morin}@univ-nantes.fr

## Abstract

Methods dealing with bilingual lexicon extraction from comparable corpora are often based on word co-occurrence observation and are by essence more effective when using large corpora. In most cases, specialized comparable corpora are of small size, and this particularity has a direct impact on bilingual terminology extraction results. In order to overcome insufficient data coverage and to make word co-occurrence statistics more reliable, we propose building a predictive model of word co-occurrence counts. We compare different predicting models with the traditional *Standard Approach* (Fung, 1998) and show that once we have identified the best procedures, our method increases significantly the performance of extracting word translations from comparable corpora.

## 1 Introduction

Using comparable corpora for bilingual lexicon extraction is becoming more and more a matter of interest, especially because of the easier availability of this kind of corpora comparing to parallel ones. Many researchers proposed a variety of approaches (Fung, 1995; Rapp, 1999; Chiao and Zweigenbaum, 2002; Déjean et al., 2002; Morin et al., 2007; Laroche and Langlais, 2010, among others). While different improvements were achieved, the starting point remains words'co-occurrences as they represent the observable evidence that can be distilled from a corpus. Hence, frequency counts for word pairs often serve as a basis for distributional methods. The main assumption underlying bilingual lexicon extraction is: two words are more likely to be a translation of each other if they share the same lexi-

cal contexts (Fung, 1998). The most popular approach named, the *Standard Approach* (Fung and Mckeown, 1997; Rapp, 1999), makes use of this assumption to perform bilingual lexicon extraction. While good results on single word terms (SWTs) can be obtained from large corpora of several million words (80% for the top 10-20 (Fung and Mckeown, 1997), 91% accuracy for the top 3 (Cao and Li, 2002)). Results drop significantly using specialized small corpora (60% for the top 20 (Chiao and Zweigenbaum, 2002; Déjean et al., 2002; Morin et al., 2007)).

The reliability of co-occurrence counts greatly relies on the amount of data. Clearly, the larger the training corpus, the more representative it is likely to be, and thus the more reliable the statistics of words. Therefore, the number and distribution of types in the available small sample are not reliable estimators (Evert and Baroni, 2007). This latter fact motivates the necessity of an alternative to the unreliable counts especially when using small specialized comparable corpora. Statistical NLP often deals in the prediction of variables ranging from text categories to linguistic structures to novel utterances. If large specialized comparable corpora are not available, one way to approach this problem and to make co-occurrence counts more reliable, is to use prediction models of word co-occurrence counts based on large training datasets. Corpus data from the general domain such as newspapers, for instance, is abundant and can be easily used for training.

The main contribution of this paper is to investigate different word co-occurrence prediction models for the task of bilingual terminology extraction from comparable corpora. Our aim is to make the observed word co-occurrence counts in small specialized comparable corpora more reliable by re-estimating their probabilities. For that purpose we explore different models such as the linear regression often used to model data using

linear predictor functions, the mean average word co-occurrence increase and the Good-Turing estimator. All of the predicting models rely on the observed counts of word co-occurrence in a training dataset of small and large corpora from the general domain. While prediction is widely used in NLP, to our knowledge no investigation of co-occurrence prediction for the task of bilingual terminology extraction from comparable corpora has been addressed so far. We show that using our method as a pre-processing step of the *Standard Approach*, leads to significant improvements on the performance of bilingual terminology extraction.

In the remainder of this paper, we present in section 2 the related work on bilingual lexicon extraction from comparable corpora. Then, we introduce in section 3 the *Standard Approach* used as baseline. Section 4 describes our method and the different predicting models of co-occurrence counts. Section 5 describes the different linguistic resources used in our experiments. Section 6 evaluates the contribution of the predicting models on the quality of bilingual terminology extraction through different experiments. We discuss our findings in section 7 and finally conclude in section 8.

## 2 Related Work

The distributional hypothesis which states that words with similar meaning tend to occur in similar contexts, has been extended to the bilingual scenario (Fung, 1998; Rapp, 1999). Hence, using comparable corpora, a translation of a source word can be found by identifying a target word with the most similar context. A popular method often used as a baseline is the *Standard Approach* (Fung, 1998). It consists of using the bag-of-words paradigm to represent words of source and target language by their context vector. After word contexts have been weighted using an association measure (the point-wise mutual information (Fano, 1961), the log-likelihood (Dunning, 1993), the discounted odds-ratio (Laroche and Langlais, 2010)), the similarity between a source word's context vector and all the context vectors in the target language is computed using a similarity measure (cosine (Salton and Lesk, 1968), Jaccard (Grefenstette, 1994)...). Finally, the translation candidates are ranked according to their similarity score.

Many variants of the *Standard Approach* have been proposed. They can differ in context representation (window-based, syntactic-based) (Morin et al., 2007; Gamallo, 2008), corpus characteristics (small, large, general or domain specific...)(Chiao and Zweigenbaum, 2002; Déjean et al., 2002; Morin et al., 2007), type of words to translate (single word terms (SWTs) or multi-word terms (MWTs))(Rapp, 1999; Daille and Morin, 2005), words frequency (less frequent, rare...)(Pekar et al., 2006), etc.

There exist other approaches for bilingual lexicon extraction. Déjean et al. (2002) introduce the *Extended Approach* to avoid the insufficient coverage of the bilingual dictionary required for the translation of source context vectors. A variation of the latter method based on centroid is proposed by Daille and Morin (2005). Haghghi et al. (2008) employ dimension reduction using canonical component analysis (CCA) and Rubino and Linares (2011) propose a multi-view approach based on linear discriminant analysis (LDA) among others.

## 3 Standard Approach

The *Standard Approach* is based on words co-occurrence vectors. The basic idea is to go through a corpus and to count the number of times  $n(c, t)$  each context word  $c$  occurs within a window of a certain size  $w$  around each target word  $t$ . According to (Fung and Mckeown, 1997; Fung, 1998; Rapp, 1999), the *Standard Approach* can be carried out as follows:

For a source word to translate  $w_i^s$ , we first build its context vector  $v_{w_i^s}$ . The vector  $v_{w_i^s}$  contains all the words that co-occur with  $w_i^s$  within windows of  $n$  words. Let's denote by  $coocc(w_i^s, w_j^s)$  the co-occurrence value of  $w_i^s$  and a given word of its context  $w_j^s$ . The process of building context vectors is repeated for all the words of the target language. An association measure such as the point-wise mutual information (Fano, 1961), the log-likelihood (Dunning, 1993) or the discounted odds-ratio (Laroche and Langlais, 2010) is used to score the strength of correlation between a word and all the words of its context vector. The context vector  $v_{w_i^s}$  is projected into the target language  $v_{w_i^t}$ . Each word  $w_j^s$  of  $v_{w_i^s}$  is translated with help of a bilingual dictionary  $D$ . If  $w_j^s$  is not present in  $D$ ,  $w_j^s$  is discarded. Whenever the bilingual dictionary provides several translations for a word, all the entries are considered but weighted according

to their frequency in the target language (Morin et al., 2007). A similarity measure is used to score each target word  $w_i^t$ , in the target language with respect to the translated context vector,  $v_{w_i^s}^t$ . Usual measures of vector similarity include the cosine similarity (Salton and Lesk, 1968) or the weighted Jaccard index (Grefenstette, 1994) for instance. The candidate translations of the word  $w_i^s$  are the target words ranked following the similarity score.

## 4 Method

### 4.1 Basic Idea

We start from the assumption that words that co-occur together more often than by chance in a small corpus, should have the same behaviour in a bigger corpus with higher co-occurrence values. Our aim is to estimate the increasing values. We choose to observe co-occurrence counts using a training dataset. Table 1 shows the increase of word co-occurrence counts in corpus of different sizes. Let's denote by  $w_i$  and  $w_j$  two given words. We take as a starting point a corpus of 500,000 words in English, French and Spanish then, for each couple of words  $(w_i, w_j)$  that occur together, we observe their co-occurrence count variation in corpus of 1, 2 and 5 million words per language. For instance, if  $coocc(w_i, w_j) = 5$  in the English corpus of 500,000 words, we observe  $coocc(w_i, w_j)$  in the English corpus of 1, 2 and 5 million words and observe how much this value increases.

Table 1 can be read as follows: Let's take  $coocc_{En} > 1$ , we can see in Table 1 that there is an increase of 37.19% of words that co-occur more than 1 time in the corpus of 1 million words, 57.06% in the corpus of 2 million words and 73.02% in the corpus of 5 million words. The observations of Table 1 confirm that word co-occurrence counts increase in most cases (97.34% for  $coocc_{Es} > 4$ , 98.87% for  $coocc_{Fr} > 4...$ )

### 4.2 Co-occurrence Counts Estimation

Let's denote by  $E_S = \{v_S^1, v_S^2, \dots, v_S^n\}$  the set of the observed co-occurrence counts in a small training corpus. Our aim is to estimate the expected co-occurrence counts  $E_L = \{v_L^1, v_L^2, \dots, v_L^n\}$  in a large corpus. To do so, one intuitive way for estimation is the mean average increase (MAI) of each co-occurrence count. A more effective model that has proven its efficiency is linear regression. For that reason, we decided to use lin-

#Co-occ	1m	2m	5m
$coocc_{En} > 0$	16.13	30.04	47.06
$coocc_{En} = 1$	10.99	23.39	40.66
$coocc_{En} > 1$	37.19	57.06	73.02
$coocc_{En} > 2$	57.50	77.50	88.54
$coocc_{En} > 3$	68.83	85.39	92.63
$coocc_{En} > 4$	77.41	90.79	95.65
$coocc_{En} > 5$	82.11	92.70	96.28
$coocc_{Fr} > 0$	17.74	30.50	47.76
$coocc_{Fr} = 1$	12.55	24.04	41.58
$coocc_{Fr} > 1$	47.84	67.79	83.39
$coocc_{Fr} > 2$	69.28	86.95	95.30
$coocc_{Fr} > 3$	80.81	93.68	98.00
$coocc_{Fr} > 4$	87.93	96.76	98.87
$coocc_{Fr} > 5$	91.30	97.84	99.14
$coocc_{Es} > 0$	18.64	35.50	51.27
$coocc_{Es} = 1$	13.15	28.55	44.91
$coocc_{Es} > 1$	40.99	63.60	76.92
$coocc_{Es} > 2$	60.93	82.93	91.42
$coocc_{Es} > 3$	71.60	89.40	94.80
$coocc_{Es} > 4$	78.91	93.74	97.03
$coocc_{Es} > 5$	83.13	95.06	97.34

Table 1: Word co-occurrence counts increase (%) in corpus of different sizes on the English, French and Spanish Newspapers

ear regression (*LReg*) for prediction. In statistical NLP, smoothing techniques for n-gram models have been addressed in a number of studies (Chen and Goodman, 1999). We chose to apply the simple Good-Turing estimator (Good, 1953) as it is an appropriate way to estimate word co-occurrence counts. We finally present a naive model based on the maximum (*Max*) and the mean average count (*Mean*) of observed word co-occurrence counts in a small and large training datasets.

#### 4.2.1 Mean Average Increase

Results shown in Table 1 lead to an intuitive model which consists of the estimation of the mean average increase of each co-occurrence count. To estimate  $E_L$  we use a training corpus divided in two sets of small (500,000 words) and large (10 million words) corpus. Hence, we estimate the increasing value for each co-occurrence pair count. Let's denote by:

$E_S^1 = \{coocc_S^1(w_i, w_j) = 1, i \in [1, N], j \in [1, M]\}$   
the set of co-occurrence pairs of count 1 observed in a small corpus and by:

$E_L^o = \{coocc_L^1(w_i, w_j) = o_{ij}, i \in [1, N], j \in [1, M]\}$   
the set of co-occurrence pairs of count  $o_{ij}$  observed in a large corpus. The mean average increase  $MAI_1$  for 1 count co-occurrence pairs is:

$$MAI_1 = \frac{1}{|E_S^1|} \sum_{i=1}^N \sum_{j=1}^M (\text{coocc}_L^1(w_i, w_j) - \text{coocc}_S^1(w_i, w_j)) \quad (1)$$

The generalized formula for a given pair co-occurrence count  $k$  is:

$$MAI_k = \frac{1}{|E_S^k|} \sum_{i=1}^N \sum_{j=1}^M (\text{coocc}_L^k(w_i, w_j) - \text{coocc}_S^k(w_i, w_j)) \quad (2)$$

#### 4.2.2 Good-Turing Estimator

Smoothing techniques (Good, 1953) are often used to better estimate probabilities when there is insufficient data to estimate probabilities accurately. They tend to make distributions more uniform, by adjusting low probabilities such as zero probabilities upward, and high probabilities downward. The Good-Turing estimator (Good, 1953) states that for any  $n$ -gram that occurs  $r$  times, we should pretend that it occurs  $r^*$  times. The Good-Turing estimator uses the count of things you have seen once to help estimate the count of things you have never seen. In order to compute the frequency of words, we need to compute  $N_c$ , the number of events that occur  $c$  times (assumes that all items are binomially distributed). Let  $N_r$  be the number of items that occur  $r$  times.  $N_r$  can be used to provide a better estimate of  $r$ , given the binomial distribution. The adjusted frequency  $r^*$  is then:

$$r^* = (r + 1) \frac{N_{r+1}}{N_r} \quad (3)$$

The function  $r^*$  is applied to all the observed co-occurrence counts of the test data.

#### 4.2.3 Linear Regression

Starting from the observations in Table 1, thanks to linear regression we attempt to model the relationship between the first variable which corresponds to the co-occurrence distribution of words in the small corpus known as the explanatory variable, and the second variable which corresponds to the co-occurrence distribution of words in the large corpus known as the dependent variable. Before applying the linear regression we want to ensure that there is a correlation between the two variables; to do so, we apply the correlation coefficient as presented in Table 2:

Cor	1m	2m	5m
$cor_{En}$	0.933	0.894	0.788
$cor_{Fr}$	0.924	0.899	0.872
$cor_{Es}$	0.904	0.854	0.801

Table 2: Word co-occurrence counts correlation between corpus of 500,000 words and corpus of different sizes (1 million, 2 million and 5 million words) on the English, French and Spanish Newspaper

We can see according to Table 2 that there is a strong correlation of word co-occurrence counts across corpora of different sizes. Let's denote by  $f$  the linear function of explanatory variables. We use in our case one explanatory variable  $X$  that corresponds to the set of word co-occurrence counts in a small corpus.

- $Y = \beta_1 X + \beta_0$
- For each  $x$  of  $X$ :  $f(x) = \beta_1 x + \beta_0$

By applying linear regression to our training dataset we obtain the following equations:

For the English corpus we obtain:

$$Y_{1m} = 1.742X - 0.686$$

$$Y_{2m} = 3.184X - 2.008$$

$$Y_{5m} = 5.997X - 3.967$$

For the French corpus we obtain:

$$Y_{1m} = 1.802X - 0.673$$

$$Y_{2m} = 3.104X - 1.773$$

$$Y_{5m} = 7.167X - 5.137$$

Where  $Y_{1m}$  for instance, corresponds to the linear regression function learned from the training corpus of 1 million words.

#### 4.2.4 Mean and Max Models

As shown in Table 1, co-occurrence counts increase automatically when corpus size increases. A straightforward and maybe naive process is to select the observed counts of co-occurrence pairs in the training large corpus as the new estimation

values. Hence, using the mean process, each co-occurrence pair count can be estimated as follows:

$$\text{Mean}_k = \frac{1}{N} \sum_{i=1}^N \text{count}(k, i) \quad (4)$$

Where  $k$  is the observed count in the small corpus and  $i$  is the observed count in the large corpus of a given words pair. In the same way, using the max process, each co-occurrence pair count is estimated as follows:

$$\text{Max}_k = \frac{1}{N} \text{MAX}_{i=1}^N \text{count}(k, i) \quad (5)$$

## 5 Linguistic Resources

In order to evaluate the prediction techniques, several linguistic resources are needed. We present hereafter the comparable corpora, the bilingual dictionary and the reference lists used in our experiments.

### 5.1 Corpus Data

Experiments have been carried out on two English-French comparable corpora. A specialized corpus of 1 million words from the medical domain within the sub-domain of breast cancer and a specialized corpus from the domain of wind energy of 600,000 words.

	Breast cancer	Wind energy
$Tokens_S$	500,000	300,000
$Tokens_T$	500,000	300,000
$ S $	8,221	6,081
$ T $	6,631	5,606

Table 3: Corpus size

For the breast cancer corpus, we have selected the documents from the Elsevier website<sup>1</sup> in order to obtain an English-French specialized comparable corpora. We have automatically selected the documents published between 2001 and 2008 where the title or the keywords contain the term 'cancer du sein' in French and 'breast cancer' in English. For the wind energy corpus, we used the *Babook* crawler (Groc, 2011) to collect documents in French and English from the web. As the documents were collected from different websites according to some keywords of the domain,

<sup>1</sup>[www.elsevier.com](http://www.elsevier.com)

this corpus is more noisy and less well structured comparing to the breast cancer corpus. The two bilingual corpora have been normalized through the following linguistic pre-processing steps: tokenization, part-of-speech tagging, and lemmatization. The function words have been removed and the words occurring once (i.e. hapax) in the French and the English parts have been discarded. As summarized in Table 3, The breast cancer corpus comprised about 8,221 distinct words in English ( $|S|$ ) and 6,631 distinct words in French ( $|T|$ ). The wind energy corpus comprised about 6,081 distinct words in English ( $|S|$ ) and 5,606 distinct words in French ( $|T|$ ).

