However, the "bag-of-words" assumption is an unrealistic oversimplification in language model case because it ignores the order of words which is critical in estimating  $n$ -gram probabilities. To remedy this problem, we use Hidden Topic Markov Models (HTMM), proposed by (Gruber et al., 2007), which models the topics of words in the document as a Markov chain. The model is based on the assumption that all words in the same sentence share the same topic and the successive sentences are more likely to have the same topic. HTMM incorporates the local dependency between words by Hidden Markov Model for better topic estimation.

#### 3.1.2 Topic Probability Assignment

We use HTMM (Gruber et al., 2007) to train topic model on our training set and obtain sentence-level topic probabilities. To avoid data sparse problems, we use the topic probability of each sentence as a soft clustering for each topic rather than force hard decisions on topic assignment. In this way, we are able to get  $n$ -gram distributions for different topics. So the topic-sensitive words will have a higher occurrence in specific topics while common words will distribute uniformly in every topic.

#### 3.1.3 Estimation

We follow the common practise in  $n$ -gram model (Goodman, 2001) and simplify  $P(\mathbf{e}|t)$  into a serial of  $n$ -gram probabilities  $P(w_i|w_{i-n+1}^i, t)$  based on Markov Assumption. Formally, we decompose the probability as follows:

$$P(\mathbf{e}|t) = P(w_1|t) \cdot P(w_2|w_1, t) \cdots P(w_i|w_{i-n+1}^i, t) \quad (2)$$

Noted that, based on HTMM, we assume that all words in one sentence share the same topic, so topic  $t$  in Equation 2 can be shared. To compute  $P(w_i|w_{i-n+1}^i, t)$ , We use Maximum-Likelihood Estimation (MLE) with the  $n$ -gram fractional count for each topic. And since some topic-based  $n$ -grams probabilities are sharply distributed, we use Witten-Bell(WB) method (Witten and Bell, 1991) for smoothing.

$$P_{MLE}(w_i|w_{i-n+1}^{i-1}, t_e) = \frac{Count(w_i|w_{i-n+1}^{i-1}, t_e)}{Count(w_{i-n+1}^{i-1}, t_e)} \quad (3)$$

$$P(w_i|w_{i-n+1}^{i-1}, t_e) = \lambda_{w_{i-n+1}^{i-1}} P_{MLE}(w_i|w_{i-n+1}^{i-1}, t_e) + (1 - \lambda_{w_{i-n+1}^{i-1}}) P(w_i|w_{i-n+2}^{i-1}, t_e) \quad (4)$$

In Equation 4,  $\lambda$  is a normalization parameter for MLE probability and back-off probability,

which can be calculated using the following equation:

$$\lambda_{w_{i-n+1}^{i-1}} = \frac{N_{1+}(w_{i-n-1}^{i-1}, t_e)}{N_{1+}(w_{i-n-1}^{i-1}, t_e) + \sum_{w_i} c(w_{i-n+1}^i, t_e)} \quad (5)$$

where  $N_{1+}(w_{i-n-1}^{i-1}, t_e)$  denotes for the number of words  $w$  following  $w_{i-n-1}^{i-1}$  in topic  $t_e$ , and  $c(w_{i-n+1}^i, t_e)$  is the count of  $n$ -gram  $w_{i-n+1}^i$  in  $t_e$ .

### 3.2 Integration with SMT

We integrate our LM into SMT system to utilize topic distribution of the test-document as a trigger to each topic-specific language model. But as we know, only source side is available before decoding in SMT. So in order to get target-side topic distribution  $P(t_e)$ , we need to estimate the source-side topic distribution  $P(t_f)$  and then project it to the target side. So Equation 1 can be further refined as the following Equation:

$$P(\mathbf{e}) = \sum_{t_e} P(\mathbf{e}|t_e) \cdot \sum_{t_f} P(t_e|t_f) \cdot P(t_f) \quad (6)$$

where  $P(t_e|t_f)$  is the topic projection probability.

#### 3.2.1 Topic Projection

Since topic distributions of bilingual sentences often share the same pattern (Gao et al., 2011), we follow the work of Xiao et al. (2012) and introduce the topic projection probability  $P(t_e|t_f)$  to project the source-side topic distribution into the target-side topic space. We train topic models on both sides of the training data, then with the help of the word alignment we estimate the projection probability by the co-occurrence of the source-side and the target-side topic assignment.

Formally, we denote each parallel sentence pair by  $(t_f, t_e, \mathbf{a})$ , where  $t_f$  and  $t_e$  are the topic assignments of source-side and target-side sentences respectively, and  $\mathbf{a}$  is a set of word alignments  $\{(f_i, e_j)\}$ . An alignment  $(i, j)$  denotes source-side word  $f_i$  aligns to target-side word  $e_j$ , so the topics of both words are also aligned. Thus, the co-occurrence of a source-side topic with index  $d_f$  and a target-side topic  $d_e$ ,  $Cnt(t_f, t_e)$  is calculated by:

$$Cnt(t_f, t_e) = \sum_{(t_f, t_e, \mathbf{a})} \sum_{(i, j) \in \mathbf{a}} \delta(t_{f_i}, d_f) * \delta(t_{e_j}, d_e) \quad (7)$$

where  $\delta(x; y)$  is the Kronecker function, which is 1 if  $x = y$  and 0 otherwise. We then compute the

probability of  $P(t = d_f, t = d_e)$  by normalizing the co-occurrence count. Overall, we obtain a correspondence matrix  $M_{d_e \times d_f}$  from target-side topic to source-side topic, where the item  $M_{i,j}$  represents the probability  $P(t_f = i, t_e = j)$ . Then with the correspondence matrix  $M_{d_e \times d_f}$ , we are able to project the source-side topic  $P(t_f)$  to the target-side topic space, which we called projected target-side topic distribution  $T(P(t_f))$ .

#### 3.2.2 Topic-triggered Estimation

During decoding, we first estimate the source-side topic distribution of the test-set  $P(t_f)$ , then using the topic projection matrix, we map  $P(t_f)$  to the target side, and generate each topic  $t_e$  with probability  $P(t_e|t_f)$ . Then topic  $t_e$  triggers its topic-specific LM  $P(e|t_e)$ . We use the weighted sum of each model as the final LM score.

## 4 Experiments and Results

We try to answer the following questions by experiments:

- Can our topic-triggered language model help improve translation quality in terms of both B and perplexity.
- How is the topic number affect the language model performance.
- Can our model make better use of training corpus than N-gram model.

### 4.1 Experiment setup

We present our experiments on the NIST Chinese-English translation tasks. The bilingual training data for translation model contain 1.5M sentence pair with 38M Chinese words and 32M English words. The monolingual data for training English language model includes the Xinhua portion of the GIGAWORD corpus, which contains 10M sentences. We used the NIST evaluation set of 2006(MT06) as our development set, and sets of MT04/05/08 as test sets. Corpus statistics are shown in Table 1.

We obtain symmetric word alignments of training data by first running GIZA++ (Och and Ney, 2004) in both directions and then applying refinement rule "grow-diag-final-and" (Koehn et al., 2003). We re-implement the Hierarchical phrase-based system (Chiang, 2007) and extract SCFG

Data	Sentence	documents
Language model training	10M	980K
Translation model training	1.5M	99.4K
Tuning	616	52
Testing(04)	1788	200
Testing(05)	1082	100
Testing(08)	1357	109

Table 1: Training, tuning and test data used for evaluating B score.

rules from this word-aligned training data. A 4-gram language model is trained on the monolingual data by SRILM toolkit (Stolcke, 2002). Case-insensitive NIST BLEU (Papineni et al., 2002) is used to measure translation performance. We use minimum error rate training (Och, 2003) for optimizing the feature weights.

To obtain topic distribution, We use the open source LDA tool Open HTMM developed by Gruber et al. (2007) for estimation and inference. During this process, we empirically set the parameter values for HTMM training as:  $\alpha = 1.5, \beta = 1.01, iters = 100$ . See Gruber et al. (2007) for the meanings of these parameters. and set the topic number to  $30^1$  for both source and target side. The source-side topic model is estimated from the Chinese part of training corpus, while the target side is estimated from both Xinhua and the English side of training corpus.

#### 4.2 Effect of topic-trigger language model

For machine translation task, our baseline is the traditional hiero system with standard features (Chiang, 2007). The baseline language model is a 4-gram model trained on Xinhua corpus. Noted that we use Keneser-Ney smoothing (Kneser and Ney, 1995) for baseline LM since it’s universally acknowledged to achieve better performance. And our topic-triggered language model is trained on the same corpus with topic distribution estimated from topic model. We add our model as a new feature into the system, denote as STLM. To prove the soundness of our approach, we re-implement two comparative experiments: HTLM makes hard-decision on topic selection in both training and decoding, assigning the topic with the highest probability to the sentence, which is in the same spirit with the Heidel et al. (2007) method. Second, we

<sup>1</sup>We determine the topic number by testing 5, 10, 15, 30, 50 in our preliminary experiments. We find that 30 topics produces a slightly better performance than other values.

ppl	04	05	08
Base LM	158.42	134.59	208.11
Topic LM	148.11	119.17	200.41

Table 3: 4-gram word perplexity results of our method in terms of *ppl*. We compare our model with baseline *n*-gram model (“Base LM”) on three test-sets.

follow the method by Tam et al. (2007), denote as “Tam”, and generate topic-based marginals to adapt *n*-gram language model.

Table 2 reports the B and TER scores on all test-sets. The baseline system achieves B score of 37.43 on NIST04, 33.67 on NIST05 and 28.54 on NIST08 set. Our method(STLM) gains an average improvement of +0.76 B and an average reduction of -0.88 TER over the baseline. Results on NIST MT 04, 05, 08 are statistically significant with  $p < 0.05$  (Koehn, 2004). This verifies that our topic-triggered language model is a good complement for *n*-gram model to further improve translation quality. We can also see that our method generally out-performs the Tam’s method, because our model can capture *n*-gram level topic information, rather than only focus on estimating 1-gram topic-based probability. Another interesting result is forcing hard-decision on topic selection (HTLM) only achieves a little improvement over the baseline. The reason is two folded: First, in LM training process, the hard-decision on topic will serve as a corpus split strategy and cause data sparse problems. Second in decoding, one sentence may not solely belong to one topic, so the hard decision will cause inaccurateness in LM prediction.

We then evaluate our method in terms of perplexity. As an initial measure to compare language models, average per-word perplexity(*ppl*), reports how surprised a model is by test data. Equation 8 calculates *ppl* using log base *b* for a test set of *T* tokens.

$$ppl = b^{\frac{-\log_b P(e_1 \dots e_T)}{T}} \quad (8)$$

we evaluate 4-gram perplexity of the translation hypotheses using baseline language model and our topic-triggered model.

Table 3 shows that our model reduces the average word perplexity by 6% compared to baseline language model. The results indicate that our model successfully leverages the source-side document and reduces the *ppl* on the target side.

Model	04		05		08		AVG	
	B	TER	B	TER	B	TER	B	TER
Baseline	37.43	39.88	33.67	42.45	28.54	47.32	33.21	43.22
Tam	37.86	39.12	34.28	41.93	29.02	46.92	33.72	42.66
HTLM	37.46	39.86	33.74	42.41	28.67	47.23	33.29	43.17
STLM	<b>38.28</b>	<b>38.95</b>	<b>34.30</b>	<b>41.93</b>	<b>29.32</b>	<b>46.14</b>	33.97	42.34

Table 2: Results of our method in terms of B /TER, "Tam" denotes using topic adaptation method from Tam et al. (2007). "HTLM" denotes using topic-triggered LM with hard decision of topic assignment, and "STLM" means topic assignment by probabilities. Scores marked in bold are statistically significantly with  $p < 0.05$  (Koehn, 2004).

Test-set	04	05	08
baseline	31.31	28.43	23.67
5 topics	30.81	27.96	23.26
10 topics	30.98	28.12	23.42
15 topics	31.32	28.40	23.64
20 topics	31.39	28.40	23.82
30 topics	31.75	28.51	24.05
50 topics	31.70	28.48	24.01

Table 4: Results on all test sets with different topic number.

### 4.3 Effect of topic number

In topic model training, topic number is a manually set parameter. However, as an empirical factor, the topic number diverse a lot in different training corpus. so it's worthy to explore the effect of topic number on the performance of our topic-trigger language model. We set topic number to 5, 10, 15, 20, 30, 50 respectively to train topic models on both sides.

Table 4 shows the B scores using 5, 10, 15, 20, 30, 50 topics. We can see that with only 5 topics, the model performance is a little worse than the baseline model. This is reasonable because the corpus has not been fully clustered into different topics, so the topic information has not been fully utilized. But we can see ,as the topic number grows larger, the performance gets better with a peak at 30 topics, resulting a 0.34 improvement average over the baseline.

But there is a little slump when it comes to 50, we think the reason is as we models topic distribution into the LM training corpus, the distribution gets too scattered as topic number grows causing data-sparse problem in topic-specific language model training, thus affecting the overall probability of the language model.

Figure 2: BLEU improvement with additional topic-modeling training corpus

### 4.4 Effect of better topic model estimation

Finally, we investigate the effect of larger topic-training corpus. One important feature of topic model is the larger the training corpus is , the better model we will get. In our experiment, we use the source of fbis which only have 10,947 documents to train source-side topic model. This may not be good enough to correctly estimate the topic distribution of the test set, since we know that NIST08 contains a large portion of web corpus. So we add different size of source-side monolingual corpus: 5K, 10K, 20K, 30K, 40K, 50K from Chinese Sohu weblog corpus<sup>2</sup> only to train different source-side topic models with 30 topics.

Figure 4 shows the B scores of the translation system on NIST04,05,08. It can be seen that additional corpus improves translations quality on NIST08. This is because the additional corpus expand the diversity of the topic model, especially for NIST08 which contains a large part of web data, generating more accurate topic distribution. The best B comes to 24.12 when the additional corpus size is 50K, achieving 0.42 gains on the

<sup>2</sup><http://blog.sohu.com>

baseline system. But on 04 and 05 test-sets, the improvement is not that significant. This may be because the 04, 05 set are not similar with the additional corpus, so they are not effected by the improvement of topic model. The results indicates that the performance of our topic-triggered language model is directly associated with the topic model, which can be improved by training with larger and more relative corpus.

## 5 Conclusion

In this paper, we follow this line and introduce a novel topic-triggered LM. We first estimate the topic distribution for each document in training data, and assign those topic probabilities to each sentence, then, we train a topic-specific  $n$ -gram LM for each topic based on those topic probabilities. At decoding time, as target translations are not available before translation, we simply project the topic distribution from source to target side. Then we compute the topic-triggered LM score according to the topic distribution of the translated-document. Experimental results show that our model achieves better performance than traditional  $n$ -gram model on both perplexity and B score.

In the future, we will verify our method in other domain and language pairs. Further more, we want to combine our work with other related works to see if it can further improve the translation quality. Finally, we will explore more robust framework to incorporate syntax and semantic information to make our language model more powerful.

## Abstract

The imbalanced sentiment distribution of microblogs induces bad performance of binary classifiers on the minority class. To address this problem, we present a semi-supervised method for sentiment classification of Chinese microblogs. This method is similar to self-training, except that, a set of labeled samples is reserved for a confidence scores computing process through which samples that are less than a predefined confidence score threshold are incorporated into training set for retraining. By doing this, the classifier is able to boost the performance on the minority class samples. Experiments on the NLP&CC2012 Chinese microblog evaluation data set demonstrated that reserved self-training outperforms the best run by 2.06% macro-averaged and 2.30% micro-averaged F-measure, respectively.

## 1 Introduction

Sentiment classification aims to label peoples opinions as different categories such as positive and negative from a given piece of text (Pang et al., 2002). Currently, related research on traditional online media, such as blogs, forums, and online reviews, has made great progress (Banerjee and Agarwal, 2012; Liu et al., 2005). However, sentiment classification of microblogs is hard to process due to some unique characteristics of microblogs, for example, short length of update messages and language variations. Moreover, topic based microblogs are related with peoples daily lives and people are more likely to post some negative messages to show their unsatisfactoriness, which may partially result in imbalanced sentiment class distributions. For example, the num-

ber of negative tweets is far more than that of positive in some topics, which is different from the previous work on sentiment classification that assumes the balance between positive and negative samples (Chawla et al., 2002; Yen and Lee, 2009).

While supervised techniques have been widely used in sentiment classification (Pang et al., 2002), the main problem that supervised methods suffered is that they rely on labeled data solely. Semi-supervised methods, which make use of both labeled and unlabeled data, are ideal for sentiment classification, since the cost of labeling data is high whereas unlabeled data are often readily available or easily obtained (Ortigosa-Hernández et al., 2012). However, there are some drawbacks of semi-supervised approaches such as most of the work assume that the positive and negative samples in both labeled and unlabeled data set are balanced, otherwise models often bias towards the majority class (Chawla et al., 2002; Yen and Lee, 2009). In addition, most existing studies on imbalanced classification focus on supervised learning methods, with few on semi-supervised approaches (Li et al., 2011).

In this study, we propose a reserved self-training method for binary sentiment classification inspired by active learning strategies (Ryan, 2011). Active learning systems interact with domain experts who are responsible for annotating unlabeled samples, and aim to achieve better performance with less training data (Wu and Ostendorf, 2013). The key to active learning is to find an appropriate query strategy such as the classifier poses queries to decide which samples are most informative. We randomly reserved a portion of labeled samples before training. Reserved self-training is the process of simulating active learning that repeatedly queries our reserved samples and then incorporates the labeled samples about which the classifier is least certain into training corpus for retraining, thus the retrained classifier is able to improve

\*Corresponding author: guanyi@hit.edu.cn

the performance of classification on the minority class.

The remainder of this paper is organized as follows. The next section reviews some related work on semi-supervised sentiment classification as well as imbalanced classification briefly. We formally define the task in section 3. Section 4 presents our approach of reserved self-training algorithm for imbalanced sentiment classification. Section 5 provides experimental results on a data set of 20 topics. Finally, section 6 summarizes the work, draws some conclusions, and suggests related future work.

## 2 Related Work

Sentiment classification ranges from the document level, to the sentence and phrase level, and we concentrate on sentence level classification. Sentence level sentiment classification methods can be categorized into three types: supervised (Pang et al., 2002) unsupervised (Turney, 2002), and semi-supervised learning methods (Singh et al., 2008) among which semi-supervised approaches are more appropriate for sentiment classification of microblogs due to their capability of making use of both labeled and unlabeled data. Another related work is imbalanced classification stems from several unique characteristics possessed by microblogs (A detailed study can be found in section 3.2).

### 2.1 Related Semi-supervised Sentiment Classification Works

Semi-supervised learning approaches make good use of a small portion of labeled and a large amount of unlabeled data to build a better classifier. One of the bottlenecks in applying supervised learning is that it needs to label many samples by domain experts. To save the work of manual annotation, Riloff et al. (2003) introduced a bootstrapping method which was able to automatically label training samples. They started on a few seeds for training, subsequently, incorporated five highest scores unlabeled samples into training corpus to retrain the model iteratively. Chang et al. (2007) added some restrictions to self-training, making it possible to produce better feedback information in the learning process. For a given classification task, one of the problems of adopting co-training is that it assumes two conditionally independent feature sets could be extracted (Blum and

Mitchell, 1998). Although further studies loosed this strong assumption (Balcan et al., 2004), two classifiers must be different enough to achieve complementation. Li et al. (2011) proposed a random subspace generation algorithm for co-training applied to imbalanced sentiment classification, but its corpus limited to English product reviews.

### 2.2 Related Imbalanced Classification Works

Imbalanced classification, as an appealing task, has been extensively studied in many research areas such as pattern recognition (Barandela et al., 2003) and data mining (Chawla et al., 2004). We pay special attention to resampling and cost-sensitive methods, since they are widely applied in imbalanced classification. Other methods such as induction technique and boosting (Weiss, 2004) are beyond the scope of this paper.

Resampling is a process in which the size of training samples is changed to modify the overall size and distribution of a corpus, among these methods downsampling and oversampling are two widely used resampling techniques. Downsampling (Barandela et al., 2003) takes a subset of majority classes samples whereas oversampling (Chawla et al., 2002) randomly repeats minority classes samples to keep balance between different classes. Downsampling needs shorter training time, at the expense of disregarding potentially useful samples. Oversampling increases the size of training data set that leads to a longer training time. Moreover, oversampling may cause over fitting due to minority class samples are randomly duplicated (Chawla et al., 2002; Drummond et al., 2003). In addition to the basic downsampling and oversampling techniques, there are some other sampling methods working in a more complicated fashion. SMOTE (Chawla et al., 2002) created some synthetic minority class examples and then performed a combination of oversampling and downsampling, which achieved better performance than only applying downsampling. Some other methods integrated different sampling strategies to obtain further improvement (Batista et al., 2004).

Cost-sensitive learning (Ling et al., 2004; Zadrozny et al., 2003) is another type of method used for dealing with imbalanced classification. Most cost-sensitive learning methods can be generally divided into two categories (Lee et al., 2012): transforming an existing cost-insensitive

classifier into an equivalent cost-sensitive via a wrapper approach, or taking the cost of misclassification into consideration when training a classifier by labeled samples.

### 3 Task Definition

We first give a formal definition of our task, and then analyze the unique characters of Chinese microblogs compared to traditional online media, such as forums and blogs.

#### 3.1 The Task

Our study involves classifying opinions of Chinese microblogs as either positive or negative. We perform sentence level sentiment classification for a given message of microblogs. We first conduct some preprocessing such as word segmentation and noisy symbols filtering. Subsequently, features for the classifier are extracted from each message. Finally, reserved self-training is employed to predict unlabeled data. Although we restrict the scope of study on Chinese microblogs, the method proposed in this study can be straightly extended in support of other languages such as English.

Here is an instance of illustrating our task. For a message “#50个人生必去的胜地# 万里长城太棒了，将来一定去看看！@李雷” (#The 50 places you must see# The Great Wall of China is amazing, I will visit it someday in future@ Lei Li, a Chinese name). The words between the # symbol refers to a relevant topic and the symbol @ means a mention or reply. This message is expected to be parsed into a triple: (Topic: The 50 places you must see), (Content: The Great Wall of China is amazing, I will visit it someday in future), (Polarity: Positive). Here, ‘Topic’ is a key word people interested; ‘Content’ refers to the content of a posted message; ‘Polarity’ denotes the predicted polarity produced by our model, and the possible values for it could be positive and negative.

#### 3.2 Characteristics of Sentiment Classification of Chinese Microblogs

Compared with traditional media such as blog and product reviews, detecting sentiment from microblogs is much harder due to the following challenges posed by microblogs. First, different from English, each written Chinese sentence need to be split into a sequence of words, however, the frequent use of informal and irregular words in mi-

croblogs may hinder the accuracy of segmentation. Second, the short length of messages and language variation contribute to the data sparsity problem. Third, different from previous work which concentrated on specific domain such as digital product reviews, sentiment classification of microblogs involves multi-domain information, thus, the model trained on one domain may perform badly when shift to another one. Lastly, the dynamic updates feature of microblogs means that sentiment class distributions may vary over time, in which case we need to handle imbalanced sentiment classification.

The NLP&CC2012<sup>1</sup> evaluation data set consists of 20 topics collected from Tencent Microblog<sup>2</sup>, involving multiple domains such as political, environmental, and health issues. Illustrated in Figure 1, it can be observed that all the classes of training corpus are biased. In particular, positive sentences account for the majority class in topic 3, 6, and 11, which is different from the other topics.

Figure 1: Class distributions of positive and negative samples in 20 topics

### 4 Reserved Self-Training for Imbalanced Classification

In this study, we incorporate a learning strategy into self-training, inspired by active learning, to tackle the imbalanced binary classification problems.

#### 4.1 Self-training

Self-training is a common method of semi-supervised learning which makes use of both the labeled and unlabeled data as training corpus. As shown in Algorithm 1, Self-training is a wrapper algorithm that iteratively applies supervised

<sup>1</sup><http://tcci.ccf.org.cn/conference/2012>

<sup>2</sup><http://t.qq.com>

---

**Algorithm 1** The self-training algorithm

---

**Input:**

Labeled data  $L$   
Unlabeled data  $U$ .

**Procedure:**

1. Apply supervised method to train a classifier  $C$  with  $L$ .
2. Make predictions on unlabeled data  $U$  with  $C$ .
3. Incorporate the most confidently predicted unlabeled data  $M$  in  $U$  along with each predicted label into  $L = L \cup M$ .
4. Loop for  $S$  iterations.

**Output:**

New labeled sample set  $L$  and classifier  $C$ .

---

method inside. It starts training on labeled data only, after each iteration, the most confidently predicted unlabeled samples would be incorporated as additional labeled data, decided by confidence scores calculation function. However, applying self-training to sentiment classification of Chinese microblogs in both subjectivity detection and sentiment classification performed not as well as expected, and the prediction results often bias towards the majority class. Comparing with fully supervised methods, the performance of self-training is even worse especially on the minority class (A detailed comparative study can be found in Section 5.2). It is not economical to revise the supervised classifier inside self-training, however, we may improve the data selection strategy to boost the performance of self-training on the minority class samples. Reserved self-training is such a technique that applies selection strategy in both labeled and unlabeled data during the learning process.

## 4.2 Reserved Self-training Classification

### Algorithm

In some cases, it seems unclear what self-training is really doing, and which theory it corresponds to (Chapelle et al., 2006). Intuitively, it is almost definite to label high confidence samples, namely with little effect on the model. However, the discriminative ability of the model could be significantly improved if we try to label those samples about which the classifier is least certain. Similar to self-training, the idea behind reserved self-training is quite simple except that we first re-

---

---

**Input:**

Labeled data  $L$  consisting of positive examples  $P$  and negative examples  $N$ , where  $|N| > |P|$ .

Unlabeled data  $U$  that is also imbalanced.

**Procedure:**

## Initialization:

1. Reserve a random portion  $R$  of  $L$ , and the remaining set  $L' = L - R$  is used for training.
2. Loop for  $M$  iterations
3. Train the classifier  $C$  with  $L'$ .
4. Make predictions on unlabeled data  $U$  with  $C$ .
5. Predict the reserved portion of labeled data  $R$  by classifier  $C$ .
6. Incorporate the most confidently predicted unlabeled data in  $U$  along with each predicted label into  $L'$ .
7. Incorporate the least confidently predicted labeled samples in  $R$  into  $L'$ .

**Output:**

New labeled sample set  $L'$  and classifier  $C$ .

---

serve a portion  $R$  of the training set  $L$  before training the initial classifier. As depicted in Algorithm 2, we apply the classifier to predict the unlabeled data  $U$  and the reserved data  $R$ , then we add those most confident unlabeled data and those least confident reserved data into training set  $T'$ . By adding training samples in this way, the classifier could increase the coverage of its decision space while not adding too many majority class samples. We use training set  $T'$  to train the model  $C$  iteratively until stopping criterion is met. Finally, assessing the performance of classifier  $C'$  on a labeled data set.

## 4.3 Labeled Data Selection

Generally, semi-supervised sentiment classification takes much less training data than supervised approaches, which forcing us to select the most effective samples from labeled data available. We resort to the principle of maximizing the diversity of samples in feature space to select seed. First, choose several samples as initial seed at random. Second, compute the centroid of the seed in feature space. Lastly, select those samples with least similarity to centroid of the seed done by cosine

similarity. By choosing seed in this manner, we aim to build a diversified data set to cover the feature space properly.

#### 4.4 Confidence Scores Calculation

For binary classification, we employ probabilistic model to determine the confidence to which class a given sentence belongs, in that case the classifier queries the samples whose posterior probability of being positive or negative is nearest to pre-defined threshold. In this study, we employ MaxEnt and SVM as basic polarity classification. Normally, we could obtain the predicted label along with their confidence scores by MaxEnt. SVM adopt linear model to classify new examples, because of which we could use distances between samples and separating hyperplane to represent confidence scores (Pang and Lee, 2004). The output  $d_i$  of SVM is a signed distance (negative = negative orientation) from hyperplane, we convert  $d_i$  to non-negative by equation (1).

$$P_{neg}(s) = \begin{cases} 1 & d_i > 1 \\ (1 + d_i)/2 & -1 \leq d_i \leq 1 \\ 0 & d_i < -1 \end{cases} \quad (1)$$

## 5 Experiments

This section details the experimental setup, including the corpora and lexicons we used, and the achieved results.

### 5.1 Experimental Setup

**Benchmark Datasets:** Our experiments are based on the Chinese Microblogs Sentiment Analysis Evaluation benchmark, China Computer Federation Conference on Natural Language Processing & Chinese Computer (NLP&CC2012). The evaluation is part of the NLP&CC2012, consisting 20 topics provided by Tencent Microblog, and there are 2207 subjective, 407 positive, and 1766 negative sentences.

**Sentiment Lexicon:** In our experiments, we integrate the following resources to construct a sentiment lexicon: (1) Sentiment lexicon provided by HowNet<sup>3</sup> which consists of 836 positive sentiment words and 1254 negative sentiment words; (2) NTU Sentiment Dictionary<sup>4</sup> from National Taiwan University. It contains 2,812 positive words and 8,276 negative words; (3) WI sentiment analysis

<sup>3</sup><http://www.keenage.com>

<sup>4</sup><http://nlg18.csie.ntu.edu.tw>

lexicon<sup>5</sup> constructed by Harbin Institute of Technology which consists of 1,428 sentiment words with sentiment scores.

**Feature selection** As described in section 3.2, microblogging services is different from traditional media such as blog and product reviews. Special features should be explored according to the characteristics of microblogs, the main features we used can be found in table.1.

Table 1: The main features for polarity classification of opinion sentences

NO.	Feature description	Example
1	sentiment words	good, bad
2	strength of sentiment words	strength of pleasure, anger, sorrow, fear
3	rhetorical structure	question
4	emoticons	^_^
5	preposition	it, he, she
6	slang	给力(geli) <sup>6</sup>
7	repeated punctuation	!!!, ???
8	condition operator relates to a sentiment statement	despite, however, negative operator

### 5.2 Experimental Results

#### Supervised Learning for Imbalanced Sentiment Classification of Chinese Microblogs

In this section, we perform SVM and MaxEnt as our basic polarity classifier for sentiment classification of Chinese microblogs. Downsampling and oversampling are two widely used resampling technique for imbalanced classification, thus for thorough comparison, we apply SVM and MaxEnt model based on full training, downsampling, and oversampling method, depicted as follows.

- 1) Full-training: using the entire labeled corpora for training.
- 2) Downsampling: drop some of the majority class samples at random to obtain a balanced data set.
- 3) Oversampling: randomly duplicate the minority class samples to keep balance between the majority class and minority class.

<sup>5</sup><http://wi.hit.edu.cn>

<sup>6</sup>“geili” is a Chinese word in English alphabet, which means something is cool, or cooperative.

Table 2: Performances of different methods for imbalanced sentiment classification

Approach		Evaluation metrics					
		Micro-average			Macro-average		
		Precision	Recall	F-Measure	Precision	Recall	F-Measure
SVM	full-training	0.8542	0.6364	0.7294	0.8581	0.6312	0.7246
	oversampling	0.8006	0.5965	0.6836	0.8007	0.5881	0.6754
	downsampling	0.8393	0.6253	0.7166	0.8432	0.6195	0.7116
Maximum Entropy	full-training	0.8899	0.6630	0.7598	0.8887	0.6527	0.7497
	oversampling	0.8869	0.6608	0.7573	0.8770	0.6461	0.7411
	downsampling	0.8452	0.6297	0.7217	0.8363	0.6231	0.7141
Self-training	full-training	0.8958	0.6674	0.7649	0.8938	0.6571	0.7544
	oversampling	0.8929	0.6652	0.7624	0.8877	0.6533	0.7497
	downsampling	0.8631	0.6430	0.7370	0.8542	0.6292	0.7217
CRFs (baseline)		0.8332	0.7172	0.7709	0.8296	0.7152	0.7682
<b>Reserved self-training</b>		0.9194	0.6829	0.7837	0.9134	0.6785	0.7786
<b>Reserved self-training with min. cuts</b>		0.9313	0.6918	0.7939	0.9254	0.6874	0.7888

Figure 2 shows the performance of supervised polarity classifiers for 20 topics based on different imbalanced classification methods. We employed MaxEnt for both self-training and reserved self-training in our subsequent experiments because MaxEnt performed better than SVM. Contrary to the results of Li et al. (2011) in which downsampling approach performed best, in our study, full-training performs at least not bad than downsampling and oversampling. We speculate that these 20 microblog topics involve multiple domains such as political, environmental, and health issues, it would lose some potentially useful information if downsampling method is applied, which induced a bad performance of downsampling. In addition, all the methods perform badly on topic 3, 6 and 11 in which positive sentences account for the major class as shown in Li et al. (2011). There are two possible reasons for these results: (1) training data set of the NLP&CC2012 is imbalanced, the number of negative sentences is 4 times that of positive one, which results in model's bias towards the majority class, namely negative sentences; (2) topic 3, 6 and 11 contain much more positive sentences than the others.

### Reserved Self-training for Imbalanced Sentiment Classification of Chinese Microblogs

In this subsection, we report the performance of reserved self-training on imbalanced sentiment classification of Chinese microblogs. We implemented a model that achieved the best run in

the NLP&CC2012 for comparison. It employed Conditional Random Fields(CRFs) to predict unlabeled data, and we treated this model as our evaluation baseline in our experiments.

The entire labeled training corpora is divided into three groups, a labeled training corpus, an unlabeled data set that is actually annotated in order to facilitate the experiments, and a reserved labeled sample set. We perform fivefold cross-validation and use the averaged results as our final estimation. In Figure 3, we can see that reserved self-training performed better than the other methods, especially on topic 3, 6, and 11 in which positive sentences accounted for the major class. A detail comparison of different methods can be found in Table 2. It is worth mentioning that incorporating context information by minimum cuts is able to enhance the performance of our results.

## 6 Conclusions and Future work

In this study, we focus on the problem of imbalanced sentiment classification of Chinese microblogs. Experiments show that reserved self-training could effectively make use of imbalanced labeled and unlabeled data to achieve better performance with less training data compared with full training, while downsampling and oversampling failed to make improvement. Additionally, combining the context information between different sentences based on minimum cuts is able to revise bad classification. Inspired by active learning,

Figure 2: Performances of supervised polarity classifiers for different topics

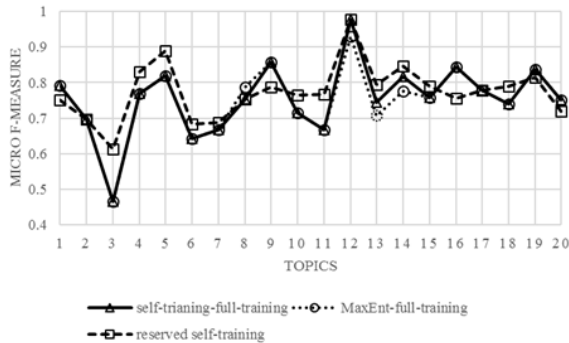

Figure 3: Comparison of different approaches with reserved self-training on imbalanced data

reserved self-training incorporate both the most confident unlabeled samples, together with their predicted labels, and the least confident labeled samples into training set. The classification error can be reduced because the least confident labeled samples would help the model better discriminate different classes. Thus, the selection strategy of reserved self-training can be applied to resolve other problems involving imbalanced binary classification, and not restricted to sentiment classification of microblogs. In the future, we will try to extend this method to address multi-label classification problems.

## Abstract

This paper presents a method of improving lexicon-based review classification by merging multiple sentiment dictionaries, and selectively removing and switching the contents of merged dictionaries. First, we compare the positive/negative book review classification performance of eight individual sentiment dictionaries. Then, we select the seven dictionaries with greater than 50% accuracy and combine their results using (1) averaging, (2) weighted-averaging, and (3) majority voting. We show that the combined dictionaries perform only slightly better than the best single dictionary (65.8%) achieving (1) 67.8%, (2) 67.7%, and (3) 68.3% respectively. To improve this, we combine seven dictionaries at a deeper level by merging the dictionary entry words and averaging the sentiment scores. Moreover, we leverage the skewed distribution of positive/negative threshold setting data to update the merged dictionary by selectively removing the dictionary entries that do not contribute to classification while switching the polarity of selected sentiment scores that hurts the classification performance. We show that the revised dictionary achieves 80.9% accuracy and outperforms both the individual dictionaries and the shallow dictionary combinations in the book review classification task.

## 1 Introduction

With the increase in opinion mining and sentiment analysis-related researches, various lexical resources that define sentiment scores/categories have been constructed and made available. Examples include SentiSense (de Albornoz *et al.*, 2012), SentiWordNet (Baccianella *et al.*, 2010), Micro-WNOp, and WordNet-Affect (Strapparava and Valitutti, 2004), which are based on a large English lexical database WordNet (Fellbaum,

1998), and AFINN (Nielsen, 2011), Opinion Lexicon (Hu and Liu, 2004), Subjectivity Lexicon (Riloff and Wiebe, 2003) and General Inquirer (Stone and Hunt, 1963), which are manually or semi-automatically constructed. These resources differ in their formats and sizes, but all can be utilized in the lexicon-based opinion mining and sentiment analysis.

The increase in the number of sentiment resources naturally gives rise to two questions: (1) How are the performances of these resources different? (2) Can we construct a better sentiment resource by combining and/or revising multiple resources? We answer these questions by comparing the book review classification performance of single and combined sentiment resources, and present a simple ‘merge, remove, and switch’ approach that revises the entries of the sentiment resource to improve its classification performance.

In the next section, we describe the experimental setup for evaluating the classification performance of sentiment resources. We then compare the positive/negative classification performance of eight widely known individual sentiment resources in Section 3. Since individual sentiment resources are originally constructed in different formats, we standardize their formats. These standardized resources will be called *sentiment dictionaries* or simply *dictionaries* throughout this paper. In Section 4 we compare the classification performances of combined dictionaries which integrate multiple individual dictionaries’ results using averaging, weighted-averaging, and majority voting. Then, we introduce a method of revising sentiment dictionaries at a deeper level by merging, removing, and switching the dictionary contents. Implications for utilizing multiple dictionaries are discussed. Related works are introduced in Section 5, and conclusion is given in Section 6.

## 2 Experimental Setup

90,000 Amazon book reviews were collected to construct a positive/negative review dataset for sentiment dictionary evaluation.

### 2.1 Dataset

5-star and 4-star book reviews were merged and labeled as positive reviews, and 1-star and 2-star reviews were merged and labeled as negative reviews. 3-star reviews were excluded. 10,000 reviews (positive reviews: 9,007 / negative reviews: 993) were randomly selected as positive/negative threshold setting data (see 2.3). The remaining 80,000 reviews (positive reviews: 71,993 / negative reviews: 8,007) were set aside as test data.

### 2.2 Review Sentiment Score Calculation

Eight sentiment resources (see Table 1) were standardized to generate eight sentiment diction-

aries ( $D_j, j=1, \dots, d$ ). (The standardization of sentiment resources is discussed in Section 3.1.)

Each book review was tokenized, lemmatized, and part-of-speech tagged using the Stanford CoreNLP suite (Toutanova *et al.*, 2003). Once the list of words in the review was obtained, the sentiment score ( $D_j(w_i)$ ) of each word was looked up in the sentiment dictionary ( $D_j$ ). The scores of all the review words listed in the dictionary ( $w_i, i=1, \dots, n$ ) were averaged to yield the *Review Sentiment Score (RSS)*.

$$RSS(D_j) = \frac{1}{n} \sum_{i=1}^n D_j(w_i)$$

Because the Stanford Part-of-Speech Tagger outputs detailed parts of speech whereas the standardized sentiment dictionaries either do not define or define only four parts of speech (e.g., noun, adjective, verb, and adverb), the Tagger's parts of speech were mapped to four parts of speech as shown in Table 3.

Resource	Entry Size	Sentiment Category & Score Range	Note
AFINN <sup>1</sup>	2,477 words	No categories. Each word has integer score ranging between -5 (very negative) and 5 (very positive).	Based on Affective Norms for English Words (ANEW).
General Inquirer <sup>2</sup>	11,788 words	Positiv/Negativ/Pstv/Ngtv/Pleasur/Pain/EMOT/etc. categories. No numerical scores.	Based on Harvard IV-4 and Lasswell dictionaries, etc.
Micro-WNOP <sup>3</sup>	1,105 synsets/ 1,960 words	Positive/negative/objective categories each with 0~1 score.	Based on WordNet 2.0.
Opinion Lexicon <sup>4</sup>	6,786 words	Positive/negative categories. No numerical scores.	Misspelled words are deliberately included.
SentiSense <sup>5</sup>	2,190 synsets/ 4,404 words	Joy/sadness/love/hate/despair/hope/etc. 14 emotion categories. No numerical scores.	Based on WordNet 2.1.
SentiWordNet <sup>6</sup>	117,659 synsets/ 155,287 words	Positive/negative/objective categories each with 0~1 score.	SentiWordNet ver. 3.0. Based on WordNet 3.0.
Subjectivity Lexicon <sup>7</sup>	8,221 words	Positive/negative/both/neutral categories. No numerical scores.	Subjectivity (weak/strong) is also defined.
WordNet-Affect <sup>8</sup>	2,872 synsets/ 4,552 words	Synsets are first categorized into emotion/mood/trait/behavior/etc., and these categories are further categorized into positive/negative/ambiguous/neutral. No numerical scores.	Based on WordNet 1.6.

Table 2. Number of shared single word entries disregarding the parts of speech between two dictionaries (**bold numbers**). Numbers in *italics* are the actual dictionary entries that match the book review words. The underlined numbers in the diagonal cells are the actual entry word size of each dictionary.

<sup>1</sup>AFINN, <sup>2</sup>General Inquirer, <sup>3</sup>Micro-WNOp, <sup>4</sup>Opinion Lexicon, <sup>5</sup>SentiSense, <sup>6</sup>SentiWordNet, <sup>7</sup>Subjectivity Lexicon, <sup>8</sup>WordNet-Affect.

### 2.3 Threshold Setting & Judgment

Each dictionary’s threshold for judging the positivity and negativity (i.e., the review label) of the book reviews was set using the threshold setting data; the threshold with the greatest accuracy was selected. A review was judged as positive if the *RSS* was greater than or equal to the threshold, and as negative, otherwise.

$$ReviewLabel = \begin{cases} \text{positive} & \text{if } RSS \geq \text{threshold} \\ \text{negative} & \text{otherwise} \end{cases}$$

### 2.4 Performance Measure

Since the book review dataset was an imbalanced dataset containing more positive reviews than negative reviews (i.e., 9:1 ratio), balanced accuracy ( $Acc_{BAL}$ ) was used to measure the overall performance.

$$Acc_{BAL} = 0.5 \times Recall_{POS} + 0.5 \times Recall_{NEG}$$

$$Recall_{POS} = \frac{\text{true positives}}{\text{true positives} + \text{false negatives}}$$

$$Recall_{NEG} = \frac{\text{true negatives}}{\text{true negatives} + \text{false positives}}$$

$Recall_{POS}$  and  $Recall_{NEG}$  each measure the positive and negative review accuracy.

Stanford POS Tagger	Senti.Dict.
NN, NNS, NNP, NNPS	Noun
JJ, JJR, JJS	Adjective
VB, VBD, VBG, VBN, VBP, VBZ	Verb
RB, RBR, RBS	Adverb

Table 3. Part-of-speech mapping from Stanford POS Tagger to the sentiment dictionary.

### 3 Individual Dictionary Comparison

The bold numbers in Table 2 indicate the number of shared *single words* between two sentiment dictionaries; note that the part-of-speech was disregarded when extracting the shared words. The underlined numbers in the diagonal cells are the actual dictionary entry word sizes. The italicized numbers are the dictionary entry words that actually match the book review words.

The eight sentiment dictionaries in Table 2 all include the following thirty-one words: “approval”, “cheer”, “cheerful”, “contempt”, “cynical”, “disdain”, “earnest”, “excitement”, “fantastic”, “glee”, “gloomy”, “good”, “guilt”, “horrible”, “marvel”, “offend”, “proud”, “reject”, “scorn”, “sick”, “sincerity”, “sore”, “sorrow”, “sorry”, “triumph”, “trouble”, “ugly”, “upset”, “vile”, “warm”, and “worry”.

Dictionary	Recall <sub>POS</sub>	Recall <sub>NEG</sub>	Acc <sub>BAL</sub>	Threshold
AFINN	59.6%	67.9%	63.8%	0.140
General Inquirer	62.2%	69.3%	<b>65.8%</b>	0.175
Micro-WNOp	40.7%	70.0%	55.4%	0.120
Opinion Lexicon	<b>67.0%</b>	63.4%	65.2%	0.025
SentiSense	61.2%	64.3%	62.8%	0.225
SentiWordNet	<b>67.0%</b>	64.3%	65.7%	0.005
Subjectivity Lexicon	58.7%	<b>70.6%</b>	64.7%	0.170
WordNet-Affect	59.8%	38.2%	49.0%	0.005

Table 4. Positive ( $Recall_{POS}$ ), negative ( $Recall_{NEG}$ ), and balanced accuracy ( $Acc_{BAL}$ ) of eight sentiment dictionaries on 80,000 book reviews.

### 3.1 Standardization

Because some sentiment resources define sentiment *categories* instead of sentiment *scores*, they were converted to sentiment scores: For example, *positive*, *negative*, and *neutral/ambiguous* categories were each converted to 1.0, -1.0, and 0.0.

In some cases, emotion categories such as *joy*, *sadness*, *love*, etc. were first mapped to *positive*, *negative*, or *ambiguous* categories and then converted to sentiment scores. The standardization process for each dictionary is explained below.

**AFINN:** AFINN contains sentiment scores ranging between  $-5 \leq score_{AFINN} \leq 5$ . These scores were normalized from  $[-5..5]$  to  $[-1..1]$ .

Normalizing  $[A..B]$  to  $[C..D]$  employed the following equation:

$$X' = \frac{D - C}{B - A} \cdot X + \frac{C \times B - A \times D}{B - A}$$

The below equation was used for AFINN:

$$X' = 0.2X$$

**General Inquirer (GI):** Each entry word in the GI contains one or more GI categories, and we selected the following sentiment-related categories and calculated the sentiment scores by averaging the assigned category values: *Positiv*, *Pstiv*, *PosAff*, *Pleasur*, *Virtue*, *Complet*, and *Yes* categories were each assigned a 1.0 score while *Negativ*, *Ngtv*, *NegAff*, *Pain*, *Vice*, *Fail*, *No*, and *Negate* categories were assigned a -1.0 score.

**Micro-WNOp:** For each entry word, the positive/negative paired sentiment scores were given by multiple human judges. These paired scores were added and averaged to obtain a single sentiment score. Note that for all WordNet-based sentiment resources, the different senses of a word (e.g., *happy#1*, *happy#2*, etc.) were aggregated and their sentiment scores were averaged.

**Opinion Lexicon:** Words in the positive word list were given a 1.0 score while words in the negative word list were given a -1.0 score. Three ambiguous words that were included in both the positive and negative lists were given a 0.0 score.

**SentiSense:** Emotional categories assigned to the synsets were converted to sentiment scores: *Joy*, *love*, *hope*, *calmness*, and *like* categories were given a 1.0 score; *fear*, *anger*, *disgust*, *surprise*, and *anticipation* categories were given a -1.0 score; and *ambiguous*, *surprise*, and *anticipation* categories were given a 0.0 score.

**Subjectivity Lexicon:** *Positive*, *negative* and *neutral* categories were converted to 1.0, -1.0, and 0.0 sentiment scores respectively. Entry words with ‘anypos’ (i.e., any parts-of-speech) were unfolded to have four parts-of-speech.

**WordNet-Affect:** Synsets having affective hierarchical categories such as *positive-emotion*, *negative-emotion*, *ambiguous-emotion*, and *neutral-emotion* were converted to 1.0, -1.0, 0.0, and 0.0 sentiment scores respectively.

Note that only the single word dictionary entries were actually looked up in the book review classification experiments; phrases or compound words (e.g., those including blank spaces, hyphens or underscores) were not matched.

### 3.2 Evaluation

The RSSs were calculated using the eight standardized sentiment dictionaries for each review, and the threshold for judging the review label was set differently for each dictionary using the 10,000 book review threshold setting data.

Table 4 compares the classification performance of the eight sentiment dictionaries on test data (80,000 book reviews).  $Recall_{POS}$ ,  $Recall_{NEG}$ , and  $Acc_{BAL}$  each indicate the classification accuracy of positive, negative, and overall reviews. Here, General Inquirer showed the best overall performance ( $Acc_{BAL}=65.8\%$ ); Opinion Lexicon and SentiWordNet performed well on positive reviews ( $Recall_{POS}=67.0\%$ ) whereas Subjectivity Lexicon performed well on negative reviews ( $Recall_{NEG}=70.6\%$ ).

Despite the significant difference between the General Inquirer and SentiWordNet’s book review-related dictionary entry word sizes (Table

2: 3,853 vs. 33,923), the two exhibited comparable classification accuracies. The same can be said for the rest of the dictionaries excluding the lowest performing two dictionaries, MicroWNOp and WordNet-Affect.

#### 4 Combining Multiple Dictionaries

We now investigate the performance of combining multiple dictionaries through averaging, weighted-averaging, and majority voting.

##### 4.1 McNemar’s Test

We applied McNemar’s test (McNemar, 1947) on the classification results of the individual sentiment dictionaries to investigate whether any two dictionaries’ hits and misses were significantly different. The worst performing WordNet-Affect was excluded from the test.

Twenty-one dictionary pairs were generated from seven sentiment dictionaries. All dictionary pairs except the Opinion Lexicon vs. SentiWordNet ( $p=0.5552$ ) exhibited significant differences in the proportion of hits and misses at 5% significance level<sup>1</sup>.

##### 4.2 Averaging, Weighted-Averaging, & Majority Voting

**Averaging:** The seven dictionaries’  $RSS$ s were averaged for each book review to calculate the combined *Averaged Review Sentiment Score* ( $RSS_{AVG}$ ). We excluded the worst performing WordNet-Affect with lower than 50% accuracy since classifiers involved should provide a lower error rate than a random classifier (Enrriquez *et al.*, 2013).

$D_j$  indicates the individual dictionary,  $j$  denotes the index of the sentiment dictionary, and  $m$  indicates the number of sentiment dictionaries to be combined; in our case  $m$  equals seven.

$$RSS_{AVG} = \frac{1}{m} \sum_{j=1}^m RSS(D_j)$$

$$ReviewLabel = \begin{cases} \text{positive} & \text{if } RSS_{AVG} \geq thres \\ \text{negative} & \text{otherwise} \end{cases}$$

A review was judged as positive if the  $RSS_{AVG}$  was greater than or equal to the threshold, and as negative, otherwise. The threshold was determined using the threshold setting data.

	Recall <sub>POS</sub>	Recall <sub>NEG</sub>	Acc <sub>BAL</sub>	Thres
AVG	66.7%	68.9%	67.8%	0.115
w-AVG	<b>67.3%</b>	68.0%	67.7%	0.045
Vote	64.1%	<b>72.5%</b>	<b>68.3%</b>	N/A

Table 5. Classification accuracy of the combined dictionaries using averaging (AVG), weighted-averaging (w-AVG), and majority voting (Vote).

**Weighted-Averaging:** The seven dictionaries’  $RSS$ s were weighted and averaged to yield a combined *Weighted-Averaged Review Sentiment Score* ( $RSS_{w-AVG}$ ).

$$RSS_{w-AVG}(weight_j) = \frac{1}{m} \sum_{j=1}^m weight_j \cdot RSS(D_j)$$

$$\sum_j weight_j = 1, (0 \leq weight_j \leq 1)$$

$$ReviewLabel = \begin{cases} \text{positive} & \text{if } RSS_{w-AVG} \geq thres \\ \text{negative} & \text{otherwise} \end{cases}$$

Grid search was performed to set the weights of the seven dictionaries during the threshold setting stage. In the experiment, AFINN was given the greatest weight of 0.4, while the remaining six dictionaries were each given 0.1 weights.

**Majority Voting:** The classification result (label) of each sentiment dictionary was used as votes in the majority voting. In the case of voting, the threshold was not set.

$$ReviewLabel = \begin{cases} \text{positive} & \text{if } Vote_{pos} > Vote_{neg} \\ \text{negative} & \text{otherwise} \end{cases}$$

Table 5 compares the classification accuracy of the three combined dictionaries on test data. AVG, w-AVG, and Vote each indicate averaging, weighted-averaging, and majority voting. The majority voting showed the best performance on the negative (72.5%) and overall (68.3%) review classification while the weighted-averaging showed the best performance on the positive (67.3%) review classification. However, the performance increase of the combined method was marginal compared to the best performing single dictionary (General Inquirer’s 65.8% vs. majority voting’s 68.3%).

##### 4.3 Merging, Removing, & Switching

Combining multiple dictionaries at the surface level did not bring much improvement. We decided to merge the dictionaries at a deeper level and revise the dictionary entry’s sentiment scores to improve the classification performance.

<sup>1</sup> AFINN vs. SentiSense ( $p=5.221e-09$ ), AFINN vs. Subjectivity Lexicon ( $p=0.0002395$ ), General Inquirer vs. SentiSense ( $p=2.886e-12$ ), and the remaining seventeen dictionary pairs ( $p<2.2e-16$ ).

Figure 1. Classification performance of (a) eight original individual dictionaries (*AFN~WNA*) and one merged dictionary (*MRG*) and (b) revised dictionaries across different thresholds. (c) Classification performance of original merged dictionary (*MRG*) and revised merged dictionaries with different values of ‘remove & switch’ (*MRG\_0.0~MRG\_0.5*).

We could have merged all eight dictionaries, but instead merged the seven dictionaries excluding the SentiWordNet; we guessed that adding the largest SentiWordNet would simply result in an expanded version of the SentiWordNet and similar performance to the SentiWordNet. When merging the dictionary entries, the sentiment scores of the overlapping entry words, disregarding the parts-of-speech, were averaged. As a result, a merged sentiment dictionary containing 12,114 word entries was created. Threshold was also set for the merged dictionary, and the 80,000 book reviews were classified.

Table 6 compares the classification performance of the individual (*AFN~WNA*) and merged dictionaries (*MRG*). The first column lists the dictionaries (see Table 2 bottom for the full names of the dictionaries.), the second column displays the performance of the original dictionaries, and the third column shows the performance of the revised dictionaries. We confirmed that the merged dictionary (*MRG*) showed better performance (69.5%) than both the individual dictionaries and the best performing combined dictionary using majority voting (68.3%). Figure 1 (a) compares the performance of the nine dictionaries across different thresholds. We see that the merged dictionary (pink curve) outperforms the rest between the 0.05~0.10 threshold ranges.

Still, the performance of the merged dictionary did not improve dramatically. Therefore, we contrived a way to update the merged dictionary’s entries to enhance performance. To do this, we leveraged the skewed distribution of positive/negative reviews. The general idea is to selectively (1) remove dictionary entries and (2) switch the polarity of sentiment scores.

Senti. Dict.	Original $Acc_{BAL}$ (thres)	Revised $Acc_{BAL}$ (thres)
<b>AFN</b>	63.8% (0.140)	73.2% (-0.030)
<b>GI</b>	65.8% (0.175)	78.0% (-0.085)
<b>MWO</b>	55.4% (0.125)	58.9% (0.045)
<b>OL</b>	65.2% (0.025)	75.1% (0.015)
<b>SS</b>	62.8% (0.225)	72.0% (0.085)
<b>SWN</b>	65.7% (0.005)	78.8% (-0.030)
<b>SL</b>	64.7% (0.170)	77.2% (0.005)
<b>WNA</b>	49.0% (0.005)	54.0% (0.075)
<b>MRG</b>	<b>69.5% (0.060)</b>	<b>80.9% (-0.025)</b>

Table 6. Classification performance of original and revised dictionaries and their thresholds.

To implement the first idea, we removed those dictionary entry words with positive/negative book review word occurrence ratios that are similar to that of positive/negative book review ratio itself. The selection of the word was determined using the threshold setting data. For example, if the word “interested” appeared in the positive and negative reviews 900 and 100 times respectively, and the positive/negative review ratio of the threshold setting data is 9:1, we removed the “interested” entry from the dictionary. Such entry words were considered as not contributing to the actual classification.

To implement the second idea, we switched the sign of the selected dictionary entry words’ sentiment scores whose positive/negative word occurrence ratio and the positive/negative review ratio’s difference yielded a value with the sign opposite of its sentiment scores. For example, if the word “horror” appeared 900 and 300 times in the positive/negative book reviews resulting in 9:3 word occurrence ratios and the review ratio itself is 9:1, we calculated the difference between

the word and review ratio as  $9/3 - 9/1$ , which resulted in  $9/2$ , a positive number. However, the sentiment dictionary originally lists the sentiment score of “horror” as negative, e.g.,  $-0.858$ ; hence the sign (polarity) of the entry word “horror” was switched to positive, e.g.,  $0.858$ .

Table 6 shows the classification performance of the revised dictionaries. We see that the performance increased for all original dictionaries after they were revised using the ‘remove & switch’ procedure. The merged and revised dictionary showed the best performance (80.9%). Figure 1 (b) shows the performance of the revised dictionaries across different thresholds. We see that our method works better with larger dictionaries than smaller dictionaries such as *MWO* and *WNA*. This may be natural since our method includes the ‘remove’ procedure.

How much dictionary contents to ‘remove & switch’ were determined using the threshold setting data by experimenting with different proportion values. Figure 1 (c) compares the merged dictionary in its original version (*MRG*) and the revised versions using different values for revising (*MRG\_0.0~MRG\_0.5*). In our experiment, the best performing merged and revised dictionary’s ‘remove & switch’ value was determined as 0.3 (*MRG\_0.3*).

Our approach employs the most basic sentiment score aggregation to perform classification; no negation handling or structural analysis of the sentences is conducted. Our focus is on revising the sentiment dictionary by utilizing multiple dictionaries. At the outset, we surmised that combining and revising multiple dictionaries will have the following effects: (1) the word coverage will broaden and different dictionaries will complement each other. (2) The sentiment scores will be updated to incorporate diverse measurements leading to less odd scores.

However, broader coverage did not necessarily guarantee better performance since irrelevant words often matched to generate noise. By incorporating the ‘remove’ procedure, we aimed to remove noise. Examples of removed words in the book reviews dataset included “book”, “interested”, and “mystery”. With regard to the assumption (2) above, we found that contextual adjustment of sentiment scores was necessary for the given domain. Consequently we proposed the ‘switch’ procedure which switched the polarity of selected dictionary entries. Examples of the switched words included “conspiracy”, “horror”, and “tragic” which were changed to have positive polarity.

## 5 Related Work

We were motivated by Taboada *et al.*’s (2011) work on lexicon-based sentiment analysis which couples hand-crafted sentiment dictionary with detailed sentence analysis. Although their sentiment calculation (SO-CAL) is more advanced than ours (it incorporates, for example, negation and intensification), we were able to confirm through the ‘remove’ procedure that “less is more”, i.e., less confounding dictionary entries will lead to more (greater) performance, with regard to the treatment of dictionary (Taboada *et al.*, 2011; p.297). Our contribution is that we provided a simple data-based method to achieve “less is more” by leveraging the skewed distribution of the threshold setting positive/negative review data. This will be useful when ample threshold setting data is available, but dictionary expert is absent or costly.

Fahrni and Klenner (2008) proposed domain-specific adaptation of sentiment-bearing adjectives. Adjectives (e.g., good, bad, etc.) possess prior polarity, but depending on the context this polarity may change; for instance, warm mittens may be desirable, but warm beer may not be. To tackle the problem of contextual polarity, Fahrni and Klenner implemented a two-stage process that first identifies domain-specific targets using Wikipedia, and then determines the target-specific polarity of adjectives using a corpus. We performed a crude polarity adaptation by selectively switching the polarity of the dictionary entry’s sentiment score based on the positive/negative distribution of the threshold setting data. Our approach, albeit crude, takes into account all dictionary entries, not restricted to adjectives, as candidates for polarity adaptation.

Neviarouskaya *et al.* (2011) described methods for automatically building and scoring new words based on sentiment-scored lemmas and types of affixes to create a sophisticated sentiment dictionary. Although we did not build sentiment dictionary from scratch, we experimented with shallow combinations and entry word merging of multiple dictionaries to show that shallow combination is insufficient, and that deeper-level merging and revising could be used as a viable method for enhancing the dictionary; in the process we generated revised dictionaries.

Various sentiment resources are built to perform different sentiment analysis tasks, so uniformly standardizing each resource may be unjust for some resources; moreover, we restrict our method’s effectiveness within the sentiment

analysis of product reviews which is considered to be an easier problem compared to shorter texts such as microblogs (Cambria *et al.*, 2013); we acknowledge these as our limitations.

## 6 Conclusion

We presented a method of merging multiple dictionaries, and removing and switching the merged dictionary's contents to achieve greater accuracy in the lexicon-based book review classification. In the future, we plan to investigate whether our approach is robust across different domains, how much threshold setting data is needed to achieve improvement in the revised dictionary, and what effects different positive/negative data distribution has on our method. We also plan to cover other sentiment resources such as SenticNet (Cambria *et al.*, 2010) in the future.

## Abstract

The inherent morphological complexity of languages such as Arabic entails the exploration of language traits that could be valuable to the task of detecting and classifying sentiment within text. This paper investigates the relevance of using the roots of words as input features into a sentiment analysis system under two distinct domains, in order to tailor the task more suitably to morphologically-rich languages such as Arabic. Different word-rooting solutions are employed in conjunction with a basic sentiment classifier, in order to demonstrate the potential of mapping Arabic words to basic roots for a language-specific development to the sentiment analysis task, showing a noteworthy improvement to baseline performance.

## 1 Introduction

An increasing need for quick and effective analysis of huge masses of text has sparked a revolution in the requirements of natural language processing systems, demanding an ability to handle varied types and formats of textual data for a wide range of language analysis tasks, both on the syntactic and semantic levels. The task of sentiment analysis in particular presents a unique form of text analytics due to the flourish of new opinionated web data in social media and otherwise, dealing with the detection and of opinions within a text, and then further with distinguishing their polarity.

Two main tasks are of great importance with respect to the classification of opinions in text, regardless of the language under inspection: the tasks of *subjectivity detection* in a set of statements to differentiate between purely *objective* reporting of information in the form of facts, as opposed to a *subjective* account of the information; and the

task of *sentiment analysis*, which entails classifying the resultant subjective statements into a set of classes, *positive*, *negative*, and *neutral*, depending on the polarity of the opinion expressed. With respect to the level of analysis performed, individual tasks may be more relevant than others: while subjectivity analysis is relevant at the sentence level to sort out opinionated statements, sentiment analysis can be appropriate at both the sentence and the document level, if the excerpts are already defined to be subjective, and the task is to distinguish the *polarity* of the opinion being expressed (Liu, 2012).

While much research has been attributed to the task of sentiment analysis in English, fewer attempts tackle the task in other more morphologically complex languages such as Arabic, and increasing amounts of information available in these languages makes the task of Arabic sentiment analysis a very relevant one, albeit a challenge for classification systems. Such language processing tasks are made more difficult in Arabic due to the lack of resources and tools available as well, despite a growing user and content base in the language.

This paper explores the implications of reducing words to their roots in order to find common, basic, sentiment-bearing components that will relate many words to a single source, and thus help to classify a larger number of words to aid in the Arabic sentiment analysis task. This is presented through comparisons within two distinct datasets where opinions are classified based on their sentiment using roots derived from three different rooting libraries. Section 2 discusses related background information on Arabic language morphology, and some intuition behind the use of rooting as an aid to such a classification task. Section 3 details related work in the fields of subjectivity and sentiment analysis. The root-based methodology proposed is presented in Section 4, followed by

results, evaluation, and analysis of the performed experiments in Section 5. Section 6 presents conclusions and possible directions for future work.

## 2 Background Information

The challenges behind the natural language processing of languages such as Arabic stem from rich morphologies, or internal word structures (Habash, 2008), and the intricate construction of words from roots and patterns specific to the language’s grammar. While Modern Standard Arabic (MSA) is the standard form of communication for written and broadcasted Arabic (Ryding, 2006), spoken Arabic exists in the form of many different dialects, all of which diverge significantly from written MSA (Habash, 2008). This makes standardizing language processing tasks in Arabic even more complicated, in addition to the problem of diacritization and text normalization for data retrieved from unregulated sources, which is often the case for the mining of data appropriate for tasks such as sentiment analysis. The following section gives a basic outline of some of the details of Arabic grammar and morphology relevant to the opinion classification task at hand as background for the proposed algorithm.

### 2.1 Roots in Morphologically-Rich Languages

In derivational languages such as Arabic, words are derived from sets of “roots”, which are commonly two, three, or four letter words that describe a basic idea (StudyQuran, 2004). Full words in Arabic are then derived from these roots by adding vowels (and/or other consonants) around the basic root, called *affixes*, which change the word pronunciation and form word derivations (Albraheem and Al-Khalifa, 2012; Ryding, 2006). These affixes can be attached to a base, stem, or root, as either *prefixes* (inserted before the word), *infixes* (inserted within the word), or *suffixes* (inserted after the word).

As an example, the Arabic letters س ل م (*siin-*

*laam-miim*) serve as the root for several words, including *salām*, *īsalām*, and *muslim* (StudyQuran, 2004), as shown in Table 1. By sharing the same root word, these three derivations also share a common base meaning. This pattern is a result of the word formation scheme in Arabic, where a root such as ك ت ب (*kaaf-ta’-ba’*) means having to do with “writing”, and where most other Arabic words “having to do with writing” are derived from additions and modifications to this basic three-letter root, such as كتاب (*kitāb*, meaning *book*), كاتب (*kātib*, meaning *writer*), مكتب (*maktab*, meaning *desk*), and مكتبة (*maktabatu*, meaning *library*) (Ryding, 2006).

The idea of words carrying meaning from their basic root derivatives is different to the system of word derivation in concept-based languages, where only some subset of words, but not most, can be likened to the root system. Such patterns do exist in languages such as English, but are not a general rule for word derivation. For example, the English “consonant sequence” *s-ng*, which can be used to compose various derived words, including *s-i-ng*, *s-a-ng*, *s-u-ng*, and *s-o-ng*, each of which shares a common base meaning having to do with “vocal music”. Attaching various prefixes and suffixes to these derivations also results in a wider array of words, including *sing-ing*, *sing-er*, and *unsung* (Ryding, 2006).

This concept maps the English consonant sequence to the Arabic *root*, and the English derivations resultant from the addition of vowels and affixes to the concept of an Arabic *pattern*. The consistence of this word-derivation scheme across most of a language gives root-based languages such as Arabic a well-defined clarity for word formation, which could be used to classify words based on common meaning or sense.

### 2.2 Intuition Behind Root-Based Matching

Due to this word formulation and root-based derivation scheme that is prevalent Arabic, many words bearing similar meanings come from the

Arabic Word	Transliteration	English Gloss
سلام	<i>salām</i>	peace
إسلام	<i>īslām</i>	submission, compliance, conformance, surrender
مسلم	<i>muslim</i>	one who submits, complies, conforms, surrenders

Table 1: Various Arabic Word Derivations for the Root Word *Siin-Laam-Miim* (StudyQuran, 2004).

same root, which in itself holds the “idea” that the derivations express.

It is this morphological property that can be exploited to enhance the efficiency of an automatic sentiment classification system. The proposed method seeks to use different rooting techniques to reduce input feature words to their most basic roots, thus mapping a larger number of words to matching source roots. Sentiment-bearing roots, once found recurrently in a positive or negative context, can be used to classify many more words than the derivations themselves, allowing for classification of a broader feature set.

Two sets of sentiment-bearing words that are derived from the positive-sentiment root ن ج ح (nun-jim-ha', having to do with “success”) and the negative-sentiment root ق ت ل (qaf-ta-lam, having to do with “killing”), are shown in Table 2 (with their respective transliterations and translations). Various derivations are shown in matching positive and negative contexts, where the root word is the same, and the meaning of the sentence, likewise, retains the same sentiment orientation.

Because the task of sentiment analysis is not enclosed at the word-level, and because the surrounding words in a phrase may change the meaning of the phrase significantly as in the case of polarity incrementing or decrementing words (or even entirely, as in the case of negation words) a root-matching scheme on its own is not sufficient for consistently accurate sentiment classification. One common handling of such problems as negations in English is to consider all words between the negation and the next clause-level punctuation mark as negative (Pang et al., 2002; Sanjiv and Chen, 2001). In an Arabic context, a more flexible free word-ordering makes such a method difficult to consistently match, so the task would require a more elaborate handling scheme. Still, the initial root-matching task can be used to enhance results as a building block for an automatic Arabic sentiment analysis system.

### 3 Related Work

While there has been much work on sentiment analysis in English, few examples of work on the

Arabic Word	Positive Word Context Excerpt
انجح ānğħ “the most successful”	يمكن اعتبار [...] من انجح المديرين ymkn āṭbār [...] mn ānğħ ālmdrbyn “[...] can be considered one of the most successful coaches”
النجاحات ālnğāħāt “successes”	النجاحات العديدة التي حققها مع المنتخب ālnğāħāt ālḍydh ālty ħqğħā m' ālmnthb “the many success that [he] achieved with the team”

مقتل mqtl “the killing [of]”	كانت حصيلة اولية اشارت مساء الجمعة الي مقتل اثنين kānt ħṣylħ āwlyħ āšārt msā ālğmħ āly mqtł ātnyn “the initial toll on Friday evening indicated the killing of two”
قتلي qtly “victims”	اعلن [...] مسؤوليته عن هجومين [...] اوقعا خمسة قتلي āḍn [...] msūwlyth n ħğwmyn [...] āwqā ħmsh qtly “[he] claimed responsibility for two attacks leaving five victims”

Table 2: Two Sets of Sentiment-Bearing Words Derived from Common Roots, in Context. (Excerpts from the PATB Part 1 v 4.1 (Maamouri et al., 2010))

task for morphologically complex language such as Arabic are available, and possibly even more rare are data sets and corpora suitable for work on Arabic sentiment classification tasks.

Pang et al. (2002) tackled the classic problem of positive and negative two-class sentiment classification of English movie reviews from the Internet Movie Database (IMDB) corpus, highlighting the effectiveness of machine-learning techniques for sentiment classification, and paving the way for further research to enhance the efficiency of such automatic classification systems. With respect to the varied levels of granularity used (term, phrase, sentence, and document) in the classification task, individual and process-oriented approaches have been addressed, where information acquired from one level of analysis can be passed on to the next level, as observed by Turney and Littman (2003) and Dave et al. (2003). At the sentence-level, the work of Kim and Hovy (2004) addresses the topic of detecting sentiment towards a specific topic.

For feature selection and optimization, Yu et Hatzivassiloglou (2003) use N-gram based features and a polarity lexicon at the sentence level to determine subjectivity of sentences on the Wall Street Journal (WSJ) corpus, while Bruce and Wiebe (1999) use the same corpus, but employ additional lexical, part-of-speech (POS), and structural features. As a more profound paradigm shift, recent research has shifted from keyword and lexical-based approaches to concept-based sentiment analysis approaches, where semantic networks and entity ontologies are employed to achieve a more semantically-oriented “understanding” of text (Cambria et al., 2013; Grassi et al., 2011; Olsher, 2012).

With respect to the task of Arabic subjectivity and sentiment analysis in specific, the work of Abdul-Mageed et al. (2011) addresses the task in Modern Standard Arabic (MSA), where a manually-annotated corpus of MSA is presented from Part 1 v 3.0 of the Penn Arabic Treebank (PATB) (Maamouri et al., 2004), in addition to a wide-scale polarity lexicon tailored to the newswire domain under analysis. By using various stemming and lemmatization settings with a rich feature-set under an SVM classifier, it is shown that taking language-specific morphological features and traits into consideration for complex languages such as Arabic results in significant improvements in performance, achieving

test results of 71.54% F (16.44% higher than the baseline) for subjectivity detection, and 95.52% F (37.14% higher than the baseline) for the sentiment analysis task using a newswire domain-specific lexicon, as compared to 57.84% F in development without the lexicon.

In the domain of positive and negative movie reviews, Rushdi-Saleh et al. (2011) present the Opinion Corpus for Arabic (OCA) movie review corpus, compiled from various Arabic web pages. Classification was performed using both Naive-Bayes and SVM classifiers, with combinations of N-grams, stemming, and stop-word removal pre-processing, and achieved a best result of 90% accuracy under SVM, as compared to a similar classification task in English with the Pang et al. (2002) IMDB corpus, which obtained 85.35% accuracy with various N-gram models.

Abbassi et al. (2008) explore the task of feature selection for the opinion classification task, using an Entropy Weighted Genetic Algorithm (EWGA), which incorporates both syntactic and stylistic features and the information gain heuristic to classify text on the document level. An accuracy of 93.6% is reported on a compiled Middle-Eastern web forum dataset. Other problems of sentiment analysis in informal and dialectal Arabic are also addressed by Albraheem and Al-Khalifa (2012) and Shoukry and Rafea (2012), for a more specific approach to the classification problem, tailored to a regional, social-media setting.

As compared to the discussed work on the sentiment analysis task in Arabic, the proposed root-based technique employs the commonalities between words of the same root to map sets of words to the same base meaning. Rather than taking a domain-specific approach to the problem, the proposed technique is tested on two corpora from very different domains: the PATB newswire corpus annotated by Abdul-mageed et al. (2011), and the OCA movie review corpus by Rushdi-Saled et al. (2011), with focus on language characteristics to enhance classification results.

## 4 Proposed Algorithm

The following section presents a detailed description of the datasets and rooting libraries used for experimentation, the various experimentation settings undergone, and the proposed classification method applied for the task sentiment analysis on the two studied domains.

## 4.1 Datasets

The proposed sentiment classification method was conducted on two different datasets, to test the root-based approach on a generic level, unconstrained by the domain of the data itself.

### 4.1.1 Penn Arabic Treebank (PATB Part 1 v 4.1) Newswire Corpus

The first corpus used pertains to the tokenized newswire-domain text from the latest version of the PATB, Part 1 v 4.1 (Maamouri et al., 2010). The corpus consists of 734 newswire stories from the Agence France Presse (AFP) with various tags attached to each token, including part-of-speech information, morphology, English gloss, treebank annotation, and vocalization.

For the purposes of the sentiment analysis task, the applied section of the dataset comes from the compiled corpus of Abdul-Mageed et al. (2011), where the first 2855 sentences (comprising 54.5% of the Part 1 v 3.0 dataset<sup>1</sup>, in 400 documents) were each manually annotated into one of four labels (Abdul-Mageed and Diab, 2011): objective (OBJ), subjective positive (S-POS), subjective negative (S-NEG), and subjective neutral (S-NEUT), depending on whether the information being conveyed in the sentence was to objectively inform, or offer a subjective sense (Wiebe et al., 1999). The number of sentences with each of the four respective tags are shown in Table 3.