### 5.2 Dictionary

We used in our experiments the French-English bilingual dictionary ELRA-M0033 of about 200,000 entries<sup>2</sup>. It contains, after linguistic pre-processing steps and projection on both corpora less than 4000 distinct words. The details are given in Table 4.

	Breast cancer	Wind energy
$ ELRA_S $	3,573	3,459
$ ELRA_T $	3,670	3,326

Table 4: Dictionary coverage

### 5.3 Reference Lists

To build our reference lists, we selected only the English/French pair of single-word terms (SWTs) which occur more than five times in each part of the comparable corpus. As a result of filtering, 321 English/French SWTs were extracted (from the UMLS<sup>3</sup> meta-thesaurus) for the breast cancer corpus and 100 pairs for the wind energy corpus. The small size of the reference lists can be explained by the fact that small specialized comparable corpora contain a limited set of specialized terms. We can also notice that in bilingual terminology extraction from specialized comparable corpora, the terminology reference list is often composed of 100 SWTs (180 SWTs in (Déjean et al., 2002), 95 SWTs in (Chiao and Zweigenbaum, 2002), and 100 SWTs in (Daille and Morin, 2005)).

<sup>2</sup>ELRA dictionary has been done by Sciper in the Technolange/Euradic project

<sup>3</sup><http://www.nlm.nih.gov/research/umls>

## 5.4 Training Dataset

Predicting models such as linear regression or the Good-Turing estimator need a large training corpus to estimate the adjusted co-occurrences. For that purpose, we chose a training corpus composed of two sets. A small set of 500,000 words and a large set of 10 million words. We selected the documents published in 1994 from newspapers *Los Angeles Times/Le Monde*.

## 6 Experiments and Results

The baseline in our experiments is the *Standard Approach* (Fung, 1998) which is often used for comparison (Pekar et al., 2006; Gamallo, 2008; Prochasson and Morin, 2009), etc. In this section, we first give the parameters of the *standard approach*, then we present the results of the experiments conducted on the two corpora presented above: 'Breast cancer' and 'Wind energy'.

### 6.1 Experimental Setup

Using the *Standard Approach*, three major parameters need to be set:

1. The size of the window used to build the context vectors (Morin et al., 2007; Gamallo, 2008)
2. The association measure (the log-likelihood (Dunning, 1993), the point-wise mutual information (Fano, 1961), the discounted odds-ratio (Laroche and Langlais, 2010)...) )
3. The similarity measure (the weighted Jaccard index (Grefenstette, 1994), the cosine similarity (Salton and Lesk, 1968),...)

Laroche and Langlais (2010) carried out a complete study of the influence of these parameters on the quality of bilingual lexicon extraction from comparable corpora. To build the context vectors we chose a 7-window size. The entries of the context vectors were determined by the log-likelihood, the point-wise mutual information and the discounted odds-ratio. As similarity measure, we chose to use the weighted Jaccard index and the cosine similarity. Other combinations of parameters were assessed but the previous parameters turned out to give the best performance.

We note that *Top k* means that the correct translation of a given word is present in the k first candidates of the list returned by the *Standard Approach*. We use also the mean average precision

*MAP* (Manning and Schutze, 2008) which represents the quality of the system.

$$MAP(Q) = \frac{1}{|Q|} \sum_{i=1}^{|Q|} \frac{1}{m_i} \sum_{m_i=1}^k P(R_{ik}) \quad (6)$$

where  $|Q|$  is the number of terms to be translated,  $m_i$  is the number of reference translations for the  $i^{th}$  term (always 1 in our case), and  $P(R_{ik})$  is 0 if the reference translation is not found for the  $i^{th}$  term or  $1/r$  if it is ( $r$  is the rank of the reference translation in the translation candidates).

### 6.2 Results

We conducted a set of two experiments on two specialized comparable corpora. We carried out a comparison between the *Standard Approach* (*SA*) and the different prediction models presented in section 4.2 namely: the maximum model (*Max*), the mean model (*Mean*), the linear regression model (*LReg*), The Good-Turing estimator (*GT*) and the mean average increase model (*MAI*). Experiment 1 shows the results on the breast cancer corpus and experiment 2 those of the wind energy corpus.

Table 5 shows the results of the experiments on the breast cancer corpus. The first observation concerns the *Standard Approach* (*SA*). The best results are obtained using the Log-Jac parameters with a MAP of 27.9%. We can also notice that for this configuration, none of the prediction models improve the performance of the *Standard Approach*. On the contrary, they even degrade the results. The second observation concerns the Odds-Cos parameters where the naive *Mean*, *Max* and *MAI* models are under the baseline. The best score is obtained by the *LReg* model with a MAP of 27.6%. The most notable result concerns the PMI-Cos parameters. We can notice that four of the five techniques improve the performance of the baseline. The best prediction model is the *Max* technique which reaches a MAP of 27.2% and improves the Top1 precision of 4.8% and the Top10 precision of 6.6%.

Table 6 shows the results of the experiments on the wind energy corpus. Generally the results follow the same behaviour as the previous experiment. The best results of the *Standard Approach* are obtained using the Log-Jac parameters with a MAP of 25.7%. Here also, none of the prediction models improve the performance of the *Standard Approach*. About the Odds-Cos parameters,

	SA	Max	Mean	LReg	MAI	GT	
P1	15.5	<b>20.2</b>	13.7	18.0	18.6	18.6	PMI-Cos
P5	31.1	<b>35.8</b>	28.3	<b>35.8</b>	34.2	32.0	
P10	34.5	41.1	32.7	<b>42.0</b>	38.3	37.0	
MAP	22.6	<b>27.2</b>	20.3	26.7	26.4	25.6	
P1	15.8	15.5	11.8	<b>19.9</b>	13.7	16.8	Odds-Cos
P5	<b>34.8</b>	30.2	28.6	34.2	27.7	34.2	
P10	40.4	36.7	35.5	<b>41.7</b>	33.0	39.8	
MAP	24.8	22.9	19.8	<b>27.6</b>	20.9	25.2	
P1	<b>20.2</b>	06.5	16.5	15.5	09.9	14.6	Log-Jac
P5	<b>35.8</b>	15.5	33.9	28.6	21.4	27.7	
P10	<b>42.6</b>	20.5	38.3	37.3	26.7	34.2	
MAP	<b>27.9</b>	11.6	24.6	22.6	15.6	21.4	

Table 5: Results of the experiments on the 'Breast cancer' corpus (the improvements indicate a significance at the 0.05 level using Student's t-test).

	SA	Max	Mean	LReg	MAI	GT	
P1	07.0	13.0	10.0	<b>18.0</b>	15.3	14.0	PMI-Cos
P5	27.0	34.0	30.0	<b>37.0</b>	33.0	31.0	
P10	37.0	<b>46.0</b>	36.0	<b>46.0</b>	43.0	43.0	
MAP	17.8	23.1	19.2	<b>28.0</b>	25.0	22.9	
P1	12.0	09.0	06.0	<b>14.0</b>	10.0	12.0	Odds-Cos
P5	31.0	20.0	27.0	<b>32.0</b>	25.0	31.0	
P10	38.0	26.0	39.0	<b>40.0</b>	33.0	36.0	
MAP	21.8	15.7	17.0	<b>23.3</b>	18.0	19.8	
P1	<b>17.0</b>	09.0	18.0	15.0	18.0	13.0	Log-Jac
P5	<b>36.0</b>	16.0	30.0	31.0	29.0	27.0	
P10	<b>42.0</b>	22.0	45.0	36.0	36.0	37.0	
MAP	<b>25.7</b>	14.0	25.1	22.9	23.7	20.5	

Table 6: Results of the experiments on the 'Wind energy' corpus (the improvements indicate a significance at the 0.05 level using Student's t-test).

here again the naive *Mean*, *Max* and *MAI* models are under the baseline. We can also notice that *GT* is slightly under the *standard approach*. The best score is obtained by the *LReg* model with a MAP of 23.3%. Finally, the most remarkable result still concerns the PMI-Cos parameters where the same four of the five predicting techniques improve the performance of the baseline. The best prediction model is the *LReg* technique which reaches a MAP of 28.0% and improves the Top1 precision of 11.0% and the Top10 precision of 10.2%.

## 7 Discussion

The aim of this work was to propose and contrast different word co-occurrence prediction approaches: naive or intuitive (*Max*, *Mean* and *MAI*) and more sophisticated (*LReg* and *GT*)

aiming to improve bilingual terminology extraction. Our approach can be used as a pre-processing step of the *Standard Approach* by applying a prediction function to word co-occurrence counts.

According to the experimental results, the first observation is that the *Standard Approach* performs better when using the log-likelihood measure comparatively to the discounted odds-ratio and the point-wise mutual information measures. This supposes that the log-likelihood provides a better estimation of word co-occurrence counts. The log-likelihood measures significance (i.e. the amount of evidence against the null hypothesis) and is known to be more robust against low expected frequencies (Dunning, 1993). The lower performance of the *Standard Approach* when using the point-wise mutual information is certainly due to the over-estimation of low frequencies. In practical applications, PMI was found to have a tendency to assign inflated scores to low-frequency word pairs. Thus, even a single co-occurrence of two words might result in a fairly high association score. The discounted odds-ratio has shown lower results when compared to log-likelihood unlike its better performance as shown in Laroche and Langlais (2010). This is certainly due to the multiple parameters and resources of the *Standard Approach* and also the cosine similarity measure which is sensitive to context vector size. In our experiments, we did not investigate this parameter as it is not the matter of our study. We considered the whole context vector of each word.

According to the PMI-Cos configuration, the baseline is consistently outperformed by every prediction model (except *Mean* on the breast cancer experiment). The good results of the proposed methods when associated to the PMI-Cos configuration suggest that the over-estimation of infrequent counts of PMI is skimmed by the prediction function. This finding can be considered as a new way to counterbalance the low-frequency bias of PMI. The best prediction approach shown in the experiments is *Max* with a MAP of 27.2%, followed by *LReg* with a MAP of 26.7% on the breast cancer corpus. Nevertheless, in the wind energy corpus *LReg* performed substantially better than *Max* with a MAP of 28.0% while *Max* reaches 23.1% only. Even the lower performance of *MAI* and *GT*, they also provide significant improvements.

In our experiments, none of the proposed algo-

rithms reached good results while associated to the Log-Jac configuration. This is certainly related to the properties of the log-likelihood association measure. While the prediction models tend to increase small co-occurrence counts, this can lead to the overrating of infrequent words renders the ranking of the log-likelihood measure useless. Concerning the Odds-Cos parameters, although there were slight improvements on the *LReg* algorithm, other methods have shown disappointing results. Here again the Odds-ratio association measure seems to be not compatible with re-estimating co-occurrence counts. More investigations are certainly needed to highlight the reasons of this poor performance. It seems that prediction functions do not fit well with association measures based on contingency table.

The most noticeable improvement concerns the PMI-Cos configuration. Aside from the *Mean* method, all the other techniques have shown better performance than the *Standard Approach*. According to the empirical results, point-wise mutual information performs better with *Max* and *LReg* techniques. Furthermore and as has been pointed out above, prediction models seem to be an alternative to the low-frequency bias of the point-wise mutual information. It is our hope that the present work may provide a starting point to co-occurrence prediction on comparable corpora as an alternative to unreliable counts. The next step is to explore more complex prediction models such as nonlinear regression that intuitively should fit better than a simple linear regression and to contrast our prediction function with the various suggested heuristics for correcting PMI bias.

## 8 Conclusion

In this paper, we have described and compared different prediction models for the task of bilingual terminology extraction from comparable corpora. Our belief is that word co-occurrence counts prediction can be an alternative to the unreliable counts observed in small corpora. The results demonstrate the viability of the proposed approach using the PMI-Cos configuration. If more investigation is certainly needed for the Odds-Cos and Log-Jac configurations, the empirical results of our proposition suggest that predicting word co-occurrence counts is an appropriate way to improve the accuracy of the *Standard Approach* in small specialized comparable corpora.

## Abstract

The work presented in this paper attempts to evaluate and quantify the use of discourse relations in the context of blog summarization and compare their use to more traditional and factual texts. Specifically, we measured the usefulness of 6 discourse relations - namely *comparison*, *contingency*, *illustration*, *attribution*, *topic-opinion*, and *attributive* for the task of text summarization from blogs. We have evaluated the effect of each relation using the TAC 2008 opinion summarization dataset and compared them with the results with the DUC 2007 dataset. The results show that in both textual genres, *contingency*, *comparison*, and *illustration* relations provide a significant improvement on summarization content; while *attribution*, *topic-opinion*, and *attributive* relations do not provide a consistent and significant improvement. These results indicate that, at least for summarization, discourse relations are just as useful for informal and affective texts as for more traditional news articles.

## 1 Introduction

It is widely accepted that in a coherent text, units should not be understood in isolation but in relation with each other through discourse relations that may or may not be explicitly marked. A text is not a linear combination of textual units but a hierarchical organized group of units placed together based on informational and intentional relations to one another. According to (Taboada, 2006), “Discourse relations - relations that hold together different parts (i.e. proposition, sentence, or paragraph) of the discourse - are partly responsible for the perceived coherence of a text”. For example,

in the sentence “*If you want the full Vista experience, you’ll want a heavy system and graphics hardware, and lots of memory*”, the first and second clauses do not bear much meaning independently; but become more meaningful when we realize that they are related through the discourse relation *condition*.

Discourse relations have been found useful in many NLP applications such as natural language generation (e.g. (McKeown, 1985)) and news summarization (e.g. (Blair-Goldensohn and McKeown, 2006; Bosma, 2004)) to improve coherence and better simulate human writing. However, most of these work have been developed for formal, well-written and factual documents. Text available in the social media are typically written in a more casual style, are opinionated and speculative (Andreevskaia et al., 2007). Because of this, techniques developed for formal texts, such as news articles, often do not behave as well when dealing with informal documents. In particular, news articles are more uniform in style and structure; whereas blogs often do not exhibit a stereotypical discourse structure. As a result, for blogs, it is usually more difficult to identify and rank relevant units for summarization compared to news articles.

Several work have shown that discourse relations can improve the results of summarization in the case of factual texts or news articles (e.g. (Otterbacher et al., 2002)). However, to our knowledge no work has evaluated the usefulness of discourse relations for the summarization of informal and opinionated texts, as those found in the social media. In this paper, we consider the most frequent discourse relations found in blogs: namely *comparison*, *contingency*, *illustration*, *attribution*, *topic-opinion*, and *attributive* and evaluate the effect of each relation on informal text summarization using the Text Analysis Conference (TAC)

2008 opinion summarization dataset<sup>1</sup>. We then compare these results to those found with the news articles of the Document Understanding Conference (DUC) 2007 Main task dataset<sup>2</sup>. The results show that in both types of texts, discourse relations seem to be as useful: *contingency*, *comparison*, and *illustration* relations provide a statistically significant improvement on the summary content; while the *attribution*, *topic-opinion*, and *attributive* relations do not provide a consistent and significant improvement.

## 2 Related Work on Discourse Relations for Summarization

The use of discourse relations for text summarization is not new. Most notably, (Marcu, 1997) used discourse relations for single document summarization and proposed a discourse relation identification parsing algorithm. In some work (e.g. (Bosma, 2004; Blair-Goldensohn and McKeown, 2006)), discourse relations have been exploited successfully for multi-document summarization. In particular, (Otterbacher et al., 2002) experimentally showed that discourse relations can improve the coherence of multi-document summaries. (Bosma, 2004) showed how discourse relations can be used effectively to incorporate additional contextual information for a given question in a query-based summarization. (Blair-Goldensohn and McKeown, 2006) used discourse relations for content selection and organization of automatic summaries and achieved an improvement in both cases. Discourse relations were also used successfully by (Zahri and Fukumoto, 2011) for news summarization.

However, the work described above have been developed for formal, well-written and factual documents. Most of these work show how discourse relations can be used in text summarization and show their overall usefulness. To the best of our knowledge, our work is the first to measure the effect of specific relations on the summarization of informal and opinionated text.

## 3 Tagging Discourse Relations

To evaluate the effect of discourse relations on a large scale, sentences need to be tagged automatically with discourse relations. For example, the sentence “Yesterday, I stayed at home because it

was raining.” needs to be tagged as containing a *cause* relation. One sentence can convey zero or several discourse relations. For example, the sentence “Starbucks has contributed to the popularity of good tasting coffee” does not contain any discourse relations of interest to us. On the other hand, the sentence “While I like the Zillow interface and agree it’s an easy way to find data, I’d prefer my readers used their own brain to perform a basic valuation of a property instead of relying on zestimates.” contains 5 relations of interest: one *comparison*, three *illustrations*, and one *attribution*.

### 3.1 Most Frequent Discourse Relations

Since our work is performed within the framework of blog summarization; we have only considered the discourse relations that are most useful to this application. To find the set of the relations needed for this task, we have first manually analyzed 50 summaries randomly selected from participating systems at the TAC 2008 opinion summarization track and 50 randomly selected blogs from BLOG06 corpus<sup>3</sup>. In building our relation taxonomy, we considered all main discourse relations listed in the taxonomy of Mann and Thompson’s Rhetorical Structure Theory (RST) (Mann and Thompson, 1988). These discourse relations are also considered in Grimes’ (Grimes, 1975) and Williams’ predicate lists. From our corpus analysis, we have identified the six most prevalent discourse relations in this blog dataset, namely *comparison*, *contingency*, *illustration*, *attribution*, *topic-opinion*, and *attributive*. The *comparison*, *contingency*, and *illustration* relations are also considered by most of the work in the field of discourse analysis such as the PDTB: Penn Discourse TreeBank research group (Prasad et al., 2008) and the RST Discourse Treebank research group (Carlson and Marcu, 2001). We considered three additional classes of relations: *attributive*, *attribution*, and *topic-opinion*. These discourse relations are summarized in Figure 1 while a description of these relations is given below.

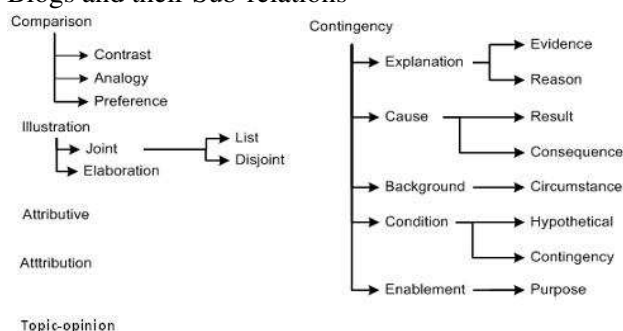

**Illustration:** Is used to provide additional information or detail about a situation. For example: “Allied Capital is a closed-end management investment company that will operate as a business development concern.”

<sup>1</sup><http://www.nist.gov/tac/>

<sup>2</sup><http://www-nlpir.nist.gov/projects/duc/guidelines/2007.html>

<sup>3</sup>[http://ir.dcs.gla.ac.uk/test\\_collections/blog06info.html](http://ir.dcs.gla.ac.uk/test_collections/blog06info.html)

Figure 1: Most Frequent Discourse Relations in Blogs and their Sub-relations

As shown in Figure 1, *illustration* relations can be sub-divided into sub-categories: *joint*, *list*, *disjoint*, and *elaboration* relations according to the RST Discourse Treebank (Carlson and Marcu, 2001) and the Penn Discourse TreeBank (Prasad et al., 2008).

**Contingency:** Provides cause, condition, reason or evidence for a situation, result or claim. For example: “*The meat is good because they slice it right in front of you.*”

As shown in Figure 1, the *contingency* relation subsumes several more specific relations: *explanation*, *evidence*, *reason*, *cause*, *result*, *consequence*, *background*, *condition*, *hypothetical*, *enablement*, and *purpose* relations according to the Penn Discourse TreeBank (Prasad et al., 2008).

**Comparison:** Gives a comparison and contrast among different situations. For example, “*Its fast-forward and rewind work much more smoothly and consistently than those of other models I’ve had.*”

The *comparison* relation subsumes the *contrast* relation according to the Penn Discourse TreeBank (Prasad et al., 2008) and the *analogy* and *preference* relations according to the RST Discourse Treebank (Carlson and Marcu, 2001).

**Attributive:** Relation provides details about an entity or an event - e.g. “*Mary has a pink coat.*”. It can be used to illustrate a particular feature about a concept or an entity - e.g. “*Picasa makes sure your pictures are always organized.*”. The *attributive* relation, also included in Grimes’ predicates (Grimes, 1975), is considered because it describes attributes or features of an object or event and is often used in query-based summarization and question answering.

**Topic-opinion:** We introduced topic-opinion relations to represent opinions which are not expressed by reported speech. This relation can be used to express an opinion: an internal feeling or belief towards an object or an event. For example: “*Cage is a wonderfully versatile actor.*”

**Attribution:** These relations are instances of reported speech both direct and indirect which may express feelings, thoughts, or hopes. For example: “*The legendary GM chairman declared that his company would make “a car for every purse and purpose.”*”

### 3.2 Automatic Discourse Tagging

Once the manual analysis identified the most prevalent set of relations, we tried to measure their frequency by tagging them automatically within a larger corpus. Only recently, the HILDA (Hernault et al., 2010) and (Feng and Hirst, 2012)’s discourse parser were made publicly available. Both of these parsers work at the text-level, as opposed to the sentence-level, and hence currently achieve the highest tagging performance when compared to the state of the art. (Feng and Hirst, 2012)’s work showed a significant improvement on the performance of HILDA by enhancing its original feature set. However, at the time this research was done, the only publicly available discourse parser was SPADE (Soricut and Marcu, 2003) which operates on individual sentences. To identify *illustration*, *contingency*, *comparison*, and *attribution* relations, we have used SPADE discourse parser. However, we have complemented this parser with three other approaches: (Jindal and Liu, 2006)’s approach is used to identify intra-sentence *comparison* relations; we have designed a tagger based on (Fei et al., 2008)’s approach to identify *topic-opinion* relations; and we have proposed a new approach to tag *attributive* relations (Mithun, 2012). A description and evaluation of these approaches can be found in (Mithun, 2012). By combining these approaches, a sentence is tagged with all possible discourse relations that it contains.

### 3.3 Distribution of Discourse Relations

To find the most prevalent discourse relations for opinion summarization, we have used the TAC 2008 opinion summarization track input document set (collection) which is a subset of BLOG06 and the answer nuggets provided by TAC 2008 as the reference summary (or model summaries), which

had been created to evaluate participants’ summaries at the TAC 2008 opinion summarization track. The collection consists of 600 blogs on 28 different topics. The dataset of the model summaries consists of 693 sentences.

Using the discourse parsers presented in Section 3.2, we computed the distribution of discourse relations within the TAC 2008 opinion summarization collection and the model summaries. *Illustration*, *contingency*, *comparison*, *attributive*, *topic-opinion*, and *attribution* are the most frequently occurring relations in our data sets. The distribution is shown in Table 1<sup>4</sup>.

Table 1: Distribution of Discourse Relations in the TAC-2008 and DUC-2007 Datasets

Discourse Relation	TAC 2008		DUC 2007	
	Coll.	Model	Coll.	Model
Illustration	52%	46%	42%	38%
Contingency	31%	37%	34%	29%
Comparison	23%	18%	15%	12%
Attributive	12%	28%	3%	4%
Topic-opinion	14%	15%	4%	5%
Attribution	11%	9%	2%	3%
other	13%	9%	28%	31%
none	14%	10%	8%	7%

Table 1 shows that in the TAC 2008 input document set, the *illustration* relation occurs in 52% of the sentences; while *attribution* is the least frequently occurring relation. In this dataset, other relations, such as *antithesis* and *temporal* relations, occur in about 13% of the sentences and about 14% of the sentences did not receive any relation tag. As indicated in Table 1, the TAC model summaries have a similar distribution as the collection as a whole. The *attributive* relation seems, however, to be more frequent in the summaries (28%) than in the original texts (12%). We suspect that the reason for this is due to the question types of this track. To successfully generate query-relevant summaries that answer the questions of this track, candidate sentences need to contain *attributive* relations. For example, to answer the questions from this track “*Why do people like Picasa?*” or “*What features do people like about Windows Vista?*”, the summary needs to provide details about these entities or illustrate a particular feature about them. As a result, the summary will be composed of many *attributive* relations since

<sup>4</sup>In Table 1, the percentages do not add up to 100 because a sentence may contain more than one relation.

*attributive* relations help to model the required information.

To compare the distribution of discourse relations within more formal types of texts such as news articles, we used the Document Understanding Conference (DUC) 2007 Main Task input document set (collection) and their associated model summaries. The DUC 2007 dataset is a news article based dataset from the AQUAINT corpus. The DUC 2007 input document set contains 1125 news articles on 45 different topics. The model summaries were used to evaluate the DUC 2007 participants’ summaries. The dataset of the model summaries contains 180 summaries generated by the National Institute of Standards and Technology (NIST) assessors with a summary length of about 250 words. The distribution of relations in this dataset are shown in Table 1.

Table 1 shows that the most frequently occurring relation in the DUC 2007 document collection and in the model summaries is *illustration*; while the *attribution* relation is the least frequently occurring relation. Here again, it is interesting to note that the distribution of the discourse relations in the document collection and in the model summaries is generally comparable.

The distribution of the *illustration*, *contingency*, and *comparison* relations in the DUC 2007 dataset is comparable to those in the TAC 2008 opinion summarization dataset. Indeed, Table 1 shows that *illustration*, *contingency*, and *comparison* relations occur quite frequently irrespective of the textual genre. However, in contrast to the TAC dataset, *attributive*, *topic-opinion*, and *attribution* relations occur very rarely in DUC 2007. We suspect that this is mostly due to the opinionated nature of blogs. Another observation is that *temporal* relations (included in “other”) occurred very frequently (30%) in the DUC 2007 dataset whereas this relation occurs rarely in the blog dataset. This is inline with our intuition that news articles present events that inherently contain temporal information.

## 4 Evaluation of Discourse Relations

To measure the usefulness of discourse relations for the summarization of informal texts, we have tested the effect of each relation with four different summarizers: BlogSum (Mithun, 2012), MEAD (Radev et al., 2004), the best scoring sys-

tem at TAC 2008<sup>5</sup> and the best scoring system at DUC 2007<sup>6</sup>. We have evaluated the effect of each discourse relation on the summaries generated and compared the results. Let us first describe the BlogSum summarizer.

#### 4.1 BlogSum

BlogSum is a domain-independent query-based extractive summarization system that uses intra-sentential discourse relations within the framework based on text schemata. The heart of BlogSum is based on discourse relations and text schemata.

BlogSum works in the following way: First candidate sentences are extracted and ranked using the topic and question similarity to give priority to topic and question relevant sentences. Since BlogSum has been designed for blogs, which are opinionated in nature, to rank a sentence, the sentence polarity (e.g. positive, negative or neutral) is calculated and used for sentence ranking. To extract and rank sentences, BlogSum thus calculates a score for each sentence using the features shown below:

$$\text{Sentence Score} = w_1 \times \text{Question Similarity} + w_2 \times \text{Topic Similarity} + w_3 \times \text{Subjectivity Score}$$

where, question similarity and topic similarity are calculated using the cosine similarity based on words *tf.idf* and the subjectivity score is calculated using a dictionary-based approach based on the MPQA lexicon<sup>7</sup>. Once sentences are ranked, they are categorized based on the discourse relations that they convey. This step is critical because the automatic identification of discourse relations renders BlogSum independent of the domain. This step also plays a key role in content selection and summary coherence as schemata are designed using these relations.

In order not to answer all questions the same way, BlogSum uses different schemata to generate a summary that answers specific types of questions. Each schema is designed to give priority to its associated question type and subjective sentences as summaries for opinionated texts are generated. Each schema specifies the types of discourse relations and the order in which they should appear in the output summary for a par-

ticular question type. Figure 2 shows a sample schema that is used to answer *reason* questions (e.g. “*Why do people like Picasa?*”). According to this schema<sup>8</sup>, one or more sentences containing a *topic-opinion* or *attribution* relation followed by zero or many sentences containing a *contingency* or *comparison* relation followed by zero or many sentences containing a *attributive* relation should be used.

Figure 2: A Sample Discourse Schema used in BlogSum

Relations & Constraints	
Relation:	{ <i>Topic-opinion/ Attribution</i> } <sup>+</sup>
Constraint:	Sentence Polarity.
Relation:	{ <i>Contingency/ Comparison</i> } <sup>*</sup>
Constraint:	Compared Objects, Sentence Focus.
Relation:	<i>Attributive</i> <sup>*</sup>
Constraint:	Sentence Focus.

Finally the most appropriate schema is selected based on a given question type; and candidate sentences fill particular slots in the selected schema based on which discourse relations they contain in order to create the final summary (details of BlogSum can be found in (Mithun, 2012)).

#### 4.2 Evaluation of Discourse Relations on Blogs

To evaluate the effect of each discourse relation for blog summarization, we performed several experiments. We used as a baseline the original ranked list of candidate sentences produced by BlogSum before applying the discourse schemata, and compared this to the BlogSum-generated summaries with and without each discourse relation. We used the TAC 2008 opinion summarization dataset which consists of 50 questions on 28 topics; on each topic one or two questions were asked and 9 to 39 relevant documents were given. For each question, one summary was generated with no regards to discourse relations and two summaries were produced by BlogSum: one using the discourse tagger and the other without using the specific discourse tagger. The maximum summary length was restricted to 250 words.

To measure the effect of each relation, we have automatically evaluated how BlogSum performs using the standard ROUGE-2 and ROUGE-SU4

<sup>5</sup><http://www.nist.gov/tac/>

<sup>6</sup><http://www-nlpir.nist.gov/projects/duc/guidelines/2007.html>

<sup>7</sup>MPQA: <http://www.cs.pitt.edu/mpqa>

<sup>8</sup>The notation / indicates an alternative, { } indicates optionality, \* indicates that the item may appear 0 to n times and + indicates that the item may appear 1 to n times

measures. For comparative purposes, Table 2 shows the official ROUGE-2 (R-2) and ROUGE-SU4 (R-SU4) for all 36 submissions of the TAC 2008 opinion summarization track. In the table, “TAC Average” refers to the mean performance of all participant systems and “TAC-Best” refers to the best-scoring system at TAC 2008.

Table 2: Results of the TAC 2008 Opinion Summarization Track

System Name	R-2	R-SU4
TAC Average	0.069	0.086
TAC-Best	0.130	0.139

Table 3: Effect of Discourse Relations on ROUGE-2 with the TAC 2008 Dataset

System Name	BlogSum R-2	MEAD R-2	TAC-Best R-2
Baseline	0.102↓	0.041↓	0.130
w/o Illustration	0.107↓	0.022↓	0.112↓
w/o Contingency	0.093↓	0.025↓	0.102↓
w/o Comparison	0.103↓	0.033↓	0.113↓
w/o Attributive	0.113↓	0.050	0.124
w/o Topic-opinion	0.112↓	0.049	0.123
w/o Attribution	0.118↓	0.051↓	0.128
with all Relations	<b>0.125</b>	<b>.053</b>	<b>0.138</b>

Table 4: Effect of Discourse Relations on ROUGE-SU4 with the TAC 2008 Dataset

System Name	BlogSum R-SU4	MEAD R-SU4	TAC-Best R-SU4
Baseline	0.107↓	0.064↓	0.139
w/o Illustration	0.110↓	0.041↓	0.120↓
w/o Contingency	0.102↓	0.046↓	0.110↓
w/o Comparison	0.108↓	0.052↓	0.122↓
w/o Attributive	0.115↓	0.072	0.130
w/o Topic-opinion	0.117	0.072	0.129
w/o Attribution	0.127↓	0.073↓	0.132
with all Relations	<b>0.128</b>	<b>0.075</b>	<b>0.151</b>

The results of our evaluation are shown in Tables 3 (ROUGE-2) and 4 (ROUGE-SU4). As the tables show, BlogSum’s baseline is situated below the best scoring system at TAC-2008, but much higher than the average system (see Table 2); hence, it represents a fair baseline. The tables further show that using both the ROUGE-2 (R-2) and ROUGE-SU4 (R-SU4) metrics, with the TAC 2008 dataset, BlogSum performs better when taking discourse relations into account. Indeed, when ignoring discourse relations, BlogSum has a R2=0.102 and R-SU4=0.107 and misses many question relevant sentences; whereas the inclusion of these relations helps to incorporate those relevant sentences into the final summary and brings

the R-2 score to 0.125 and R-SU4 to 0.128. In order to verify if these improvements were statistically significant, we performed a 2-tailed t-test. The results of this test are indicated with the ↓ symbol in Tables 3 and 4. For example, the baseline setup of BlogSum performed significantly lower for both R-2 and R-SU4 compared to BlogSum with all relations. This result indicates that the use of discourse relations as a whole helps to include more question relevant sentences and improve the summary content.

To ensure that the results were not specific to our summarizer, we performed the same experiments with two other systems: the MEAD summarizer (Radev et al., 2004), a publicly available and a widely used summarizer, and with the output of the TAC best-scoring system. For MEAD, we first generated candidate sentences using MEAD, then these candidate sentences were tagged using discourse relation taggers used under BlogSum. Then these tagged sentences were filtered using BlogSum so that no sentence with a specific relation is used in summary generation for a particular experiment. We have calculated ROUGE scores using the original candidate sentences generated by MEAD and also using the filtered candidate sentences. As a baseline, we used the original candidate sentences generated by MEAD. As a best case scenario, we have passed these candidate sentences through the discourse schemata used by BlogSum (see Section 4.1). In Tables 3 and 4, this is referred to as “MEAD with all relations”. We have applied the same approach with the output of the TAC best-scoring system. In the tables, “TAC-Best Baseline” refers to the original summaries generated by the TAC-Best system and “TAC-Best with all relations” refers to the summaries generated by applying discourse schemata using the summary sentences generated by the TAC-Best system.