Tag Class	Number of Sentences
OBJ	1281
S-POS	491
S-NEG	689
S-NEUT	394

Table 3: Distribution of Sentiment Classes in the Manually-Tagged Portion of the PATB Corpus (Abdul-Mageed et al., 2011).

### 4.1.2 Opinion Corpus for Arabic (OCA) Movie Review Corpus

For another perspective for testing the proposed root-based method, the distinctly subjective OCA corpus (Rushdi-Saleh et al., 2011) was also experimented with. The corpus is comprised of

<sup>1</sup>The differences between the two versions of the PATB Part 1 lie in improvements to the organization of the data, and updates to certain aspects of the annotation (Maamouri et al., 2010).

500 movie reviews (250 positive and 250 negative) which were collected from 15 Arabic web pages, after which a series of spelling correction, tokenization, basic stop-word and special character removal, and stemming processes were performed. In addition, normalization of the rating schemes used for each site was conducted to appropriately partition the reviews into positive and negative categories, and prepare the text for the classification task (Rushdi-Saleh et al., 2011).

## 4.2 Rooting Libraries

Three different rooting libraries were applied to derive the roots of each of the input words in the classification examples, each applying a slightly different approach to the complex Arabic rooting problem.

### 4.2.1 Khoja Arabic Stemmer

The Khoja Arabic Stemmer (Khoja and Garside, 1999) is a fast Arabic stemmer that works by removing the longest prefix and suffix present in the input word and then matching the rest of the word with known verb and noun patterns using a root library. The stemmer attempts to take into account the unavoidable irregularities in the language in order to extract the correct root from words that do not follow the general rules. The Khoja stemmer has been used in various Arabic natural language processing tasks, and has been noted to produce good improvements to various natural language tasks, despite many tagging errors (Larkey and Connell, 2001).

### 4.2.2 Information Science Research Institute (ISRI) Arabic Stemmer

The Information Science Research Institute's (ISRI) stemmer (Taghva et al., 2005) uses a similar approach to word rooting as the Khoja stemmer, but does *not* employ a root dictionary for lookup. Additionally, if a word cannot be rooted, the ISRI stemmer normalizes the word and returns a normalized form (for example, removing certain determinants and end patterns) instead of leaving the word unchanged. The ISRI stemmer has been shown to give good improvements to language tasks such as document clustering, as opposed to a non-stemmed approach (Bsoul and Mohd, 2011).

### 4.2.3 Tashaphyne Light Arabic Stemmer

The Tashaphyne Light Arabic Stemmer (Tashaphyne, 2010) works by first normalizing words in

preparation for the “search and index” tasks required for stemming, including removing diacritics and elongation from input words. Next, segmentation and stemming of the input is performed using a default Arabic affix lookup list, allowing for various levels of stemming and rooting (Tashaphyne, 2010).

### 4.3 Experimental Setup

Two different sets of experiments were conducted to test the effect of the root-based method for the sentiment analysis task, varying somewhat for the different corpora under analysis.

For the PATB corpus, only the subjective data was taken into consideration for the two-class positive and negative sentiment classification problem (the 1180 sentences in total: 491 S-POS and 689 S-NEG sentences). The task was conducted at the sentence-level, with 5-fold cross-validation splits across the dataset (Abdul-Mageed et al., 2011).

For the OCA corpus, with already-defined opinions in the form of movie reviews, the entire dataset was used for classification. The task was conducted at the document-level (with each document composed of sets of sentences, ranging from an average of 13 sentences in the positive review sets, and 20 sentences in the negative reviews), with 10-fold cross-validation splits (Rushdi-Saleh et al., 2011).

Each of the corpora was tested using the basic words as features to the classifier, then by iteratively adding roots using each of the three rooting libraries. After experimentation with parameters, the classification task was performed using a linear kernel (Abdul-Mageed et al., 2011) under the SVM<sup>light</sup> classifier (Joachims, 2008). Precision and recall values are reported for the average of the K-fold runs (5 folds for the first corpus, and 10 folds for the second), along with F-measure (F1) and accuracy results for each respective experiment.

### 4.4 Pre-processing

As pre-processing to prepare the text for the classification and analysis tasks, the already undiacritized corpus sentences were tokenized from the set of documents into word sets, and testing with stop-word removal (the removal of commonly used words) was done to filter out words that could be unnecessary for the task of opinion classification.

### 4.5 Feature Sets

For each document, the basic unigrams (individual words) composing the document were used as initial input features to the SVM, after which the three rooting libraries (Khoja, ISRI, and Tashaphyne) were then iteratively used to derive the roots of each of the input word features. Finally, the resultant roots were then added as additional features (along with the unigrams) to each of the examples. Binary presence vectors were used to indicate the existence of a feature (Abdul-Mageed et al., 2011). For the purposes of exploring the effect of adding the root-based features, only independent unigrams and unigrams with roots were experimented with for the basic evaluation task.

## 5 Results and Evaluation

The results of the sentiment analysis tasks on the two datasets are illustrated in Table 4 for the PATB corpus, and Table 5 for the OCA corpus, detailing the task statistics. The basic results using a standard *unigram* feature (the encountered word itself) are depicted initially, along with a *baseline* result (in F-measure and accuracy, as available for the two datasets, respectively) without the use of root features, as presented by previous work with the datasets (Abdul-Mageed et al., 2011; Rushdi-Saleh et al., 2011).

With respect to the sentiment analysis task on the PATB newswire-domain corpus shown in Table 4, all three of the individual rooting libraries resulted in improvements to the initial unigram results. The largest observable improvement to all measures reported came from the Khoja stemmer, with a 4.9% increase in F-measure, and a 4.7% increase in accuracy as compared to the unigram result. Also, a 3.4% increase in F-measure is observed from the sentiment baseline of 57.8% (previously achieved on the dataset using various morphological features, without a domain-specific lexicon (Abdul-Mageed et al., 2011)).

For the OCA movie-domain corpus shown in Table 5, slight improvements can be seen by adding root features to the unigram classifier input, particularly with the Tashaphyne rooting library. An increase of 3.2% accuracy after the addition of root features is observed from the baseline accuracy of 90.0% (Rushdi-Saleh et al., 2011).

While an increase in overall accuracy and F-measure is notable in the task of basic two-class opinion classification, two main points are of im-

	Precision	Recall	F1	Accuracy
<b>Unigrams (No Roots)</b>	58.1	58.1	56.3	63.8
<b>+ Khoja Roots</b>	<b>63.8</b>	<b>61.9</b>	<b>61.2</b>	<b>68.5</b>
<b>+ ISRI Roots</b>	61.5	60.4	59.3	66.8
<b>+ Tashaphyne Roots</b>	61.7	58.8	58.8	67.0
Baseline	57.8			

Table 4: PATB Sentiment Classification Results for the Proposed Method under Three Rooting Libraries. (Baseline: Abdul-Mageed et al. (2011))

	Precision	Recall	F1	Accuracy
<b>Unigrams (No Roots)</b>	90.0	95.2	92.8	92.6
<b>+ Khoja Roots</b>	90.7	94.4	92.3	92.2
<b>+ ISRI Roots</b>	90.5	95.6	92.8	92.6
<b>+ Tashaphyne Roots</b>	<b>91.1</b>	<b>96.0</b>	<b>93.4</b>	<b>93.2</b>
Baseline	90.0			

Table 5: OCA Sentiment Classification Results for the Proposed Method under Three Rooting Libraries. (Baseline: Rushdi-Saled et al. (2011))

portance: the nature of the words in the dataset under analysis, and the efficiency of the stemming systems themselves. The divergence in the most effective rooting library on each of the corpora can be attributed to various factors, including the style of writing used in the datasets, the formality of the text, and the existence of irregular words and words that cannot be rooted, depending on the accuracy and robustness of the employed stemming library.

The PATB news domain corpus, for example, is expected to have less opinion-bearing content than the OCA movie review corpus, due to the less subjective nature of the domain. The overall accuracy and F-measure results for the OCA movie corpus are thus significantly higher than those observed in the PATB corpus. Another difference between the corpora lies in the formality of the language employed: while the PATB corpus uses a strict Modern Standard Arabic (MSA), the use of slang and dialect-specific language is frequent in the OCA corpus. This type of varied language presents a layer of difficulty for sentiment classification in general, as well as for the rooting systems applied for language mapping.

Furthermore, with respect to the stemming tools themselves, the overall inaccuracy of current stemmers is another important consideration. The best-performing stemming libraries, Khoja and Tasha-

phyne, for each of the two domains, are those that employ some form of root-lookup dictionary in order to verify the correctness of the affixes and resultant roots generated. Another consideration is the limitation imposed by employing only unigrams enriched with the root features, while features beyond word level could be used to further predict sentiment patterns changes over a more complex language structure.

## 6 Conclusion

The composition scheme and complex morphology of Arabic make the task of root-extraction to normalize words to their basic functional units a very relevant one for various natural language processing tasks. With respect to the sentiment analysis tasks presented in this paper, some notable improvements to the classification performance when using various rooting libraries as input features can be observed, warranting further research on enhancements to existent rooting techniques and handling of the intricacies of the Arabic language structure to predict more sentence forms and correctly classify their polarity.

As detailed, the reasoning behind the root-based method and its enhancement of the sentiment classification task in the two explored domains relies on the semantic similarities between different word derivations, allowing for a broader map of

interconnections between words with similar polarity orientation to be created. Such valid interconnections between words also warrants the exploration of semantic expansion of words and their synonyms (Magdy et al., 2013), expanding the word map and serving to better connect and understand sentiment-bearing ideas and expressed opinions.

By applying various rooting schemes at different granularities in two separate domains, it is also shown that word roots can serve to enhance the sentiment analysis task results on a more generic level, instead of using a domain-specific approach that may not always be applicable. Thus, using root derivation techniques such as that presented for Arabic sentiment analysis in particular are applicable and valid to help enhance the performance of natural language processing tasks on morphologically rich and complex languages.

## Abstract

Concept extraction is a primary subtask of ontology construction. It is difficult to extract new concepts from traditional text corpus. Moreover, building a single ontology for multiple-topic corpus may lead to misconception. To deal with these problems, this paper proposes a novel framework to extract topical key concepts from folksonomy. Folksonomy is a valuable data source due to real-time update and rich user-generated contents. We first identify topics from folksonomy using topic models. Next the tags are ranked according to their importance for a certain topic by applying topic-specific random walk methods. The top-ranking tags are extracted as topical key concepts. Especially, a novel link weight function which combines the local structure information and global semantic similarity is proposed in importance score propagation. From the perspectives of qualitative and quantitative investigation, our method is feasible and effective.

## 1 Introduction

Ontology can be seen as an organized structure of concepts according to their relations (Cui et al., 2009). Therefore, concept extraction is an important subtask of ontology construction. Existing works mainly focus on extracting concepts from text corpus (Buitelaar et al., 2005). However, it is difficult to find text corpus that accurately characterize a highly focused, even fast-changing topic (Liu et al., 2012) of the domain. For instance, it is easier to find text corpus for a common topic of movie such as “comedy”, but it

is much more difficult to find one for a specific topic such as “cult”. Since “cult” movies often do not follow traditional standards of mainstream movies. Moreover, it is not easy for them to find a formal definition and description in text corpus. However, we can more easily find some tags (arbitrary words assigned by people to the resources of interest) to describe this kind of movie, such as cult, non-mainstream, small budgets and so on. Motivated by the fact that social tags give us flexibility and ease to describe a topic, we try to use folksonomy (Trant, 2009) as a new data source. The word ‘folksonomy’ is a blend of the words ‘folk’ and ‘taxonomy’. It is the achievement of collective wisdom derived from the practice of collaboratively creating tags to annotate and categorize web resource.

Figure 1. A folksonomy example

Take Douban.com for example, which is a Chinese SNS website allowing registered users to record information and create tags related to

\*Correspondence author

their interested resources, such as film, books, music and recent activities. As shown in Fig. 1, in the folksonomy-driven web site 豆瓣电影网站‘Douban.com Movie<sup>1</sup>’, the resource 致我们终将逝去的青春‘So Young’ is annotated with a set of tags including 青春‘youth’, 爱情‘romance’, and 成长‘growth’ ordered by the frequency of use which update automatically.

Compared with traditional text corpus, folksonomy can overcome the knowledge acquisition bottleneck. It is superior to text corpus in three aspects. (1) tag is more free and easier to characterize a highly focused, even fast-changing topic; (2) tag as a candidate concept has been extracted by collective wisdom, which avoids a series of natural language processing tasks applied to text corpus such as word segmentation, part of speech tagging, and syntactic parsing and so on; (3) the associated relationships among resources, tags and users through tagging provide a large amount of potentially valuable semantic information for mining. However, folksonomy also has two disadvantages, such as ambiguity and lack of hierarchy. To avoid misconception, we think of building multiple topic-specific ontologies instead of a single one.

In this paper, we propose to automatically extract topical key concepts from folksonomy. The topical key concept should be abstract, representative of the corresponding topic. It should contain common features that can be inherited by other non-core relevant concepts under the same topic. For example, the topical key concepts in the field of movie may be comedy, biography and action and so on. To extract the topical key concepts, we learn the topic distribution of the tags by applying LDA (Latent Dirichlet Allocation) (Blei et al., 2003) at first. After that, the tags are ranked on the basis of the importance scores for a certain topic by a variant of topic-specific PageRank (Page et al., 1999). Specially, the novel contribution of the variant is a new link weight function in importance propagation, which combines the local similarity (defined as co-occurrence of tags in a same resource assigned to the given topic) with the global similarity (defined as cosine similarity of two tags over all the topic dimensions in the whole collection considered). Then, the top-ranking tags that best represent the corresponding topic are extracted as topical key concepts.

In view of limited Chinese corpus and complex Chinese syntax for ontology construction, we tried on Chinese folksonomy data. Experiments on movie data from Douban.com show that new link weight function can largely help boost the performance. To the best of our knowledge, our work is the first to study how to extract topical key concepts from folksonomy in the field of Chinese ontology construction. We perform a thorough analysis of the proposed method, which can be useful for future work in this direction.

Although our goal is to build Chinese ontology based on the topical key concepts from this work, our method can be widely used in many other tasks such as information navigation and recommendation system. Furthermore, our method is unsupervised and language independent, which is applicable in the web era with enormous information.

The rest of the paper is organized as follows. Section 2 reviews some related works; Section 3 describes our proposed method; Section 4 presents our experiments and resultant analysis; and Section 5 draws the conclusions and directions for the future work.

## 2 Related Work

Many efforts have been made to extract the key concepts for ontology construction. These methods can be divided into two categories according to topic-sensitive or not.

**Topic-free** Some key concepts of famous ontologies are usually defined by linguists or domain experts. The suggested upper merged ontology (SUMO) is such a kind of ontologies. The expert-based methods are accurate and standard. However, to tackle the time-consuming and laborious problems, efforts are also made to use semi-automatic and automatic methods.

Among semi-automatic methods, rule-based methods are known for high accuracy if the patterns are carefully chosen according to morphological structure or special format of corpus (Nakayama et al., 2008), either manually or via automatic bootstrapping (Hearst, 1992). However, the methods suffer from sparse coverage of patterns in a given corpus.

Some researchers try to map the words to a thesaurus or an existed ontology (WordNet or Wikipedia) automatically so as to get key concepts (Angeletou et al., 2008). The coverage and openness of existed ontologies seriously limit the scope of these works. Simple statistical methods

---

<sup>1</sup> <http://movie.douban.com>

such as TF-IDF weighting (Hulth, 2003) are not feasible for folksonomy since short text snippets only. Graph-based ranking methods are the state of the art. They are superior to the statistic-based methods because of considering structure information between words. Mihalcea and Tara (2004) propose to use TextRank, a modified PageRank algorithm to extract key concepts from text. But TextRank only maintain a single importance score for each word. Hotho et al. (2006) propose a graph-based ranking algorithm for folksonomy, named FolkRank. They convert triadic hypergraph in folksonomy into an undirected tripartite graph. But we consider that the tripartite graph may include much noise for key concept extraction.

As a word usually spans multiple topics, the importance of the word with respect to different topics would be different. It seems that the previous works mentioned above may lead to misconception by mixing different topics together.

**Topic-sensitive** In order to overcome misconceptions, the topic models and other clustering models such as DA (Deterministic annealing) (Zhou et al., 2007) are used to derive topical key concepts from corpus based on word occurrence information. These clustering models usually regard corpus as a bag of words. They can find the topic or the leading word in each cluster, but cannot distinguish concrete entity well.

It is intuitive to consider topic information in graph-based ranking methods for topical key concept extraction.

Haveliwala (2002) proposes topic-sensitive PageRank (TSPR) to get a set of PageRank vectors biased a set of representative topics and generate more accurate rankings than a single PageRank vector. Nie et al. (2006) propose a topical link analysis model (TLA) to affect the importance propagation. However, the topics in TSPR and TLA are both from ODP (Open Directory Project)<sup>2</sup> extracted manually. Based on their works, Jin et al. (2011) implement a topic-sensitive tag ranking (TSTR) approach in folksonomy automatically through LDA. TSTR performs better than TSPR and TLA because topics extracted by LDA are more conformed to the actual situation than the topics of ODP. They pay more attention to the effect of the transfer action probability on the importance score of tags which benefit us to know the propagation process. It seems that mixing together the random

walks of all the topics in one graph may cause noise compared to independent topic graphs.

Liu et al. (2010) decompose a traditional random walk into multiple random walks specific to various topics, named Topical PageRank (TPR). The novel contribution is the study on topic-specific preference value setting. And then, Zhao et al. (2011) argue that context-free propagation may cause the importance scores to be off-topic. They model the score propagation with topic context when setting the link weights and then denote this context-sensitive topical PageRank as cTPR. Enlightened by TPR and cTPR, we further propose a new link weight function to express the semantic similarity between two tags of folksonomy. The novel link weight function combines the local similarity (defined as co-occurrence of tags in a same resource assigned to the given topic) with the global similarity (defined as cosine similarity of two tags over all the topic dimensions in the whole collection considered).

### 3 Method

In this section, we will introduce our method. We firstly give some definitions and then overview our method, and finally introduce topic identification and tag ranking in detail.

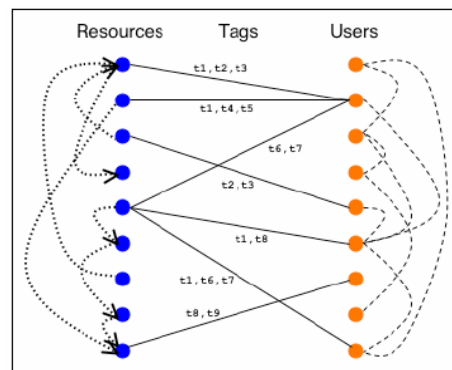

Figure 2. A conceptual model of folksonomy

From the Fig. 2 (Marlow, 2006), we can see a conceptual model of social tagging behavior in folksonomy. It consists of users  $u \in U$ , tags  $w \in V$ , and resources  $s \in S$ . The conceptual model illustrates visually the implicit association among resources, tags and users joined with straight lines and dashed lines. Folksonomy is composed of  $\langle U, V, S \rangle$  triples. For simplicity, we only regard a resource  $s \in S$  as a document which includes a set of tags assigned by all the users of collection  $U$ . Moreover, we suppose that there is

<sup>2</sup> <http://www.dmoz.org/>

a set of topics  $Z$  over the resource collection  $S$ . Hence, we extract topics from  $S$ .

The basic idea of our method is to incorporate topic distribution into importance score propagation of tags when setting the link weight as well as the preference value. Especially, the link weight function considers both the local and global similarity with respect to different topics.

First of all, we identify topics from folksonomy resource collection  $S$  using topic models (Section 3.1). Next for each topic, we build the tag graph and use the random walk techniques to measure the tag importance. Based on the importance scores, we extract the top-ranking tags as the topical key concepts (Section 3.2).

### 3.1 Topic Identification

Latent Dirichlet Allocation (LDA) is a typical representative of topic models. In LDA, each word  $w$  in a document  $d$  is regarded to be generated by first sampling a topic  $z$  from  $d$ 's topic distribution  $\theta$ , and then sampling a word from the distribution over words  $\Phi$  that characterizes topic  $z$ .  $\theta$  and  $\Phi$  are drawn from conjugate Dirichlet priors  $\alpha$  and  $\beta$ , separately.

We use resource set  $S$  represented by a set of tag as our input file to run LDA. After the parameters converge by Gibbs sampling, we mainly use two of these output files in this paper. One is model-final.phi, which is a  $|Z|*|V|$  matrix about  $\Phi$ , whose element is the probability of tag  $w_i$  conditional on topic  $z_j$  i.e.  $P(w_i | z_j)$ . The other is model-final.tassign, which is a  $|S|*|V|$  matrix, where each row of data stands for a resource  $s$  followed by a set of elements, and each element consists of a tag and a topic which the tag most likely to be assigned to.

Through LDA, we can obtain the topic distribution of each tag  $w_i \in V$  by Eq. 1, namely  $P(z | w_i)$  for given topic  $z \in Z$ ,

$$P(z | w_i) = \frac{P(z)P(w_i | z)}{\sum_{z'} P(z')P(w_i | z')} \quad (1)$$

where  $P(w_i | z)$  can be found in the model-final.phi directly, and  $P(z)$  is calculated by Eq. 2.

$$P(z) = \frac{C(z)}{\sum_{z'} C(z')} \quad (2)$$

In which,  $C(z)$  is calculated as the number of times topic  $z$  appears in the model-final.tassign.

Obviously,  $\sum_{z'} C(z')$  is calculated as the number of times all the topics appear in the model-final.tassign. Then, we can calculate the local and global similarity between two tags using Eq. 3 and Eq. 4.

$$Local_s(w_j, w_i) = \frac{C_{w_j, w_i, z}^S}{C_{w_j, w_i}^S} \quad (3)$$

$$Global_s(w_j, w_i) = \frac{\sum_z^S p(z | w_j)p(z | w_i)}{\sqrt{\sum_z^S p(z | w_j)^2 \sum_z^S p(z | w_i)^2}} \quad (4)$$

Among them,  $Local_s(w_j, w_i)$  stands for the local semantic similarity between tag  $w_i$  and  $w_j$ . In Eq.

3,  $C_{w_j, w_i, z}^S$  counts the number of co-occurrences of tag  $w_i$  and  $w_j$  in a same resource of  $S$  assigned to the topic  $z$ .  $C_{w_j, w_i}^S$  counts the number of co-occurrences of tag  $w_i$  and  $w_j$  in a same resource of  $S$ . We can get them from statistical calculation of the model-final.tassign.  $Global_s(w_j, w_i)$  stands for the global semantic similarity between tag  $w_i$  and  $w_j$ . From the whole resource collection  $S$ , we can get the cosine similarity between tag  $w_i$  and  $w_j$  over all the topic dimensions by plugging Eq. 1 into Eq. 4.

### 3.2 Tag Ranking

After topic identification, we perform topical key concept extraction followed by two steps, namely, tag graph construction and tag ranking.

Above all, some formal notations are given. We denote  $G = (V, E)$  as the graph composed of tags, with vertex set  $V = \{w_1, w_2, \dots, w_N\}$  and link set  $(w_i, w_j) \in E$  if there is a link from node  $w_i$  to  $w_j$ . In a tag graph, each vertex represents a tag, and each link indicates the correlation between every two tags. We denote the weight of the link  $(w_i, w_j)$  as  $e(w_i, w_j)$ , and the out-degree of vertex  $w_i$  as  $O(w_i) = \sum_{j: w_i \rightarrow w_j} e(w_i, w_j)$ .

PageRank assigns global importance scores to vertices using link information. In PageRank, the score  $R(w_i)$  of the word  $w_i$  is defined as

$$R(w_i) = \lambda \sum_{j: w_j \rightarrow w_i} \frac{e(w_j, w_i)}{O(w_j)} R(w_j) + (1 - \lambda) \frac{1}{|V|} \quad (5)$$

where damping factor  $\lambda$  ranges from 0 to 1, and  $|V|$  is the number of vertices. The damping factor indicates that each vertex has a probability of  $(1-\lambda)$  to perform a random jump to another vertex within this graph while has a probability of  $\lambda$  to follow the out-degree link. The PageRank importance scores are obtained by running Eq. 5 iteratively until convergence. The second term in Eq. 5 can be regarded as a smoothing factor to make the graph fulfill the property of being aperiodic and irreducible, so as to guarantee that PageRank converges to a unique stationary distribution.

In fact, the second term of PageRank in Eq. 5 can be set to be non-uniformed. The idea of Topical PageRank (TPR) is to run Biased PageRank for each topic separately. Formally, in the PageRank of a specific topic  $z$ , they assign a topic-specific preference value  $\text{Pr}_z(w)$  to each word  $w$  as its random jump probability with  $\sum_{w \in V} \text{Pr}_z(w) = 1$ . For topic  $z$ , the topic-specific PageRank importance scores are defined as follows,

$$R_z(w_i) = \lambda \sum_{j:w_j \rightarrow w_i} \frac{e(w_j, w_i)}{O(w_j)} R_z(w_j) + (1-\lambda) \text{Pr}_z(w_i) \quad (6)$$

However, TPR ignores the topical context in the link weight settings; the link weight  $e(w_j, w_i)$  in Eq.6 is calculated as the number of co-occurrences of two words within a certain window size. Zhao et al. (2011) propose to use a topical context-sensitive PageRank method (cTPR). Formally, they have

$$R_z(w_i) = \lambda \sum_{j:w_j \rightarrow w_i} \frac{e_z(w_j, w_i)}{O_z(w_j)} R_z(w_j) + (1-\lambda) \text{Pr}_z(w_i) \quad (7)$$

where they calculate the propagation from  $w_j$  to  $w_i$  in the context of the topic  $z$ , namely, the link weight  $e_z(w_j, w_i)$  from  $w_j$  to  $w_i$  is parameterized by  $z$ . In Eq.7, the link weight between two words is calculated as the number of co-occurrences of the two words in tweets assigned to the topic  $z$ .

However, we believe that the link weight only contains the co-occurrence information is not enough. On the basis of cTPR, we further propose a new link weight function (Eq.8).

$$e_z(w_j, w_i) = \text{Local}_s(w_j, w_i) \rho + (1-\rho) \text{Global}_s(w_j, w_i) \quad (8)$$

The weight factor  $\rho$  controls the proportion of the local structure information (Eq.3) and global semantic similarity (Eq.4) in Eq.8. Through the new link weight, the propagation of our method not only reflects the specific local co-occurrence information of two tags in a single resource, but also reflects the non-specific global semantic similarity of two tags in the whole resource set.

In our tag ranking method, we obtain the importance scores for each tag in different topics by Eq.7. In which,  $e_z(w_j, w_i)$  is calculated by Eq.8, and  $O_z(w_j) = \sum_{i:w_j \rightarrow w_i} e(w_j, w_i)$ . The topic-specific preference value  $\text{Pr}_z(w_i) = P(z | w_i)$  is calculated as Eq.1, which is the best one among the three choices discussed by Liu et al. (2010).

## 4 Experiments

### 4.1 Dataset

Our evaluation dataset is crawled from Douban.com Movie, which is a popular Chinese Social Networking Service (SNS) website allowing registered users to create content related to movies. The dataset contains top 250 movies with 1760 tags assigned by users up to June 2012. After removing stop words and noises, we prepare 1737 tags corresponding to 249 movies for LDA. Empirically, we set the number of topics to 40 and ran LDA with 1000 iterations of Gibbs sampling.

We further select two baseline methods that most similar to ours, i.e., TPR and cTPR. All of them are iterative algorithms. We terminate the algorithms when the number of iterations reaches 100 or the difference of importance scores about each vertex between two neighbor iterations is less than 0.000001.

There are three parameters in our method that may affect the performance of the topical key concept extraction including (1) damping factor  $\lambda$  that reconciles the influence of adjacent nodes' importance (the first item in Eq. 7) and preference value (the second item in Eq. 7) to the modified PageRank importance of our method; (2) weight factor  $\rho$  that controls the proportion of the local structure information (Eq. 3) and global semantic similarity (Eq. 4) on two tags; (3) threshold  $Q$ ; If the global semantic similarity between two tags is less than  $Q$ , we will remove the link between them. We separately set parameters  $\lambda$ ,  $\rho$  and  $Q$  from 0.1 to 0.9 with a step size of 0.1, and then each parameter has 9 candidate values. Finally, 729 experiment results of the

baseline and our method based on permutation and combination of the three parameters are presented.

## 4.2 Gold Standard Annotation

We construct the evaluation standard by pooling (Voorhees et al., 2005) method. The reason lies in two aspects. One is that there is no existing gold standard for topical key concept extraction from folksonomy, and the other is that it is impossible to determine all the topics and key concepts manually. We randomly mix 729 results from TPR, cTPR and our method, and then ask two judges to score as 1 (relevant, abstract and representative) or 0 (irrelevant or too specific). Only if the two judges score 1 for the same tag, the tag will be determined as correct topical key concept. Otherwise, the tag will be determined as wrong.

## 4.3 Evaluation Metrics

The traditional evaluation metrics represented as follows,

$$\begin{aligned} P &= \frac{C_{correct}}{C_{extract}}, \\ R &= \frac{C_{correct}}{C_{standard}}, \\ F &= \frac{2PR}{P+R} \quad (9) \end{aligned}$$

where  $C_{correct}$  denotes the number of correct topical key concepts extracted by a method,  $C_{extract}$  denotes the number of automatically extracted topical key concepts by a method, and  $C_{standard}$  denotes the total number of topical key concepts referenced by gold standard. Three of them are averaged on all the topics.

In addition to the traditional metrics precision/recall/F-measure, we use another two metrics to take the order into account.

One metric is mean average precision (MAP). MAP is desirable to measure the overall performance of topical key concept ranking,

$$MAP = \frac{1}{|Z|} \sum_{z \in Z} \frac{1}{N_z} \sum_{j=1}^{|M_z|} \frac{N_{M_z, z, j}}{j} I(score(M_{z, j}) \geq 1) \quad (10)$$

where  $I(S)$  denotes an indicator function which returns 1 when  $S$  is true and 0 otherwise,  $N_{M_z, z, j}$  denotes the number of correct key concepts among the top  $j$  candidates returned by

method  $M$  for topic  $z$ , and  $N_z$  denotes the total number of correct key concepts of topic  $z$  referenced by the gold standard.

The other metric is mean reciprocal rank (MRR) (Voorhees, 1999) which is used to evaluate how the first correct topical key concept for each topic is ranked. For a topic  $z$ ,  $rank_z$  is denoted as the rank of the first correct topical key concept with all extracted candidates, MRR is defined as follows,

$$MRR = \frac{1}{|Z|} \sum_{z \in Z} \frac{1}{rank_z} \quad (11)$$

where  $Z$  is the topic set for topical key concept extraction.

## 4.4 Quantitative Evaluation

As for the same folksonomy dataset from Douban.com Movie, we realize the baseline methods, i.e., TPR and cTPR. The TPR calculates the co-occurrence number of two tags in a same resource as the link weight, namely  $e(w_j, w_i) = C_{w_j, w_i}^S$ .

In cTPR, the link weight is calculated as the co-occurrence number of two tags in a same resource assigned to the same given topic, namely  $e_z(w_j, w_i) = C_{w_j, w_i, z}^S$ .

The grid-search algorithm is applied to obtain the optimal parameter combination from 729 candidates. Through an exhaustive combination of three parameters, we obtain the best value of every evaluation indicator in three methods.

Method	P	R	F	MRR	MAP
TPR	0.617	0.404	0.465	0.670	0.405
cTPR	0.625	0.406	0.473	0.675	0.407
Our method	<b>0.700</b>	<b>0.440</b>	<b>0.518</b>	<b>0.713</b>	<b>0.440</b>

Table 1. Comparisons of our method and the baselines (t-test, p-value<0.0001)

The comparison of our method to the baselines is shown in table 1. Our method achieves a 7.5% improvement in Precision over the cTPR and 8.3% over the TPR, also increased by more than 3.3% in other indicators.

We also investigate the influence of different parameter values. Due to space limitation, we only provide comparison analysis on MRR. As shown in Fig.3, the bar chart illustrates that the comparisons of our method to the baselines on MRR when  $\lambda$  is set 0.1, 0.3, 0.5, 0.7, 0.9, while

the curve diagram describes the fluctuation of the methods. Although our method is influenced by parameter  $\lambda$ , ours is superior to the baselines in all parameter values.

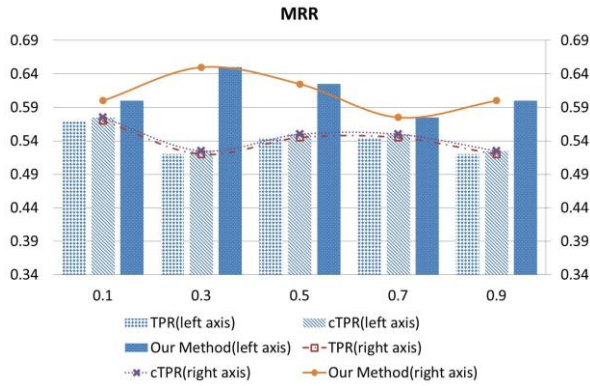

Figure 3. Comparison of the methods on MRR while varying  $\lambda$  (t-test, p-value<0.0001)

Similarly, we can see clearly from Fig.4 that significant promotion of our method compared to the baselines through introducing  $\rho$ . In addition, our method keeps stable with the variations of  $\rho$ .

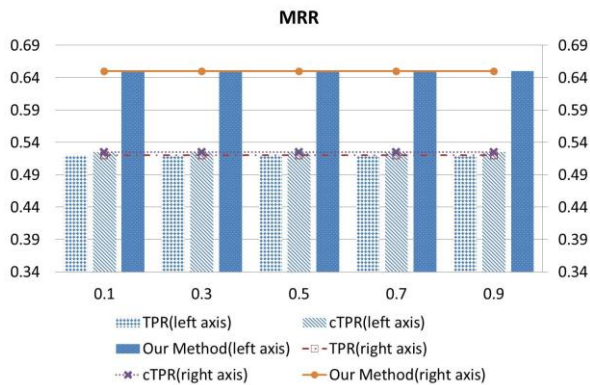

Figure 4. Comparison of the methods on MRR while varying  $\rho$  (t-test, p-value<0.0001)

The statistics in Fig.5 illustrate that our method remains stable when Q is from 0.1 to 0.7, and the curve improves significantly by increasing Q until Q reaches 0.9. While the other two methods change greatly as Q varies. Especially, the baseline methods become rather poor when Q is equal to 0.9. We infer that the baseline methods may lose many links in the tag graph when faced with a high threshold Q, because the link between two tags which the global semantic similarity lower than Q will be removed. Nevertheless, our method can deal with this problem very

well. These experimental results demonstrate the robustness of our method.

Figure 5. Comparison of the methods on MRR while varying Q (t-test, p-value<0.0001)

#### 4.5 Qualitative Evaluation

In this subsection, some qualitative evaluations are provided on the basis of the resultant graphs with respect to different topics generated by our method.

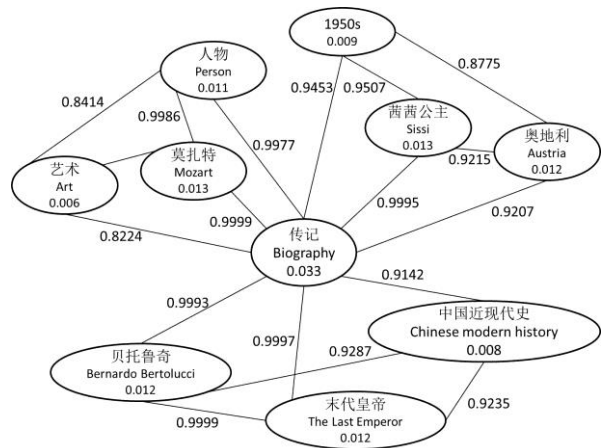

Figure 6. An example of topical graphs generated by our method

The vertex is composed of the tag name and the topical importance score, while the link weight value stands for the degree of semantic similarity between two vertices. As shown in Fig. 6 about biography topic, we can intuitively observe that the vertex '传记' 'Biography' stands in the center while surrounded by a wealth of connectivity. Compared with other vertices, it has the highest importance score in this topic and on behalf of this topic. These observations also confirm the effectiveness of our method.

To our surprise, it seems that some apparently unrelated tags are closely connected in our resultant graph. The interesting findings help us to further detect the fact that usually obtained through common sense or reasoning. For example, 末代皇帝‘The Last Emperor’ and 贝纳尔多·贝托鲁奇‘Bernardo Bertolucci’, which can be used to infer the fact that ‘The Last Emperor’ is a biographical film directed by ‘Bernardo Bertolucci’. Likewise, we observe that the dense connections among 茜茜公主‘Sissi’, 奥地利‘Austria’ and “1950s” can help us to infer the fact that ‘Sissi’ is a “1950s” film in ‘Austria’. All of them are connected to ‘Biography’, which means ‘The Last Emperor’ and ‘Sissi’ all belong to ‘Biography’. These insights further prove that our method can well connect the most related tags together with respect to the topic through the novel link weight model.

In addition, a few unusual genres of movie emerge in our works which enrich the traditional movie categories. For example, 公路‘road movie’, 默片‘silent movie’, 黑色电影‘film noir’, and 神片 shen-pian and so on. The sensibility for upcoming concepts indicates that our method is a necessary complement for traditional concept extraction.

#### 4.6 Error Analysis

We perform error analysis after experiments. A typical error is 姜文‘Jiang Wen’, a famous movie actor in China which is wrongly recognized as a topical key concept. The vertices that closely related to 姜文‘Jiang Wen’ in the graph are 宁静‘Jing Ning’, 夏雨‘Yu Xia’ and 阳光灿烂的日子‘In the Heat of the Sun’. We believe that the best topical key concept about this topic is 文艺‘literature’. However, ‘literature’ cannot be created if it never appears in the tags of Douban.com. This error is due to randomness of folksonomy tagging itself. We consider integrating other relative folksonomy data sources such as Baidu video<sup>3</sup> to overcome this defect in the future work.

## 5 Conclusion

In this paper we study the novel problem of topical key concept extraction from folksonomy. A new link weight function is proposed to improve graph-based ranking method for topical key concept extraction. Quantitative and qualitative

evaluations indicate the robustness and effectiveness of our method. In the future, we will make full use of the topical key concepts and relevant entities, and also the relationships by-product for Chinese ontology construction. Experiments on the folksonomy data from Douban.com Movie show that our method is feasible. We will further explore our method in other domains such as music and more large-scale data with the help of other folksonomy-based systems.

## Abstract

For many NLP applications such as Information Extraction and Sentiment Detection, it is of vital importance to distinguish between synonyms and antonyms. While the general assumption is that distributional models are not suitable for this task, we demonstrate that using suitable features, differences in the contexts of synonymous and antonymous German adjective pairs can be identified with a simple word space model. Experimenting with two context settings (a simple window-based model and a ‘co-disambiguation model’ to approximate adjective sense disambiguation), our best model significantly outperforms the 50% baseline and achieves 70.6% accuracy in a synonym/antonym classification task.

## 1 Introduction

One notorious problem of distributional similarity models is that they tend to not only retrieve words that are strongly alike to each other (such as *synonyms*), but also words that differ in their meaning (i.e. *antonyms*). It has often been argued that this behaviour is due to the distributional similarity of synonyms and antonyms: despite conveying different meanings, antonyms also seem to occur in very similar contexts (Mohammad et al., 2013).

In many applications, such as information retrieval and machine translation, the presence of antonyms can be devastating (Lin et al., 2003). While a number of approaches have addressed the issue of synonym and antonym distinction from a computational point of view, they are usually limited in some way, for example by requiring the antonymous words to co-occur in certain patterns (Lin et al., 2003; Turney, 2008), or by relying on external resources such as thesauri (Mohammad et

al., 2013; Yih et al., 2012). Probably due to this strong similarity of their contexts, there have been no successful attempts so far to distinguish the two relations via a standard distributional model such as the word space model (Sahlgren, 2006).

Prominent work in psycholinguistics, however, has shown that humans are able to distinguish the contexts of antonymous words, and that these are by no means interchangeable (Charles and Miller, 1991). The goal of our research is to show that using suitable features these differences can be identified via a simple word space model, relying on contextual clues that govern the ability to distinguish the relations in context. For this purpose, we present a word space model that exploits window-based features for synonymous and antonymous German adjective pairs. Next to investigating the contributions of the various parts-of-speech with regard to the word space model, we experiment with two context settings: one that takes into account all contexts in which the members of the word pairs occur, and one where we approximate context disambiguation by applying ‘co-disambiguation’: establishing the set of nouns that are modified by both members of the pair, and only including distributional information from contexts in which the adjectives premodify one of the set of shared nouns. Two different scenarios relying on Decision Trees then assess our main hypothesis, that the contexts of adjectival synonyms and antonyms are distinguishable from each other.

Our paper is structured as follows: Section 2 reviews some of the theoretical and psycholinguistic hypotheses and findings concerning synonymy and antonymy, and Section 3 reviews previous approaches to synonym/antonym distinction. Based on these theoretical and practical insights, we introduce our hypotheses and approach in Section 4. Section 5 describes the data and implementation of the word space model used in our experiments, and, finally, in Section 6 we discuss our findings.

## 2 Theoretical background

Synonymy and antonymy are without doubt two of the most well-known semantic relations between words, and can be broadly defined as words that are ‘similar’ in meaning (synonyms), and words that are ‘opposite’ in meaning (antonyms).<sup>1</sup> The fascinating issue about antonymy is that even though antonymous words are said to be opposites, they are nevertheless semantically very similar. Cruse (1986) observes that there is a notion of simultaneous closeness and distance from one another, and notes that this can be partially explained by the fact that opposites share the same semantic dimension. For example, the antonyms *hot* and *cold* share the dimension ‘TEMPERATURE’, but unlike synonyms, which are located at identical or close positions on the dimension (such as *hot* and *scorching*), antonyms occupy opposing poles (cf. the schematic representation in Figure 1). Antonymous words are thus similar in all respects but one, in which they are maximally opposed (Willners, 2001).

Figure 1: Semantic dimension

There has been extensive work on linguistic and cognitive aspects of synonyms and antonyms (Lehrer and Lehrer, 1982; Cruse, 1986; Charles and Miller, 1989; Justeson and Katz, 1991). Both relations have played a special role in the area of distributional semantics, which investigates how the statistical distribution of words in context can be used to model semantic meaning. Many approaches in this area are based on the *distributional hypothesis*, that words with similar distributions have similar meanings (Harris, 1968).

In a seminal study, Rubenstein and Goodenough (1965) provided support for the distributional hypothesis for synonyms by comparing the collocational overlap of sentences generated for 130 target words (i.e. 65 word pairs ranging from highly synonymous to semantically unrelated) with synonymy judgements for the pairs, showing that there is a positive relationship between the degree of synonymy between a word pair and the degree to which their contexts are similar. The

<sup>1</sup>In the following, we work with this simple definition of the two relations. For an account of other, more complex definitions, please refer to Murphy (2003).

situation for antonyms with respect to the distributional hypothesis has however been less clear. In fact, Charles and Miller (1991) used the contextual distribution of antonyms to argue *against* the reliability of the co-occurrence approach: they measured how often antonyms co-occur within the same sentence (for example, in contrastive constructions such as ‘either x or y’), and show that the co-occurrence counts for antonyms such as *big/little*, and *large/small* in the Brown corpus are larger than chance.<sup>2</sup> Charles and Miller claim that the fact that antonyms tend to co-occur in the same contexts constitutes a true counter-example to the co-occurrence approach: they display high contextual similarity, but are of low semantic similarity.

As an alternative to the co-occurrence approach, Charles and Miller (1991) proposed a technique based on *substitutability* (cf. also Deese (1965)). Here, the contextual similarity of synonyms/antonyms is determined by presenting human subjects with sentences in which the occurrences of the two words have been blanked out, and by assessing the amount of confusion between the words when asking the subjects which word belongs in which context. While, as anticipated, the level of confusion was high for synonyms, subjects rarely confused the sentential contexts of antonyms, contrary to Charles and Miller’s expectations. They had assumed that direct antonyms<sup>3</sup> such as *strong/weak*, or *powerful/faint*, were interchangeable in most contexts, based on the insight that any noun phrase that can be modified by one member of the pair can also be modified by the other. However, human subjects were very efficient at identifying the correct antonym.

Charles and Miller’s findings suggest that in contrast to synonyms, whose distributional properties are similar, there are clear contextual differences that allow humans to distinguish between the members of an antonym pair. In this paper we aim to show that these differences can be detected with a simple distributional word space model, thereby refuting the claim that antonyms are a counter-example to the co-occurrence approach.

## 3 Previous computational approaches

Due to their special status as both ‘similar’ and ‘different’, work in computational linguistics has sometimes included antonymy under the heading

<sup>2</sup>Similar results were found by Justeson and Katz (1991).

<sup>3</sup>Commonly associated adjectives (Paradis et al., 2009).

of semantic similarity. Recent research however has called for a strict distinction between *semantic similarity* (where entities are related via likeness) and *semantic relatedness* (where dissimilar entities are related via lexical or functional relationships, or frequent association), cf. Budanitsky and Hirst (2006). Accordingly, antonyms fall into the broader category of ‘semantic relatedness’, and should not be retrieved by measures of semantic similarity. That this is of crucial importance was highlighted by Lin et al. (2003), who noted that in many NLP applications the presence of antonyms in a list of similar words can be devastating.

A variety of measures have been introduced to measure semantic similarity, for example by drawing on lexical hierarchies such as WordNet (Budanitsky and Hirst, 2006). In addition, there are corpus-based measures that attempt to identify semantic similarities between words by computing their distributional similarity (Hindle, 1990; Lin, 1998). While these are efficient at retrieving synonymous words, they fare less well at identifying antonyms as non-similar words, and routinely include them as semantically similar words. However, despite the problems resulting from this, there have only been few approaches that explicitly tackle the problem of synonym/antonym distinction, rather than focussing on only synonyms (e.g. Edmonds (1997)) or antonyms (e.g. de Marneffe et al. (2008)).

Lin et al. (2003), who implemented a similarity measure to retrieve distributionally similar words for constructing a thesaurus, were one of the first to propose methods for excluding retrieved antonyms. Lin’s measure uses dependency triples to extract distributionally similar words. In a post-processing step, they filter out any words that appear with the patterns ‘from X to Y’ or ‘either X or Y’ significantly often, as these patterns usually indicate opposition rather than synonymy. They evaluate their technique on a set of 80 synonym and 80 antonym pairs randomly selected from Webster’s Collegiate Thesaurus that are also among their top-50 list of distributionally similar words, and achieve an F-score of 90.5% in distinguishing between the two relations.

Turney (2008) also tackles the task of distinguishing synonyms from antonyms as part of his approach to identifying analogies. Like Lin et al. (2003), he relies on a pattern-based approach, but instead of hand-coded patterns, his algorithm

uses seed pairs to automatically generate contextual patterns (in which both related words must appear). Using ten-fold cross-validation, his approach achieves an accuracy of 75.0% on a set of 136 ‘synonyms-or-antonyms’ questions, compared to a majority class baseline of 65.4%.

A recent study by Mohammad et al. (2013), whose main focus is on the identification and ranking of opposites, also discusses the task of synonym/antonym distinction. Using Lin (2003) and Turney (2008)’s datasets, they evaluate a thesaurus-based approach,<sup>4</sup> where word pairs that occur in the same thesaurus category are assumed to be close in meaning and marked as synonyms, while word pairs occurring in contrasting thesaurus categories or paragraphs are marked as opposites. To determine contrasting thesaurus categories, Mohammad et al. rely on what they call the ‘contrast hypothesis’. Starting with a set of seed opposites across thesaurus categories, they assume that all word pairs across the respective contrasting categories are also contrasting word pairs. The method achieves 88% F-measure on Lin et al. (2003)’s dataset (compared to Lin’s 90.5%), and 90% F-measure on Turney (2008)’s set of ‘synonyms-or-antonyms’ questions, an improvement of 15% compared to Turney’s results.

While all three approaches perform fairly well, they all have certain limitations. Mohammad et al. (2013)’s approach requires an external structured resource in form of a thesaurus. Both Lin et al. (2003) and Turney (2008)’s methods require antonyms to co-occur in fixed patterns, which may be less successful for lower-frequency antonyms. Incidentally, Lin et al. (2003)’s antonyms were chosen from a list of high-frequency terms to increase the chances of finding them in one of their patterns, while Turney (1998)’s data was drawn from websites for Learner English, and is therefore also likely to consist of higher-frequency words.<sup>5</sup> Our proposed model is not subject to such limitations: it does not require external structured resources or co-occurrences in fixed patterns.

## 4 Approach

**Our hypotheses** So far, there have been no successful attempts to distinguish synonymy and antonymy via standard distributional models such as the word space model (Sahlgren, 2006). This

<sup>4</sup>Yih et al. (2012) is another thesaurus-based approach.

<sup>5</sup>Mohammad et al. (2013) show that Lin et al. (2003)’s patterns have a low coverage for their antonym set.

is likely to be due to the assumed similarity of their contexts: Mohammad et al. (2013), for example, state that measures of distributional similarity typically fail to distinguish synonyms from semantically contrasting word pairs. They back up this claim with their own findings: Applying Lin (1998)'s similarity measure to a set of highly-contrasting antonyms, synonyms, and random pairs they show that both the high-contrast set and the synonyms set have a higher average distributional similarity than the random pairs. Interestingly, they also found that, on average, the set of opposites had a higher distributional similarity than the synonyms.

From an intuitive viewpoint such results are surprising: according to Charles and Miller (1991)'s substitutability experiments, there must be contextual clues that allow humans to distinguish between synonyms and antonyms. It appears, however, that these contextual differences are not captured by current measures of semantic similarity, leading to the assumption that synonyms and antonyms are distributionally similar and the claim that antonyms are counter-examples to the distributional hypothesis (cf. Section 2). The goal of our research is to show that this assumption is incorrect, and that contextual differences can be identified via standard distributional approaches using suitable features. In particular, we aim to provide support for the following hypotheses:

- **Hypothesis A.** The contexts of adjectival synonyms and antonyms are *not* distributionally similar.
- **Hypothesis B.** Not all word classes are useful for modelling the contextual differences between adjectival synonyms and antonyms.

We claim that the assumption that synonyms and antonyms are distributionally similar is incorrect. Their distributions may well be similar with respect to certain features (namely the ones commonly used in similarity measures), but our goal is to show that it is possible to identify distributional features that allow an automatic distinction between synonyms and antonyms (Hypothesis A). In particular, we expect synonyms to have a higher level of distributional similarity than antonyms (contrary to Mohammad et al. (2013)'s findings).

We further hypothesise that only some word classes are useful for modelling the contextual differences between adjectival synonyms and antonyms (Hypothesis B). For this purpose, we

plan to investigate the influence of the following parts of speech in our distributional model: adjectives (ADJ), adverbs (ADV), verbs (VV), and nouns (NN). Our prediction is that the class of nouns will not be a useful indicator for distributional differences. This is motivated by Charles and Miller (1991)'s substitutability experiment, in which they claim that a noun phrase that can incorporate one adjective can also incorporate its antonym. As nouns relate to the semantic dimension denoted by the adjectives (cf. Section 2), they are in fact likely to co-occur with both the synonym (SYN) and the antonym (ANT) of a given target (T), resulting in high mutual information values for both, but not necessarily expressing the potential semantic differences between them:

- T: *unhappy* {**man, woman, child, ...**}
- SYN: *sad* {**man, woman, child, ...**}
- ANT: *happy* {**man, woman, child, ...**}

We expect to find more meaningful distributional differences in the *contexts* of such adjective-noun pairs, as illustrated in a simplified example:

- T: *unhappy man* – {*cry, moan, lament, ...*}
- SYN: *sad man* – {*cry, frown, moan, ...*}
- ANT: *happy man* – {*smile, laugh, sing, ...*}

We would for example assume that the set of verbs co-occurring with the target *unhappy* is more similar to the set of verbs co-occurring with its synonym *sad* than to the sets of verbs co-occurring with the antonym *happy*, resulting in higher similarity values for the pair of synonyms than for the pair of antonyms.

**Addressing polysemy** Addressing polysemy is an important task in distributional semantics, both with regard to type-based and token-based word senses: a distributional vector for a word type comprises features and associated feature strengths across all word senses, and a distributional vector for a word token does not indicate a sense if no disambiguation is performed. In recent years there have been a number of proposals that explicitly address the representation and identification of multiple senses in vector models, such as (Erk, 2009; Erk and Padó, 2010; Reisinger and Mooney, 2010; Boleda et al., 2012), with some focussing on identifying predominant word senses, such as (McCarthy et al., 2007; Mohammad and Hirst, 2006). In our experiments, we also aim to incorporate methods for dealing with multiple word senses.

In the task of synonym/antonym distinction, polysemy plays a central role as semantic relations tend to hold between specific *senses* of words rather than between *word forms* (cf. Mohammad et al. (2013)). For adjectives, polysemy directly relates to the semantic dimension they express. For example, depending on the dimension denoted by *hot* (cf. Section 2) we may expect different synonyms and antonyms. If we position *hot* on the dimension of TEMPERATURE, we might expect *scorching* as a synonym, and *cold* as an antonym. However, when *hot* is used to describe a person, we might instead use *attractive* as synonym, and *unattractive* as antonym. In their experiments on adjective synonym and antonym generation, Murphy and Andrew (1993) found that there was indeed considerable context sensitivity depending on the nouns that were modified by the target adjectives, with different synonyms and antonyms being generated.

Based on these insights we experiment with two different context settings: one that takes into account *all* contexts in which the target word and its synonym/antonym occur ('All-Contexts'), and one where we aim to resolve polysemy by applying the method of 'co-disambiguation' ('Codis-Contexts'). The co-disambiguation method attempts to exclude contexts of unrelated senses from consideration by establishing the set of nouns that are modified by both members of the synonym/antonym pair, and only including distributional information from contexts in which the adjectives co-occur (premodify) one of the set of shared nouns. This approach is motivated by the way in which humans might identify the semantic dimension of a pair of synonyms or antonyms out of context: using one member to disambiguate the other by figuring out which common property they express. For example, we intuitively realise that the synonyms *sweet* and *cute* are not related via the dimension of TASTE (as *sweet* might otherwise imply), but are used to describe a pleasing disposition. The co-disambiguation approach attempts to model this strategy by first identifying the nouns shared by the two adjectives across the corpus (such as *sweet/cute* {kid, dog, cottage, ...}), and then only collecting distributional information from such contexts. In the experiments described in the next sections we investigate if this smaller, but more focussed set of contexts can improve the results of our standard 'All-Contexts' model.

## 5 Experimental setup

This section provides an overview of the experimental setup and the distributional model we implemented to test our hypotheses. We work with German data in these experiments, but expect that the findings extend to other languages.

### 5.1 Training and test data

Our dataset is part of a collection of semantically related word pairs compiled via two separate experiments hosted on Amazon Mechanical Turk (AMT)<sup>6</sup>. The experiments were based on a set of 99 target adjectives which were selected from the lexical database GermaNet<sup>7</sup> using a stratified sampling technique accounting for 16 semantic categories, three polysemy classes, and three frequency classes. The first experiment asked AMT workers to propose synonyms, antonyms, and hypernyms for each of the targets. In the second experiment, workers were asked to rate the resulting pairs for the strength of antonymy, synonymy, and hypernymy between them, on a scale between 1 (minimum) and 6 (maximum). Both experiments resulted in 10 solutions per task.

To validate the generated synonym and antonym pairs, we carried out an assessment of their rating means (calculated over 10 ratings per word pair). The results show that there is a highly negative correlation between them with a Pearson  $r$  value of -0.895. This means that the higher a pair's rating as antonym, the lower its rating as synonym, and vice versa, which corresponds to our intuition that synonymy and antonymy are mutually exclusive relations. Figure 2 illustrates the relationship by plotting the average antonym and synonym ratings of all pairs in the dataset against each other.

For the current study we selected 97 synonym and 97 antonym pairs from this data as follows:

- The pairs have a rating means of  $\geq 5$ , representing strong examples of the respective relation types. This narrowed the set of 99 adjective targets to 91 targets, participating in 116 antonym pairs and 145 synonym pairs.
- To decrease sparse data problems we excluded pairs where at least one of its members had a token frequency of  $< 20$  in the sDeWaC-v3 corpus (Faaß et al., 2010), removing 6 antonym and 4 synonym pairs.

<sup>6</sup><https://www.mturk.com>

<sup>7</sup><http://www.sfs.uni-tuebingen.de/lsd>

Figure 2: Scatter plot of rating means

- To allow a target-based assessment (cf. Section 5.2), our dataset was reduced to those targets which participate in at least one synonymy and one antonymy relation: 63 targets in total; examples are shown in Table 1. Note that the synonym and antonym pairs of a given target are not necessarily located on the same semantic dimension, as illustrated by the target *süß* (‘sweet’).
- Based on these targets, we sampled an equal number of synonym and antonym pairs from the set, including at least one synonym and one antonym relation for each target, and giving preference to pairs with higher rating means. The resulting set includes 97 synonym and 97 antonym pairs altogether.

Target	Synonym	Antonym
<i>fett</i> (‘fat’)	<i>dick</i> (‘thick’)	<i>dünn</i> (‘thin’)
<i>süß</i> (‘sweet’)	<i>niedlich</i> (‘cute’)	<i>sauer</i> (‘sour’)
<i>dunkel</i> (‘dark’)	<i>düster</i> (‘gloomy’)	<i>hell</i> (‘light’)

Table 1: Dataset examples

## 5.2 Distributional model

**Overview** The main goal of this research is to show that there are distributional differences between synonym and antonym pairs that allow an automatic distinction between them (cf. Hypothesis A). The automatic method we use to address this task is an implementation of the word space model (Sahlgren, 2006; Turney and Pantel, 2010; Erk, 2012) where the members of the word pairs are represented as vectors in space, using contextual co-occurrence counts as vector dimension elements. The distributional similarity of two words is then calculated by means of the cosine function (a standard way of measuring vector similarity in word space models), which quantifies similarity

by measuring the angle between two vectors  $v_T$  and  $v_{SYN}$  (or  $v_{ANT}$ ) in vector space:

$$sim_{COS}(v_T, v_{SYN}) = \frac{v_T \cdot v_{SYN}}{|v_T| \cdot |v_{SYN}|}$$

Following from the discussion in Section 4, we expect higher cosine similarity values for synonyms, and lower values for antonyms. We establish the effectiveness of our proposed model for synonym/antonym distinction by means of an automatic classifier on the set of relation pairs introduced in Section 5.1.

**Co-occurrence information** The co-occurrence information included in the model is drawn from the sDeWaC-v3 corpus (Faaß et al., 2010), a cleaned version of the German web corpus deWaC<sup>8</sup>, which contains around 880 million tokens and has been parsed with Bohnet’s MATE dependency parser (Bohnet, 2010). The corpus further provides lemma and part-of-speech annotations (STTS tagset). We varied the window sizes we took into account as co-occurrence information; here we report our findings for the best window size of 5 tokens to the left and right of the adjectives (but not crossing sentence boundaries).

Instead of simple co-occurrence frequencies, our model uses *local mutual information (LMI)* scores as vector values. LMI is a measure from information theory that compares observed frequencies  $O$  with expected frequencies  $E$ , taking marginal frequencies into account:  $LMI = O \times \log \frac{O}{E}$ , with  $E$  representing the product of the marginal frequencies over the sample size.<sup>9</sup> In comparison to (pointwise) mutual information (Church and Hanks, 1990), LMI improves the well-known problem of propagating low-frequent events through multiplying mutual information by the observed frequency.

**Experimental settings** To address our hypothesis that only some word classes are useful for modelling the contextual differences between adjectival synonyms and antonyms (Hypothesis B), we build separate word spaces for the following collocate types: adjectives (ADJ), adverbs (ADV), verbs (VV), and nouns (NN). In addition, we also consider a combination of all four word classes (COMB). For this purpose, we compiled co-occurrence vectors for each word class by counting the frequencies of all adjective–collocate tuples that appeared in the sDeWaC corpus within

<sup>8</sup><http://wacky.sslmit.unibo.it/doku.php?id=corpora>

<sup>9</sup>See <http://www.collocations.de/AM/> for a detailed illustration of association measures (incl. LMI).

the specified window (here, size 5). For example, the model ‘VV in window w5’ includes all verbs that appear in a context window of five words from the adjectives, such as [*süß* – *verspeisen* – 3 – 12.4448] (‘sweet’ – ‘devour’ – frequency – LMI).

As discussed in Section 4, we consider two context settings: one that collects co-occurrence information from *all* contexts of the adjectives (‘All-Contexts’), and one that applies co-disambiguation to address polysemy (‘Codis-Contexts’). For the latter, word vectors only include co-occurrence information from contexts in which the members of a synonym/antonym pair modify a shared noun.

**Classifier** To establish whether there are significant distributional differences between synonyms and antonyms, and to assess the discriminative power of the different word class models, we experimented with several WEKA<sup>10</sup> classifiers and measures (e.g. Jaccard) and assessed their performance at synonym/antonym distinction using 10-fold cross-validation. Here we describe the results of the best-performing combination of classifier and measure: a Decision Tree classifier (‘J48’) with one single feature (*standard-cosine*, or *cosine-difference* values). Thus, for each of the experimental settings described above we run the classifier twice. In the first scenario, we use the plain cosine values (i.e. the distributional similarity values of the synonym/antonym pairs) as features in the classification. This default scenario is somewhat unrealistic, as it assumes a specific cosine cut-off value that distinguishes synonyms from antonyms. The second scenario addresses this issue and refers to a target-based point of view: It may be the case that for the majority of targets, the cosine values of their synonyms are significantly higher than those of their antonyms, indicating clear distributional differences. However, such information is lost when training the classifier on *all* cosine values in cases where the cosine value of the antonym of a target  $T_1$  is greater than the synonym value of another target  $T_2$ , as illustrated in Figure 3, making it difficult to find an appropriate cut-off value to split the data in classes. We take this into consideration as follows: for each synonym and antonym pair involving target T (cf. Section 5.1), we calculate the difference between their cosine values and use these difference values as input to the classifier. For exam-

ple, the cosine values for the synonym pair *süß* – *niedlich* and antonym pair *süß* – *sauer* (cf. Table 1) are 0.94 (T:SYN) and 0.18 (T:ANT), respectively, and the difference value is calculated as (T:SYN – T:ANT). The resulting value (which may be positive or negative) is used as input for the synonym pair (here, 0.76), while the negated value is used as input for the antonym pair (-0.76). For cases where several synonym or antonym pairs are available, an average difference value is calculated.

Figure 3: Relative cosine values

## 6 Results

This section presents the results of the Decision Tree classification of synonyms vs. antonyms, using *standard-cosine* values as features (Figure 4) and using *cosine-difference* values (Figure 5). The graphs show the performance of the classifiers in % accuracy for the five part-of-speech-based word space models (ADJ, ADV, NN, VV, and COMB), while at the same time comparing the performances of the two context settings ‘Codis-Contexts’ (dark bars) and ‘All-Contexts’ (light bars). The results are compared against a 50% baseline (dotted line), and significant improvements are marked with a star.

Figure 4: Classification results (*standard-cosine*)

## 7 Discussion

**Hypothesis A** The graphs in Figures 4 and 5 clearly show that it is possible to automatically distinguish between synonymy and antonymy by means of a word space model, with significant improvements over the 50% baseline. These results support our hypothesis that synonyms and antonyms are *not* distributionally similar, and refute the claim that antonyms constitute a counterexample to the distributional hypothesis. An in-

<sup>10</sup>[www.cs.waikato.ac.nz/ml/weka](http://www.cs.waikato.ac.nz/ml/weka)

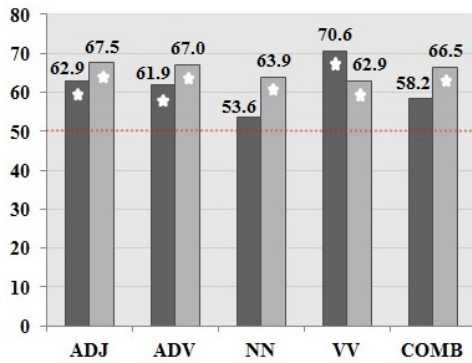

Figure 5: Classification results (*cosine-difference*)

investigation of the decision trees underlying the best-performing classifiers in Figure 4 further shows surprisingly clearly that there *is* a cut-off point over the cosine values that separates synonyms from antonyms, with antonyms in the lower-value and synonyms in the higher-value partition. For example, the cut-off value for the ‘All-Contexts’ model for verbs (light bar in Figure 4) is 0.1186, and any instances with lower cosine values are labelled as antonyms, and with higher values as synonyms, achieving 66.5% accuracy. This is in line with our prediction that synonyms are more distributionally similar than antonyms.

**Hypothesis B** Our second hypothesis, that not all word classes are useful for modelling the contextual differences between adjectival synonyms and antonyms, is also supported by the findings: the word space models built on the class of collocate verbs (VV) appear to be the best discriminators of the relations overall, outperforming the baseline in all four scenarios shown in Figures 4 and 5. All except one of these improvements are statistically significant.<sup>11</sup> The second-best class according to our statistical analysis is the class of adjectives (ADJ), which outperforms the baseline in three of four scenarios (all three being statistically significant). The class of adverbs occupies middle ground, significantly outperforming the baseline only in the *cosine-difference* scenario. As predicted, the noun class (NN) fares worst in the experiments, only (significantly) beating the baseline in one scenario (*cosine-difference*, ‘All-Contexts’).

**Polysemy** The graphs in Figures 4 and 5 show that in most experiment conditions the ‘All-Contexts’ setting (which incorporates

<sup>11</sup> *standard-cosine*, ‘All-Contexts’:  $\chi^2 = 10.85, p < .001$ ; *cosine-difference*, ‘All-Contexts’:  $\chi^2 = 6.55, p < .05$ ; *cosine-difference*, ‘Codis-Contexts’:  $\chi^2 = 8.18, p < .005$ .

co-occurrence information from all contexts) achieves better results than the ‘Codis-Contexts’ setting (which aims to address polysemy by means of ‘co-disambiguation’). However, in the *cosine-difference* scenario, which aims to provide a more accurate representation of distributional differences, the ‘Codis-Contexts’ setting provides a much clearer picture of the differences between the word classes than the ‘All-Contexts’ setting (with accuracy values ranging from 53.6% for nouns to 70.6% for verbs for the former, and 62.9% for verbs to 67.5% for adjectives for the latter). Furthermore, the overall best result (i.e. relying on verbs in the *cosine-difference* scenario) is achieved in the ‘Codis-Contexts’ setting.

A closer analysis of the vector sizes shows that the performance of the ‘co-disambiguation’ approach might be affected by sparse data. Given a larger source of co-occurrence data, the approach may achieve better results than shown in Figures 4 and 5. Overall, our findings suggest that the ‘co-disambiguation’ approach to dealing with polysemy represents a worthwhile avenue for future research, especially on consideration of its other advantages such as ease of implementation and reduced space requirements.

## 8 Conclusion

Our experiments demonstrated that synonyms and antonyms can be distinguished by means of a distributional word space model, refuting the general assumption that synonyms and antonyms are distributionally similar. With 66.5% and 70.6% accuracy in two different classification settings, our model achieves significant improvements over a 50% baseline, and compares favourably to previous approaches by Turney (2008), who achieved an improvement of 9.6% over his baseline, and Lin et al. (2003), whose method is assumed to only work for high-frequency antonyms.

What are the implications of our findings for distributional semantics? First of all, we have shown that the distributional hypothesis holds true even for antonyms. Secondly, our finding that not all word classes are equally useful for modelling the contextual differences between synonyms and antonyms suggests that the performance of distributional measures may be improved by excluding certain word classes from consideration, depending on the task. Finally, we introduced a simple ‘co-disambiguation’ approach to dealing with polysemy in distributional word space models.

## Abstract

We present three approaches to word sense disambiguation that use Wikipedia as a source of sense annotations. Starting from a basic monolingual approach, we develop two multilingual systems: one that uses a machine translation system to create multilingual features, and one where multilingual features are extracted primarily through the interlingual links available in Wikipedia. Experiments on four languages confirm that the Wikipedia sense annotations are reliable and can be used to construct accurate monolingual sense classifiers. The experiments also show that the multilingual systems obtain on average a substantial relative error reduction when compared to the monolingual systems.

## 1 Introduction and Motivation

Ambiguity is inherent to human language. In particular, word sense ambiguity is prevalent in all natural languages, with a large number of the words in any given language carrying more than one meaning. For instance, the English noun *plant* can mean *green plant* or *factory*; similarly the French word *feuille* can mean *leaf* or *paper*. The correct sense of an ambiguous word can be selected based on the context where it occurs, and correspondingly the problem of *word sense disambiguation* is defined as the task of automatically assigning the most appropriate meaning to a polysemous word within a given context.

Two well studied categories of approaches to word sense disambiguation (WSD) are represented by knowledge-based (Lesk, 1986; Galley and McKeown, 2003; Navigli and Velardi, 2005) and data-driven (Yarowsky, 1995; Ng and Lee, 1996; Pedersen, 2001) methods. Knowledge-based methods rely on information drawn from

wide-coverage lexical resources such as WordNet (Miller, 1995). Their performance has been generally constrained by the limited amount of lexical and semantic information present in these resources.

Among the various data-driven WSD methods proposed to date, supervised systems have been observed to lead to highest performance in the Senseval evaluations<sup>1</sup>. In these systems, the sense disambiguation problem is formulated as a supervised learning task, where each sense-tagged occurrence of a particular word is transformed into a feature vector which is then used in an automatic learning process. Despite their high performance, the supervised systems have an important drawback: their applicability is limited to those few words for which sense tagged data is available, and their accuracy is strongly connected to the amount of available labeled data.

In this paper, we address the sense-tagged data bottleneck problem by using Wikipedia as a source of sense annotations. Starting with the hyperlinks available in Wikipedia, we first generate sense annotated corpora that can be used for training accurate and robust monolingual sense classifiers (WIKIMONONSENSE, in Section 2). Next, the sense tagged corpus extracted for the *reference* language is translated into a number of *supporting* languages. The word alignments between the reference sentences and the supporting translations computed by Google Translate are used to generate complementary features in our first approach to multilingual WSD (WIKITRANSSENSE, in Section 3). The reliance on machine translation (MT) is significantly reduced during the training phase of our second approach to multilingual WSD, in which sense tagged corpora in the supporting languages are created through the interlingual links available in Wikipedia. Separate classifiers are

<sup>1</sup><http://www.senseval.org>

trained for the reference and the supporting languages and their probabilistic outputs are integrated at test time into a joint disambiguation decision for the reference language (WIKIMUSENSE, in Section 4).

Experimental results on four languages demonstrate that the Wikipedia annotations are reliable, as the accuracy of the WIKIMONONSENSE systems trained on the Wikipedia dataset exceeds by a large margin the accuracy of an informed baseline that selects the most frequent word sense by default. We also show that the multilingual sense classifiers WIKITRANSSENSE and WIKIMUSENSE significantly outperform the WIKIMONONSENSE systems (Section 5).

## 2 The WikiMonoSense System

In an effort to alleviate the sense-tagged data bottleneck problem that affects supervised learning approaches to WSD, the WIKIMONONSENSE system uses Wikipedia both as a repository of word senses and as a rich source of sense annotations. Wikipedia is a free online encyclopedia, representing the outcome of a continuous collaborative effort of a large number of volunteer contributors. Virtually any Internet user can create or edit a Wikipedia webpage, and this “freedom of contribution” has a positive impact on both the quantity (fast-growing number of articles) and the quality (potential mistakes are quickly corrected within the collaborative environment) of this online resource. Wikipedia editions are available for more than 280 languages, with a number of entries varying from a few pages to three millions articles or more per language.

A large number of the concepts mentioned in Wikipedia are explicitly linked to their corresponding article through the use of links or piped links. Interestingly, these links can be regarded as *sense annotations* for the corresponding concepts, which is a property particularly valuable for words that are ambiguous. In fact, it is precisely this observation that we rely on in order to generate sense tagged corpora starting with the Wikipedia annotations (Mihalcea, 2007; Dandala et al., 2012).

### 2.1 A Monolingual Dataset through Wikipedia Links

Ambiguous words such as e.g. *plant*, *bar*, or *argument* are linked in Wikipedia to different articles, depending on their meaning in the context

where they occur. Note that the links are *manually* created by the Wikipedia users, which means that they are most of the time accurate and referencing the correct article. The following represent four example sentences for the ambiguous word *bar*, with their corresponding Wikipedia annotations (links):

1. In 1834, Sumner was admitted to the [[bar (law)|bar]] at the age of twenty-three, and entered private practice in Boston.
2. It is danced in 3/4 time (like most waltzes), with the couple turning approx. 180 degrees every [[bar (music)|bar]].
3. Jenga is a popular beer in the [[bar (establishment)|bar]]s of Thailand.
4. This is a disturbance on the water surface of a river or estuary, often cause by the presence of a [[bar (landform)|bar]] or dune on the riverbed.

To derive sense annotations for a given ambiguous word, we use the links extracted for all the hyperlinked Wikipedia occurrences of the given word, and map these annotations to word senses, as described in (Dandala et al., 2012). For instance, for the *bar* example above, we extract five possible annotations: *bar (establishment)*, *bar (landform)*, *bar (law)*, and *bar (music)*.

In our experiments, the WSD dataset was built for a subset of the ambiguous words used during the SENSEVAL-2, SENSEVAL-3 evaluations and a subset of ambiguous words in four languages: English, Spanish, Italian and German. Since the Wikipedia annotations are focused on nouns (associated with the entities typically defined by Wikipedia), the sense annotations we generate and the WSD experiments are also focused on nouns. We also avoided those words that have only one Wikipedia label. This resulted in a set of 105 words in four different languages: 30 for English, 25 for Italian, 25 for Spanish, and 25 for German. Table 1 provides relevant statistics for the corresponding monlingual dataset.

### 2.2 The WikiMonoSense Learning Framework

Provided a set of sense-annotated examples for a given ambiguous word, the task of a supervised WSD system is to automatically learn a disambiguation model that can predict the correct sense

Language	#words	#senses	#examples
English	30	5.3	632
German	25	4.5	550
Italian	25	5.4	815
Spanish	25	4.6	484

Table 1: #words = number of ambiguous words, #senses = average number of senses, #examples = average number of examples.

for a new, previously unseen occurrence of the word. Assuming that such a system can be reliably constructed, the implications are two-fold. First, accurate disambiguation models suggest that the data is reliable and consists of correct sense annotations. Second, and perhaps more importantly, the ability to correctly predict the sense of a word can have important implications for applications that require such information, including machine translation and automatic reasoning.