When looking at individual relations, Tables 3 and 4 show that considering *illustrations*, *contingencies* and *comparisons* make a statistically significant improvement in all scenarios, and with all summarisers. For example, if TAC-Best does not consider *illustration* relations, then the R-2 score decreases from 0.138 to 0.112, 0.102 and 0.113, respectively. On the other hand, the relations of *topic-opinion*, *attribution*, and *attributive* do not consistently lead to a statistically significant improvement on ROUGE scores.

It is interesting to note that although informal texts may not exhibit a clear discourse structure, the use of individual discourse relations such as *illustration*, *contingency* and *comparison* is nonetheless useful in the analysis of informal documents such as those found in the social media.

### 4.3 Effect of Discourse Relations on News

To compare the results found with blogs with more formal types of texts, we have performed the same experiments but, this time with the DUC 2007 Main Task dataset. In this task, given a topic (title) and a set of 25 relevant documents, participants had to create an automatic summary of length 250 words from the input documents. In the dataset, there were 45 topics and thirty teams participated to this shared task. Table 5 shows the official ROUGE-2 (R-2) and ROUGE-SU4 (R-SU4) scores of the DUC 2007 main task summarization track. In Table 5, “DUC Average” refers to the mean performance of all participant systems and “DUC-Best” refers to the best scoring system at DUC 2007.

Table 5: DUC 2007 Main Task Summarization Results

System Name	R-2	R-SU4
DUC Average	0.095	0.157
DUC-Best	0.124	0.177

Table 6: Effect of Discourse Relations on ROUGE-2 with the DUC 2007 Dataset

System Name	BlogSum R-2	MEAD R-2	DUC-Best R-2
Baseline	0.089	0.099	0.124↓
w/o Illustration	0.079↓	0.061↓	0.103↓
w/o Contingency	0.074↓	0.060↓	0.097↓
w/o Comparison	0.086↓	0.078↓	0.114↓
w/o Attributive	0.092	0.099	0.119↓
w/o Topic-opinion	0.092	0.099	0.115↓
w/o Attribution	0.093	0.099	0.120↓
with all Relations	<b>0.093</b>	<b>0.110</b>	<b>0.157</b>

Tables 6 and 7 show the results with this dataset with respect to ROUGE-2 and ROUGE-SU4, respectively. As the tables show, BlogSum’s performance with all discourse relations (R2=0.093 and R-SU4=0.132) is similar to the DUC average performance shown in Table 5 (R2=0.095 and R-SU4=0.157) which is much

Table 7: Effect of Discourse Relations on ROUGE SU-4 with the DUC 2007 Dataset

System Name	BlogSum R-SU4	MEAD R-SU4	DUC-Best R-SU4
Baseline	0.110↓	0.142↓	0.177↓
w/o Illustration	0.117↓	0.118↓	0.138↓
w/o Contingency	0.113↓	0.118↓	0.123↓
w/o Comparison	0.122↓	0.130↓	0.144↓
w/o Attributive	0.131	0.141↓	0.159↓
w/o Topic-opinion	0.130	0.141↓	0.153↓
w/o Attribution	0.131	0.142↓	0.164↓
with all Relations	<b>0.132</b>	<b>0.168</b>	<b>0.196</b>

lower than the DUC-Best performance (R2=0.124, R-SU4=0.177) shown in Table 5). However, these results show that even though BlogSum was designed for informal texts, it still performs relatively well with formal documents. Tables 6 and 7 further show that with the news dataset, the same relations have the most effect as with blogs. Indeed BlogSum generated summaries also benefit most from the *contingency*, *illustration*, and *comparison* relations; and all three relations bring a statistically significant contribution to the summary content.

Here again, as shown in Tables 6 and 7, we performed the same experiments with two other systems: the MEAD summarizer and the output of the DUC-Best system. Again, for the DUC 2007 dataset, each discourse relation has the same effect on summarization with all systems as with the blog dataset: *contingency*, *illustration*, and *comparison* provide a statistically significant improvement in content; while *attributive*, *topic-opinion* and *attribution* do not reduce the content, but do not see to bring a systematic and significant improvement.

## 5 Conclusion and Future Work

In this paper, we have evaluated the effect of discourse relations on summarization. We have considered the six most frequent relations in blogs - namely *comparison*, *contingency*, *illustration*, *attribution*, *topic-opinion*, and *attributive*. First, we have measured the distribution of discourse relations on blogs and on news articles and show that the prevalence of these six relations is not genre dependent. For example, the relations of *illustration*, *contingency*, and *comparison* occur frequently in both textual genres. We have then evaluated the effect of these six relations on summa-

rization with the TAC 2008 opinion summarization dataset and the DUC 2007 dataset. We have conducted these evaluations with our summarization system called BlogSum, the TAC best-scoring system, the DUC best-scoring system, and the MEAD summarizer. The results show that for both textual genres, some relations have more effect on summarization compared to others. In both types of texts, the *contingency*, *illustration*, and *comparison* relations provide a significant improvement on summary content; while the *attribution*, *topic-opinion*, and *attributive* relations do not provide a systematic and statistically significant improvement. These results seem to indicate that, at least for summarization, discourse relations are just as useful for informal and affective texts as for more traditional news articles. This is interesting, because although informal texts may not exhibit a clear discourse structure, the use of individual discourse relations is nonetheless useful in the analysis of informal documents.

In the future, it would be interesting to evaluate the effect of other relations such as the *temporal* relation. Indeed, *temporal* relations occur infrequently in blogs but are very frequent in news articles. Such an analysis would allow us to tailor the type of discourse relations to include in the final summary as a function of the textual genre being considered. In the future, it would also be interesting to use other types of texts such as reviews and evaluate the effect of discourse relations using other measures than ROUGE-2 and ROUGE-SU4. Finally, we would like to validate this work again with the newly available discourse parsers of (Hernault et al., 2010) and (Feng and Hirst, 2012).

# Supervised Sentence Fusion with Single-Stage Inference

Kapil Thadani and Kathleen McKeown

Department of Computer Science

Columbia University

New York, NY 10025, USA

{kapil, kathy}@cs.columbia.edu

## Abstract

Sentence fusion—the merging of sentences containing similar information—has been shown to be useful in an abstractive summarization context. We present a new dataset of sentence fusion instances obtained from evaluation datasets in summarization shared tasks and use this dataset to explore supervised approaches to sentence fusion. Our proposed inference approach recovers the highest scoring output fusion under an n-gram factorization using a compact integer linear programming formulation that avoids cycles and disconnected structures. In addition, we introduce simple fusion-specific features and constraints that outperform a compression-inspired baseline as well as a variant that relies on human-identified concept spans for perfect content selection.

## 1 Introduction

Abstractive text summarization has long been a high-level goal of natural language processing. Although progress in text-to-text (T2T) generation tasks such as sentence compression and paraphrase generation has been steady, the fusion of multiple sentences offers a particularly formidable challenge. Sentence fusion refers to the task of combining two or more sentences which overlap in information content, avoiding extraneous details and preserving common information. This procedure has been observed in human summarization (Jing and McKeown, 2000) and has been shown to be a valuable component of automated summarization systems (Barzilay and McKeown,

2005). However, research in sentence fusion has long been hampered by the absence of datasets for the task, and the difficulty of generating one has cast doubt on the viability of automated fusion (Daumé III and Marcu, 2004).

This paper presents a new fusion dataset generated from existing human annotations and also introduces a discriminative T2T system that generalizes the single sentence compression approach of Thadani and McKeown (2013) to n-way sentence fusion. Our fusion dataset is constructed from evaluation data for summarization shared tasks in the Document Understanding Conference (DUC)<sup>1</sup> and the Text Analysis Conference (TAC).<sup>2</sup> Specifically, we use human-generated annotations produced for the pyramid method (Nenkova et al., 2007) for summarization evaluation to produce a dataset of natural human fusions with quantifiable agreement. This offers advantages over previous datasets used for standalone English sentence fusion which contain annotator-induced noise (McKeown et al., 2010) or cannot be distributed (Elsner and Santhanam, 2011). In addition, both these datasets contain approximately 300 instances of fusion while the new dataset presented here contains 1858 instances.

Crucially, this larger corpus encourages supervised approaches to sentence fusion and we leverage this to explore new strategies for the task. Previous approaches to fusion have generally relied on variations of dependency graph combination (Barzilay and McKeown, 2005; Filippova and Strube, 2008b; Elsner and Santhanam, 2011) for content selection with a separate step for linearization that is usually based on a language model (LM). In contrast, we experiment with combin-

ing linearization with content selection to produce a single-stage joint approach to fusion. For this, we adapt the sequential *structured transduction* approach described in Thadani and McKeown (2013) for sentence compression and extend it to process multiple input sentences for fusion tasks. This discriminative approach to sentence generation permits rich features that estimate the informativeness of specific tokens chosen from the input sentences as well as the fluency of the n-grams used to assemble them for the output sentence. Furthermore, our inference formulation allows all potential orderings of input tokens to be considered in the output and prevents degenerate cyclic or disjoint orderings via *commodity flow* constraints (Magnanti and Wolsey, 1994).

The primary contributions of this work are:

- A novel dataset of natural sentence fusions drawn from a corpus of pyramid evaluations for summarization shared tasks which is available to the NLP community.
- A supervised approach to sentence fusion that jointly addresses non-redundant content selection and linearization.

We evaluated the proposed fusion system against a basic compression baseline that does not include fusion-specific features as well as a proposed strong baseline that directly leverages human-annotated concept boundaries in the original dataset, thereby avoiding the issue of content selection. An evaluation under a variety of automated metrics indicates that our proposed approach strongly outperforms the former and appears competitive with the latter.

## 2 Pyramid fusion corpus

The pyramid method is a technique for summarization evaluation that aims to quantify the semantic content of summaries and compare automated summaries to human summaries on the basis of this semantic content (Nenkova et al., 2007). For each summarization topic to be evaluated, a number of human-authored summaries are first produced. In the DUC and TAC evaluations, the number of summaries is usually fixed at 7 per topic. A collection of *summarization content units* or SCUs—intended to correspond to atomic units of information—are then generated by annotators reading these summaries. Each SCU comprises a *label* which is a concise English sentence that states the meaning of the SCU<sup>3</sup> and a list of *contributors* which are discontinuous character spans from the summary sentences—hereafter referred to as *source* sentences—in which that SCU is realized. Table 1 contains examples of SCUs drawn from DUC 2005–2007 and TAC 2008–2011 data.

Our fusion corpus is constructed by taking the source sentences of an SCU as input and the SCU labels as the gold fusion output. The fusion task posed by this corpus is similar to sentence *intersection* as defined by Marsi and Kraemer (2005) although it does not fit the criteria for *strict* intersection as addressed in Thadani and McKeown (2011) since source sentences do not always expressly mention all the information in an SCU label due to unresolved anaphora and entail-

<sup>3</sup>An SCU annotation guide from DUC 2005 is available at <http://www1.cs.columbia.edu/~ani/DUC2005/AnnotationGuide.htm>.

ment. The following procedure was used to extract meaningful fusion instances from the SCUs.

1. SCUs that have no more than one contributor which covers a single summary sentence are dropped. In addition, we chose to restrict the number of input sentences to at most four<sup>4</sup> since larger SCUs are very infrequent.
2. Although SCU descriptions are required to be full sentences, we found that this was not upheld in practice. We therefore removed SCUs whose labels contain fewer than 5 words and did not have an identifiable verb beyond the first token. As a practical consideration, SCUs with source sentences which have more than 100 tokens were also dropped.
3. Annotated concepts in this dataset often only cover a small fraction of source sentences and may not represent the full overlap between them. To account for this, we ignored SCUs without contributors that are at least half the length of their source sentences as well as SCUs whose labels are less than half the length of the smallest contributor.
4. Finally, we chose to retain only SCUs whose labels contain terms present in at least one source sentence, thus ensuring that gold fusions are reachable without paraphrasing.

This yields 1858 fusion instances of which 873 have two inputs, 569 have three and 416 have four.

### 3 Single-stage Fusion

Previous approaches to fusion have often relied on dependency graph combination (Barzilay and McKeown, 2005; Filippova and Strube, 2008b; Elsner and Santhanam, 2011) to produce an intermediate syntactic representation of the information in the sentence. Linearization of output fusions is usually performed by ranking hypotheses with a language model (LM), sometimes with language-specific heuristics to filter out ill-formed sentences. This approach is also known as *overgenerate-and-rank* and is often found to be a source of errors in T2T problems (Barzilay and McKeown, 2005).

Although syntactic representations are natural for assembling text across sentences, recent work in unsupervised multi-sentence fusion has shown that well-formed output can often be constructed

<sup>4</sup>This is accomplished by removing additional contributors that share the fewest words with the SCU label.

purely on the basis of adjacency relationships in a word graph (Filippova, 2010). Similarly, systems for related T2T tasks such as sentence compression (McDonald, 2006; Clarke and Lapata, 2008) and strict sentence intersection (Thadani and McKeown, 2011) have also seen promising results by linearizing n-grams without explicitly relying on syntactic representations.

Our framework takes a similar perspective and assembles output text directly from n-grams over input tokens, but we employ a discriminative structured prediction approach in which likelihood under an LM is one of many features of output quality and parameters for all features are learned from a training corpus. Moreover, rather than rely on pipelined stages to first select the output content and then linearize an intermediate representation, we jointly address token selection alongside phrase-based ordering thereby yielding a single-stage approach to fusion.

#### 3.1 ILP formulation

The starting point for this work is the sequential structured transduction<sup>5</sup> model of Thadani and McKeown (2013), originally devised for single sentence compression. This approach relies on integer linear programming (ILP) to find a globally optimal solution to generation problems involving heterogeneous substructures. ILP has been used frequently in recent T2T generation systems including many for sentence fusion (Filippova and Strube, 2008b; Elsner and Santhanam, 2011), intersection (Thadani and McKeown, 2011) and compression (Clarke and Lapata, 2008; Filippova and Strube, 2008a; Berg-Kirkpatrick et al., 2011), as well as other natural language processing tasks. Although LPs with integer constraints are NP-hard in the general case, the availability of optimized general-purpose ILP solvers and the natural limits on English sentence length make ILP inference attractive for sentence-level optimization problems.

Consider a single fusion instance involving  $k$  source sentences  $\mathcal{S} \triangleq \{S_1, \dots, S_k\}$ . The notation  $F_{\mathcal{S}}$  is used to denote a fusion of the sentences in  $\mathcal{S}$ . The inference step aims to retrieve the output sentence  $F_{\mathcal{S}}^*$  that is the most likely fusion of  $\mathcal{S}$ , i.e., the sentence that maximizes  $p(F_{\mathcal{S}}|\mathcal{S})$  or equivalently maximizes some scoring function  $score(F_{\mathcal{S}})$ . In

<sup>5</sup>The full joint model presented in Thadani and McKeown (2013) also explicitly infers tree-structured dependencies, but we found in preliminary experiments that this did not perform well with multiple sentence inputs. See discussion in §5.

our feature-based discriminative setting, we define  $score(F_S)$  as a dot product of weights  $\mathbf{w}$  and a feature map  $\Phi(S, F_S)$  defined over the fusion and its input; in other words

$$F_S^* \triangleq \arg \max_{F_S} \mathbf{w}^\top \Phi(S, F_S) \quad (1)$$

The feature map  $\Phi$  for an arbitrary fusion sentence is defined to factor over the words and potential n-grams from the input text. Let  $T \triangleq \{t_i : 1 \leq i \leq N_j, 1 \leq j \leq |\mathcal{S}|\}$  represent the set of tokens (including duplicates) in  $\mathcal{S}$  and let  $x_i \in \{0, 1\}$  represent a token indicator variable whose value corresponds to whether token  $t_i$  is present in the output sentence  $F_S$ . We also consider n-gram phrases defined over the tokens in  $T$  and assume the use of bigrams without loss of generality.<sup>6</sup> Let  $U$  represent the set of all possible bigrams that can be constructed from the tokens in  $T$ ; in other words  $U \triangleq \{(t_i, t_j) : t_i \in T \cup \{\text{START}\}, t_j \in T \cup \{\text{END}\}, i \neq j\}$ . Following the notation for token indicators, let  $y_{ij} \in \{0, 1\}$  represent a bigram indicator variable for whether the contiguous pair of tokens  $\langle t_i, t_j \rangle$  is in the output sentence. We represent entire token and bigram configurations with incidence vectors  $\mathbf{x} \triangleq \langle x_i \rangle_{t_i \in T}$  and  $\mathbf{y} \triangleq \langle y_{ij} \rangle_{\langle t_i, t_j \rangle \in U}$  which are equivalent to some subset of  $T$  and  $U$  respectively. With this notation, (1) can be rewritten as

$$\begin{aligned} F_S^* &= \arg \max_{\mathbf{x}, \mathbf{y}} \sum_{t_i \in T} x_i \cdot \mathbf{w}_{\text{tok}}^\top \phi_{\text{tok}}(t_i) \\ &\quad + \sum_{\langle t_i, t_j \rangle \in U} y_{ij} \cdot \mathbf{w}_{\text{ngr}}^\top \phi_{\text{ngr}}(\langle t_i, t_j \rangle) \\ &= \arg \max_{\mathbf{x}, \mathbf{y}} \mathbf{x}^\top \boldsymbol{\theta}_{\text{tok}} + \mathbf{y}^\top \boldsymbol{\theta}_{\text{ngr}} \end{aligned} \quad (2)$$

where  $\phi$  is a feature vector for tokens or bigrams and  $\mathbf{w}$  is a corresponding vector of weight parameters. Each  $\boldsymbol{\theta} \triangleq \langle \mathbf{w}^\top \phi(s) \rangle$  is therefore a vector of feature-based scores for either tokens or bigrams.