The WIKIMONOSENSE system integrates local and topical features within a machine learning framework, similar to several of the top-performing supervised WSD systems participating in the SENSEVAL-2 and SENSEVAL-3 evaluations. The disambiguation algorithm starts with a preprocessing step, where the text is tokenized, stemmed and annotated with part-of-speech tags. Collocations are identified using a sliding window approach, where a collocation is defined as a sequence of words that forms a compound concept defined in Wikipedia. Next, local and topical features are extracted from the context of the ambiguous word. Specifically, we use the current word and its part-of-speech, a local context of three words to the left and right of the ambiguous word, the parts-of-speech of the surrounding words, the verb and noun before and after the ambiguous words, and a global context implemented through sense-specific keywords determined as a list of words occurring at least three times in the contexts defining a certain word sense. We used TreeTagger for part-of-speech tagging<sup>2</sup> and Snowball stemmer<sup>3</sup> for stemming as they both have publicly available implementations for multiple languages. The features are integrated in a Naive Bayes classifier, which was selected for its state-of-the-art performance in previous WSD systems.

<sup>3</sup> [snowball.tartarus.org](http://snowball.tartarus.org)

### 3 The WikiTransSense System

Consider the examples centered around the ambiguous noun “chair”, as shown in Figure 1, where English is the reference language and German is a supporting language. The figure shows only 2 out of the 5 possible meanings from the Wikipedia sense inventory. The two examples illustrate two important ways in which the translation can help disambiguation. First, two different senses of the target ambiguous word may be translated into a different word in the supporting language. Therefore, assuming access to word alignments, knowledge of the target word translation can help in disambiguation. Second, features extracted from the translated sentence can be used to enrich the feature space. Even though the target word translation is a strong feature in general, there may be cases where different senses of the target word are translated into the same word in the supporting language. For example, the two senses “bar (unit)” and “bar (establishment)” of the English word “bar” translate to the same German word “bar”. In cases like this, words in the context of the German translation may help in identifying the correct English meaning.

#### 3.1 A Multilingual Dataset through Machine Translation

In order to generate a multilingual representation for the monolingual dataset, we used Google Translate to translate the data from English into several other languages. The use of Google Translate is motivated by the fact that Google’s statistical machine translation system is available for many languages. Furthermore, through the University Research Program, Google Translate also provides the word alignments. Given a target word in an English sentence, we used the word alignments to identify the position of the target word translation in the translated sentence. Each of the four languages is used as a reference language, with the remaining three used as supporting languages. Additionally, French was added as a supporting language in all the multilingual systems, which means that each reference sentence was translated in four supporting languages.

#### 3.2 The WikiTransSense Learning Framework

Similar to the WIKIMONOSENSE approach described in Section 2.2, we extract the same types

An airline seat is a <u>chair</u> on an airliner in which passengers are accommodated for the duration of the journey. Ein Flugzeugsitz ist ein <u>Stuhl</u> auf einem Flugzeug, in dem Passagiere fr die Dauer der Reise untergebracht sind.
For a year after graduation, Stanley served as <u>chair</u> of belles-lettres at Christian College in Hustonville. Seit einem Jahr nach dem Abschluss, diente Stanley als <u>Vorsitzender</u> Belletristik bei Christian College in Hustonville.

Figure 1: English to German translations from Google Translate, with the target words aligned.

Language	WikiTransSense	WikiMuSense
English	75,832	13,151
German	54,984	8,901
Italian	81,468	4,697
Spanish	48,384	6,560

Table 2: Total number of sentence translations per language, in the two multilingual approaches.

of features from the reference sentence, as well as from the translations in each of the supporting languages. Correspondingly, the feature vector will contain a section with the reference language features, followed by a multilingual section containing features extracted from the translations in the supporting languages. The resulting multilingual feature vectors are then used with a Naive Bayes classifier.

## 4 The WikiMuSense System

The number of sentence translations required to train the WIKITRANSSENSE approach is shown in the second column of Table 2. If one were to train a WSD system for all ambiguous nouns, the large number of translations required may be prohibitive. In order to reduce the dependency on the machine translation system, we developed a second multilingual approach to WSD, WIKIMUSENSE, that exploits the interlingual links available in Wikipedia.

### 4.1 A Multilingual Dataset through Interlingual Wikipedia Links

Wikipedia articles on the same topic in different languages are often connected through interlingual links. These are the small navigation links that show up in the “Languages” sidebar in most Wikipedia articles. For example, the English Wikipedia sense “Bar (music)” is connected through an interlingual link to the German Wikipedia sense “Takt (Musik)”. Given a sense inventory for a word in the reference language, we automatically build the sense repository for a

supporting language by following the interlingual links connecting equivalent senses in the two languages. Thus, given the English sense repository for the word “bar”  $EN = \{bar (establishment), bar (landform), bar (law), bar (music)\}$ , the corresponding German sense repository will be  $DE = \{Bar (Lokal), noteank, NIL, Takt (Musik)\}$ <sup>4</sup>. The resulting sense repositories can then be used in conjunction with Wikipedia links to build sense tagged corpora in the supporting languages, using the approach described in Section 2.1. However, this approach poses the following two problems:

1. There may be reference language senses that do not have interlingual links to the supporting language. In the “bar” example above, the English sense *bar (law)* does not have an interlingual link to German.
2. The distribution of examples per sense in the automatically created sense tagged corpus for the supporting language may be different from the corresponding distribution for the reference language. Previous work (Agirre et al., 2000; Agirre and Martinez, 2004) has shown that the WSD performance is sensitive to differences in the two distributions.

We address the first problem using a very simple approach: whenever there is a sense gap, we randomly sample a number of examples for that sense in the reference language and use Google Translate to create examples in the supporting language. The third column in Table 2 shows the total number of sentence translations required by the WIKIMUSENSE system. As expected, due to the use of interlingual links, it is substantially smaller than the number of translations required in the WIKITRANSSENSE system.

To address the second problem, we use the distribution of reference language as the true distribution and calculate the number of examples to

<sup>4</sup>NIL stands for a missing corresponding sense in German.

be considered per sense from the supporting languages using the statistical method proposed in (Agirre and Martinez, 2004).

#### 4.2 The WikiMuSense Learning Framework

Once the datasets in the supporting languages are created using the method above, we train a Naive Bayes classifier for each language (reference or supporting). Note that the classifiers built for the supporting languages will use the same senses/classes as the reference classifier, since the aim of using supporting language data is to disambiguate a word in the reference language. Thus, for the word “bar” in the example above, if English is reference and German is supporting, the Naive Bayes classifier for German will compute probabilities for the four English senses, even though it is trained and tested on German sentences.

For each classifier, the features are extracted using the same approach as in the WIKIMONOSENSE system.

At test time, the reference sentence is translated into all four supporting languages using Google Translate. The five probabilistic outputs – one from the reference ( $P_R$ ) and four from the supporting classifiers ( $P_S$ ) – are combined into an overall disambiguation score using Equation 1 below. Finally, disambiguation is done by selecting the sense that obtains the maximum score.

$$P = P_R + \sum_S P_S * \min(1, |D_S|/|D_R|) \quad (1)$$

In Equation 1,  $D_R$  is the set of training examples in the reference language  $R$ , whereas  $D_S$  is the set of training examples in a source language  $S$ . When the number of training examples in a supporting language is smaller than the number of examples in the reference language, the probabilistic output from the corresponding supporting classifier will have a weight smaller than 1 in the disambiguation score, and thus a smaller influence on the disambiguation output. In general, the influence of the supporting classifier will always be less than or equal with the influence of the reference classifier.

## 5 Experimental Evaluation

We ran 10-fold cross-validation experiments on the Wikipedia dataset <sup>5</sup>, with all three systems: WIKIMONOSENSE (WMS), WIKITRANSSENSE

<sup>5</sup>The dataset is available from <http://lit.csci.unt.edu>.

Language	MFS	WMS	WTS	WMuS
English	62.2	78.9	<b>81.9</b>	81.3
German	69.5	81.2	84.6	<b>85.6</b>
Italian	66.0	81.8	84.0	<b>84.7</b>
Spanish	66.8	76.0	78.7	<b>79.7</b>

Table 3: WSD macro accuracies.

Language	MFS	WMS	WTS	WMuS
English	59.2	79.3	80.6	<b>80.3</b>
German	75.6	83.9	86.5	<b>87.0</b>
Italian	74.3	84.6	86.3	<b>87.5</b>
Spanish	72.6	79.8	81.1	<b>82.7</b>

Table 4: WSD micro accuracies.

(WTS), and WIKIMUSENSE (WMUS). For the WIKIMUSENSE system, since the gaps in the supporting language datasets are addressed using reference language translations, we enforced the constraint that a translation of the test example does not appear in the training data of the supporting language.

We used two different accuracy metrics to report the performance:

1. *macro accuracy*: an accuracy number was calculated separately for each ambiguous word. Macro accuracy was then computed as the average of these accuracy numbers.
2. *micro accuracy*: the system outputs for all ambiguous words were pooled together and the micro accuracy was computed as the percentage of instances that were disambiguated correctly.

Tables 3 and 4 show the micro and macro accuracies for the three systems. The tables also show the accuracy of a simple WSD baseline that selects the Most Frequent Sense (MFS).

Overall, the Wikipedia-based sense annotations were found reliable, leading to accurate sense classifiers for the WIKIMONOSENSE system with an average relative error reduction of 44%, 38%, 44%, and 28% compared to the most frequent sense baseline in terms of macro accuracy. WIKIMONOSENSE performed better for 76 out of the 105 words in the four languages compared to the MFS baseline, which further indicates that Wikipedia data can be useful for creating accurate and robust WSD systems.

Compared to the monolingual WIKIMONOSENSE system, the multilingual WIKITRANSSENSE system obtained an average relative error reduction of 13.7%, thus confirming the utility of using translated contexts. Relative to the MFS baseline, WIKITRANSSENSE performed better on 83 of the 105 words. Finally, WIKIMUSENSE had an even higher average error reduction of 16.5% with respect to WIKIMONOSENSE, demonstrating that the multilingual data available in Wikipedia can successfully replace the machine translation component during training. Relative to the MFS baseline, the multilingual WIKIMUSENSE system performed better on 89 out of the 105 words.

Since WIKIMUSENSE is still using machine translation when interlingual links are missing, we ran an additional experiment in which MT was completely removed during training to demonstrate the advantage of sense-annotated corpora available in supporting language Wikipedias. Thus, for the 105 ambiguous words, we eliminated all senses that required machine translation to fill the sense gaps. After filtering, 52 words from the four languages had 2 or more sense in Wikipedia for which all interlingual links were available. The results averaged over the 52 words are shown in Table 5 and demonstrate that WIKIMUSENSE still outperforms WIKIMONOSENSE substantially.

Accuracy	WikiMonoSense	WikiMuSense
Macro	83.9	<b>87.2</b>
Micro	87.5	<b>89.8</b>

Table 5: WSD performance with no sense gaps.

We have also evaluated the proposed WSD systems in a coarse-grained setting on the same dataset. Two annotators were provided with the automatically extracted sense inventory from Wikipedia along with the corresponding Wikipedia articles and requested to discuss and create clusters of senses for the 105 words in the four languages. The results on this coarse-grained sense inventory are shown in Tables 6 and 7 indicate that our multilingual systems outperform the monolingual system.

## 5.1 Learning Curves

One aspect that is particularly relevant for any supervised system is the learning rate with respect to the amount of available data. To determine the

learning curve, we measured the disambiguation accuracy under the assumption that only a fraction of the data were available. We ran 10-fold cross-validation experiments using 10%, 20%, ..., 100% of the data, and averaged the results over all the words in the data set. The learning curves for the four languages are plotted in Figure 2. Overall, the curves indicates a continuously growing accuracy with increasingly larger amounts of data. Although the learning pace slows down after a certain number of examples (about 50% of the data currently available), the general trend of the curve seems to indicate that more data is likely to lead to increased accuracy. Given that Wikipedia is growing at a fast pace, the curve suggests that the accuracy of the word sense classifiers built on this data is likely to increase for future versions of Wikipedia.

Another relevant aspect is the dependency between the amount of data available in supporting languages and the performance of the WIKIMUSENSE system. To measure this, we ran 10-fold cross-validation experiments using all the data from the reference language and varying the amount of supporting language data from 10% to 100%, in all supporting languages. The accuracy results were averaged over all the words. Figure 3 shows the learning curves for the 4 languages. When using 0% fraction of supporting data, the results correspond to the monolingual WIKIMONOSENSE system. When using 100% fraction of the supporting data, the results correspond to the final multilingual WIKIMUSENSE system. We can see that WIKIMUSENSE starts to perform better than WIKIMONOSENSE when

Figure 2: Learning curves for WIKIMONOSENSE.

Figure 3: Learning curves for WIKIMUSENSE.

at least 70-80% of the available supporting data is used, and continues to increase its performance with increasing amounts of supporting data.

Finally, we also evaluated the impact that the number of supporting languages has on the performance of the two multilingual WSD systems. Both WIKITRANSSENSE and WIKIMUSENSE are evaluated using all possible combinations of 1, 2, 3, and 4 supporting languages. The resulting macro accuracy numbers are then averaged for each number of supporting languages. Figure 4 indicates that the accuracies continue to improve as more languages are added for both systems.

## 6 Related Work

Despite the large number of WSD methods that have been proposed so far, there are only a few methods that try to explore more than one lan-

Figure 4: Impact of the number of supporting languages on the two multilingual WSD systems.

guage at a time.

Brown et al. (1991) made the observation that mappings between word-forms and senses may differ across languages and proposed a statistical machine learning technique that exploits these mappings for WSD. Subsequently, several works (Gale et al., 1992; Resnik and Yarowsky, 1999; Diab and Resnik, 2002; Diab, 2004; Ng et al., 2003; Chan and Ng, 2005; Chan et al., 2007) explored the use of parallel translations for WSD.

Li and Li (2004) introduced a bilingual bootstrapping approach, in which starting with in-domain corpora in two different languages, English and Chinese, word translations are automatically disambiguated using information iteratively drawn from the bilingual corpora. Khapra et al. (2009; 2010) proposed another bilingual bootstrapping approach, in which they used an aligned multilingual dictionary and bilingual corpora to show how resource deprived languages can benefit from a resource rich language. They introduced a technique called *parameter projections*, in which parameters learned using both aligned multilingual Wordnet and bilingual corpora are projected from one language to another language to improve on existing WSD methods.

In recent years, the exponential growth of the Web led to an increased interest in multilinguality. Lefever and Hoste (Lefever and Hoste, 2010) introduced a SemEval task on cross-lingual WSD in SemEval-2010 that received 16 submissions. The corresponding dataset contains a collection of sense annotated English sentences for a few words

with their contextually appropriate translations in Dutch, German, Italian, Spanish and French.

Recently, Banea and Mihalcea (2011) explored the utility of features drawn from multiple languages for WSD. In their approach, a multilingual parallel corpus in four languages (English, German, Spanish, and French) is generated using Google Translate. For each example sentence in the training and test set, features are drawn from multiple languages in order to generate more robust and more effective representations known as *multilingual vector-space representations*. Finally, training a multinomial Naive Bayes learner showed that a classifier based on multilingual vector representations obtains an error reduction ranging from 10.58% to 25.96% as compared to the monolingual classifiers. Lefever (2012) proposed a similar strategy for multilingual WSD using a different feature set and machine learning algorithms. Along similar lines, (Fernandez-Ordonez et al., 2012) used the Lesk algorithm for unsupervised WSD applied on definitions translated in four languages, and obtained significant improvements as compared to a monolingual application of the same algorithm. Although these three methodologies are closely related to our WIKITRANSENSE system, our approach exploits a sense inventory and tagged sense data extracted automatically from Wikipedia.

Navigli and Ponzetto (2012) proposed a different approach to multilingual WSD based on *BabelNet* (2010), a large multilingual encyclopedic dictionary built from WordNet and Wikipedia. Their approach exploits the graph structure of *BabelNet* to identify complementary sense evidence from translations in different languages.

## 7 Conclusion

In this paper, we described three approaches for WSD that exploit Wikipedia as a source of sense annotations. We built monolingual sense tagged corpora for four languages, using Wikipedia hyperlinks as sense annotations. Monolingual WSD systems were trained on these corpora and were shown to obtain relative error reductions between 28% and 44% with respect to the most frequent sense baseline, confirming that the Wikipedia sense annotations are reliable and can be used to construct accurate monolingual sense classifiers.

Next, we explored the cumulative impact of features originating from multiple supporting lan-

guages on the WSD performance of the reference language, via two multilingual approaches: WIKITRANSENSE and WIKIMUSENSE. Through the WIKITRANSENSE system, we showed how to effectively use a machine translation system to leverage two relevant multilingual aspects of the semantics of text. First, the various senses of a target word may be translated into different words, which constitute unique, yet highly salient signals that effectively expand the target words feature space. Second, the translated context words themselves embed co-occurrence information that a translation engine gathers from very large parallel corpora. When integrated in the WIKITRANSENSE system, the two types of features led to an average error reduction of 13.7% compared to the monolingual system.

In order to reduce the reliance on the machine translation system during training, we explored the possibility of using the multilingual knowledge available in Wikipedia through its interlingual links. The resulting WIKIMUSENSE system obtained an average relative error reduction of 16.5% compared to the monolingual system, while requiring significantly fewer translations than the alternative WIKITRANSENSE system.

## Abstract

Work on information retrieval has shown that language model smoothing leads to more accurate estimation of document models and hence is crucial for achieving good retrieval performance. Several smoothing methods have been proposed in the literature, using either semantic or positional information. In this paper, we propose a unified proximity-based framework to smooth language models, leveraging semantic and positional information simultaneously in combination. The key idea is to project terms to positions where they originally do not exist (i.e., zero count), which is actually a word count propagation process. We achieve this projection through two proximity-based density functions indicating semantic association and positional adjacency. We balance the effects of *semantic* and *positional* smoothing, and score a document based on the smoothed language model. Experiments on four standard TREC test collections show that our smoothing model is effective for information retrieval and generally performs better than the state of the art.

## 1 Introduction

Recently, statistical language models have attracted much attention in the information retrieval community due to their solid theoretical background as well as their success in a variety of retrieval tasks (Ponte and Croft, 1998; Zhai and Lafferty, 2001b). Queries and documents are assumed to be sampled from hidden generative models, and the similarity between a document and a query is then calculated through the similarity between their underlying language models. Clearly,

good retrieval performance relies on the accurate estimation of the query and document models. As queries are generally too short (Zhai and Lafferty, 2001a), the entire retrieval problem is essentially reduced to the problem of estimating a document language model (Lavrenko and Croft, 2001; Liu and Croft, 2004).

Larger observed data generally allow people to establish a more accurate statistical model. Unfortunately, in retrieval, we often have to estimate a model based on a small sample of data (e.g., a single document or only a few documents). Therefore, given limited data sampling, a language model estimation sometimes encounters with the zero count problem: the maximum likelihood estimator would give unseen terms a zero probability, which is not reliable because a larger sample of the data would likely contain the term. Language model smoothing is proposed to address the problem, and has been demonstrated to affect retrieval performance significantly (Zhai and Lafferty, 2001b).

To this end, the quality of retrieval tasks heavily relies on proper smoothing of the document language model. Although much work on language model smoothing has been investigated, two related retrieval heuristics remain to be further explored: 1) *intra-document* smoothing, a propagation of word count to positions where the term does not exist, within the local document; 2) *inter-document* smoothing, a projection of non-existence terms from the entire collection globally. Both heuristics are implemented in this paper.

As the key idea is to propagate term counts via intra-document and inter-document projection to positions where they originally do not exist, we have two ways of projection: we propose a unified proximity-based framework to smooth language models, formulating semantic and position information simultaneously into a single objective function with balance. Intuitively, a smoothed language model should enhance the coherence between terms with large semantic association, and

This work was partially done when Rui Yan was an intern in Intel Center, National Taiwan University

<sup>†</sup>Indicates equal contributions

analogously for those positional adjacent terms. In other words, the terms that are close to each other (either semantically related or positionally adjacent) should have similar (smoothed) language models; the closer they are, the more similar their smoothed language models are. The smoothing method is based on two density functions of propagated counts of words. Our proposed framework can combine both semantic and positional proximity for intra-/inter-document smoothing naturally, which has not been addressed in the previous works. To the best of our knowledge, we are the first to balance the effect of these proximities for both intra-/inter-document smoothing.

Another main technical challenge lies in how to define the propagation functions of semantic projection and positional adjacency in order to estimate the language model accordingly. As the adjacency function has been carefully explored in (Lv and Zhai, 2009), we mainly focus on proposing and evaluating several different semantic association functions for term propagation. In these density functions, “close-by” terms would receive more propagated counts than “far-away” terms, which captures the proximity heuristics.

We evaluate the retrieval performance using several standard TREC test collections. Experimental results show that our proposed proximity-based smoothing consistently outperforms the baseline smoothing methods, indicating the effectiveness of our approach. The results show that the derived smoothing method can improve over the baseline position-based smoothing method significantly, and either outperform or perform comparably to the corresponding state-of-art semantic proximity-based smoothing method.

The rest of the paper is organized as follows. We start by reviewing previous works. Then we introduce the balanced language model smoothing, based on semantics and positions separately. We describe the experiments and evaluation in the next section and finally draw the conclusions.

## 2 Related Work

Language modeling approaches have recently enjoyed much attention for many different tasks ever since the pioneering work applying on information retrieval (Ponte and Croft, 1998). In the past decade, many variants of language models have been proposed, mostly focusing on improving the estimation of query language models (Zhai and Lafferty, 2001a; Lavrenko and Croft, 2001) and document language models (Liu and Croft, 2004; Tao et al., 2006). These methods

boil down to retrieval functions that implement retrieval heuristics similar to those implemented in a traditional model, such as TF-IDF weighting and document length normalization (Zhai and Lafferty, 2001b). Yet with sound statistical foundation, language models make it easier to optimize parameters and often outperform traditional retrieval models (Song and Croft, 1999).

Due to the importance of smoothing, many approaches have been proposed and tested. To smooth a document language model, most early smoothing methods relied on using a background language model, which is typically estimated based on the whole document collection (Ponte and Croft, 1998; Zhai and Lafferty, 2001b; Miller et al., 1999). In contrast to the simple strategy which smooths all documents with the same background, recently corpus structures have been exploited for more accurate smoothing. The basic idea is to smooth a document language model with the documents similar to the document under consideration through clustering (Liu and Croft, 2004; Xu and Croft, 1999; Mei et al., 2008), document expansion (Kurland and Lee, 2004; Tao et al., 2006), or relevance propagation (Kurland and Lee, 2010; Kurland and Lee, 2006; Qin et al., 2005). All these methods are based on document-level semantics similarity to offer “customized” smoothing for each individual document.

Besides semantics, positional heuristics for retrieval have been examined in (Keen, 1992; Tao and Zhai, 2007; Liu and Croft, 2002; Büttcher et al., 2006). Positional language models are proposed to examine the positional proximity in (Lv and Zhai, 2009; Zhao and Yun, 2009). In their work, the key idea is to define a language model for each position within a document, and score it based on the language models on all its positions: hence the effect of positional adjacency is revealed, while semantic information is hardly incorporated.

There is a study in (Karimzadehgan and Zhai, 2010) which smooths language model by term translation model with backgrounds, while we operate term-to-term association on every term position, which is actually a new granularity. Besides, our method takes both semantic and positional information into account, and formulates the two intrinsically different proximity-based heuristics into a unified term-level smoothing framework. To the best of our knowledge, this is the first approach that achieves the combined smoothing.

### 3 Proximity Based Language Smoothing

We propose a term-level proximity based smoothing approach in the positional language model framework. Each word propagates the evidence of its occurrence to all other positions in the document based on semantic and/or positional projection via density functions. To capture the proximity heuristics, we assign “close-by” words with higher propagated counts than those “far away” from the current word. In other words, most propagated counts come from “nearby” words. Here, *close* and *far* could either be semantic or positional. Each position receives propagated counts of words from an intra-document or an inter-document vocabulary set. All positions have a full vocabulary with different term distributions: each word has a certain non-zero probability to occur in each of the positions, as if all words had appeared in any position with a variety of discounted counts, shown in Figure 1.

Figure 1: Illustration of different term distributions on different positions for the short document of “To be or not to be”. x-axis denotes all terms in vocabulary, while y-axis indicates the term occurrence probability.

#### 3.1 Semantic Proximity based Propagation

The idea for semantic projection is that if a word  $w$  occurs at position  $i$ , we would like to assume that the highly associated words have also occurred here, with a discounted count. The larger the semantic association is, the larger the propagated count will be. Generally, each propagated count has a value less than 1, which is estimated as the count of  $w$  at position  $i$ .

Let  $d = (w_1, \dots, w_i, \dots, w_j, \dots, w_{|d|})$  be a document, where  $1, i, j$ , and  $|d|$  are absolute positions of the corresponding terms in the document, and obviously  $|d|$  is the length of the document.

$c(w, i, d)$ : the original count of term  $w$  at position  $i$  in document  $d$  before smoothing. If  $w$  occurs at position  $i$ ,  $c(w, i, d)$  is 1, otherwise 0. Similarly,  $c(w, d)$  is the term count in  $d$  and  $c(w)$  is the term count within the collection.

$\phi(w_i, w)$ : the propagated count of  $w$  to position  $i$  based on the existence of  $w_i$ . Intuitively,  $\phi(w_i, w)$  serves as a discounting factor measured by the semantic association between the term  $w_i$  and  $w$ .

$c'(w, i, d)$ : the total propagated count of term  $w$  at position  $i$  from its occurrences in all the positions in the document  $d$ , i.e.,  $c'(w, i, d) = \sum_{j=1}^{|V|} c(w, j, d)\phi(w_i, w) = c(w, d)\phi(w_i, w)$ . Even if  $c(w, i, d)$  is 0,  $c'(w, i, d)$  may be greater than 0.

Note that the **semantic association** function  $\phi(\cdot)$  here is not the same as “similarity”. Generally, association denotes the association between two terms based on the broader background, e.g., co-occurrence or mutual information, etc. Clearly, a major technical challenge for semantic based smoothing lies in a proper model to define the association function. We present here 4 representative association calculations.

**Co-occurrence Likelihood.** Given the term  $w_i$  at position  $i$ , we calculate the co-occurrence probability for the word  $w$  from other positions using:

$$p(w|w_i) = \frac{\#c(w, w_i)}{\#c(w_i)} \quad (1)$$

$\#c(w, w_i)$  is the times of co-occurrence for these two terms. Generally, we need to predefine a sliding window to measure this co-occurrence count, and hence we count  $\#c(w, w_i)$  within the same sentence out of the whole collection.  $\#c(w_i)$  is the term frequency in the document collection.  $p(w|w_i)$  denotes the occurrence probability of  $w$  when  $w_i$  occurs.

Apparently, this definition is asymmetric because  $p(w|w_i) \neq p(w_i|w)$ . When calculate the propagated counts for  $w$ , it is more reasonable to measure the probability given the existence of  $w_i$ . Especially when  $w_i$  is a low-frequency term, we will find the most likely terms with high co-occurrence probability. The semantic association by co-occurrence likelihood is  $\phi_{cl}(w_i, w) = p(w|w_i)$ .

**Mutual Information.** In Information Theory, the mutual information of two random variables is a quantity that measures their mutual dependence, which in our case, is the dependence of co-occurrence probability. The mutual information between the two terms  $w$  and  $w_i$  can be represented as:

$$\text{MI}(w_i, w) = \log \frac{p(w, w_i)}{p(w)p(w_i)} \quad (2)$$

where

$$p(w_i, w) = p(w|w_i)p(w_i) \quad (3)$$

$p(w|w_i)$  is defined in Equation (1), and  $p(w) =$

$\frac{\#c(w)}{\sum_{w' \in V} \#c(w')}$ . Equation (2) can be rewritten as:

$$\text{MI}(w_i, w) = \log \left( \frac{\#c(w, w_i)}{\#c(w) \#c(w_i)} \sum_{w' \in V} \#c(w') \right) \quad (4)$$

Generally, a larger value of mutual information between terms indicates larger association while low value or negative value indicates independency. Although low mutual information is proved to be less dependent, high mutual information does not necessarily guarantee high association, especially for low-frequency terms. Therefore, we apply the Refined Mutual Information (RMI) as an improvement (Manning and Schütze, 1999).

$$\text{RMI}(w_i, w) = \begin{cases} \#c(w, w_i) \text{MI}(w, w_i) \\ 0 \quad (\text{if } \text{MI}(w, w_i) < 0) \end{cases} \quad (5)$$

Finally, we normalize RMI into [0, 1] by using  $\text{RMI}_{\max}$ , the maximum value of RMI, as the semantic association by mutual information:

$$\phi_{mi}(w_i, w) = \frac{\text{RMI}(w, w_i)}{\text{RMI}_{\max}} \quad (6)$$

**Thesaurus-Based Correlation.** A word thesaurus represents the semantic associations of terms, which is often formed into a tree with synonyms, hyponyms and hypernyms modeled by “parent-to-child” relationships, e.g., WordNet<sup>1</sup> or Wikipedia<sup>2</sup>. We illustrate part of WordNet as follows in Figure 2:

Figure 2: Hierarchical structure of WordNet: red lines imply a possible path between *car* and *bike*.

There could be many paths from one term to the other, and we define the shortest path as the distance between two terms, denoted as  $\text{dist}(w_i, w)$ . Intuitively, the shorter distance is, the larger semantic association is expected. Hence, we utilize a decreasing sigmoid function to model the semantic association based on thesaurus, denoted as  $\phi_{tc}$ :

$$\phi_{tc}(w_i, w) = \frac{1}{1 + e^{\text{dist}(w_i, w)}} \quad (7)$$

<sup>1</sup><http://wordnet.princeton.edu>

<sup>2</sup><http://wikipedia.org>

**Topic Distribution.** “Topics” have long been investigated as the significant latent aspects for linguistic analysis (Hofmann, 2001; Landauer et al., 1998). The utilization of topic models provides a new horizon to investigate the latent correlations between terms and documents. We apply the unsupervised Latent Dirichlet Allocation (Blei et al., 2003) to discover topics<sup>3</sup>. We obtain the probability distribution over topics assigned to a term  $w$ , i.e.,  $p(w|z)$ . The inferred topic representation is the probabilities of terms belonging to the topic  $z$ , which is

$$z = \{p(w_1|z), p(w_2|z), \dots, p(w_i|z)\}$$

We empirically train a  $k$ -topic model ( $k=100$ ) and invert the topic-term representation in Table 1, where each  $w$  is represented as a topic vector  $\vec{w}$ . The semantic association based on topic distribution  $\phi_{td}(w_i, w)$  between  $w_i$  and  $w$  is measured by the cosine similarity on topic vector  $\vec{w}_i$  and  $\vec{w}$ .

$$\phi_{td}(w_i, w) = \frac{\vec{w}_i \cdot \vec{w}}{\|\vec{w}_i\| \|\vec{w}\|} \quad (8)$$

Table 1: Inverted *topic-term* vector representation.

$\vec{w}_1$	$p(w_1 z_1)$	$p(w_1 z_2)$	...	$p(w_1 z_k)$
$\vec{w}_2$	$p(w_2 z_1)$	$p(w_2 z_2)$	...	$p(w_2 z_k)$
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$
$\vec{w}_{ V }$	$p(w_V z_1)$	$p(w_V z_2)$	...	$p(w_V z_k)$

### 3.2 Intra-/Inter-Document Smoothing

For every position  $i$  to estimate the language model, we can project a term from other positions within the document through the defined semantic association functions, namely *intra-document* smoothing. We can also project all terms from the whole vocabulary set to position  $i$  via  $\phi(\cdot)$ , which is actually an *inter-document* smoothing effect from the global collection and hence solve the zero probability problem.

Before smoothing, the original word count distribution for position  $i$  in document  $d$  is  $\mathcal{D}(i, d)$ , with only  $c(w_i, i, d)=1$  while all other items are 0.

$$\mathcal{D}(i, d) = \left[ \underbrace{[c(w_1, i, d), \dots, c(w_i, i, d), \dots, c(w_{|V_d|}, i, d)]}_{V_d}, \underbrace{[0, \dots, 0]}_{V \setminus V_d} \right]$$

After the semantic based intra-document smoothing, the word count distribution becomes:

$$\mathcal{D}_s(i, d) = \left[ \underbrace{[c'(w_1, i, d), \dots, c'(w_i, i, d), \dots, c'(w_{|V_d|}, i, d)]}_{V_d}, \underbrace{[0, \dots, 0]}_{V \setminus V_d} \right]$$

<sup>3</sup>We use Stanford TMT (<http://nlp.stanford.edu/software/tmt/>), with default parameter settings.

Imagine the whole collection as a long *virtual document*, the terms outside the document vocabulary of  $V_d$  could also be smoothed by inter-document smoothing, i.e.,  $c'(w, i) = c(w)\phi(w_i, w)$ . To control the impact of out-of-document vocabulary, we add a parameter  $\mu \in [0, +\infty)$  here:

$$\mathcal{D}_s(i, d) = \left[ \underbrace{[c'(w_1, i, d), \dots, c'(w_{|V_d|}, i, d)]}_{V_d}, \underbrace{[\mu c'(w_j, i), \dots, \mu c'(w_{|V|}, i)]}_{V \setminus V_d} \right]$$

### 3.3 Positional Proximity based Propagation

Analogously, for the positional-based smoothing, the smoothed count by positional proximity is  $c''(w, i, d) = \sum_{j=1}^{|V|} c(w, j, d)\psi(i, j)$ . We apply the best positional proximity based density function of Gaussian projection  $\psi(i, j)$  in (Lv and Zhai, 2009).  $\sigma$  is a fixed parameter here.

$$\psi(i, j) = \exp\left[\frac{-\Delta(i, j)^2}{2\sigma^2}\right] \quad (9)$$

Analogously to the semantic smoothing, we also include the intra-/inter-document smoothing in the positional count propagation. It is natural to measure the distance offset between two terms within the same document. To measure the position distance between terms from different documents, we define  $\Delta(i, j) = +\infty$  when the term  $w$  at a certain position  $j$  is not from the document which contains  $w_i$ , i.e.,

$$\Delta(i, j) = \begin{cases} |i - j| & (w_j \in d) \\ +\infty & (w_j \notin d) \end{cases} \quad (10)$$

In this way, the projection value of  $\psi(i, j)$  is calculated to be 0 when  $w_j \notin d$ . Actually the definition is rather flexible, the value of projection for terms from different documents is easy to adjust to be non-zero when Equation (10) is changed.

The word count distribution  $\mathcal{D}_p(i|d)$  is as follows after positional proximity based smoothing:

$$\mathcal{D}_p(i, d) = \left[ \underbrace{[c''(w_1, i, d), \dots, c''(w_i, i, d), \dots, c''(w_{|V_d|}, i, d)]}_{V_d}, \underbrace{[0, \dots, 0]}_{V \setminus V_d} \right]$$

### 3.4 Balanced Proximity Combination

We can estimate a language model for the position  $i$  based on the propagated counts reaching the position. Since we have two smoothed language distributions, i.e.,  $\mathcal{D}_s(i|d)$  and  $\mathcal{D}_p(i|d)$ , with uniform representation, we can combine both smoothing

Figure 3: Linear interpolation of two smoothed language models. The upper two word distributions are overlaid into one.

strategies with balance by distribution function superposition, illustrated in Figure 3.

Based on the term propagation, we have a term frequency vector  $\langle w_1, w_2, \dots, w_{|V_d|}, \dots, w_V \rangle$  at position  $i$ , forming a virtual document  $d_i$ .  $\lambda$  is to control the relative contributions from semantic proximity based smoothing and positional proximity based smoothing, formulated as:

$$\begin{aligned} \hat{c}(w, i, d) &= \lambda c'(w, i, d) + (1 - \lambda)c''(w, i, d) \\ &= \lambda \sum_{j=1}^{|V|} c(w, j, d)\phi(w_i, w) + \\ &\quad (1 - \lambda) \sum_{j=1}^{|V|} c(w, j, d)\psi(i, j) \end{aligned} \quad (11)$$

$\phi(w_i, w)$  is to measure the semantic association between  $w$  and the word  $w_i$  from position  $i$ , and  $\psi(i, j)$  is the distance discount factor.

Thus the language model of this virtual document can be estimated as:

$$p(w|i, d) = \frac{\hat{c}(w, i, d)}{\sum_{w' \in V} \hat{c}(w', i, d)} \quad (12)$$

where  $V$  is the vocabulary set.  $\sum_{w' \in V} \hat{c}(w', i, d)$  is actually the length of the virtual document.  $p(w|i, d)$  is the language model at position  $i$ . Thus given a query  $q$ , we can adopt the KL-divergence retrieval model (Lafferty and Zhai, 2001) to score each language model at every position as follows:

$$Score(q, d, i) = - \sum_{w \in V} p(w|q) \log \frac{p(w|q)}{p(w|i, d)} \quad (13)$$

$p(w|q)$  is a query language model. We apply the 1) *best* scoring and 2) *average* scoring of all positions in the document as the retrieval ranking strategy (Lv and Zhai, 2009).

## 4 Experiments

### 4.1 Dataset and Evaluation

In this section, we evaluate the effectiveness of our smoothing strategies empirically. We use four representative TREC data sets: AP (Associated Press news 1988-90), LA (LA Times), WSJ (Wall Street Journal 1987-92) and TREC8 (Disk 4 & 5, the ad hoc data used in TREC8). They represent different sizes and genres, with the same source, queries, and preprocessing procedure as in (Tao et al., 2006; Lv and Zhai, 2009). Table 2 shows the basic statistics of these datasets in detail. We used the title field of a TREC topic description to simulate short keyword queries in our experiments.

Table 2: Detailed basic information of 4 datasets.

	AP	LA	WSJ	TREC8
#doc	242,918	131,896	173,252	528,155
avg(dl)	442.4	492.5	388.7	468.3
qry id	51-150	301-400	51-100 151-200	401-450
#qry	100	100	100	50
#t_qrel	21,819	2,350	10,141	4,728
avg(ql)	4.55	2.63	4.68	2.46

#doc/#qry: number of docs/queries; #t\_qrel: number of relevant docs; avg(dl)/avg(ql): average length of doc/qry.

In each experiment, we first use the baseline model (KL-divergence) to retrieve 2,000 documents for each query, and then use the smoothing methods (or a baseline method) to re-rank them. The top-ranked 1,000 documents for all runs are compared using P@10 and the Mean Average Precisions (MAP) as the main metric.

$$\text{MAP} = \frac{1}{|Q|} \sum_{q \in Q} \frac{1}{|D_r|} \sum_{i=1}^k P_i \times rel_i$$

$|Q|$  is the number of queries,  $|D_r|$  denotes the total number of relevant documents,  $P_i$  is the precision at  $i$ -th position for, also called P@ $i$  (Manning et al., 2008).  $rel_i$  is an indicator function equaling 1 if the item at rank  $i$  is a relevant document, 0 otherwise.

### 4.2 Algorithms for Comparison

We examine the retrieval performance on the standard datasets. The first baseline group is based on the traditional language model. **LM** is the language model without smoothing at all, while **LM+JM** and **LM+Diri** are to smooth the language model with the whole collection as background information, using Jelinek-Mercer (JM) and Dirichlet (Diri) smoothing methods correspondingly (Zhai and Lafferty, 2001b).

We also examine a series of semantic based language smoothing. The most representative semantic smoothing is the Cluster-Based Document

Model (**CBDM**) proposed by Liu et al. (2004). We apply the default settings for the method, (e.g., clustering methods, etc). Semantic based methods use semantically similar documents as a smoothing corpus for a particular document: CBDM clusters documents and smooths a document with the cluster where that document belongs to. However, this method is only based on document-level semantic similarity rather than term-level semantic association.

We also include Positional Language Model (**PLM**) proposed by Lv et al. (2009), which is the state-of-art positional proximity based language smoothing. PLM mainly utilizes positional information while no semantic association is considered. We implemented the best reported PLM kernel with Dirichlet smoothing from the collection for comparison.

Finally we include our proposed Balanced Proximity-based Model, denoted as **BPM**, which formulates semantic proximity and positional proximity into a unified language smoothing framework, with flexible intra-document smoothing and inter-document smoothing. In all, we have 7 methods to compare their performance.

### 4.3 Overall Performance Comparison

In this section, we compare BPM smoothing with several previously proposed methods, using the Dirichlet smoothing prior which performs best as mentioned in these works. The prior parameter is set at 1000 for all methods to rule out any potential influence of Dirichlet smoothing (Liu and Croft, 2004; Tao et al., 2006). For fairness, we conduct the same pre-processing to all methods. The parameter is chosen by 10-fold cross validation.

For baselines, we use the source code from the original author, and report the results we get. The advantage of CBDM, PLM (and BPM) over the simplest language smoothing with Dirichlet and Jelinek-Mercer smoothing has long been proved. We hence focus on the meaningful comparison between the sophisticated smoothing techniques. Note that under the real scenario, as we could not always predefine which kernel would perform best on a particular dataset, for fairness, we take the average performance of all semantic association kernels as the results of BPM, and the parameters are chosen using 10-fold cross validation described in Section 4.4.2. Tables 3 and 4 show that our model outperforms PLM in MAP and P@10 values on four data sets. The improvement presumably comes from the combination of both semantic and positional proximity based smooth-

MAP	LM	LM+JM	LM+Diri	CBDM	PLM	BPM
AP	0.169133	0.179245	0.180625	0.204361	0.204216	<b>0.207428***</b>
LA	0.204195	0.222077	0.219500	<b>0.240332</b>	0.221190	0.231593
WSJ	0.206986	0.220919	0.221066	0.253834	0.269038	<b>0.277115**</b>
TREC8	0.181040	0.214923	0.209676	0.219018	0.240894	<b>0.248852</b>
P@10	LM	LM+JM	LM+Diri	CBDM	PLM	BPM
AP	0.402020	0.403030	0.403030	<b>0.432323</b>	0.418501	0.400000
LA	0.251020	0.256122	0.245918	0.288776	0.278571	<b>0.289913*</b>
WSJ	0.365142	0.369204	0.379826	0.435036	0.423628	<b>0.446802*</b>
TREC8	0.360508	0.368204	0.358496	<b>0.442242</b>	0.425900	0.438028
Time (in sec)	LM	LM+JM	LM+Diri	CBDM	PLM	BPM
PerQuery	0.151803	0.174667	0.180906	337.08198	0.683829	0.918593

Table 3: Overall performance comparison on MAP and P10 results among all methods. \*, \*\*, \*\*\* indicate that we accept the improvement hypothesis of BPM over the best rival baseline by Wilcoxon test at a significance level of 0.1, 0.05, 0.01 respectively. Efficiency is measured in seconds.

ing; intuitively, the lower bound of BPM is the performance of PLM by tuning the combination parameter  $\lambda$  fixed at 1, which is actually a special case for BPM. It is interesting to find that CBDM based on semantic smoothing performs well in some datasets. We further examine into the datasets of LA and TREC8: in these sets, the semantic proximity weights more than positional proximity, i.e., a smaller  $\lambda$  in Figure 4. As CBDM conducts a more principled way of exploiting semantic smoothing by clustering structures, it should not be too surprising for its performance on datasets which emphasize semantic proximity.

**Efficiency.** The LM group is naturally faster without sophisticated calculations. BPM is a little slower than PLM but with consistent better performance. CBDM shows the lowest efficiency due to mass calculations of similarity for clustering.

#### 4.4 Strategy Analysis

Generally speaking, strategies can be sorted into two categories: component selection and parameter tuning. Each time, we tune one strategy while the other one remains fixed.

##### 4.4.1 Component Selection

There is one substitutive component of designing the semantic propagation function, where the term association can be calculated by co-occurrence likelihood  $\phi_{cl}$ , mutual information  $\phi_{mi}$ , thesaurus-based correlation  $\phi_{tc}$  and topic distribution  $\phi_{td}$ . We examine the performance of different functions to calculate the semantic association and the results are listed in Table 4 and 5.

From the tables above, we can see that most of the semantic association functions have slightly different performance, indicating that these four

MAP	$\phi_{cl}$	$\phi_{mi}$	$\phi_{tc}$	$\phi_{td}$
AP	<b>0.208971</b>	0.207159	0.206713	0.206868
LA	<b>0.231850</b>	0.231557	0.231482	0.231483
WSJ	0.276261	<b>0.278372</b>	0.276829	0.276999
TREC8	0.242348	<b>0.251085</b>	0.250977	0.250996

Table 4: MAP of different semantic associations.

P@10	$\phi_{cl}$	$\phi_{mi}$	$\phi_{tc}$	$\phi_{td}$
AP	<b>0.409091</b>	0.392929	0.398990	0.398991
LA	<b>0.294898</b>	0.285571	0.288592	0.290592
WSJ	<b>0.447102</b>	0.436101	0.446986	0.446019
TREC8	0.438008	<b>0.438103</b>	0.437998	0.438002

Table 5: P@10 of different semantic associations.

measurements are all able to capture the semantic proximity based association among terms. Among all semantic proximity functions, the co-occurrence likelihood  $\phi_{cl}$  performs best in most cases, which means it is reasonable and most natural to smooth the zero count of terms if the co-occurred terms appear.

##### 4.4.2 Parameter Settings

There are two free parameters to tune, i.e.,  $\lambda$  and  $\mu$ .  $\lambda$  is to balance the relative contributions from semantic proximity and positional proximity, while  $\mu$  is to control the weight of inter-document smoothing from the whole collection. Keeping one parameter fixed, we vary the other one to examine the changes of its performance based on all datasets. For each of the 4 datasets, we divide the set and use the 10-fold cross validation to train parameters for testings. We illustrate the performance of parameter sensitivity by tuning  $\lambda$  and  $\mu$  based on all semantic association kernels, as shown in Figure 4.

To control the tradeoff between semantic and positional proximity combination, we gradually

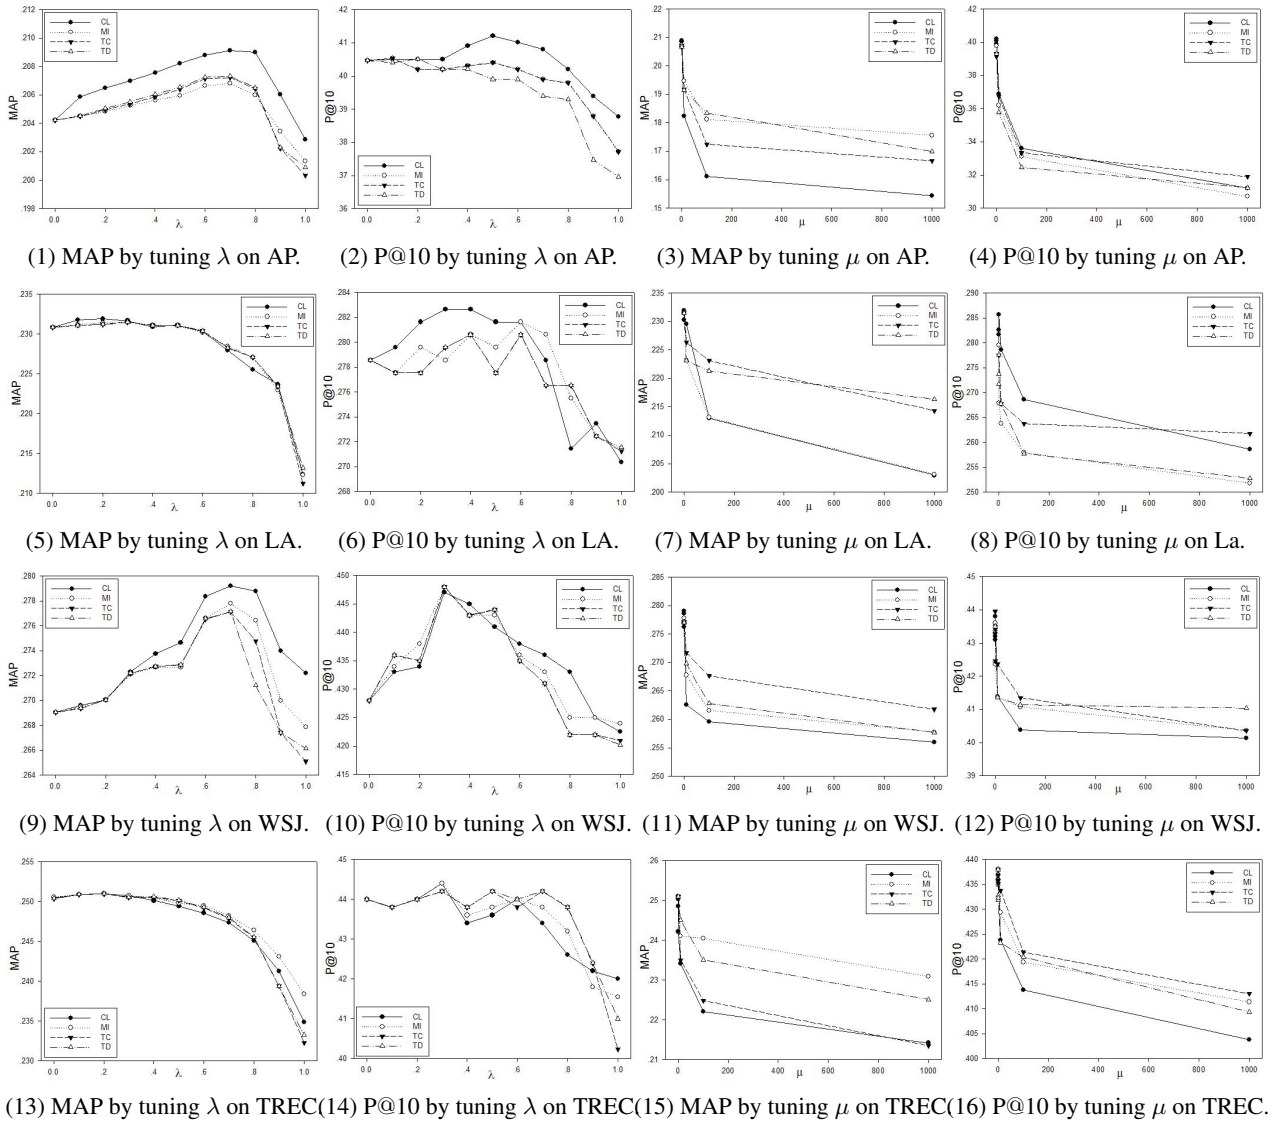

Figure 4: Examine the sensitivity of  $\lambda$  and  $\mu$  by all semantic association functions on all datasets.

change  $\lambda$  from 0 to 1 at the step of 0.1 to examine the effect in Figure 4. The combination of both proximity outperforms the performance in isolation ( $\lambda = 1$  or 0). An interesting observation is that due to the instinct difference of used queries and datasets, the optimal  $\lambda$  varies from one set to another: for AP and WSJ, a larger  $\lambda$  is needed and for LA and TREC8, a small  $\lambda$  is desired perhaps due to the semantic association is more biased for these datasets/corresponding queries: in general, the combination is a better strategy.

We then examine the impact of out-of-document vocabulary controlled by  $\mu$  in Figure 4. Although the performance varies on different datasets as well, for MAP, the performance is generally downward when  $\mu$  grows larger, and for P@10, the performance achieves best when  $\mu$  is relatively small ( $\mu=0.1$  or 0.01), which indicates the impact of inter-document smoothing should not be excessively over introduced.

## 5 Conclusions

In this paper, we combined both semantic and positional proximity heuristics to improve the effect of language model smoothing, which has not been addressed before. We proposed and studied four different semantic proximity-based propagation functions as well as the positional proximity density function to estimate the smoothed language model. Experimental results show that BPM outperforms most alternative baselines in terms of MAP and P@10, which indicates the effectiveness of our proposed method.

Besides the effective fusion of semantic and positional proximity ( $\lambda \neq 0$ ), we further investigate the semantic propagation function, and find that co-occurrence likelihood association performs best. In the future, we will incorporate corpus information such as clustering features into the semantic proximity function for better smoothing.

## Abstract

We design a language model based on a generative dependency structure for sentences. The parameter of the model is the probability of a *dependency N-gram*, which is composed of lexical words with four kinds of extra tags used to model the dependency relation and valence. We further propose an unsupervised expectation-maximization algorithm for parameter estimation, in which all possible dependency structures of a sentence are considered. As the algorithm is language-independent, it can be used on a raw corpus from any language, without any part-of-speech annotation, tree-bank or trained parser. We conducted experiments using four languages: English, German, Spanish and Japanese. The results illustrate the applicability and the properties of the proposed approach.

## 1 Introduction

Statistical language models are a fundamental component of speech recognition systems, machine translation systems, and so forth. Presently, the N-gram language model is the most widely used approach. This model focuses on sequences of neighboring lexical words (Fig. 1), and uses the probabilities of these sequences as model parameters. Due to the full lexicalization of the N-gram language model, local features of word sequences can be well modeled. However, an N-gram language model cannot capture relatively long-range features, because it regards a sentence as a flat string and ignores its structure.

Figure 1: The N-gram language model treats the English sentence “*all things pass*” composed of (*all*, *things*) and (*things*, *pass*), for  $N = 2$ .

Figure 2: The constituency-based parsing (A) and the dependency-based parsing (B)<sup>1</sup> for the English sentence “*all things pass*”.

On the other hand, revealing the structure of a sentence is the task of parsing, which is based on linguistically oriented formulations and focuses on generating the likeliest structure for a given sentence. For this purpose, there are constituency-based and dependency-based formulations (Fig. 2). The former organizes continuous word sequences in a hierarchy of small range to large range groups with linguistically oriented labels; the latter links words with dependency relations<sup>2</sup>.

Figure 3: All possible dependency structures for the English sentence “*all things pass*”. (I) is the linguistically correct structure while the original N-gram language model handles the sentence as if it has the structure labeled (II). We consider all these structures in our unsupervised estimation algorithm.

In this paper, we focus on introducing sentence structure into language modeling. We propose a generative dependency N-gram language model that integrates a generative dependency structure of a sentence into the original N-gram language model. We prefer the dependency-based formula-

<sup>1</sup>For the illustrations in this paper, we use the following representation to show the dependency structure. If two aligned words are on different levels, the upper one is the head of the lower one; if they are on the same level, they are siblings.

<sup>2</sup>In general, the dependency relations can be further classified using linguistically oriented labels. However, they are not indispensable and we do not use them in our approach.

tion because it can directly model the relations between words. In the proposed model, the parameter is the probability of the dependency N-gram, which is a sequence of words along the dependency structure rather than along a flat left-to-right string. The proposed model is thus as fully lexical as the original N-gram language model. We further propose an expectation-maximization (EM) algorithm for estimating the probability of arbitrary order<sup>3</sup> dependency N-grams, by considering all possible dependency structures<sup>4</sup> of a sentence (Fig. 3). The proposed algorithm is unsupervised, language-independent and needs no linguistic information.

## 2 Related Work

The technical report by Chen and Goodman (1998) has compared various approaches to the N-gram language model and the modified Kneser-Ney discounting proposed in it is still the state-of-the-art approach. Since the N-gram language model only captures local lexical features, there have been proposals to generalize the lexical N-gram by word-class (Brown et al., 1992) or to model long-range word co-occurrences by word triggers (Tillmann and Ney, 1997). However, these models are unaware of the sentence structure and basically take a sentence as a flat string.

Many approaches have been proposed for constituency-based parsing (Collins, 1998; Klein and Manning, 2003; Klein and Manning, 2004) and for dependency-based parsing (Eisner, 1996; Lee and Choi, 1997; Kudo and Matsumoto, 2002; Klein and Manning, 2004; Nivre, 2008). Presently, discriminative approaches (Kudo and Matsumoto, 2002; Nivre, 2008) are used more than generative ones for dependency-based parsing, because a generative model is usually restricted to being bi-lexical (i.e., the components are bi-grams of head-modifier pairs) and it is hard to handle more lexical information.

There have been some attempts to integrate sentence structure into language modeling. Chelba and Jelinek (2000) have proposed a constituency-based approach, but the use of language-dependent non-terminals cannot be avoided. There are also dependency-based approaches (Stolcke et al., 1997; Gao and Suzuki, 2003; Graham and van Genabith, 2010). However,

these approaches need a trained dependency parser because they construct a language model based on the decisive best structure produced by the parser.

In our approach, we utilize a generative dependency model to guarantee the constituency of a language model<sup>5</sup>, but our model and algorithm can handle arbitrary numbers of lexical words. Furthermore, our approach needs no extra parser to generate the best structure of a sentence but, instead, takes all possible dependency structures into consideration.

## 3 Generative Dependency Model

We model the marginal probability of a sentence  $S$  over the set  $D$  of all possible dependency structures of  $S$ ,  $P(S) = \sum_{d \in D} P(S, d)$ . As described in Klein and Manning (2004), if we separate the dependency structure and lexicalization, then  $\sum_{d \in D} P(S, d) = \sum_{d \in D} P(d)P(S|d)$ . The term  $P(S|d)$  is given by a model of fully lexical word sequences with dependency relations. However, the term  $P(d)$  is difficult to model and is usually taken to be a constant, as in Paskin (2002). To deal with this problem, the *dependency model with valence* (DMV)<sup>6</sup> proposed by Klein and Manning (2004) introduces a special mark *STOP*. However, it is necessary to distinguish two kinds of parameters,  $P_{\text{STOP}}$  and  $P_{\text{CHOOSE}}$  in the bi-gram estimation, which makes it difficult to extend the approach to higher orders.

In a similar approach to that used in the DMV, we introduce four kinds of tags to normalize the distribution of modifier numbers (the valence) of a head word. In this paper, we use  $\langle L \rangle$ ,  $\langle /L \rangle$ ,  $\langle R \rangle$  and  $\langle /R \rangle$  to show the start and end of the left and right modifier word sequences of a head word, respectively. The dependency structure can thus be organized as nested word sequences. Specifically, a modifier word sequences of a head word is in a form of  $M = m_0^{\phi+1} \equiv m_0, m_1, \dots, m_{\phi+1}$ , where  $m_0 \equiv \langle O \rangle$ ,  $m_{\phi+1} \equiv \langle /O \rangle$  ( $O \in \{L, R\}$ ) and  $m_1^{\phi}$  is a lexical  $\phi$ -word sequence. We show an example of the dependency structure in Fig. 4. On the other hand, in contrast to the DMV, we treat the tags as ordinary words in the parameter estimation. So the parameters of our model have a uniform representation, by which our approach can be easily extended to arbitrary high orders.

<sup>3</sup>“Order” here means the number of lexical words ( $N$ ).

<sup>4</sup>Only projective dependency structures are considered.

<sup>5</sup> $\sum_{S \in L} P(S) = 1$  for the set  $L$  composed of all the sentences  $S$  in a language.

<sup>6</sup>A generative model.

Figure 4: A dependency structure for the English sentence “*i get a book from him .*”, with  $\langle L \rangle$ ,  $\langle R \rangle$ ,  $\langle /L \rangle$ ,  $\langle /R \rangle$  tags. The root of the sentence is marked as  $\langle /s \rangle$  and for a word without modifiers, its modifier word sequences are  $\langle O \rangle \langle /O \rangle$  where  $O \in \{L, R\}$ .

Because our model is essentially equivalent to the generative *Model C* in Eisner (1996), the consistency of the language model can be guaranteed. That is,  $\langle O \rangle m_1^\phi \langle /O \rangle$  ( $O \in \{L, R\}$ ) is generated as a Markov sequence to serve as the modifier word sequences (left/right separately) of the head word. The “start tag”  $\langle O \rangle$  always satisfies  $P(m_0 = \langle O \rangle) \equiv 1$  to represent the nested structure. The “end tag”  $\langle /O \rangle$  terminates the generation process, so: the larger  $P(m_{\phi+1} = \langle /O \rangle)$  is, the smaller  $\phi$ , which is the number of generated words, becomes, and vice versa.

Without loss of generality, the probability of  $m_{\kappa+1}$  ( $0 \leq \kappa \leq \phi$ ) in  $M = m_0^{\phi+1}$  can be represented by  $P(m_{\kappa+1} | m_0^\kappa, H)$ , where  $H$  is the history of  $M$  along the generated path<sup>7</sup>. We use the independent assumption that the probability of a word in the generation process depends on only its direct ancestors and the orientation between them. So, the general probability can be simplified to:

$$P(h^0 | o^1, h^1, \dots, o^{n-1}, h^{n-1}) \quad (1)$$

where  $h^k$  is a lexical word,  $h^{k+1}$  is the head word of  $h^k$ , and  $o^k \in \{\langle L \rangle, \langle R \rangle\}$  is retained in the history to show the dependency orientation.  $\langle /L \rangle$  and  $\langle /R \rangle$  tags can and only can<sup>8</sup> take the place of  $h^0$ .

The sequence  $(h^0, o^1, h^1, \dots, o^{n-1}, h^{n-1})$  in Exp. (1) is referred as a dependency N-gram in this paper. For example, a dependency N-gram is  $(\langle /L \rangle, \langle L \rangle, \text{him}, \langle R \rangle, \text{from}, \langle R \rangle, \text{get}, \langle L \rangle, ., \langle /s \rangle)$  in the dependency structure illustrated in Fig. 4. Exp. (1) is the probability of the dependency N-gram and thus the parameter of our model, where the dependency relation and valence are modeled uniformly for arbitrary order parameters.

<sup>7</sup>The generation process can be realized in a depth-first or a breadth-first way but the distinction is unessential.

<sup>8</sup>Because they cannot have further modifiers.

## 4 Parameter Estimation

### 4.1 Notation

For a sentence  $S = w_0^{l+1} \equiv w_0, w_1, \dots, w_{l+1}$ , where  $w_0 \equiv \langle s \rangle$  and  $w_{l+1} \equiv \langle /s \rangle$ , a dependency N-gram  $(h^0, o^1, h^1, \dots, o^{n-1}, h^{n-1})$  can be denoted by  $\mathbf{d} = (d_0, d_1, \dots, d_{n-1})$  where  $h^k = w_{d_k}$ . That is, a dependency N-gram can be denoted by an N-tuple of the absolute positions of words in a given sentence. As the magnitudes of  $d_k$  and  $d_{k+1}$  show the orientation,  $o^{k+1}$  can be omitted.<sup>9</sup>

Lee and Choi (1997) propose the *complete-link set* and *complete-sequence set* for head-modifier pair (i.e., a dependency bi-gram in our model) to handle all possible projective dependency structures of a sentence in a recursive manner. We follow the terms they use and extend their definitions to adapt them to our dependency N-gram model. We use  $Link(\mathbf{d})$  to denote the complete-link set of an N-tuple  $\mathbf{d}$ , and  $Seq(\mathbf{d})$  for the complete-sequence set.

In Lee and Choi (1997), the complete-link set of a span  $[i, j]$  in a sentence is composed of all possible dependency structures within the span, with the directional dependency link of the two words  $w_i$  and  $w_j$ . The complete-sequence set of a span  $[i, j]$  is defined as the set of all possible sequences with any number (including zero) of adjacent complete-link sets having the same direction within the span. By our notation, i.e. the word at  $d_1$  is the direct head of the word at  $d_0$  for  $Link(d_0, d_1)$ ; but the word at  $d_1$  is an ancestor (not only a direct head) of the word at  $d_0$  for  $Seq(d_0, d_1)$ . The two kinds of sets can be defined recursively and the set of all possible dependency

<sup>9</sup>If  $h^0$  is  $\langle /L \rangle$  or  $\langle /R \rangle$ , we retain them in  $\mathbf{d}$ . The orientations can also be unambiguously omitted for these two tags.

Figure 5:  $Link(\mathbf{d} = (i, j))$ . In Lee and Choi (1997), for a span  $[i, j]$ ,  $Link(i, j)$  is composed of the dependency link of  $w_i$  and  $w_j$ , and all possible pairs of complete-sequence sets  $Seq(x, i)$  and  $Seq(x + 1, j)$ .

Figure 6:  $Seq(\mathbf{d} = (i, j))$ . In Lee and Choi (1997), for a span  $[i, j]$ ,  $Seq(i, j)$  is composed of all possible pairs of complete-sequence set  $Seq(i, x)$  and complete-link set  $Link(x, j)$ .

structures of a sentence  $S = w_0^{l+1}$  is the complete-sequence set over the span  $[1, l + 1]$ . We illustrate these recursive relations in Fig. 5 and Fig. 6.

Because more than two words are involved in the proposed dependency N-gram, we generalize the two kinds of sets for the N-tuples  $\mathbf{d}$  rather than just spans. The generalization still retains the properties of  $d_0$  and  $d_1$  in  $Link(\mathbf{d})$  and  $Seq(\mathbf{d})$ , as well as the recursive properties of the two kinds of sets. We show examples of a dependency tri-gram in Fig. 7 and Fig. 8.

#### 4.2 Recursive Definition

Here, we give the formulation of the recursive definition of the complete-link set and complete-sequence set for an arbitrary order dependency N-gram. First, due to the properties of the projective dependency structure, any  $d_k$  ( $k \in [1, n - 1]$ ) in the N-tuple  $\mathbf{d} = (d_0, d_1, \dots, d_{n-1})$  needs to satisfy the following constraint to guarantee that a head word is outside of the range covered by a chain of its descendants.

$$\begin{aligned} d_k &> \max(d_0, \dots, d_{k-1}), \text{ or} \\ d_k &< \min(d_0, \dots, d_{k-1}) \end{aligned} \quad (2)$$

Trivially, we take  $\langle /s \rangle$  as the *root* mark of a sentence  $S = w_0^{l+1}$ , and the  $\langle s \rangle$  as the head of itself or the  $\langle /s \rangle$ . So, we have the following constraints.

$$d_{k+1} = 0, \text{ if } d_k = l + 1, \text{ or } d_k = 0 \quad (3)$$

For convenience, we introduce three kinds of operations, *Push*, *Cover*, and *Insert* over an in-

Figure 7:  $Link(\mathbf{d} = (i, j, k))$ . In our model, an extended high-order (3 is shown here) complete-link set  $Link(i, j, k)$  is composed of the N-tuple  $\mathbf{d}$ , and all possible pairs of complete-sequence sets  $Seq(x, i, j)$  and  $Seq(x + 1, j, k)$ .

Figure 8:  $Seq(\mathbf{d} = (i, j, k))$ . In our model, an extended high-order (3 is shown here) complete-sequence set  $Seq(i, j, k)$  is composed of all possible pairs of complete-sequence set  $Seq(i, x, j)$  and complete-link set  $Link(x, j, k)$ .

dex  $x$  (absolute word position) and an N-tuple  $\mathbf{d} = (d_0, d_1, \dots, d_{n-1})$ :

$$Push(x, \mathbf{d}) = (x, d_0, d_1, \dots, d_{n-2}) \quad (4)$$

$$Cover(x, \mathbf{d}) = (x, d_1, d_2, \dots, d_{n-1}) \quad (5)$$

$$Insert(x, \mathbf{d}) = (d_0, x, d_2, \dots, d_{n-1}) \quad (6)$$

Then, the  $Link(\mathbf{d})$  and  $Seq(\mathbf{d})$  can be defined by Exp. (7) and Exp. (9) below, where “ $\times$ ” indicates the direct product of sets.

$$\begin{aligned} Link(\mathbf{d}) = & \bigcup_{\substack{\text{if } d_1=l+1, \text{ then } i=d_1-1; \\ \text{else } i \in [\min(d_0, d_1), \max(d_0, d_1)-1]}} \\ & \{Seq(Left(i, \mathbf{d})) \times \\ & Seq(Right(i + 1, \mathbf{d})) \times \mathbf{d}\} \end{aligned} \quad (7)$$

where

$$\begin{aligned} (Left, Right) = & \\ & \begin{cases} (Push, Cover), \text{ if } d_0 < d_1 \\ (Cover, Push), \text{ if } d_0 > d_1 \end{cases} \end{aligned} \quad (8)$$

$$\begin{aligned} Seq(\mathbf{d}) = & \bigcup_{\substack{i \in [\min(d_0, d_1), \max(d_0, d_1)] \\ \text{and } i \neq d_1}} \\ & \{Seq(Insert(i, \mathbf{d})) \times \\ & Link(Cover(i, \mathbf{d}))\} \end{aligned} \quad (9)$$

Exp. (7) shows that a complete-link set is recursively composed of the direct product of all possible complete-sequence set pairs, with the N-tuple  $\mathbf{d}$  itself.<sup>10</sup> Exp. (9) shows that a complete-sequence set is recursively composed of the direct product of all possible pairs of a complete-link set and a smaller complete-sequence set.

To start the recursive definition, we replace  $d_0$  by  $\langle /L \rangle$  and  $\langle /R \rangle$  for all  $Seq(\mathbf{d})$  with  $d_0 = d_1$ <sup>11</sup>.

$$\begin{aligned} Left(x, \mathbf{d}) &= Left(\langle /R \rangle, \mathbf{d}), \\ &\text{if } x = \min(d_0, d_1) \text{ in Exp. (7)} \end{aligned} \quad (10)$$

$$\begin{aligned} Right(x, \mathbf{d}) &= Right(\langle /L \rangle, \mathbf{d}), \\ &\text{if } x = \max(d_0, d_1) \text{ in Exp. (7)} \end{aligned} \quad (11)$$

$$\begin{aligned} Insert(x, \mathbf{d}) &= Push(\langle /L \rangle, \mathbf{d}), \\ &\text{if } x = d_0, \text{ and } d_0 < d_1 \text{ in Exp. (9)} \end{aligned} \quad (12)$$

$$\begin{aligned} Insert(x, \mathbf{d}) &= Push(\langle /R \rangle, \mathbf{d}), \\ &\text{if } x = d_0, \text{ and } d_0 > d_1 \text{ in Exp. (9)} \end{aligned} \quad (13)$$

### 4.3 Estimation

According to the recursive definition, it is natural to derive an inside-outside algorithm (Lari and Young, 1990), which is an adaption of the EM algorithm (Dempster et al., 1977) to tree structures, to conduct parameter re-estimation by calculating the inside and outside probabilities of all complete sets in sentences.

We generalize the expressions in Exp. (7) and Exp. (9) to Exp. (14) and Exp. (15) respectively, where the notation  $\langle \cdot, \cdot \rangle$  stands for an unordered 2-tuple of a complete-set pair.

$$Link(\mathbf{d}) = \bigcup_{\forall \langle Sub_1, Sub_2 \rangle} \{Sub_1 \times Sub_2 \times \mathbf{d}\} \quad (14)$$

$$Seq(\mathbf{d}) = \bigcup_{\forall \langle Sub_1, Sub_2 \rangle} \{Sub_1 \times Sub_2\} \quad (15)$$

We further define  $R_{Link}(Link(\mathbf{d}), \langle Sub_1, Sub_2 \rangle)$  as a relation for  $Link(\mathbf{d}), \langle Sub_1, Sub_2 \rangle$  satisfying Exp. (14). Similarly,  $R_{Seq}(Seq(\mathbf{d}), \langle Sub_1, Sub_2 \rangle)$  is a relation for  $Seq(\mathbf{d}), \langle Sub_1, Sub_2 \rangle$  satisfying Exp. (15). Then, the inside probability  $\beta$  and outside probability  $\alpha$  of the two kinds of complete sets can be calculated by Exp. (16) to Exp. (19),

<sup>10</sup>We further restrict the *root* mark  $\langle /s \rangle$  to take only one modifier (the situation when  $d_1 = l + 1$  in Exp. (7)), according to the general restrictions of the dependency grammar.

<sup>11</sup>From the restriction in Exp. (2),  $d_0$  should not be equal to  $d_1$ . This is only possible for those  $Seq(\mathbf{d})$  at the start of the recursive definition, where the word at  $d_0$  is actually a  $\langle /L \rangle$  tag or a  $\langle /R \rangle$  tag, which does not have an absolute position in a sentence.

where  $p(\mathbf{d})$  is the probability of the lexical dependency N-gram represented by  $\mathbf{d}$  in a sentence.

$$\begin{aligned} \beta(Link(\mathbf{d})) &= \\ &\sum_{\substack{\langle Sub_1, Sub_2 \rangle, \text{ s.t.} \\ R_{Link}(Link(\mathbf{d}), \langle Sub_1, Sub_2 \rangle)}} \beta(Sub_1)\beta(Sub_2)p(\mathbf{d}) \end{aligned} \quad (16)$$

$$\begin{aligned} \beta(Seq(\mathbf{d})) &= \\ &\sum_{\substack{\langle Sub_1, Sub_2 \rangle, \text{ s.t.} \\ R_{Seq}(Seq(\mathbf{d}), \langle Sub_1, Sub_2 \rangle)}} \beta(Sub_1)\beta(Sub_2) \end{aligned} \quad (17)$$

$$\begin{aligned} \alpha(Link(\mathbf{d})) &= \\ &\sum_{\substack{\langle Sup, Con \rangle, \text{ s.t.} \\ R_{Seq}(Sup, \langle Link(\mathbf{d}), Con \rangle)}} \alpha(Sup)\beta(Con) \end{aligned} \quad (18)$$

$$\begin{aligned} \alpha(Seq(\mathbf{d})) &= \\ &\sum_{\substack{\langle Sup, Con \rangle, \text{ s.t.} \\ R_{Link}(Sup, \langle Seq(\mathbf{d}), Con \rangle)}} \alpha(Sup)\beta(Con)p(\mathbf{d}') \\ &+ \sum_{\substack{\langle Sup, Con \rangle, \text{ s.t.} \\ R_{Seq}(Sup, \langle Seq(\mathbf{d}), Con \rangle)}} \alpha(Sup)\beta(Con) \end{aligned} \quad (19)$$

(where  $\mathbf{d}'$  is the N-tuple of *Sup*)

Specifically, Exp. (16) and Exp. (17) can be directly derived from the definitions of Exp. (7) and Exp. (9), respectively. Further, a complete-link set can only be a component of a complete-sequence set from Exp. (9), while a complete-sequence set can be both a component of a complete-link set from Exp. (7), and a component of a complete-sequence set from Exp. (9). As a result, Exp. (18) and Exp. (19) can be derived respectively.

For all  $Seq(\mathbf{d})$  with  $\langle /L \rangle$  or  $\langle /R \rangle$ , we use:

$$\beta(Seq(\mathbf{d})) = p(\mathbf{d}) \quad (20)$$

as the start of the calculation. At the end of the calculation, the probability of the whole sentence  $S = w_0^{l+1}$  can be obtained as:

$$P(S) = \beta(Seq(\mathbf{d} = (1, l + 1, 0, \dots, 0))) \quad (21)$$

For the re-estimation, we can get the probabilistic counts<sup>12</sup> of a dependency N-gram represented by  $\mathbf{d}$  in a sentence using:

$$\beta(Link(\mathbf{d})) \cdot \alpha(Link(\mathbf{d})) \cdot P(S)^{-1} \quad (22)$$

according to the inside-outside algorithm. Finally, all the counts of a dependency N-gram in the training corpus are added and normalized using Exp. (1), to update the model parameters.

<sup>12</sup>They are no longer integers.

<sup>13</sup>For the situation in Exp. (20), we use  $\frac{\beta(Seq(\mathbf{d})) \cdot \alpha(Seq(\mathbf{d}))}{P(S)}$ .

## 5 Experiments

### 5.1 Experiment Setting

#### Corpus

As the proposed dependency N-gram model and estimation algorithm are language-independent, we conduct experiments using four different languages: English, German, Spanish and Japanese. The corpora we use for English, German, and Spanish are the sets of sentences with 5 – 15 words from the corresponding single-language corpora of **Europarl**<sup>14</sup> (Koehn, 2005). The corpus for Japanese is the set of sentences with 5 – 20 words from the Japanese side of the **NTCIR-8** corpus (Fujii et al., 2010). We take one two-hundredth of the sentences from a corpus to form each of the development and test sets used in experiments, and the remaining sentences are used for training. The details of training, development and test sets are shown in Tables 1 and 2.

language	sentences	types	tokens
English	400,100	40,913	4,355,333
German	422,951	105,303	4,545,263
Spanish	370,791	58,314	4,007,816
Japanese	477,118	47,930	7,758,437

Table 1: The training sets.

language	development set	test set
English	2,020	2,021
German	2,136	2,136
Spanish	1,872	1,873
Japanese	2,409	2,410

Table 2: The numbers of sentences in development and test sets.

#### Parameter Collection and Initialization

In order to investigate the fundamental properties of the model and algorithm, we do not use any pruning or approximating methods in the parameter estimation. Specifically, we collect from the raw corpora all possible lexical dependency N-grams<sup>15</sup> without any cut-off thresholds for models of every order. Before estimation, we use relative frequency to initialize the probabilities.

<sup>14</sup><http://www.statmt.org/europarl/>

<sup>15</sup>As Japanese is a typical head-final language, that is, the head word always comes after its modifiers, we only take the left-oriented (from head to modifier) dependency links into account. For the other three languages, dependency links of both two orientations are considered. The parameter collection and initialization do not take the structure into account.

## 5.2 Results

### Algorithm Convergence

Figure 9: The English training set perplexities before each iteration. (The y-axis is logarithmic.)

Figure 9 shows the change of English training set perplexities before each iteration by the proposed estimation algorithm, for 2 (bi-) and 3 (tri-) order dependency N-gram models. The convergence trend along with the iteration times can be observed. For the dependency bi-gram, the training set perplexity becomes nearly stable after 5 iterations. However, for the dependency tri-gram, the first iteration already reaches a very low training set perplexity and it does not change much in further iterations. This phenomenon suggests that the non-pruned dependency tri-gram model may already be too complex a model with too many parameters, so the features of the training set are represented well, resulting in a low perplexity. This suggests the model is over-fitting the data. We discuss this in Sec. 5.3.

#### Test Set Perplexity

As well as the training set perplexity, the perplexity of a test set which has not been used in parameter estimation should be investigated in evaluation. Because different order dependency N-gram models are trained separately, we use linear interpolation in calculating the test set perplexity. Specifically, we use the hand-out development set to tune the interpolation coefficients (weights) and to select the iteration times of different order models to minimize the development set perplexity. Then we use the tuned weights to combine the iteration-time-selected models in the test set perplexity calculation. The reason for using simple and straightforward linear interpolation is also that we want to discover the essential aspects of the proposed model and algorithm, so we use no further smoothing approaches. As the lowest order of a dependency N-gram is two, we use a uni-gram model with modified Kneser-Ney discounting to handle the unknown words. The uni-gram model is interpolated with the dependency bi-gram model. Fur-

language	dev-ppl (bi / tri)	test-ppl (bi / tri)	$iter_{bi}$	$iter_{tri}$	$\lambda_{uni}$	$\lambda_{bi}$	$\lambda_{tri}$
English	145 / 143	159 / 156	6	1	0.93	0.99	0.13
German	268 / 256	265 / 261	12	1	0.88	0.98	0.04
Spanish	165 / 164	159 / 158	7	1	0.92	0.99	0.04
Japanese (left-only)	88 / 67	88 / 67	4	1	0.86	0.99	0.70

Table 3: The development set perplexities (dev-ppl) and test set perplexities (test-ppl) of dependency N-gram models ( $N = 2$  (bi),  $3$  (tri)). The iteration times in dependency bi- and tri-gram model training are  $iter_{bi}$  and  $iter_{tri}$ , respectively. The weights of uni-gram, dependency bi- and tri-gram models are  $\lambda_{uni}$ ,  $\lambda_{bi}$  and  $\lambda_{tri}$ .  $(1 - \lambda_{bi})$  and  $(1 - \lambda_{tri})$  are assigned to the interpolated lower order models and  $(1 - \lambda_{uni})$  is assigned to the  $\langle /L \rangle$  and  $\langle /R \rangle$  tags.

thermore, as the  $\langle /L \rangle$  tag and  $\langle /R \rangle$  tag are taken as general words but they never really appear in a training set, we treat them separately, and interpolate them with the uni-gram model.

language	MLE (bi / tri)	MKN (bi / tri)
English	162 / 457	157 / 86
German	396 / 1371	252 / 139
Spanish	176 / 499	161 / 86
Japanese	62 / 87	91 / 39

Table 4: The test set perplexities of the original N-gram models. MLE is the maximum likelihood estimation realized by setting the *adding delta* to 0 in adding smoothing. MKN is the interpolated modified Kneser-Ney discounting.

In Table 3, we show the development and test set perplexities of the linear-interpolated dependency bi- and tri-gram models. For comparison, we used **SRILM**<sup>16</sup> (Stolcke, 2002) to build two original N-gram language models on the same training sets: one is constructed by maximum likelihood estimation without any smoothing, the other one is constructed by state-of-the-art interpolated modified Kneser-Ney discounting. We calculate the test set perplexities of the two N-gram language models on the same test sets. The results are listed in Table 4. In both Table 3 and Table 4, the perplexities are calculated according to the number of lexical words, and the tags used for normalization are not counted<sup>17</sup>. We discuss these results in Sec. 5.3.

<sup>16</sup><http://www.speech.sri.com/projects/srilm/>

<sup>17</sup>That is, we do not count the  $\langle /s \rangle$  tag in the original N-gram language models, or  $\langle /L \rangle$  and  $\langle /R \rangle$  in our models. If they are included, the perplexities decrease. In the original N-gram model, this is because a  $\langle /s \rangle$  tag nearly always appears after the period mark. The effect is even more dramatic in our model, as each word in a sentence has a  $\langle /L \rangle$  and a  $\langle /R \rangle$  tag to normalize its modifier numbers, so the token number in a sentence is multiplied by. Therefore, we only count the lexical words in perplexity calculation for fairness.

### 5.3 Discussion

#### Parameter Number

For a sentence with  $l$  words, the number of dependency N-gram that can be collected increases exponentially as  $O(l^N)$  if we consider all possible combinations. Although for a given  $N$ , the proposed algorithm takes a time which is polynomial in the sentence length  $l$ , a large  $N$  will be practically intractable, especially for long sentences. In Fig. 10, we show the numbers of complete sets of different order dependency N-gram models for different sentence lengths.

Figure 10: The numbers of complete sets. (The y-axis is logarithmic.)

This behavior is also related to the over-fitting problem because our algorithm is essentially an iterative maximum likelihood estimation. A model that is too complex will be too specific to the training set. From Table 3, we see that the performance of a dependency tri-gram model will saturate after only one iteration, which is also indicated in Fig. 9, and does little to improve the test set perplexities. The exception is Japanese, where the dependency tri-gram does improve the performance. The linguistic reason for this is that Japanese is a head-final language with a simpler syntactic structure, so we restrict the dependency link in Japanese to “left only”, which leads to a model with fewer parameters. Consequently, the high order model performs better. From the experimental results, we can see that the proposed algorithm has the usual strengths and weaknesses of an EM algorithm.

Figure 11: The best dependency structure of the English sentence “*i would , however , add one important caveat .*”

Figure 12: The best dependency structure of the German sentence “*trotzdem möchte ich der kommission einige fragen stellen .*”

### Test Set Perplexity

Comparing the test set perplexities in Tables 3 and 4, we can see the dependency bi-gram model achieves the same, or sometimes better performance of the original N-gram language models. However, when we look at the tri-grams, the interpolated modified Kneser-Ney (KN) discounting method, which is state-of-the-art, shows its strength and our dependency model does not produce much improvement for the reasons we described above<sup>18</sup>. As the modified KN method uses an efficient discounting to avoid the over-fitting problem, and our model has no smoothing, the difference in performance is reasonable for complex models. On the other hand, the generally competitive results of our bi-gram model and its performance on Japanese show that our model is a promising one, particularly if the number of parameters can be reduced.

### Model Preference

In Fig. 11 to Fig. 14, we present examples of the best dependency structures generated by our approach of sentences in test sets. We used the settings in Table 3 and generated them by the Viterbi algorithm (Viterbi, 1967). It can be seen the proposed approach can reveal features of specific languages even though it is unsupervised: e.g. the final-position verb “*stellen*” and its relation with the second-position auxiliary verb “*möchte*” in the German sentence. The results also show a preference for associating semantic relations and making the function words<sup>19</sup> of a language the modifiers of the content words. For example, in the Spanish sentence, syntactically the preposition “*a*”

<sup>18</sup>For Japanese, the result is improved by the dependency tri-gram model, but the original tri-gram model with interpolated modified KN discounting method performs much better.

<sup>19</sup>Articles, prepositions, etc.

Figure 13: The best dependency structure of the Spanish sentence “*la comision está haciendo muchas cosas a este respecto .*”

Figure 14: The best dependency structure of the Japanese sentence “*図 3 は、その実際の配置例である。*”

is the head of the noun “*respecto*”, but in unsupervised training, our model prefers to assign “*a*” to be the modifier of “*respecto*” and directly link two content words: “*respecto*” and the verb “*haciendo*”. We think this is because the probabilities of  $\langle /L \rangle$  and  $\langle /R \rangle$  tags have large estimates, especially when they appear after function words, which prevents them from having modifiers<sup>20</sup>.

## 6 Conclusion and Future Work

In this paper, we proposed a generative dependency N-gram language model and the definition of the complete sets for arbitrary order, by which an unsupervised parameter estimation algorithm is facilitated. The experimental results demonstrate the applicability and the properties of the proposed approach. In future work, we will develop methods of parameter pruning and discounting to handle the over-fitting problem. As the the proposed dependency language model is intrinsically complex, we also plan to do more fundamental simplifications. On the other hand, although our proposed algorithm is unsupervised, the output of a trained parser, which can provide clear and lexical heuristics, can be integrated in it. We will investigate this possibility and evaluate the performance by linguistically motivated criteria.

### Acknowledgment

## Abstract

Discriminative models such as logistic regression profit from the ability to incorporate arbitrary rich features; however, complex dependencies among overlapping features can often result in weight undertraining. One popular method that attempts to mitigate this problem is logarithmic opinion pools (LOP), which is a specialized form of product of experts model that automatically adjusts the weighting among experts. A major problem with LOP is that it requires significant amounts of domain expertise in designing effective experts. We propose a novel method that learns to induce experts — not just the weighting between them — through the use of a mixed  $\ell_2\ell_1$  norm as previously seen in *elitist lasso*. Unlike its more popular sibling  $\ell_1\ell_2$  norm (used in group lasso), which seeks feature sparsity at the group-level,  $\ell_2\ell_1$  norm encourages sparsity within feature groups. We demonstrate how this property can be leveraged as a competition mechanism to induce groups of diverse experts, and introduce a new formulation of elitist lasso MaxEnt in the FOBOS optimization framework (Duchi and Singer, 2009). Results on Named Entity Recognition task suggest that this method gives consistent improvements over a standard logistic regression model, and is more effective than conventional induction schemes for experts.

## 1 Introduction

Conditionally trained discriminative models like logistic regression (a.k.a., MaxEnt models) gain

power from their ability to incorporate a large number of arbitrarily overlapping features. But such models also exhibit complex feature dependencies and therefore are susceptible to the problem of weight undertraining — the contributions of certain features are overlooked because of features they co-occur with (Sutton et al., 2007; Hinton et al., 2012).

One popular method that attempts to mitigate this problem is logarithmic opinion pools (LOP) (Heskes, 1998; Smith et al., 2005; Sutton et al., 2007). LOP works in a similar fashion to a product of experts model, in which a number of experts are individually assembled first, and then their predictions are combined multiplicatively to create an ensemble model. Experts are generated by first partitioning the feature space into subsets, then an independent model (expert) is trained on each subset of features (Sutton et al., 2007). Under the assumption that strongly correlated features are partitioned into separate subsets, this method effectively forces the models to learn how to make predictions with each subset of the features independently. It also helps in scenarios where some strong features stop other features from getting weight, a problem known as feature co-adaptation. The theoretical justification for favoring a product ensemble over an additive ensemble is that inference with a product of log-linear models is significantly easier than inference with a sum. Sutton et al. (2007) also suggests that product ensembles give better results than additive mixtures on sequence labeling tasks.

Smith et al. (2005) and Sutton et al. (2007) showed that the quality of experts and diversity among them have a direct impact on the final performance of the ensemble. Designing effective and diverse experts was left as an art, and requires

a great deal of domain expertise.

In this paper, we directly learn to induce diverse experts by using a mixed  $\ell_2\ell_1$  norm known as *elitist lasso* in the context of generalized linear models (Kowalski and Torr esani, 2009). We design a novel competition mechanism to encourage experts to use non-overlapping feature sets, effectively learning a partition of the feature space. Efficient optimization of a maximum conditional likelihood objective with respect to  $\ell_2\ell_1$  norm is non-trivial and has not been previously studied. We propose a novel formulation to incorporate  $\ell_2\ell_1$  norm in the FOBOS optimization framework (Duchi and Singer, 2009). Experiments on Named Entity Recognition task suggest that our proposed method gives consistent improvements over a baseline MaxEnt model and conventional LOP experts. In particular, our method gives the most improvements in recognizing entity types for out-of-vocabulary words.

## 2 MaxEnt Model

Given an input sequence  $\mathbf{x}$  (e.g., words in a sentence), a MaxEnt model defines the conditional probability of an output variable  $y$  (e.g., named-entity tag of a word) as follows:

$$P(y = v_i | \mathbf{x}) = \frac{\exp\left(\sum_{k=1}^K \theta_k(v_i) f_k(\mathbf{x})\right)}{\sum_{j=1}^V \exp\left(\sum_{k=1}^K \theta_k(v_j) f_k(\mathbf{x})\right)}$$

where  $f_k(\mathbf{x})$  is the  $k$ th input feature,  $K$  is the total number of input features, and  $\theta_k(y)$  is the weight parameter associated with feature  $f_k$  for output class  $v_i$ . We denote the output classes of  $y$  to be  $\{v_1, v_2, \dots, v_V\}$ , where  $V$  is the total number of output classes.

It is helpful to consider the connection between a MaxEnt model and a Linear Network model commonly seen in the neural network literature, by re-expressing this objective using a *softmax* activation function. The softmax function is defined as:

$$\text{softmax}(q(y)) = \frac{\exp(q(y))}{\sum_{y'} \exp(q(y'))}$$

in our case  $q(y) = \sum_{k=1}^K \theta_k(y) f_k(\mathbf{x})$ , and we have:

$$P(y | \mathbf{x}) = \text{softmax}\left(\sum_{k=1}^K \theta_k(y) f_k(\mathbf{x})\right)$$

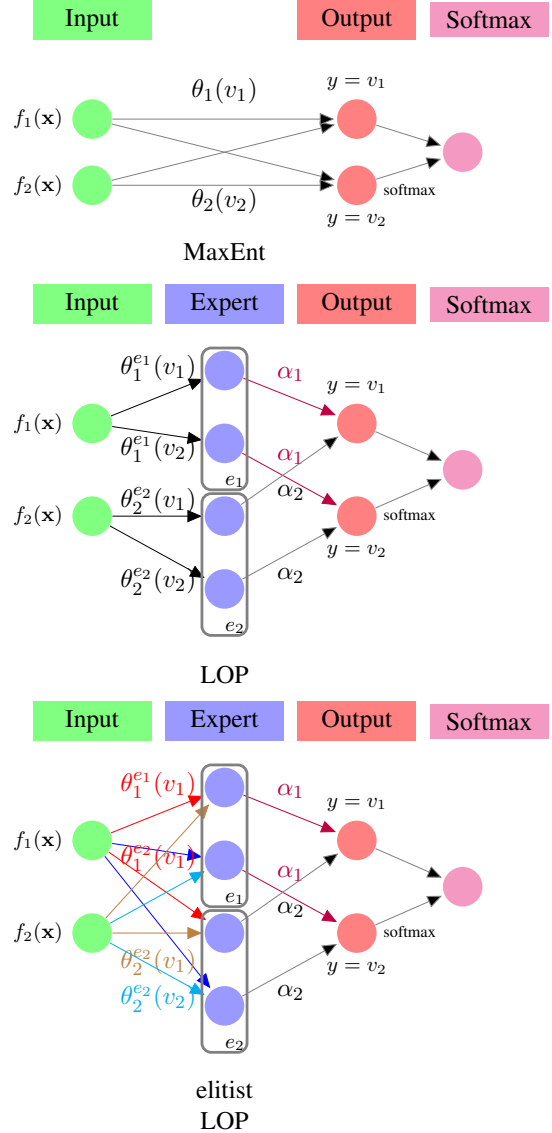

Figure 1: The top part shows a regular MaxEnt model with 2 features and 2 output classes. The middle part shows a LOP with two experts.  $\alpha_1$  and  $\alpha_2$  are the expert mixing coefficients to be learned in the LOP model. The bottom part shows an elitist LOP expert induction model with two experts. For each feature weight parameter  $\theta$ , the superscript denotes which feature group it belongs to (e.g.,  $\theta^{e_1}$  belongs to expert  $e_1$ ); the subscript denotes which input feature it belongs to (e.g.,  $\theta_1$  means it applies to input feature  $f_1(\mathbf{x})$ ); and the value in parentheses denotes which output class this feature is associated with (e.g.,  $\theta(v_1)$  applies to output class  $y = v_1$ ). Features that belong to the same group are shown in the same color.

We visualize this using a neural network style diagram in the top part of Figure 1. In this diagram, the value at each node is computed as the sum of all incoming edge weights (parameters in the model) multiplied by the values of nodes on the originating end of edges. In this example,  $K = 2$  and we have two input features ( $f_1(\mathbf{x})$  and  $f_2(\mathbf{x})$ ); there are two possible value assignments for  $y$  ( $v_1$  and  $v_2$ ). Correspondingly, there are four weight parameters ( $\theta_i(v_j)$ , for  $i = 1, 2, j = 1, 2$ ) as shown by the directed edge going from “Input” layer nodes to “Output” layer nodes. We apply a softmax function to the “Output” layer to produce the probability assignment of each output class.

### 3 Weight Undertraining

The problem of weight undertraining occurs in discriminatively trained classifiers when some strongly indicative features occur during training but not at test time. Because of the presence of such strong features during training, weaker features that occur at both training and test time do not receive enough weight, and thus impede the classifier from reaching its full potential at test time. This phenomenon is also known as feature co-adaptation (Hinton et al., 2012). Sutton et al. (2007) gave an excellent demonstration of this problem using a synthetic logistic regression model. In their example, the output function is the softmax of the linear sum of a set of weights  $x_1$  to  $x_n$ , where each of the  $x_i$  acts as a “weak” predictor. A “strong” feature which takes the form of  $x' = \sum_{i=1}^n x_i + \mathcal{N}$  (where  $\mathcal{N}$  is an added Gaussian noise) is then added to the classifier during training but removed at test time, which simulates a feature co-adaptation scenario. Simulation results show that classifier accuracy can drop by as much as 40% as a result of weight undertraining.

This problem is difficult to combat because we do not know a priori what set of features will be present at test time. However, a number of methods including feature bagging (Sutton et al., 2007), random feature dropout (Hinton et al., 2012), and logarithmic opinion pools (Heskes, 1998; Smith et al., 2005) have been introduced as ways to alleviate weight undertraining.

### 4 Logarithmic Opinion Pools

The idea behind logarithmic opinion pools (LOP) is that instead of training one classifier, we can train a set of classifiers with non-overlapping or

competing feature sets. At test time, we can combine these classifiers and average their results. By creating a diverse set of classifiers and training each of them separately, we can potentially reduce the effect of weight undertraining. For example, when two strongly correlated features are partitioned into different classifiers, they do not overshadow each other. Unlike voting or feature bagging where an additive ensemble of experts is used, LOP derives a joint model by taking a product of experts.<sup>1</sup>

The conditional probability of a LOP ensemble can be expressed as:

$$P_{LOP}(y|\mathbf{x}) = \frac{\prod_{j=1}^n [P_j(y|\mathbf{x})]^{\alpha_j}}{\sum_{y'} \prod_{j=1}^n [P_j(y'|\mathbf{x})]^{\alpha_j}}$$

$$P_j(y|\mathbf{x}) = \text{softmax} \left( \sum_{k=1}^K \theta_k^{e_j}(y) f_k(\mathbf{x}) \right)$$

where  $n$  is the total number of experts,  $P_j(y|\mathbf{x})$  is the probability assignment of expert  $j$ , and  $\alpha_j$  is the mixing coefficient for this expert.

The experts are typically selected so that they capture different signals from the training data (e.g., via feature subsetting). Each expert is trained separately, and their model parameters  $\theta_k^{e_j}(y)$  are fixed during LOP combination.

Early work on LOPs either fixed the expert mixing coefficients to some uniformly assigned value (Hinton, 1999), or used some arbitrary hand-picked values (Sutton et al., 2007). In both of these two cases, no new parameter values need to be learned, therefore no extra training is required.

Smith et al. (2005) proposed to learn the weights by maximizing log-likelihood of the ensemble product model, and showed that the learned weights work better than uniformly assigned values.

We can visualize the LOP again using a network diagram, as shown in the middle part of Figure 1. Two experts are shown in this diagram, each represented by a plate in the “Expert” layer. This example illustrates an expert generation scheme by partitioning the features into non-overlapping subsets – expert  $e_1$  has feature function  $f_1(\mathbf{x})$  while expert  $e_2$  has feature function  $f_2(\mathbf{x})$ . The weights of the two experts are pre-trained and remain fixed. Training the LOP model involves only learning the  $\alpha$  mixing parameters.

<sup>1</sup>A product in the raw probability space is equivalent to a sum in the logarithmic space, and hence the name “logarithmic” opinion pools.

## 5 Automatic Induction of Experts

A major concern in adopting existing LOP methods is that there are no straightforward guidelines on how to create experts. Different feature partition schemes can result in dramatically different performance (Smith et al., 2005). A successfully designed LOP expert ensemble typically involves non-trivial engineering effort and a significant amount of domain expertise. Furthermore, the improvements shown in one application domain by a well-designed feature partition scheme do not necessarily carry over to other domains.

Therefore, it is our goal to investigate and search for effective methods to automatically induce LOP experts. We would like to find a set of experts that are diverse (i.e., having non-overlapping feature sets) and accurate. The main idea here is that we can train multiple copies of MaxEnt models together to optimize training likelihood, but at the same time we encourage the MaxEnt models to differ as much as possible in their choice of features to employ. To meet this end, we use a  $\ell_2\ell_1$  mixed norm to regularize a LOP, and denote the new model as *elitist LOP*.

### 5.1 Elitist LOP

Before we introduce the  $\ell_2\ell_1$  norm, which has not been frequently used in NLP research, let us revisit a closely related but much better known sibling – the  $\ell_1\ell_2$  norm used in group lasso.

For a set of model parameters  $\theta$ , assume we have some feature grouping that partitions the features into  $G$  sub-groups. For simplicity, let us further assume that each feature group has the same number of features ( $M$ ). We denote the index of each feature by  $g$  (for “group”) and  $m$  (for “member”), and use  $\theta_{\hat{g}}$  to denote the feature group of index  $g$ .

The  $\ell_1\ell_2$  mixed norm used in group lasso takes the following form:

$$\begin{aligned} \|\theta\|_{1,2} &= \left( \sum_{g=1}^G \left( \sum_{m=1}^M |\theta_{g,m}|^2 \right) \right)^{1/2} \\ &= \|(\|\theta_{\hat{1}}\|_2, \dots, \|\theta_{\hat{G}}\|_2)\|_1 \end{aligned}$$

This norm applies  $\ell_2$  regularization to each group of features, but enforces  $\ell_1$  regularization at the group level. Since  $\ell_1$  norm encourages sparse solutions, therefore the effect of the mixed norm is to sparsify features at the group level by eliminating a whole group of features at a time.

It is easy to see how it relates to the  $\ell_2\ell_1$  mixed norm, which is given as:

$$\begin{aligned} \|\theta\|_{2,1} &= \left( \sum_{g=1}^G \left( \sum_{m=1}^M |\theta_{g,m}| \right) \right)^2 \Big)^{1/2} \\ &= \|(\|\theta_{\hat{1}}\|_1, \dots, \|\theta_{\hat{G}}\|_1)\|_2 \end{aligned}$$

Like  $\ell_1\ell_2$ , this is also a group-sensitive sparsity-inducing norm, but instead of encouraging sparsity across feature groups, it promotes sparsity within each feature group.

We illustrate how we apply  $\ell_2\ell_1$  norm to induce diverse experts in the bottom diagram in Figure 1. Similar to the case of LOP, we create two “Expert” layer plates, one for each expert ( $e_1$  and  $e_2$ ). But unlike traditional LOP, where each expert only gets a subset of the input features (e.g.,  $f_1(\mathbf{x}) \mapsto e_1$  and  $f_2(\mathbf{x}) \mapsto e_2$ ), each input feature is fully connected to each expert plate (i.e., there are four edges with the same expert superscript from the “Input” layer going into each plate in the “Expert” layer, shown in different colors).

We group every pair of feature weights that originate from the same input feature and end at the same output class into a separate feature group (e.g.,  $\theta_1^{e_1}(v_1)$  and  $\theta_1^{e_2}(v_1)$  belongs to one group, while  $\theta_2^{e_1}(v_1)$  and  $\theta_2^{e_2}(v_1)$  belongs to another group, etc.). In total we have four feature groups, each shown in a different color.

When we apply  $\ell_2\ell_1$  norm to this feature grouping while learning the parameter weights in the LOP model, the regularization will push most of the features that belong to the same group towards 0. But since we are optimizing a likelihood objective, if a particular input feature is indeed predictive, the model will also try to assign some weights to the weight parameters associated with this feature. These two opposite forces create a novel competition mechanism among features that belong to the same group.

This competition mechanism encourages the experts to use different sets of non-overlapping features, thus achieving the diversity effect we want. But because we are also optimizing the likelihood of the ensemble, each expert is encouraged to use parameters that are as predictive as possible. Learning all the experts together can also be seen as a form of *feature sharing*, as suggested by Ando and Zhang (2005) for multi-task learning.

## 5.2 FOBOS with $\ell_2\ell_1$ norm

In our automatic expert induction model with  $\ell_2\ell_1$  norm, the overall objective is given as:

$$\mathcal{L} = \underset{\boldsymbol{\theta}}{\operatorname{argmin}} \left( -\log \left( \frac{\prod_{j=1}^n [P_j(y|\mathbf{x})]^{\alpha_j}}{\sum_{y'} \prod_{j=1}^n [P_j(y|\mathbf{x})]^{\alpha_j}} \right) + \lambda \|(\|\boldsymbol{\theta}_{\hat{1}}\|_1, \dots, \|\boldsymbol{\theta}_{\hat{G}}\|_1)\|_2 \right)$$

where  $\lambda$  is a parameter that controls the regularization strength.

The feature groups are given as:

$$\begin{aligned} \boldsymbol{\theta}_{\hat{1}} &= \{\theta_1^{e_1}(v_1), \theta_1^{e_2}(v_1), \dots, \theta_1^{e_n}(v_1)\} \\ \boldsymbol{\theta}_{\hat{2}} &= \{\theta_2^{e_1}(v_1), \theta_2^{e_2}(v_1), \dots, \theta_2^{e_n}(v_1)\} \\ &\dots \\ \boldsymbol{\theta}_{\hat{K}} &= \{\theta_K^{e_1}(v_1), \theta_K^{e_2}(v_1), \dots, \theta_K^{e_n}(v_1)\} \\ \boldsymbol{\theta}_{\hat{K+1}} &= \{\theta_1^{e_1}(v_2), \theta_1^{e_2}(v_2), \dots, \theta_1^{e_n}(v_2)\} \\ \boldsymbol{\theta}_{\hat{K+2}} &= \{\theta_2^{e_1}(v_2), \theta_2^{e_2}(v_2), \dots, \theta_2^{e_n}(v_2)\} \\ &\dots \\ \boldsymbol{\theta}_{\hat{G}} &= \{\theta_K^{e_1}(v_V), \theta_K^{e_2}(v_V), \dots, \theta_K^{e_n}(v_V)\} \end{aligned}$$

There is a total of  $G = K \times V$  feature groups, and each feature group has  $M = n$  features.

The key difference here from LOP is that the  $\boldsymbol{\theta}$  parameters are not pre-trained and fixed, but jointly learned with respect to  $\ell_2\ell_1$  regularization. In the LOP case, learning the mixing coefficients  $\alpha_i$  ( $i = \{1, \dots, n\}$ ) can be done by taking the gradients of  $\alpha_i$  with respect to the training objective and directly plugging it into a gradient-based optimization framework, such as the *limited memory variable metric* (LMVM) used by Smith et al. (2005) or Stochastic Gradient Descent. However, learning the  $\boldsymbol{\theta}$  parameters in our case is not as straightforward, since the objective is non-differentiable at many points due to the  $\ell_2\ell_1$  norm. We cannot simply throw in an off-the-shelf gradient-based optimizer.

To alleviate the problem of non-differentiability, the recently proposed FOrward-Backward Splitting (FOBOS) optimization framework (Duchi and Singer, 2009) comes to mind. FOBOS is a (sub-)gradient-based framework that solves the optimization problem iteratively in two steps: in each iteration, we first take a sub-gradient step, and then take an analytical minimization step that incorporates the regularization term, which can often be solved with a closed form solution. Formally, each iteration at timestamp  $t$  in FOBOS

consists of the following two steps:

$$\begin{aligned} \boldsymbol{\theta}_{t+\frac{1}{2}} &= \boldsymbol{\theta}_t - \eta_t \mathbf{g}_t & (1) \\ \boldsymbol{\theta}_{t+1} &= \underset{\boldsymbol{\theta}}{\operatorname{argmin}} \left\{ \frac{1}{2} \|\boldsymbol{\theta} - \boldsymbol{\theta}_{t+\frac{1}{2}}\|^2 + \eta_t \varphi(\boldsymbol{\theta}) \right\} & (2) \end{aligned}$$

$\mathbf{g}_t$  is the subgradient of  $-\log(P_{LOP}(y|\mathbf{x}))$  at  $\boldsymbol{\theta}_t$ . Step (1) is just a regular gradient-based step, where  $\eta_t$  is the step size and  $\mathbf{g}_t$  is the sub-gradient vector of parameter vector  $\boldsymbol{\theta}$ . Step (2) finds a new vector that stays close to the interim vector after step (1), but also has a low penalty score according to the regularization term  $\varphi(\boldsymbol{\theta})$  (in our case,  $\varphi(\boldsymbol{\theta}) = \|\boldsymbol{\theta}\|_{2,1}$ ). In the case of  $\ell_1$  and  $\ell_2$  regularization, each feature  $\theta_i$  is independent in step (2), and thus can be solved separately.<sup>2</sup>

Duchi and Singer (2009) gave closed form solutions for solving the minimization problem in step (2) for  $\ell_1$ ,  $\ell_2$ , and  $\ell_1\ell_2$  norms, but no past research has demonstrated how to solve it for  $\ell_2\ell_1$  norm. We leverage the results given by Kowalski and Torr sani (2009) for elitist lasso, and show that parameter  $\theta_{t+1,g,m}$  (the  $m^{\text{th}}$  feature of group  $g$  at timestamp  $t+1$ ) can be solved analytically as follows:

$$\begin{aligned} \theta_{t+1,g,m} &= \operatorname{sign}(\theta_{t+\frac{1}{2},g,m}) \left( |\theta_{t+\frac{1}{2},g,m}| - \tau_g \right)^+ \\ \tau_g &= \frac{\lambda'}{1 + \lambda' M_{\hat{g}}(\lambda')} \left\| x_{t+\frac{1}{2},g,1:M_{\hat{g}}(\lambda')} \right\|_1 \end{aligned}$$

$\operatorname{sign}(x)$  is the mathematical sign function. For  $x \in \mathcal{R}$ , we have  $x^+ = x$  if  $x \geq 0$  and  $x^+ = 0$  if  $x \leq 0$ .  $\lambda' = \eta_t \lambda$  is the regularization weight adjusted by the current step size.

Let  $\bar{\theta}_{\hat{g}}$  denote a new vector that holds the positive absolute value of  $\boldsymbol{\theta}_{\hat{g}}$ , sorted in descending order, i.e.,  $\bar{\theta}_{g,1} \geq \bar{\theta}_{g,2} \geq \dots \bar{\theta}_{g,M}$ .  $M_{\hat{g}}(\lambda')$  is a positive integer given by the following definition:

$$\bar{\theta}_{g,M_{\hat{g}}(\lambda')+1} \leq \sum_{m=1}^{M_{\hat{g}}(\lambda')+1} \left( \bar{\theta}_{g,m} - \bar{\theta}_{g,M_{\hat{g}}(\lambda')+1} \right)$$

and

$$\bar{\theta}_{g,M_{\hat{g}}(\lambda')} > \lambda' \sum_{m=1}^{M_{\hat{g}}(\lambda')} \left( \bar{\theta}_{g,m} - \bar{\theta}_{g,M_{\hat{g}}(\lambda')} \right)$$

<sup>2</sup>This property turns out to be of great importance in real-world large scale scenarios, since it allows the optimization of high-dimensional feature vectors to be parallelized.

$x_{t+\frac{1}{2},g,1:M_{\hat{g}}(\lambda')}$  is then the subset of features from 1 to  $M_{\hat{g}}(\lambda')$  – in descending order of their absolute value – in group  $g$  at timestamp  $t + \frac{1}{2}$ .

One problem with finding the exact solution of elitist lasso as illustrated above is that computing the value  $M_{\hat{g}}(\lambda')$  involves sorting the parameter vector  $\theta$ , which is a  $O(n \log n)$  operation. When the number of features within each group is large, this could be prohibitively expensive. An approximate solution simply replaces  $M_{\hat{g}}(\lambda')$  with the size of the group  $M$ . Kowalski and Torr sani (2009) found that approximated elitist lasso works nearly as well as the exact version, but is faster and easier to implement. We adopt this approximation in our experiments.

With this, we have described a general-purpose method for solving any convex optimization problem with  $\ell_2\ell_1$  norm.

## 6 Experiments

We evaluate the performance of our proposed method on the task of Named Entity Recognition (NER). The first dataset we evaluate on is the standard CoNLL-2003 English shared task benchmark dataset (Sang and Meulder, 2003), which is a collection of documents from Reuters newswire articles, annotated with four entity types: *Person*, *Location*, *Organization*, and *Miscellaneous*. We adopt the BIOES-style annotation standard. Beginning and intermediate positions of an entity are marked with *B*- and *I*- tags, and non-entities with *O* tag. The training set contains 204K words (14K sentences), the development set contains 51K words (3.3K sentences), and the test set contains 46K words (3.5K sentences). The second dataset is the MUC6/7 set, which contains 255K words for training and 59K words for testing. The MUC data is annotated with 7 entity types. It is missing the *Miscellaneous* entity type, but includes 4 additional entity types that do not occur in CoNLL-2003: *Date*, *Time*, *Money*, and *Percent*.

We used a comprehensive set of features from Finkel et al. (2005) for training the MaxEnt model. A total number of 437905 features were generated on the CoNLL-2003 training dataset. The most important features are listed in Table 1.

### 6.1 Experimental Setup

We tuned the regularization parameters in the  $\ell_1$ ,  $\ell_2$  and  $\ell_1\ell_2$  norms on the development dataset via grid search. We used a tuning procedure similar to

<ul style="list-style-type: none"> <li>– The word, word shape (e.g., whether capitalized, numeric, etc.), and letter n-grams (up to 6gram) at current position</li> <li>– The word and word shape of the previous and next position</li> <li>– Previous word shape in conjunction with current word shape</li> <li>– Disjunctive word set of the previous and next 4 positions</li> <li>– Capitalization pattern in a 3 word window</li> <li>– The current word matched against a list of name titles (e.g., Mr., Mrs.)</li> <li>– Previous two words in conjunction with the word shape of the previous word</li> </ul>
--

Table 1: MaxEnt features.

the one used in Turian et al. (2010) where we evaluate results on the development set after each optimization iteration, and terminate the procedure after not observing a performance increase on the development set in 25 continuous iterations. We found 150 to be a good  $\lambda$  value for  $\ell_2$ , 0.1 for  $\ell_1$  and 0.1 for  $\ell_2\ell_1$ . Similarly, we tuned the number of experts for both LOP baselines and the elitist LOP induction scheme. All model parameters were initialized to a random value in  $[-0.1, 0.1]$ .

Results are measured in precision (P), recall (R) and F<sub>1</sub> score. Statistical significance is measured using the paired bootstrap resampling method (Efron and Tibshirani, 1993). We compare our results against a MaxEnt baseline model with both  $\ell_1$  and  $\ell_2$  regularization, as well as an automatic expert induction model with  $\ell_1$  norm.

Two commonly used LOP expert induction schemes were also compared. In the first scheme (*LOP random*), experts are constructed by randomly partitioning the features into  $n$  subsets, where  $n$  is the number of experts. Each expert therefore has  $\frac{1}{n}$ th of the full feature set. The second scheme (*LOP sequential*) works in a similar way, but instead of random partition, we create feature subsets sequentially and preserve the relative order of the features. We also list results reported in Smith et al. (2005) on the same dataset for comparison. They experimented with three manually crafted expert induction schemes (*Smith et al. 05 {simple;positional;label}*) for LOP with a Conditional Random Field (CRF), which is a more powerful sequence model than our MaxEnt baseline.

### 6.2 Main Results

Results on the CoNLL and MUC dataset are shown in Table 2. The proposed automatic expert induction scheme (row *elitist LOP*) gives consistent and statistically significant improvements over the MaxEnt baselines on both CoNLL and MUC test sets.

In particular, on the CoNLL test set, we ob-

	Models	# of experts	Dev Set			Test Set		
			Precision	Recall	F <sub>1</sub>	Precision	Recall	F <sub>1</sub>
CoNLL	MaxEnt- $\ell_2$	1	88.46	87.73	88.09	81.42	81.64	81.53

	Models	IV			OOV		
		Precision	Recall	F <sub>1</sub>	Precision	Recall	F <sub>1</sub>
CoNLL	MaxEnt- $\ell_2$	89.21	86.81	88.00	85.69	80.61	83.08
	elitist LOP	90.25	89.85	90.05 <sup>†</sup>	86.30	86.67	86.49 <sup>†</sup>
MUC	MaxEnt- $\ell_2$	90.21	80.88	85.29	84.90	78.80	81.74
	elitist LOP	92.27	80.02	85.71	87.49	80.62	83.91 <sup>†</sup>

Table 3: OOV and IV results breakdown. <sup>†</sup> indicates statistically significantly better F<sub>1</sub> scores than the MaxEnt- $\ell_2$  baseline.

serve an improvement of 3.7% absolute F<sub>1</sub> over *MaxEnt- $\ell_2$* . The gains are particularly large in recall (by 5% absolute score), although there is also a 2.5% improvement in precision. The two conventional LOP induction schemes also show significant improvements over the MaxEnt baselines on this dataset, with the sequential feature partition scheme working slightly better than the random feature partition. However, elitist LOP outperforms the two LOP schemes by as much as 1% in absolute F<sub>1</sub>, and also gives better results than manually crafted experts for CRFs in Smith et al. (2005).

On the MUC test set, while elitist LOP still outperforms the MaxEnt baselines, the LOP schemes do not help or in some cases hurt performance. This suggests the lack of robustness of LOP which was discussed in Section 5. The automatically learned LOP experts are more robust on this data set, and gives a 0.8% improvement measured in absolute F<sub>1</sub> score over the *MaxEnt- $\ell_2$*  baseline.

The elitist LOP model is more expressive than MaxEnt since it has more parameters to be combined. To understand whether performance gain is obtained by the expressiveness or by the regularization of  $\ell_2\ell_1$  norm, we compare against an elitist

LOP model with just  $\ell_1$  regularization (*LOP- $\ell_1$* ). Results show that the  $\ell_2\ell_1$  norm is a better regularizer for avoiding overfitting with these models. We also see a significant gain in *LOP- $\ell_1$*  over *MaxEnt- $\ell_1$* , suggesting that the expressiveness of the model also helps.

### 6.3 Out-of-vocabulary vs. In-vocabulary

To further understand *how* our method improves over the MaxEnt baseline, we break down the test results into two subsets: words that were seen in the training dataset (in-vocabulary, or IV), versus words that were not (out-of-vocabulary, or OOV). We removed the entity boundary tags (e.g. “I-ORG” becomes “ORG”) so that each word token is evaluated separately. Dividing IV and OOV subsets can be done by checking each word against a lexicon compiled from training dataset.

If our automatic expert induction LOP method does successfully mitigate the weight undertraining problem, we would expect to see an improvement in OOV recognition. The result of this analysis is shown in Table 3.

On the CoNLL dataset, our method gives significant improvements over MaxEnt in both OOV and IV category. In particular, improvement from

OOV subset (3.4% in  $F_1$ ) is larger than the improvement from IV subset (2% in  $F_1$ ). This matches that our hypothesis that our method mitigates the weight undertraining problem and thus gives a stronger boost in OOV recognition.

This effect is even more pronounced on the MUC dataset. The improvement in IV subset in this case is actually quite modest (0.5%), but we get a significant 2.2% improvement from the OOV subset.

## 7 Related Work

Beyond the several aforementioned works that address the issue of weight undertraining, another recent work that looks at this problem is Wang and Manning (2013). They examined the objective function of dropout training prescribed by Hinton et al. (2012), and proposed an approximation of dropout by directly sampling from a Gaussian approximation. The resulting algorithm is orders of magnitude faster than the iterative algorithm given by Hinton et al. (2012). It will be interesting to compare our proposed method with this method in the future.

The use of group-sparsity norms in NLP research is relatively rare. Martins et al. (2011) proposed the use of structure-inducing norms, in particular  $\ell_1\ell_2$  norm (group lasso), for learning the structure of classifiers. A key observation is that during testing, most of the runtime is consumed in the feature instantiation stage. Since  $\ell_1\ell_2$  norm discards whole groups of features at a time, there are fewer feature templates that need to be instantiated, therefore it could give a significant runtime speedup.

Our use of  $\ell_2\ell_1$  norm takes a different flavor in that we explore the internal structure of the model. There is, however, one recent paper that also makes use of  $\ell_2\ell_1$  norm for a similar reason. Das and Smith (2012) employed  $\ell_2\ell_1$  norm for learning sparse structure in a network formed by lexical predicates and semantic frames. Their results show that  $\ell_2\ell_1$  norm yields much more compact models than  $\ell_1$  or  $\ell_2$  norms, with superior performance in learning to expand lexicons.

However, the optimization problem in Das and Smith (2012) was much simpler since all parameters can only take on positive values, and therefore they could directly use a gradient-descent method with specialized edge condition checks. In our work, we have shown a general-purpose method

in the FOBOS framework for optimizing any convex function with  $\ell_2\ell_1$  norm.

A related  $\ell_1$ - $\ell_2$  mixed norm is called *elastic net* (Zou and Hastie, 2005). It was proposed to overcome a problem of lasso (i.e.,  $\ell_1$  regularization), which occurs when there is a group of correlated predictors, and lasso tends to pick one and ignore all the others. Elastic net takes the form of a sum of a  $\ell_1$  and a  $\ell_2$  norm. It was used in Lavergne et al. (2010) for learning large-scale Conditional Random Fields.

Another popular approach that also explores diversity in model predictions is system combination, which is related to bagging predictors (Breiman, 1996). For example, Sang et al. (2000) reported that by combining systems using different tagging representation and diverse classifier models (e.g., support vector machine, logistic regression, naive Bayes), they were able to achieve significantly higher accuracy than any individual classifier alone. This approach has also been applied extensively in Machine Translation (DeNero et al., 2010) and Speech Recognition (Mikolov et al., 2011).

## 8 Conclusion

Our results show that previous automatic expert definition methods used in logarithmic opinion pools lack robustness across different tasks and data sets. Instead of manually defining good (i.e., diverse) experts, we demonstrated an effective way to induce experts automatically, by using a sparsity-inducing mixed  $\ell_1\ell_2$  norm inspired by elitist lasso. We proposed a novel formulation of the optimization problem with  $\ell_2\ell_1$  norm in the FOBOS framework. Our method gives consistent and significant improvements over a MaxEnt baseline with fine-tuned  $\ell_2$  regularization on two NER datasets. The gains are most evident in recognizing entity types for out-of-vocabulary words.

## Abstract

From an efficiency viewpoint, information extraction means to filter the relevant portions of natural language texts as fast as possible. Given an extraction task, different pipelines of algorithms can be devised that provide the same precision and recall but that vary in their run-time due to different pipeline schedules. While recent research investigated how to determine the run-time optimal schedule for a collection or a stream of texts, this paper goes one step beyond: we analyze the run-times of efficient schedules *as a function of the heterogeneity* of the texts and we show how this heterogeneity is characterized from a data perspective. For extraction tasks on heterogeneous big data, we present a self-supervised online adaptation approach that learns to predict the optimal schedule depending on the input text. Our evaluation suggests that the approach will significantly improve efficiency on collections and streams of texts of high heterogeneity.

## 1 Introduction

Information extraction analyzes natural language text in order to find relevant information about entities and the events they participate in. An extraction task often requires to fill event templates with considerable numbers of slots. Such a task implies several analysis steps, e.g. certain types of entity and relation extraction, and it is therefore typically tackled with a pipeline  $\Pi = \langle \mathbf{A}, \pi \rangle$ , where  $\mathbf{A}$  is a set of extraction algorithms and  $\pi$  a schedule that prescribes the order of algorithm application. The information sought for is anchored in text units of a certain size, e.g. in a sentence or paragraph.

In times of big data, the run-time efficiency of information extraction receives much attention in research and industry (Chiticariu et al., 2010).

Among others, a growing need for business intelligence can be regarded as the driving force behind. This trend is equally observed by consulting companies who see evolving markets for predictive analytics (Harper, 2011), by global software players who exploit big data for decision making (White, 2011), and by researchers who seek to annotate tables at web scale (Limaye et al., 2010).

Generally, a pipeline  $\Pi = \langle \mathbf{A}, \pi \rangle$  can be sped up by parallelization (Agichtein, 2005), if given enough resources, or by using faster but less effective algorithms (Al-Rfou' and Skiena, 2012). In addition, information extraction can always be approached as a filtering task as discussed in detail in (Wachsmuth et al., 2013b): By filling a template slot, each algorithm in  $\mathbf{A}$  implicitly classifies certain units of an input text as relevant. Only these units need to be filtered for the next algorithm in  $\pi$ . As a result, a smart schedule  $\pi$  will often significantly improve the overall extraction efficiency. If the input requirements of all algorithms in  $\mathbf{A}$  are met within  $\pi$ , the effectiveness of  $\Pi$  (in terms of both precision and recall) will be maintained, since the output of  $\Pi$  exactly lies in the filtered text units (Wachsmuth and Stein, 2012).<sup>1</sup>

When given a big data filtering task, the designer of a pipeline faces two challenges: (1) How to determine the most efficient schedule for a set of extraction algorithms and a collection or a stream of texts? (2) How to maintain efficiency under heterogeneous text characteristics? With regard to the former challenge we resort to existing research (cf. Section 2). The latter becomes an issue where input texts are not fully known or come from different sources as in the web. Moreover, streams of texts can undergo substantial changes in the distri-

<sup>1</sup>The simplest filtering task is to extract a relation between two entity types, such as  $\langle \text{ORG} \rangle$  was founded in  $\langle \text{TIME} \rangle$ . E.g., the sentence "Google was established by two Stanford students." needs not to be filtered for relation extraction, as it contains no time entity. The schedule of the two implied entity recognition steps will affect the extraction efficiency.

bution of relevant information. We argue that such kinds of uncertainty and lack of a-priori knowledge cannot be tackled offline, but they require to learn and to adapt to the characteristics of input texts to avoid a noticeable efficiency loss.

### 1.1 Contributions and Outline

In this paper, we analyze to what extent the heterogeneity of natural language texts in the distribution of relevant information affects the efficiency of an information extraction pipeline. For a high heterogeneity, we propose an adaptation of the pipeline’s schedule, which we address with online learning. Our learning algorithm maps basic linguistic characteristics of a text to run-times of pipelines and chooses the pipeline with the lowest predicted run-time. The algorithm learns self-supervised and it is language-independent. To measure the impact of heterogeneity, we evaluate the algorithm on precisely constructed text corpora of different heterogeneity. Our contributions are three-fold:

1. We develop a self-supervised online adaptation algorithm that learns the efficiency of information extraction pipelines (Section 3).
2. We quantify the heterogeneity of natural language texts with regard to the distribution of relevant information (Section 4).
3. We evaluate the need for online adaptation in efficient information extraction as a function of the heterogeneity of input texts (Section 5).

## 2 Related Work

One line of research on extraction efficiency refers to *declarative information extraction* (Shen et al., 2007). In particular, Krishnamurthy et al. (2009) created SYSTEMT to address the needs of enterprise extraction applications. SYSTEMT involves optimization strategies such as the ordering and integration of analysis steps (Reiss et al., 2008), but it is restricted to rule-based extraction.

In (Wachsmuth et al., 2011a), we introduced a method that optimizes the schedule of an arbitrary set of extraction algorithms. This method captures much optimization potential and it can be automated using techniques from artificial intelligence (Wachsmuth et al., 2013a). Unlike the approach in this paper, however, the method does not handle variances in the characteristics of input texts.

Our approach applies to all extraction tasks with dependencies between the relevant types of information. We target at template filling, which con-

sists in relating a number of entities to events of predefined types (Cunningham, 2006). Recent research, e.g. (Jean-Louis et al., 2011), and major evaluation tracks, e.g. (Kim et al., 2011), show the ongoing importance of template filling.

We consider extraction pipelines that perform filtering, which have a long tradition (Cowie and Lehnert, 1996). Sarawagi (2008) sees the efficient filtering of relevant portions of input texts as a main challenge. In the pipelines we focus on, each algorithm takes on one analysis (Grishman, 1997). Other approaches such as *joint information extraction* (Choi et al., 2006) can be effective, but they are not suitable when efficiency is important.

van Noord (2009) trades parsing efficiency for parsing effectiveness by learning a heuristic filtering of useful parses. In contrast, we develop a self-supervised online learning algorithm to achieve efficient extraction without reducing effectiveness. While our approach works with every predefined relation and event type, arbitrary binary relations are found in self-supervised *open information extraction* (Fader et al., 2011). Self-supervised learning aims to fully overcome manual text labeling, mostly for learning language like McClosky et al. (2010). To our knowledge, we are the first to apply it for predicting extraction efficiency.

## 3 Learning Efficient Extraction

The run-time efficiency of an information extraction pipeline depends on the distribution of relevant information in its input texts (Wachsmuth and Stein, 2012). For situations where this distribution varies, we now present an approach that chooses a pipeline schedule depending on the text at hand. To maintain precision and recall, we consider only schedules that fulfill the input requirements of all algorithms employed in a pipeline.

### 3.1 Splitting the Pipeline

Most extraction tasks require some analyses (e.g. tokenization) to be performed on the whole input texts, as they are needed for most or all subsequent analyses. We exploit this notion in that we use the results of the first algorithms in a pipeline to predict the best schedule of the remaining algorithms. To this end, we split a pipeline into a fixed first part and a variable second part. We call the first part the *prefix pipeline*, denoted as  $\Pi_{pre}$ , and each second part  $\Pi_1, \dots, \Pi_k$  a *main pipeline*.

In general,  $k$  has an upper bound of  $m!$  where  $m$  is the number of algorithms in a main pipeline.

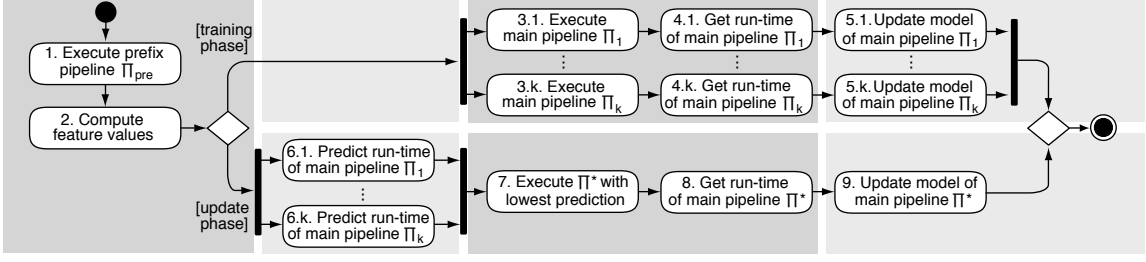

Figure 1: Illustration of the online adaptation algorithm with a prefix pipeline  $\Pi_{pre}$  and  $k$  main pipelines  $\Pi_1, \dots, \Pi_k$  for one input text, which either goes through the training phase or through the update phase.

Due to the algorithms' input constraints, however,  $k$  is normally much lower in practice. Also, there might be ways to restrict the set of candidate schedules to a reasonable selection, which is itself a non-trivial problem that is beyond the scope of this paper. In the following, we simply assume that  $k \leq m!$  main pipelines are given.

### 3.2 Self-Supervised Learning of Run-times

For a collection or a stream of texts  $\mathbf{D}$ , our goal is to determine the most efficient main pipeline for each text in  $\mathbf{D}$ . We approach this goal as an online regression problem by learning to predict the run-time per text unit  $t(\Pi_i)$  of each main pipeline  $\Pi_i \in \{\Pi_1, \dots, \Pi_k\}$ . Based on the results of  $\Pi_{pre}$ , we represent each text  $D \in \mathbf{D}$  as a feature vector  $(x_1, \dots, x_p)$  in order to create a regression model for each  $t(\Pi_i)$ . Concretely, we map the feature values  $x_1^{(D)}, \dots, x_p^{(D)}$  for  $D$  to a predicted run-time  $\tilde{t}(\Pi_i)$ . Then,  $D$  is processed by the main pipeline  $\Pi^*$  with the lowest prediction.

In this manner, learning can be approached self-supervised, as all training data is generated automatically: the feature values and the observed run-time  $t(\Pi^*)$  of  $\Pi^*$  on  $D$  serve as a new training instance, and the prediction error is given by the difference between  $\tilde{t}(\Pi^*)$  and  $t(\Pi^*)$ . Still, an explicit training set that is processed by all main pipelines helps to create initial regression models.

### 3.3 The Online Adaptation Algorithm

Let a prefix pipeline  $\Pi_{pre}$ , a set of main pipelines  $\Pi_1, \dots, \Pi_k$ , and a collection or a stream of texts  $\mathbf{D}$  be given. Then  $\mathbf{D}$  is split into two parts  $\mathbf{D}_T$  and  $\mathbf{D}_U$  to serve the following two phases of the *online adaptation algorithm*:

1. *Training*. On each text  $D \in \mathbf{D}_T$ , execute  $\Pi_{pre}$  and each  $\Pi_i \in \{\Pi_1, \dots, \Pi_k\}$ . Update the regression model of each  $\Pi_i$  wrt. the results of  $\Pi_{pre}$  and the run-time  $t(\Pi_i)$  of  $\Pi_i$  on  $D$ .

2. *Update*. On each text  $D \in \mathbf{D}_U$ , execute  $\Pi_{pre}$  and predict  $\tilde{t}(\Pi_i)$  for all  $\Pi_i \in \{\Pi_1, \dots, \Pi_k\}$ . Execute the  $\Pi^*$  with the lowest prediction and update its regression model wrt. the results of  $\Pi_{pre}$  and the run-time  $t(\Pi^*)$  of  $\Pi^*$  on  $D$ .

Figure 1 illustrates the online adaptation algorithm on one single text. An intuitive extension is to iteratively schedule each extraction algorithm separately. This would allow us to use detailed knowledge in later predictions. Since the first predictions are most decisive, however, we do not consider the iterative scenario here for simplicity.

### 3.4 Baselines and the Gold Standard

One way to evaluate our approach is to compare it to each pipeline  $(\Pi_{pre}, \Pi_i)$ ,  $\Pi_i \in \{\Pi_1, \dots, \Pi_k\}$ . In practice, relying on such a fixed pipeline involves the danger of choosing a slow one. Hence, we also consider two baseline approaches below:

1. *Random baseline*. For each text  $D \in \mathbf{D}_U$ , choose a main pipeline (pseudo-) randomly.
2. *Optimal baseline*. For each text  $D \in \mathbf{D}_U$ , choose the main pipeline that has achieved the best overall run-time on  $\mathbf{D}_T$ .

The optimal baseline serves as a strong competitor on homogeneous collections and streams of texts, where it will often find the run-time optimal fixed pipeline. In contrast, the random baseline appears rather weak, but it will never fail completely.

Besides, we compute the *gold standard* below, i.e., an oracle that knows the fastest main pipeline for each text beforehand. The gold standard defines the upper ceiling for a set of main pipelines, thereby quantifying the general optimization potential. In that, it helps to evaluate whether online adaptation is suitable for the input texts at hand.

## 4 The Heterogeneity of Texts

The introduced algorithm is domain-independent and language-independent. It targets at situations

where input texts are heterogeneous in content or style, as is typical for the results of an exploratory web search. From an extraction perspective, the heterogeneity of a collection or a stream of texts  $\mathbf{D}$  can be regarded as the extent to which the texts in  $\mathbf{D}$  vary in the distribution of instances of the relevant *information types*  $C_1, \dots, C_m$ , i.e., the entity, relation, and event types to be extracted.

As motivated in Section 1, text units need to be analyzed only if they may contain instances of all relevant information types. Hence, a pipeline’s efficiency depends on the *density*  $\rho_i(\mathbf{D})$  of each type  $C_i$  in the input texts in  $\mathbf{D}$ . Here, the density corresponds to the fraction of text units in  $\mathbf{D}$  that contain an instance of  $C_i$ . The density  $\rho_i(D)$  of  $C_i$  in a single text  $D \in \mathbf{D}$  can be defined accordingly. Now, differences in the run-time per text unit of a pipeline mainly result from varying densities  $\rho_i(D)$ . In this regard, the heterogeneity of  $\mathbf{D}$  can be quantified by measuring the variance of all densities in the texts in  $\mathbf{D}$ . The outlined considerations give rise to the following measure:

**Averaged Deviation** Let  $\mathbf{C} = \{C_1, \dots, C_m\}$  be the set of relevant information types for an extraction task, and let  $\sigma_i(\mathbf{D})$  be the standard deviation of the density  $\rho_i(\mathbf{D})$  of  $C_i \in \mathbf{C}$  in a collection or a stream of texts  $\mathbf{D}$ . Then, the averaged deviation of  $\mathbf{C}$  in  $\mathbf{D}$  is

$$\sigma(\mathbf{C}|\mathbf{D}) = \frac{1}{m} \cdot \sum_{i=1}^m \sigma_i(\mathbf{D}).$$

We compute exact values  $\sigma(\mathbf{C}|\mathbf{D})$  in Section 5 to measure the impact of heterogeneity. In general, the averaged deviation can also be estimated on a sample of texts. For illustration, Table 1 lists the deviations for the three most common named entity types in the German part of the *CoNLL’03 corpus* (Tjong Kim Sang and De Meulder, 2003), in the *Revenue corpus* (Wachsmuth et al., 2010), in a sample of the German Wikipedia (the first 10,000 articles according to internal page ID), and in the *LFA-11 smartphone corpus*, which is a web crawl of blog posts (Wachsmuth and Bujna, 2011). Here, we recognized entities using *Stanford NER* (Finkel et al., 2005; Faruqui and Padó, 2010).

Different from other sampling-based efficiency estimations, cf. (Wang et al., 2011), the averaged deviation does *not* measure the typical characteristics of input texts, but it quantifies how much these characteristics vary. By that, it helps pipeline designers to decide whether an online adaptation of pipeline schedules is needed to ensure efficient ex-

Information type $C_i$	$\sigma_i(\mathbf{D}_{\text{co}})$	$\sigma_i(\mathbf{D}_{\text{rv}})$	$\sigma_i(\mathbf{D}_{\text{wk}})$	$\sigma_i(\mathbf{D}_{\text{bp}})$
Person entities	18.4%	11.1%	15.9%	16.6%
Organization entities	18.1%	16.0%	14.1%	23.4%
Location entities	16.6%	10.9%	16.0%	15.3%
<b>Averaged deviation</b>	<b>17.7%</b>	<b>12.7%</b>	<b>15.3%</b>	<b>18.4%</b>

Table 1: The standard deviation  $\sigma_i$  of the density of three entity types in the CoNLL’03 corpus  $\mathbf{D}_{\text{co}}$ , the Revenue corpus  $\mathbf{D}_{\text{rv}}$ , a sample of 10,000 Wikipedia articles  $\mathbf{D}_{\text{wk}}$ , and a crawl of blog posts  $\mathbf{D}_{\text{bp}}$ . The bottom line shows their averaged deviations.

traction. However, its current form leaves unclear how to compare deviations across tasks. In future work, a solution will be to normalize the averaged deviation—either with respect to a reference corpus or with respect to the given task, e.g. to a situation where all schedules perform equally well.

#### 4.1 Text Corpora of Different Heterogeneity

For a careful evaluation of online adaptation, we need input texts that refer to different levels of heterogeneity while being appropriate for analyzing a single and sufficiently complex filtering task at the same time. Most corpora for extraction tasks are too small to create reasonable subsets of different heterogeneity like  $\mathbf{D}_{\text{co}}$  and  $\mathbf{D}_{\text{rv}}$ . As an alternative, a web crawl such as  $\mathbf{D}_{\text{bp}}$  typically yields high heterogeneity, but it tends to include a large fraction of task-irrelevant texts. This conceals which efficiency differences are due to scheduling and, thus, is not suitable for controlled experiments.

To address this difficulty, we also use precisely constructed text corpora below, which consist of both original texts from existing corpora and artificially modified versions of these texts. Concretely, we modified a text by randomly duplicating one of its sentences, ensuring that each text in a corpus comprises a unique set of sentences while being grammatically valid. Thereby, we limit the online adaptation algorithm to a certain degree in learning linguistic features from the texts, but we gain that we can measure the benefit of online adaptation as a function of the averaged deviation.

## 5 Evaluation

We now present controlled experiments with the online adaptation algorithm on text corpora of different heterogeneity. The goal is to show the circumstances under which online adaptation will be needed for efficiency and, conversely, when a run-time optimal fixed pipeline appears sufficient.

## 5.1 Experimental Set-up

We consider the filtering task to extract financial forecast statements with resolvable time information and a monetary value for an organization. An example for such a statement is “*Apple’s annual revenues could hit \$400 billion by 2015*”. Accordingly, we have a set  $C$  of five relevant information types: time entities, money entities, organization entities, financial statements, and forecast events.

**Algorithms** Table 2 outlines the eight algorithms that we used in all experiments. We employed the *UIMA tokenizer*<sup>2</sup> to generate tokens and sentences, and the *TreeTagger* for part-of-speech tagging and chunking (Schmid, 1995). As in (Wachsmuth et al., 2011a), we relied on regexes for money and time recognition, while we applied support vector machines SD and FD for event detection. Organization names were extracted with the CRF-based *Stanford NER* (cf. Section 4). Finally, we implemented a rule-based time normalizer TN.

While, in general, our approach works for each kind of extraction algorithm, all algorithms in Table 2 perform only in-sentence extraction.

**Pipelines** As stated in Section 3, we split all pipelines into two parts. The prefix pipeline consists of the two algorithms used for preprocessing only:  $\Pi_{pre} = (UT, TT)$ . For the reasons given below, we evaluated the following  $k = 3$  main pipelines:

$$\Pi_1 = (TR, FD, MR, SD, TN, OR)$$

$$\Pi_2 = (TR, MR, FD, TN, OR, SD)$$

$$\Pi_3 = (MR, TR, FD, OR, SD, TN)$$

Only 108 of the  $6! = 720$  possible main pipelines fulfill all dependencies listed in Table 2. Based on the method from (Wachsmuth et al., 2011a), we found that main pipelines starting with TR, MR, and FD (which are significantly faster than OR, SD, and TN) dominate others. We selected  $\Pi_1$ ,  $\Pi_2$ , and  $\Pi_3$ , as they target at very different distributions of relevant information. While  $k = 3$  appears small, it allows for a concise evaluation and suffices to discuss the impact of online adaptation. Still, we evaluate all 108 main pipelines in Section 5.4.

**Features** For generality, we restricted our view to simple features that neither require a preceding run over the training set nor exploit knowledge about the employed algorithms: (1) *Lexical statistics*, namely, the average and maximum number of characters in a token and of tokens in a sentence as

<sup>2</sup>UIMA tokenizer, <http://uima.apache.org/sandbox.html>.

Algorithm $A$	$t(A)$	depends on
UT UIMA tokenizer	0.06 ms	–
TT TreeTagger	0.59 ms	UT
TR Time recognition	0.36 ms	UT
MR Money recognition	0.64 ms	UT
OR Organization recognition	2.52 ms	UT, TT
SD Financial statement detection	3.95 ms	UT, TR, MR
FD Forecast event detection	0.29 ms	UT, TT, TR
TN Time normalization	0.95 ms	UT, TR

Table 2: Each evaluated algorithm  $A$  with its estimated average run-time per sentence  $t(A)$  and the algorithm  $A$  depends on.

well as the length of the text, (2) the average *run-times* per sentence of each algorithm in  $\Pi_{pre}$ , and (3) the frequencies of all *part-of-speech tags*.

In the feature evaluation in Section 5.4, we also have two further types that capture general characteristics of entities: (4) The frequency of each unigram and bigram of all *chunk tags* and (5) the frequencies of *regex matches* of a regex for arbitrary numbers and of a regex for upper-case words.<sup>3</sup>

**Learning Algorithm** For run-time prediction, we applied *Stochastic Gradient Descent (SGD)* from *Weka 3.7.5* (Hall et al., 2009). After some preliminary tests, we set the learning rate of SGD to 0.01 for all experiments. Accordingly, we always used  $10^{-5}$  for regularization and we always let SGD iterate 10 epochs over the training texts.

**Datasets** We constructed four partly artificial corpora  $D_0, \dots, D_3$  as motivated in Section 4.1. In case of  $D_0$ , we randomly mixed 1500 texts of the German CoNLL’03 corpus and the Revenue corpus (cf. Section 4).<sup>4</sup> For  $D_1$ , we took the 300 texts from  $D_0$  with the highest differences in the density of relevant information. We created modified versions of these texts in order to obtain a corpus size of 1500.  $D_2$  and  $D_3$  were built analogously for the 200 and 100 highest-difference texts, respectively. Table 3 lists all averaged deviations for the text unit “sentence”. Where not stated otherwise, we used the first 500 texts of each corpus for training and the remaining 1000 for testing.

**Efficiency** The efficiency of all pipelines on each text was measured as the *run-time in milliseconds per sentence*, averaged over 10 runs. All run-times and their standard deviations were saved. For determinism, we loaded these run-times during eval-

<sup>3</sup>We experimented with further regexes, but their impact was low. Therefore, we do not report on them in this paper.

<sup>4</sup>Notice that the evaluated set of features does not target at characteristics that are specific to the German language.

Information type	$C_i$	$\sigma_i(\mathbf{D}_0)$	$\sigma_i(\mathbf{D}_1)$	$\sigma_i(\mathbf{D}_2)$	$\sigma_i(\mathbf{D}_3)$
Time entities		19.1%	22.5%	24.6%	25.9%

Organization entities		19.3%	21.6%	22.4%	25.0%
Financial statements		7.1%	7.8%	8.9%	10.6%
Forecast events		3.8%	5.9%	6.7%	8.5%
<b>Averaged deviation</b>		<b>13.8%</b>	<b>15.4%</b>	<b>16.6%</b>	<b>18.5%</b>

Table 3: The standard deviation  $\sigma_i(\mathbf{D})$  of the density of each relevant information types  $C_i \in \mathbf{C}$  for each corpus  $\mathbf{D} \in \{\mathbf{D}_0, \dots, \mathbf{D}_3\}$  as well as the averaged deviation  $\sigma(\mathbf{C}|\mathbf{D})$  of  $\mathbf{C}$  in each  $\mathbf{D}$ .

uation instead of executing pipelines.<sup>5</sup> In case of the online adaptation algorithm, we also computed the *mean run-time prediction error* and the *classification error*, i.e., the fraction of texts the best main pipeline was not found for.

**Effectiveness** We omit to evaluate effectiveness here for lack of relevance: Our experiment setting, which is similar to (Wachsmuth et al., 2011a), yields no trade-off between efficiency and effectiveness, since we only consider schedules that fulfill all dependencies in Table 2. Thus, all pipelines always achieve the same precision and recall.

**System and Software** All experiments were conducted on a 2 GHz Intel Core 2 Duo MacBook with 4 GB memory. The Java source code and the pre-computed run-time files used in the evaluation can be accessed at <http://www.arguana.com>.

## 5.2 The Impact of Heterogeneity

We ran the online adaptation algorithm and the baselines from Section 3 on the test set of each of the corpora  $\mathbf{D}_0, \dots, \mathbf{D}_3$ . Both the algorithm and the optimal baseline were trained on the respective training sets. Figure 2 illustrates the run-times of the main pipelines for each approach as a function of the averaged deviation and compares them to the gold standard. The shown confidence intervals result from the run-times’ standard deviations  $\sigma$ , which ranged between 0.029ms and 0.043ms.

On the least heterogeneous corpus  $\mathbf{D}_0$  with an averaged deviation of 13.8%, the online adaptation algorithm achieved an average run-time of 0.98ms per sentence, which is faster than the random baseline but slower than the optimal baseline at a low confidence level. For  $\sigma(\mathbf{C}|\mathbf{D}_1) = 15.4\%$ , the online adaptation algorithm succeeded with 0.87ms per sentence as opposed to 0.9ms of the optimal baseline. This gap gets significantly larger un-

<sup>5</sup>Section 5.4 shows the effects of errors of measurement.

Figure 2: The average run-times of the main pipelines of both baseline approaches, the online adaptation algorithm, and the gold standard as a function of the averaged deviation. The background areas denote the 95% confidence intervals ( $\pm 2\sigma$ ).

der higher averaged deviation. At 18.5%, both baselines are clearly outperformed, taking 37% and 40% more time on average, respectively.<sup>6</sup>

One reason for the weak result of online adaptation on  $\mathbf{D}_0$  lies in the low optimization potential for that corpus: the main pipeline of the optimal baseline took only 12% more time on average than the gold standard (0.95ms vs. 0.85ms), which implies very small differences in the main pipelines’ run-times. This does not only render online adaptation hard but also unnecessary. Conversely, Figure 3 shows an optimization potential of over 50% for  $\mathbf{D}_3$ . A reasonable hypothesis is therefore that online adaptation succeeds only on collections and streams of texts of high heterogeneity as indicated by large differences in the pipelines’ run-times.

## 5.3 Run-time and Error Analysis

Figure 3 details the run-times of the three fixed pipelines, the online adaptation algorithm, and the gold standard on  $\mathbf{D}_0$  and  $\mathbf{D}_3$ . The small black indicators denote the standard deviations.

In total, the fixed pipelines are 16% to 25% slower than the online adaptation algorithm on  $\mathbf{D}_3$ . The algorithm’s run-time mainly breaks down into 0.51ms of the prefix pipeline and 0.73ms of the main pipelines, while the time for feature computations (0.03ms) and regression (0.01ms) is almost negligible. A similar situation is observed for  $\mathbf{D}_0$ . Here, online adaptation is worse only than  $(\Pi_{pre}, \Pi_1)$ , which did best on 598 of the 1000 test texts.  $(\Pi_{pre}, \Pi_2)$  and  $(\Pi_{pre}, \Pi_3)$  had the lowest run-time on 229 and 216 texts, respectively.<sup>7</sup>

<sup>6</sup>On the training set of  $\mathbf{D}_3$ , the optimal baseline did not find the fastest main pipeline. This might be coincidence, but is, of course, more likely under higher heterogeneity.

<sup>7</sup>The numbers of texts sum up to more than 1000 because on some texts different pipelines performed equally well.

Figure 3: Average run-times of the fixed pipelines and online adaptation on the test sets of  $D_0$  and  $D_3$ .

The online adaptation algorithm did not succeed on  $D_0$ , since its mean run-time prediction error of 0.45ms was almost half as high as the average run-times to be predicted, which is too inaccurate under the small differences in the pipelines’ run-times. As a result, for only 39% of the input texts, the best pipeline was chosen (i.e., a classification error of 0.61). However, the impact on  $D_3$  does not emanate from a low mean prediction error (that was in fact 0.24ms higher), but the classification error was reduced to 0.45. Consequently, the main reason lies in larger differences in the pipelines’ run-times, which supports our hypothesis.

An insightful linguistic phenomenon is that the prefix pipeline  $\Pi_{pre}$  took significantly more time per sentence on  $D_0$  than on  $D_3$ . Since the run-times of both algorithms in  $\Pi_{pre}$  scale linearly with the number of input tokens, the average sentence length of  $D_0$  must exceed that of  $D_3$ . The reason is that shorter sentences tend to contain less relevant information. Hence, many sentences can be discarded after a few analysis steps, which increases the need for input-dependent scheduling.

#### 5.4 Parameter Analysis

To give further evidence for the hypothesis from Section 5.2 and to test the applicability of online adaptation, we evaluated some major parameters:

**Impact of Features** For each of the five feature types in isolation, we trained a regression model on  $D_0$  and analyzed its impact. The *lexical statistics* achieved the lowest classification error (0.41), followed by the *run-times* (0.53). In terms of run-time prediction, the *regex matches* (0.46ms) and the *part-of-speech tags* (0.48ms) performed best, whereas the *chunk tags* failed both in classification (0.57) and prediction (0.58ms).<sup>8</sup> We used feature types 1–3 in all other experiments, since comput-

<sup>8</sup>The low correlation of the prediction and classification error seems counterintuitive, but it indicates the limitations of these measures: E.g, a small prediction error can still be problematic if run-times differ only slightly, while a high classification error may have few negative effects in this case. If both errors are small, however, this normally implies success.