The joint objective in (2) conveniently permits content-based features in  $\phi_{\text{tok}}$  for content selection and fluency features such as LM log-likelihoods in  $\phi_{\text{ngr}}$  for linearization. However, decoding a valid sentence with this objective is non-trivial. Merely selecting the tokens and bigrams that maximize (2) is liable to produce degenerate structures, i.e., cycles, disconnected components, branches and inconsistency between the token and bigram configurations in  $\mathbf{x}$  and  $\mathbf{y}$ . Most prior T2T linearization

<sup>6</sup>This approach permits n-grams of any order (Thadani and McKeown, 2013) but we use bigrams here to produce ILPs that scale quadratically with the number of input tokens.

approaches such as the Viterbi-based approach of McDonald (2006) and the ILP of Clarke and Lapata (2008) cannot be applied when the tokens in the input do not have a total ordering, as is the case when the input consists of more than one sentence.

### 3.2 Structural Constraints

We now briefly describe the structural constraints proposed by Thadani and McKeown (2013) to address the problem of degeneracy in sentential structure. First, we consider the problem of output *consistency*—more formally, bigram variables  $y_{ij}$  that are non-zero must activate their token variables  $x_i$  and  $x_j$  while token variables can only activate a single bigram variable in the first and second position each.

$$x_i - \sum_j y_{ij} = 0, \quad \forall t_j \in T \quad (3)$$

$$x_j - \sum_i y_{ij} = 0, \quad \forall t_i \in T \quad (4)$$

The second requirement for non-degenerate output is that non-zero  $y_{ij}$  must form a sentence-like *linear ordering* of tokens, avoiding cycles and branching. For this purpose, auxiliary variables are introduced to establish *single-commodity flow* (Magnanti and Wolsey, 1994) between all pairs of tokens that may appear adjacent in the output. Linear token ordering is maintained by defining real-valued commodity flow variables  $\gamma_{ij}$  which are non-negative.

$$\gamma_{ij} \geq 0, \quad \forall \langle t_i, t_j \rangle \in U \quad (5)$$

Each active token in the solution must have some positive incoming commodity and *consumes* one unit of this commodity, transmitting the remaining value to outgoing flow variables. This ensures that cycles cannot be present in the flow structure.

$$\sum_i \gamma_{ij} - \sum_k \gamma_{jk} = x_j, \quad \forall t_j \in T \quad (6)$$

The acyclic flow structure can be imparted to  $\mathbf{y}$  by constraining bigram indicators to be active only if their corresponding tokens have positive commodity flow between them.

$$\gamma_{ij} - C_{\max} y_{ij} \leq 0, \quad \forall \langle t_i, t_j \rangle \in U \quad (7)$$

where  $C_{\max}$  is the maximum amount of commodity that the  $\gamma_{ij}$  variables may carry and serves as an upper bound on the number of output tokens.

Figure 1: An illustration of commodity values for a valid solution of the ILP.

Finally, in order to establish *connectivity* in the output, we also introduce indicator variables  $y_{*j}$  and  $y_{i*}$  to denote the sentence-starting and terminating bigrams  $\langle \text{START}, t_j \rangle$  and  $\langle t_i, \text{END} \rangle$  respectively. A valid output sentence must be started and terminated by exactly one bigram.

$$\sum_j y_{*j} = 1 \quad (8)$$

$$\sum_i y_{i*} = 1 \quad (9)$$

Flow variables  $\gamma_{*j}$  and  $\gamma_{i*}$ , are also defined for START and END respectively. Since START has no incoming flow variables, the amount of commodity in  $\gamma_{*j}$  are unconstrained. This provides the only point of origin for the commodity and, in conjunction with (7), induces connectivity in  $\mathbf{y}$ .

### 3.3 Further Extensions for Fusion

The constraints specified above are adequate to enforce structural soundness in an output sentence and are applicable to a range of T2T linearization problems. We now address the issue of *redundancy*, which is unique to sentence fusion. The input sentences are expected to contain overlapping information which is useful to identify because: (a) it is a signal of salience, and (b) it is reasonable to expect that this repeated information should not appear redundantly in the output.

#### 3.3.1 Supported content words

To address the first point above, we iterate through each sentence and generate groups  $G$  of similar or identical tokens across sentences, which we refer to as *supported* tokens. The selection of tokens is limited to open-class words such as nouns, verbs, adjectives and adverbs. Matching is accomplished via stemming, lemmatization, Wordnet synonymy and abbreviation expansion, and each group  $G_k$  is closed under transitivity. We expect that tokens from large groups, i.e., occurrences in multiple sentences or repeated occurrences in a single sentence, will be more likely to appear in the output. In the

following section, we design features over supporting tokens so that the learning algorithm can encourage or discourage their occurrence following the patterns seen in the training corpus.

#### 3.3.2 Redundancy constraints

While we expect largely positive weights on features for supporting tokens, this will also have the effect of encouraging of more than one token from the same group to occur in the output. In order to avoid this problem, we add a constraint for each group  $G_k \in \mathcal{G}$  that prevents tokens within a group from appearing more than once.

$$\sum_{i:t_i \in G_k} x_i \leq 1, \quad \forall G_k \in \mathcal{G} \quad (10)$$

### 3.4 Features

We now describe the features  $\phi$  over tokens and bigrams that guide inference for fusion instances.

- **Salience:** Fluent output fusions might require specific words to be preserved, highlighted or perhaps rejected. This can be expressed through features on token variables that indicate *a priori* salience, for which we consider patterns of part-of-speech (POS) tags and dependency arc labels obtained from input parses. Specifically, we define indicator features for POS sequences of length up to 2 that surround the token and the POS tag of the token's syntactic governor conjoined with the label. We also maintain features for whether tokens appear within parentheses and if they are part of a capitalized sequence of tokens (an approximation of named entity markup).
- **Fluency:** These features are intended to capture how the presence of a given bigram contributes to the overall fluency of a sentence. The bigram variables are scored with a feature expressing their log-likelihood under an LM. We also include features that indicate the sequence of POS tags and dependency labels corresponding to the tokens an bigram variable covers.

- **Fidelity:** One might reasonably expect that many bigrams in the input sentences will appear unchanged in the output fusion. We therefore propose boolean features that indicate whether a bigram was seen in the input.
- **Pseudo-normalization:** A major drawback of using linear models for generation problems is an inability to employ output sentence length normalization when scoring structures. Word penalty features are used for this purpose following their use in machine translation (MT) systems. These features are simply set to 1 for every token and bigram and their parameters are intended to balance out biases in output length that are induced by other features.
- **Support:** We note the amount of support—repetitions across input sentences—for nouns, verbs, adjectives and adverbs, as described in §3.3. We define features that count the number of repetitions for each of these tokens, and conjoin this with the POS class of each token. We also include binary variants of these features that indicate whether a token has support across 2, 3 or 4 input sentences. The constraint in (10) prevents these features from encouraging redundancy in the output.

Each scale-dependent feature is recorded absolutely as well as normalized by the average length of an input sentence. This was done in order to encourage the model to be robust to variation in sentence length during training.

### 3.5 Learning

The structured perceptron (Collins, 2002) was used in our experiments to recover good parameter settings  $w^*$  for the above features from training corpora. We used a fixed learning rate, averaged parameters over all iterations, and tracked performance in each epoch against a held-out development corpus. Following Martins et al. (2009), inference was sped up during training by only solving an LP relaxation of the fusion ILP.

## 4 Experiments

In order to evaluate our proposed fusion approach, we ran experiments over the corpus described in §2. For ease of reproducibility, we did not split the corpus randomly, rather, the 593 instances from

the DUC evaluations covering the years 2005–2007 were chosen as a testing corpus, while the 1265 instances from the TAC evaluations over 2008–2011 were used as a training corpus. This yields an approximate 70/30 train-test split with near-identical proportions of 2-way, 3-way and 4-way fusions. In addition, we used 10% of the training section (all from 2011) as a development corpus in order to tune the features.

Dependency parses for features were generated using the Stanford parser<sup>7</sup> and LMs were constructed from the Gigaword corpus. All ILPs were solved using Gurobi.<sup>8</sup> All possible token orderings were permitted for fusion inference with the exception of those that flipped the order of two tokens from the same input sentence, which we assumed to be highly unlikely.

### 4.1 Baselines

The lack of a standard corpus and domain makes comparisons against previous systems difficult. Indeed, we propose that the pyramid fusion corpus described here may be well suited for comparing fusion systems in the future.<sup>9</sup>

We therefore use two baselines for this evaluation. First, we consider a compression baseline that is a variant of the system under study but without the fusion-specific modifications, i.e., the support features and the redundancy constraint from (10). This is not a strong baseline—we do not expect it to outperform our system for this task—but it serves as a useful measure of how linearization performs in the absence of content selection.

Our second baseline uses an identical system to the first but operates on different input data—the SCU *contributors* for each instance instead of the full source sentences. These are human-selected text spans that realize the SCU as defined in the pyramid evaluation guidelines and therefore approximate gold content selection. One-third of the instances in the corpus (659 instances) have SCUs that are exact string matches of one of the contributors;<sup>10</sup> the corresponding count for SCU-matching source sentences is less than half (300 instances).

<sup>7</sup><http://nlp.stanford.edu/software/>

<sup>8</sup><http://www.gurobi.com>

<sup>9</sup>We hope to eventually distribute the extracted corpus directly but interested researchers can currently retrieve the raw data from NIST and reconstruct it from our guidelines in §2.

<sup>10</sup>We chose to leave these contributors in the corpus in order to more accurately model the decisions of human annotators who were generating the fusions.

Configuration	Input	n-grams F <sub>1</sub> %				Content words			Syntactic rels F <sub>1</sub> %	
		<i>n</i> = 1	2	3	4	P%	R%	F <sub>1</sub> %	Stanford	RASP

Table 2: Experimental results under various quality metrics (see text for descriptions). Boldfaced entries in each column indicate statistically significant differences ( $p < 0.05$ ) over other entries under Wilcoxon’s signed rank test while <sup>†</sup> indicates the same under the paired t-test.

## 4.2 Evaluation Metrics

Sentence fusion is notoriously hard to evaluate (Daumé III and Marcu, 2004) and previous work tends to rely on human evaluations with Likert scales. However, we choose to follow work in machine translation and, more recently, sentence compression (Napoles et al., 2011; Thadani and McKeown, 2013) in moving towards transparent automated metrics for fusion quality in order to engender more repeatable evaluations of fusion systems. As our test corpus is larger than most previously-studied fusion corpora in their entirety, statistical measures of text quality are preferable.

Our basic evaluation metric is n-gram F<sub>1</sub>, used in numerous tasks and evaluation scenarios; we consider all  $1 \leq n \leq 4$ . In addition, since n-gram metrics do not distinguish between content words and function words, we also include an evaluation metric that observes the precision, recall and F-measure of only nouns and verbs as a proxy for the informativeness of a given fusion.

In addition to the direct measures discussed above, we consider syntactic metrics that act as surrogates for grammaticality. Napoles et al. (2011) indicates that F<sub>1</sub> metrics over syntactic relations such as those produced by the RASP parser (Briscoe et al., 2006) correlate significantly with human judgments of compression quality; we expect that the same holds for our fusion scenario. Output fusions were therefore parsed with RASP as well as the Stanford dependency parser and their resulting dependency graphs were compared to those of the gold fusions.

## 4.3 Results

Table 2 summarizes the results from the fusion experiments. We first observe that the proposed fusion system as well as the contributor+compression baseline outperform the source+compression baseline significantly on all metrics evaluated. We also observe a significant

gain for the fusion system over all baselines for F<sub>1</sub> over unigrams and bigrams, vindicating the proposed content-selection extensions to the baseline compression approach. Results for trigrams and 4-grams are statistically indistinguishable under the paired t-test, indicating that the proposed system is at least competitive with the ‘cheating’ baseline.

Turning to the content-word metrics, we see that the primary contribution of the discriminative joint approach is in enhancing the recall of meaning-bearing words. The gain in recall is larger than the loss in precision against the contributor+compression baseline, leading to a significant improvement in content word F<sub>1</sub>.

Finally, the results from the syntactic measures of fluency are less clear. The proposed fusion system outperforms the strong baseline on RASP F<sub>1</sub> but the gain is only statistically significant under Wilcoxon’s signed rank test. Both systems significantly outperform the weaker baseline.

Table 3 contains an example of system output illustrating the quirks of the different systems. We note that the results are often noisy in all scenarios and that the supported tokens do not entirely override the LM. For example, ‘ABC’ appears in only one of the input sentences in the second example from Table 3 but is seen in multiple system fusions, likely due to the influence of an LM trained on newswire text.

## 5 Discussion & Future Work

While the focus of this paper is on linearization, we also considered expanding the objective from (2) to include syntactic structures as presented in Thadani and McKeown (2013); however, initial results were not promising. We hypothesize that this is partly to the vulnerability of such representations to parse errors—also noted in Filipova (2010)—and partly to the severe independence assumptions involved in arc-factored dependency representations which are exacerbated when

working with multiple input sentences. We are currently working on extending this approach to produce richer formulations of syntax that will be more appropriate for this task.

## 6 Related Work

Sentence fusion is the general label applied to tasks which take multiple sentences as input to produce a single output sentence. Barzilay & McKeown (Barzilay et al., 1999; Barzilay and McKeown, 2005) first introduced fusion in the context of multidocument summarization as a way to better capture the information in a cluster of related sentences than just using the centroid. The fusion task has since expanded to include other forms of sentence combination, such as the merging of overlapping sentences in a multidocument context (Marsi and Krahmer, 2005; Krahmer et al., 2008; Filippova and Strube, 2008b) and the combination of two (usually contiguous) sentences from a single document (Daumé III and Marcu, 2004; Elsner and Santhanam, 2011). Variations on the fusion task include the set-theoretic notions of *intersection* and *union* (Marsi and Krah-

mer, 2005; McKeown et al., 2010), which forego the problem of identifying relevance and are thus less dependent on context. Query-based versions of these tasks have been studied by Krahmer et al. (2008) and have produced better human agreement in annotation experiments than generic sentence fusion (Daumé III and Marcu, 2004). McKeown et al. (2010) produced an annotated fusion corpus which was employed in experiments on decoding for sentence intersection (Thadani and McKeown, 2011). While most work in the area has covered pairwise sentence combination, recent work by Filippova (2010) has also addressed fusion—referred to as multi-sentence compression—within a cluster of sentences.

## 7 Conclusion

We have presented a new corpus for sentence fusion which is built from readily-available data used for summarization evaluation. To our knowledge, this is the largest corpus of fusion data studied to date. In addition, we proposed a supervised discriminative approach for sentence fusion that jointly selects content from the input and recovers a linearization without an intermediate representation. Our system uses a flexible integer linear programming formulation for generating acyclic paths in token graphs, generalizing a state-of-the-art sentence compression approach to multiple sentences and a supervised setting which permits rich, linguistically-motivated features that factor over tokens and n-grams. We demonstrate that this approach leads to significant performance gains over a baseline compression system as well as comparable performance to an approach which directly leverages human content selection.

## Abstract

We detect errors in Korean post-positional particle usage, focusing on optimizing omission detection, as omissions are the single-biggest factor in particle errors for learners of Korean. We also develop a system for predicting the correct choice of a particle. For omission detection, we model the task largely on English grammatical error detection, but employ Korean-specific features and filters; likewise, output analysis and the omission correction system illustrate how unique properties of Korean, such as the distinct types of particles used, need to be accounted for in adapting the system, thereby moving the field one step closer to robust multi-lingual methods.

## 1 Introduction

Grammatical error detection is useful to produce an improved final document for writing assistance, provide feedback to language learners, provide features for automatic essay scoring, and post-edit machine translation output (see references in Chodorow et al., 2012, sec. 2). Within this growing field, most of the work has focused on English, but there has been a small community of researchers working on other languages. We continue this trend by advancing the state-of-the-art in detecting errors in Korean particle usage.

Expanding to other languages and language families obviously presents new challenges, such as being able to handle word segmentation and greater morphological complexity (e.g., Basque (de Ilarraza et al., 2008), Korean (Lee et al., 2012), Hungarian (Dickinson and Ledbetter, 2012), Japanese (Mizumoto et al., 2011)); greater varieties of word order (Czech (Hana et al., 2010),

German (Boyd, 2012)); case ending errors (Czech, German, Hungarian); differing definitions of function words (Korean, Japanese, Basque); and so forth. Investing in methods which apply across languages will make techniques more robust and applicable for even more languages.

An additional challenge for many of these languages is the lack of resources. Much previous work on detecting errors in Korean, for example, focused less on techniques and more on acquiring training data (Dickinson et al., 2011) and evaluation data (Lee et al., 2012). We thus desire techniques that work using smaller and/or unannotated data sets that may be less reliable than some of the corpora for better-resourced languages.