Figure 4: The mean run-time prediction error for the pipelines chosen by the online adaptation algorithm on 15,000 modified versions of the texts in  $D_0$  for training size 1. The values of the two interpolated learning curves denote the mean of 1000 and 100 consecutive predictions, respectively.

ing them took only 0.05ms per sentence on average. In contrast, the *regex matches* needed 0.16ms alone, which exceeds the difference between the optimal baseline and the gold standard on  $D_0$  (cf. Section 5.2) and, thus, renders the *regex matches* useless in the given setting.

The *regex matches* emphasize the obvious need for a scheduling mechanism that avoids spending more time than can be saved later on. At the same time, such a mechanism should capture characteristics of a text that reliably model its complexity, which the evaluated features did not fully achieve.

**Impact of Training Size** We evaluated the online adaptation algorithm on  $D_0$  for nine training sizes between 1 and 5000. As the training set of  $D_0$  is limited, we created modified versions of its texts where needed (cf. Section 4.1). Online adaptation always did better than the random baseline but not than the optimal baseline except for training size 1. In case of 1000 or more training texts, the algorithm mimicked the optimal baseline, i.e., it chose  $\Pi_1$  for about 90% of the texts.

**Online Learning** For training size 1, we ran the online adaptation algorithm on 15,000 modified versions of the texts in  $D_0$ . Figure 4 shows two levels of detail of the algorithm’s learning curve in its update phase. As the bold curve conveys, the mean run-time prediction error decreases on the

Figure 5: The average run-times and standard deviations of the online adaptation algorithm on  $D_0$  and  $D_3$  when run-times are a) loaded from a pre-computed file or b) measured during execution.

first 5000 texts to an area around 0.4ms where it stays most of the time afterwards, though the light curve discovers many outliers. Still, online learning apparently seems to work well.

**Overall Optimization Potential** To measure the overall optimization potential of scheduling, we made an experiment with all  $k = 108$  correct main pipelines on  $D_0$  (cf. Section 5.1).<sup>9</sup> The resulting average run-times of the fixed main pipelines span from 0.79ms per sentence in case of  $\Pi_{best} = (TR, FD, MR, OR, TN, SD)$  to 3.27ms of  $\Pi_{worst} = (OR, TR, TN, MR, SD, FD)$ . This shows that the efficiency loss of choosing a wrong schedule can be very high. The online adaptation algorithm achieved 0.86ms with a mean run-time prediction error of 0.37ms. Altogether, 21 of the 108 schedules were used on the 1000 test texts, and the best schedule was chosen for 30% of the texts.

**Real Execution** As mentioned, we loaded all run-times from a precomputed file, which is not possible in case of real execution. In Figure 5, we compare the results of loading run-times to the run-times measured during the execution of the online adaptation algorithm. The measured values mainly differ in terms of larger standard deviations, i.e., 0.16ms on  $D_0$  and 0.12ms on  $D_3$ . This seems to have a fairly negative effect on the main pipelines’ run-times. However, the measured prefix pipeline run-times also exceed the saved ones, which suggests that the effect is due to a higher system load only. In any case, the measured run-time on  $D_3$  indicates that the online adaptation algorithm applies for practical applications.

## Conclusion

In this paper, we analyze the efficiency of information extraction pipelines as a function of the het-

<sup>9</sup>Notice that the training time increases linear to  $k$ , so a high  $k$  implies a high training overhead. For space reasons, we omit to report on training time here at all. However, training time will always be amortized in large-scale scenarios.

erogeneity of their input texts. In particular, we quantify heterogeneity with regard to the distribution of relevant information and we provide a self-supervised online adaptation algorithm that learns which pipeline schedule to choose for what input text in order to optimize efficiency while maintaining precision and recall. On this basis, we investigate the need for pipelines that adapt to their input within time-critical extraction tasks.

Our experiments suggest that the benefit of online adaptation is significant on heterogeneous collections and streams of texts: The online adaptation algorithm achieves gains of about 30% over the most efficient fixed schedule, which we see as important in times of big data. Conversely, when relevant information is uniformly distributed, finding an efficient fixed schedule appears sufficient, as approached in (Wachsmuth et al., 2013a).

A setting still to be evaluated refers to streams of input texts whose characteristics change slowly over time. Also, other extraction tasks may yield more insights. In order to decide how to approach a task at hand, a better understanding of the processing complexity of collections and streams of texts is required, to which our research contributes substantial building blocks.

In general, our self-supervised learning concept can be transferred to each natural language processing task that meets two basic conditions: (1) The task can be approached in different manners where each approach performs best for certain situations or inputs. (2) The performance of each approach can be measured or it is clear by definition.

# TopicRank: Graph-Based Topic Ranking for Keyphrase Extraction

Adrien Bougouin and Florian Boudin and Béatrice Daille

Université de Nantes, LINA, France

{adrien.bougouin,florian.boudin,beatrice.daille}@univ-nantes.fr

## Abstract

Keyphrase extraction is the task of identifying single or multi-word expressions that represent the main topics of a document. In this paper we present TopicRank, a graph-based keyphrase extraction method that relies on a topical representation of the document. Candidate keyphrases are clustered into topics and used as vertices in a complete graph. A graph-based ranking model is applied to assign a significance score to each topic. Keyphrases are then generated by selecting a candidate from each of the top-ranked topics. We conducted experiments on four evaluation datasets of different languages and domains. Results show that TopicRank significantly outperforms state-of-the-art methods on three datasets.

## 1 Introduction

Keyphrases are single or multi-word expressions that represent the main topics of a document. Keyphrases are useful in many tasks such as information retrieval (Medelyan and Witten, 2008), document summarization (Litvak and Last, 2008) or document clustering (Han et al., 2007). Although scientific articles usually provide them, most of the documents have no associated keyphrases. Therefore, the problem of automatically assigning keyphrases to documents is an active field of research.

Automatic keyphrase extraction methods are divided into two categories: supervised and unsupervised methods. Supervised methods recast keyphrase extraction as a binary classification task (Witten et al., 1999), whereas unsupervised methods apply different kinds of techniques such as language modeling (Tomokiyo and Hurst, 2003), clustering (Liu et al., 2009) or graph-based ranking (Mihalcea and Tarau, 2004).

In this paper, we present a new unsupervised method called TopicRank. This new method is an improvement of the TextRank method applied to keyphrase extraction (Mihalcea and Tarau, 2004). In the TextRank method, a document is represented by a graph where words are vertices and edges represent co-occurrence relations. A graph-based ranking model derived from PageRank (Brin and Page, 1998) is then used to assign a significance score to each word. Here, we propose to represent a document as a complete graph where vertices are not words but topics. We define a topic as a cluster of similar single and multi-word expressions.

Our approach has several advantages over TextRank. Intuitively, ranking topics instead of words is a more straightforward way to identify the set of keyphrases that covers the main topics of a document. To do so, we simply select a keyphrase candidate from each of the top-ranked clusters. Clustering keyphrase candidates into topics also eliminates redundancy while reinforcing edges. This is very important because the ranking performance strongly depends on the conciseness of the graph, as well as its ability to precisely represent semantic relations within a document. Hence, another advantage of our approach is the use of a complete graph that better captures the semantic relations between topics.

To evaluate TopicRank, we follow Hasan and Ng (2010) who stated that multiple datasets must be used to evaluate and fully understand the strengths and weaknesses of a method. We use four evaluation datasets of different languages, document sizes and domains, and compare the keyphrases extracted by TopicRank against three baselines (TF-IDF and two graph-based methods). TopicRank outperforms the baselines on three of the datasets. As for the fourth one, an additional experiment shows that an improvement could be achieved with a more effective selection strategy.

The rest of this paper is organized as follows. Section 2 presents the existing methods for the keyphrase extraction task, Section 3 details our proposed approach, Section 4 describes the evaluation process and Section 5 shows the analyzed results. Finally, Section 6 concludes this work and suggests directions for future work.

## 2 Related Work

The task of automatic keyphrase extraction has been well studied and many supervised and unsupervised approaches have been proposed. For supervised methods, keyphrase extraction is often treated as a binary classification task (Witten et al., 1999). Unsupervised approaches proposed so far have involved a number of techniques, including language modeling (Tomokiyo and Hurst, 2003), clustering (Liu et al., 2009) and graph-based ranking (Mihalcea and Tarau, 2004). While supervised approaches have generally proven to be more successful, the need for training data and the bias towards the domain on which they are trained remain two critical issues.

In this paper, we concentrate on graph-based ranking methods for keyphrase extraction. Starting with TextRank (Mihalcea and Tarau, 2004), these methods are becoming the most widely used unsupervised approaches for keyphrase extraction. In TextRank, a document is represented as a graph in which vertices are words connected if they co-occur in a given window of words. The significance of each vertex is computed using a random walk algorithm derived from PageRank (Brin and Page, 1998). Words corresponding to the top ranked vertices are then selected and assembled to generate keyphrases.

Wan and Xiao (2008) propose SingleRank, a simple modification of TextRank that weights the edges with the number of co-occurrences and no longer extracts keyphrases by assembling ranked words. Keyphrases are noun phrases extracted from the document and ranked according to the sum of the significance of the words they contain. Although it improves the results, this scoring method has no proper justification and tends to assign high scores to long but non important phrases. For example, “nash equilibrium”, from the file *J-14.txt* of our evaluation dataset named SemEval, is a keyphrase composed of the two most significant words in the document, according to SingleRank. Therefore, SingleRank succeeds to extract it, but

candidates such as “unique nash equilibrium” or “exact nash equilibrium” which are longer, then have a better score, are extracted too. With TopicRank, we aim to circumvent this by ranking clusters of single and multi-word expressions instead of words.

Wan and Xiao (2008) use a small number of nearest neighbor documents to compute more accurate word co-occurrences and reinforce edge weights in the word graph. Borrowing co-occurrence information from multiple documents, their approach improves the word ranking performance. Instead of using words, Liang et al. (2009) use keyphrase candidates as vertices. Applied to Chinese, their method uses query log knowledge to determine phrase boundaries. Tsatsaronis et al. (2010) propose to connect vertices employing semantic relations computed using WordNet (Miller, 1995) or Wikipedia. They also experiment with different random walk algorithms, such as HITS (Kleinberg, 1999) or modified PageRank.

Liu et al. (2010) consider the topics of words using a Latent Dirichlet Allocation model (Blei et al., 2003, LDA). As done by Haveliwala (2003) for Information Retrieval, they propose to decompose PageRank into multiple PageRanks specific to various topics. A topic-biased PageRank is computed for each topic and corresponding word scores are combined. As this method uses a LDA model, it requires training data. With TopicRank, we also consider topics, but our aim is to use a single document, the document to be analyzed.

## 3 TopicRank

TopicRank is an unsupervised method that aims to extract keyphrases from the most important topics of a document. Topics are defined as clusters of similar keyphrase candidates. Extracting keyphrases from a document consists in the following steps, illustrated in Figure 1. First, the document is preprocessed (sentence segmentation, word tokenization and Part-of-Speech tagging) and keyphrase candidates are clustered into topics. Then, topics are ranked according to their importance in the document and keyphrases are extracted by selecting one keyphrase candidate for each of the most important topics.

Section 3.1 first explains how the topics are identified within a document, section 3.2 presents the approach we use to rank them and section 3.3 describes the keyphrase selection.

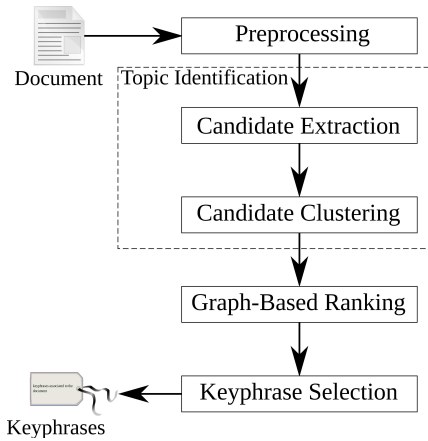

Figure 1: Processing steps of TopicRank.

### 3.1 Topic Identification

Keyphrases describe the most important topics of a document, thus the first step is to identify the keyphrase candidates that represent them. Hulth (2003) stated that most keyphrases assigned by human readers are noun phrases. Hence, the most important topics of a document can be found by extracting their most significant noun phrases. We follow Wan and Xiao (2008) and extract the longest sequences of nouns and adjectives from the document as keyphrase candidates. Other methods use syntactically filtered n-grams that are most likely to contain a larger number of candidates matching with reference keyphrases, but the n-gram restricted length is a problem. Indeed, n-grams do not always capture as much information as the longest noun phrases. Also, they are less likely to be grammatically correct.

In a document, a topic is usually conveyed by more than one noun phrase. Consequently, some keyphrase candidates are redundant in regard to the topic they represent. Existing graph-based methods (TextRank, SingleRank, etc.) do not take that fact into account. Keyphrase candidates are usually treated independently and the information about the topic they represent is scattered throughout the graph. Thus, we propose to group similar noun phrases as a single entity, a topic.

We consider that two keyphrase candidates are similar if they have at least 25% of overlapping words<sup>1</sup>. Keyphrase candidates are stemmed to reduce their inflected word forms into root forms<sup>2</sup>. To automatically group similar candidates into

<sup>1</sup>The value of 25% has been defined empirically.

<sup>2</sup>We chose to use stems because of the availability of stemmers for various languages, but using lemmas is another possibility that could probably work better.

topics, we use a Hierarchical Agglomerative Clustering (HAC) algorithm. Among the commonly used linkage strategies, which are complete, average and single linkage, we use the average linkage, because it stands as a compromise between complete and single linkage. In fact, using a highly agglomerative strategy such as complete linkage is more likely to group topically unrelated keyphrase candidates, whereas a strategy such as single linkage is less likely to group topically related keyphrase candidates.

### 3.2 Graph-Based Ranking

TopicRank represents a document by a complete graph in which topics are vertices and edges are weighted according to the strength of the semantic relations between vertices. Then, TextRank’s graph-based ranking model is used to assign a significance score to each topic.

#### 3.2.1 Graph Construction

Formally, let  $G = (V, E)$  be a complete and undirected graph where  $V$  is a set of vertices and the edges  $E$  a subset<sup>3</sup> of  $V \times V$ . Vertices are topics and the edge between two topics  $t_i$  and  $t_j$  is weighted according to the strength of their semantic relation.  $t_i$  and  $t_j$  have a strong semantic relation if their keyphrase candidates often appear close to each other in the document. Therefore, the weight  $w_{i,j}$  of their edge is defined as follows:

$$w_{i,j} = \sum_{c_i \in t_i} \sum_{c_j \in t_j} \text{dist}(c_i, c_j) \quad (1)$$

$$\text{dist}(c_i, c_j) = \sum_{p_i \in \text{pos}(c_i)} \sum_{p_j \in \text{pos}(c_j)} \frac{1}{|p_i - p_j|} \quad (2)$$

where  $\text{dist}(c_i, c_j)$  refers to the reciprocal distances between the offset positions of the candidate keyphrases  $c_i$  and  $c_j$  in the document and where  $\text{pos}(c_i)$  represents all the offset positions of the candidate keyphrase  $c_i$ .

Our approach to construct the graph differs from TextRank.  $G$  is a complete graph and topics are therefore interconnected. The completeness of the graph has the benefit of providing a more exhaustive view of the relations between topics. Also, computing weights based on the distances between offset positions bypasses the need for a manually defined parameter, such as the window of words used by state-of-the-art methods (TextRank, SingleRank, etc).

<sup>3</sup> $E = \{(v_1, v_2) \mid \forall v_1, v_2 \in V, v_1 \neq v_2\}$

### Inverse problems for a mathematical model of ion exchange in a compressible ion exchanger

A mathematical model of ion exchange is considered, allowing for ion exchanger compression in the process of ion exchange. Two inverse problems are investigated for this model, unique solvability is proved, and numerical solution methods are proposed. The efficiency of the proposed methods is demonstrated by a numerical experiment.

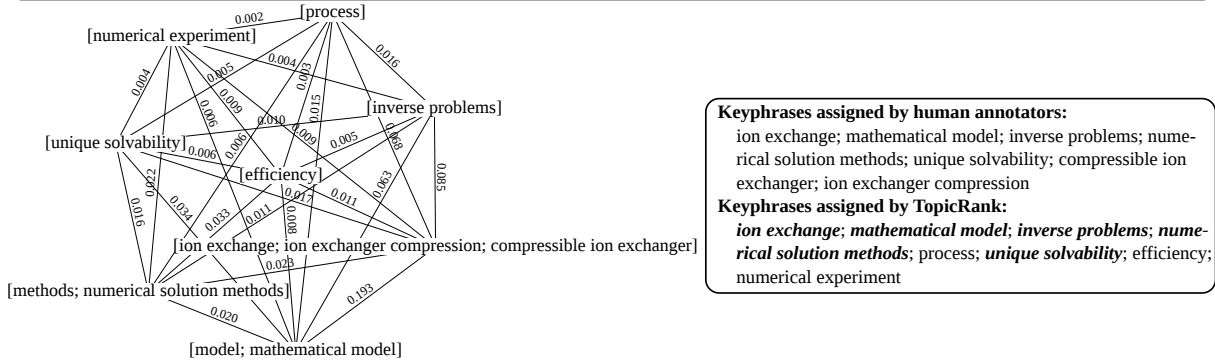

Figure 2: Sample graph build by TopicRank from Inspec, file 2040.abstr.

Figure 2 shows a sample graph built for an abstract from one of our evaluation datasets (Inspec). Vertices are topics, represented as clusters of lexically similar keyphrase candidates, and connected with all the others. In the example, we see the naivety of our clustering approach. Indeed, the clustering succeeds to group “ion exchanger”, “ion exchanger compression” and “compressible ion exchanger”, but the clustering of “methods” with “numerical solution methods” and “model” with “mathematical model” may be ambiguous as “methods” and “model” can be used to refer to other methods or models.

### 3.2.2 Subject Ranking

Once the graph is created, the graph-based ranking model TextRank, proposed by Mihalcea and Tarau (2004), is used to rank the topics. This model assigns a significance score to topics based on the concept of “voting”: high-scoring topics contribute more to the score of their connected topic  $t_i$ :

$$S(t_i) = (1 - \lambda) + \lambda \times \sum_{t_j \in V_i} \frac{w_{j,i} \times S(t_j)}{\sum_{t_k \in V_j} w_{j,k}} \quad (3)$$

where  $V_i$  are the topics voting for  $t_i$  and  $\lambda$  is a damping factor generally defined to 0.85 (Brin and Page, 1998).

### 3.3 Keyphrase Selection

Keyphrase selection is the last step of TopicRank. For each topic, only the most representative keyphrase candidate is selected. This selection avoids redundancy and leads to a good cover-

age of the document topics, because extracting  $k$  keyphrases precisely covers  $k$  topics.

To find the candidate that best represents a topic, we propose three strategies. Assuming that a topic is first introduced by its generic form, the first strategy is to select the keyphrase candidate that appears first in the document. The second strategy assumes that the generic form of a topic is the one that is most frequently used and the third strategy selects the centroid of the cluster. The centroid is the candidate that is the most similar to the other candidates of the cluster<sup>4</sup>.

## 4 Experimental Settings

### 4.1 Datasets

To compare the keyphrases extracted by TopicRank against existing methods, we employ four standard evaluation dataset of different languages, document sizes and domains.

The first dataset, formerly used by Hulth (2003), contains 2000 English abstracts of journal papers from the Inspec database. The 2000 abstracts are divided into three sets: a training set, which contains 1000 abstracts, a validation set containing 500 abstracts and a test set containing the 500 remaining abstracts. In our experiments we use the 500 abstracts from the test set. Several reference keyphrase sets are available with this dataset. Just as Hulth (2003), we use the uncontrolled reference, created by professional indexers.

The second dataset was built by Kim et al. (2010) for the keyphrase extraction task of the SemEval 2010 evaluation campaign. This dataset is

<sup>4</sup>The similarity between two candidates is computed with the stem overlap measure used by the clustering algorithm.

Corpus	Documents				Keyphrases		
	Type	Language	Number	Tokens average	Total	Average	Missing
Inspec	Abstracts	English	500	136.3	4913	9.8	21.8%
SemEval	Papers	English	100	5179.6	1466	14.7	19.3%
WikiNews	News	French	100	309.6	964	9.6	4.4%
DEFT	Papers	French	93	6844.0	485	5.2	18.2%

Table 1: Dataset statistics (missing keyphrases are counted based on their stemmed form).

composed of 284 scientific articles (in English) from the ACM Digital Libraries (conference and workshop papers). The 284 documents are divided into three sets: a trial set containing 40 documents, a training set, which contains 144 documents and a test set containing 100 documents. In our experiments we use the 100 documents of the test set. As for the reference keyphrases, we use the combination of author and reader assigned keyphrases provided by Kim et al. (2010).

The third dataset is a French corpus that we created from the French version of WikiNews<sup>5</sup>. It contains 100 news articles published between May 2012 and December 2012. Each document has been annotated by at least three students. We combined the annotations of each document and removed the lexical redundancies. All of the 100 documents are used in our experiments.

The fourth dataset is a French corpus made for the keyphrase extraction task of the DEFT 2012 evaluation campaign (Paroubek et al., 2012). It contains 468 scientific articles extracted from *Érudit*. These documents are used for two tasks of DEFT and are, therefore, divided in two datasets of 244 documents each. In our experiments we use the test set of the second task dataset. It contains 93 documents provided with author keyphrases.

Table 1 gives statistics about the datasets. They are different in terms of document sizes and number of assigned keyphrases. The Inspec and WikiNews datasets have shorter documents (abstract and news articles) compared to SemEval and DEFT that both contain full-text scientific articles. Also, the keyphrases provided with the datasets are not always present in the documents (less than 5% of missing keyphrases for Wikinews and about 20% of missing keyphrases for the other datasets). This induces a bias in the re-

sults. As explained by Hasan and Ng (2010), some researchers avoid this problem by removing missing keyphrases from the references. In our experiments, missing keyphrases have not been removed. However, we evaluate with stemmed forms of candidates and reference keyphrases to reduce mismatches.

## 4.2 Preprocessing

For each dataset, we apply the following preprocessing steps: sentence segmentation, word tokenization and Part-of-Speech tagging. For word tokenization, we use the TreebankWordTokenizer provided by the python Natural Language Toolkit (Bird et al., 2009) for English and the Bonsai word tokenizer<sup>6</sup> for French. For Part-of-Speech tagging, we use the Stanford POS-tagger (Toutanova et al., 2003) for English and MElt (Denis and Sagot, 2009) for French.

## 4.3 Baselines

For comparison purpose, we use three baselines. The first baseline is TF-IDF (Spärck Jones, 1972), commonly used because of the difficulty to achieve competitive results against it (Hasan and Ng, 2010). This method relies on a collection of documents and assumes that the  $k$  keyphrase candidates containing words with the highest TF-IDF weights are the keyphrases of the document. As TopicRank aims to be an improvement of the state-of-the-art graph-based methods for keyphrase extraction, the last two baselines are TextRank (Mihalcea and Tarau, 2004) and SingleRank (Wan and Xiao, 2008). In these methods, the graph is undirected, vertices are syntactically filtered words (only nouns and adjectives) and the edges are created based on the co-occurrences of words within a window of 2 for

<sup>5</sup>The WikiNews dataset is available for free at the given url: <https://github.com/adrien-bougouin/WikinewsKeyphraseCorpus>.

<sup>6</sup>The Bonsai word tokenizer is a tool provided with the Bonsai PCFG-LA parser: [http://alpage.inria.fr/statgram/frdep/fr\\_stat\\_dep\\_parsing.html](http://alpage.inria.fr/statgram/frdep/fr_stat_dep_parsing.html).

Methods	Inspec			SemEval			WikiNews			DEFT		
	P	R	F	P	R	F	P	R	F	P	R	F
TF-IDF	32.7	38.6	33.4	13.2	8.9	10.5	33.9	35.9	34.3	10.3	19.1	13.2
TextRank	14.2	12.5	12.7	7.9	4.5	5.6	9.3	8.3	8.6	4.9	7.1	5.7
SingleRank	34.8	40.4	<b>35.2</b>	4.6	3.2	3.7	19.4	20.7	19.7	4.5	9.0	5.9
TopicRank	27.6	31.5	27.9	14.9	10.3	<b>12.1</b> <sup>†</sup>	35.0	37.5	<b>35.6</b> <sup>†</sup>	11.7	21.7	<b>15.1</b> <sup>†</sup>

Table 2: Comparison of TF-IDF, TextRank, SingleRank and TopicRank methods, when extracting a maximum of 10 keyphrases. Results are expressed as a percentage of precision (P), recall (R) and f-score (F). † indicates TopicRank’s significant improvement over TextRank and SingleRank at 0.001 level using Student’s t-test.

TextRank and 10 for SingleRank. As well as their window size, they differ in the weighting of the graph: TextRank has an unweighted graph and SingleRank has a graph weighted with the number of co-occurrences between the words. A graph-based ranking model derived from PageRank (Brin and Page, 1998) ranks each vertex and extracts multi-word keyphrases according to the ranked words. In TextRank, the  $k$ -best words are used as keyphrases and the adjacent sequences in the document are collapsed into multi-word keyphrases. Although  $k$  is normally proportional to the number of vertices in the graph, we set it to a constant number, because experiments conducted by Hasan and Ng (2010) show that the optimal value of the ratio depends on the size of the document. In SingleRank, noun phrases extracted with the same method as TopicRank are ranked by a score equal to the sum of their words scores. Then, the  $k$ -best noun phrases are selected as keyphrases.

For all the baselines, we consider keyphrase candidates which have the same stemmed form as redundant. Once they are ranked we keep the best candidate and remove the others. This can only affect the results in a positive way, because the evaluation is performed with stemmed forms, which means that removed candidates are considered equal to the retained candidate.

#### 4.4 Evaluation Measures

The performances of TopicRank and the baselines are evaluated in terms of precision, recall and f-score (f1-measure) when a maximum of 10 keyphrases are extracted ( $k = 10$ ). As said before, the candidate and reference keyphrases are stemmed to reduce the number of mismatches.

## 5 Results

To validate our approach, we designed three experiments. The first experiment compares TopicRank<sup>7</sup> to the baselines<sup>8</sup>, the second experiment individually evaluates the modifications of TopicRank compared to SingleRank<sup>9</sup> and the last experiment compares the keyphrase selection strategies. To show that the clusters are well ranked, we also present the results that could be achieved with a “perfect” keyphrase selection strategy.

Table 2 shows the results of TopicRank and the three baselines. Overall, our method outperforms TextRank, SingleRank and TF-IDF. The results of TopicRank and the baselines are lower on SemEval and DEFT (less than 16% of f-score), so we deduce that it is more difficult to treat long documents than short ones. On Inspec, TopicRank fails to do better than all the baselines, but on SemEval, WikiNews and DEFT, it performs better than TF-IDF and significantly outperforms TextRank and SingleRank. Also, we observe a gap between TF-IDF’s and the two graph-based baselines results. Although TopicRank is a graph-based method, it overcomes this gap by almost tripling the f-score of both TextRank and SingleRank.

Table 3 shows the individual modifications of TopicRank compared to SingleRank. We evaluate SingleRank when vertices are keyphrase candidates (+phrases), vertices are topics (+topics) and when TopicRank’s graph construction is used

<sup>7</sup>Results reported for TopicRank are obtained with the first position selection strategy.

<sup>8</sup>TopicRank and the baselines implementations can be found at the given url: [https://github.com/adrien-bougouin/KeyBench/tree/ijcnlp\\_2013](https://github.com/adrien-bougouin/KeyBench/tree/ijcnlp_2013).

<sup>9</sup>The second experiment is performed with SingleRank instead of TextRank, because SingleRank also uses a graph with weighted edges and is, therefore, closer to TopicRank.

Methods	Inspec			SemEval			WikiNews			DEFT		
	P	R	F	P	R	F	P	R	F	P	R	F
SingleRank	34.8	40.4	35.2	4.6	3.2	3.7	19.4	20.7	19.7	4.5	9.0	5.9
+phrases	21.5	25.9	22.1	9.6	7.0	8.0 <sup>†</sup>	28.6	30.1	28.9 <sup>†</sup>	10.5	19.7	13.5 <sup>†</sup>
+topics	26.6	30.2	26.8	14.7	10.2	11.9 <sup>†</sup>	31.0	32.8	31.4 <sup>†</sup>	11.5	21.4	14.8 <sup>†</sup>
+complete	34.9	41.0	<b>35.5</b>	5.5	3.8	4.4	20.0	21.4	20.3	4.4	9.0	5.8
TopicRank	27.6	31.5	27.9	14.9	10.3	<b>12.1<sup>†</sup></b>	35.0	37.5	<b>35.6<sup>†</sup></b>	11.7	21.7	<b>15.1<sup>†</sup></b>

Table 3: Comparison of the individual modifications from SingleRank to TopicRank, when extracting a maximum of 10 keyphrases. Results are expressed as a percentage of precision (P), recall (R) and f-score (F). <sup>†</sup> indicates a significant improvement over SingleRank at 0.001 level using Student’s t-test.

with word vertices (+complete). Using keyphrase candidates as vertices significantly improves SingleRank on SemEval, WikiNews and DEFT. On Inspec, it induces a considerable loss of performance caused by an important deficit of connections that leads to connected components, as shown in Figure 3. When we look at the distribution of “fuzzy” into the graph, we can see that it is scattered among the connected components and, therefore, increases the difficulty to select “fuzzy Bayesian inference techniques” as a keyphrase (according to the reference). The other datasets contain longer documents, which may dampen this problem. Overall, using topics as vertices performs better than using keyphrase candidates. Using topics significantly outperforms SingleRank on SemEval, WikiNews and DEFT. As for the new graph construction, SingleRank is improved on Inspec, SemEval and WikiNews. Results on DEFT are lower than SingleRank, but still competitive. Although the improvements are not significant, the competitive results point out that the new graph construction can be used instead of the former method, which requires to manually define a window of words. Experiments show that the three contributions are improvements and TopicRank benefits from each of them.

Table 4 shows the results of TopicRank when selecting either the first appearing candidate, the most frequent one or the centroid of each cluster. Selecting the first appearing keyphrase candidate is the best strategy of the three. It significantly outperforms the frequency and the centroid strategies on SemEval, WikiNews and DEFT. On SemEval and DEFT, we observe a huge gap between the results of the first position strategy and the others. The two datasets are composed of scientific articles where the full form of the main topics are

often introduced at the beginning and then, conveyed by abbreviations or inherent concepts (e.g. the file *C-17.txt* from SemEval contains *packet-switched network* as a keyphrase where *packet* is more utilized in the content). These are usually more similar to the generic form and/or more frequent, which explains the observed gap.

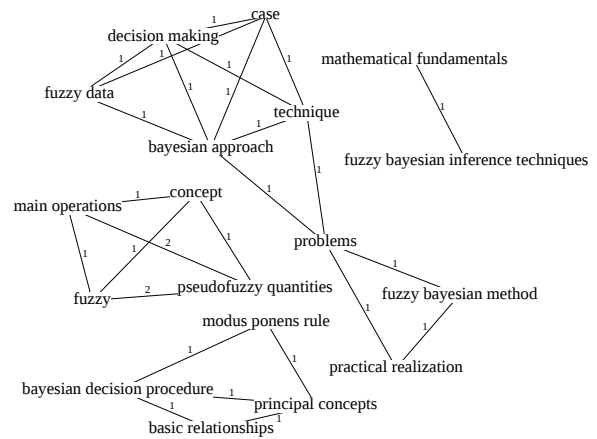

Figure 3: Connected component problem with the method SingleRank+phrases. Example taken from Inspec, file *1931.abstr*.

To observe the ranking efficiency of TopicRank, we also evaluate it without taking the keyphrase selection strategy into account. To do so, we extract the top-ranked clusters and mark the reference keyphrases into them. We deduce the upper bound results of our method by computing the precision, recall and f-score where the number of correct matches is equal to the number of clusters containing at least one reference keyphrase. The upper bound results show that our method could possibly perform better than all the baselines for the four datasets. Even on Inspec, the loss of performance can be bypassed by a more efficient keyphrase selection strategy.

Results are expressed as a percentage of precision (P), recall (R) and f-score (F). † indicates the first position strategy’s significant improvement over the frequency and the centroid strategies at 0.001 level using Student’s t-test.

## 6 Conclusion and Future Work

In this paper we presented TopicRank, an unsupervised method for keyphrase extraction. TopicRank extracts the noun phrases that represent the main topics of a document. The noun phrases are clustered into topics and used as vertices in a complete graph. The resulting graph stands as a topical representation of the document. Topics are scored using the TextRank ranking model and keyphrases are then extracted by selecting the most representative candidate from each of the top-ranked topics. Our approach offers several advantages over existing graph-based keyphrase extraction methods. First, as redundant keyphrase candidates are clustered, extracted keyphrases cover the main topics of the document better. The use of a complete graph also captures the relations between topics without any manually defined parameters and induces better or similar performances than the state-of-the-art connection method that uses a co-occurrence window. We conducted experiments on four standard evaluation datasets of different languages, document sizes and domains. Results show that TopicRank outperforms TF-IDF and significantly improves the state-of-the-art graph-based methods on three of them.

In future work, we will further improve the topic identification and the keyphrase selection. More precisely, we will develop an evaluation process to determine cluster quality and then focus on experimenting with other clustering algorithms and investigate the use of linguistic knowledge for similarity measures. As for the keyphrase selection, our experiments show that the current method does not provide the best solution that could be achieved with the ranked clusters. We plan to improve it using machine learning methods.

# Understanding the Semantic Intent of Domain-Specific Natural Language Query

Juan Xu, Qi Zhang, Xuanjing Huang

Fudan University

School of Computer Science

{11210240066, qz, xjhuang}@fudan.edu.cn

## Abstract

Queries asked on search engines nowadays increasingly fall in full natural language, which refer to Natural Language queries (NL queries). Parsing that kind of queries for the purpose of understanding user's query intent is an essential factor to search engine. To this end, a hierarchical structure is introduced to represent the semantic intent of NL query and then we focus on the problem of mapping NL queries to the corresponding semantic intents. We propose a parsing method by conducting two steps as follows: (1) predicting semantic tags for a given input query; (2) building an intent representation for the query using the sequence of semantic tags based on a structured SVM classification model. Experimental results on a manually labeled corpus show that our method achieved a sufficiently high result in term of precision and F1.

## 1 Introduction

Nowadays, with the development of voice search, queries asked on search engines often fall in full natural language, which refer to NL queries. For example, for the purpose of looking for a restaurant, it is natural for us to ask "find the best Italian restaurant near seattle washington" rather than "Italian restaurant seattle wa". This means that voice search users are liable to express their intent in natural language which differs significantly from Web users. In addition to the developing of voice search, the increasing use of smartphones with voice assistant further boosts the number of such natural language queries.

This increasing amount of natural language queries brings a big challenge to search engines. Many search engines today, generally speaking,

are based on matching keywords against structured information from relational database. Consider the query "find the best Italian restaurant near seattle washington". Without understanding the semantic intent, it may retrieval some unsatisfying results that merely contain all these keywords, which are not really search terms (e.g. restaurant). But when the search engine understands the intent of this query is to "find restaurant", and also knows the meanings of individual constituents (i.e the "restaurant" is head search terms, "the best Italian" and "near seattle washington" are modifier), then it would be able to route the query to a specialized search module (in this case restaurant search) and return the most relevant and essential answers rather than results that merely contain all these keywords.

In no small part, the success of such approach relies on robust understanding of query intent. Most previous works in this area focus on query tagging problem, i.e., assigning semantic labels to query terms (Li et al., 2009; Manshadi and Li, 2009; Sarkas et al., 2010; Bendersky et al., 2011). Indeed, with the label information, a search engine is able to provide users with more relevant results. But previous works have not considered the issue for understanding the semantic intent of NL queries and their methods are not suitable for interpreting the semantic intent of this kind of complex queries. In this work, in order to enable search engines to understand natural language query, we focus on the problem of mapping NL queries from a particular search engine like Google maps, Bing maps etc, to their semantic intents representation. A key contribution of this work is that we formally define a hierarchical structure to represent the semantic intents. As an example, consider a query about finding a local business near some location such as:

**Example** : *find the best Italian restaurant near space needle seattle washington*

This query has four constituents: the Business that the user is looking for (restaurant), the Neighborhood (space needle seattle washington), the condition and cuisine type that the user specified (the best Italian) and the term that helps user to ask (find). To understand the semantic intent of the query, the model should not only be able to recognize the four constituents but also needs to understand the structure of each constituent. Therefore we are looking for a model that is able to generate the semantic intent representation for this query as shown in Figure 1.

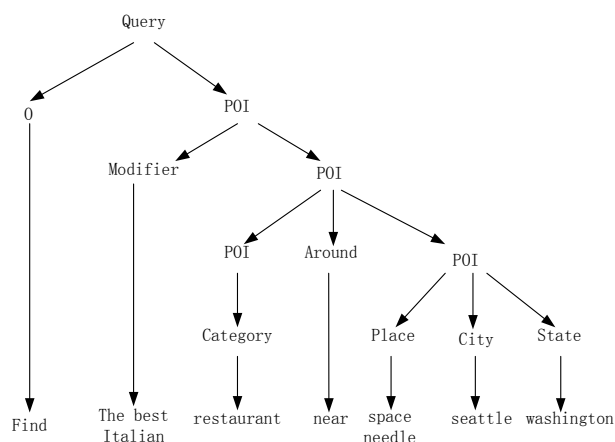

Figure 1: A simple grammar tree for local businesses search.

Generating the hierarchical structure of queries can be beneficial to information retrieval. Knowing the semantic role of each query constituent, we can reformulate the query into a structured form or reweight different query constituents for structured data retrieval (Kim et al., 2009; Paparizos et al., 2009; Gollapudi et al., 2011; Kim and Croft, 2012). Alternatively, the knowledge of the structure of the constituents helps route the query to a specialized search module.

The second contribution of this work is that we define a grammar which is isomorphic to a Context Free Grammar (CFG), and also present an approach which can automatically generate the semantic intent representation for NL queries by considering it as a structure classification problem.

The rest of this paper are organized as follows. Section 2 details the related work. In Section 3 we demonstrate the hierarchical structured representation of queries and introduce our grammar for it. Then, in Section 4, we propose our method for parsing the queries. Section 5 presents the experi-

mental results. We draw the conclusions from our work in Section 6.

## 2 Related Works

### 2.1 Query Intent Understanding

To capture the underlying information need encoded within diverse user queries, considerable works have been conducted from many aspects. Most previous works in this area focus on query intent classification as one aspect, i.e., automatically mapping queries into semantic classes or patterns (Li et al., 2008; Arguello et al., 2009; Duan et al., 2012). There is another aspect to study the problem, query tagging, i.e., assigning semantic labels to query terms (Li et al., 2009; Sarkas et al., 2010; Bendersky et al., 2011). For example, in “Restaurant Rochester Chinese MN”, the word “Restaurant” should be tagged as *Business*. In particular, Li et al. leverage clickthrough data and a database to automatically derive training data for learning a CRF-based tagger. Manshadi and Li develop a hybrid, generative grammar model for a similar task. Sarkas et al. consider an annotation as a mapping of a query to a table of structured data and attributes of this table, while Bendersky et al. mark up queries with annotations such as part-of-speech tags, capitalization, and segmentation.

There are relatively little published work on understanding the semantic intent of natural language query. Manshadi and Li (2009) and Li (2010) consider the semantic structure of queries. In particular, Li (2010) defines the semantic structure of noun-phrase queries as intent heads (attributes) coupled with some number of intent modifiers (attribute values), e.g., the query [alice in wonderland 2010 cast] is comprised of an intent head *cast* and two intent modifiers *alice in wonderland* and *2010*. Our approach differs from the earlier work in that we investigate the natural language query intent understanding problem, and build a hierarchical representation for it.

### 2.2 Semantic Parsing

For the purpose of enabling search engines to understand user’s query intent, we present an approach to parse NL queries to the corresponding semantic intents, which is similar to the task in semantic parsing (Kate et al., 2005). We parse the queries to a hierarchical structure consisting of all query terms. While the task of semantic parsing is mapping NL input to its interpretation ex-

pressed in well-defined formal *meaning representation*(MR) language. For example, “How many states does the Colorado river run through?”, the output of semantic parsing is “count( state( traverse( river( const(colorado))))”. Although it can express the meanings of NL inputs, it is not suitable for search engines to use, which, generally speaking, are based on matching keywords against documents.

### 3 Query Intent Representation and Grammar for NL Query

The task we defined is mapping the natural language query (NL query) to the corresponding intent representation(IR), which is specifically for a particular search scenario like Google maps and Bing maps etc, but can generalize well to other search scenarios by redefining the grammar.

#### 3.1 Query Intent Representation

In this work, we propose to use a tree structure to represent the semantic intent of a query. Consider the instance in section 1, the NL query “find the best Italian restaurant near space needle seattle washington” consists of 10 words. The IR is a hierarchical tree structure, as shown in Figure 1.

There are 9 different non-terminal symbols in the tree, of which Query is the start symbol. And it contains 11 rules to formulate the tree structure. As shown in the Figure 1, it clearly depicts that the query has 2 constituents and also depicts the structure of each constituent. After having that tree structure, search engines can easily understand the semantic intent of the query as we discussed in introduction.

#### 3.2 Grammar for NL Query

We have manually designed a grammar for the purpose of automatic generating the hierarchical structure of queries. As mentioned above, we focus on a particular search scenario (i.e map search domain). Based on analysis of NL queries from that domain, we observe that most queries carry an underlying structure. Therefore a set of CFG rules were written for the map search scenario. Below

are some sample rules from those CFG rules:

Query -- > O POI Around POI  
 POI -- > Place IN City State  
 POI -- > Num Road IN City State  
 POI -- > Road  
 POI -- > Category IN City  
 Query -- > Modifier Transition From POI TO POI

And we also define a set of semantic tags for that kind of queries which indicate the semantic role of each query constituent. More formally we define a Context-Free Grammar (CFG) for NL query as a 4-tuple  $G=(N, T, S, R)$  where

- $N$  is a set of non-terminals;
- $T$  is a set of terminals;
- $S \in N$  is a special non-terminal called start symbol,
- $R$  is a set of rules  $\{A \rightarrow \beta\}$  where  $A$  is non-terminal and  $\beta$  is a string of symbols from the infinite set of strings of  $(N \cup T)^*$ .

The sequence of  $\implies$  used to derive  $w$  from  $S$  is called a derivation of  $w$ . Here  $\implies^*$  is defined as the reflexive transitive closure of  $\implies$ . We can then formally define the language  $L(G)$  generated by the grammar  $G$  as the set of strings composed of terminal symbols that can be drawn from the designated start symbol  $S$ .

$$L = \{w | w \text{ is in } T^* \text{ and } S \implies^* w\}$$

Given the above definitions, parsing a string  $w$  means to find all (if any) the derivations of  $w$  from  $S$ .

Our grammar composes a constraint ordering on queries. And it is reasonable, because the query we investigated is full natural language query. While there are some NL queries whose words sequences are arbitrary, which is not in our consideration.

## 4 Methodology

To produce the semantic intent representation for an NL query from map search domain, we need to extract the basic semantic query constituents and build the semantic intent representation with them according to the query. Summarily, the input of our parsing task is a NL query and the output is the intent representation. The proposed method for this problem consists of two phases:

Semantic category	Meaning	Example
O	The useless information for search	where is
M	The modifier which indicates user's personal interests	the best and cheapest
F	The information of predicting the start address in direction search	from
Q	The information of predicting the end address in direction search	to
C	The city	New York
S	The state	North Carolina(Abbr. NC)
P	The place	White House
T	The town	Forbes
A	The predicted information of the area range of a point	nearby
L	The POI category	restaurant
I	The predicted information of a point within an area	in
D	The district	Brooklyn
N	The number of an address	Room 606
R	The road	Church St
G	The country	USA
W	The transition	via subway

Table 1: Illustration for each semantic category.

1. Predicting a sequence of semantic tags for a given input sentence.
2. Building an intent representation with the sequence of semantic tags

We describe a method using CRFs and structured support vector machine (SSVMs) in the following subsection for the first step and the second step, respectively.

#### 4.1 Semantic Tagging with CRFs

Let  $w_1w_2\dots w_N$  be a NL sentence in which  $N$  is the number of words and  $w_i$  is  $i^{th}$  word. Assuming that a chunk tag for a sequence of words  $w_i\dots w_j(1\leq i\leq j\leq N)$  is  $t_i$ , the lexical semantic prediction problem is to determine a lexical semantic tag  $s_i$  for a sequence of words  $w_i\dots w_j(1\leq i\leq j\leq N)$ . In the meantime, semantic tag  $s_i$  is structural and consists of two parts:

1) **Boundary Category:**  $BC = \{B, I\}$ . Here B/I means that current word is at the beginning/in the middle of a semantic chunk.

2) **Semantic Category:**  $SC = \{O, M, F, Q, C, S, P, T, A, L, I, D, N, R, G, W\}$ . This is used to denote the class of the semantic name. The meaning of each semantic class name represented is illustrated in Table 1.

The conditional random fields CRFs (Lafferty et al., 2001) have shown empirical successes in label sequence labelling problem. Therefore, we exploit

the use of CRFs to our semantic tagging problem in which a feature set for this task is presented in Table 2.

#### 4.2 Generating Intent Representation with Structural SVMs

This subsection first gives some background about the SSVMs for structured prediction, and then we focus on how to use SSVMs to our intent representation learning problem.

##### 4.2.1 Structural SVMs

Suppose a training set of input-output structure pairs  $S = \{(x_1, y_1), \dots, (x_n, y_n)\} \in (X \times Y)^n$  is given. Structured classification is the problem of predicting  $y$  from  $x$  in the case where  $y$  has a meaningful internal structure. Elements  $y \in Y$  may be, for instance, sequences, strings, labeled trees, lattices, or graphs.

The approach we pursue is to learn a discriminant function  $F : X \times Y \rightarrow R$  over  $S$ . For a specific given input  $x$ , we can derive a prediction by maximizing  $F$  over the response variable. Hence, the general form of our hypotheses  $f$  is

$$f(x; w) = \operatorname{argmax}_{y \in Y} F(x; y; w) \quad (1)$$

where  $w$  denotes a parameter vector.

As the principle of the maximum-margin presented in (Vapnik, 1995), in the structured classification problem, Tsochantaridis (2004) proposed several maximum-margin optimization problems

Feature index	Definition
1	The current word and the preceding word
2	The current word and the following word
3	The current word
4	The knowledge of Pre-1 word in Geo-Knowledge Database
5	The knowledge of Pre-2 word in Geo-Knowledge Database
6	The knowledge of Post-1 word in Geo-Knowledge Database
7	The knowledge of Post-2 word in Geo-Knowledge Database
8	The knowledge of current word in Geo-Knowledge Database

Table 2: Features for CRFs Model.

$\delta\psi_i(y) \equiv \psi(x_i, y_i) - \psi(x_i, y)$ . The soft-margin criterion was proposed in order to allow errors in the training set, by introducing slack variables.

$$\text{SVM}_1 : \underbrace{\min_w}_{w} \frac{1}{2} \|w\|^2 + \frac{C}{n} \sum_{i=1}^n \xi_i \quad s.t. \forall i, \xi_i \geq 0 \quad (2)$$

$$\forall i, \forall y \in Y \setminus y_i : \langle w, \delta\psi_i(y) \rangle > 1 - \xi_i \quad (3)$$

Alternatively, using a quadratic term  $\frac{C}{2n} \sum_i \xi_i^2$  to penalize margin violations,  $\text{SVM}_2$  would be obtained. Here  $C > 0$  is a constant that control the tradeoff between training error minimization and margin maximization.

To deal with problems in which  $|Y|$  is very large, such as Natural Language parsing, Tsochantaridis (2004) proposed two approaches that generalize the formulation  $\text{SVM}_1$  and  $\text{SVM}_2$  to the cases of arbitrary loss function. We use  $\text{SVM}_1$  to introduce that two approaches and they are also work for  $\text{SVM}_2$ . The first approach is to rescale the slack variables according to the loss incurred in each of the linear constraints.

$$\text{SVM}_1^{\Delta_s} : \underbrace{\min_w}_{w} \frac{1}{2} \|w\|^2 + \frac{C}{n} \sum_{i=1}^n \xi_i \quad s.t. \forall i, \xi_i \geq 0 \quad (4)$$

$$\forall i, \forall y \in Y \setminus y_i : \langle w, \delta\psi_i(y) \rangle \geq \frac{1 - \xi_i}{\Delta(y_i, y)} \quad (5)$$

The second approach to include loss function is to rescale the margin as a special case of the Hamming loss. The margin constraints in this setting take the following form:

$$\forall i, \forall y \in Y \setminus y_i : \langle w, \delta\psi_i(y) \rangle \geq \Delta(y_i, y) - \xi_i \quad (6)$$

This set of constraints yields an optimization problem, namely  $\text{SVM}_1^{\Delta^m}$ .

The algorithm to solve the maximum-margin problem in structured learning problem is presented in detail in (Tsochantaridis et al., 2004). And

it can be applied to all SVM formulations mentioned above. The only difference between them is the cost function.

Following the successes of the Structural SVMs algorithm to structured prediction, we exploit the use of SSVM to our parsing task. As discussed in (Tsochantaridis et al., 2004), the major problem to apply the Structural SVMs is to implement the feature mapping  $\psi(x, y)$ , the loss function  $\Delta(y_i, y)$ , as well as the maximization algorithm. In the following section, we apply a Structural SVMs to the problem of semantic intent learning in which the mapping function, the maximization algorithm, and the loss function are introduced.

#### 4.2.2 Feature mapping

For our task, we can choose a mapping function to get a model that is isomorphic to a probabilistic grammar in which each rule within the grammar is defined by our own based on the application area. Each node in a parse tree  $y$  for an NL query  $x$  corresponds to a grammar rule  $g_j$ , which in turn has a score  $w_j$ .

All valid parse trees  $y$  for an NL query  $x$  are scored by the sum of the  $w_j$  of their nodes, and the feature mapping  $\psi(x, y)$  is a histogram vector counting how often each grammar rule  $g_j$  occurs in the tree  $y$ . The example shown in Figure 2 clearly depicts the way features are mapped from a tree structure intent representation of an NL query.

#### 4.2.3 Loss function

Typically, the correctness of a predicted parse tree is measured by its F1 score (see e.g. (Johnson, 1998)), the harmonic mean of precision of recall as calculated based on the overlap of nodes between the trees. In this work, we follow this loss function and introduce the standard zero-one classification loss as a baseline measure method.

Let  $z$  and  $z_i$  be two parse tree outputs and  $|z|$  and  $|z_i|$  be the number of brackets in  $z$  and  $z_i$ , re-

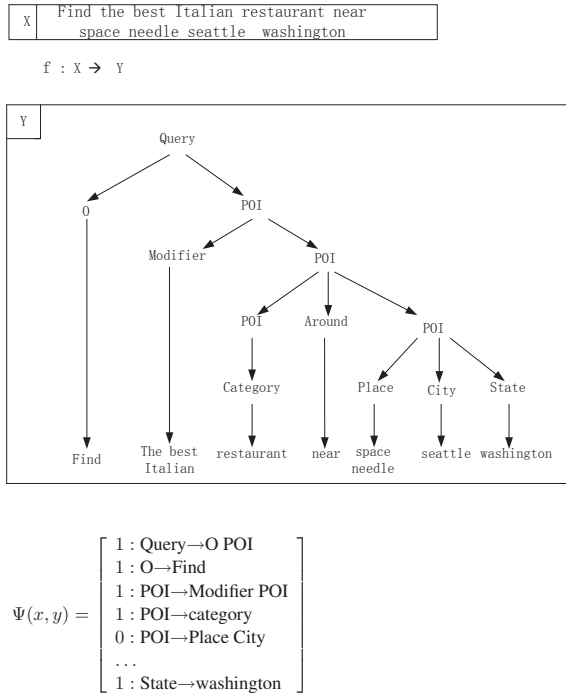

Figure 2: Example of feature mapping using tree representation.

spectively. Let  $n$  be the number of common brackets in the two trees. The loss function between  $z_i$  and  $z$  is computed as bellow.

$$F - \text{loss}(z_i, z) = 1 - \frac{2 \times n}{|z| + |z_i|} \quad (7)$$

$$\text{zero} - \text{one}(z_i, z) = \begin{cases} 1 & \text{if } z_i \neq z \\ 0 & \text{otherwise} \end{cases} \quad (8)$$

#### 4.2.4 Maximization algorithm

Note that the learning function can be efficiently computed by finding the structure  $y \in Y$  that maximizes  $F(x; y; w) = \langle w, \delta\psi_i(y) \rangle$  via a maximization algorithm. To this end, we use a modified version of the CKY parser of Mark Johnson<sup>1</sup> and incorporated it into our algorithm.

#### 4.2.5 SSVM learning algorithm

Algorithm 1 shows our generation of SSVM learning for the semantic intent representation learning problem. The algorithm can apply to all SVM formulations discussed in section 4.2.1. The only difference is in the way the cost function gets set up in step 3 and the other three optional cost function are:

$$\text{SVM}_2^{\Delta^s} : H(y) \equiv (1 - \langle \delta\psi_i(y), w \rangle) \sqrt{\Delta(y_i, y)}$$

### Algorithm 1 Algorithm of SSVM learning for query parsing

**Input:**  $I = (x_i; y_i), i = 1, 2, \dots, l$  in which  $x_i$  is the NL query's semantic tags sequence and  $y_i$  is the corresponding tree structure.

**Output:** SSVM model

- 1: **repeat**
- 2:   **for**  $i = 1$  **to**  $l$  **do**
- 3:     set up cost function based on the corresponding optimization problem;  
 $\text{SVM}_1^{\Delta^s} : H(y) \equiv (1 - \langle \delta\psi_i(y), w \rangle) \Delta(y_i, y)$
- 4:     compute  $\hat{y} = \text{argmax}_{y \in Y} H(y)$
- 5:     compute  $\xi_i = \max\{0, \max_{y \in S_i} H(y)\}$
- 6:     **if**  $H(\hat{y}) > \xi_i + \epsilon$  **then**
- 7:        $S_i \leftarrow S_i \cup \{\hat{y}\}$
- 8:     solving optimization with SVM;
- 9:     **end if**
- 10:  **end for**
- 11: **until** no  $S_i$  has changed during iteration

$$\text{SVM}_1^{\Delta^m} : H(y) \equiv (\Delta(y_i, y) - \langle \delta\psi_i(y), w \rangle)$$

$$\text{SVM}_2^{\Delta^m} : H(y) \equiv (\sqrt{\Delta(y_i, y)} - \langle \delta\psi_i(y), w \rangle)$$

The feature mapping  $\psi(x, y)$ , the loss function  $\Delta(y_i, y)$ , as well as the maximization in step 6 were implemented as mentioned in above. A working set  $S_i$  is maintained for each training example  $(x_i, y_i)$  to keep track of the selected constraints which define the current relaxation. The algorithm stops, if no constraint is violated by more than  $\epsilon$  and then we get a SSVM model. Note that the SVM optimization problems from iteration to iteration differ only by a single constraint. We therefore restart the SVM optimizer from the current solution, which really reduces the runtime.

## 5 Experiments

### 5.1 Corpus

To facilitate the study we need benchmark corpus with ground-truth semantic intent representations in map search area. Since there is no such kind of corpus publicly available, we constructed a corpus MSIntent from answers.yahoo.com, which have a large number of queries submitted by users. The MSIntent corpus contains 1200 NL queries. Since those queries were crawled from an open question domain which contains many noises, 670 NL queries were finally chosen and manually labeled.

Two annotators labeled the corpus independently. The annotators first tagged each query with a set of semantic tags, and then build it's corre-

sponding semantic intent representation tree based on a given grammar, which consists of 17 non-terminal and 269 productions, defined specifically for our task. In order to keep the reliability of annotations, another annotator was asked to check the corpus and determine the conflicts. Finally we got a corpus includes 670 NL queries and their corresponding semantic intent representation. Table 3 shows the statistic on our corpus MSIntent.

Statistic	Numbers
No.of. Examples	670
Avg. NL sentence length	10.11
No. of non-terminals	17
No. of productions	227

Table 3: Statistics on MSIntent corpus. The average length of an NL query in the corpus is 10.11 words. This indicates that MSIntent is the hard corpus.

## 5.2 Experiments Configurations

We use the standard 10-fold cross validation test for evaluating the method. NL test queries were first tagged with a sequence of semantic tags, and those sequences were used to build trees, which has been detailed in section 3, via a structured support vector machine.<sup>2</sup> We evaluate the accuracy of tagging an NL query to a sequence of semantic tags by computing the total number of correct semantic tags in comparison with the gold-standard. For this purpose, CRF model<sup>3</sup> obtains a high result, with 91.73% accuracy.

Our main focus is to evaluate the proposed method in parsing NL queries to IR, we measure the number of test queries that produced complete IR, and the number of those IR that were correct. For our task, a IR is correct if it exactly matches the correct representation, we use the evaluation method for semantic parsing problem presented in (Kate et al., 2005) as the formula be:

$$\text{Precision} = \frac{\#correct\ IR}{\#completed\ IR}$$

$$\text{Recall} = \frac{\#correct\ IR}{\#queries}$$

$$\text{F1} = \frac{2Precision \cdot Recall}{Precision + Recall}$$

<sup>2</sup><http://svmlight.joachims.org/>

<sup>3</sup>We use CRF++ toolkit, <http://crfpp.sourceforge.net/>

## 5.3 Results

In this section we show that with high tagging accuracy as mentioned above, our proposed method for parsing NL queries to IR is effective. To this end, we conducted two sets of experiment. The first experiment was to show the performance of our proposed method in terms of precision, recall and F-score measurements. The second was to investigate the effect of other kernel functions in our learning algorithm.

**1. Performance of our method.** The results are given in Table 4, which shows recall, precision and F1 for test set. The first line shows the performance for PCFG model as trained on our MSIntent corpus by Johnson’s implementation. The following two lines show the  $SVM_2^{\Delta^m}$  and  $SVM_2^{\Delta^s}$  with zero-one loss, while the rest lines give the results for the F1-loss. All results are for  $C = 39$  and  $\epsilon = 0.1$ . All values of  $C$  between 0.1 to 100 gave comparable results. Table 4 indicates that our method achieved high accuracy results.  $SVM_2^{\Delta^m}$  using the F-loss gives better F1, outperforming the PCFG substantially. We conjecture that we can achieve further gains by incorporating more complex features into the grammar, which would be impossible or at least awkward to use in a PCFG model.

**2. The effect of kernel functions in our learning algorithm.** As seen in Table 5, it shows the training and testing results for various kernel functions including linear kernel, polynomial kernel, and RBF kernel. The regularization parameter  $C$  and the criterion parameter  $\epsilon$  are set to the same values as that in the first experiment. From the results,  $SVM_2^{\Delta^s}$  with polynomial kernel obtains 83.86% recall, 89% precision and 86.43% F1, which is the best result. But we observe that our proposed method can perform well with different kernel functions without significantly difference.

In addition, when performing SSVM on the test set, we might obtain some ‘NULL’ outputs since the grammar generated by SSVM could not derive this sentence, but generally we obtained high recall. Summarily, Table 5 depicts that the proposed method using different parameters achieved high performance in term of precision.

## 6 Conclusions

This paper presented a new facet to investigate the semantic intent of NL queries, which maps N-L queries to the corresponding semantic intents.

Parameter	Test Recall	Test Precision	Test F1
<b>PCFG</b>	79.10	89.83	84.12
<b>0/1-loss(SVM<math>\Delta_2^m</math>)</b>	83.43	88.05	85.78
0/1-loss(SVM $\Delta_2^s$ )	83.26	88.57	85.47
<b>F-loss(SVM<math>\Delta_2^m</math>)</b>	<b>83.42</b>	<b>88.72</b>	<b>85.97</b>
F-loss(SVM $\Delta_2^s$ )	83.01	88.39	85.60

Table 4: Results for parsing NL queries to IR on MSIntent corpus using cross-validation test.

Parameter	Training Accuracy	Test Recall	Test Precision	Test F1
linear+F-loss( $\Delta_m$ )	92.37	83.42	88.72	85.97
polynomial(d=2)+ F-loss( $\Delta_m$ )	91.66	82.98	88.23	85.13
<b>polynomial(d=2)+ F-loss(<math>\Delta_s</math>)</b>	<b>91.98</b>	<b>83.86</b>	<b>89.00</b>	<b>86.43</b>
RBF+F-loss( $\Delta_m$ )	92.00	83.11	88.22	85.17
RBF+F-loss( $\Delta_s$ )	92.34	82.67	87.96	84.92

Table 5: Experiment results for parsing NL queries to IR on MSIntent corpus using SSVMs with various kernel functions.

We also proposed a method of using a hierarchical structure to represent the semantic intent of N-L query, and then presented an automatic method to learn the semantic intent representation with the corpus of NL queries and their semantic intent representation in tree structure.

Experimental results with a manually labeled corpus have demonstrated that our method achieves a very good performance in term of precision and F1-scores. We thus can confidently conclude that the structured support vector models are suitable to the problem of our semantic intent learning problem. We also provide a semantic tagging tool with a very high accuracy by using a CRF model that can be beneficially used as pre-processing for the semantic intent learning problem.

The main drawback with our approach is that we strict the ordering of NL queries. Note that although strict ordering constraints such as those imposed by CFG is appropriate for modeling query structure in our task, it might be helpful to somehow ignore the ordering. We leave this for future work. Another interesting and practically useful problem that we have left for future work is

to extend our method to a version of SVM semi-supervised learning. Having such a capability, we are able to automatically learn the semantic intent of NL queries by processing labeled and unlabeled data.

## Abstract

Sentiment classification is able to help people automatically analyze customers' opinions from the large corpus. In this paper, we collect some Chinese movie reviews from Bulletin Board System and aim at making sentiment classification so as to extract several frequent opinion words in some movie elements such as plots, actors/actresses, special effects, and so on. Moreover, we result in a general recommendation grade for users. Focusing on the movie reviews in Chinese, we propose a novel procedure which can extract the pairs of opinion words and feature words according to dependency grammar graphs. This parsing-based approach is more suitable for review articles with plenty of words. The grading results will be presented by a 5-grade scoring system. The experimental results show that the accuracy of our system, with the deviation of grades less than 1, is 70.72%, and the Mean Reciprocal Rank (MRR) value is 0.61. When we change the 5-grade scoring system into producing two values: one for recommendation and the other for non-recommendation, we get precision rates 71.23% and 55.88%, respectively. The result shows an exhilarating performance and indicates that our system can reach satisfied expectancy for movie recommendation.

## 1 Introduction

As the rapid growth of text data, text mining has been applied to discover hidden knowledge from text in many applications and domains. Nowadays, reviews are increasing with a rapid speed and are available over internet in natural languages. Sentiment analysis tries to identify and extract subject information from reviews. The problem of automatic sentiment analysis has received significant attention in recent years, largely due to the explosion of online social-oriented

content (e.g., user reviews, blogs, etc). Furthermore, sentiment analysis can be used in various ways and in many applications such as suggestion systems based on the user likes and ratings, recommendation systems, or insisting in election campaigns. As one of the important applications, sentiment classification targets to rate the polarity of a given text accurately towards a label or a score, predicting whether the expressive opinion in the text is positive, negative, or neutral.

Identifying the sentiment polarity is a complex task. To address the problem of sentiment classification, various methodologies have been applied earlier. Generally, there are two types of approaches tackling the sentiment classification task according to the knowledge the systems used. One is corpus-based and the other is lexicon-based. Corpus-based approaches are usually supervised, i.e., requiring training sets, and performing well when the training set is large enough and correctly labeled. The approaches are studied in (Bakliwal *et al.*, 2011; Bessalv *et al.*, 2011; Kennedy and Inkpen, 2006; Jin *et al.*, 2009; Narayanan *et al.*, 2009; Pang *et al.*, 2002; Schuller and Knaup, 2011). On the contrary, the lexicon-based approaches are mostly unsupervised, requiring a dictionary or a lexicon of pre-tagged words. Each word that is present in a text is compared against the dictionary. If a word is present in the dictionary, then the polarity value in the dictionary is added to the polarity score. The recent related works to lexicon-based approaches include (Baloglu and Aktas, 2010; Hu and Liu, 2004; Montejo-Raez *et al.*, 2012; Qiu *et al.*, 2009; Taboada *et al.*, 2011; Thet *et al.*, 2010; Zhao and Li, 2009). Additionally, some researchers use natural language processing techniques to discover statistical and/or linguistic patterns in the text in order to reveal the sentiment polarity. We can find such works in (Bonev

*et al.*, 2012; Harb *et al.*, 2008; Lin and He, 2009; Su *et al.*, 2008; Turney, 2002).

From the previous studies, we know the problem of sentiment analysis is of much attention by many researchers. Most of researchers investigate English reviews rather than ones with other languages. Therefore, we motivate to explore the movie reviews on Chinese Bulletin Board System (BBS). The aim of the study is to classify the sentiment of Chinese articles, and it will help readers understand the sentiment orientation. Besides, we are concerned with matching opinion with movie elements, called feature words in this paper. It is a finer-grained classification comparing to the article view.

The rest of this paper is organized as follows. Section 2 presents the overview of our system architecture. We describe the proposed method in details, i.e., the components of the system, in Section 3. The experimental data used by the system and the results achieved by the proposed methods are shown and discussed in Section 4. Finally, we express our main conclusions and the possible future directions.

## 2 Architecture Overview

Figure 1 shows the overall architecture of our methods for the sentiment analysis on movie reviews in the Chinese language. At first, we segment the words where the Chinese Knowledge Information Processing (CKIP) word segmentation system is utilized.<sup>1</sup> We then divide the document collection into two parts: one for training and one for testing. For the training corpus, we manually annotate opinion words to be positive, negative or neutral. In the following, we manually annotate feature words which are related to some movie elements such as plots, actors/actresses, special effects, and so on, and hence we get a list of feature words and their corresponding categories. After that, a Chinese parser is applied and we propose an algorithm to relate feature words to opinion words based on the parsing information. Subsequently, we apply an approach to determine the classification of opinion words and thus build an opinion word database. For the testing corpus, besides opinion and feature word lists, we use three more databases to help extract opinion and feature words. The rest processes are like ones of the training corpus, including parsing the documents and making an association between feature words

and opinion words. Finally, we calculate the scores of reviews and produce the movie recommendation results.

## 3 Methods

As shown in Figure 1, the methods of classifying sentiment are separated into several parts. The details of each part are explained in the following.

### 3.1 Word segmentation

We use CKIP word segmentation system in this phase. When we input a Chinese sentence, CKIP word segmentation system will segment the word and show the part of speech for each word. For example, if we input a Chinese sentence 我覺得很好看 wo-jue-de-hen-hao-kan ‘I thought it was very good to see’ to CKIP, the result will be “我(Nh) 覺得(Vt) 很(ADV) 好看(Vi).” It segments the sentence into four words 我 wo ‘I’, 覺得 jue-de ‘thought’, 很 hen ‘very’ and 好看 hao-kan ‘good to see’. The parts of speech are pronoun, transitive verb, adverb and intransitive verb for states, respectively. From the above example, we see a word in the Chinese language can be regarded as a “lexical item,” which is a sequence of one or more Chinese characters. In this paper, we use “word” to represent the “lexical item,” not limiting to the Chinese character numbers.

### 3.2 Opinion word manual annotation

In the Chinese language, the parts of speech of opinion words are subcategories of verbs, for example, Vi (intransitive verb for states), Vt (transitive verb for states or actions), and so on. There is no “adjective” tagged in Chinese, but the corresponding part of speech is “verb.” Therefore, we extract vocabularies that are verbs and treat them as opinion words. Meanwhile, we give the sentiment polarity as positive, negative and neutral for each opinion word. We also observe that adverbs can imply the strength of sentiment polarity. For example, 很 hen ‘very’ and 非常 fei-chang ‘very much’ can put emphasis on the opinion words. The negation words, 不 bu ‘no’ and 沒有 mei-you ‘not’, are able to put oppositeness on the opinion words. The parts of speech of above words are adverbs (ADV). Hence we extract the adverbs from the documents and annotate them as emphasis, oppositeness and irrelevance. Some examples of positive opinion words, negative opinion words, adverbs for emphasis and adverbs for oppositeness are listed in Table 1.

<sup>1</sup> <http://ckipsvr.iis.sinica.edu.tw/>

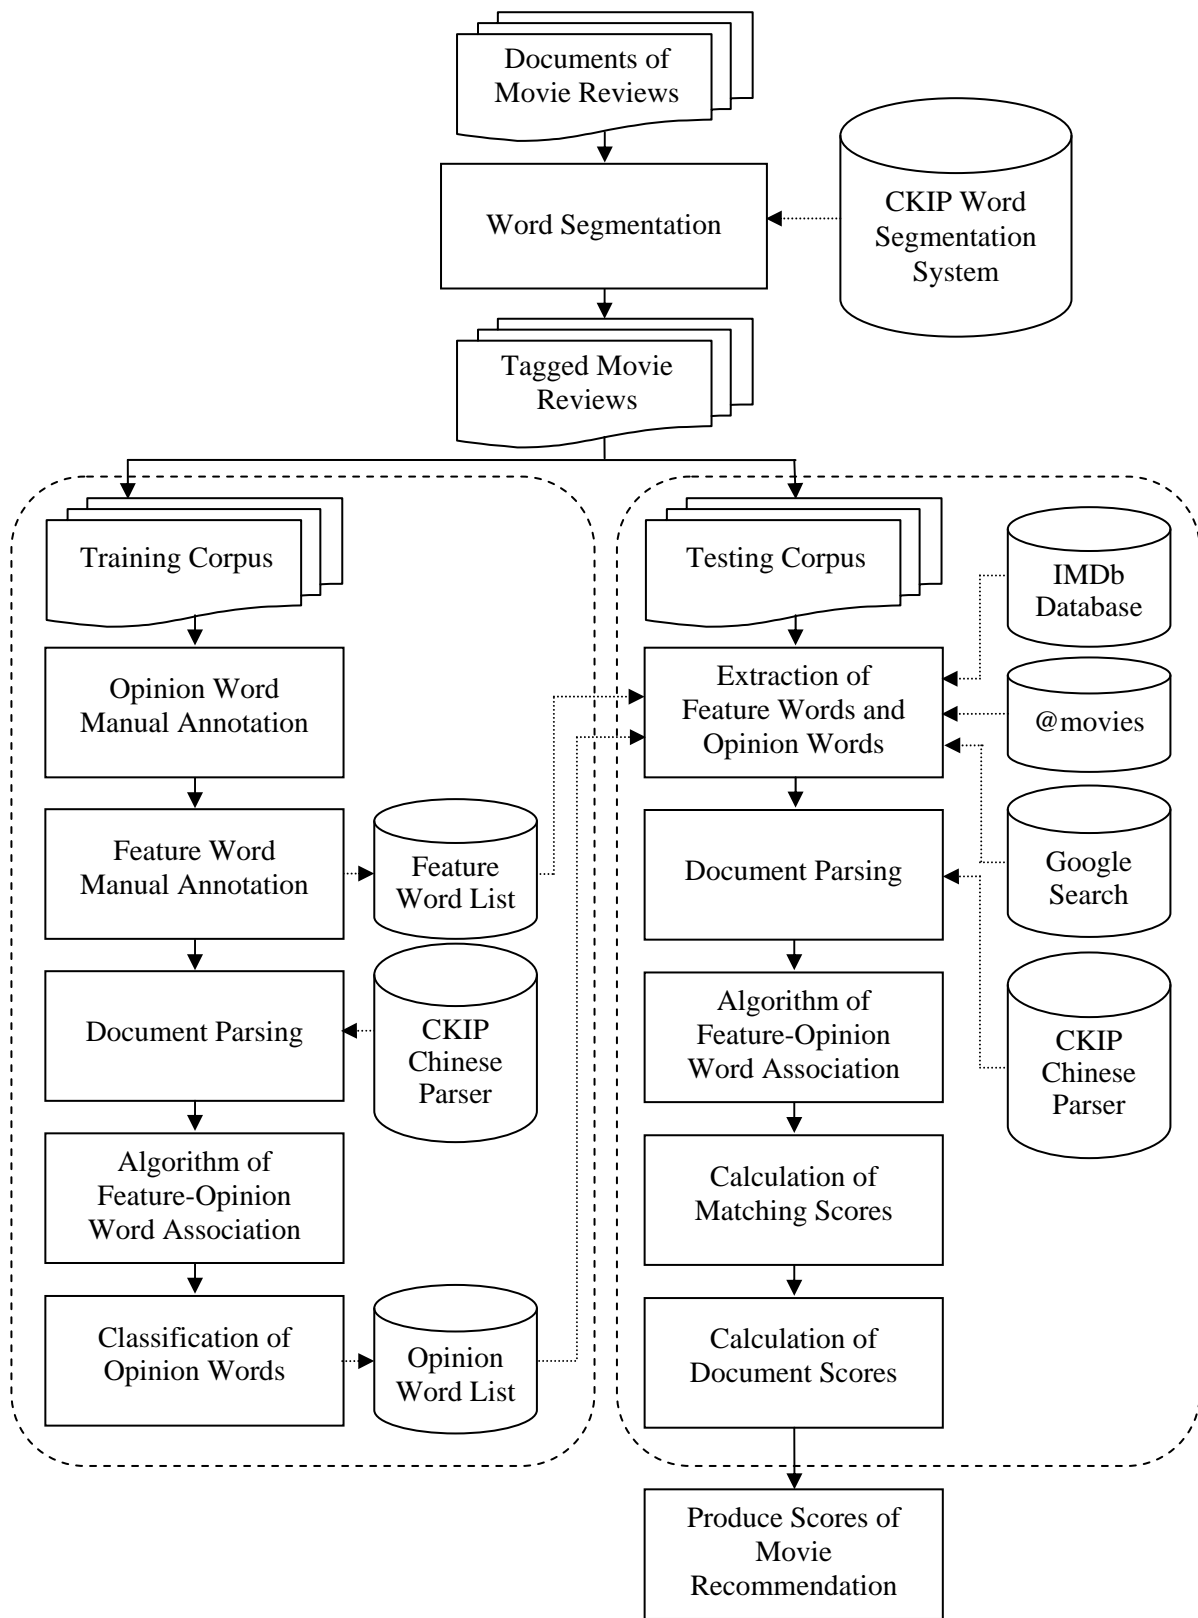

Figure 1. System architecture for the sentiment analysis on Chinese movie reviews.

Category	Examples
Positive opinion words	一氣呵成 yi-qi-he-cheng ‘ac-complish something at one go’, 鮮明 xian-ming ‘bright’, 討喜 tao-xi ‘satisfactory’
Negative opinion words	不清不楚 bu-qing-bu-chu ‘unclear’, 落伍 luo-wu ‘superannuated’, 莫名其妙 mo-ming-qi-miao ‘odd’
Adverbs for emphasis	十分 shi-fen ‘perfectly’, 愈來愈 yu-lai-yu ‘even more’, 格外 ge-wai ‘especially’
Adverbs for oppositeness	不可能 bu-ke-neng ‘impossible’, 尙未 shang-wei ‘not yet’, 無法 wu-fa ‘unable’

Table 1. Examples of opinion word annotations.

### 3.3 Feature word manual annotation

At this phase, we first manually annotate vocabularies related to movies from the training corpus and then build our own general feature word list. From the training corpus, we do not include some special proper noun related to movies such as names of actors/actresses (e.g., 湯姆克魯斯 tang-mu-ke-lu-si ‘Tom Cruise’) and character names (e.g., 哈利波特 ha-li-po-te ‘Harry Potter’) because it is not complete enough to cover all of the latest movies.

To include more complete movie-related people names, we reference to IMDb<sup>2</sup> and @movies<sup>3</sup> from which we get Chinese and English names of directors, playwrights and stars. Because authors often use hypocorisms or different translated Chinese names in the review articles, we search for hypocorisms and translated Chinese names from Google.<sup>4</sup> Finally, we combine searching data from Google with information from IMDb and @movies, and build a specific feature word list.

For classifying sentiment words at a finer-grained level, we reference to the study of Zhuang *et al.* (2006) and give the classification to each feature word. In this paper, we design four categories, including (1) entirety of movie, (2) story, (3) people (directors, playwrights, actors/actresses and characters), and (4) special effect and others. Table 2 shows some annotated feature word examples for each category.

<sup>2</sup> <http://www.imdb.com>

<sup>3</sup> <http://www.atmovies.com.tw>

<sup>4</sup> <http://www.google.com.tw>

Category	Examples
Entirety of movie	電影 dian-ying ‘movie’, 影片 ying-pian ‘film’, 場面 chang-mian ‘scene’
Story	伏筆 fu-bi ‘foreshadow’, 劇本 ju-ben ‘scenario’, 情節 qing-jie ‘action’
People	主角 zhu-jiao ‘leading role’, 人物 ren-wu ‘figure’, 配角 pei-jiao ‘minor actor’
Special effect and others	主題曲 zhu-ti-qu ‘theme song’, 動畫 dong-hua ‘animation’, 布景 bu-jing ‘stage settings’

Table 2. Examples of feature word annotations.

### 3.4 Document parsing

The structure of a sentence is important for understanding and analysis of sentence semantics. In this phase, we utilize CKIP Chinese parser for the parsing task.<sup>5</sup> The parser is based on probabilistic context-free grammar and is refined with probabilities of word-to-word association in disambiguation. After parsing, we get the syntactic structure trees of the documents in the corpus.

### 3.5 Algorithm of feature-opinion word association

In a sentence of movie reviews, some feature word is associated with some opinion word. Generally, most of algorithms (e.g., Hu and Liu, 2004) relate a feature word to an opinion word if they collocate closely in a sentence. For example, a sentence 這部電影很吸引人 zhe-bu-dian-ying-hen-xi-yin-ren ‘The movie is very attractive’ includes an association between the feature word (電影 dian-ying ‘movie’) and the opinion word (吸引人 xi-yin-ren ‘attractive’). But the algorithm is too simple to find all correct associations. Let us look at the following sentence.

再好看的電影也會變得無聊 zai-hao-kan-de-dian-ying-ye-hui-bian-de-wu-liao ‘The even more interesting film will become boring too.’ (1)

If we use a simple rule of only considering collocation, the opinion word 好看 hao-kan ‘interesting’ will associate with the feature word 電影 dian-ying ‘film’. But the semantics of the sentence means there should be an association be-

<sup>5</sup> <http://godel.iis.sinica.edu.tw/CKIP/parser.htm>

tween the feature word 電影 dian-ying ‘film’ and the opinion word 無聊 wu-liao ‘boring’. It is due to no syntactic information is adapted. Consequently, we introduce a Chinese parser and try to solve this problem.

From analyzing the parsing tree, we find the feature word 電影 dian-ying ‘film’ and the opinion word 無聊 wu-liao ‘boring’ are at the same level where the feature word 電影 dian-ying ‘film’ is related to the opinion word 無聊 wu-liao ‘boring’. It is an important clue in the study.

The other problem occurs if there are two feature words appearing in a sentence because we have to decide which feature word (or both words) should be related to the opinion word. Let us see the following sentences.

周杰倫的電影實在不吸引人 zhou-jie-lun-de-dian-ying-shi-zai-bu-xi-yin-ren ‘The film of Jay Chou is not attractive at all.’ (2)

周杰倫和電影都不吸引人 zhou-jie-lun-han-dian-ying-dou-bu-xi-yin-ren ‘Jay Chou and his film are not attractive at all.’ (3)

In Sentence (2), the opinion word 不吸引人 bu-xi-yin-ren ‘not attractive at all’ is to modify the feature word 電影 dian-ying ‘film’. But in Sentence (3), the opinion word 不吸引人 bu-xi-yin-ren ‘not attractive at all’ is to modify the feature words 周杰倫 zhou-jie-lun ‘Jay Chou’ and 電影 dian-ying ‘film’. We investigate this problem using the information of the syntactic structure tree.

By the above analysis, we propose the following algorithm to make an association between feature words and opinion words.

1. Traverse the syntactic structure tree by breadth-first search, and get the levels for all nodes.
2. Starting from the root, find whether there exists any feature word or opinion word.
  - 2.1 If feature words and opinion words are found, associate each feature word to all opinion words. For example, if there are three feature words and two opinion words, there will be six pairs of association. Stop searching in the tree.
  - 2.2 If only feature words exist, search for a subtree rooted with VP (verb phrase). If there is, search all nodes in the VP subtree for opinion words. If there is no VP subtree or no opinion word exists, stop searching in the tree.
  - 2.3 If only opinion words exist, search for a subtree rooted with NP. If there is,

search all nodes in the NP subtree for feature words. If there is no NP subtree or no feature words, stop searching in the tree.

- 2.4 If there are no opinion words and feature words, but we can find a subtree rooted with NP and a subtree rooted with VP, then search for feature words in the NP subtree and opinion words in the VP subtree. Make associations with all feature words and opinion words.
- 2.5 If no association is found in Steps 2.1 – 2.4, recursively, search the subtree at the different level and repeat Step 2.
3. At the levels of existing feature words and opinion words, find if there is any adverb built in our list. If there is, add the adverb to the feature-opinion word pair.
4. When the system stops searching for feature words and opinion words, only opinion words are extracted from the tree. Associate the opinion words with the special feature word NULL.
5. According to the category of feature words, the pair of feature-opinion words is put into the proper category. The special feature word NULL is classified to a new category.

Applying the algorithm, the matching pairs of Sentences (1) – (3) are presented in Table 3.

Sentence	Matching Pair
(1)	電影 dian-ying ‘film’ – 無聊 wu-liao ‘boring’
(2)	電影 dian-ying ‘film’ – 不 bu ‘not’ – 吸引人 xi-yin-ren ‘attractive’
(3)	周杰倫 zhou-jie-lun ‘Jay Chou’ – 不 bu ‘not’ – 吸引人 xi-yin-ren ‘attractive’ 電影 dian-ying ‘film’ – 不 bu ‘not’ – 吸引人 xi-yin-ren ‘attractive’

Table 3. Matching pairs for Sentences (1), (2) and (3).

### 3.6 Classification of opinion words

Based on the matching pairs extracting from Section 3.5, we can count the number of opinion words in the different categories. We introduce the concept of Term Frequency – Inverse Document Frequency (TF – IDF) to compute the importance of opinion words in the specific categories. The equations are listed as follows.

$$tf_{i,j} = \frac{n_{i,j}}{\sum_k n_{k,j}} \quad (1)$$

$$idf_{i,j}^* = \log \frac{\sum_p n_{i,p}}{1 + \sum_{p,p \neq j} n_{i,p}} \quad (2)$$

$$tf\_idf_{i,j}^* = tf_{i,j} \times idf_{i,j}^* \quad (3)$$

where  $n_{i,j}$  is the number of opinion word  $t_i$  appearing in the category  $g_j$ .  $tf_{i,j}$  is the normalized frequency of term  $t_i$  appearing in the category  $g_j$ .  $idf_{i,j}^*$  is a variation of traditional  $idf_{i,j}$ . In the traditional  $idf_{i,j}$ , it is obtained by dividing the total number of documents by the number of documents containing the term, and then taking the logarithm of that quotient. In this study, there are only four categories, the numerator will be 4 and it causes no discrimination with other terms. Hence, we design a new  $idf_{i,j}^*$  as Equation (2). The numerator is the total number of opinion word  $t_i$  in all categories. The denominator is one plus the total count of opinion word  $t_i$  in other three categories that  $t_i$  does not belong to (a summand one is for avoiding divided by zero).

According to our previous approach, the category of opinion words is the same as the associated feature word. If there is no feature word in the sentence but with an opinion word in a sentence, we must devise some strategy to decide the category. To solve this problem, we propose two thresholds  $M_1$  and  $M_2$ , and Equation (4). In this way, all opinion words  $t_i$  can have their mapping categories  $g_j$ .

$$t_i \in g_i \text{ if } tf\_idf_{i,j}^* > M_1 \text{ and } \frac{tf_{i,j} - idf_{i,j}^*}{\max\{tf\_idf_{i,k} \mid \forall k, k \neq j\}} > M_2 \quad (4)$$

We assign  $M_1=2.0$  and  $M_2=0.02$ . Table 4 lists examples of opinion words using Equation (4).

Category	Opinion Word Examples
Entirety of movie	推薦 tui-jian ‘recommend’ 叫座 jiao-zuo ‘box-office’
Story	動人 dong-ren ‘touching’ 冗長 rong-chang ‘long’
People	迷人 mi-ren ‘charming’ 成熟 cheng-shou ‘mature’
Special effect and others	逼真 bi-zhen ‘lifelike’ 震撼 zhen-han ‘vibrate’

Table 4. Examples of opinion words.

### 3.7 Calculation of document scores

Now, we have a set of matching pairs between opinion words and feature words. We design an

equation to compute the scores for the pairs. The equation is listed in Equation (5).

$$S_{i,j} = opS(Opinion_{i,j}) \times \prod_k advS(Adv_{i,j,k}) \quad (5)$$

where  $S_{i,j}$  presents the score of the  $i$ th matching pair in category  $g_j$ .  $Opinion_{i,j}$  stands for the opinion word of the  $i$ th matching pair in category  $g_j$ . The function  $opS$  will output 1 if  $Opinion_{i,j}$  is a positive sentiment vocabulary, and output  $-1$  if  $Opinion_{i,j}$  is a negative sentiment vocabulary.  $Adv_{i,j,k}$  is the adverb of the  $i$ th matching pair in category  $g_j$ . Since there is perhaps more than one adverb in the matching pair, we give a third index  $k$  in the equation. The function  $advS$  has values of 1.2 and  $-1$  as its range. If it produces the value 1.2, it means the adverb  $adv_{i,j,k}$  is used for emphasis on the opinion word  $Opinion_{i,j}$ . If it generates the value  $-1$ , it means the adverb  $adv_{i,j,k}$  puts oppositeness on the opinion word  $Opinion_{i,j}$ . The final score of the  $i$ th matching pair in category  $g_j$  is the product of  $opS$  and  $advS$ .

When we get the scores of all opinion words in the categories, we can compute the score of the opinion word in the review article that is the summation of individual scores. The equation is listed as below.

$$Score = \sum_{j=1}^4 \sum_k S_{k,j} \quad (6)$$

where  $Score$  is the sentiment score of the document. We then map  $Score$  into five levels, i.e., 1, 2, 3, 4 and 5, and call it as “level score”. Levels 1 and 2 identify that the document is with negative sentiment, and level 1 is more negative than level 2. Level 3 means that the document is neutral. Levels 4 and 5 identify the positive sentiment polarity in the document, and level 5 is stronger.

## 3.8 Make movie recommendation

In the last phase, we average the level scores of reviews for each movie, and then the recommendation for each movie is presented with the averaged level scores.

## 4 Experiments and Results

### 4.1 Experimental data

The experimental data were obtained from the movie discussion board of website ptt BBS.<sup>6</sup> Users can post their opinions on BBS that acts as a platform for users to share their opinions. From the latest movies, we first select seven movies

<sup>6</sup> telnet://ptt.cc

with different styles. The movies are Mission: Impossible - Ghost Protocol, Treasure Hunter, The A-Team, The Avengers, Toy Story 3, You are the Apple of My Eye, and The Hunger Games. Then we automatically retrieve 50 articles for each movie. To get richer information, the length of retrieved articles is restricted to more than 100 Chinese words. In the following, we filter out the articles that are irrelevant to reviews. For example, some articles are filled with the same words such as 好看 hao-kan ‘good to see’ and no other words are appeared, so the articles will be filtered out. Finally, we get 321 articles with 379,360 Chinese words.

## 4.2 Experimental results and discussion

In our experiments, we retrieve 11,837 pairs of feature-opinion word matching where 6,906 pairs are useful and 4,931 pairs are useless. The 6,906 pairs are used as evaluation.

**Evaluation of reliability of agreement:** First, we invite three humans (A, B and C) who often go to the movies to read the review articles and give the level scores (1, 2, 3, 4, and 5). The average scores will be the gold standard for evaluation. For assessing the reliability of agreement between three scores the humans give, we use the weighted Kappa coefficient (Sim and Wright, 2005) with the quadratic weighting scheme. The formula is given as below.

$$k_w = \frac{\sum (w \cdot f_o) - w \cdot f_c}{n - \sum (w \cdot f_c)},$$

$$quadratic\ weight = 1 - \left(\frac{i-j}{k-1}\right)^2 \quad (7)$$

where  $w$  is the weight,  $f_o$  is the value of the observed disagreement, and  $f_c$  is the value of the chance disagreement.  $k$  is the number of the ratings and  $(i-j)$  is the value of disagreement. Kappa’s possible values are constrained to the interval  $[0, 1]$ ;  $k_w=0$  means that agreement is not different from by chance, and  $k_w=1$  means perfect agreement.

The agreement evaluation results are shown in Table 5. It shows that human answers agree with each other almost perfect since the values of the weighted kappa are larger than 0.8.

Human Pairs	Weighted Kappa $k_w$
A, B	0.87
A, C	0.89
B, C	0.89

Table 5. Human agreement evaluation results.

### Evaluation of results with human scores:

We use the Mean Reciprocal Rank (MRR) to evaluate the difference between the scores produced by the system and the scores given by the humans. The formula of MRR is as follows.

$$MRR = \frac{1}{|A|} \sum_{i=1}^{|A|} \frac{1}{rank_i}, \quad (8)$$

$$rank_i = |human(A_i) - system(A_i)| + 1$$

where  $A$  is the set of all review documents.  $|A|$  is the number of review documents.  $A_i$  is the  $i$ th review document.  $human(A_i)$  is the average score given by humans.  $system(A_i)$  is the score given by our proposed system.  $rank_i$  means the difference between humans and the system, and a summand 1 is used for avoiding divided by zero. The MRR value to our system is 0.61. Table 6 shows the rank distribution.

$rank_i$	Article Numbers	Ratio
1	110	34.27%
2	117	36.45%
3	67	20.87%
4	18	5.61%
5	9	2.80%

Table 6. Rank distribution of the evaluation.

From Table 6, 34.27% articles get the same scores between the system and humans. If the score difference of the system and humans is less than 1, there are 70.72% articles. Only 8.41% articles have the deviation greater than 2. The result demonstrates that the scores produced by our system are reliable.

If we classify the scores of 4 and 5 as recommendable and others as non-recommendable, then the evaluation results are shown in Table 7.

Class	Totals	System	Correct	Recall	Precision
Re	201	219	156	77.61%	71.23%
Non-re	120	102	57	47.50%	55.88%

Table 7. Rank distribution of the evaluation.

In Table 7, ‘‘Re’’ means recommendable and ‘‘Non-re’’ means non-recommendable. ‘‘Totals’’ is the article amount that humans give and ‘‘System’’ is the article amount that the system produces. ‘‘Correct’’ presents number of consistency between humans and the system. ‘‘Recall’’ is the value of ‘‘Correct’’ dividing ‘‘Totals’’. ‘‘Precision’’ is the value of ‘‘Correct’’ dividing ‘‘System’’. The result shows that the performance of ‘‘recommendable’’ is better than ‘‘non-recommendable’’.

To explore the difference between humans and the system more detailed, we observe that most of the scores generated by the system and humans are similar. Especially, there is no difference for the movie “Mission: Impossible”. The largest difference exists in the movie “Treasure Hunter”. It is because the reviews have some sentences damn the movie with faint praise, i.e., with negative sentiment but seems positive to the system. Let us see the following sentence.

很意外的發現這是一部中等以上的優良惡搞片 hen-yi-wai-de-fa-xian-zhe-shi-yi-bu-zhong-deng-yi-shang-de-you-liang-e-gao-pian ‘Unexpectedly we find that it is a good spoof movie with an average level or better.’ (4)

For Sentence (4), the system produces a feature-opinion pair of “movie – good” and marks it positive. But in effect, the opinion should be negative. It is the main reason why the performance of non-recommendation is worse.

In addition, the system can retrieve opinion words that reviewers often use for different categories. Table 8 lists some opinion words that are frequently used for the movie “Mission: Impossible - Ghost Protocol”. These extracted opinion words are reasonable for commenting about a Hollywood action movie.

Category	Opinion Words
Story	緊湊 jin-cou ‘compact’ 刺激 ci-ji ‘exciting’ 幽默 you-mo ‘humorous’ 驚人 jing-ren ‘amazing’
People	好 hao ‘good’ 強 qiang ‘strong’ 帥氣 shuai-qi ‘smart’ 鮮明 xian-ming ‘bright’
Special effect and others	經典 jing-dian ‘classic’ 精彩 jing-cai ‘splendid’ 罕見 han-jian ‘rarely seen’ 豐富 feng-fu ‘rich’

Table 8. Some frequently used opinion words.

#### Evaluation of results with IMDb scores:

Except for the scores produced by humans, we also compare the results with the scores in the IMDb website. IMDb is a popular movie database and its registered members can give scores for movies. This aspect of evaluation will tell us the consistence between Taiwanese and members in the IMDb website. Because the scores pro-

posed by IMDb are ranged from 1 to 10, we divide them by 2 to mapping into our 5-graded scores. The result is shown in Table 9.

Movies	System	IMDb
Mission: Impossible - Ghost Protocol	4.1	3.7
Treasure Hunter	3.5	2.0
The A-Team	4.0	3.5
The Avengers	4.1	4.3
Toy Story 3	4.2	4.3
You are the Apple of My Eye	3.9	3.8
The Hunger Games	2.9	3.8

Table 9. Comparison to the system and IMDb.

Although the reviewers from IMDb are different from ones from our movie discussion board, the comparison also demonstrates that the recommendable trend is consistent.

## 5 Conclusion

In this paper, we propose a sentiment classification system based on parsing models. We present a matching algorithm for feature-opinion words, and make effective analysis for reviews with plenty of words.

The experimental results show 70.72% precision rate under the difference less than 1. If the scores are mapped to two levels (recommendable, non-recommendable), the precision rates are 71.23% and 55.88%, respectively. We also compare the result with a popular movie website IMDb, and we discover most of the score trend is similar. It shows the results are exhilarating and indicates that our system can reach satisfied expectancy for movie recommendation.

In the future, we plan to adapt learning methods for matching feature words and opinion words. Besides, we want to explore word polarity according to opinion holders. It will help users understand sentiment orientation for each review more thoroughly.

# Sentiment Aggregation using ConceptNet Ontology

Subhabrata Mukherjee and Sachindra Joshi

IBM India Research Lab

{subhabmu, jsachind}@in.ibm.com

## Abstract

Sentiment analysis of reviews traditionally ignored the association between the features of the given product domain. The hierarchical relationship between the features of a product and their associated sentiment that influence the polarity of a review is not dealt with very well. In this work, we analyze the influence of the hierarchical relationship between the product attributes and their sentiments on the overall review polarity. ConceptNet is used to automatically create a product specific ontology that depicts the hierarchical relationship between the product attributes. The ontology tree is annotated with feature-specific polarities which are aggregated bottom-up, exploiting the ontological information, to find the overall review polarity. We propose a weakly supervised system that achieves a reasonable performance improvement over the baseline without requiring any tagged training data.

## 1 Introduction

In recent years there has been a huge surge of activity in the social networking sites, blogs and review sites. The voluminous amount of data generated is a goldmine of information for the retail brands to find out the customer needs, concerns and potential market segments. Sentiment analysis aims to mine this information to find out the popular sentiment about any product and its associated features.

Traditionally sentiment analysis has been posed as a text classification task on features derived from the given text. In the product review domain, the initial works in sentiment analysis focused on classifying the entire review as positive or negative using various word-based and phrase-based features (Turney *et al.*, 2003; Turney 2002; Kamps *et al.*, 2002; Hatzivassiloglou *et al.*, 2000; Hatzivassiloglou *et al.*, 2002). The more recent works focused on product feature

extraction from a review and performing feature-specific sentiment analysis (Hu *et al.*, 2004; Mukherjee *et al.*, 2012). For example, the review, *The audio quality of my new phone is absolutely awesome but the picture taken by the camera is a bit grainy*, is positive with respect to the *audio quality* and negative with respect to the *camera*. However, once the feature-specific polarities are obtained, the works do not describe any systematic approach to aggregate the feature-specific polarities to obtain the overall review polarity. A naïve count-based feature-specific polarity aggregation will not work well for reviews having different features with diverse opinions. A bag-of-words based model will pick up *awesome* and *grainy* as the sentiment features and mark the overall review as *neutral*. One may argue that the *audio quality* is more important to a *cell phone* than the *camera* and hence the overall review polarity should be positive. While the feature-specific model associates sentiment to features, it cannot do a polarity aggregation in absence of feature association information to find the overall review polarity.

Let us consider the following review taken from Amazon.com which more clearly depicts the necessity of learning the hierarchical product-attribute relationship and associated sentiments.

*I bought a Canon EOS 7D (DSLR). It's very small, sturdy, and constructed well. The handling is quite nice with a powder-coated metal frame. It powers on quickly and the menus are fairly easy to navigate. The video modes are nice, too. It works great with my 8GB Eye-Fi SD card. A new camera isn't worth it if it doesn't exceed the picture quality of my old 5Mpixel SD400 and this one doesn't. The auto white balance is poor. I'd need to properly balance every picture taken so far with the ELPH 300. With 12 Mpixels, you'd expect pretty good images, but the problem is that the ELPH 300 compression is turned up so high that the sensor's acuity gets lost (softened) in compression.*

The above example depicts the complexity involved in analyzing product reviews. The review has a mix of good and bad comments about various features of the product. A flat classification model which considers all features to be equally important will fail to capture the proper polarity of the review. The reviewer seems happy with the *camera size, structure, easy use, video modes, SDHC support etc.* However, the *auto-white balance* and *high compression* leading to sensor acuity seem to disappoint him. Now, the primary function of a camera is to take good pictures and videos. Thus *picture, video quality, resolution, color balance etc.* are of primary importance whereas *size, video mode, easy use etc.*, are secondary in nature. The overall review polarity should be negative as the reviewer shows concerns about the most important features of the camera.

In this paper, we propose a weakly supervised approach to aggregate the sentiment about various features of a product to give the overall polarity of the review, without requiring expensive labeled training data. The approach is weakly supervised due to the requirement of ConceptNet (created by crowd-sourcing), a dependency parser and a sentiment lexicon.

The objectives of the paper can be summarized as:

1. Automatically learning the product-attribute hierarchy from a knowledge resource, where we leverage ConceptNet (Hugo *et al.*, 2004) to learn the product *attributes, synonyms, essential components, functionalities etc.* and create a domain specific ontology tree
2. Discovering the various features of a product in the review and extracting feature-specific sentiment
3. Mapping the product features with their associated sentiments to the ontology tree and aggregating the feature-specific sentiments to determine the overall review polarity

## 2 Related Works

The initial works in sentiment analysis used bag-of-words features like unigrams, bigrams, adjectives *etc.* which gave way to the usage of phrase-based features like part-of-speech sequences (Ex: adjectives followed by nouns) (Turney *et al.*, 2003; Turney 2002; Kamps *et al.*, 2002; Hatzivassiloglou *et al.*, 2000; Hatzivassiloglou *et al.*, 2002). These works did not consider the attributes or features of the underlying product domain in the review. A review may contain multiple

features with a different opinion about each feature. This makes it difficult to come up with an overall polarity of the review. The latter works addressed this issue by focusing on feature-specific sentiment analysis.

Feature-specific sentiment analysis attempts to find the polarity of a review with respect to a given feature. Approaches like dependency parsing (Wu *et al.*, 2009; Chen *et al.*, 2010; Mukherjee *et al.*, 2012), joint sentiment topic model using LDA (Lin *et al.*, 2009) have been used to extract feature-specific expressions of opinion. Although these works extract the feature-specific polarities, they do not give any systematic approach to aggregate the polarities to obtain the overall review polarity.

Wei *et al.* (2010) propose a hierarchical learning method to label a product's attributes and their associated sentiments in product reviews using a Sentiment Ontology Tree (HL SOT). Although our work stems from a similar idea, it differs in a number of ways. The HL-SOT approach is completely supervised, requiring the reviews to be annotated with *product-attribute relations*, as well as *feature-specific opinion expressions*. The approach requires a lot of labeling information which needs to be provided for every domain. Also, the authors do not describe any elegant approach to aggregate the feature-specific polarities of the children nodes to obtain the overall review polarity.

In this work, we use ConceptNet (Hugo *et al.*, 2004) as a knowledge resource to automatically construct a domain-specific ontology tree for product reviews, without requiring any labeled training data. ConceptNet relations have an inherent structure which helps in the construction of an ontology tree from the resource. ConceptNet has been used in information retrieval tasks in other domains (Guadarrama *et al.*, 2008; Kotov *et al.*, 2012). But there has been a very few works (Sureka *et al.*, 2010) in sentiment analysis using ConceptNet. Unlike the previous works, we present an approach to deal with noisy and one-to-many relations in ConceptNet as well as the myriad of relations and the ensuing topic drift. We also present a novel sentiment aggregation approach to combine the feature-specific polarities with ontological information to find the overall polarity of the review.

## 3 Ontology Creation from ConceptNet

Ontology can be viewed as a knowledge base, consisting of a structured list of concepts, rela-

tions and individuals (Estival *et al.*, 2004). The hierarchical relationship between the product attributes can be best captured by an *Ontology Tree*. Wei *et al.* (2010) use a tree-like ontology structure that represents the relationships between a product’s *attributes* or *features*. They define a Sentiment Ontology Tree (SOT) where each of the non-leaf nodes of the SOT represents an attribute of a camera and all leaf nodes of the SOT represent sentiment (positive/negative) nodes respectively associated with their parent nodes.

We adopt a similar idea and consider an *Ontology Tree* for a product domain (say, *camera*) where the *feature nodes* (attributes like *body*, *lens*, *flash* etc.) are annotated with *feature-specific polarities* of the review.

Figure 1. Snapshot of Camera Ontology Tree

The *feature nodes* in our *ontology tree* depict features of interest or attributes (Ex: *lens*, *flash*, *picture* etc.) of the given product (Ex: *camera*). The edges in the ontology tree depict the *relation type* connecting a feature with its parent. For example, a *lens* is a *partof* a *camera*, a *camera* is *usedfor* taking *pictures*, *time\_delay* is *derivedfrom* *time* etc. The *feature nodes* are annotated with *polarities* (+ and – denoting positive and negative sentiment, respectively) of the feature with respect to the review.

Figure 1 shows a snapshot of the ontology tree of a camera for the given example review in Section 1. The figure shows more positive feature-polarities than negative feature-polarities, but the review is still negative. This is because the feature polarities in the higher level of the ontology tree dominate those at a lower level, *i.e.* the importance of a feature dilutes with the increase in the ontology depth.

### 3.1 Domain Ontology Tree Creation

In this work, we leverage ConceptNet (Hugo *et al.*, 2004) to construct a domain-specific ontology tree for product reviews. ConceptNet is a very large semantic network of common sense knowledge which can be used to make various inferences from text. It is the largest, machine-usable common sense resource consisting of more than 250,000 propositions. Mining infor-

mation from ConceptNet can be difficult as one-to-many relations, noisy data and redundancy undermine its performance for applications requiring higher accuracy (Smith *et al.*, 2004). However, we use ConceptNet for the following reasons:

1. The relational predicates in ConceptNet have an inherent structure suitable for building ontology. For example, relations like *partof*, *hasa*, *madeof* can be readily conceptualized as hierarchical relations.
2. ConceptNet has a closed class of well-defined relations. The relations can be suitably weighted and used for various purposes.
3. The continual expansion of the knowledge resource through crowd-sourcing incorporates new data and enriches the ontology.
4. Ontology creation using ConceptNet does not require any labeling of product reviews.

#### 3.1.1 ConceptNet Relations

ConceptNet<sup>1</sup> has a closed class of 24 primary relations, expressing connections between various concepts.

camera	UsedFor	take_picture
camera	IsA	tool_for_take_picture
camera	AtLocation	store
tripod	UsedFor	keep_camera_steady
camera	CapableOf	record_image
camera	IsA	device
flash	PartOf	camera
lens	AtLocation	camera
tripod	AtLocation	camera_shop
camera	IsA	photo_device
cannon	ConceptuallyRelatedTo	camera
photograph	ConceptuallyRelatedTo	camera
picture	ConceptuallyRelatedTo	camera

Table 1. ConceptNet Relation Examples

We categorize the ConceptNet relations into 3 primary categories – *hierarchical* relations, *synonymous* relations and *functional* relations. *Hierarchical* relations represent parent-child relations and can be used to construct the tree top-down, as the relations are transitive. *Synonymous* relations help to identify related concepts. Thus similar nodes can be merged during tree construction. *Functional* relations help to identify the purpose or property of interest of the concept. The relation categorization helps to weigh various relations differently. Consider the case where the *functional* relation “a camera is *usedfor* taking\_picture” may be of more interest to an individual than the hierarchical relation “a camera

<sup>1</sup><http://csc.media.mit.edu/docs/conceptnet/conceptnet4.html#relations>

hasa tripod”. Thus a product which takes good pictures but lacks a tripod will have a high positive polarity. This is, of course, subjective and can be used to personalize the ontology tree. The other advantage of relation categorization is to deal with one-to-many relations, as will be discussed in the next section.

Hierarchical	: LocatedNear, HasA, PartOf, MadeOf, IsA, InheritsFrom
Synonymous	: Synonym, ConceptuallyRelatedTo
Functional	: UsedFor, CapableOf, HasProperty, DefinedAs

**Table 2.** ConceptNet Relation Type Categorization

### 3.1.2 Algorithm for Ontology Construction

Ontology construction from ConceptNet is hindered by the following obstacles:

1. One-to-many relations exist between the concepts. For example, the concepts *camera* and *picture* can be associated by relations like - camera *UsedFor* take\_picture, camera *HasA* picture, picture *ConceptuallyRelatedTo* camera, picture *AtLocation* camera etc.

2. There is a high degree of *topic drift* during relation extraction. For example, the predicates camera *HasA* lens, lens *IsA* glass and glass *HasA* water places water at a high level in the ontology tree, although it is not at all related to camera.

The hierarchical relations in ConceptNet are much more definitive, have much less topic drift and can be used to ground the ontology tree. Hence, they are preferred over other relations during a relational conflict. In the above example, where *picture* is *ConceptuallyRelatedTo* *camera*, putting camera and picture at the same level will generate an incorrect ontology tree. The issue can be averted by preferring the hierarchical relation between camera and picture over the synonymous relation. The relational conflict is averted by ordering the predicate relations where hierarchical relations > synonymous relations > functional relations. In order to avoid topic drift, the ontology feature nodes extracted from ConceptNet are constrained to belong to a list of frequently found concepts in the domain, which is obtained from an unlabeled corpus.

In the first step of ontology construction, all the unlabeled reviews in the corpus are Part-of-Speech tagged and all *Nouns* are retrieved. The frequently occurring concepts are then added to the *feature set*. In the second step, the ConceptNet relations are partitioned into three disjoint sets *hierarchical*, *synonymous* and *functional*. The domain name is taken as the root of the *Ontology Tree*.

Input: Raw unlabeled corpus of product reviews and ConceptNet Knowledge Network

1. Part-of-speech tag the reviews and retrieve all *Nouns*. Let  $\bar{N}$  be the set of all potential features.
  2. A feature  $n_i \in \bar{N}$  is considered relevant and added to the feature set  $N$  if  $tf - idf(f_i) > \vartheta$ , where  $\vartheta$  is the corpus threshold
  3. Let  $R$  be the set of all ConceptNet relations which is partitioned into the relation sets  $H$  (hierarchical),  $S$  (synonymous) and  $F$  (functional).
  4. Every relation tuple  $r_{ij}(f_i, f_j) \in R$  is assigned to one of the sets  $S, F$  or  $H$  with ties being broken as  $H > S > F$
  5. Construct the ontology tree  $T(V, E)$  top-down. The root of the tree is taken as the domain name. Initially  $V = \{domain\_name\}, E = \{\emptyset\}$ .
  6. Add a vertex  $v_j$  to  $V$  and an edge  $e_{ij}(v_i, v_j)$  to  $E, \forall r_{ij}(v_i, v_j) \in H$  s.t.  $v_i \in V$  and  $v_j \in N$
  7. Merge  $v_j$  with  $v_i \forall r_{ij}(v_i, v_j) \in S$  s.t.  $v_i \in V$  and  $v_j \in N$
  8. Add a vertex  $v_j$  to  $V$  and an edge  $e_{ij}(v_i, v_j)$  to  $E, \forall r_{ij}(v_i, v_j) \in F$  s.t.  $v_i \in V$  and  $v_j \in N$
- Output:  $T(V, E)$

#### Algorithm 1. Ontology Tree Construction from ConceptNet

The *hierarchical relation set* is taken first, and the tree is constructed recursively, such that the parent concept in any hierarchical relation is already in the tree and the child concept belongs to the set of frequently occurring concepts in the domain. The *synonymous relation set* is taken next, and similar concepts are merged recursively, such that one of the concepts in any synonymous relation is already in the tree and the other concept belongs to the frequently occurring *feature set*. In the last step, the *functional relation set* is taken and processed in the same way as the hierarchical relation set.

The constructed ontology tree depicts the product attributes in the domain and the different parent-child relations. The ontology creation does not require any labeled training data. Algorithm 1 shows the detailed steps for the ontology creation. Figure 1 shows a snapshot of the constructed ontology.

### 3.2 Feature Specific Sentiment Extraction

A review or a given sentence may contain multiple features with a different opinion regarding each feature. Given a sentence and a target fea-

ture, it is essential to obtain the polarity of the sentence with respect to the feature. For example the sentence, “*The movie had a nice plot but the acting was too shabby*”, is *positive* with respect to *plot* but *negative* with respect to *acting*.

In this work, we use the feature-specific sentiment extraction approach in Mukherjee *et al.* (2012), which do not need labeled review data for training. The authors use *Dependency Parsing* to capture the association between any specific feature and the expressions of opinion that come together to describe that feature.

Given a sentence  $S$ , let  $W$  be the set of all words in the sentence. Let  $R$  be the list of *significant* dependency parsing relations (like *nsubj*, *doobj*, *advmod*, *amod* etc.), which are learnt from a corpus. A Graph  $G(W, E)$  is constructed such that any  $w_i, w_j \in W$  are directly connected by  $e_k \in E$ , if  $\exists R_i$  s.t.  $R_i(r_i, r_j) \in R$ . The *Nouns* are extracted by a POS-Tagger which form the initial feature set  $F$ . Let  $f_i \in F$  be the target feature.

We initialize ‘ $n$ ’ clusters  $C_i$ , corresponding to each feature  $f_i \in F$  s.t.  $f_i$  is the clusterhead of  $C_i$ . We assign each word  $w_i \in S$  to the cluster whose clusterhead is closest to it. The distance is measured in terms of the number of edges in the shortest path, connecting any word and a clusterhead. Any two clusters are merged if the distance between their clusterheads is less than some threshold. Finally, the set of words in the cluster  $C_i$ , corresponding to the target feature  $f_i$  gives the opinion about  $f_i$ .

The words in the cluster  $C_i$  are classified with the help of a lexicon (*majority voting*) to find the polarity  $p_i \in \{-1, 0, 1\}$  about the target feature  $f_i$ .

### 3.3 Sentiment Aggregation

Consider the camera review example in Section 1, and Figure 1 where the facets of the review are mapped to the camera ontology with their specific polarities. It can be observed that the product attributes at a higher level of the tree dominate those at the lower level. If a reviewer says something positive or negative about a particular feature, which is at a higher level in the ontology tree (say *picture*), it weighs more than the information of all its children nodes (say *light*, *resolution*, *color* and *compression*). This is because the parent feature abstracts the information of its children features. The feature importance is captured by the height of a feature node in the ontol-

ogy tree. In case the parent feature polarity is neutral, its polarity is given by its children feature polarities. Thus the information at a particular node is given by its self information and the weighted information of all its children nodes. The information propagation is done bottom-up to determine the information content of the root node, which gives the polarity of the review.

Consider the ontology tree  $T(V, E)$  where  $V_i \in V$  is a *product attribute set*. The product attribute set  $V_i$  is represented by the tuple  $V_i = \{f_i, p_i, h_i\}$ , where  $f_i$  is a product feature,  $p_i$  is the review *polarity score* with respect to  $f_i$  and  $h_i$  is the height of the *product attribute* in the *ontology tree*.  $e_{ij} \in E$  is an *attribute relation type* (Section 3.1.1) connecting  $f_i \in V_i, f_j \in V_j$  and  $V_i, V_j \in V$ . Let  $V_{ij}$  be the  $j^{\text{th}}$  child of  $V_i$ .

The *positive sentiment weight* (PSW) and *negative sentiment weight* (NSW) of a vertex  $V_i$  are defined as,

$$PSW(V_i) = h_i \times p_i^+ + \sum_j PSW(V_{ij}) \times u_{ij}$$

$$NSW(V_i) = h_i \times p_i^- + \sum_j NSW(V_{ij}) \times u_{ij}$$

where  $p_i^+ \in \{0, 1\}$  and  $p_i^- \in \{-1, 0\}$ .

The review polarity is given by the *expected sentiment-weight* (ESW) of the tree defined as,

$$ESW(\text{root}) = PSW(\text{root}) + NSW(\text{root})$$

Consider Figure 1 and assume the edge-weights of the tree to be 1.

$$PSW(\text{accessories}) = 2 \times 0 + (1 \times 1 + 1 \times 1 + 1 \times 1) = 3$$

$$NSW(\text{accessories}) = 0, PSW(\text{picture}) = 0, PSW(\text{video}) = 1$$

$$NSW(\text{picture}) = 3 \times -1 + (-1 \times 2 - 1 \times 2) = -7$$

$$PSW(\text{camera}) = 4, NSW(\text{camera}) = -7, ESW(\text{camera}) = -3$$

Figure 2 shows a snapshot of the camera ontology tree annotated with positive and negative sentiment weights. Each feature node  $f_i$  is annotated with a tuple  $[p_i^+, p_i^-]$  corresponding to its positive sentiment weight and negative sentiment weight respectively. Absence of a weight indicates that the feature node has a neutral sentiment. The figure depicts the importance of hierarchical learning as the negative sentiment weight of *picture*, at a higher level of the tree, dominates the positive sentiment weight of the other feature nodes at a lower level in the tree, resulting in the overall review polarity being negative.

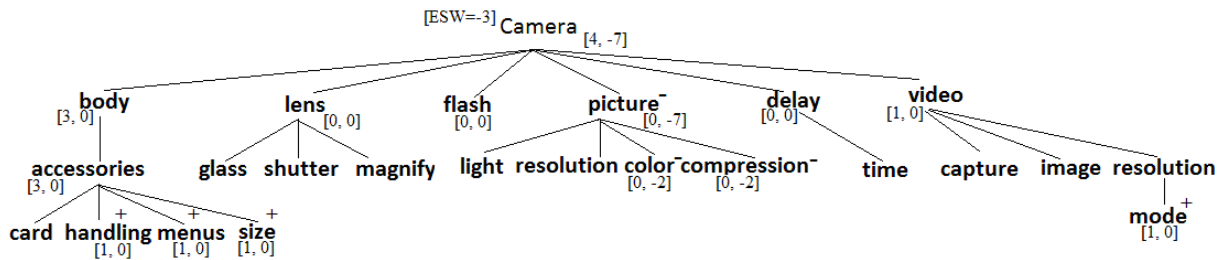

Figure 2. Snapshot of Camera Ontology Tree with Sentiment Weights

## 4 Experimental Evaluation

Analysis is performed in three domains corresponding to *automobile*, *camera* and *software*.

### 4.1 Dataset Preparation

Domain	Positive Reviews	Negative Reviews	Total Reviews
Automobile	584	152	736
Camera	986	210	1196
Software	1000	915	1915

Table 3. Dataset Statistics

The camera reviews are collected from Amazon.com and manually tagged as positive or negative. The automobile and software reviews<sup>2</sup> are taken from Blitzer *et al.* (2007). Table 3 shows the dataset statistics.

All the words are lemmatized in the reviews so that camera and cameras are reduced to the same root word camera.

Words like *hvnt*, *dnt*, *cnt*, *shant* etc. are replaced with their proper form in both our model and the baseline to capture negation.

### 4.2 Baselines

In this work, we consider three unsupervised baselines to compare the proposed approach.

**1. Lexical Baseline:** Lexical classification (Taboada *et al.*, 2011) is taken as the *first* baseline for our work. A sentiment lexicon is taken which contains a list of positive and negative terms. If the number of positive terms is greater than the number of negative terms, the review is considered to be positive and negative otherwise. The same approach is also used in our work while finding the polarity of the cluster representing the feature-specific opinion about a review. The lexical baseline considers all unigrams to be equally important, whereas we distinguish features by their position in the ontology hierarchy. This baseline model does not incorporate feature-specificity.

We experimented with three publicly available lexicons to obtain unigram polarities:

1. SentiWordNet 3.0 (Baccianella *et al.*, 2010)
2. General Inquirer (Stone *et al.*, 1966)
3. Bing Liu Lexicon (Hu *et al.*, 2004)

**2. Corpus Feature-Specific Baseline:** Tf-Idf measure is used to obtain the frequently occurring concepts in the domain from an unlabeled corpus. A feature-specific sentiment extraction model (Mukherjee *et al.*, 2012) is used to find the review polarity regarding each feature. A linear aggregation of the feature-specific polarities is done to obtain the overall review polarity. If the aggregation of the positive feature-specific polarities is greater than the aggregation of the negative feature-specific polarities, the review is considered to be positive and negative otherwise.

This model resembles the approach of LARA (Wang *et al.*, 2010) in a loose way, where the authors jointly learn the feature weights and feature-specific polarities.

**3. ConceptNet and Corpus Feature-Specific Baseline:** In this baseline, the features are extracted using ConceptNet and an unlabeled corpus using Algorithm 1. The feature set  $\bar{F} = H \vee S \vee F$  is considered and the same feature-specific sentiment extraction model is used to aggregate all the feature-specific polarities in the set.

All the baselines lack sentiment aggregation (refer Section 3.3) using ontological information.

A simple *negation* handling approach is used both in our work and the baselines. A window of size 5 (Hu *et al.*, 2004) is taken and polarities of all the words appearing in the window starting from any of the negation operators *not*, *neither*, *nor* and *no* are reversed.

Table 4 shows the three baselines and the proposed approach with the different features used in the models.

<sup>2</sup> <http://www.cs.jhu.edu/~mdredze/datasets/sentiment/>

Models	Lexical	Corpus	ConceptNet	Sent. Aggr.
Lexical Baseline	Y			
Corpus Feature Specific Baseline	Y	Y		
Corpus and ConceptNet Feature Specific Baseline	Y	Y	Y	
Sent. Aggr. With Ontology Info.	Y	Y	Y	Y

**Table 4.** Models and Baselines

### 4.3 Results

Stanford Pos-Tagger<sup>3</sup> is used to part-of-speech tag the reviews to find the frequently occurring concepts (*Nouns*) in the domain. The ontology construction is done using ConceptNet 5<sup>4</sup>. The depth of the ontology tree is taken till level 4. The ontology depth has been empirically fixed. Further increase in depth leads to topic drift and domain concept dilution. Table 5 shows the number of frequently occurring concepts in the corpus, and the total number of nodes, leaf nodes and edges in the ontology tree for each domain.

Domains	Corpus Frequent Features	Ontology Nodes	Ontology Edges	Leaf Nodes
Automobile	268	203	202	76
Camera	768	334	333	148
Software	1020	764	763	208

**Table 5.** Ontology Tree Statistics

Table 6 shows the accuracy of the three lexical baselines in different domains in the dataset.

Lexicons	Auto-mobile	Camera	Software
SentiWordNet 3.0	60.88	59.32	60.76
General Inquirer	65.70	68.15	66.14
Bing Liu Lexicon	64.43	63.65	69.38

**Table 6.** Lexical Baselines

Stanford Dependency Parser<sup>5</sup> is used to parse the reviews for dependency extraction during feature-specific sentiment analysis (refer *Section*

<sup>3</sup> <http://nlp.stanford.edu/software/tagger.shtml>

<sup>4</sup> <http://conceptnet5.media.mit.edu/>

<sup>5</sup> <http://nlp.stanford.edu/software/lex-parser.shtml>

3.2). All the edge weights  $u_{ij}$  are taken to be 1. Table 7 shows the overall accuracy comparison of the proposed approach with the baselines. Bing Liu sentiment lexicon is used in all the approaches as it is found to deliver a better performance compared to the other lexicons in our model.

Models	Automobile	Camera	Software
Lexical Baseline (Bing Liu)	64.43	63.65	69.38
Corpus	68.34	65.25	72.54
ConceptNet + Corpus	70.19	67.15	74.74
ConceptNet + Corpus + Sent. Aggr.	<b>71.38</b>	<b>72.90</b>	<b>76.06</b>

Figure 3 shows the accuracy of different models on the positive and negative dataset in each domain.

**Figure 3.** Positive and Negative Accuracy of Models in Each Domain

## 5 Discussions

In this section, we discuss the observations from the experimental results of using sentiment aggregation approach with ConceptNet Ontology.

**1. Ontology Construction:** The first part of our work outlines an approach to leverage ConceptNet to construct a domain-specific ontology for product reviews. It is a difficult task to evaluate the purity of any ontology. In our work, we only perform a qualitative analysis where the constructed ontology is found to contain most of the relevant concepts in the given domain with appropriate hierarchy.

It is observed that 75.75% of the concepts in the automobile domain are mapped to some relevant concept in the corresponding product ontology; the corresponding figures for the camera and software domain being 43.49% and

74.90% respectively. In the camera domain, although the number of ontology feature nodes is much less than the frequently occurring concepts in the reviews, the proposed model performs much better than the baseline, which considers all features to be equally relevant. This shows that the ontology feature nodes capture concepts which are most relevant to the product and hence, makes a difference to the overall review polarity.

**2. Lexical Baseline Performance:** General Inquirer and Bing Liu sentiment lexicons outperform SentiWordNet in our dataset. Bing Liu sentiment lexicon was subsequently found to work better in our model than General Inquirer.

**3. Corpus Feature-Specific Baseline:** A significant accuracy improvement is observed over the lexical baseline due to the consideration of feature-specific polarities of relevant features mined from the frequently occurring concepts in the domain corpus.

**3. ConceptNet and Corpus Feature-Specific Baseline:** Incorporating ConceptNet information during the feature extraction process from the corpus improves the model performance. Only the features that frequently occur in the domain and form an important concept in the ontology hierarchy are retained.

**4. Sentiment Aggregation:** The model using sentiment aggregation approach by combining the feature-specific polarities with ontology information achieved the best accuracy in all the three domains.

**5. Negative Opinion Detection:** Reviews have much more explicit positive expressions of opinion than negative ones (Kennedy *et al.*, 2006; Voll *et al.*, 2007; Mukherjee *et al.*, 2012). This is because negative emotions are often very implicit and difficult to capture, as in sarcasm and thwarting. This is evident from Figure 3, where the lexical baseline attains a high accuracy on positive reviews in all the domains, but fares very poorly on negative reviews. The other two models, on the other hand, perform much better on the negative reviews. This shows that the ontology based sentiment extraction method is able to capture negative sentiment much more strongly. The model also paves the way for analyzing reviews which contain more positive expressions of opinion than negative ones, but are still tagged as negative;

which cannot be captured by a feature-counting classifier.

**6. Sentiment Ontology Tree Personalization:** In this work, we have assumed all relations to be equally important, and thus considered the edge weights in the tree to be 1. However, the model allows the ontology tree to be personalized to suit the purpose of an individual and incorporate subjectivity in the reviews. If an individual prefers functional relations or use of certain features over its components, this information can be incorporated in the tree. This allows the general domain-specific ontology tree to be customized to an individual's interest.

## 6 Conclusions and Future Work

In this work, we outline an approach to combine the feature-specific polarities of a review with ontology information to give better sentiment classification accuracy. The proposed approach leverages ConceptNet to automatically construct a domain specific ontology tree. We performed experiments in multiple domains to show the performance improvement induced by the sentiment aggregation approach using ontology information over simple aggregation of feature-specific polarities.

The work is mostly unsupervised, requiring no labeled training reviews. The performance of the classifier is subject to the coverage of the lexicon and the accuracy of the feature-specific classifier.

The work also addresses the idea of personalizing a sentiment ontology tree to suit an individual's interest over specific features and parent-feature relations. This is also the first work, to the best of our knowledge, to discuss an approach to deal with reviews having majority positive (or negative) features but still tagged as negative (or positive). Reviews, of such kind, can be aptly handled using ontology information which captures the intrinsic specificities of product-feature relations in a given product domain.

## Abstract

We propose a novel method to detect cyberbullying entries on the Internet. “Cyberbullying” is defined as humiliating and slandering behavior towards other people through Internet services, such as BBS, Twitter or e-mails. In Japan members of Parent-Teacher Association (PTA) perform manual Web site monitoring called “net-patrol” to stop such activities. Unfortunately, reading through the whole Web manually is an uphill task. We propose a method of automatic detection of cyberbullying entries. In the proposed method we first use seed words from three categories to calculate semantic orientation score PMI-IR and then maximize the relevance of categories. In the experiment we checked the cases where the test data contains 50% (laboratory condition) and 12% (real world condition) of cyberbullying entries. In both cases the proposed method outperformed baseline settings.

## 1 Introduction

“Cyberbullying” is a new form of bullying. It is carried out on the Internet instead of classrooms. It takes form of hate messages sent through e-mails, electronic Bulletin Board System (BBS), etc., with the use of personal computers or mobile phones. Recently it has become a serious social problem in many countries, one of which is Japan (MEXT, 2008). Examples of cyberbullying that actually happened, include ridiculing student personality, body type, or appearance on informal school BBS, slandering students and insinuating they had performed deviate sexual intercourses. Some cases of cyberbullying lead the students who were bullied to assault or kill themselves or the student who wrote the bullying entry on the BBS.

To deal with the problem members of Parent-Teacher Association (PTA)<sup>1</sup> perform Web site monitoring activities called “net-patrol”. When a harmful entry is detected the net-patrol member who found it sends a request to remove the entry to the Internet provider or Web site administrator. Some of the actual examples of harmful entries which were requested for deletion are represented in Table 1 (names, phone numbers and other personal information was changed).

Unfortunately, net-patrol has been carried out mostly manually. It takes much time and effort to find harmful entries (entries that contain harmful information and expressions) in a large amount of contents appearing on countless number of bulletin board pages. Moreover, the task comes with a great psychological burden on mental health to the net-patrol members. To solve the above problem and decrease the burden of net-patrol members, Matsuba et al. (2011) proposed a method to detect harmful entries automatically.

In their method they extended the method of relevance calculation PMI-IR, developed by Turney (2002) to calculate relevance of a document with harmful contents. With the use of a small number of seed words they were able to detect effectively large numbers of document candidates for harmful entries.

Their method was proved to determine harmful entries with an accuracy of 83% on test data for which about a half contained harmful entries. However, it was not yet verified how well the method would perform in real life conditions, where the ratio of cyberbullying entries and normal contents is not equal.

In this research, based on Matsuba et al.’s method of obtaining maximal relevance values for seed words, we propose a method for maximization of relevance score of seed words. In our

<sup>1</sup>An organization composed of parents, teachers and school personnel.

method we divide seed words into multiple categories and calculate maximal relevance value for each seed word with each category. By calculating the score, representing semantic orientation of “harmfulness”, the method is expected to detect harmful entries more effectively than in the previous research. Moreover, we evaluate our method on data sets with different ratios of harmful contents to verify the usability of the method in the most realistic way.

The paper outline is as follows. Firstly, we describe research on extraction of harmful entries in Section 2. Next, we describe the proposed method in Section 3. Furthermore, in Section 4 we construct evaluation data sets with different ratios of cyberbullying entries, perform evaluation experiments based on these data sets, and describe the results of the experiments. We present a discussion and explain the results in detail in Section 5. Finally, in Section 6 we conclude the paper and propose some of the ideas for future improvement of the method.

## 2 Related research

There has been a number of research on extracting harmful information before. For example, Ishisaka and Yamamoto (2010) have focused on developing an abusive expression dictionary based on a large Japanese electronic bulletin board “2 channel”. In their research Ishisaka and Yamamoto firstly defined words and paragraphs in which the speaker directly insults or slanders other people with the use of explicit words and phrases such as バカ (*baka*) “stupid”, or マスゴミのクズ (*masugomi no kuzu*) “trash of mass-mudia”. Next, they studied the use of abusive language, in particular which words appear the most often with abusive expressions, and based on this study they extracted abusive expressions from the surrounding context.

In other research Ikeda and Yanagihara (2010) have manually collected and divided separate sentences into harmful and non-harmful, and based on word occurrence within the corpus they created a list of keywords for classification of harmful contents. Next they utilized context of dependency structures of sentences containing harmful and non-harmful contents to improve the system performance. However, on the Web there are numerous variations of the same expressions dif-

<sup>2</sup>*Mobage* and *Gree* are online game service Web sites.

Table 1: Examples of harmful entries which were requested for deletion. Japanese (above), transliteration (middle), English translation (below).

- 調子乗りすぎいつべん殺らなあかんで ( <i>Chōshi nori sugi ippen yara na akan de</i> ) “Don’t get excited that much or I’ll kill ya!”
- 新田キモイつかキショイほんま死んで ( <i>Nitta kimoi tsuka kishoi honma shinde</i> ) “Nitta [proper noun], you’re ugly, or rather fugly, just die, man”
- ンな奴どつき回したれ ( <i>N’na yatsu dotsuki mawashi tare</i> ) “What an ass, slap him”
- 性格わるーい ぶちやいく一笑 ( <i>Seikaku waru-i buchaiku-warai</i> ) “Baaad personality, and an ugly hag, lol”
- >> 17 あの女、昔、モバだったかグりに登録してたヤリマンじゃん。 ( <i>Ano onna mukashi Moba dattaka Guri ni tōroku shiteta yariman jan</i> ) “>> 17 that woman is the same one who was bitching around before on <i>Mobage</i> or <i>Gree</i> .”
- すぐにヤレる。01234567890。 めっちゃカワイイで ( <i>Sugu ni yareru. 01234567890. Meccha kawaii de.</i> ) “You can take her out even now. 01234567890. She’s a great lay.”

fering with only one or two characters, such as 爆破 (*bakuha*) “blow up” and 爆一破 (*baku-ha*) “blooow up”. The weakness of this method is that all of the variations of the same expression need to be collected manually, which is very time-consuming.

Fujii et al. (2010) proposed a system for detecting documents containing excessive sexual descriptions using a distance between two words in a sentence. In their method they determine as harmful those words which are in closer distance to words appearing only in harmful context (“black words”) rather than those in closer distance to words which appear in both harmful and non-harmful context (“grey words”).

Hashimoto et al. (2010) proposed a method for detecting harmful meaning in jargon. In their method they assumed that the non-standard meaning is determined by the words surrounding the

word in question. They detected the harmful meaning based on calculating co-occurrence of a word with its surrounding words.

In our research we did not consider the surrounding words. Instead, we determine the harmfulness of input by calculating the harmfulness score for all word sequences in input. Moreover, since we check the co-occurrence of word sequences on the Web, our method greatly reduces the cost of manual construction of training data. Furthermore, in calculating the harmfulness score we apply dependency relations between phrases. Therefore there is no need to check all words proceeding and succeeding the queried words, which greatly reduces processing time.

### 3 Proposed method

In this section we present an overview of the method for maximization of category relevance. In the proposed method we extend the method proposed by Turney (2002) to calculate the relevance of seed words with entries from the bulletin board pages. Moreover, we apply multiple categories of harmful words and calculate the degree of association separately for each category. Finally, as the harmfulness score (or polarity of “harmfulness”) we choose the maximum value achieved by all categories. The method consists of three steps. (1) Phrase extraction, (2) Categorization and harmful word detection together with harmfulness polarity determination, (3) Relevance maximization. Each of the steps is explained in detail in the following paragraphs.

#### 3.1 Phrase extraction

In cyberbullying entries the harmful character of an entry can be determined by looking at separate words. For other cases however, even if a word in itself is not harmful, it gains harmful meaning when used in a specific context, or in combination with other words. For example, for a pair of words 性格が悪い (*seikaku ga warui*) “bad personality”, neither “bad”, nor “personality” on their own express harmful meaning. However, when these words are used together in a dependency relation, they become harmful (negative depiction of a person’s personality). Therefore, methods for detecting harmful contents using separate words only, will fail when they encounter an entry which gained harmful meaning by phrases containing words in dependency relation.

Table 2: Types of phrases applied in the proposed method with examples.

Phrase	Example
noun-noun	サル顔 ( <i>sarugao</i> ) “monkey face” →Description ridiculing person’s features
noun-verb	新田を殺す ( <i>Nitta wo korosu</i> ) “Kill Nitta” →Threatening expressions
noun-adjective	性格が悪い ( <i>seikaku ga warui</i> ) “bad personality” →Description criticizing person’s features

To solve this issue, we use the polarity calculation score for the morphemes<sup>3</sup> combined in the dependency relation. We define such a combination as a “phrase”. One phrase consists of a morpheme pair in dependency relation. The dependency relation is calculated using a standard morphological analyzer for Japanese (MeCab<sup>4</sup>) and a Dependency parser for Japanese (Cabocha<sup>5</sup>). The phrases defined this way are extracted from all target entries.

#### 3.2 Harmful word detection and categorization

In this process we detect words of potential harmful connotations, or “harmful words”. Harmful words often include newly coined words or informal modifications of normal transcriptions, thus are not recognized by standard preprocessing tools, such as morphological analysers or dependency parsers. Therefore, it is possible such words, unless specifically annotated, would not be handled properly and cause error in morphological analysis. We investigated the entries of informal school Websites using the definition of harmful words proposed by the Japanese Ministry of Education, Culture, Sports, Science and Technology (MEXT, 2008, later referred to as “Min-

<sup>3</sup>In this report, we use the words “word” and “morpheme” in the same meaning.

<sup>4</sup><http://mecab.sourceforge.net/>

<sup>5</sup><http://code.google.com/p/cabocha/>

istry of Education”), and registered 255 harmful words (nouns, adjectives and verbs) in the dictionary of morphological analyzer. In addition, we categorized harmful words into three categories: obscene, violent and abusive. The Ministry of Education defined words considered as cyberbullying to include obscene, violent, or abusive words used on BBS. In this study, we applied the above definition, and therefore we also classified harmful words into the three categories: obscene, violence, or abusive. Next, we selected from each category three most often occurring words as seed words and registered them in the system. The words we selected include セックス (*sekkusu*) “[to have] sex”, ヤリマン (*yariman*) “slut”, フェラ (*fera*) “fellatio” for the obscene category, 死ぬ (*shinu*) “die [imperative]”, 殺す (*korosu*) “[to] kill”, 殴る (*naguru*) “[to] slap” for the violent category, and うざい (*uzai*) “annoying”, きもい (*kimoi*) “gross”, 不細工 (*busaiku*) “ugly” for the abusive category.

### 3.3 Maximization of relevance score

In this process we calculate harmfulness polarity score of phrases with each seed word for all three categories. We use pointwise mutual information (PMI) score as a measure of relevance between a phrase and harmfulness polarity words from each category. PMI here indicates a co-occurrence frequency of the queried phrase with the three words registered for each category. To calculate the co-occurrence frequency we use information retrieval (IR) score. Countless number of various pages exists on the Web, and thus various words are written there. Therefore, it is possible to obtain a high coverage by using the IR score.

We calculate the relevance of a phrase with words from each category according to the following equation (1).  $p_i$  is a phrase extracted from the entry,  $w_j$  are three words that are registered in one category of harmfulness polarity words,  $hits(p_i)$  and  $hits(w_j)$  are Web search hits for each category for  $p_i$  and  $w_j$  respectively,  $hits(p_i \& w_j)$  is a number of hits when  $p_i$  and  $w_j$  appear on the same web page. Finally,  $PMI - IR(p_i, w_j)$  is the relevance of  $p_i$  and  $w_j$ .

$$PMI - IR(p_i, w_j) = \log_2 \left\{ \frac{hits(p_i \& w_j)}{hits(p_i)hits(w_j)} \right\} \quad (1)$$

From all three scores calculated for the phrase with seed words from the three categories, we select the category which achieved the highest score

as the one of the highest relevance with the phrase. We calculate the relevance score this way for all phrases extracted from the entry. Finally we select the category with the maximal overall score as the one with the highest relevance with the entry. The *score* is calculated according to the following equation (2).

$$score = \max(\max(PMI - IR(p_i, w_j))) \quad (2)$$

In the baseline settings (Matsuba et al., 2011) the relevance was calculated as a sum of all scores for all phrases with each harmful word separately. In this method instead of taking all words separately we group them in categories and calculate the relevance with three most common harmful words from each category. By incorporating this improvement during the Web search the retrieved pages are those for which the phrase appeared not only with one of the harmful words, but with all three words from one category. This not only reduces the processing time, but also improves the calculation of the relevance score, since only the strongest (most harmful) phrases are selected. Moreover, since it is easier to find a Web page containing a phrase and the only one harmful word, than the phrase with three words together, calculating the relevance for all harmful words separately allowed phrases with low actual relevance to achieve high scores in the baseline system. Maximization of the relevance *score* prevents low relevance phrases to erroneously achieve high scores.

We explain this process on the following example: 可愛いけど性格が悪い女 (*kawaii kedo seikaku ga warui onna*) “Cute girl, but bad personality”. Firstly, from the entry the extracted phrases are: 可愛い-女 (*kawaii-onna*) “cute-girl”, 性格-悪い (*seikaku-warui*) “bad-personality”, 悪い-女 (*warui-onna*) “bad-girl”. Next, we calculate the relevance between “cute-girl” and the three groups of words separately (“sex, slut, fellatio”, “die, kill, slap”, “annoying, gross, ugly”). The highest maximal score is selected as the relevance (harmfulness score) of this phrase. Similarly the score is calculated for “bad-personality” and “bad-girl”. From all the scores for all phrases the highest overall score is considered as the maximized harmfulness *score* of the phrase. All entries are then sorted beginning with the one with the highest harmfulness score. Finally, we set a

Table 3: The numbers of entries on informal school BBS including the number and percentage of cyberbullying entries.

BBS	Overall number of entries	Cyberbullying entries	Percentage (%)
BBS(1)	600	75	12.5
BBS(2)	736	90	12.2
BBS(3)	886	100	11.3

harmfulness threshold  $n$  and consider  $n$  entries with the highest score as harmful, and discard other as irrelevant to check how many of the entries within the specified threshold are in fact harmful.

## 4 Evaluation experiment

We performed an experiment to evaluate the performance of the proposed method, and compared the results with the baseline. Below we describe the preliminary study for carrying out the experiment (Section 4.1), explain the experiment settings (Section 4.2) and report the results of experiments (Section 4.3).

### 4.1 Preliminary study

It is necessary to create a test data with harmful and non-harmful entries mixed at an appropriate rate. In previous research the mixing was set at the same rate (half of the entries included cyberbullying). However, it cannot be assumed that harmful entries appear in real life with the same rate as normal ones. Therefore to evaluate our method in conditions closer to reality we performed a preliminary study to verify how much of the entries are harmful on actual Web pages. We counted the harmful entries mixing ratio on three informal school Websites, in particular we focused on informal school bulletin boards (BBS). The result of the study is represented in Table 3. We performed the study during four days between January 27 and 30, 2012. The number of obtained entries was 2,222.

As of the result of the study, the first BBS contained a total number of 600 entries from which 75 were harmful, which indicates that harmful entry appearance rate was 12.5%. Similarly, for the second BBS, 90 out of 736 total entries were harmful (12.2%). On the third BBS there were 886 total entries with 100 harmful ones (11.3%). From the above results, we concluded that about 12%

of all entries appearing on informal school BBS can be accounted as cyberbullying. Therefore in the experiment we verified the performance of the method under the condition when harmful entries cover 12% of the whole data.

### 4.2 Experiment settings

In the evaluation experiment we compared the performance of the proposed method to the baseline. We did this firstly for the case where the test data contained 50% of harmful entries. Next, we prepared a different test data, which contained 12% of harmful entries and compared the performance under this condition for both the baseline and the proposed method.

The test data containing 50% of harmful entries contains 2,998 entries in total with 1,508 of harmful entries and 1,490 of non-harmful entries. The dataset contains actual collection gathered by the net-patrol members from bulletin boards, and additional data gathered manually by Matsuba et al. (2011) (the latter were collected from the BBS sites limited to schools from the Mie Prefecture, Japan). We performed a 10-fold cross validation on this dataset. We processed the dataset by both the baseline and the proposed method and calculated the harmful polarity score for entries where the phrases could be extracted. Then we ranked all entries decreasingly according to the harmful polarity score, and evaluated the performance looking at the top  $n$  entries by increasing the threshold of  $n$  by 50 each time.

To prepare the dataset for the real world condition (12% of harmful entries), we prepared five test sets by randomly extracting 60 harmful and 440 non-harmful, 500 entries in total from the original dataset. On these datasets we did not perform a 10-fold cross validation, since it would make the results not statistically relevant (each set for cross validation would contain only 60 harmful entries). Instead we calculated the results for each of the five sets separately. This allowed us to include all entries from the original test set in the evaluation. We processed these datasets with both the baseline and the proposed method and calculated the harmfulness polarity score for entries for which the phrases could be extracted. Then, similarly to the original dataset, we ranked all entries based on the harmfulness polarity score, and evaluated the performance by taking the top  $n$  and increasing the threshold  $n$  by 10 each time.

We considered automatic setting of the threshold using machine learning methods, however it was difficult due to the small size of test data for the real world condition. In the future for automatic threshold setting we plan to develop a machine learning method capable of handling small sized data. Therefore this time we increased the threshold manually each time and investigated Precision and Recall for each threshold.

As evaluation criteria we used Precision (P) and Recall (R), calculated according to the equations (3) and (4). The Precision is a ratio of the number of entries that could be properly determined as harmful to the number of all entries determined as harmful among the top  $n$ . The Recall is a ratio of the number of entries that could be properly determined to be harmful to the overall number of harmful entries. The final performance is calculated as an average of Recall and Precision for each test data in this experiment.

$$P = \frac{\text{correct annotations}}{\text{all system annotations}} \quad (3)$$

$$R = \frac{\text{correct annotations}}{\text{all harmful annotations}} \quad (4)$$

### 4.3 Results

The results showing Precision and Recall for both the baseline and the proposed method for both datasets (50% and 12% of cyberbullying entries) are represented in Figure 1. The horizontal axis and the vertical axis represent percentage of Recall and Precision for each threshold, respectively.

For the test data containing 50% of harmful entries, Precision was between 49% - 79% for the baseline, while for the proposed method Precision was between 49% - 88%.

For the test data containing 12% of harmful entries, Precision was between 11% - 31% for the baseline, while for the proposed method Precision was between 10% - 61%.

## 5 Discussion

The experiment results showed that the proposed method achieved higher overall performance comparing to the baseline. The shape of the correlation curve for Recall and Precision shows that that performance for the baseline is significantly reduced

in general comparing the test data containing 12% of harmful entries to the test data containing 50% of harmful entries. However, for the proposed method, although the performance is reduced as well, there is no sudden drop in the shape of the correlation curve when comparing both datasets.

This could suggest that the performance is more stable in the proposed method than in the baseline. There were several cases of threshold  $n$  where the Recall was slightly higher for the baseline than for the proposed method in the test data containing 12% of harmful entries. This happened because for some harmful entries the harmfulness score could not be calculated highly enough due to the fact that the score calculation is more strict (Precision-oriented) in the proposed method. Therefore, although Recall is slightly higher in the baseline for large thresholds, the Recall is higher for the proposed method for small and medium thresholds, with the Precision being constantly higher for the proposed method. Therefore, it can be said that the proposed method achieved higher general performance than the baseline.

Next we explain the results for the test data containing 12% of harmful entries. We investigated the threshold cases of entries where the Precision reaches 48%. Entries found there included, for example “アトピーのやつ死ぬよ” (*atopii no yatsu shine yo*) “The bastard with atopy must die” and “ウザイキモイぶす” (*uzai kimoi busu*) “annoying, gross and ugly”. From those entries high relevance score was calculated for phrases like “アトピー-死ぬ” (*atopii-shine*) “atopy-die” and “ウザイ-ぶす” (*uzai-busu*) “annoying-ugly”. Since the phrases included seed words as well, this most probably increased the polarity value of the harmful entry.

On the other hand, there were many non-harmful entries classified as harmful with harmfulness polarity score equally high or higher than the actual harmful entries. An example of a non-harmful entry of this kind was “県外に住んでいる” (*kengai ni sun de iru*) “living outside of the prefecture”. The phrase extracted from this entry was “外-住ん” (*soto-sun*) “outside-live”. This is a neutral phrase, and appears similarly often in non-harmful entries as well as in harmful entries in cases of exposing personal information about where a person lives. Therefore, the relevance of a harmful entry containing such a phrase is increased, and as a result overall harmfulness po-

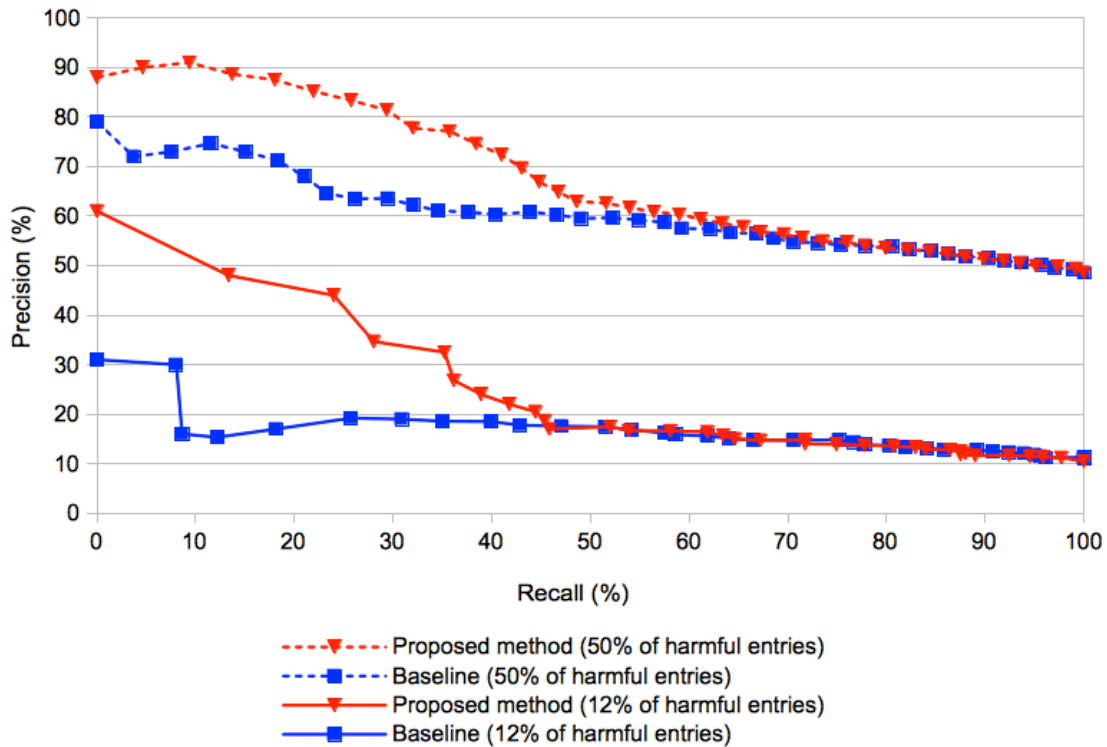

Figure 1: Precision and Recall for both the baseline and the proposed method for both datasets (50% and 12% of cyberbullying entries). The horizontal axis and the vertical axis represent percentage of Recall and Precision for each threshold, respectively. All results statistically significant. For the 50% data the results were extremely statistically significant on 0.0001 level. For the 12% data the results were statistically significant on 0.05 level.

larity score of such non-harmful entries becomes higher.

As a countermeasure it could be considered to register some words, which appear only in non-harmful entries, like “splendid”, with non-harmful polarity and calculate the relevance of non-harmful entries as well. In particular, firstly, the non-harmful words could be registered in the dictionary. Then the relevance could be calculated for the phrases with both, the non-harmful polarity words and harmful polarity words. In such cases the phrase could be considered as non-harmful when the relevance score of the phrase with non-harmful words was higher than the relevance with the harmful words. This could reduce the influence of neutral phrases on the overall performance.

We also investigated the cases where Recall reaches 100%. These cases include entries which contain personal information only such as school names or person’s names, such as “Nitta of Kitami Institute of Technology, 4th grade”, etc. The relevance of such entries with harmful words reg-

istered at present in the dictionary is low, which influenced their overall harmfulness score as well. To solve this problem we plan to register in the dictionary words which have high relevance with personal information and use them in the relevance score calculation as well.