We focus on detecting errors in the presence or absence of Korean postpositional particles. Korean is a Less Commonly Taught Language (LCTL) needing proficient speakers and more pedagogical research (see Dickinson et al., 2008, sec. 2), making computational tools for Korean language learning important. Particles are used to mark properties akin to prepositions and also to case markers, as discussed in section 2. This makes our task applicable to similar languages like Japanese and more generally to agglutinative languages like Basque, Hungarian, and Turkish, as discussed in section 3 on related work. Particles are our focus because of the high prevalence of particle errors in learner data, accounting for 20–30% of learner errors (section 2).

One of the most frequent errors relating to particles is not using them when required (section 4); thus, simply detecting whether a particle is necessary can pinpoint nearly half the particle errors language learners make. In the interest of extending methods to new languages, we develop an omission error detection system rooted in work on

English preposition error detection (section 5), accounting for Korean-specific properties in the features and filtering of results (section 6). We then see the impact of such error detection on predicting the specific omitted particles (section 7).

We make the following contributions in this paper: 1) We present a functional Korean particle omission error detection system, adapted from previous English preposition work but tailored towards Korean in its morpheme-based approach and its novel features. 2) We outline system mistakes, highlighting unique properties of Korean, and point towards how to fix them. 3) We provide an error correction system—incorporating new discourse-based features and optimized separately from the first-stage classifier—which corrects a high percentage of omission errors. In so doing, we also discover that accounting for distinctions in types of Korean particles opens the door to further improvements. The overall lesson is that work from English can be adapted, but only if incorporating the nuances of the new language.

## 2 Korean Particles

Korean postpositional particles are units that appear after a nominal to indicate different linguistic functions, including grammatical functions, e.g., subject and object; semantic roles; and discourse functions. In (1), for instance, *가* (*ka*) marks the subject (function) and agent (semantic role).<sup>1</sup>

- (1) 그래서 제가 한국말을 열심히 배우고  
 thus I-SBJ Korean-OBJ hard learn  
 싶어요  
 want  
 ‘Thus, I really want to learn Korean’

Similar to English prepositions, particles can also have modifier functions, adding meanings of time, location, instrument, possession, and so forth. For further discussion of Korean particles, see, e.g., chapter 3 of Yeon and Brown (2011).

**Learner Errors** Particle errors are very frequent for Korean language learners, accounting for 28% of beginner errors in one corpus study (Ko et al., 2004). In (2a), for instance, a learner omitted a subject particle after the word *것* (*kes*, ‘thing’). The error has been corrected in (2b).

- (2) a. 각 곳에 여러 좋은 것 있어요  
 each place-AT many good thing exist

- b. 각 곳에 여러 좋은 것이  
 each place-AT many good thing-SBJ  
 있어요  
 exist  
 ‘There are many good things’

## 3 Related Work

While there is much related work on detecting preposition and article errors in English, e.g., the 2012 Helping Our Own (HOO) shared task (Dale et al., 2012), we will focus here on work on detecting errors in functional items in agglutinative languages (Korean, Japanese, Basque), as we most directly build from this. Roughly, agglutinative languages here are ones which “glue” syntactic categories, in the form of affixes, onto a word.

For Korean particle error detection, Dickinson and Lee (2009) train two parser models, one with particles included and one without, to compare mismatches. Their main purpose is to adapt tree-bank annotation to be more particle-aware, and they did not evaluate on real learner data.

We build more directly from Dickinson et al. (2011), who build web corpora of Korean in order to train machine learning models for particle prediction. They obtain 81.6% accuracy for particle presence. While the work is similar, comparing the current work to their results is problematic for a number of reasons. First, the work in Dickinson et al. (2011) was very preliminary, focusing on acquiring training data, and did not examine different levels of learners. Also, they used a different learner corpus with different annotation guidelines (see comparison in Lee et al., 2012), along with training data that was specifically tailored for the domains in the test corpus. Finally, for particle presence, they focus on overall system accuracy, rather than error detection, making direct comparison of results difficult (cf. Chodorow et al., 2012).

There has been more work in the comparable language of Japanese, which we review briefly. To begin with, Oyama (2010) uses a basic SVM model trained on well-formed Japanese to detect particle errors, focusing on eight different case particles and finding that the particle frequency distribution in the training corpus affects accuracy, ultimately evaluating on 200 learner particle instances of a single particle (*wo*).

Mizumoto et al. (2011) use statistical machine translation (SMT) techniques to detect and correct all errors within Japanese, using a “parallel” cor-

<sup>1</sup>Examples come from the learner corpus; see section 4.2.

pus of ill-formed and correctly-formed Japanese, based on correction logs from a collaborative language learning website. Our paradigm is much different, basing our method only on a correct model of the target language, given a relative lack of corrected data available in Korean and other lesser-resourced languages. We are, however, able to use some correction logs for building confusion sets (section 7.1). Imamura et al. (2012) correct Japanese particle errors using an approach similar to SMT ones, relying on a corpus of generated errors to learn a model of alignment to correct forms. We could explore generated errors in the future, but rely only on a model of correct Korean here.

Suzuki and Toutanova (2006) predict case markers in Japanese for an MT system, basing their techniques on semantic role labeling. They predict 18 case particles, a subset of all Japanese particles. They use a two-stage classifier, first identifying whether case is needed and then assigning the particular case ending, training the second classifier only on instances where a case marker was required. This breakdown and parts of their feature sets are similar to ours, but: a) they use (gold standard) parse features and treat the problem as one of predicting markers for *phrases*; and b) they correct machine errors, while we correct learner errors, allowing us to investigate methods such as using learner-based filters.

Turning to Basque, de Ilarraza et al. (2008) detect errors in five complex postpositions, where the postposition itself has a suffix, by developing 30 constraint grammar rules which use morphological, syntactic, and semantic information. While the rule-based system can work well, we pursue a strategy which incorporates different types of linguistic information through contextual features.

## 4 Data

### 4.1 Training Data: Collecting Web Data

In order to control the data for domain specificity, we follow the recommendations laid out in Dickinson et al. (2010) and extended in Dickinson et al. (2011). Namely, we use data collected from the web using search terms based on topics likely to be discussed in a learner corpus, in order to find semantically-relevant instances. This data is passed through an encoding filter to ensure that at least 90% of any document retrieved is written using Hangul (the Korean writing system). The resultant corpus is over 23 million words.

### 4.2 Testing Data: A Learner Korean Corpus

For testing data, we use a corpus of learner Korean (Lee et al., 2012, 2013) featuring 100 error-annotated essays from learners evenly split into four different categories: beginning (B) vs. intermediate (I) learners, and foreign (F) vs. heritage (H) learners, where *heritage* refers to learners who had Korean spoken at home.<sup>2</sup> We split the corpus into development and test sets by taking  $\approx 20\%$  of each subcorpus for development, and using the rest as testing. Table 1 gives the numbers of sentences, tokens, nouns, particles, total errors, and omission errors in the development and testing sets.

	Sen.	Tok.	Noun	Part.	Err.	Om.
Dev	331	2673	955	849	103	51
Test	1079	8987	3266	2872	430	234
All	1410	11660	4221	3721	533	285

Table 1: Annotated corpus statistics (*sentences, tokens, nouns, particles, errors, omissions*)

Particle errors are marked as omissions, insertions (omissions), or substitutions, in a multi-layered framework. Spacing and spelling errors are corrected before the target form and correct segmentation are marked, segmentation being necessary since nouns and particles are written as a single orthographic unit. For our experiments, we use the correctly-spelled layer, mitigating the effect of spelling errors for testing an error detection system, as done for English (e.g., Tetreault and Chodorow, 2008; Chodorow et al., 2007).

All particles (erroneous or correct) are labeled as to their function (e.g., locative), allowing us to group particles into categories, to see how classifier performance differs. Figure 1 provides the four groups we consider (cf. tables 5 and 6). Additionally, some nominals require multiple particles in sequence (*Seq.*), and some of the annotations allow for particles from more than one category as a correct answer, i.e., a set of correct answers (*Set*).

### 4.3 Learner Error Analysis

Lee et al. (2009) annotate another corpus of learner Korean, divided using the same four-way split among learner level and type as the corpus described in section 4.2. We examine this corpus

<sup>2</sup>The corpus will be publicly released at: <http://cl.indiana.edu/~kolla/>.

Category	Example Functions
Structural Case	subject, object, genitive
Inherent Case	time, location, goal, etc.
Auxiliary	auxiliary, topic
Conjunction	conjunction

Figure 1: Particle Categories

to get a sense of the types of errors that learners of Korean make in essays. In this corpus, omission errors, i.e., instances where the learner has mistakenly omitted a particle, make up the biggest proportion of the errors (47.6%). The next most common are replacement errors, where the learner has used the wrong particle (44.6%). Commission errors—using a particle where none is necessary—make up the remainder of the errors (7.8%).

## 5 Approach

Particles have a range of functions, including case marking and preposition-like functions, but, since they are a closed class of functional elements, we can adapt techniques from English for other closed class functional items, namely prepositions and articles, to detect errors in usage.

We view the task of detecting and correcting errors as two steps (cf. Gamon et al., 2008). The first step is a binary choice that only involves determining whether or not a particle is required, a so-called *presence* (yes/no) classifier. The second classifier, the particle *choice* classifier, attempts to guess the best particle, once it has been established that a particle is needed. We actually treat the first step as a particle omission detection system because the expected rate of errors of commission is so low, and thus we specify that the classifier cannot reject a particle that is already present. Commission errors may require their own system.

We utilize the omission classifier as it nicely performs two functions. First, because it posits instances requiring particles, it also filters out instances that do not need a particle to be grammatical. Thus, the particle choice classifier does not need to include *NULL* as a possible class, cutting down on training size and complexity. Secondly, many errors can be found at this stage, as a lot of errors stem from learners omitting necessary particles (see section 4.3). Nearly half of the learner errors could be detected with an accurate omission particle detection system at this step. Thus, this classifier can provide useful feedback to learners,

especially higher-level ones who may know the correct particle once its omission is highlighted.

## 6 Particle Omission Error Detection

We describe the particle presence classifier here, treating it as a task of particle omission detection. Any particle a learner uses is passed on, while we posit where a particle should have been used.

### 6.1 CRF Classifier

Conditional Random Fields (CRFs) have been utilized in a variety of NLP tasks in the last few years, and have been used recently for learner error detection tasks, especially those which can be seen as sequence labeling tasks (e.g., Israel et al., 2012; Tajiri et al., 2012; Imamura et al., 2012). We use the comma error detection work in Israel et al. (2012) as a basis, and employ CRF++<sup>3</sup> to set up a binary classifier at this step based on 1.5 million instances from our web corpus. Here we consider all nominals, as annotated in the corpus, as possible candidates for particle insertion. When we derive features based on POS tags (section 6.2), however, we rely on an automatic POS tagger.

### 6.2 Features

The feature set for particle omission detection is mainly composed of words and POS tags in the surrounding context, where tags are derived from a POS tagger (Han and Palmer, 2004). We use a five-word sliding window, processing each token in the document, although only nominals are possible candidates for particle insertion. The five-word window includes the target word and two words on either side for context; the feature set, with examples, is given in table 2.

We break all words into their root and a string of affixes, each with its own POS tag (or tags, for multiple affixes) to better handle the morphological complexity of Korean and avoid sparsity issues. Particles are removed when extracting affixes, so as not to include what we are trying to guess. For the text and POS of the root, we use unigram, bigram, and trigram features, as shown in the table; for the affixes, we use only unigrams. We also have a feature (*combo*) for each root that combines the text and POS into a single string.

In addition to these adjacency-based features, we also encode the previous and following nouns

<sup>3</sup><http://crfpp.googlecode.com/svn/trunk/doc/index.html>

position	Unigrams					Next		Prev		# of nouns passed	# of nouns remain						
	text		POS		combo	Noun	Pred	Noun	Pred								
	Root	Affix	Root	Affix													
Target	것	NONE	NNX	NONE	것_NNX	NONE	있	곳	좋	1	0						
Word <sub>-1</sub>	좋	은	VJ	EAN	좋_VJ	NONE	NONE	것	좋	1	1						
Word <sub>-2</sub>	여러	NONE	DAN	NONE	여러_DAN	것	좋	곳	NONE	1	1						
Word <sub>+1</sub>	있	어요	VJ	EFN	있_VJ	NONE	NONE	것	좋	2	0						
Word <sub>+2</sub>	.	NONE	SFN	NONE	..SFN	NONE	NONE	것	있	2	0						
Bigrams - text					Bigrams - POS												
W <sub>-2</sub> +W <sub>-1</sub>		W <sub>-1</sub> +T		T+W <sub>+1</sub>		W <sub>+1</sub> +W <sub>+2</sub>		W <sub>-2</sub> +W <sub>-1</sub>		W <sub>-1</sub> +T		T+W <sub>+1</sub>		W <sub>+1</sub> +W <sub>+2</sub>			
여러+좋		좋+것		것+있		있+.		DAN+VJ		VJ+NNX		NNX+VJ		VJ+SFN			
Trigrams - text					Trigrams - POS												
W <sub>-2</sub> +W <sub>-1</sub> +T			W <sub>-1</sub> +T+W <sub>+1</sub>			T+W <sub>+1</sub> +W <sub>+2</sub>			W <sub>-2</sub> +W <sub>-1</sub> +T			W <sub>-1</sub> +T+W <sub>+1</sub>			T+W <sub>+1</sub> +W <sub>+2</sub>		
여러+좋+것			좋+것+있			것+있+.			DAN+VJ+NNX			VJ+NNX+VJ			NNX+VJ+SFN		

Table 2: Features and examples for *것* in (2b) - '각 곳에 여러 좋은 것이 있어요'

and predicates, to approximate syntactic parent features. The *predicates* can be verbs, adjectives that function like verbs in Korean, and auxiliary verbs. Finally, we use two features to encode the amount of nouns that have already occurred in the sentence, as well as how many still remain. The usage of topic particles, for instance, relies in part on knowing where in the sentence a noun occurs, with respect to other nouns.

### 6.3 Filtering

Because learners are more often correct than erroneous in their usage of particles, we want to ensure that the output of classifier does not predict errors in too many instances. To this end, we have built a filter into the classifier. For these errors of omission, we check how confident the classifier is in its answer and only posit omission errors if the classifier's confidence is above a certain threshold. Tuning on the development corpus (section 6.4), we tried a variety of thresholds, in a hill-climbing approach, and found 85% to be the best.

### 6.4 Results

For all results in this paper, we follow the recommendations from Chodorow et al. (2012). We evaluate by comparing the writer, annotator, and system's answer for each instance; true positives (TP), for example, are cases where the annotator (gold standard) and system agree, but the writer (learner) disagrees. In our case, positives are cases where the system posits a particle while the learner did not. We count only instances of nominals without particles in the writer's data, as these are the only ones which could have omission errors. Along with precision (P), recall (R), and an F-score ( $F_{0.5}$ ), we provide the number of errors ( $n$ ),

true positives (TP), true negatives (TN), false positives (FP), and false negatives (FN), for the sake of clarity and future comparison. As a baseline, we use the majority class, i.e., guessing a particle for every nominal in the corpus.

Table 3 provides the results for particle omission detection on our development corpus. Here we present the baseline, the results based only on the classifier's decision (no filter), and the results for the best filter. We use precision-weighted  $F_{0.5}$  rather than the traditional  $F_1$  because precision is more important than recall for most error detection applications. As the 85% threshold results in the best  $F_{0.5}$ , we use this system on the test data.

Table 4 provides the results for particle omission detection broken down by subcorpus. The FB (foreign beginner) subcorpus has the worst performance, most likely due to their language being most distant from the well-formed Korean of the training corpus, as well as the most distant from the development set. Overall, however, the system has a solid 84.9% precision on all test subcorpora.

### 6.5 Analysis

In looking over some FPs, i.e., cases where the system predicted a particle not in the gold standard, we discovered that some of these cases involved the optionality of particles. For example, in (3), the system posits a particle after *사람들* (*salamtul*, 'people'). This is a case of a nominal being used in a genitive fashion, and so a genitive particle could be used here, but it is not required. In some sense, the system rightly points to particle usage being *licensed* in this setting. However, the corpus annotation only marks particles that are *necessary* for grammaticality (Lee et al., 2013). Fully teasing apart particle licensing from particle

	<i>n</i>	TN	TP	FP	FN	Precision	Recall	$F_{0.5}$
Dev baseline	51	0	51	98	0	34.23	100.00	39.41
Test baseline	233	0	233	391	0	37.34	100.00	42.69
Dev no filter	51	64	43	34	8	55.84	84.31	59.89
Dev 85% filter	51	90	27	8	24	77.14	52.94	70.68
Test 85% filter	233	373	101	18	132	84.87	43.35	71.23

Table 3: Particle omission error detection results

	<i>n</i>	TN	TP	FP	FN	Precision	Recall	$F_{0.5}$
FI	66	153	33	6	33	84.62	50.00	74.32
FB	51	45	18	5	33	78.26	35.29	62.94
HB	53	46	20	4	33	83.33	37.74	67.11
HI	63	129	30	3	33	90.91	47.62	76.92

Table 4: Particle omission error detection results by learner type (test data)

requirement requires more thorough discussion of when particle dropping is permitted.