## 6 Conclusions and future work

In this study, we proposed a method of maximization of category relevance to automatically detect cyberbullying entries on the Internet. With this research we wish to contribute to reducing the burden of Internet patrol personnel who make efforts to manually detect harmful entries appearing on the Internet. In order to verify the actual usefulness of the proposed method we evaluated the performance for the test data containing similar percentage of harmful entries as in reality. Firstly, in a preliminary study we verified the usual ratio of harmful entries on the Internet. Next, we prepared test datasets containing the same amount of cyberbullying entries as in reality and evaluated the method on these test sets. In addition, we re-

produced the baseline method and compared the performance to the proposed method.

The experiment results showed that the proposed method obtained higher results than the baseline. Under the fair condition (test dataset with 50% of harmful entries) the proposed method achieved over 90% of Precision at 10% Recall and keeping up high Precision (80-70%) at Recall close to 50%. Under the real world condition (test dataset with 12% of harmful entries) the method achieved nearly 50% of Precision at about 10% of Recall. The relevance curve have decreased slowly with growing Recall for the proposed method, while for the baseline the relevance curve has dropped suddenly from 30% to around 15% at the same Recall rate. As for drawbacks in our method, harmful entries consisting of personal information were scored as less harmful due to the appearance of neutral phrases which appear often in both harmful and non-harmful entries.

In the near future, we plan to register non-harmful polarity words which have a high relevance with non-harmful entries to lower the overall harmfulness polarity score of non-harmful entries containing neutral phrases. We will also investigate a method for assessing the harmfulness score to entries including personal information. Furthermore, we plan to increase the data set, and determine the optimal threshold automatically by using machine learning.

## Abstract

Event factuality is information about whether events mentioned in natural language correspond to either actual events that have occurred in the real world or events that are of uncertain interpretation. Factuality analysis is useful for information extraction and textual entailment recognition, among others, but sufficient performance has not yet been achieved by the machine learning-based approach. It is now important to take a closer look at the linguistics phenomena involved in factuality analysis and identify the technical research issues more precisely. In this paper, we discuss issues regarding lexical knowledge through error analysis of a Japanese factuality analyzer based on lexical knowledge and compositionality.

## 1 Introduction

Event factuality is information about whether events mentioned in natural language correspond to either actual events that have occurred in the real world or events that are of uncertain interpretation.

- (1) a. 彼はさきほど部屋を出た。  
*kare-wa sakihodo heya-wo de-ta.*  
(He left the room a little while ago.)
- b. もう遅いから、彼は先に帰ったのだろう。  
*mou osoi-kara, kare-wa saki-ni kaet-ta-no-daro-u.*  
(It's late now, so he may have gone home.)
- c. 問題が発生するのを防いだ。  
*mondai-ga hassei-suru-no-wo fusei-da.*  
(We prevented the occurrence of the problem.)

For example, we can interpret that the event “*de*” (*leave*) in (1a) is factual in the real world, the event “*kaet*” (*go home*) in (1b) is possibly factual because of the modal auxiliary “*-ta-no-daro-u*” (*may have -ed*), and the event “*hassei-suru*”

(*occurrence*) in (1c) is counterfactual because of the implicative predicate “*fusei-da*” (*prevented*).

Factuality analysis is useful for a broad range of NLP applications such as information extraction, question answering, and textual entailment recognition. Prior work on factuality analysis has made considerable efforts for designing and creating corpora manually annotated with factuality-related information (Saurí and Pustejovsky, 2009; Matsuyoshi et al., 2010; Tanaka et al., 2013, etc.) and several empirical studies on those resources are reported revealing the difficulties of the task (Inui et al., 2008; Matsuyoshi et al., 2010; Morante and Blanco, 2012; Saurí and Pustejovsky, 2012). For Japanese, Matsuyoshi et al. (2010) report that their factuality classes are highly skewed and the minority classes are very difficult for their machine learning-based models to precisely identify. The minority classes include uncertain statements as in example (1b) and counterfactual statements as in (1c). Such “marked” statements are far less frequent than unmarked statements (i.e. certain factual statements) and thus are not as easy to collect as unmarked statements. While the label distribution is reported to be less skewed in English (Szarvas et al., 2008), still uncertain and counterfactual statements constitute minority classes. In addition, uncertain and counterfactual statements exhibit a very broad variety of linguistic devices for expressing uncertainty and negation. For those reasons, the whole task is not as easy as it appears and simple strategies based on supervised machine learning do not work well.

Given this background, rather than putting everything simply into a machine learning algorithm, it is now important to take a closer look at the linguistics phenomena involved in factuality analysis and identify the technical research issues more precisely. One promising way for it is to make use of existing lexical resources and divide the whole issues into those related to lexical knowledge and the rest. We take this approach in this

paper because (i) the factuality status is primarily expressed by lexical devices such as auxiliaries (e.g. “*-ta-no-darou*” (*may have -ed*)) and factual and counterfactual predicates (e.g. “*fusegu*” (*prevent*)), and (ii) there are existing Japanese lexicons of such factuality-related expressions (factuality markers, henceforth) available with a reasonably broad coverage. As a platform for computing factuality with factuality markers, we adopt Saurí and Pustejovsky’s rule-based model for English factuality analysis (Saurí and Pustejovsky, 2012) and adapt it to the Japanese language. Saurí and Pustejovsky’s model is suitable as it assumes the availability of a factuality lexicon and uses it to identify the factuality status of each subordinate event in a compositional manner from the factuality status of its superordinate event. For lexical resources, we use the dictionary of Japanese functional expressions (Matsuyoshi et al., 2007) and the dictionary of Japanese clue expressions for extended modality (Eguchi et al., 2010). This paper presents a *first* comprehensive investigation in Japanese factuality analysis, which is based on these sufficient lexicons.

This paper is organized as follows. Section 2 describes related work. In Section 3, we construct a Japanese factuality analyzer based on compositional approach by Saurí and Pustejovsky (2012). In Section 4, we discuss issues regarding lexical knowledge through error analysis by applying our analyzer with Japanese text. Based on the analysis in Section 4, Section 5 discusses lexicon-based scope detection. Section 6 concludes this paper.

## 2 Related work

Previous work for an annotation schema of factuality and other associated information includes FactBank (Saurí and Pustejovsky, 2009), Japanese corpus with extended modality (Matsuyoshi et al., 2010), and so on. Saurí and Pustejovsky annotate event mentions with its source, epistemic modality (certainty) and polarity for representing the event factuality. Additionally, their FactBank is extended with pragmatically informed factuality judgments by de Marneffe et al. (2012). Matsuyoshi et al. mark up an event mention with seven components (*source, time, conditional, primary modality type, actuality, evaluation, and focus*). Our factuality corresponds to *actuality*. Tanaka et al. (2013) annotate the sense and usage of ambiguous expressions related to factuality.

For automatically analyzing factuality in text, there are approaches based on machine learning.

Inui et al. (2008) have proposed a method of analyzing modality and polarity of event mentions in Japanese text with an approach based on conditional random field. However, it is very difficult that their machine learning-based models precisely identify the minority classes.

There are also approaches based on rules. MacCartney and Manning (2009) have proposed a model of *natural logic*, which has focused on semantic containment and monotonicity. They also infer implicatives and factives based on *implication signatures* (Nairn et al., 2006) compositionally. But certainty is not considered in their approach. Saurí and Pustejovsky (2012) have proposed a rule-based method using information that can influence the factuality of events such as polarity particles, modality markers, and epistemic predicates. In their algorithm, factuality values of the event, consisting of certainty and polarity, are determined by the upper factuality values and rules, one by one, from the top of the dependency tree. Their model is suitable as it assumes the availability of a factuality lexicon and uses it to identify the factuality status of each subordinate event in a compositional manner from the factuality status of its superordinate event. So we adopt their model and adapt it to the Japanese language to discuss issues regarding lexical knowledge.

## 3 Japanese factuality analyzer

To discuss the problems about lexical knowledge, we construct a Japanese factuality analyzer based on the lexicon-based compositional approach proposed by Saurí and Pustejovsky (2012). Their analyzer is suitable for analyzing issues because it is based on the availability of a factuality-related simple lexicon and analogous lexicons for Japanese are also available. When we input a result of syntactic parsing to our factuality analyzer, it outputs the factuality of each event.

### 3.1 Factuality values

Saurí and Pustejovsky characterized a degree of event factuality as a pair of certainty (what is certain *vs* what is only possible) and polarity (positive *vs* negative). They divided the certainty axis into the values *certain* (CT), *probable* (PR), *possible* (PS) and *underspecified* (U), and the polarity axis into *positive* (+), *negative* (−) and *underspecified* (u). For example, an event “*de*” (*leave*) in (1a) is labeled with CT+. This means that it is certain that the event happened or will happen according to the author of the text. In the same way,

Table 1: Our Factuality values

certainty \ polarity	positive (+)	negative (-)
<i>certain</i> (CT)	fact (CT+)	counterfact (CT-)
<i>probable</i> (PR)	probable (PR+)	not probable (PR-)
<i>underspecified</i> (U)	unknown or uncommitted (U)	

an event “*kaet*” (*go home*) in (1b) is labeled with PR+ and “*hassei-suru*” (*occurrence*) in (1c) is labeled with CT-. We use Saurí and Pustejovsky’s factuality values; however, we make some changes to compensate for Japanese sentences.

The first is the distinction between PR and PS. In English, event factuality can be interpreted by specific expressions. For instance, PR is interpreted by *probable* and PS is interpreted by *possible*. However, in Japanese, it is not so straightforward to distinguish between PR and PS due to a diverse variety of modality expressions. Furthermore, PR and PS are minority classes. We therefore combine PR and PS into PR in order to focus on the distinction between certain and uncertain.

The second is underspecified values. Saurí and Pustejovsky used two underspecified values: the partially underspecified CTu and the fully underspecified Uu. For simplification, we do not distinguish two underspecified values. Instead we use U as the underspecified value.

Furthermore, in the present study, we start with focusing only on event factuality attributed to the author of the text. Analyzing factuality for other discourse participants is left for our future work.

We use Saurí and Pustejovsky’s factuality values except for these changes. In other words, we divide the certainty axis into the values *certain* (CT), *probable* (PR) and *underspecified* (U), and we also divide the polarity axis into *positive* (+) and *negative* (-). Table 1 shows factuality values by a combination of certainty and polarity.

### 3.2 Lexical knowledge

In Saurí and Pustejovsky’s model, the factuality is analyzed based on lexical knowledge, expressions (called *factuality markers*) that can influence the event factuality. For example, polarity particles of negation, such as the adverb *not*, switch the original polarity of its context, and particles of certainty, such as the auxiliary *may*, change the original certainty of its context. Saurí and Pustejovsky consider not only particles but also predicates. For instance, in the case of the expression *know that*, it presupposes that the event in *that*-clause is fac-

Table 2: Example entries of the dictionary of Japanese functional expressions

Sense Category	Expressions	Effects on Factuality
negation	<i>-nai</i> <i>-nu</i>	polarity: + → - - → +
speculation	<i>-daro-u</i> <i>-kamo-shire-nai</i>	certainty: CT → PR
question	<i>-ka</i> <i>-ka-na</i>	certainty: CT → U PR → U

Table 3: Example entries of the dictionary of Japanese clue expressions for extended modality

Expression	Tense of Embedded Event	Context Polarity	Factuality
<i>fusegu</i> ( <i>prevent</i> )	non-perfective	+	CT- CT+
<i>wasureru</i> ( <i>forget</i> )	non-perfective	+	CT-
	perfective	-	CT+
		+	CT+
		-	CT+

tual. Therefore, the predicate *know* is a factuality marker which changes the factuality of the event in *that*-clause into CT+.

Similarly, in Japanese, some expressions correspond to English factuality markers. We use the dictionary of Japanese functional expressions (Matsuyoshi et al., 2007) and the dictionary of Japanese clue expressions for extended modality (Eguchi et al., 2010) as factuality markers.

The dictionary of Japanese functional expressions is semantically categorized and contains a lot of functional expressions using a hierarchy with nine abstraction levels such as sense and grammatical function. This dictionary includes 341 direction words (16,711 expressions). We can use some categories as factuality markers. Table 2 shows example entries of this dictionary and corresponding effects on factuality. For instance, expressions categorized as speculation, such as “*-daro-u*” (*may*) seen in (1b), change the original certainty of its context. We use 5,345 expressions selected according to categories as factuality markers.

The dictionary of Japanese clue expressions for extended modality contains how predicates influence extended modality of surrounding events. This dictionary includes 8,122 predicates selected from Bunrui Goiho (National Institute for Japanese Language and Linguistics, 2004). These predicates also relate to the factuality. Therefore, we can use these predicates as factuality markers. Table 3 shows example entries of this dictionary and corresponding factuality. For example, the predicate “*fusei-da*” (*prevented*), seen in (1c), is regarded as the factuality marker that switches the polarity of the preceding event “*hassei-suru*” (*occurrence*).

Dependency tree	Factuality markers	Contextual factuality	Event factuality
		CT+ (initial value)	
知らない <i>shira-nai</i> (does not know)	-nai (not) polarity: + → -	CT-	<i>shira</i> (know): <u>CT-</u>
相手を <i>aite-wa</i> (the opponent)	<i>shira</i> (know) certainty: CT polarity: + → -	CT+	
ことを <i>koto-wo</i> (that)		CT+	
断念した <i>dannen-shi-ta</i> (had abandoned)	<i>dannen-shi</i> (abandon) polarity: + → -	CT+	<i>dannen-shi</i> (abandon): <u>CT+</u>
彼が <i>kare-ga</i> (he)		CT-	
出場を <i>shutsujou-wo</i> (the participation)		CT-	<i>shutsujou</i> (participation): <u>CT-</u>

Figure 1: Computing event factuality in (2)

### 3.3 Algorithm

The factuality analyzer determines an event factuality by propagating a pair of certainty and polarity along a dependency tree from the root of the sentence. The algorithm can reflect dependency between events by the propagation of the factuality. The algorithm determines the factuality of an event based on following components:

#### Predicates

The factuality is updated by predicates of its context.

#### Functional Expressions

The factuality is updated by functional expressions attached to the event.

#### Propagated Factuality

The factuality is determined based on the original factuality of the preceding event.

Figure 1 shows the analysis process when our algorithm is applied to (2). The input is the dependency tree of the sentence (2) (the left side of Figure 1) and the output is the factuality of each event (the right side of Figure 1).

- (2) 彼が出場を断念したことを相手は知らない。  
*kare-ga shutsujou-wo dannen-shi-ta-koto-wo aite-wa shira-nai.*  
 (The opponent does not know that he had abandoned the participation.)

First of all, the factuality at the top level is set to CT+ as initial value (by the naïve assumption), and

the factuality is propagated along a dependency tree from the root of the sentence. The process at each phrase consists of 3 steps.

As a first step, the analyzer updates the contextual factuality if the functional expression is found in the dictionary of Japanese functional expressions. For the first phrase “*shira-nai*” (does not know) in this example, the contextual factuality is updated to CT- by the negation “-nai” (not). As a second step, the factuality value is assigned to every found event. The factuality value CT- is assigned to the event “*shira*” (know) in the example. As a third step, the analyzer updates if the predicate is found in the dictionary of Japanese clue expressions for extended modality. In the example, the contextual factuality is updated to CT+ by the factive predicate “*shira*” (know). In referring to dictionaries in first and third steps, we adopt simple longest match for the surface. The third step needs to be performed after the second step due to the double nature of predicates, which are both event-denoting expressions and, at the same time, factuality markers.

Similarly, for the phrase “*dannen-shi-ta*” (had abandoned), the algorithm outputs CT+ as the factuality of the event “*dannen-shi*” (abandon), because of *Propagated Factuality* CT- (the factuality of the preceding event “*shira*” (know)), *Predicates* “*shira*” (know) (CT- → CT+) and *Functional Expressions* (empty for this case). The analyzer iterates the propagation and updates the con-

Table 4: Correspondence of *actuality* to factuality

certainty \ polarity	+	-
CT	certain+ certain- → certain+	certain- certain+ → certain-
PR	probable+ probable- → probable+	probable- probable+ → probable-
U	unknown	

textual factuality. As a result, CT- as the factuality of the event “*shira*” (*know*), CT+ as the factuality of the event “*dannen-shi*” (*abandon*), and CT- as the factuality of the event “*shutsujou*” (*participation*) are obtained.

## 4 Findings from empirical evaluation

### 4.1 Data and experimental setup

We apply our algorithm to 6,404 sentences on the Yahoo! Japan Q&A section for the Japanese corpus with extended modality (Matsuyoshi et al., 2010). These sentences are included in the *Balanced Corpus of Contemporary Written Japanese* (BCCWJ)<sup>1</sup>, and each event mention is labeled with extended modality (*source, time, conditional, primary modality type, actuality, evaluation, and focus*). *Actuality* denotes the degree of certainty and corresponds to our factuality. Table 2 shows the correspondence of *actuality* to our factuality.

In this experiment, we apply our algorithm to 11,395 event mentions, where *source* is “wr” (writer of the sentence). These event mentions are also selected by part-of-speech, such as verb and adjective. For the identification of the event mention, we give the gold data to the analyzer because we discuss only about lexical knowledge.

If the analyzer makes an error in regards to the factuality of an event, then this error will have an influence on the factuality of the next event, because the analyzer propagates the updated factuality to the next event. Our intent for this experiment is not to analyze this kind of error. Therefore, we use the gold label as *Propagated Factuality* in order to prevent the error propagation.

### 4.2 Discussion

We discuss issues about lexical knowledge through the error analysis of the analyzer based on lexical knowledge and compositionality. Our algorithm computes the event factuality based on *Predicates, Functional Expressions* and *Propagated Factuality*, but for matrix clauses, it determines the factuality based only on *Functional Expressions*. We expect issues to arise for func-

tional expressions at matrix clauses. At subordinate clauses, on the other hand, we expect complex issues involving multiple components. We therefore analyze both the issues at matrix clauses and the issues at subordinate clauses, respectively.

Table 5 shows accuracy and Tables 6-9 show each confusion matrices for the certainty axis and the polarity axis for each case. These tables show that minority classes PR and U are difficult on the certainty axis. On the polarity axis, we obtain relatively high accuracy. Comparing matrix clauses to subordinate clauses, accuracy at subordinate clauses, which is based on some components, is lower than the accuracy at matrix clauses, which is based only on functional expressions. For each minority label (PR and U on the certainty axis, and - on the polarity axis), subordinate clauses have lower precision relative to matrix clauses. One reason for this is that we do not consider the scope of negation and speculation.

Table 10 shows the error type distribution. At

Table 10: Error type distribution

	Analyzed errors	Error type		Errors
Matrix clauses	108	functional expressions	semantic ambiguity	102
			insufficient coverage	4
		others		2
Subordinate clauses	1,041	functional expressions	semantic ambiguity	412
			insufficient coverage	16
		predicates	semantic ambiguity	4
			insufficient coverage	34
		scope		656

matrix clauses, the issue regarding functional expressions is found for 106 errors when analyzing 108 errors, and the rest of errors are due to an adverb and the parsing error. At subordinate clauses, we analyze 1,041 errors. Issues regarding the functional expressions (428 errors), predicates (38 errors), and the scope (656 errors) are found. Some errors are due to multiple issues. In the following paragraphs, we describe these issues in detail.

#### 4.2.1 Functional expressions

Out of the 106 errors for functional expressions, 53 false-positive errors regarding U were most common. Almost all of these errors are due to semantic ambiguity for functional expressions.

- (3) 知らないのも不思議ではないです。  
*shira-nai-no-mo fushigi-de-wa-nai-desu.*  
*(It is no wonder that he doesn't know.)*  
 (Gold: CT-, System output: U)

(3) is an example for semantic ambiguity of the functional expressions. Our analyzer refers to dictionaries by simple longest match. Therefore, the factuality of the event “*fushigi*” (*wonder*) is wrongly assigned as U because “*-de-wa*” is recognized as a recommendation (*how about*). In this context, the expression “*-de-wa*” is a part of inflection. So it has no special meaning.

As seen above, semantic ambiguity for functional expressions is a critical problem for Japanese factuality analysis. But disambiguation of Japanese functional expressions is not simple. Some previous work is engaged on this task, such as Tanaka et al. (2013). They construct MCN corpus for the disambiguation of expressions related to factuality. It is important to import this line of prior work to our analyzer.

Coverage for the dictionary of Japanese functional expressions also becomes a problem. However, the number of problems contains only 4 errors. We find that coverage for the dictionary of Japanese functional expressions is sufficient.

#### 4.2.2 Predicates

At subordinate clauses, 38 errors arise which are caused by predicate issues. 34 of the 38 errors are due to insufficient coverage for predicates and the other 4 errors are due to semantic ambiguity for predicates.

- (4) 正しいことを確認してください。  
*tadashii koto-wo kakunin-shi-te-kudasai.*  
*(Please check that it is correct.)*  
 (Gold: CT+, System output: U)

(4) is an example of insufficient coverage for predicates. In (4), our algorithm assigns U as the factuality of the event “*tadashii*” (*correct*) because U (the factuality of the event “*kakunin-shi*” (*check*), which is influenced by the request expression “*kudasai*” (*please*)) is propagated without any update. However, the predicate “*kakunin-shi*” (*check*) presupposes that the preceding context is factual, so it should be assigned CT+ as the factuality of the event “*tadashii*” (*correct*). This incorrect assignment occurs because that predicate does not exist in the dictionary of Japanese clue expressions for extended modality.

Out of 1,041 errors at subordinate clauses, 417 events are that predicates in the dictionary of Japanese clue expressions for extended modality are used. Only 4 errors, however, are due to semantic ambiguity for predicates. We therefore find that semantic ambiguity for predicates poses little problem. Furthermore, we focus on correct events by predicates. Out of the 1,128 correct instances in the area analyzed by the corpus, 351 are correct by predicates in the dictionary. In contrast to this, only 34 errors are due to insufficient coverage for predicates. For this reason, we find that insufficient coverage for predicates is a small issue.

#### 4.2.3 Scope

In Section 3, we described that our analyzer determines the event factuality based on three components: *Predicates*, *Functional Expressions*, and *Propagated Factuality*. However, we find that it

is crucial to determine boundaries whether the analyzer should propagate the factuality. In other words, it should resolve the scope of negation and speculation though the actual analyzer regards all embedded contexts as the scope. The errors due to the scope, in fact, are the majority of errors at subordinate clauses (656/1,041).

- (5) 少し郊外にでると音が聞き取れません。  
*sukoshi kougai-ni deru-to onsei-ga kikitore-mase-n.*  
*(I cannot hear the voice if I leave the suburbs.)*  
 (Gold: CT+, System output:  $\overline{\text{CT-}}$ )

Our algorithm wrongly assigns – as the polarity of the event “*deru*” (*leave*) in (5). This is because – (the polarity of the event “*kikitore*” (*hear*), which is influenced by the negation “*-n*” (*cannot*)) is propagated with no update. The negation “*-n*” (*cannot*) denies only the event “*kikitore*” (*hear*) but not the event “*deru*” (*leave*). As exemplified, the issue regarding the scope of negation and speculation is very crucial.

Of the 233 events where the analyzer outputs – as the polarity and the gold *Propagated Factuality* is –, 28 events are correct for the polarity, whereas 112 events are errors due to the scope. As shown, there are many cases where the analyzer should not propagate due to scope, and there are also many cases where the analyzer should propagate as –. We find that resolving the scope is a significant, but difficult challenge.

Next, we focus on the conjunction particles, such as “*-to*” in (5), as the key to detect scope in practice. Out of 656 errors due to the scope, the conjunction particle “*-to*” follows 126 events, “*-ga*” follows 78 events, “*-te*” follows 70 events, and so on. Therefore, when we detect scope in practice, we assume to use conjunctive particles as the key to determine propagation boundaries. In the next section, we investigate scope detection based on such expressions.

## 5 Lexicon-based scope detection

In the previous section, we found that detecting a scope is very crucial. In this section, we investigate the limitation of the lexical knowledge for a scope and identify the technical research issues more precisely through experiments for rule-based scope detection.

### 5.1 Related work for scope detection

In recent years, the detection of negation and speculation scopes is intensively being researched for English (Szarvas et al., 2008; Apostolova et al., 2011), such as Shared Task

in CoNLL-2010 (Farkas et al., 2010) and \*SEM 2012 (Morante and Blanco, 2012). For example, the BioScope corpus (Szarvas et al., 2008) is annotated with negation and modality expressions with their scope, and it is extensively used for resolution of the scope. However, studies for the detection for scope are insufficient for Japanese. Detection of scope in Japanese is a significant challenge, and will be highly beneficial for Japanese factuality analysis.

### 5.2 Knowledge-based scope detection

We take a rule-based scope detection approach to block propagating a contextual factuality. Before the first step on each phrase as described in Section 3, this approach blocks the propagation when the specific expressions are found in the event. The approach then assigns the contextual factuality as initial value CT+ and restarts the propagation. When such expressions are not found, the propagation is not blocked.

We used the terms shown in Table 11 to detect such expressions. When one of the terms appears at the end of an event, the event blocks the propagation. The terms are categorized by Minami (1974) according to the intensities of the constructing subordinate clauses: A is high, C is low and B is intermediate. These intensities would be used as a tendency of blocking the propagation. However, because there are some ambiguities such as “*~ ㇿ*” (*-te*) which belongs to all categories, we used all terms to detect scope and block the propagation.

### 5.3 Results

Table 12 shows the experimental results with/without lexical knowledge for scope. In the previous experiments as described in Section 4, in order to avoid the propagation error, we used gold contextual factuality. However, in our experiment, we focus on the propagation, so we do not use gold contextual factuality.

Table 12 shows that  $F_1$ -score increases 19.2% (0.112) by adding lexical knowledge. Focusing on each labels, our approach had no negative effect except recall of U. This means that our approach based on lexical knowledge works well, especially for minor labels. However, some errors still remain.

### 5.4 Remaining issues

We identify the remaining issues through the error analysis of the result. We focus on the

Table 11: Expressions to prevent propagating a contextual factuality

Category	Expressions
A	～ながら (-nagara), ～つつ (-tsutsu), ～て (-te), ～で (-de)
B	～て (-te), ～と (-to), ～ながら (-nagara), ～ので (-no-de), ～のに (-no-ni), ～ば (-ba), ～たら (-tara), ～なら (-nara), ～ても (-te-mo), ～て (-te), ～ず (-zu), ～ずに (-zu-ni), ～ないで (-nai-de)
C	～が (-ga), ～から (-kara), ～けれど (-keredo), ～けれども (-keredo-mo), ～けども (-kedo-mo), ～けど (-kedo), ～し (-shi), ～て (-te)

Table 12: Performance with/without lexical knowledge for scope

		CT+	PR+	PR-	CT-	U	Micro-Average	Macro-Average
The number of events		7,569	678	104	848	2,196	11,395	
With lexical knowledge	Precision	0.850	0.372	0.123	0.605	0.455	0.696	0.481
	Recall	0.753	0.178	0.067	0.672	0.697	0.696	0.474
	$F_1$	0.799	0.241	0.087	0.637	0.551	0.696	0.463
Without lexical knowledge	Precision	0.850	0.321	0.060	0.451	0.348	0.584	0.406
	Recall	0.584	0.156	0.048	0.542	0.756	0.584	0.417
	$F_1$	0.692	0.210	0.053	0.492	0.477	0.584	0.385

events which have a propagated factuality; in other words, it is not the last event of the sentence. In addition, the events whose propagated factuality is CT+ are also excluded from the analysis target, because when a CT+ is propagated to an event, even if the event blocks or doesn't block the CT+, the propagated factuality to the first step is CT+.

There are 1,739 events which satisfy the above conditions and we apply the block rule to 925 of them (i.e. some terms in Table 11 are found in the events). Table 13 shows the changes in the number of correct and incorrect results by adding the lexical knowledge. When using the block rule, 553 out of 925 incorrect events become correct. On the other hand, 100 of the correct events became incorrect. This suggests some ambiguities of expressions caused too much blocking.

- (6) a. 資格をうまく活かして働くことができなかった。  
shikaku-wo umaku ikashi-te hataraku koto-ga deki-nakat-ta.  
(I could not work by making best of my qualification.)
- b. 今は諸事象があって離婚できない。  
ima-wa shojijou-ga at-te rikon-deki-nai.  
(I cannot get a divorce because I have various reasons.)

For example, “～て” (-te) in (6a) causes blocking but in (6b) should not cause blocking.

Focusing on the coverage of the lexical knowledge, as described in Section 4, there are 656 errors due to the error of scope detection. 402 of them do not have CT+ as the propagated factuality and all of them should block the factuality propagation. However, only 229 of 402 blocked the propagation. This shows that the coverage of the lexical knowledge is still limited.

- (7) 半年前の点検では異常がみられなかった。  
hantoshi-mae-no tenken-de-wa ijou-ga mi-rare-nakat-

Table 13: Result changes by adding lexical knowledge

		with	
		correct	wrong
without	correct	49	100
	wrong	553	223

ta.  
(There are no defect in checking half a year ago.)

For example, “～では” (-de-wa) in (7) is not covered in this lexical knowledge.

## 6 Conclusion

We described Japanese factuality analysis, which is useful for information extraction and textual entailment recognition, among others. We discussed issues regarding lexical knowledge through error analysis by using a Japanese factuality analyzer based on lexical knowledge and compositionality. As a result, coverage of existing lexical resources is sufficient but issues regarding the semantic ambiguity of functional expressions and issues regarding scope were found. In particular, it was revealed that the problem regarding scope is most significant. We therefore performed an additional experiment with lexical knowledge for scope and discussed its helpfulness. However, the issue regarding scope includes the issue by profound meaning and context. Therefore, we consider that this issue is high-priority challenge.

In the future, we will address these challenges toward a high-performance Japanese factuality analyzer with other lexical knowledge and linguistic phenomena. Furthermore, we aim to construct a Japanese modality analyzer through the extension of the framework for factuality.

## Abstract

The context type and similarity calculation are two essential features of a distributional similarity scheme (DSS). In this paper, we propose a hierarchical semantic-aware DSS that exploits semantic relation words as extra context information to guide the similarity calculation. First, we define and extract five types of semantic relations, and then develop relation-based similarities from the distributional similarities among the top-ranked relation words. Finally, we integrate various similarities using learning-to-rank technique. Experiments show that semantic relations are beneficial to predicting accurate similarity. On 6904 pairwise similarity comparisons, the predictive accuracy of our approach reaches 83.9%, which significantly outperforms the baseline approaches. We also conduct intrinsic analysis by varying the quality of semantic relations and the usage of individual similarities.

## 1 Introduction

Distributional similarity is an essential measure of the semantic relatedness between a pair of linguistic objects, including words, phrases, or even sentences. Confident distributional similar objects, are useful in various NLP applications, such as word sense disambiguation (Lin, 1997), lexical substitution (McCarthy and Navigli, 2009), paraphrase ranking (Dinu and Lapata, 2010), text classification (Baker and McCallum, 1998), etc. In this paper, we focus on the semantic similarity between words.

Well-known implementations of word-level distributional similarity scheme (DSS) mainly fall

---

This work was done when the first author was visiting Baidu.

into two categories according to the choice of the context: a) text-window based, and b) dependency path based. The former has the advantages of language-independence and computational efficiency, while the latter captures finer word-word relationships. However, both approaches focus on the usage aspect of words' meanings, which is only indirect indicator of the underlying semantic interactions.

Meanwhile, a great many successful efforts have been made to extract word-level semantic knowledge from the text, including synonyms / antonyms, sibling terms, hypernyms / hyponyms, holonyms / meronyms, etc. Despite of such deliberated studies, there are few considerations about how these semantics-oriented outcomes could contribute to the construction of DSS.

To realize the full potential of such semantic evidences, we propose a semantics-aware DSS by using semantic relation words to guide the similarity calculation. Our motivation is that words having similar semantic relational words, e.g. sibling terms or hypernyms, tend to be more semantically similar. The proposed DSS has a hierarchical layout, in which text-window based distributional similarity is first established from the corpus serving as the basis of the relation-specific similarities for 5 semantic relations. Finally, these similarities are linearly combined using learning-to-rank technique into a single measure, capturing both the context distributions and the semantic relations of the target words.

Our contribution is three-fold. First, by deriving semantic relation based similarities from distributional similarity, we develop a semantics-aware DSS in a hierarchical fashion. The DSS eventually fuses these similarities, and yields significant improvement over several baseline approaches. Second, our design of DSS relies solely on the same corpus where distributional similarity can be derived. It is adaptable to different languages, in

which distributional similarity and semantic relations are available. Third, our DSS's hierarchical nature allows us to individually replace each component with better implementations to adapt to specific applications or new languages.

## 2 Related Work

Distributional similarity (a.k.a. contextual similarity) has been elaborately studied to predict semantic similarity, and the type of the context is a main concern. A variety of context types have been proposed to capture the underlying semantic interactions between linguistic objects, including text-window based collocations (Rapp, 2003; Agirre et al., 2009), lexico-syntactic patterns (Turney, 2006; Baroni and Lenci, 2010), grammatical dependencies (Lin, 1998; Padó and Lapata, 2007; Thater et al., 2010), click-through data (Jain and Pennacchiotti, 2010), selectional preferences (Erk and Padó, 2008), synsets in thesaurus (Agirre et al., 2009), and latent topics (Dinu and Lapata, 2010). There are also researches that focus on distribution compositions (Mitchell and Lapata, 2008; Grefenstette et al., 2013) or context constrained similarity calculation (Erk and Padó, 2008).

Extracting sibling or hierarchical semantic relations from corpora forms a different track of research, in which exist ample efforts. Most of them make use of hand-crafted or automatically bootstrapped patterns. Various types of patterns have been tried out, including plain texts (Hearst, 1992; Paşca, 2004), semi-structured HTML tags (Shinzato and Torisawa, 2007), or their combinations (Shi et al., 2010). Bootstrapping approach is shown useful given a number of seeds, which could be either relation instances (Snow et al., 2004; Pantel and Pennacchiotti, 2006), or initial patterns (Pantel et al., 2004). To improve the quality of raw extraction results, some studies also resort to optimizing one relation using other relations (Zhang et al., 2011; Kozareva et al., 2011) or using distributional similarity (Shi et al., 2010).

Despite the great progress made in the field of semantic relation extraction, few studies explicitly use semantic relations to guide the similarity calculation. In this paper, we use instance-pattern iteration on a massive corpus to populate semantic relation instances, and derive relation-specific similarities on top of text-window based distributional similarity. Indeed, previous studies did resort to a closed set of lexical patterns that indicate

sibling / hypernym / hyponym relations (Baroni and Lenci, 2010; Bansal and Klein, 2012), concept properties (Baroni et al., 2010), and attribute information (Baroni and Lenci, 2010). Compared with these studies, our approach systematically exploits specific semantic relations instead of counting co-occurrence under surface patterns. We also develop a hierarchical similarity fusion architecture, rather than blending the heterogeneous evidences in a single distribution vector (Baroni and Lenci, 2010). It is also notable that sibling term extraction, in which various semantic evidences (e.g. hypernyms) also help, is not in the track of our study. Sibling term extraction focuses on words sharing the same super concept, and does not quantify the pair-wise similarity between them. Nevertheless, sibling terms work fine as an evidence of semantic similarity, as shown in our experiments.

Machine learning based integration of multiple evidences are shown useful in semantic class construction and semantic similarity calculation. Pennacchiotti and Pantel (2009) use gradient boosting decision tree to combine evidences from Web page, query log, Web tablet, and Wikipedia to populate instances of *Actors*, *Athletes*, and *Musicians*. There are also studies that combine distribution and pattern information in lexical entailment (Mirkin et al., 2006) and word clustering (Kaji and Kitsuregawa, 2008). Close to our work, Agirre et al. (2009) train SVM classification models to combine individual similarities derived from dependency path, text-window, and WordNet synsets. The synsets are highly accurate in representing words' meanings. However, the size of the thesaurus is limited, and not equally available in different languages. Although Agirre et al. (2009) tried machine translation techniques to tackle with this issue, abundant named entities and translation errors in the Web corpus still challenge the performance of their approach.

## 3 Hierarchical Semantics-aware DSS

Our proposed DSS has a four-layer structure, as shown in Figure 1. The bottom layer is the *corpus layer* where a massive Web page repository is pre-processed. Upwards, we build a *distribution layer* to obtain basic text-window based distributional similarity between any pair of target words. The distribution layer provides a distributional similarity database upon which a *semantics layer* takes effect. At this layer we adopt an extraction system

Figure 1: Hierarchical approach to semantics-aware DSS.

that iteratively populates instances for 5 types of semantic relations. Then, for each type of semantic relation, we develop a relation-specific similarity measure. Finally at the *fusion layer*, the similarities at the distribution and semantics layers are integrated linearly using learning-to-rank.

### 3.1 Corpus Layer

The corpus we work on is a repository of Chinese Web pages collected in 2011. It contains 1.1 billion pages ( $5.8 \times 10^{11}$  words in total), and takes 4.7TB of storage. All pages are de-tagged, leaving only their titles and textual content, and then segmented with a word segmentor based on dictionaries plus conditional random field (CRF) models. The segmentor is efficiently implemented, and is able to process 40K words per second with an accuracy around 98%. Based on the segmentation results, two more steps of pre-processing: POS tagging and named entity (NE) recognition are also performed.

### 3.2 Distribution Layer

The most widely studied types of context for distributional similarity are text-window based context and grammatical context. The construction of the latter requires syntactic or dependency parsing, which is highly language-dependant and may be extremely time-consuming on large corpora.

Therefore, at the distribution layer, we build the distributional similarity database using simple text-window based co-occurrences. Two different lengths of the text-window are experimented: 3 words and 6 words. The window slides one word per step from the beginning of each sentence to the end. Thus, the 3-length and 6-length windows capture two and five words at most on each side of the target word respectively. For each pair of words  $w$  and  $w'$ , four association measures are

tried out, covering a range of common practices, including (1) raw number of co-occurrence, (2) point mutual information (PMI), (3) Jaccard index, and (4) local mutual information (LMI) (Evert, 2008). To reduce the amount of computation, we preserve top 5000 context words for each target word. Processing the whole corpus yields  $\sim 6.5$  million unique target words<sup>1</sup>. For any pair of words  $w$  and  $w'$  in the vocabulary, the distribution layer provides it a cosine similarity between their context distributions, denoted by  $ds(w, w')$ .

### 3.3 Semantics Layer

We deem that semantic relationship is a more direct clue of a word’s *meaning* than either its text-window co-occurrences or syntactic dependencies. Therefore, we introduce a semantics layer upon the distribution layer to exploit semantic relations. Specifically, we adopt an extraction system to populate semantic relation instances, and then derive relation-based similarities from the system’s output.

#### 3.3.1 Relation Extraction

Here, we present a fully-featured, yet lightweight semantic relation extraction system that is capable to conduct in-depth mining in massive corpora. The system follows the line of instance-pattern iteration on a massive corpus, and can be substituted by any implementation of such fashion.

We define and extract five types of semantic relations, as listed in Table 1. The extraction starts in the first iteration with a number of seed relation instances. A relation instance is defined as a triple  $(w, r, w')$ , which means words  $w$  and  $w'$  have the relation  $r$ .

$r$	Relation	Description
$r_1$	$w [Sibling]_{is} w'$	$w, w'$ are sibling terms
$r_2$	$w [Hyponym]_{is} w'$	$w'$ “is a” $w$ $w'$ is a “Instance-of” $w$
$r_3$	$w [Hypernym]_{is} w'$	$w$ “is a” $w'$ $w$ is a “Instance-of” $w'$
$r_4$	$w [Meronym]_{is} w'$	$w'$ is a “Part-of” $w$ $w'$ is a “Member-of” $w$ $w'$ is a “Substance-of” $w$
$r_5$	$w [Holonym]_{is} w'$	$w$ is a “Part-of” $w'$ $w$ is a “Member-of” $w'$ $w$ is a “Substance-of” $w'$

Table 1: List of semantic relations.

In a nutshell, during a full iteration, the system

<sup>1</sup>This is much larger than the number of typical Chinese words, which is mainly caused by the huge amount of NEs in the Web corpus, plus typos and word segmentation errors.

first uses seed instances to populate initial patterns that match them from the corpus, and assigns a unique semantic relation to each pattern according to the seeds it matches. Then, the system uses these patterns to extract new word pairs, and assigns relations to the word pairs according to the patterns that extracted them. The whole procedure is described in detail as the following four steps:

**(1) Pattern initialization** Find all sentences that contain the words  $w$  and  $w'$  in any seed relation instance  $(w, r, w')$ . Each sentence is then split into *prefix*, *infix*, and *suffix* by  $w$  and  $w'$ . The total length limit of these three parts is 10 words. Within this limitation, the system exhaustively enumerates all possible *prefixes* and *suffixes* (the *infix* remains unchanged). For example, in the sentence “A B  $w$  C  $w'$  D E”, the *prefixes* can be {‘A’, ‘B’, ‘A B’, ‘ ’} and the *suffixes* can be {‘D’, ‘E’, ‘D E’, ‘ ’}. Then, each combination of “*prefix SLOT<sub>1</sub> infix SLOT<sub>2</sub> suffix*” forms the word level of a pattern. Plus the POS and NE tags, a pattern finally contains three levels of information. In addition, to increase the recall of the patterns, named entities at the word level are replaced by their NE tags. This means at these positions, the pattern would match an arbitrary word as long as the word’s NE tags are matched. For instance, say the following sentence matches a seed (苹果(Apple), [*Sibling*]<sub>is</sub>, 三星(Samsung)):

近日, [苹果]和[三星]在美国进行了专利诉讼。  
(Recently, [Apple] and [Samsung] conducted patent litigation in the U.S.)

A pattern derived from this sentence could be:

Recently {*SLOT<sub>1</sub>*} and {*SLOT<sub>1</sub>*} in U.S.  
Word: 近日 {*SLOT<sub>1</sub>*} 和 {*SLOT<sub>1</sub>*} 在 LOC  
POS: t nz c nz p ns  
NE: NOR BRD NOR BRD NOR LOC

where BRD, LOC stand for brand and location, and NOR means the word is not a NE.

**(2) Pattern-relation mapping** For pattern  $p$ , consider all seed instances  $(w, r, w')$  it matched. For each relation  $r$  in those seeds, count it w.r.t.  $p$ . Then,  $r$  is scored by *tfidf*, where *tf* is  $r$ ’s count, and *df* is the number of relations that have a non-zero count. Finally, map  $p$  to the relation  $r_{max}$  with the highest score  $s_{max}$ , and assign  $s_{max}$  to  $p$  as its score.

**(3) Instance extraction** For each semantic relation  $r$ , extract word pairs using top scored 1,000 patterns that are mapped to  $r$ . For each sentence, if it matches a pattern  $p$ ’s word sequence and meets

the POS / NE tag constraints at  $SLOT_1$  and  $SLOT_2$  in  $p$ , then the words falling into the two slots are extracted.

Note that different patterns (even those with different relations) may extract the same word pair. To determine the final relation of a word pair  $\langle w, w' \rangle$ , the system traverses all the patterns that can extract it. The patterns are then grouped by the relations they map to. Within each group, the patterns’ scores are added up. The relation  $r^*$  whose group has the highest sum score  $S$  is selected. Then, with  $r^*$ , a new instance  $(w, r^*, w')$  is generated, with  $S$  as its weight. The system will also generate a reversed instance  $(w', r^{*-1}, w)$ . E.g., for (Intel, [*Sibling*]<sub>is</sub> AMD) and (Intel, [*Hypernym*]<sub>is</sub> Company), the system also generates (AMD, [*Sibling*]<sub>is</sub> Intel) and (Company, [*Hypernym*]<sub>is</sub> Intel) respectively.

**(4) New seed generation** Add the top-weighted relation instances obtained in step (3) into the seed set. In the current setting, each relation’s top-500 weighted instances are added as new seeds in each iteration.

In practice, the seed set used is small ontology of totally 222k instances of the five relations. The system produces 27M instances after 2 iterations, which are used in our experiments. For each word  $w$ , we define its relation words as the words appearing in the slot “ $w$  [*relation*]<sub>is</sub> □”. E.g.,  $w$ ’s [*Hypernym*]<sub>is</sub> relation words are its hypernyms.

### 3.3.2 Similarity

Recall that at the distribution layer, each pair of words has a distributional similarity, denoted by  $ds(\cdot, \cdot)$ . On top of this, we individually develop a relation-based similarity  $rs_i(\cdot, \cdot)$  for each semantic relation  $r_i \in \{r_1, r_2, \dots, r_5\}$ . For two words  $w$  and  $w'$ ,  $rs_i(w, w')$  is defined as the average of non-zero distributional similarities between their top- $N$  (at most) relation words under  $r_i$  (denoted by  $r_i^N(\cdot)$ ):

$$rs_i(w, w') = \frac{1}{|\{(u, v) | ds(u, v) > 0\}|} \sum_{\substack{u \in r_i^N(w) \\ v \in r_i^N(w')}} ds(u, v) \quad (1)$$

In our experiments, we universally set  $N$  to 10.

One alternate practice is to directly calculate the traditional cosine similarity between the relation word distributions of  $w$  and  $w'$ . We do not take this approach because such manner suffers from data sparseness. In particular, sometimes the relation words of  $w$  and  $w'$  are quite similar, but none

of them are shared by  $w$  and  $w'$  (this means the cosine similarity will be 0). For instance:

- *hand* and *head* may not share any meronym, e.g. *hand* only has meronym *finger* while *head* has *eye*, *nose*, ...;
- *Carmel* (a small city in IN, U.S.) may only have the hypernym  $\{small\ city\}$  while *New York* may have  $\{city, big\ city\}$ .

In our approach, owing to the non-zero  $ds(\cdot, \cdot)$  between *finger* / *eye*, or between *small city* / *big city*, the two pairs of words will have positive relation-based similarities.

### 3.4 Fusion Layer: Learning-to-rank

Eventually, we fuse  $ds(\cdot, \cdot)$  and  $rs_i(\cdot, \cdot)$  together to get the final similarity prediction of each pair of words. We choose a straightforward manner by linearly combining  $ds(\cdot, \cdot)$  and  $rs_i(\cdot, \cdot)$ :

$$FUSE(w, w') = \alpha_d \cdot ds(w, w') + \sum_i \alpha_i \cdot rs_i(w, w') \quad (2)$$

Note that the relation-based similarities are built upon  $ds(\cdot, \cdot)$  (Eq. 1), so FUSE is essentially a hierarchical combination of  $ds(\cdot, \cdot)$  guided by semantic relations. Linear combination is simple, but turns out to be effective through the experiments. More elaborated fusion method may be invested in future studies.

To get the weights  $\alpha_d$  and  $\alpha_i$ , we adopt pair-wise learning-to-rank technique rather than regression. This is because it is difficult to assign an absolute score of semantic similarity to a pair of words, especially when seasoned linguists are not available. On the other hand, given two word pairs  $\langle A, B \rangle$  and  $\langle A, C \rangle$ , it is relatively easier to tell whether  $\langle A, B \rangle$  is more similar than  $\langle A, C \rangle$ , or vice versa.

We use the ranking option of SVM<sup>light</sup> v6.02 (Joachims, 1999) with linear kernel to optimize the weights against human judgements. The goal of the learning process is to minimize the number of wrong pair-wise similarity comparisons. In the testing phase, the model assigns to each testing sample a real-value prediction, which is exactly a linear fusion of the corresponding sub-similarities. As for the technical details in SVM<sup>light</sup>, each word pair  $\langle X, Y \rangle$  yields a sample. If the human judgement suggests  $\langle A, B \rangle$  is more similar than  $\langle A, C \rangle$ , then the corresponding samples will be assigned to an unique sample group, with the target values 1 and 0 respectively. If a sub-similarity

value does not exist due to out-of-vocabulary issue, the corresponding feature is set to “missing”.

The judgement is obtained from a Chinese thesaurus (HIT-SCIR, 2006), containing 77,458 words that are manually grouped according to a five-level category hierarchy. Words grouped together at the lowest(fifth) level include both synonyms (e.g. *sea* / *ocean*) and comparable terms (e.g. *Germany* / *France*). The lower the level two words appear in together, the more semantically related they are. We directly use this clue to determine the semantic similarity between words. For instance, words that appear together in a level-3 category but not in any level-4 category have a similarity of 3. Words do not appear together in any category have a zero-similarity.

After a pilot study, we found that words with similarities 0-2 are indistinguishably dissimilar. So we merged these similarity levels together as zero-similarity. Moreover, to further distinguish semantically-similar and comparable words, we set the similarity between synonyms to 6 instead of 5 for comparable terms. Finally, we got five similarity levels: 0, 3, 4, 5, and 6. To make the experiment manageable, we randomly sample 200 nouns from the thesaurus and extract their similar words at every level, and arrange them as a serial of similarity judgements like  $sim(w, w') > sim(w, w'')$ . The whole dataset contains 2,204 words and 6,904 judgements. To avoid the randomness in data, we adopt five-fold cross-validation on it. In each fold, we use 3 parts of the data to train the model, and tune / test it using the other two parts.

## 4 Evaluation

### 4.1 Experiment Settings

We compare our fused similarity with three baselines. The first one is classical text-window based distributional similarity  $ds(\cdot, \cdot)$ . The other two baseline approaches are listed as follows:

*Lin’s similarity* (Lin, 1998) (LIN98). LIN98 combines PMI values from different distributions linearly. The formula uses dependency paths, and we extend it to semantic relations extracted as in Section 3.3.1. As a by-product in the extraction phase, words’ co-occurrence counts under each semantic relation are acquired to compute the PMI values. The text-window based distribution is also included in the combination.

*Joint cosine similarity* (JCS). There is also previous work that uses pattern-constrained context

information as extra clue of semantic similarity (Baroni and Lenci, 2010). Different from LIN98, words’ co-occurrence counts under each semantic relation are replaced by the number of patterns that extract them (Baroni and Lenci, 2010). Here, the text-window and the relation based distributions are mingled into a single distribution, and cosine similarity is obtained. Baroni and Lenci (2010) uses LMI in relation based distributions, but we found PMI achieves better performance.

The text-window distribution used in both LIN98 and JCS is based on 3-length window and PMI, since this configuration shows the best performance in our experiments. For the relation based distribution in LIN98 and JCS, we initially use the whole (noisy) relation extraction result, and make further analysis by varying the amount (and quality) of the relation instances. LIN98 and JCS also generate integrated similarities based on multiple evidences, we will compare their effectiveness with our approach.

Two evaluations metrics are used:

*Accuracy of comparison (Acc.)*. We say a system makes a correct comparison if it returns  $S(A, B) > S(A, C)$  that coincides with human judgement. The overall accuracy is defined as the percentage of correct comparisons over the whole dataset.

*Spearman’s  $\rho$* . For each word pair  $\langle A, B \rangle$ , we count the number of word pairs  $\langle A, x \rangle$  that are judged less similar than  $\langle A, B \rangle$ , and use it as an absolute score of similarity between  $A$  and  $B$ . This allows us to compare similarity predictions with such scores globally, and get the  $\rho$  coefficient.

To get meaningful conclusions, we use approximate randomization (Noreen, 1989) to test the significance of *Acc.* comparison, and Steiger’s Z-test (Steiger, 1980) for Spearman’s  $\rho$  comparison.

## 4.2 $ds(\cdot, \cdot)$ Configurations

Distributional similarity  $ds(\cdot, \cdot)$  is an important baseline. Moreover, by substituting Eq. 1 into Eq. 2, one will find that  $ds(\cdot, \cdot)$  is also the basic building block of the fused similarity. With the multiple choices of the text-window lengths (3 and 6) and association measures (Raw co-occurrence, PMI, Jaccard, and LMI) listed in subsection 3.2, we now try to find out an optimal configuration of  $ds(\cdot, \cdot)$ . The results are obtained based on the whole dataset, as shown in Table 2. For the  $ds(\cdot, \cdot)$  configurations (the first 8 rows), the subscripts are

the text-window’s length and the superscripts are the association measures used. Performance of LIN98 and JCS is also included (rows 9~10).

	<i>Acc.</i>	$\rho$
$ds_{3wd}^{Raw\ cooc}(\cdot, \cdot)$	77.0	0.458
$ds_{6wd}^{Raw\ cooc}(\cdot, \cdot)$	75.2	0.427
$ds_{3wd}^{PMI}(\cdot, \cdot)$	<b>80.8</b>	0.522
$ds_{6wd}^{PMI}(\cdot, \cdot)$	77.4	0.438
$ds_{3wd}^{Jac.}(\cdot, \cdot)$	80.1	0.527
$ds_{6wd}^{Jac.}(\cdot, \cdot)$	79.0	0.501
$ds_{3wd}^{LMI}(\cdot, \cdot)$	80.0	<b>0.544</b>
$ds_{6wd}^{LMI}(\cdot, \cdot)$	78.2	0.497
LIN98	79.4	0.496
JCS	<b>82.2</b>	<b>0.553</b>

Table 2: Performance of  $ds(\cdot, \cdot)$ , LIN98, and JCS

In both *Acc.* and  $\rho$ ,  $ds(\cdot, \cdot)$  with the 3-length window significantly ( $p < 0.01$ ) outperforms that with the 6-length window, except when using Jaccard ( $p = 0.12$  for *Acc.*). Although the window length is easy to choose, it remains unclear which association measure is the most appropriate. With the 3-length window, the performance of PMI, Jaccard, and LMI are comparable. Thus, we will have to try out all PMI, LMI and Jaccard in the fusion phase.

As for the other two baseline approaches, JCS significantly outperforms all  $ds(\cdot, \cdot)$  configurations in both *Acc.* ( $p < 0.05$ ) and  $\rho$  ( $p < 0.07$ ) as shown in bold font, but LIN98 does not.

## 4.3 Similarity Fusion

In similarity fusion (Eq. 2), for the sake of conciseness, we use the same  $ds(\cdot, \cdot)$  configuration to compute both the distributional similarity and the relation-based similarities (Eq. 1). The *Acc.* and  $\rho$  of the fused similarity (denoted by FUSE) using different  $ds(\cdot, \cdot)$  configurations are shown in Table 3. Recall that because of the indistinguishable *Acc.*, three configurations need to be examined:  $ds_{3wd}^{PMI}(\cdot, \cdot)$ ,  $ds_{3wd}^{LMI}(\cdot, \cdot)$ , and  $ds_{3wd}^{Jac.}(\cdot, \cdot)$ .

	$ds(\cdot, \cdot)$ configuration used		
	$ds_{3wd}^{PMI}(\cdot, \cdot)$	$ds_{3wd}^{LMI}(\cdot, \cdot)$	$ds_{3wd}^{Jac.}(\cdot, \cdot)$
<i>Acc.</i>	<b>83.9</b>	81.9	78.9
$\rho$	<b>0.591</b>	0.558	0.500

Table 3: Performance of our proposed fused similarity (FUSE) using different  $ds(\cdot, \cdot)$  configurations.

In both *Acc.* and  $\rho$ ,  $ds_{3wd}^{PMI}(\cdot, \cdot)$  based FUSE has

significantly ( $p < 0.005$ ) superior performance (shown in bold font). In both metrics, it also significantly ( $p < 0.01$ ) outperforms all baseline approaches, including all  $ds(\cdot, \cdot)$  configurations, LIN98, and JCS. The results suggest that on our dataset, the most suitable  $ds(\cdot, \cdot)$  to use in FUSE is  $ds_{3wd}^{PMI}(\cdot, \cdot)$ , which achieves 83.9% accuracy in predicting whether a word pair  $\langle A, B \rangle$  is more similar than  $\langle A, C \rangle$ .

As a global comparison, we have the following performance rankings:

$$\begin{aligned} Acc. : & \text{LIN98} <_{0.05} ds_{3wd}^{PMI}(\cdot, \cdot) <_{0.05} \text{JCS} <_{0.01} \text{FUSE} \\ \rho : & \text{LIN98} <_{0.01} ds_{3wd}^{LMI}(\cdot, \cdot) <_{0.01} \text{JCS} <_{0.01} \text{FUSE} \end{aligned}$$

where the subscripts show the significance level. JCS outperforms the best  $ds(\cdot, \cdot)$  configurations in both  $Acc.$  and  $\rho$ , confirming the contribution of the semantic evidences obtained by the in-depth mining in the corpus. Moreover, FUSE achieves even better performance, showing the effectiveness of the design of relation-based similarity (Eq. 1) and the linear combination mechanism (Eq. 2).

Ideally, an effective fusion should have worked for all  $ds(\cdot, \cdot)$  configurations. However, FUSE using  $ds_{3wd}^{Jac}(\cdot, \cdot)$  yields bad performance. Through intrinsic analysis we found that  $ds_{3wd}^{Jac}(\cdot, \cdot)$  is more sensitive to the noise in the relation data than  $ds_{3wd}^{PMI}(\cdot, \cdot)$ .

#### 4.4 Quality of Semantic Relations

Initially, we use all of the extracted relation instances in the experiments without threshold based filtering. Without doubt, there is much noise in the bottom of the extraction results. Through controlling the weight threshold of the relation instances, we now shrink the global extraction results to top  $\sim 5\%$ ,  $\sim 10\%$ ,  $\sim 30\%$ , and  $\sim 60\%$  subsets to see how their quality and coverage change, and how they affect the performance of FUSE, LIN98, and JCS.

FUSE uses top 10 relation words to calculate the relation-based similarity. Thus, instead of examining the global extraction results, we focus on the top 10 relation words of the target words in our dataset, because FUSE’s performance is our main concern.

The full evaluation is expensive. There are totally 2,204 target words in the dataset, involving 70,000 relation words. So we randomly sample 200 words from the 2,204 words, and evaluate the accuracy of their relation words by varying the amount of the global extraction results. The results are summarized in Table 4. While the amount

Figure 2: Accuracy of LIN98, JCS, and FUSE varying the amount of the global extraction results.

of global extraction results shrink, low-weight relation words are gradually removed, and the coverage of the relation words decreases. Only the top  $\sim 5\%$  results have acceptable accuracies. Intrinsic study shows that holonyms and meronyms concentrate to location names due to the bias in the seeds. This causes a significantly low quality and coverage for these two relations.

The low-quality extraction results pose an austere challenge. Here, we re-examine LIN98, JCS, and FUSE (5-fold CV using  $ds_{3wd}^{PMI}(\cdot, \cdot)$ ,  $ds_{3wd}^{LMI}(\cdot, \cdot)$ , or  $ds_{3wd}^{Jac}(\cdot, \cdot)$ ) based on the four subsets of the global extraction results, and assemble the performance figures in Figure 2. For the sake of space limit, we only include the  $Acc.$  results. Spearman’s  $\rho$  shows a similar trend.

The results further confirms the ranking listed in subsection 4.3. A common finding is that the bottom 40% of the global extraction results are hardly useful. FUSE based on  $ds_{3wd}^{PMI}(\cdot, \cdot)$  handles the noise in the data quite well. FUSE based on  $ds_{3wd}^{LMI}(\cdot, \cdot)$ , or  $ds_{3wd}^{Jac}(\cdot, \cdot)$  seems partial to high-quality data. Similar to  $ds_{3wd}^{PMI}(\cdot, \cdot)$  based FUSE, performance of LIN98 and JCS drops while shrinking the number of relation instances. This indicates they prefer recall to precision of the extraction results.

#### 4.5 Feature Analysis

We have shown that the fusion of  $ds_{3wd}^{PMI}(\cdot, \cdot)$  and  $rs_i(\cdot, \cdot)$  shows superior performance, yet each sub-similarity’s contribution remains unclear. Using 100% global extraction results, we incrementally add relation-based similarities to  $ds_{3wd}^{PMI}(\cdot, \cdot)$ , and report the fusion’s cross-validation performance in Table 5. The order of addition is coincide to the quality of the relations (see Table 4).

	Relation words	~5%		~10%		~30%		~60%		100%	
		# wd.	Acc.	# wd.	Acc.	# wd.	Acc.	# wd.	Acc.	# wd.	Acc.
$r_1$	$w$ [Sibling] <sub>is</sub> $\sqcup$	1,115	96.6	1,325	88.3	1,532	80.9	1,615	78.7	1,648	77.9
$r_2$	$w$ [Hyponym] <sub>is</sub> $\sqcup$	263	77.6	627	38.8	1,018	27.8	1,227	23.9	1,378	21.8
$r_3$	$w$ [Hypernym] <sub>is</sub> $\sqcup$	608	73.8	1,059	52.0	1,376	44.6	1,488	42.7	1,561	40.9
$r_4$	$w$ [Meronym] <sub>is</sub> $\sqcup$	266	41.7	416	29.6	586	22.7	741	19.4	972	15.1
$r_5$	$w$ [Holonym] <sub>is</sub> $\sqcup$	141	55.3	161	50.9	197	42.6	388	23.2	462	20.1

Table 4: Quantity and quality analysis of the 200 sampled words’ relation words.

Feature set	Acc.	$\rho$
$ds_{3wd}^{PMI}$	80.8	0.522
$ds_{3wd}^{PMI} + rs_1$	83.1	0.559
$ds_{3wd}^{PMI} + rs_1 + rs_3$	83.4	0.587
$ds_{3wd}^{PMI} + rs_1 + rs_3 + rs_2$	83.6	0.587
$ds_{3wd}^{PMI} + rs_1 + rs_3 + rs_2 + rs_5$	83.7	0.590
$ds_{3wd}^{PMI} + rs_{1\sim 5}$	83.9	0.591
$ds_{3wd}^{PMI} + rs_2$	81.3	0.522
$ds_{3wd}^{PMI} + rs_3$	82.3	0.574
$ds_{3wd}^{PMI} + rs_4$	81.2	0.532
$ds_{3wd}^{PMI} + rs_5$	81.1	0.550

Table 5: FUSE’s performance on sub feature sets.

Unsurprisingly,  $rs_1(\cdot, \cdot)$ , i.e. [Sibling]<sub>is</sub> based similarity is the most effective, owing to its high quality.  $rs_3(\cdot, \cdot)$  ([Hypernym]<sub>is</sub>) dominates the rest of the performance improvement, and adding it alone to  $ds_{3wd}^{PMI}(\cdot, \cdot)$  also largely improves the performance. It is reasonable since comparing the sibling terms or hypernyms (i.e. “what is it”) are natural ways to compare words’ meanings. Though “masked” by [Sibling]<sub>is</sub> and [Hypernym]<sub>is</sub>, other relations also show their contribution (yet small) when added to  $ds_{3wd}^{PMI}(\cdot, \cdot)$  alone.  $rs_2(\cdot, \cdot)$  ([Hyponym]<sub>is</sub>) is an exception, and its weight is also negative in the trained models. This indicates that hyponyms may not be an adequate evidence for semantic similarity.

Given the bad quality of [Meronym]<sub>is</sub> and [Holonym]<sub>is</sub> relations, their effectiveness seems bizarre. In fact, though a great number of relation words are not correct, they can be considered as special context words. Owing to the design of the relation-based similarity (Eq. 1), the distributional similarities of those words still contribute to the target words’ similarity calculation. This finding allows us to relax the quality restriction of semantic relation extraction. Our hierarchical approach to semantics-aware distributional similarity would work on the basis of noisy relation databases.

## 5 Conclusion

In this paper, we propose a hierarchical semantics-aware distributional similarity scheme (DSS). We introduce a semantic layer over the classical dis-

tribution layer by employing a semantic relation extraction system and a mechanism that computes words’ relation-specific similarities based on simple distributional similarity. Finally, the fusion of the distributional and relation-based similarities is completed by learning-to-rank.

Experiments show that the in-depth mining in the corpus provides effective evidences for semantic similarity. On our dataset, the fused similarity significantly improves distributional similarity, and also outperforms the baseline approaches that blend the heterogeneous evidences in a single vector. Additionally, intrinsic analysis shows that [Sibling]<sub>is</sub> and [Hypernym]<sub>is</sub> relations are the most effective semantic clues.

In future studies, we will experiment on more elaborated combination similarity fusion mechanisms other than linear combination. We will also explore more types of semantic evidences, e.g. synonym, antonym, semantic attribute, or thematic relations such as agent / patient relations.

## Abstract

Recognizing Textual Entailment (RTE) is to predict whether one text fragment can semantically infer another, which is required across multiple applications of natural language processing. The conventional alignment scheme, which is developed for machine translation, only marks the paraphrases and hyponyms to justify the entailment pairs, while provides less support for the non-entailment ones. This paper proposes a novel alignment scheme, named labeled alignment, to address this problem, which introduces negative links to explicitly mark the contradictory expressions to justify the non-entailment pairs. Thus the alignment-based RTE method employing the proposed scheme, compared with those employing the conventional one, can gain accuracy improvement through actively detecting the signals of non-entailment. The experimental results on the data sets of two shared RTE tasks indicate the implemented system significantly outperforms both the baseline system and all the other submitted systems.

## 1 Introduction

Textual Entailment (TE) is a directional relation between two text fragments. One natural-language premise, noted as  $P$ , entails one natural-language hypothesis, noted as  $H$ , if typically a human read-

ing  $P$  would infer that  $H$  is most likely true (Dagan et al., 2006).

Recognizing Textual Entailment (RTE) is proposed as a generic task that captures the semantic inference need across a wide range of natural language processing applications. For example, a question answering system should identify the texts that entail a hypothesized answer, e.g., given the question “*What does Peugeot manufacture?*”, the text “*Chrétien visited Peugeot’s newly renovated car factory*” entails the hypothesized answer form “*Peugeot manufactures cars*” (Dagan et al., 2006). Similarly, in Machine Translation (MT) evaluation, a correct translation should be semantically equivalent to the gold translation, that is, both translations should entail each other (Padó et al., 2009).

RTE has attracted extensive attention ever since it was proposed. A wide range of methods have been proposed, and quite a few successful approaches treat RTE as an alignment problem. Alignment is originally developed for MT to bridge two languages (Brown et al., 1993). Alignment is to establish links between the semantically equivalent atom expressions in two sentences. (Marsi and Krahrmer, 2005) first advocates pipelined system architectures that contain distinct alignment components. This latter becomes a strategy crucial to the top-performing systems of (Hickl et al., 2006). In addition, human-generated alignment annotations for the second PASCAL<sup>1</sup> RTE challenge is released by Microsoft Research to facilitate related research (Brockett, 2007).

The principle of the existing alignment-based RTE methods is that a sufficiently good alignment between  $P$  and  $H$  means a close lexical and structural correspondence, thus  $P$  probably entails  $H$ . For example, Fig. (1a) shows that the entailment

\* B. L. Lu and X. L. Wang are supported by the National Natural Science Foundation of China (Grant No. 61272248), the National Basic Research Program of China (Grant No.2013CB329401), and the Science and Technology Commission of Shanghai Municipality (Grant No. 13511500200). H. Zhao is supported by the National Natural Science Foundation of China (Grant No. 60903119 and Grant No. 61170114).

<sup>1</sup>PASCAL is the European Commission’s ICT-funded Network of Excellence for Cognitive Systems, Interaction & Robotics.

relation can be correctly predicted through recognizing “*read into*” → “*interpreted*”<sup>2</sup> and “*what he wanted*” → “*in his own way*”.

However, the alignment developed in MT does not solve the non-alignment samples well. It usually links the words in  $H$ , which have no counterparts in  $P$ , to  $NULL$  regardless their impacts on the entailment relation. For example, in Fig. (1b), “*ferry sinking*”, “*cause*” and “*that*” are all linked to  $NULL$ <sup>3</sup>, while only “*ferry sinking*” is the cause for non-entailment. Thus such an alignment is improper for RTE.

This paper extends the normal alignment scheme to meet the challenge of RTE. The proposed scheme, named labeled alignment, introduce another type of links, named negative links, to mark those critical RTE-related linguistic phenomena that cannot be captured by the normal alignment. For example, Fig. (1c) shows that the previous vital expressions “*ferry sinking*” is linked to “*flood*” through a negative link, noted as “*ferry sinking*”  $\nrightarrow$  “*flood*”.

The proposed labeled alignment, which explicitly marks the causes of non-entailment, can facilitate the design of RTE method. This paper proposes an RTE method based on the labeled alignments that actively looks for the signal of negative links in order to correctly recall non-entailment samples.

The main contributions of this paper are as follows,

- A labeled alignment scheme is proposed for RTE;
- An RTE data set annotated with the proposed scheme is released;
- High prediction accuracies are achieved on two RTE data sets.

## 2 Related Work

RTE has attracted extensive attention in the past decade, and a wide range of approaches have been proposed besides the alignment-based methods (Androutsopoulos and Malakasiotis, 2009). The logic-based methods interpret sentences to first-order-logic expressions and then invoke theorem provers (Bos and Markert, 2005). Similarity-based methods employ classifiers to learn from

<sup>2</sup>The notation means that the expression “*read into*” in  $P$  is connected to the expression “*interpreted*” in  $H$ .

<sup>3</sup> $NULL$  means an empty expression.

multiple similarity measures including lexical similarities (Watanabe et al., 2012), edit distance (Rios and Gelbukh, 2012), measurements from MT (Volkh and Neumann, 2011), syntactic tree similarity (Mehdad, 2009) and dependency similarity (Wang and Zhang, 2009). Transform-based methods take entailment as finding a credible transform from the premise to the hypothesis (Kouylekov et al., 2011).

(MacCartney et al., 2008) argues the alignment techniques and tools for MT such as GIZA++ (Och and Ney, 2003) do not readily transfer to RTE. They compare the alignment for RTE with that for MT, and state the following differences:

- The alignment for RTE is monolingual rather than cross-lingual, opening the door to utilizing abundant monolingual resources on semantic relatedness.
- The alignment for RTE is asymmetric, since  $P$  is often much longer than  $H$ .
- One cannot assume approximate semantic equivalence, since  $P$  might be contradictory or independent with  $H$ .
- Little training data is available.

They propose a new alignment tool named MANLI for RTE, but still adopts a alignment scheme similar with the one in MT (Brockett, 2007). This paper, however, revises the alignment scheme to support RTE, especially to address the third difference.

(MacCartney et al., 2006) argues that some critical RTE-related linguistic phenomena such as negations and modalities cannot be captured by alignment. They propose a wide range of features to represent them, and employ a classifier to learn from these specialized features as well as the alignment features to predict the entailment relation. The proposed labeled alignment in this paper, however, can natively process these phenomena, e.g., Fig. (2g) solves negations and (2h) solves modalities.

(Sammons et al., 2010) argues that a single label (whether entailment or not) is insufficient to effectively evaluate the performance of RTE system as well as to guide researchers. They raise a group of detailed entailment phenomena such as simple rewriting rules, lexical relations and passive-active transform, as well as a group of detailed

Figure 1: Illustration of Alignment for RTE. Each subfigure presents an RTE sample. The vertical text is the premise, and the horizontal text is the hypothesis. The solid squares represent positive links, and the crosses represent negative links. (a) is of entailment relation, while (b) and (c) are of non-entailment relations.

non-entailment phenomena such as missing arguments, named entities mismatches and missing modifiers. This paper greatly favors their work, and the proposed labeled alignment scheme can annotate most of the non-entailment phenomena mentioned in their paper, which is beneficial to researchers.

### 3 Labeled Alignment

Labeled alignment consists of two types of links, named positive link and negative link, respectively. The positive link is inherited from the normal alignment, while the negative link is newly introduced.

#### 3.1 Positive Link

The positive link is inherited from the normal alignment to handle the variability of natural language expressions, that is, the same meaning can be expressed by different texts. The positive link connects the atom expressions  $e_p$  in  $P$  and  $e_h$  in  $H$ , if  $e_p$  and  $e_h$  are paraphrases or  $e_p$  infers  $e_h$ , noted as  $e_p \rightarrow e_h$ . As the occurrence of this type of links suggests the entailment relation between  $P$  and  $H$ , they are named positive links.

This paper partially follows the alignment scheme in (Brockett, 2007; MacCartney et al., 2008) where the links are token-based but many-to-many is allowed, thus multi-word phrases can be explicitly aligned.

The positive links are mainly applied to the following cases:

- identical words;

- synonyms or near synonyms, e.g., “*bought*”  $\rightarrow$  “*purchased*” in Fig. (2a);
- hyponyms, e.g., “*patent*”  $\rightarrow$  “*technology*” in Fig. (2a);
- same named entities, e.g., “*the Microsoft Corporation*”  $\rightarrow$  “*Microsoft*” in Fig. (2a);
- paraphrases or semantically inferable expressions which cannot be further decomposed into smaller links, e.g., “*read into*”  $\rightarrow$  “*interpreted*” and “*what he wanted*”  $\rightarrow$  “*in his own way*” in Fig. (1a);
- trivial words in  $H$  versus  $NULL$ , e.g.,  $NULL \rightarrow$  “*just*” in Fig. (1a).

#### 3.2 Negative Link

The negative link is introduced to annotate why a RTE sample does not possess an entailment relation. The negative link is noted as  $e_p \not\rightarrow e_n$  where  $e_p$  and  $e_n$  are the expressions in  $P$  and  $H$ , respectively. As the occurrence of this type of links suggests the non-entailment relation, they are named negative links.

The usage of negative links can be divided to three categories – contradictory expressions, unmatched sentence-level modifier and hypothesis novelty.

The contradictory expressions refer to the two expressions from  $P$  and  $H$ , respectively, which should be compared as motivated by the syntactic structures, but actually convey inconsistent semantics. Such phenomena usually lead to the conflic-

tion between  $P$  and  $H$ . The contradictory expressions include, but are not limited to, the following cases:

- antonyms, e.g., “*catalyst*”  $\nrightarrow$  “*deterrent*” in Fig. (2b);
- mismatches between numbers, dates and times, e.g., “*3 millions*”  $\nrightarrow$  “*10,000*” in Fig. (2c);
- different named entities, e.g., “*Mircrosoft*”  $\nrightarrow$  “*Sony*” in Fig. (2d);
- heads of noun phrases, e.g., “*drill*”  $\nrightarrow$   $NULL$  in Fig. (2e);
- vital modifiers of noun phrases, e.g., “*Hispanic*”  $\nrightarrow$   $NULL$  in Fig. (2f);
- contradictory content words<sup>4</sup>, e.g., “*flood*”  $\nrightarrow$  “*ferry sinking*” in Fig. (1c).

The unmatched sentence-level modifier refers to the modifier in either  $P$  or  $H$  which impacts the meaning of the whole sentence but has no counterpart in the other sentence. Such phenomena usually flip the entailment relation. The unmatched sentence-level modifier is marked through connecting it to  $NULL$  through a negative link. The usage includes the following cases:

- negations including simple negation (not), negative quantifiers (no, few), prepositions (without, except), adverbs (never, seldom, nearly), e.g., “*never*”  $\nrightarrow$   $NULL$  in Fig. (2g);
- Virtual modalities, e.g., “*could*”  $\nrightarrow$   $NULL$  in Fig. (2h);
- phrases that suggest the sentence is not stating a happened event, e.g., “*ready to*”  $\nrightarrow$   $NULL$  in Fig. (2i);
- hypothetical conjunctions, e.g., “*if*”  $\nrightarrow$   $NULL$  in Fig. (2j).