- (3) 특히 외국 사람들 눈에는 더욱  
particularly foreign **people** eye more  
그렇습니다.  
is-so.

‘In particular, it is thus for the eyes of foreign people.’

Other cases do not license particles, but the nominals still have particle-like functions. In (4), for instance, the nominal phrase 이 때 (*i tay*, ‘this time’) carries a temporal meaning—much like that conveyed in the temporal particle 에 (*ey*), but no particle is allowed here, because the function is more like an adverb (cf. *today* in English).

- (4) 이 때 너무 감정에 치우치지  
**this time** too feeling-at give-way-to  
않도록 주의하여야 해.  
don’t pay-attention-to must.

‘This time, you must pay attention to not giving way to feeling.’

Regarding false negatives, i.e., cases where we do not posit a particle when we should, one major problem we observe involves noun-verb and noun-noun sequences. If a learner views a noun and a following word like a compound, it conceals the fact that the noun requires a particle. For instance, in (5) (learner-omitted particles in curly brackets), the word 성격 (*sengkyek*, ‘personality’) needs a subject particle, but it forms a compound with 좋 (*choh*, ‘good’), obscuring the noun’s role.

- (5) 성격{이} 좋은 아{가}  
personality{-**SBJ**} good-REL kid{-**SBJ**}  
태어날 때 환경이 나쁘다면 ...  
born time environment-**SBJ** bad-if ...  
‘When a child who has good personality is born, if the environment is bad ...’

Another complication is the variability of particle requirements due to minor changes in the amount of information presented, for example, the addition of one prepositional phrase changing whether a particle is necessary or not. Combined with misclassifications resulting from segmentation errors from the POS tagger, it seems like the false negative set can be reduced with better linguistic preprocessing fed into the system.

## 7 Particle Choice for Omission Errors

Once we have established that there is a missing particle, the next step is to select the best particle to be placed in the given context. Thus, we send all instances classified as missing a particle to a second classifier that makes this selection.

### 7.1 Confusion Set for Particle Omission

The scope of the training data selected, i.e. what particles should be allowed to be guessed by the classifier, is a significant decision at this stage. There are hundreds of particles in the Korean language, but many of these are not used often, e.g., 9 particles cover 70% of particle use in a data set of thesis abstracts and 32 cover 95% in a study by Kang (2002). Thus, the training data should only include particles which can reasonably be ex-

pected to appear when the learner has omitted one. Utilizing similar methodology to Mizumoto et al. (2011), we build a confusion set from data collected from the language learning and social networking website, Lang-8.<sup>4</sup>

To build the set, we searched the user-edited versions of the essays for any word corrected by appending text resembling a particle. Due to the somewhat ambiguous nature of particles with respect to other morphemes and root endings, we cannot be certain that all of these edits are in fact particles, but can be confident that a majority are.

After compiling all possible insertion candidates, we prune the list by requiring a particle’s frequency to be at least 10% of the most frequent particle. For example, if  $\text{ㄱ}$  appears 100 times as the most frequently inserted particle, any particle appearing less than 10 times would be removed.

## 7.2 TiMBL

For this task, we use memory-based learning, namely TiMBL (Daelemans and van den Bosch, 2005). The nearest neighbor algorithm is desirable as training data is sparse, and there are a variety of possible classes to choose from. After filtering the web-corpus to only include instances based on the confusion set extracted from the Lang-8 data, we have 5.7 million instances for training.

## 7.3 Features

For the particle selection system, we build upon the particle omission detection features (cf. section 6): we use unigrams, bigrams, and trigrams of the words and POS tags, a combination word+POS unigram, the previous and following verbs and nouns, and the count of nouns passed and remaining in the sentence. We only use nominals as targets for instances, using a five-word window for context. Some of the  $n$ -gram features with high numbers of possible values are less helpful, and we remove them, namely the unigram features for the two words farthest from the target, as well as the bigrams that do not include the target.

We then extend this information by adding features, some of which provide discourse information. 1) Knowing if there is already a subject, object, or topic particle in the sentence often means that there should not be another of the same type used; thus, we add binary features encoding if any of these have occurred yet. 2) We also add binary

features relating to the usage of the target word in the previous sentence, encoding if the target was marked as the topic, subject, or object, or if it was in the previous sentence at all. 3) A numeric feature is used that tracks how far along we are in the sentence, based on the idea that certain particles, e.g. subjects, are more likely to occur earlier in the sentence, whereas others, e.g. objects, occur later. 4) Finally, we include the previous particle used by the learner, again because some particles are not likely to be reused in a sentence.

## 7.4 Results and Analysis

Here we present the results for the selection classifier in terms of the accuracy of the classifier on choosing the best particle for an instance already defined as erroneous. By the definition of this task—selecting the correct particle for an *error*—there are no FNs or TNs. Thus, recall is rather meaningless, and accuracy and precision reduce to the same metric ( $\frac{TP}{TP+FP}$ ). Additionally, as mentioned in section 4.2, the particles in the test corpus can be grouped into different categories, and we provide results broken down by category and sub-corpus. Instances that require a sequence of multiple particles to be correct (*Seq.*) are not currently handled, but we leave them in the results for clarity and completeness. FPs from the error detection step are also included, although the system clearly cannot select a correct particle for them.

Table 5 shows the performance of the selection classifier on the instances identified as omission errors by the binary classifier (i.e., TPs and FPs identified by the *pipeline*). Overall, this classifier selects the correct particle 52.9% (63/119) of the time in the test data when presented with instances from the previous classifier.

Table 5: Results for particle selection on instances from binary omission classifier (*pipeline*)

Table 6 provides the results for testing on all instances with omission errors (based on the *gold*

<sup>4</sup><http://lang-8.com>

standard), i.e., including the FN instances from the binary omission classifier mistakenly marked as correct, but not FPs. For all corpora combined, the classifier selects the best particle 58.4% (136/233) of the time in the test data. The overall accuracy gleaned from Tables 5 and 6 is encouraging as we move forward, as it means that the classifier performs reasonably well on cases where it has a chance of selecting the best particle in both the *pipeline* and *gold* experimental environments.

### 7.5 Further Restricting the Task

It is clear from the number of errors for each particle category that structural particles are the type most often omitted by learners of Korean, accounting for 68% (193/284) of omission errors in all subcorpora combined. Based on this finding, we ran a set of experiments in which we trained a classifier to only insert structural case particles.

	<i>pipeline</i>		<i>gold</i>	
	Dev	Test	Dev	Test
Str.	17/20	67/80	23/29	133/164
%	85	83.8	79.3	81.1
Total	17/35	67/119	23/51	133/233
%	48.6	56.3	45.1	57.1

Table 7: Results for particle selection using a structural case-only classifier

This classifier actually performs better than when restricting selection to the particles from the confusion set for the *pipeline* experiment setting (cf. Table 5, 56% > 52%), though there is a slight drop in performance as compared to the confusion set classifier in the *gold* experiments (cf. Table 6, 57% < 58%). In both cases, however, there are significant gains made when only examining structural particles; this classifier correctly identifies the best particle over 80% of the time in both the *pipeline* and *gold* test settings. These results show the potential in handling specific linguistic

types of particles in Korean differently.

## 8 Conclusion and Outlook

We have presented a system for detecting and correcting learner Korean particle omission errors. We used a two-stage pipeline utilizing CRFs to make a binary decision as to whether or not a nominal without a particle should be followed by a particle, followed by a memory-based learner to select the best particle in the case of an omission. The binary classifier performs with 85% precision and 44% recall in the testing data, for an  $F_{0.5}$ -score of 71%; these results could lead to a useful error detection tool for learners and/or teachers. The selection classifier is also fairly accurate, choosing the best particle close to 60% of the time to correct omission errors. These results compare favorably with English preposition and determiner error correction work (cf. Dale et al., 2012), though those results involve all error types, not just omissions.

Our experiments for the selection task using specific particle types indicate that constraining the set of particles for a given context helps greatly. We saw improvement in choice accuracy by using only structural case particles to train a classifier for selecting structural case. This encouraging result can help direct research moving forward. One could build a classifier to identify what category of particle is most likely for a given context after determining a particle is missing and before sending it to a final selection classifier.

Finally, as we improve the omission detection/correction pipeline, the next logical step for building a tool for more robust grammatical error detection is to take on errors of substitution and commission. The lessons learned here from particle choice, using a feature set that incorporates dialog-based features and constraining the set of particles that can be selected for a given context, should prove particularly useful for the substitution task. Just as we have seen that structural case particles are the most likely to be dropped, we may be able to find patterns for what types of particles can be substituted or over-used by learners. Confusion sets for the types of errors made by learners (cf., e.g., Rozovskaya and Roth, 2010) should be even more useful for substitution errors.

## Abstract

The goal of this study is to investigate whether learners' written data in highly inflectional Czech can suggest a consistent set of clues for automatic identification of the learners' L1 background. For our experiments, we use texts written by learners of Czech, which have been automatically and manually annotated for errors. We define two classes of learners: speakers of Indo-European languages and speakers of non-Indo-European languages. We use an SVM classifier to perform the binary classification. We show that non-content based features perform well on highly inflectional data. In particular, features reflecting errors in orthography are the most useful, yielding about 89% precision and the same recall. A detailed discussion of the best performing features is provided.

## 1 Introduction

The role of a learner's native language (L1) in second language (L2) acquisition has been widely discussed in the theories of Second Language Acquisition (SLA) (Lado, 1957; Richards, 1971; Corder, 1975). The literature suggests that writers' spelling, grammar and lexicon in second languages are often influenced by patterns in their native language. However, the extent of the importance of L1 for acquiring L2 still cannot be determined exactly and remains a controversial topic of SLA research. Recently, the availability of learner corpora (e.g., Granger, 2003) has provided opportunities for verifying

SLA hypotheses. The previous literature suggests that the best performing features for native language identification are largely the features that rely on the content of the data, such as word n-grams, function words and character n-grams (Kochmar, 2011; Koppel et al., 2005; Tsur et al., 2007). This means that future applicability of these features is limited to corpus specific data. The primary goal of our work is to address this problem. We use only non-content based features, part-of-speech tags (POS) and error tags. Exploring these features is useful for corpora independent approaches to native language identification. Our secondary goal is to analyze the features that perform best for highly inflectional data. We approach binary classification as the beginning step in the development of a systematic tool for recognizing a specific L1 from morphologically complex L2 data. We use machine learning techniques to identify features contributing to the classification between Indo-European (IE) and non-Indo-European (NIE) L1 backgrounds of learners of L2 Czech. We employ Support Vector Machines (Joachims, 1999) to perform the classification. The results of the experiments show that the non-content based features, especially error tags, are the strongest indicators of the learners' language background.

## 2 Related Work

The task of native language identification has branched out from authorship attribution and profiling. For instance, Mosteller and Wallace (1964) have worked with the Federalist Papers to

identify the papers' authors. They looked at function words as their features. There is plenty of work addressing authorship profiling for data in languages other than English, for instance Dutch, Greek and Arabic (Van Halteren, 2004; Stamatos et al., 2001; Estival et al., 2007).

For automatic native language identification researchers have been exploiting learner corpora (Koppel et al., 2005; Wong and Dras, 2009; Tsur et al., 2007; Kochmar, 2011). Several SLA theoretical foundations have been taken as the basis for this task, for instance, the Contrastive Analysis Hypothesis (CAH) (Lado, 1957). CAH posits that difficulties in second language learning are derived from the differences between the source and target languages. It is expected that the more similar L1 and L2 are, the acquisition of L2 is more natural for a learner, and fewer mistakes are made, or positive transfer takes place. At the same time, learners have more difficulties in acquiring L2 if there are more differences between the source and target languages, which results in negative transfer, or errors. Richards (1971) addresses the nature of errors within the Error Analysis approach. He outlines interlingual and developmental types of errors. Developmental errors are common errors for any learner of a given L2, while interlingual errors are specific for each L1 or a group of L1s. Hence, interlingual errors should possess a discriminatory nature (Corder, 1975) and are of primary interest for the purpose of the native language identification.

In the search for empirical evidence, the researchers have looked at learners' errors and other idiosyncrasies in non-native writings as cues to predict a learner's native language and to conform to the above theoretical approaches as well as the phenomenon of language transfer in particular (Jarvis et al., 2012; Tsur et al., 2007). Koppel et al. (2005) look at 185 error types, including misspellings and syntactic errors as features. Besides errors, function words, character n-grams, and rare POS bigrams of non-standard English extracted from the Brown Corpus are used in the study. Koppel et al. (2005) experiment with essays from the International Corpus of Learner English in five source languages: Bulgarian, Czech, French, Russian and Spanish, and demonstrate that some types of errors are particularly useful for native language identification. Koppel et al. (2005) report slightly above 80% accuracy (with all features combined) compared to 20% baseline for 5-class classification. However, it is unclear from the study if the utili-

zation of error-based features would improve the performance with the same significance if taken on their own. We can only infer from the diagram in the paper that error features perform at slightly higher than 50% on their own and do not contribute significantly to the performance when combined with other features. Koppel et al. (2005) make valuable observations about function words and character n-grams as the most discriminative features.

Wong and Dras (2009) explore the contribution of three syntactic errors to the same task: subject-verb disagreement, noun-number disagreement and misuse of articles. The L1 backgrounds in the experiments are Bulgarian, Czech, French, Russian, Spanish, Chinese and Japanese. The accuracy obtained from classification based on these three features is 24.57% for multi-class classification. This, compared to the baseline of 14.29%, appears to be a significant improvement at the 95% confidence level. To achieve better results, the syntactic features are combined with function words, character n-grams and POS n-grams. The best accuracy is 73.71% using a combination of all the features. The results of this study demonstrate that the three syntactic errors do not contribute noticeably to classification if used without other features.

Tsur et al. (2007) investigate native language identification in the domain of phonology. Tsur et al. (2007) work with essays of Bulgarian, Czech, Russian, Spanish and French L1 backgrounds. The essays are taken from the International Corpus of Learner English. Tsur et al. (2007) suggest that learners' L1 has a strong effect on word choice in their L2 writings. The results of the classification, based only on character bi-grams, yield an accuracy of 66% in a 5-class task. The results demonstrate that the learners' choice of words when writing in a second language is influenced by the phonology of their native language suggesting evidence for language transfer (Tsur et al., 2007).

Kochmar (2011) explores the Cambridge Learner Corpus and provides a systematic error analysis for a number of two-class classification experiments. From her results, we can see that errors contribute to native language identification for learner English data. The highest result of 100% classification accuracy is achieved for misspelled character quad-grams for the Danish-Swedish group of languages. Besides specific L1s, she also looks at binary classification between language families, such as Romance and Germanic. The best result, 84% accuracy, for

this group is achieved for the combination of character tri-grams, POS n-grams and corpus derived error rates.

While the previous research widely exploits content based features, in our work we evaluate the usability of non-content based features and show that these features are reliable cues for native language identification. Moreover, all the above studies focus on learners' writings in English. In our work we investigate learner Czech data.

### 3 Experiments

#### 3.1 Corpus

We use the Czech as a Second Language (CzeSL) (Hana et al., 2010; Jelinek et al., 2012; Rosen et al., 2013) corpus, a newly developed learner corpus of Czech. Czech is a West Slavic language that belongs to the Indo-European language family. It is a morphologically complex language with very rich derivational and inflectional morphology. It has seven noun cases, a complex declension and conjugation system, pronominal clitics and other morpho-syntactic structures, which all make the Czech language difficult for language learners. The CzeSL corpus is unique because it provides opportunities for a researcher to analyze learners' linguistic output of a highly inflectional target language. The corpus consists of several sub-corpora, with a total of 2 million words.

Out of this, about 200K words are corrected and error annotated using a two level annotation scheme. The first layer corrects individual words disregarding their context, for example spelling errors. In addition to manually annotated tags, e.g., error in ending (*incorInfl*) or error in stem (*incorBase*), some tags are added automatically, e.g., missing vowel accent (*formQuant0*) or erroneous character substitution (*formSingCh*). The second layer describes corrections within context that concern mostly morpho-syntactic and stylistic errors, e.g., the valency error (*dep*) includes noun declension and verb-noun agreement errors. For our purpose, we use both layers of annotation. The tagset is described in the annotation manual (Štindlová et al., 2012), in addition to the papers mentioned above.

Each document in the corpus is labeled with metadata information, including the author's proficiency level and native language background. The essays are encoded in the Prague Markup Language format.<sup>1</sup>

---

<sup>1</sup> <http://ufal.mff.cuni.cz/jazz/pml/>

We report our findings for a binary classification between IE and NIE language backgrounds. We use 38<sup>2</sup> essays for lower intermediate (A2) and 38 essays for intermediate (B1) levels of proficiency. The essays are equally distributed among the language backgrounds within these levels. The essays are written on several topics, which are consistent throughout the groups. The topics include "My life in Prague", "The best/worst day in my life" and "Holidays", among several others. Every essay is written by a different author.

#### 3.2 Native Speakers' Predictions

Prior to implementing machine learning classification, we decided to conduct an experiment with native speakers of Czech using the same data. The motivation for this experiment is to see whether it is possible for a native speaker to predict the learners' IE vs. NIE language backgrounds based on their essays.

We asked 24 Czech native speakers with NLP and/or linguistic backgrounds to read the essays and make their predictions about the language background of the writers. To avoid content bias, we substituted all proper names of places with a capital X; and personal names with generic names across all essays, e.g., Eva and Pavel.

There were a total of 76 essays to evaluate. An online questionnaire was created,<sup>3</sup> where native speakers read as many randomly assigned essays as they wanted and filled in the keys according to their predictions. The possible answers were "IE", "NIE" and "unclear". As the result of this experiment, an average accuracy of 55% was achieved. This result is only slightly better than the baseline of 50% for two-group classification.

The participants of our experiment all had some training in linguistics. This suggests that if the participants did not have any linguistic background, their performance on the task would probably be even lower. Moreover, the essays could have still contained some contextual cues about the authors' background, which might have triggered a higher result as well. The partic-

---

<sup>2</sup> The CzeSL corpus is in final stages of development prior to public release. We used only those essays where we had access to all of: data itself, error annotation, morphological annotation and L1 metadata. We are planning to repeat the experiments, once there are more essays with such properties available.

<sup>3</sup> Using the open-source system developed by Jan Štěpánek <https://github.com/choroba/inquiry/>

ipants expressed their intuitions about the predictions. Specifically, they said they looked at the way the essays were written, the overall amount of errors. If an essay was written reasonably well the participants assumed that the author belonged to the IE group of learners, and vice versa. However, even having these intuitions in mind, our participants' performance was only slightly better than chance.

Overall, the experiment provided interesting observations and guided us towards a machine learning experiment.

### 3.3 SVM Classification

#### Data representation

For this experiment, our first goal is to see whether machine learning techniques are able to categorize the same set of data at higher performance rates than human native speakers using non-content based features. Our second goal is to see whether the native speakers' intuitions can be validated, specifically if it is the number of errors or other criteria that help to discriminate between the two classes.

We use the SVM-light classifier (Joachims, 1999). Each feature value is represented as a term weight of the feature, computed as a logarithmic ratio of the token frequency in the file to the total amount of tokens in the file.

$$S_{ij} = \text{round} (10 \times (1 + \log (tf_{ij})) / (1 + \log (l_j)))$$

Equation 1. The formula for computing the term weight of a feature where  $S_{ij}$  is a term weight,  $tf_{ij}$  is the number of occurrences of term  $i$  in document  $j$ , and  $l_j$  is the length of the document. (Manning and Schuetze, 1999, p.580).

The feature set includes 264 most frequent POS bi-grams (3 or more occurrences in the data), 305 most frequent POS tri-grams and 35 error types extracted from the corpus. The total of POS n-grams for all essays amounts to 20,000. For error types, the total amount of error type tokens is 2000. After preprocessing, each essay is characterized by a vector with no more than 604 dimensions.

We report the classification results for the best performing parameters ( $C, \gamma$ ) of the radial basis function (RBF) kernel SVM on the data set. Classification is performed by running the leave-one-out cross validation technique.

## Results

Our best model is trained on a corpus that contains essays of the lower intermediate level of learners and receives 89% precision and the same recall using only orthographic types of errors as features. This is almost 40% higher than the baseline of 50% for the two-class classification. The precision and recall measures for each experiment are described in Tables 1-3.

Features	Precision	Recall
POS bigrams	<b>78</b>	74
POS trigrams	70	74
Errors	70	<b>78</b>
Errors+POS n-grams	71	75

Table 1. Classifier performance on Level B1 (intermediate) Czech

Features	Precision	Recall
POS bigrams	70	74
POS trigrams	70	78
Errors	<b>89</b>	<b>89</b>
Errors+POS n-grams	78	<b>95</b>

Table 2. Classifier performance on Level A2 (lower intermediate) Czech

Features	Precision	Recall
POS bigrams	74	<b>89</b>
POS trigrams	68	79
Errors	84	84
Errors+POS n-grams	<b>85</b>	<b>89</b>

Table 3. Classifier performance on Level A2 + Level B1 (combined) Czech

The results also demonstrate that the error features of the two levels combined perform distinctively well, at 84%. All features together show 85% precision and 89% recall. From the above experiments, we can see that non-content features such as POS tags and error tags perform well for highly inflectional language data. Moreover, error tags, on their own, may be considered good indicators of a class for this classification. Using features that do not reflect content makes our method more general and topic- and genre independent.

### 3.4 Classification experiment using error tags only

Following the native speakers' intuitions from the experiment described in Section 3.2, we can assume that the discriminative power of errors should not be surprising; learners of Czech of a NIE language background are likely to make more errors than the learners of the IE group due to the differences between L1 and L2. However, we need to perform a more detailed error analysis to conform or disagree with these intuitions. The SVM classifier performs fairly well by using only error tags as features. In this section, we further investigate the results of the previous experiment, considering each feature separately. To verify what error types are good markers for the two groups, we run additional classification experiments on each error-tag feature using the Weka implementation of the Naïve Bayes classifier (Witten et al., 2011). Naïve Bayes is a probability-based classifier. It implements Bayes' Theorem, the basic idea of which is the independence assumption, i.e. the presence or absence of one feature does not depend on the presence or absence of another feature. Naïve Bayes is simple to implement and interpret. We perform the 10-fold cross-validation technique on each data set for this task. We report the precision and F-measure which are calculated from the feature values normalized by total token amounts.

#### Results

The results of the Naïve Bayes classification experiments for both levels of proficiency are described in Table 4 and Table 5. The best performing features are shown in bold.

Table 4 displays the results for the intermediate level (B1) with morpho-syntactic and stylistic errors, the second layer in CzeSL. At this level, 5 errors out of 13 perform with precision and F-measure higher than 50%. These errors are the errors in valency (*dep*), errors in incorrect use of bookish, dialectal expressions and hypocorrections (*stylOther*), misuse of grammatical forms (*use*), and odd constituent error (*odd*). The results suggest that these types of errors mostly contribute to the classification performance at this level.

Table 5 shows the results for the lower intermediate level (A2), the first layer of corrections in CzeSL. This level contains corrections of word-level errors, often of orthographic character.

The errors that perform with precision and F-measure higher than 50% (6 out of 22) are missing vowel accent (*formQuant0*), erroneous character substitution (*formSingCh*), incorrect use of 'i' instead of 'y' (*formY0*) ('i' and 'y' have the same pronunciation in Czech), incorrect use of 'y' instead of 'i' (*form Y1*), errors in inflections (*incorInfl*), and errors in stems (*incorBase*).

We also calculate error scores in order to identify which group (IE or NIE) tends to make more errors. The error scores are the ratios of the total frequency of an error type for all files to the total amount of errors in files.

The results of the Naïve Bayes classification suggest that depending on their nature, some errors contribute significantly to classification performance, but some have low discriminative power. For our purposes, these results are important for further analysis of the variety in the performance of the errors.

## 4 Discussion

Our results demonstrate that written texts regardless of the level of proficiency can be classified at 85% precision using non-content features, POS n-grams, and error tags combined. The results show that error-based features of two levels combined demonstrate a high performance of 84% suggesting that error annotated written learner Czech data provide reliable cues for distinguishing between the learners' IE and NIE backgrounds. The results show 89% precision and the same recall for a lower intermediate level (A2), which is annotated mostly for orthographic errors. The errors at the intermediate level (B1) with error tags of morpho-syntactic and stylistic character perform lower, at 70% precision and 78% recall.

The significant difference in the precision between the two levels suggests that the errors made by learners of a lower level of proficiency discriminate better than the errors made by higher level, i.e. if we have a fairly advanced learner, it would be harder to predict his or her language background. These results are not surprising, though more evidence is needed. It is more important to point out that the noticeably higher performance of orthographic errors suggests that these errors discriminate well between two language backgrounds within one level of proficiency. Consequently, this means that learners of two language backgrounds make errors specific for their L1 group. These results can be compared with previous observations made by other

researchers (Tsur et al., 2007; Kochmar, 2011) that character n-grams extracted from learner data contribute significantly to classification performance. As Tsur et al. (2007) hypothesized, the learners' choice of characters in L2 reflects the phonology of their L1. Although we do not specifically look at character n-grams, the better discriminating power of errors of orthographic nature achieved in our experiments might as well reflect spelling conventions of a specific L1 group. Thus, such errors are more likely to be learners' L1 to L2 transfer errors.

Below, we provide a more detailed error analysis to verify the nature of errors and possible reasons for their contribution to the performance.

#### 4.1 Error Analysis

Table 4 describes the results for Level B1. Lexical error (*lex*) shows 69% precision and 66% F-measure. These are lexicon or phraseology errors which occur, for instance, when learners misuse prepositions, choose false friends or false cognates instead of the correct variants. In the phrase *dopadlo to přírodně* the use of the adverb *přírodně* in this context results in an error. The intention of the author is more likely to say 'it ended naturally', but the word *přírodně* means 'naturally' in a sense of nature/non-artificial. The error scores show that learners of the IE language background tend to make more errors of this type (19.9/11.5). IE learners might use false cognates in Czech more often because of the similarity between L1 and L2 languages, e.g., Russian and Polish.

Stylistic errors (*stylOther*) reflect stylistic discrepancies, such as misuse of bookish, dialectal forms, slang, and hyper-corrections. For instance, in the phrase *pláči nad vejdělkem* 'be unhappy about the result' the correct use will be *pláču nad vydelkem*. There is a hypercorrection in the use of *pláči* instead of *pláču*. These types of errors occur exclusively within the IE group of learners (5.4/0) and perform with the highest precision of 79% and F-measure of 59%. This result together with the observations made for the *lex* type of error suggests that the L1s which are closer related to Czech influence the production of the L2 in a less subtle way than more distant languages. Specifically, the use of cognates in the incorrect context or use of incorrect stylistic variants might result in a transfer error in this case (Kroll et al., 2002).

The valency error (*dep*), e.g., using *bojí se pes* instead of *bojí se psa* 'he is scared of a dog' (dog

is a direct object, thus accusative *psa* instead of nominative *pes* must be used) yields 61%

Table 5. Results of Naïve Bayes classification, Level A2.

precision and 56% F-measure. Valency errors reflect the differences between the morpho-syntactic structures of L1 and L2. The use of grammar category (*use*) type of error shows 64% precision and 64% F-measure. This type includes errors in tense and aspect, incorrectly

formed comparative, and singular instead of plural among others. For instance, using *včera bude sněžit* ‘yesterday it will snow’ instead of *včera sněžilo* results in a verb tense error, future form *bude sněžit* is used instead of the past *sněžilo*. The two errors above largely concern Czech morpho-syntax. Thus, greater differences between L1 and L2 grammatical structures might trigger a higher amount of errors within the NIE group. However, a more detailed analysis of error distribution within each group and probably a larger data set are needed to investigate this claim.

The results for Level A2 are displayed in Table 5. The missing vowel accent (*formQuant0*) error occurs in such cases as incorrect *vzpomínám* vs. correct *vzpomínám*, or *doufam* vs. *doufám*. This error type performs at 76% precision and 73% F-score. The erroneous character substitution error (*formSingCh*), e.g., incorrect *otevrila* vs. correct *otevrela* or *vezmíme* vs. *vezmeme*, performs well at 74% precision and 70% F-measure. The error scores show that the NIE learners tend to make more errors of this type (6/11). Errors in inflectional endings (*incolInfl*), e.g., using *plavám* instead of *plavu* ‘I swim’ (1Sg ending ‘-ám’ of one paradigm is used with a verb of another), perform at 67% precision and 65% F-measure. Errors in stems (*incorBase*) e.g., using *dítem* instead of *dítětem*, discriminate rather well, at 80% precision and 79% F-measure. The two types of errors that describe incorrect use of ‘i’ and ‘y’ (*formY0* and *formY1*, respectively) show high precision (70% and 81%) and F-measure (55% and 65%). The NIE learners make more errors of type *Y0* (1.4/7.4), e.g., *pražských* instead of *pražských*, *vypije* vs. *vypije*, whereas the IE group solely makes errors in the other type, *Y1* (1.5/0), e.g., *hlavným* instead of *hlavním*, *líbyl* vs. *líbil*. The above results suggest that learners might make some motivated spelling choices related to their L1 backgrounds (Jarvis et al., 2012; Tsur et al., 2007). For instance, speakers of Russian and Belarusian, IE group, would use the letter ‘y’ more often in the ending because it corresponds to the phonological equivalent of the letter ‘ы’ of the Cyrillic alphabet, e.g., *главным* in Russian will be a phonological equivalent of incorrect *hlavným* in Czech.

Our analysis of the best performing features shows that learners of *both* language backgrounds within each level of proficiency produce errors that discriminate well and vary in nature between IE and NIE learners. Thus, we cannot

strictly follow the intuition that the NIE learners make more errors, although these results might change with a larger number of learner essays. The error analysis at Level B1 shows that the best performing morpho-syntactic errors occur more within the NIE group of learners, whereas errors of stylistic and lexical character discriminate better for the IE group compared to NIE within the same level of proficiency. From the analysis of Level A2, we can conclude that the learners’ L1 can be traced from some errors which provides evidence for L1 to L2 transfer. At the same time, for other errors, it is impossible to identify their nature and group prevalence based on the data available.

Our results also suggest that a wide range of manually and automatically annotated error tags is a valuable venue to explore in the context of native language identification. Error-based features have been approached by other researchers as it is mentioned in Section 2. Koppel et al. (2005) use 185 error types, which do not appear to contribute significantly to the performance. Wong and Dras (2009) use only three features which do not improve the overall results, and do not perform as high as our error-based features on their own. Kochmar (2011) provides a very systematic error analysis and conducts a number of two-group classifications. Her results demonstrate that using character quad-grams achieves the highest precision of 100% for the Danish - Swedish group. However, the author points out that character quad-grams are likely to create content bias. In our case, tags are used for errors and a high result is achieved.

At the same time, our results cannot be directly compared with the studies described above for several reasons. First, we formulate our task differently – we only identify the learners’ L1 language family rather than a specific language. Second, we use a language with a different and more complex morphological structure which might have caused a large amount of learner errors and thus, provided with the discriminative power of these features. Third, we use essays of an intermediate level of proficiency which might have contained more errors than the intermediate to advanced levels discussed previously (Argamon et al., 2009; Tsur et al., 2007). As we emphasized above, we intentionally do not use lexical features such as function words, because some function words might reflect the content of the essays to a higher degree than other, e.g., pronouns or prepositions. For instance, if learners write about their daily routines they tend

to use more prepositions and adverbs of time. If learners write about themselves, they tend to use personal pronouns. Argamon et al. (2009) describe function words as the most effective features for the task. However, when interpreting their results, we should keep in mind that the results might be artifacts of topical bias, since the topics were not strictly controlled in this study.

## 4.2 SLA Implications

We believe that our results are important for SLA. In particular, the results provide empirical evidence for the different types of errors discussed within the Error Analysis approach. We observe that some of the best performing errors occur when a learner's L1 interferes and affects the production of L2. We suggest that some of the highly discriminative spelling errors at the lower intermediate level are likely to be transfer errors for both groups, in support of the observations made by other researchers in regards to character n-grams. We also suggest that some stylistic errors are highly discriminative at the intermediate level within the IE group. At the same time, some of the errors that occur often within both IE and NIE groups might be developmental, and at this point these observations are not completely evident. Further experiments with more fine-grained error annotation and linguistic analysis might provide better insights on whether the best performing errors are of interlingual or developmental character. Overall, our results suggest that native speakers of Indo-European and non-Indo-European languages approach Czech differently, in their specific L1 background ways and make consistent types of errors across different linguistic levels, in particular lexicon and orthography, based on our data.

## 5 Conclusions and Future Work

We have described several experiments in which we explore various features to distinguish between two large language groups of learners, Indo-European and non-Indo-European. We have addressed non-content based features, and have shown that they work well for highly inflectional data. Exploring non-content based features is important because it provides opportunities for corpus independent approaches for native language identification. We have also discussed the best performing features and their contribution to the task.

Section 4.2 discussed the implications of our work to the field of SLA, but this work has further applications. By knowing what typical errors L1 learners make, language instructors can concentrate on helping their students to erase their “non-native” footprints. Other applications include marketing research, automatic error-correction and grading applications.

Our results go along with similar observations made for learner English data, that data-driven machine learning approaches are valuable for verifying SLA hypotheses (Jarvis et al., 2012). In addition, we look at Czech as the target language, which has not been discussed in the context of language background identification thus far, to the best of our knowledge. Also, our data shed light on the acquisition of target languages with complex morphology.

As for the future directions of our work, we would like to develop methods to derive best performing error tags automatically. Further, we would like to perform experiments with larger sets of data and to compare the performance of features for other levels of proficiency. Ultimately, we would like to develop a method that will be able to make more fine-grained distinctions between learners' language backgrounds using non-content based features and pin down the actual native language of the learner based on this type of data.

## Acknowledgements

We would like to thank the native speakers of Czech for their participation in our experiment and to Jan Štěpánek for tailoring his questionnaire system to our needs. We would also like to thank Jing Peng and the anonymous reviewers for their comments.