The hypothesis novelty refers to the expression in  $H$  that conveys novel information against  $P$ . It is also marked through connecting it to  $NULL$  through a negative link. Such an expression is usually among the following cases:

- numbers, e.g.,  $NULL$   $\nrightarrow$  “*20-30 percent*” in Fig. (2k);
- novel content words, e.g.,  $NULL$   $\nrightarrow$  “*property damage*” in Fig. (2l).

## 4 Alignment-based RTE Methods

In this section, the conventional alignment-based RTE method is introduced first. This method is then augmented to leverage the proposed labeled alignment to improve the prediction accuracy.

### 4.1 RTE Method Based on Normal Alignment

The conventional alignment-based RTE method measures the quality of the alignment between the premise  $P$  and the hypothesis  $H$  to predict their entailment relation (Fig. 3a). An automated aligner is first learned from the annotation of positive links, the normal alignment consists of positive links (see Sec. 3.1). Then this aligner produces an alignment for each input ( $P$ ,  $H$ ). After that, a feature extractor measures the quality of the alignment. Finally a classifier utilizes these measures as features to predict the entailment relation. Commonly used quality measurements for alignment include the confidence score of the aligner and the ratio of linked words in  $P$  (Tab. 1).

### 4.2 RTE Method Based on Labeled Alignment

The augmented RTE method based on the labeled alignment not only measures the quality of the alignment, but also detects the signals of negative links to improve the prediction accuracy (Fig. 3b). The augmentation is conducted in two aspects. First, the aligner is trained with both positive and negative links, thus the produced alignment for each input ( $P$ ,  $H$ ) contains both positive and potentially negative links (but two types of links are not distinguished). Second, the feature extractor not only measures the quality of the alignment, but also analyzes the type of each link. A wide range of type-related features can be extracted from each link of the alignment (Tab. 1). These type-related features together with the quality-related features are added into a feature vector for classification.

Notably, besides the above RTE method, a pipeline framework based on the labeled alignment has been tried, but its accuracy turns to be lower than that of the baseline. The

<sup>4</sup>This phenomenon is actually hard to recognize in a practical system. Multiple relevant weak features for classification are employed.

(a) Synonym, hyponym and named entity

(b) Atonym

(c) Mismatched numbers

(d) Different named entities

(e) Head of noun phrase

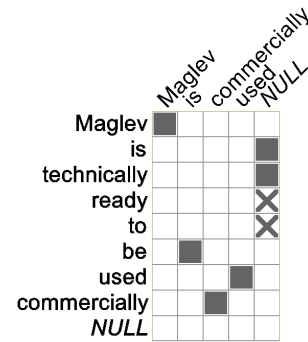

(f) Vital modifier

(g) Unmatched negation

(h) Virtual modality verb

(i) Non-happened event

(j) Hypothetical conjunction

(k) Novel number

(l) Novel content word

Table 2: Experimental Data Sets

pipeline method first employs a classifier to predict whether each link is positive or negative, and then employs another classifier to predict the entailment relation based on the confidence scores of the first classifier.

## 5 Experiment

The data sets of the NTCIR-9<sup>5</sup> RITE1<sup>6</sup> and NTCIR-10 RITE2 shared tasks (simplified Chinese binary-class track) are taken as the experimental data sets (Shima et al., 2011; Watanabe et al., 2013). This section first describes the annotating process of the labeled alignment, then presents the experimental settings and finally reports the experimental results.

### 5.1 Data Set Annotation

The data sets from the simplified Chinese binary-class tracks of NTCIR-9 RITE1 and NTCIR-10 RITE2 contains 1,595 sentence pairs in all (Tab. 2). Note that all the training and test samples of RITE1 are reused as the training samples of RITE2, while newly collected 781 sentence pairs are taken as the test samples.

The annotating process follows the methodology employed by (Brockett, 2007). The training set of NTCIR-9 RITE1 is used for training annotators, and three Chinese native-speaking undergraduates are actively encouraged to discuss the arising cases, resolve questions and reconcile results with the authors. In annotating the test set of NTCIR-9 RITE1, however, they are first instructed not to discuss the annotations either with the authors or among themselves in order to measure annotator agreement. After that, they reconcile the results on the test set with the authors.

The measure of annotator agreement indicates the alignment annotations are reliably consistent. All three annotators concurred on about 72% of proposed links on the test set, two out of three

<sup>5</sup>NTCIR is the abbreviation of NII Test Collection for IR Systems where NII abbreviates the National Institute of Informatics in Japan.

<sup>6</sup>RITE is the abbreviation of Recognizing Inference in Text.

agreed on about 24% of cases, and three-way disagreements were as rare as about 4%.

### 5.2 Experimental Settings

The supervised learning aligner described in (Chambers et al., 2007) and (MacCartney et al., 2008) is adopted in this paper. This aligner is a structured learning algorithm that employs a linear weighted scoring function to evaluate each candidate alignment. We adapt the original algorithm from two aspects. First, the candidate alignment links are generated from a wide range of NLP analysis results, as follows,

- each segmented word in  $P \rightarrow$  each segmented word in  $H$ ;
- each syntactic node in  $P \rightarrow$  each syntactic node in  $H$ ;
- each NE in  $P \rightarrow$  each NE in  $H$ ;
- each expression  $e_P$  in  $P \rightarrow$  each expression  $e_H$  in  $H$  as long as  $(e_P, e_H)$  appears in a synonym list, a antonym list, or an ontology.

Second, the alignment-learning features contains all the link type features in Tab. 1. These two enhancements, abstractly, convert aligning to a comprehensive NLP process.

The BaseSeg toolkit based on the conditional random field is employed to segment the Chinese texts (Zhao et al., 2006). The Stanford factored parser, which is reported to be more accurate than the PCFG parsers (Klein and Manning, 2002), is employed to analyze the segmented Chinese text. The BaseNER toolkit is employed to recognize named entities (Zhao and Kit, 2008).

We take two Chinese ontologies – CiLin<sup>7</sup> (Mei et al., 1983) and HowNet (Dong and Dong, 2003) – as the knowledge-base for extracting features. Three methods of computing the semantic similarity proposed in (Liu and Li, 2002; Xia, 2007) are employed.

We take the RBF-kernelled SVM as the entailment classifier. The implementation of LibSVM is employed. The parameters are tuned through 5-fold cross-validation on the training set.

The conventional RTE method based on the normal alignment, which is presented in Sec. 4.1, is taken as the baseline method.

<sup>7</sup>This term means a word forest of synonyms in Chinese.

Table 3: Entailment Prediction Accuracy on NTCIR-9 RITE and NTCIR-10 RITE2 Data Sets

### 5.3 Experimental Results

The experimental results of the prediction accuracy on NTCIR-9 RITE1 and NTCIR-10 RITE2 data sets are presented at Tab. 3. The participants mainly employ committees of classifiers to learn from a wide range of features including multi-level similarities, occurrences of negative words, mismatches of named entities and numbers, syntactic correspondences, and so on (Zhang et al., 2011; Ren et al., 2011). The results show that the proposed RTE method outperforms not only the baseline method, but also the official entries of the shared tasks.

## 6 Conclusion and Future Work

In this paper, a labeled alignment scheme is proposed to address the shortage of the normal alignment scheme for non-entailment RTE samples. To verify the proposed scheme, an augmented alignment-based RTE method that employs the labeled alignment is compared with a conventional one that employs the normal alignment. The data sets of two shared RTE tasks are taken as the experimental data sets and manually annotated with the proposed scheme. Experimental results indicate that the augmented RTE method outperforms not only the baseline method, but also all the submitted systems of the shared tasks. Therefore, the proposed labeled alignment scheme proves to be effective.

The future work of this paper is two-fold. First, during the research, though two Chinese ontology resources – CiLin and HowNet – are employed to detect negative links, it is found that quite a few critical semantic relations are not covered. Therefore we plan to merge and scale existing Chinese ontologies through data mining techniques

such as (Liu and Singh, 2004). Second, the proposed method is actually applicable to multiple languages, though it is only tested on Chinese in this paper. We plan to apply it to other languages such as the Microsoft English RTE corpus in the future.

## Abstract

This paper presents a new machine-learning Chinese word segmentation (CWS) approach, which defines CWS as a break-point classification problem; the break point is the boundary of two subsequent words. Further, this paper exploits a support vector machine (SVM) classifier, which learns the segmentation rules of the Chinese language from a context model of break points in a corpus. Additionally, we have designed an effective feature set for building the context model, and a systematic approach for creating the positive and negative samples used for training the classifier. Unlike the traditional approach, which requires the assistance of large-scale known information sources such as dictionaries or linguistic tagging, the proposed approach selects the most frequent words in the corpus as the learning sources. In this way, CWS is able to execute in any novel corpus without proper assistance sources. According to our experimental results, the proposed approach can achieve a competitive result compared with the Chinese knowledge and information processing (CKIP) system from Academia Sinica.

## 1 Introduction

Chinese sentences contain sequences of characters that are not delimited by white spaces or any other symbol used for word identification, so Chinese word segmentation (CWS) is one of the fundamental issues in Chinese natural language processing studies.

One of the major aspects in existing CWS researches is the resolution of word segment ambiguities. The conventional approach of ambiguity detection is to use two maximum matching methods (MMs), which scan corpora forward

(Forward Maximum Matching, FMM) and backward (Backward Maximum Matching, BMM) based on dictionaries (Kit, Pan, & Chen, 2002). Meanwhile, disambiguation methods can be classified into two different categories: rule-based methods and statistical-based methods. (Ma & Chen, 2003b). Problem disambiguity is often accompanied by the problem resolution of an unknown word or out-of-vocabulary (OOV) extraction (K.-J. Chen & Ma, 2002). Besides the MMs with dictionaries, which are also known as word-based approaches, there are character-based approaches. The word-based approach treats words as the basic unit of a language, and the character-based approach labels each character as the beginning, middle, or end of a word. Character-based approaches are often implemented with a machine-learning classification algorithm for handling disambiguation (Wang, Zong, & Su, 2012). In addition to dictionaries, other linguistic resources such as part-of-speech (POS) or semantic information can be integrated for further improvement (M.-y. Zhang, Lu, & Zou, 2004).

In addition to the disambiguation strategy, many researchers provide the best word sequence identification methods for their CWS. The Hidden Markov model (HMM) (Lin, 2006; M.-y. Zhang et al., 2004), maximum entropy (ME), mutual information (MI) and boundary dependency (Peng & Schuurmans, 2001) are often used. Theoretically, to get the best CWS result is to obtain the optimized word sequence.

As described above, existing CWS research takes either words or characters as the core unit of their methodologies. Instead of identifying word ambiguity, finding word sequence or joining characters into words, we redefine the CWS problem as the identification of “break points” among the “joint points” in Chinese character sequences. In this paper, we define a “joint

point” as a point between adjacent characters, and a “break point” as the boundary of two subsequent words; further, the characters between two break points will consist of words.

The identification of break points among joint points is a binary classification problem. In this study, we use a support vector machine (SVM) machine-learning algorithm with contextual statistical measures to construct the feature vector model of the joint points. Based on our assumption that the Chinese word segmentation rule can be learned from non-linguistic contextual information, all features selected for the joint point model are purely statistical measures without any linguistic tagging information. Moreover, a systematic approach for creating effective positive and negative samples is provided for training the SVM classifier.

Furthermore, in order to meet the need of a CWS approach for a novel corpus, which has no appropriate dictionaries or linguistic tagging, in this study, we select a small set of assistant known source from the experimental corpus as the learning samples, which can be reduced to only 3 words: the most frequent bi-gram, tri-gram, and four-gram words. The experimental results show that by using the joint point model within long contextual information, a small set of learning samples can lead to competitive CWS results compared with the Chinese knowledge and information processing (CKIP) system, which is supported by a large-scale term database that contains approximately 5 million Chinese terms, from Academia Sinica.

## 2 Related Works

Conventionally, ambiguity and OOV are two major problems in the field of CWS research (K.-J. Chen & Ma, 2002). From the methodological perspective, there are rule-based, statistical-based, and machine-learning approaches (Kit et al., 2002; Peng & Schuurmans, 2001; Wang et al., 2012). Moreover, on the basis of the basic language unit used, existing research can be categorized into either word-based or character-based methods (Y. Zhang & Clark, 2007; Zhao, Huang, Li, & Lu, 2010). Most CWS research has resolved problems using labeled corpora while a few have managed CWS using pure text corpora (Dai, Loh, & Khoo, 1999; Jin Kiat Low, 2005). In labeled corpora, the tagging of dictionary matches, parts-of-speech, semantics, and character positions inside a word, are all popular meth-

ods for incorporating known information (Kit et al., 2002).

### 2.1 Ambiguity and the unknown word

There are two types of ambiguities in CWS: overlapping and combinational ambiguities. They can be defined as follows: given a dictionary  $D$  and a string “abc,” if the set of sub-strings  $\{ab, bc\} \subset D$ , “abc” involves an overlapping ambiguity; given a dictionary  $D$  and a string “ab,” if the set of sub-strings  $\{a, b, ab\} \subset D$ , “ab” involves a combinational ambiguity.

Conventional dictionary-based FMM and BMM are straightforward strategies for detecting ambiguities (Kit et al., 2002) and certainly provide an applicable foundation for disambiguation methods. However, dictionaries can never contain all words. Every corpus will have, on average, 3% to 5% OOV words (K.-J. Chen & Ma, 2002); hence, the identification of unknown words has become an important branch of CWS studies (K.-J. Chen & Ma, 2002; Ma & Chen, 2003a). Besides MMs, there are other corpus-based learning approaches to detect ambiguities for CWS (K.-J. Chen & Bai, 1998).

### 2.2 Word-based and character-based approaches

Another way to catalogue CWS is dependent on the basic information unit used; there are both word-based and character-based CWS methods. Word-based approaches treat the word as the basic unit, and POS and other word-based linguistic resources are often integrated into such approaches in order to improve the CWS results. From this point of view dictionary-based approaches can be treated as word-based approaches. Character-based approaches disregard the linguistic information and directly calculate the character-to-character statistical features. One popular way is to label each character as the beginning, middle, or the end of a word, and generate sequence words in sentences on the basis of the position labels of the characters (Goh, 2005; Peng & Schuurmans, 2001; Zhao et al., 2010). There are few character-based CWS approaches that use pure text corpora without additional label information (Dai et al., 1999; Jin Kiat Low, 2005).

### 2.3 Rule-based, statistical-based, and machine-learning methods

From the methods perspective, the earlier CWS used heuristic rules to resolve ambiguities (Ma &

Chen, 2003b) accompanied by the development of unknown word extraction or identification technologies (Ma & Chen, 2003a). Besides rule-based approaches, statistic-based approaches involved the concept of language models trained on large-scale corpora, and many such algorithms have been used and improved over time, such as Maximum Entropy (ME), Mutual Information (MI), and boundary dependency (Jin Kiat Low, 2005; Peng & Schuurmans, 2001). Some statistic-based approaches do not focus on resolving ambiguities, but provide strategies for word sequence identification in sentences. In general, statistical-based approaches tend to provide a generative or discriminative (Wang et al., 2012) probability formula for Chinese words. In contrast, machine-learning approaches pay more attention to the selection of effective features for Chinese word representations. The HMM (Lin, 2006; M.-y. Zhang et al., 2004) and SVM (Li, Huang, Gao, & Fan, 2005) are popular in CWS studies. Currently, a combination of a character-based approach and statistical or machine-learning algorithms is a common strategy for CWS (Goh, 2005; Wang et al., 2012; Zhao et al., 2010).

## 2.4 Contextual information

Dai and Loh have proposed “The Contextual Information Formula” of Chinese bi-gram words (Dai et al., 1999). It is an MI improving formula trained on a large-scale corpus. In this formula, the frequency of a sample bi-gram, the frequencies of its context characters and document frequencies of its context bi-grams are used. They suggest that Chinese words can be defined by a non-linguistic formula that depends on context character measures. Low and Ng conducted a series of studies using context features for their CWS research (Jin Kiat Low, 2005). Further, the concept of contextual information has often been used in information extraction research as well as in existing Chinese term extraction research for entity identification (Gao, 2005; Lee, 2012). In addition, Japanese has no word delimiter like Chinese. Sassano and Neubig et al. have defined Japanese word segmentation (JWS) as a classification task of word boundaries, and also used contextual feature sets in their studies (Neubig, Nakata, & Mori, 2011; Sassano, 2002). Inspired by these ideas of using contextual information, our research aims to extract a contextual information feature vector of “joint points” and uses an SVM algorithm to train a break point classifier.

## 2.5 Complete lexical patterns

Chien has proposed the estimation of complete lexical patterns (Figure 1) (Chien, 1999) in a series of Chinese term extraction papers. There are three important measures used in these lexical patterns, including association, and left and right dependency. These three measures will be integrated into our contextual information feature vector.

Figure 1. The estimation of complete lexical patterns

- (1)  $Association(AEc) = \frac{f(x)}{(f(y)+f(z)-f(x))}$   
 $x$  is the lexical pattern;  $x = x_1, x_2, \dots, x_n$ ;  $y = x_1, \dots, x_{n-1}$ ,  $z = x_2, \dots, x_n$ ;  $f(x)$  is the frequency of  $x$ ;  $f(y)$  is the frequency of  $y$ ;  $f(z)$  is the frequency of  $z$
- (2)  $Left\ Context\ Dependency(LCD) = \frac{f(\max_{x_l})}{f(x)}$   
 $f(\max_{x_l})$  is the maximum frequency of distinct characters to the left of  $x$
- (3)  $Right\ Context\ Dependency(RCD) = \frac{f(\max_{x_r})}{f(x)}$   
 $f(\max_{x_r})$  is the maximum frequency of distinct characters to the right of  $x$

## 3 Method

In the proposed approach, the CWS was treated as the problem of identifying word break points among joint points in a corpus, and we resolved it by using a SVM machine-learning classifier. The term “joint point” in this paper refers to a point between two adjacent Chinese characters. Our approach is to classify all joint points into either a break point class or non-break point class. The function of break points is similar to that of white spaces in sentences in English.

The SVM is a multi-vector classification algorithm (Boser, Guyon, & Vapnik, 1992). It is also a two-phase algorithm that employs a model-training phase and a model-using (predicting) phase. The major task of the model-training phase is collecting learning samples in different classes and extracting sample feature vectors for training the SVM model. In the model-using phase, the SVM will predict which class an un-

known sample belongs to. Unknown samples need to be formed using the same feature vector as the learning samples. In this paper, we set two classes, the break point class and the non-break point class, and the final predicted break-point outputs are the results of our CWS.

### 3.1 Positive and negative contextual sample generation

In this paper, we propose an efficient method of contextual learning sample generation to build a two class SVM classifier with positive learning samples for the break point class and negative learning samples for the non-break point class. Because break points are the boundaries of words, we first collect the known words in the corpus, and take their boundary points as the positive samples. In contrast, the negative samples are the joint points inside these words. This means that every matching of a word will get two positive learning samples. It will also get one negative (learning sample) for a bi-gram match, two negatives for a tri-gram match and three negatives for a four-gram match.

Take the sentence, "... 我行菩薩道時, ..." (Figure 2), from the experimental corpus as an example, there are nine joint points, p1~p9, in this case. In this sentence, "。" is the period and "，" is the comma in Chinese, and "我行菩薩道時" means 'As I practice the way of Bohdhisattva.' In this case, if 菩薩道 'the way of Bohdhisattva', is a collected known word, then p4 and p7 will be the positive samples and p5 and p6 will be the negative samples; the other joint points will be the unknown samples.

Figure 2. Sample selection example

Joint points, including positive and negative learning samples, and unknown samples, are not characters and therefore do not take up space in a corpus. For making specific samples of the joint points, we always take the same number of characters before and after the joint point to generate contextual samples. Take "p4" in Figure 2 as an example, depending on how long the context information we want to integrate, it can be sampled as a short-distance bi-gram 行菩, which takes one character on both sides of p4, a four-gram 我行菩薩, or a longer-distance n-gram contextual positive sample. In our experiments, a six-gram

contextual sample, catching three characters on both sides of a learning sample, support a better SVM CWS classifier.

The known words, or learning words, for contextual learning sample generation can be collected from dictionaries. However, for the purpose of reducing the preparation loading of CWS for a novel corpus without appropriate dictionaries, in this study, we also set the highest-frequency bi-gram, tri-gram and four-gram words in the corpus for the learning samples generation. Hence, the known words can be collected systematically in this way, and the experiment results suggest that the small size of the known words leads to a competitive result compared with the big numbers of known words, which collected from dictionaries.

The reason for using the most frequent bi-gram, tri-gram and four-gram words, but not uni-gram words is that single-character words do not have a negative case, which would cause an imbalance of positive and negative learning samples. Further, bi-gram words are found to be the majority in Chinese texts, and long words tend to be combinations of short words (梁曉虹, 2005). Further, based on our observation, the highest-frequency bi-gram, tri-gram and four-gram in a Chinese corpus are almost always words and nouns, as well.

### 3.2 Feature vector extraction

The contextual learning sample needs to be modeled as a feature vector for the machine-learning algorithm. There are 10 types of features chosen for the feature vector extraction of the contextual learning sample, including frequency, the number of distinct characters to the left and right, the number of breaking symbols (non-Chinese characters and paragraph marks) to the left and right, association, and the usage freedom to the left and right of characters in the contextual sample. Among these features, association and the usage freedom (also called left and right context dependency) refer to "The Estimation of Complete Lexical Patterns" as proposed by Chien (Chien, 1999). Table 1 shows the complete feature set used in our experiment.

For feature vector extraction, we applied the feature set to every bi-gram plus all uni-gram frequencies within the contextual learning sample. In this way, the long-context feature vector was modeled by measures of short strings, and it could keep particular context information and avoid the probability sparsity to features. Take

the four-gram learning sample, 我行菩薩, generated from p4 in Figure 2 as an example, there are a total of 34 features in its feature vector, including the four uni-gram frequencies of 我, 行, 菩, and 薩, and 30 features from three bi-gram feature sets of 我行, 行菩, and 菩薩. Hence, depending on different extended length of context, there will be 56 features for a six-gram sample and 78 features for an eight-gram sample. Table 2 shows the numbers of features in different lengths of contextual samples.

No.	Features	
1	Frequency	
2	Association (AEc) measure	
3	Number of distinct characters	to the left side
4	Maximum frequency of distinct characters	
5	Number of breaking symbols	
6	Left-context dependency (LCD) measure	
7	Number of distinct characters	to the right side
8	Maximum frequency of distinct characters	
9	Number of breaking symbols	
10	Right-context dependency (RCD) measure	

Table 1. Feature set

Contextual sample length	4	6	8
-uni-grams	4	6	8
-bi-grams	3	5	7
-frequency of each uni-gram	4	6	8
-feature set of bi-grams	30	50	70
Total number of features	34	56	78

Table 2. Number of features in a four-gram feature vector

### 3.3 SVM algorithm and Libsvm package

The Support Vector Machine (SVM) algorithm constructs a hyper-plane in a high-dimensional space for classification and other tasks (Cristianini & Shawe-Taylor, 2000). A good separation is achieved by the hyper-plane farthest from the nearest training data point of any class.

Figure 3. Support Vector Machine (SVM)

In Figure 3,  $W$  is the good separation (the classification hyper-plane) of the two classes—white spots and black spots—and  $H_1$  and  $H_2$  are the support hyper-planes.

$$\mathbf{W}^T \mathbf{X} + b = 0$$

$$H_1: \mathbf{W}^T \mathbf{X} + b = 1$$

$$H_2: \mathbf{W}^T \mathbf{X} + b = -1$$

To maximize the distance between  $H_1$  and  $H_2$  ( $2 / \|\mathbf{w}\|$ ):

$$L(w, b, \alpha) = \frac{1}{2} \|\mathbf{w}\|^2 - \sum_{i=1}^N \alpha_i [y_i (w^T x_i + b) - 1]$$

In our study, Libsvm tools (Chang & Lin, 2011) were used for executing the SVM algorithm. The SVM algorithm includes two phases: model training and model using, called break-point-predicting phases. In the model-training phase, the input data for the Libsvm package is the feature vector data set of all the learning samples, both positives and negatives, and the output data is a classification model file. Meanwhile, all joint points are considered to be unknown samples. The unknown samples should be converted to the feature vector data set in the exactly same way as the learning samples are. In the break-point-predicting phase, the input data is the feature vector data set of the unknown samples and the classification model file output from the earlier phase, and the output data contents of the joint points, which are predicted to be break points. The predicted output data are the CWS results.

## 4 Experiment

### 4.1 Corpus

The collection of Saddharma Puṇḍarīka (Lotus of the True Dharma), which is part of a Chinese text archive from the Middle Ages provided by the Chinese Buddhist Electronic Text Association (CBETA), was selected as the experimental corpus. It consists of 16 sutras labeled T0262 to T0277 of the Taisho Revised Tripitaka. This corpus contains 514,722 Chinese characters without punctuation, and there are a total of 514,721 joint points available for the experiment.

Generally speaking, CWS in ancient Chinese corpora is usually difficult than in modern Chinese collections, as the modern dictionaries are not very suitable for ancient Chinese collections, plus ancient Chinese collections lack punctuations and stop-words. Since the proposed method was designed to solve the CWS without the use of a dictionary, this collection is a good corpus to

demonstrate the powerfulness of the proposed method.

## 4.2 Performance evaluation method

In this study, we selected paragraphs, evaluation texts, from the experimental corpus, and compared the results of the evaluation texts from a subject matter expert's answers and the SVM CWS predicted answers as a means of evaluating the system's performance.

Sātānfēntuólǐjīng, a sutra (T0265) from the collection of Saddharma Puṇḍarīka was chosen as the evaluation text. In Sātānfēntuólǐjīng, there are 1,588 joint points; the ratio size of the evaluation text is 0.3% of the entire corpus. The evaluation text was not included in the training data, and experts provided 616 break points, true answers, and 972 non-break points, false answers for it. Precision, recall, and f-measure were used for evaluating the effectiveness of the CWS results. The evaluation definitions were as follows:

$$\text{Precision} = \frac{\text{True Positive}}{\text{True Positive} + \text{False Positive}}$$

$$\text{Recall} = \frac{\text{True Positive}}{\text{True Positive} + \text{False Negative}}$$

$$\text{F-measure} = \frac{2 \cdot \text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}}$$

## 4.3 Experiments

In order to reveal the effectiveness of the training data size, we prepared three training sets; each had different numbers of training data. The first set consisted of learning samples collected from the highest-frequency bi-gram, tri-gram and four-gram, for a total of three Chinese words in the corpus. The second set consisted of learning samples from the top-10 high-frequency words of each bi-gram, tri-gram, and four-gram in the corpus, and the third set consisted of learning samples from 7,309 words, which were collected from the book index of the corpus (大藏經學術用語研究會, 198-?). Table 3 shows the number of learning samples for each training size.

At the end of the experiment, we compared the overall performance with that of CKIP, which is a Chinese word segmentation system supported by 4,892,324 Chinese-word database (Sinica, 2013).

In Table 3, the three highest-frequency words in the first training set are 菩薩 'bodhisattva' (the bi-gram), which had a frequency of 3133; 摩訶薩 'mahasattva' (the tri-gram), which had a frequency of 382; and 文殊師利 'manjushri', a name of the bodhisattvas (the four-gram), which

had a frequency of 514. This is a total of 4,029 matched strings, which contributed 7,658 positive and 5,439 negative samples. Since the matched strings are adjacent in some places, the total number of positives is not exactly twice the summation of the three frequencies. However this does not apply to the negatives samples because there is no commonality of location.

	Highest-frequency words	Top-10 high-frequency words	Dictionary-based group
bi-gram	1	10	2678
tri-gram	1	10	2227
four-gram	1	10	2404
Total words	3	30	7,309
Total positives	7658	35,199	150,441
Total negatives	5439	23,677	105,035

Table 3. Learning sample comparison of three training sets

Besides setting a different size of the training data, we set different context distances, character extensions in context, of samples. The more the context characters are extended, the more is the contextual information involved in the feature vector model. Hence, a two-character extension in context means catching 2 characters on both sides of the joint points to make a 4-gram context learning sample. Table 4 shows the CWS results for the highest-frequency training set, Table 5 shows the results of the top-10 high-frequency training set, and Table 6 shows the results of the dictionary-based training set. Every group was segmented in three different context distances.

Sample length	Four-gram	Six-gram	Eight-gram
Context extension	2 characters	3 characters	4 characters
Precision	51.1%	51.2%	49.5%
Recall	94.5%	94.2%	96.3%
F-measure	66.3%	66.3%	65.3%

Table 4. CWS results of the highest frequency words

In the tables, the dictionary-based results (Table 6) exhibit stable performances; the results growing with context distances. Although the performance of the set of the highest-frequency words is not as good as that of the dictionary-based ones, it is still competitive, and most importantly, it used no assistant sources outside of the corpus.

We believe that this shows the potential of the non-dictionary CWS method proposed in this paper.

Sample length	Four-gram	Six-gram	Eight-gram
Context extension	2 characters	3 characters	4 characters
Precision	56.6%	56.7%	57.0%
Recall	83.4%	82.1%	81.7%
F-measure	67.4%	67.1%	67.2%

Table 5. CWS results of the top 10 high frequency words

Sample length	Four-gram	Six-gram	Eight-gram
Context extension	2 characters	3 characters	4 characters
Precision	57.9%	58.6%	59.1%
Recall	79.5%	80.4%	81.2%
F-measure	67.0%	67.8%	68.4%

Table 6. CWS results of the known words from the index book

#### 4.4 Feature selection analysis

This section analyzes the importance of features used in the SVM classifier. A total of 56 features, in the highest frequency word dataset with 6-gram learning samples, were calculated and sorted by the f-score algorithm proposed by Chen and Lin’s SVM feature-selected research (Y.-W. Chen & Lin, 2006).

Table 7, the top 10 features of the training dataset, shows that the contextual dependency measures around joint points have a significant influence on the SVM classifier.

#### 4.5 Iterative CWS strategy

Because the learning samples can be collected systematically and generated from very few words in the proposed CWS method, we provide an iterative training process to improve the CWS results. In the iterative CWS strategy, we select training samples for the next SVM CWS iterative round from the previous SVM CWS results.

Libsvm provides a probability measure for every joint point in the predicting phase, and in the Libsvm default setting, joint points will be classified in to the break point class when their predicting probability is greater than 50%, which is also the SVM classifier predicting threshold in our experiments.

Based on the probability measure, in the iterative experiment, points whose probability was greater than 90% were taken as positives and

points whose probability was less than 10% were taken as the negatives for the next round. In this way, the size of positives and negatives is imbalanced, so we set a stricter threshold on the side having bigger numbers to make both sides have the same number of learning samples.

Table 8 shows a three-round iterative CWS result using the highest-frequency words training set with the context extension of three characters, the Six-gram learning samples, which led to better performance in the earlier experiment. Based on the performance evaluation over all rounds, the precision in the second round increased by approximately 10%, but other CWS results did not improve as expected.

No.	Features of six-character context sample “ABCDEF”	f-score
1	RCD of “CD”	0.4420
2	LCD of “CD”	0.3304
3	LCD of “DE”	0.3281
4	RCD of “BC”	0.3144
5	Number of distinct characters to the left of “CD”	0.2284
6	Number of distinct characters to the right of “CD”	0.2199
7	AEC of “CD”	0.2108
8	Number of distinct characters to the left of “DE”	0.1598
9	LCD of “BC”	0.1513
10	Number of breaking symbols to the left of “CD”	0.1480

Table 7. Top 10 features of training dataset

	Iteration 1	Iteration 2	Iteration 3
Positives	7658	39520	163849
Negatives	5439	39520	163849
Total learning samples	13097	79040	327698
Precision	51.2%	62.3%	61.6%
Recall	94.2%	66.2%	65.3%
F-measure	66.3%	64.2%	63.4%

Table 8. CWS results of the iterative experiment

#### 4.6 Comparison

Table 9 compares four different CWS results: the highest-frequency words, top-10 high-frequency words, the dictionary group, and the results from CKIP. The best results of each method are shown in this table. CKIP is the segmentation tool by Sinica, which enhances the segmentation using a large-scale term database having approximately 5-million, cross-field Chinese words (Group; Ma & Chen, 2003b). The comparison table shows

that the control group has higher recall, the dictionary-based group has higher precision and the CKIP exhibits a more balanced result.

	Highest frequency words	Top10 high-frequency words	Dictionary	CKIP
Precision	51.2%	57.0%	59.1%	57.4%
Recall	94.2%	81.7%	81.2%	88.3%
F-measure	66.3%	67.2%	68.4%	69.6%

Table 9. Performance comparison

## 5 Conclusion and Discussion

In this paper, we proposed a novel corpus machine-learning CWS approach that identified break points from joint points. The proposed approach is different from existing researches, which tended to create a generating model or formula of Chinese words. In this study, we provided a long-distance context model of joint points and defined the model by non-linguistic contextual features. The experimental results suggested that break points among Chinese texts could be identified on the basis of their non-linguistic contextual features in our chosen corpus.

According to the experimental results, the proposed approach can achieve precision 51.2% and recall 94.2% with only 3 learning words systematically selected from the experiment corpus. It is a very competitive result comparing with the CKIP system, which achieves precision 57.4% and recall 88.3%, and it is supported by an approximately 5-million Chinese-word database. Therefore, this study met the need of carrying out CWS in a novel corpus without appropriate dictionaries.

Further, the proposed approach can systematically select balanced positive and negative learning samples starting from a very small number of learning words. Hence, we chunked long-distance context samples into short-distance strings, uni-grams and bi-grams, for feature vector extraction. Thus, we could collect long-distance context information without dealing with the probability sparsity problem.

Since the CWS rules can be trained from context without linguistic information, the proposed CWS method might also work for Chinese texts from different ages. However, there are some issues and problems that require further investigation.

First, the selection of learning words can affect the final performances. Different learning

words may cause the different results, and this affection needs to be further studied. For instance, if we took learning words by their parts-of-speech instead of frequency, the proposed approach might change its behavior.

Further, the detection of combination words and the overlapping problem needs to be addressed. The Libsvm classifier can assign a predicting probability measure to every joint point. Instead of setting a threshold to filter out break points via these probabilities, these probability measures can be used for identifying the combination words and detecting overlapping problems, as well.

Finally, the effect of iterative process needs to be further studied. Currently, the iterative results can lead to better precision in the second round. However, it performs worse in recall and f-measure. Besides, other iteration parameters need to be decided, such as the number of iteration, the optimal predicting threshold, and the saturation condition for stopping the iterative process properly.

## Abstract

Feature augmentation is a well-known method for domain adaptation and has been shown to be effective when tested on several NLP tasks (Daume III, 2007). However, a limitation of the method is that it requires labeled data from the target domain and very often such data is unavailable. In this paper, we propose to use training data selection to divide the source domain training data into two parts, pseudo target data (the selected part) and source data (the unselected part), and then apply feature augmentation on the two parts of the training data. This approach has two advantages: first, feature augmentation can be applied even when there is no labeled data from the target domain; second, the approach can take advantage of all the training data including the part that is not selected by training data selection. We evaluate the approach on Chinese word segmentation and part-of-speech tagging and show that it outperforms the baseline where no feature augmentation is applied.

## 1 Introduction

The goal of domain adaptation is to alleviate the degradation of NLP systems when training and test data are from different domains. There have been many approaches to domain adaptation, and two of well-known ones are feature augmentation and training data selection. Feature augmentation makes three copies of each feature in the original feature set (one for the source domain, one for the target domain, and one for the general domain) so that features appeared in the source and the target domains can be differentiated in case they behave differently in the two domains; the method has been shown to be effective for several NLP

tasks (Daume III, 2007). However, a limitation of the method is that it requires labeled data in the target domain, a condition that is hard to meet when creating labeled data in the target domain is expensive and time-consuming.

Training data selection addresses the differences between the source and target domains by choosing a subset of the training data in the source domain that is similar to the data in the target domain. When the amount of source training data is large, this method often provides better performance than using the entire training data (Moore and Lewis, 2010; Axelrod et al., 2011; Plank and van Noord, 2011; Song et al., 2012). However, when the amount of the training data is small, the selected subset is unlikely to outperform the entire training data because the trained model cannot benefit from unselected labeled data.

To address the limitations of both methods, we propose to divide the whole source training data into two subsets via training data selection. We then treat the selected subset as coming from a *pseudo target domain* (i.e., a pseudo domain that is similar to the target domain) and keep the unselected data in the source domain. Now we have labeled data from both domains, we can apply feature augmentation in the usual way; that is, we distinguish features from the source domain and the ones from the pseudo target domain. Notice that the ‘unselected subset’ is also used by the trainer, unlike the standard training data selection method where the unselected part is totally discarded by the trainer. In addition, we propose a coverage-based measure for training data selection. We evaluate our approach on two NLP tasks, Chinese word segmentation (CWS) and part-of-speech (POS) tagging, and show that it outperforms the systems which use the entire training data without training data selection or feature augmentation.

The remainder of this paper is organized as fol-

lows. Section 2 presents previous work on training data selection and feature augmentation. Section 3 describes our approach in details and introduces a coverage-based measure for training data selection. Section 4 reports experimental results on two NLP tasks with discussion on the results.

## 2 Related Work

Two main aspects of our work are dividing training data and applying feature augmentation. In this section, we discuss related work in these aspects.

### 2.1 Training Data Selection

Training data selection is a common approach to domain adaptation. Moore and Lewis (2010) proposed to rank training sentences according to the difference of the cross entropy values of a given sentence, and showed that training data selection improved the performance of statistical machine translation systems. Axelrod et al. (2011) used cross entropy in three ways: the first one directly measured cross entropy for the source side of the text; the second one was similar to (Moore and Lewis, 2010) and ranked the data using cross entropy difference; the third one took into account the bilingual data on both the source and the target side of translations. Both studies showed that the selected subset of training data worked better than the entire training corpus for machine translation. In addition to these studies, there has been other work (e.g., (Eck et al., 2005; Munteanu and Marcu, 2005; Hildebrand et al., 2005; Lu et al., 2007)) that shows training data selection is an effective way to improve MT.

Plank and van Noord (2011) experimented with several training data selection methods to improve the performance of dependency parsing and POS tagging. These methods fell into two categories: probabilistically-motivated and geometrically-motivated. Their experiments demonstrated that the proposed training data selection methods outperformed random selection.

In our previous study (Song et al., 2012), we proposed several entropy-based measures for training data selection, including averaged entropy gain (AEG), cross entropy, difference of entropy, and description length gain (DLG)-based measures. Among them, AEG worked well on CWS and POS tagging and outperformed other measures including difference of cross entropy. In this study, we are using the same data sets as in

that study and we will compare our new coverage-based measure with AEG.

### 2.2 Feature Augmentation

Feature augmentation (Daume III, 2007) is a well-known domain adaptation method in the supervised setting, when labeled data exist for both source and target domains. The idea is to distinguish instances from the source and target domains by making three copies of each original feature: one copy for the source domain, one copy for the target domain and a third copy for the general domain that contains both the source and target domains. Daume evaluated the method on several sequence labeling tasks (e.g., named entity recognition, POS tagging and shallow parsing) and showed that this method outperformed several baselines and previous approaches. The method is easy to implement and does not require modifications to the trainer.

## 3 Our Approach

In order to perform feature augmentation on the whole training data, the very first step is to split the training data into two subsets. Training data selection is an effective way to choose a subset from the whole source domain data that is similar to the target domain. The question is what measures should be used for calculating similarity between a source sentence and the target domain. In this section, we discuss some existing entropy-based measures and propose a novel coverage-based measure. Then we explain how we apply feature augmentation to the two subsets.

### 3.1 Entropy-based Measures

Among the existing similarity measures used by training data selection, many of them focus on the similarity of probability distributions from the training and test data and use entropy-based formulas (Moore and Lewis, 2010; Axelrod et al., 2011; Song et al., 2012). Cross entropy is the most prevailing metric to evaluate the probability distribution similarity between a training sentence and the test data. Eq. 1 shows the formula for cross entropy for a language (marked as CEL, as in the context of evaluating a language model), where  $n$  is the length of sentence  $s$ ,  $p$  is an ngram language model, and  $x_i$  represents the  $i$ -th word in the sen-

tence given the previous words.

$$CEL(s, p) = -\frac{1}{n} \sum_{i=1}^n \log p(x_i) \quad (1)$$

The difference of cross entropy (DCE) for a sentence  $s$  is formulated as

$$DCE(s, p, q) = |CEL(s, p) - CEL(s, q)| \quad (2)$$

where  $p$  and  $q$  are two language models, built from the source domain and the target domain respectively. For training data selection, sentences are sorted by DCE scores and the ones with low scores are considered to be similar to the target domain (Moore and Lewis, 2010; Axelrod et al., 2011).

Another well-performed measure is AEG (Song et al., 2012). Let  $C$  be a corpus and  $s$  be a sentence from the source domain; we define entropy gain (EG) of  $s$  according to  $C$  as in Eq 3, where  $q$  is a probability distribution estimated from  $C$  and  $q_1$  is one estimated from  $C + s$ , a new corpus formed by adding  $s$  to  $C$ . Intuitively, if  $s$  is similar to  $C$ ,  $q_1$  will be very similar to  $q$  and  $EG(s, c)$  will be small.

$$EG(s, C) = |H(C + s, q_1) - H(C, q)| \quad (3)$$

$H(X, p)$  follows the standard definition of entropy in information theory, where  $X$  is a discrete random variable with  $m$  possible outcomes  $\{x_1, \dots, x_m\}$  and  $p$  is a probability distribution of  $X$ . Given a corpus  $C$ , one can collect a set of ngrams (in words or characters) from  $C$  and  $X$  is then derived from the set.

$$H(X, p) = -\sum_{i=1}^m p(x_i) \log p(x_i) \quad (4)$$

Average entropy gain (AEG) is EG normalized by sentence length, shown in Eq 5.

$$AEG(s, C) = \frac{EG(s, C)}{\text{length}(s)} \quad (5)$$

### 3.2 Coverage-based Data Selection

We propose a coverage-based measure, which differs from the entropy-based measures in two aspects. First, this measure uses ngram coverage, not probability similarity, as the criterion for selecting training data. The rationale is that we would like the selected data to have a good coverage of the test data, because in many NLP tasks, especially in CWS and POS tagging, out-of-vocabulary (OOV)

is a main problem affecting system performance and the problem is more severe when the training and test data come from different domains. Second, existing training data selection methods (such as the ones listed in Section 3.1) select the current sentence without considering the effect of adding that to the previously selected sentences. Our method tackles this problem by considering the overall effect of the selected subset. As checking all the subsets is computationally expensive, we use a greedy search to find the best training sentence based on the current selected subset.

The coverage-based data selection is presented in Algorithm 1. Here,  $L$ ,  $T$ , and  $p$  refer to the original training data, test data and the proportion (in percentage) of training data to be selected.  $L_s$  and  $L_u$  are the output, which refer to the selected and unselected subsets of the training data respectively. By conducting such selection method, training data is divided into two parts.

---

**Algorithm 1** Coverage-based data selection.

---

**Input:**  $L, T, p$

**Output:**  $L_s, L_u$

```

1:  $L_s = \phi, L_u = L$ 
2: while  $Sizeof(L_s) < Sizeof(L) * p$  do
3:   for each sentence  $s_i$  in  $L_u$  do
4:     compute  $cov(L_s \cup \{s_i\}, T)$ 
5:   end for
6:    $id = argmax_i cov(L_s \cup \{s_i\}, T)$ 
7:    $L_s = L_s \cup \{s_{id}\}, L_u = L_u - \{s_{id}\}$ 
8: end while
9: return  $L_s, L_u$ 

```

---

In Algorithm 1, coverage function  $cov(C, T)$  represents the coverage of ngrams in a test data  $T$  given a corpus  $C$ , as shown in Eq. 6. Here,  $ng$  is an ngram<sup>1</sup> and  $NgramSet(T)$  refers to the set of ngram types in  $T$ , and the denominator  $|NgramSet(T)|$  is the size of the set.<sup>2</sup>

$$cov(C, T) = \frac{\sum_{ng \in NgramSet(T)} count(ng, C)}{|NgramSet(T)|} \quad (6)$$

To handle the problem of data sparsity, we use the following back-off counting method to find

<sup>1</sup>Where the units for composing an ngram are different with respect to different tasks, i.e., they are characters in word segmentation and words in POS tagging.

<sup>2</sup>We also investigated using ngram tokens for coverage computation; we will include the comparison of ngram types and ngram tokens in the final version of this paper.

partial covered low order ngrams inside the high order ngram. The idea of such ngram counting is similar to back-off methods in language modeling. Given an ngram  $t_{i-n+1} \dots t_{i-1} t_i$  in  $T$ , we calculate the  $count()$  function as in Eq. 7.  $\alpha$  is used to determine the value of the ‘‘partial credit’’ given to a substring of the ngram appearing in  $C$ . The value of  $\alpha$  is set to 0.5 empirically.<sup>3</sup>

$$count(t_{i-n+1} \dots t_{i-1} t_i, C) = \begin{cases} 1, & \text{if } t_{i-n+1} \dots t_{i-1} t_i \text{ appears in } C \\ \alpha \cdot count(t_{i-n+2} \dots t_{i-1} t_i), & \text{otherwise} \end{cases} \quad (7)$$

In Eq. 7,  $t_i$  is a token in the ngram, i.e., a character in the CWS task and a word in the POS tagging task. If a high order ngram is not found in  $C$ , the  $count()$  function is called recursively until a shorter ngram inside the original ngram is found. The value of the  $count()$  function is zero only if the token  $t_i$  itself is an OOV. For the experiments in this paper, we use trigram to count the ngram coverage.

### 3.3 Feature Augmentation

As we mentioned before, a limitation of feature augmentation (Daume III, 2007) is that it requires labeled data from the target domain, and very often such data is not available. To overcome this limitation, we use training data section on the source domain data, treat the selected part of data as from a *pseudo target domain*, and leave the unselected part in the source domain. Then a feature augmentation is performed on such two ‘‘new’’ domains; that is, it makes three copies of each original feature:  $f_s$  for the source domain,  $f_t$  for the target domain, and  $f_g$  for the general domain. Following Daume (Daume III, 2007), the general domain is simply the union of the source and the target domains. In this case, the target domain refers to our pseudo target domain; the features associated to the pseudo target domain and the test data are augmented as in Eq. 8, and the features associated to the unselected source domain data are shown in Eq. 9.

$$f \rightarrow \langle f_g, 0, f_t \rangle \quad (8)$$

<sup>3</sup>We tried different value of  $\alpha$  in ranging from 0 to 1, where  $\alpha = 0$  means there is no back-off. The results indicate that when  $\alpha = 0$ , selection performance is much worse than the case  $\alpha > 0$ , while when  $\alpha > 0$ , selection performance varies so little by using different values of  $\alpha$ .

$$f \rightarrow \langle f_g, f_s, 0 \rangle \quad (9)$$

Another potential issue with feature augmentation is that making several copies of all the features could worsen the problem of data sparsity. It is worth exploring whether duplicating only certain features would produce better performance than duplicating all the features. To test out the idea, we ran another set of experiments where only unlexicalized features (e.g., word type, POS tags of previous words) are duplicated. The experimental results in Section 4 confirmed our intuition and showed that augmenting only unlexicalized features works better.

## 4 Experiments

In this study, we ran several sets of experiments. We compared our training data selection with other methods, and then evaluated our revised feature augmentation method on the CWS and POS tagging tasks.

### 4.1 Data

The Chinese Penn Treebank (CTB) version 7.0<sup>4</sup> (Xia et al., 2000) is used in our experiments. It contains about 1.2 million words from five genres: Broadcast Conversation (BC), Broadcast News (BN), Magazine (MZ), Newswire (NW), and Weblog (WB). The details of the five genres of CTB 7.0 are shown in Table 1.

We divide the data in each genre into ten folds based on character counts, and use the first eight folds for training, the next fold for development, and the last fold for testing. In order to make the size of the training data for each genre to be the same, we set the training size to be the size of the training folds in the BC genre (the smallest genre in the CTB 7.0). We do the same for the development data. For testing, we use the whole test fold for each genre. The sizes of the data sets used in the experiments are shown in Table 2.<sup>5</sup>

Without loss of generality, we use BC and NW as the test genres; for each test genre, we use the union of training folds from other four genres as the training data.

<sup>4</sup>Linguistic Data Consortium No. LDC2010T07

<sup>5</sup>Although we are not using the development fold for the experiments in this study, we still split the data into training, development, and test folds to facilitate comparison with other studies that use the same data split.

Genre	# of chars	# of words	# of files	Sources
Broadcast Conversation (BC)	275,289	184,161	86	China Central TV, CNN, MSNBC, Phoenix TV, etc.
Broadcast News (BN)	482,667	287,442	1,146	China Broadcasting System, China Central TV, China National Radio, Voice of America, etc.
Magazine (MZ)	402,979	256,305	137	Sinaroma
Newswire (NW)	442,993	260,164	790	Xinhua News, Guangming Daily, People’s Daily, etc.
Weblog (WB)	342,116	208,257	214	Newsgroups, Weblogs

## 4.2 Training Data Selection

To demonstrate our coverage-based training data selection method, we first compare its performance on POS tagging with other two methods, AEG (Song et al., 2012) and random selection.<sup>6</sup> The selected proportion of training data range from 10% to 90%, based on character counts. Here, we use Stanford POS Tagger (Toutanova et al., 2003). The results on BC and NW are shown in Table 3 and 4, with comparison to random selection methods.<sup>7</sup>

Our coverage-based training data selection method outperforms random selection on both BC and NW. It also outperforms AEG when a low percentage of data is selected, while its performance is comparable or slightly lower than AEG when a higher percentage of data is selected. To understand this behavior, we compare some statistics of the data sets, as in Table 5.

Since OOV rate is important for CWS and POS tagging, we want to compare our coverage-based method and AEG for this factor, and the results are presented in Table 6.

The table shows that when a small percentage

<sup>6</sup>Song et al. (2012) showed that AEG works better than cross entropy, as well as difference of cross entropy, on CWS and POS tagging. Therefore we only compare our method with AEG in this paper.

<sup>7</sup>For each percentage, the result of random selection are the average of three runs of random selection.

(e.g., 10%, 20%) of source-domain data is selected, the OOV rate of the test data is much lower when Cov is used. In contrast, when a large percentage (e.g., 80% and 90%) of training data is selected, the OOV rates are similar between Cov and AEG. This could be the reason why Cov outperforms AEG when a small percentage of training data is selected, but not so when more training data is selected.

For the rest of the experiments, we will use Cov for training data selection and test whether our revised feature augmentation approach provides some improvement for CWS and POS tagging.

## 4.3 Chinese Word Segmentation

To evaluate feature augmentation on CWS, we use a conditional random fields (CRF) word segmenter as described in (Song and Xia, 2012). A nice property of the segmenter is that it incorporates unsupervised learning to identify possible new words in the test data in order to enhance the segmenter’s performance on OOVs. To be more specific, the segmenter uses description length gain (DLG) (Kit and Wilks, 1999) for lexical acquisition as that was performed in (Kit, 2000; Kit, 2005). Then the decision of the unsupervised word segmentation is represented as features  $T_0^i$ , which indicates the tag of the current character  $C_0$  when it belongs to a word whose length  $i$  ranges from 1 to 5 charac-

ters. These features are added to the standard feature set for supervised learning. The new feature set is in Table 7, where the subscript -1, 0, and +1 refer to the previous, current and next character, respectively.

Description	Features
Char Unigrams	$C_{-1}, C_0, C_{+1}$
Char Bigrams	$C_{-1}C_0, C_0C_{+1}, C_{-1}C_{+1}$
DLG Features	$T_0^1, T_0^2, T_0^3, T_0^4, T_0^5$

Table 7: Feature template of our CRF segmenter.

For feature augmentation, we compare two settings: one duplicates all the features and the other duplicates only the unlexicalized features. The results when tested on BC are in Table 8. It shows that augmenting unlexicalized features provides better performance than augmenting all features. For the rest of experiments, feature augmentation will duplicate only the unlexicalized features.

Table 9 shows the performance of using feature augmentation on CWS when tested on NW. Table 8 and 9 both show that our approach on divided training data improves system performance significantly (e.g., over 0.6% when tested on BC) without using any external resources. For Tables 9 and 11, we use a ten-partition two-tailed paired Student t-test for significance test.

#### 4.4 POS Tagging

To evaluate feature augmentation on POS tagging, we used an in-house CRF tagger.<sup>8</sup> Table 10 shows the feature set used by the tagger, where subscript -1, 0, and +1 refer to the previous, current and

<sup>8</sup>The reason that we use our in-house CRF POS tagger, instead of the Stanford POS tagger, is that we have not found an easy way to extend Stanford POS tagger to support feature augmentation.

90%	<b>93.84</b>	94.03	93.64

Table 9: Performance of feature augmentation on CWS, with unlexicalized features augmented. The pseudo target data is selected by coverage-based method. The segmenter is tested on *NW*, and trained on the other four genres in CTB 7.0. F-score (F), Precision (P) and Recall (R) are presented. F-scores higher than the baseline are in bold. Symbols \* and \*\* indicate significance at  $p=0.05$  and  $p=0.01$  against the baseline, respectively.

next word, respectively. This feature set is similar to the one used in the Stanford POS tagger, but our tagger does not include some hard coded treatment and rules (e.g., bidirectional transition rules) used by the Stanford tagger. As a result, the performance of our tagger is slightly lower than the Stanford tagger. For instance, when tested on *BC* and trained on the other four genres, the tagging accuracy of our tagger is 91.95%, compared to 92.30% by the Stanford tagger (see the last row

Description	Features

in Table 11 and Table 3).

Table 11 shows the results of POS tagging with feature augmentation. The test genre is *BC* or *NW*, and the training data come from the other four genres. The first row lists the percentage of training data chosen by our coverage-based training data selection. The baseline shows the performance of our CRF tagger when the whole training set is used without training data selection and feature augmentation. In the table, the higher-than-baseline tagging accuracy in each test are marked in bold-face. Similar to CWS, training data selection followed by feature augmentation improves the performance of the POS tagger.

#### 4.5 Discussion

In all, there are several observations from Tables 8 and 9 for CWS, and Table 11 for POS tagging. First, there is a small, but statistically significant, improvement when we treat selected and unselected data as two domains and apply fea-

Percentage	BC	NW

60%	<b>92.43**</b>	<b>92.42</b>
70%	<b>92.45**</b>	<b>92.38</b>
80%	<b>92.40**</b>	92.33
90%	<b>92.31*</b>	92.31
baseline	91.95	92.36

Table 11: Performance of our POS tagger with feature augmentation when tested on BC and NW. Numbers presented in the table are tagging accuracy, and the ones higher than the baseline are in bold. Symbols \* and \*\* indicate significance at  $p=0.05$  and  $p=0.01$  against the baseline, respectively.

ture augmentation (e.g., 91.95% vs. 92.45% on BC in Table 11). Second, duplicating only a subset of features outperforms duplicating all the features, as the large number of features for the latter strategy could aggravate the data sparsity problem. Augmenting some features (e.g., lexicalized) could actually hurt the performance. Third, with regard to the percentage of training data selected for the pseudo target domain, system performance improves when the percentage of selected data increases from 10% up to a certain point (70% for testing on BC and 30% for testing on NW on POS tagging), and afterwards it starts to degrade because newly added pseudo target domain data is no longer quite similar to the target domain. The optimal size of the selected subset may depend on how similar the training data is to the test data. Fourth, when comparing CWS and POS tagging, we can find the same trend in feature augmentation across different tasks. That is, when feature augmentation on CWS has higher improvement, usually it also brings higher improvement on POS tagging when comparing across different test data (e.g., the improvement on BC is higher than NW for CWS, and the same is true for POS tagging).

## 5 Conclusion

This study has made two contributions to domain adaptation. First, we proposed an approach that combines training data selection and feature augmentation. It tackles the limitations of both feature

augmentation and training data selection methods as it does not require labeled data from the target domain while it takes advantage of the entire training data. Consequently, it significantly improves system performance over the baseline. We also demonstrate that augmenting some features works better than augmenting all the features because the latter setting triples the number of features which could lead to severe data sparsity problem. Our experimental attempts confirmed the fact that augmenting less-sparse features (unlexicalized one, e.g., prefix and suffix, character type) led to better performance than all features. Second, we proposed a new measure for training data selection, which selects training sentences to maximize the coverage of ngrams on the test data. It showed a better performance than other measures especially when a small subset of training data is selected. The approaches has been evaluated on two NLP tasks, namely, Chinese word segmentation and part-of-speech tagging. Both tasks confirmed the effectiveness of our approaches and yield better performance than the baseline settings.

For future work, we would like to apply automatic feature selection to determine what kind of features should be duplicated to boost the benefits of feature augmentation. We would also like to evaluate our approach on other NLP tasks, and test its performance with other machine learning algorithms.

## Abstract

This paper presents a methodology to identify polysemous German prepositions by exploring their vector spatial properties. We apply two cluster evaluation metrics (the *Silhouette Value* (Kaufman and Rousseeuw, 1990) and a fuzzy version of the *V-Measure* (Rosenberg and Hirschberg, 2007)) as well as various correlations, to exploit hard vs. soft cluster analyses based on Self-Organising Maps. Our main hypothesis is that polysemous prepositions are outliers, and thus represent either (i) singletons or (ii) marginals of the clusters within a cluster analysis. Our analyses demonstrate that (a) in a subset of the clusterings, singletons have a tendency to contain polysemous prepositions; and (b) misclassification and cluster membership rate exhibit a moderate correlation with ambiguity rate.

## 1 Introduction

Vector space models have become a steadily increasing, integral part of data-intensive lexical semantics over the past 20 years (cf. Turney and Pantel (2010) and Erk (2012) for two recent surveys). They have been exploited in psycholinguistic (Lund and Burgess, 1996) and computational linguistic research (Schütze, 1998), to explore distributional properties of target objects and the notion of “similarity” within a geometric setting.

While individual vector space approaches have been concerned with sense discrimination, it is still largely unknown how to identify polysemous objects within a vector space model, and which geometric properties characterise the polysemous objects. For example, Schütze (1998) performed sense discrimination of ambiguous word tokens, based on their second-order co-occurrence

distributions; Erk (2009) presented two variants of defining regions of word meaning in vector spaces; Erk and Padó (2010) defined a model where polysemous words activated several word vectors; Boleda et al. (2012b) compared two models of representing regular polysemy, one with multiple class assignments for multiple senses, and one incorporating classes with polysemy properties. Our work is different from all these approaches, since we aim to investigate prototypical spatial properties of polysemous objects.

More specifically, this paper is part of a larger framework that systematically explores the vector spatial properties of German prepositions, a notoriously polysemous closed word class. Relying on Self-Organising Maps (SOMs, cf. Kohonen (2001)) and preposition-dependent nouns as vector-space features, we present a methodology to identify the degree of polysemy of the prepositions. For this task, the methodology applies two cluster evaluation metrics, the *Silhouette Value* (Kaufman and Rousseeuw, 1990) and the *V-Measure* (Rosenberg and Hirschberg, 2007), to hard vs. soft cluster analyses based on the Self-Organising Maps. Since we start out with a hard clustering, a sub-task is concerned with transferring the SOM hard clusters to soft clusters. Similarly, the original V-Measure applies to hard clusters only, so a second sub-task is concerned with defining a Fuzzy V-Measure that applies to soft clusters. Our main hypothesis is that polysemous prepositions are outliers, and thus represent either (i) singletons or (ii) marginals of the clusters within a cluster analysis.

The paper is organised as follows. After introducing our preposition data in Section 2, Section 3 describes the preposition vector-space features, and the hard and soft clusterings. Section 4 is devoted to the evaluations, and Section 5 relies on the cluster analyses and the evaluations, to detect and discriminate polysemous prepositions.

## 2 Preposition Data

Although prepositions contribute a considerable portion to the meaning of texts, comparably little effort in computational semantics has gone beyond a specific choice of prepositions (such as spatial prepositions), towards a systematic classification of preposition senses. In recent years, computational research on prepositions has been enforced, mainly driven by the ACL Special Interest Group on Semantics (ACL-SIGSEM). The SIG has organised a series of workshops on prepositions, and a special issue in the *Computational Linguistics* journal (Baldwin et al., 2009).

Related work across languages includes *The Preposition Project* for English prepositions (Litkowski and Hargraves, 2005), *PrepNet* for French prepositions (Saint-Dizier, 2006), and a German project on the role of preposition senses in determiner omission in prepositional phrases (Kiss et al., 2010). The latter is most closely related to the present work, as it is also aimed at German. Their focus however is on manual classifications and corpus annotation, in contrast to our automatic classification approach.

As in many other languages, German prepositions are notoriously ambiguous, e.g. note the quite distinct senses of the German preposition *nach* in *nach drei Stunden/Berlin/Meinung* ‘after three hours/to Berlin/according to’, referring to a temporal, directional, and accordance meaning. Our gold standard in terms of preposition senses is the German grammar book by Helbig and Buscha (1998). Starting with their class hierarchy, we selected the classes of prepositions that contained more than one preposition. We deleted those prepositions from the classes that appeared less often than 10,000 times in our web corpus containing 880 million words (cf. Section 3.1). This selection process resulted in 12 semantic classes covering between 2 and 27 prepositions each (cf. Table 1). The included prepositions exhibit ambiguity rates of 1 (monosemous) up to 6 (cf. Table 2). Out of the 47 prepositions, 24 are polysemous (51%).

## 3 Cluster Analyses

The pipeline in our framework is as follows.

1. The prepositions are associated with a distributional feature set.
2. The vector space of prepositions is hard-clustered using Self-Organising Maps.

	Class	Size
lokal	‘local’	27
modal	‘modal’	24
temporal	‘temporal’	21
kausal	‘causal’	5
distributiv	‘distributive’	6
final	‘final’	4
urheber	‘creator’	3
konditional	‘conditional’	3
ersatz	‘replacement’	2
restriktiv	‘restrictive’	2
partitiv	‘partitive’	2
kopulativ	‘copulative’	2

Table 1: Preposition classes.

#Senses	#Prepositions
6	1
5	3
4	3
3	11
2	6
1	23

Table 2: Degrees of preposition ambiguity.

3. The hard clustering is transferred to a soft clustering.
4. The cluster analyses are evaluated.

The following subsections describe these steps in more detail. While the larger framework plans to perform this pipeline for various cluster algorithms and many feature sets, the current setup of experiments focuses rather on the methodology towards polysemy detection, and is thus restricted to one algorithm (SOMs) and one feature set (nouns).

### 3.1 Preposition Corpus Features

The distributional features for the German prepositions were induced from the *sdeWaC* corpus (Faaß and Eckart, 2013), a cleaned version of the German web corpus *deWaC* created by the *WaCky* group. The corpus cleaning had focused mainly on removing duplicates from the *deWaC*, and on disregarding sentences that were syntactically ill-formed (relying on a parsability index provided by a standard dependency parser (Schiehlen, 2003)). The *sdeWaC* contains approx. 880 million words.

In this paper, we focus on one specific feature set that is expected to provide salient properties towards preposition meaning, i.e., the nouns that are subcategorised by the prepositions. This dependency information was extracted from a parsed version of the *sdeWaC* using Bohnet’s MATE dependency parser (Bohnet, 2010). So each preposition was associated with a feature vector over its

subcategorised nouns. The overall set of noun features was restricted to the 10,000 nouns from the corpus which co-occurred with the largest number of prepositions.

### 3.2 Hard Clustering

For hard-clustering the German prepositions, we relied on the Self-Organising Maps (SOMs) artificial neural networks provided by the `kohonen` library of the *R Project for Statistical Computing*<sup>1</sup>. We expected SOMs to be especially useful for this task, as they create typology-preserving maps, and should thus provide a suitable model to look into the spatial properties of polysemous vectors. Furthermore, SOMs have successfully been applied to semantic classification before (Ontrup and Ritter, 2001; Kanzaki et al., 2002; Guida, 2007).

We created SOM maps with  $k$  clusters, for  $2 \leq k \leq 47$ , where 47 represents the total number of prepositions. For each  $k$ , we initiated two-dimensional spacings for all possible hexagonal grids. For example, we trained four SOM maps with 30 clusters, using a  $30 \times 1$  grid, a  $15 \times 2$  grid, a  $10 \times 3$  grid, and a  $6 \times 5$  grid. The distance measure used in the maps was *Euclidean Distance*, which is the only option for SOMs in *R*.

### 3.3 Soft Clustering

The soft clustering of the German prepositions was based on the various hard cluster analyses. We performed the *hard*  $\rightarrow$  *soft* clustering transfer in two alternative ways, providing two different types of soft cluster analyses.

**(1) Centroid-based softening:** For each cluster  $c$  within a hard cluster analysis  $C$ , we calculated the mean distance  $prep2cluster(c)$  over all prepositions  $p$  to the cluster centroid  $z_c$ , ignoring any hard assignments in the hard clustering, cf. Equation 1. The individual distances between a preposition  $p$  and a cluster centroid  $z_c$  are denoted as  $d(p, z_c)$ .

$$prep2cluster(c) = \frac{\sum^p d(p, z_c)}{|p|} \quad (1)$$

For the corresponding soft cluster analysis  $S_t(C)$  of a hard cluster analysis  $C$ , a preposition  $p$  was assigned to a cluster  $c$  if the distance  $d(p, z_c)$  was below a threshold  $t \times prep2cluster(c)$ , with  $t = 0.05, 0.1, 0.15, \dots, 0.95$ . For example, if a distance of a preposition  $p$  to a cluster  $c$  was

5, and the mean distance  $prep2cluster(c)$  was 10, then  $p$  would *not* be assigned to  $c$  for  $t = 0.05, 0.1 \dots, 0.5$  but for  $t = 0.6, \dots, 0.95$ . In this way, we created 19 different soft cluster analyses  $S_t(C)$  for each hard clustering  $C$ , one for each  $t$ . With low values of  $t$ , few prepositions (i.e., only those that were very close to the respective cluster centroids) were assigned to the clusters, and the resulting cluster analyses were likely to contain not all of our prepositions, and a low ambiguity rate; with high values of  $t$ , more prepositions were assigned to each of the clusters, and the resulting cluster analyses were likely to contain many of the 47 prepositions, and a high ambiguity rate.

**(2) Preposition-based softening:** For each preposition  $p$  within a hard cluster analysis  $C$ , we calculated the mean distance  $cluster2prep(p)$  over all cluster centroids  $z_c$  to the preposition  $p$ , ignoring any hard assignments in the hard clustering, cf. Equation 2. Again, the individual distances between a preposition  $p$  and a cluster centroid  $z_c$  are denoted as  $d(p, z_c)$ .

$$cluster2prep(p) = \frac{\sum^c d(p, z_c)}{|c|} \quad (2)$$

Similarly to the centroid-based softening, for the corresponding soft cluster analysis  $S_t(C)$  of a hard cluster analysis  $C$ , a preposition  $p$  was assigned to a cluster  $c$  if the distance  $d(p, z_c)$  was below a threshold  $t \times cluster2prep(p)$ , with  $t = 0.05, 0.1, 0.15, \dots, 0.95$ . By relying on the threshold, we again created 19 different soft cluster analyses  $S_t(C)$  for each hard clustering  $C$ , one for each  $t$ . In this case, however, we compared the mean distances of an individual preposition to all cluster centroids, and only performed soft cluster assignments if the preposition was close to a cluster centroid in comparison to its distance to other cluster centroids. With low values of  $t$ , the prepositions were assigned to none or few clusters, and the resulting cluster analyses were likely to contain not all of our prepositions, and a low ambiguity rate; with high values of  $t$ , the prepositions were assigned to many clusters, and the resulting cluster analyses were likely to contain many of the 47 prepositions, and a high ambiguity rate.

## 4 Evaluation

The evaluation metrics play an important role in our work. On the one hand, we created a large number of hard clustering SOMs (i.e., 96 cluster

<sup>1</sup><http://www.r-project.org/>

analyses since we took all possible grids for each  $2 \leq k \leq 47$  into account), and for each hard cluster analysis we created 38 soft cluster analyses (19 centroid-based versions, and 19 preposition-based versions). We thus needed evaluation measures to decide about the quality of a cluster analysis. On the other hand, our methodology relies on evaluation metrics to identify polysemous prepositions, so the measures are crucial to perform this work.

There is a large body of research regarding the question of how to compare and evaluate two cluster analyses. For example, with respect to the specific task of semantic classification, Schulte im Walde (2003), compared a range of evaluation measures. Related work in this area partly adopted the suggested measures, and in addition relied on *Purity* or *Accuracy* (Korhonen et al., 2003; Stevenson and Joanis, 2003). In more general terms, there is an ongoing discussion about cluster comparison, mainly in the field of Machine Learning, but also elsewhere. Recent examples include Meila (2007), Rosenberg and Hirschberg (2007), and Vinh and Bailey (2010). These approaches all concentrate on evaluations relying on the entropy between two cluster analyses, in order to compare them. Entropy is an information-theoretic measure of uncertainty; in our context, entropy measures how uncertain a clustering is, given the information provided by a gold standard, and vice versa.

We decided to make use of two evaluation measures, in order to (i) evaluate and compare our hard and soft cluster analyses, and (ii) detect polysemy. The two measures were expected to provide complementary perspectives on the properties of our cluster analyses, and on the properties of ambiguous prepositions. The following paragraphs describe these measures, and how they were applied.

(1) With the *Silhouette Value* (Kaufman and Rousseeuw, 1990), each cluster is represented by a silhouette displaying which objects lie well within a cluster and which objects are marginal to a cluster. The evaluation appeared specifically suited to our task, as according to our hypotheses, ambiguous prepositions were expected to represent marginals in a cluster analysis, i.e., to be comparably far away from all cluster centroids.

To obtain the silhouette value  $sil$  for an object  $o_i$  within a cluster  $c_A$ , we compared the average distance  $a$  between  $o_i$  and all other objects in  $c_A$  with the average distance  $b$  between  $o_i$  and all objects

in the neighbouring cluster  $c_B$ , cf. Equations 3 to 5. For each object  $o_i$ ,  $-1 \leq sil(o_i) \leq 1$ . If  $sil(o_i)$  is large, the average object distance within the cluster is smaller than the average distance to the objects in the neighbour cluster, so  $o_i$  is well classified. If  $sil(o_i)$  is small, the average object distance within the cluster is larger than the average distance to the objects in the neighbour cluster, so  $o_i$  has been misclassified. The silhouette value was only calculated if cluster  $c_A$  has at least two members, i.e. if it is not a singleton.

$$a(o_i) = \frac{1}{|c_A| - 1} \sum_{o_j \in c_A, o_j \neq o_i} d(o_i, o_j) \quad (3)$$

$$b(o_i) = \min_{c_B \neq c_A} \frac{1}{|c_B|} \sum_{o_j \in c_B} d(o_i, o_j) \quad (4)$$

$$sil(o_i) = \frac{b(o_i) - a(o_i)}{\max\{a(o_i), b(o_i)\}} \quad (5)$$

In addition to providing information about the quality of classification of a single object, the silhouette value can be extended to evaluate the individual clusters and the entire clustering. The *average silhouette width*  $sil(c)$  of a cluster  $c$  is defined as the average silhouette value for all objects within cluster  $c$ , cf. Equation 6, and the *average silhouette width for the clustering*  $C$  with  $k$  clusters  $sil(C_k)$  is defined as the average silhouette value for the individual clusters, cf. Equation 7.

$$sil(c) = \frac{1}{|c|} \sum_{o_i \in c} sil(o_i) \quad (6)$$

$$sil(C_k) = \frac{1}{k} \sum_{i=1}^k sil(c) \quad (7)$$

(2) The *V-Measure* (Rosenberg and Hirschberg, 2007) is an entropy-based cluster evaluation measure. We chose this measure over other entropy-based measures (e.g., *Variance of Information* (VI) (Meila, 2007), and variants suggested by Vinh and Bailey (2010)) because the V-Measure  $v(C)$  balances two desirable properties for a clustering  $C$  of a given dataset: homogeneity (*hom*) and completeness (*com*), cf. Equations 8 to 10.<sup>2</sup>

<sup>2</sup>Note that Equations 8 and 9 differ from those in Rosenberg and Hirschberg (2007) in the denominators of the *else* condition because there were typos in the definitions (personal communication with Andrew Rosenberg).

*Homogeneity* is similar to *purity*, and measures how well the clusters within a cluster analysis map to the classes within a gold standard. If each cluster contains only objects from one gold-standard class, then the entropy is at its minimum,  $H(C|G) = 0$ . This represents a maximally homogeneous clustering. *Completeness* measures how well the classes within a gold-standard map to the clusters within a cluster analysis. If each gold-standard class contains only objects from one cluster, then the entropy is at its minimum,  $H(G|C)$ . This represents a maximally complete clustering, because each gold-standard class is completely contained in a cluster.

$$hom(C) = 1 \text{ if } H(C, G) = 0; \text{ else } 1 - \frac{H(C|G)}{H(C, G)} \quad (8)$$

$$com(C) = 1 \text{ if } H(G, C) = 0; \text{ else } 1 - \frac{H(G|C)}{H(G, C)} \quad (9)$$

$$v(C) = \frac{2 \times hom(C) \times com(C)}{hom(C) + com(C)} \quad (10)$$

There is however a limitation to the V-Measure because it can only be applied to hard classifications which represent an  $N : 1$  relationship between data points and gold-standard classes. This means a given object only belongs to a single class. In our data, this is clearly not the case due to the inherent ambiguity of the prepositions. We thus extended the V-Measure to a fuzzy version *Fuzzy V-Measure (fuzzy v)* that applies to  $N : M$  classifications, where a data point can belong to any number of classes.<sup>3</sup>

As for the original calculation of the entropy values, we must define the joint and conditional probabilities across clusters and gold-standard classes. In Rosenberg and Hirschberg (2007), the joint probability of a cluster  $c$  and a gold-standard class  $g$  was estimated as

$$\hat{p}(c, g) = \frac{a_{cg}}{N}, \quad (11)$$

where  $a_{cg}$  is the number of prepositions shared by  $c$  and  $g$  and  $N$  is the total number of prepositions. Due to the polysemy of prepositions, we must assume that a preposition occurs in multiple classes. Calculating the probability as above would however give too much weight to highly ambiguous prepositions. Our approach is to give each preposition a total mass of 1 and then equally divide its

<sup>3</sup>Thanks to Andrew Rosenberg for valuable discussions.

	$g_1$	$g_2$	$g_3$	$g_4$
$p_1$	0.5	0.5	0	0
$p_2$	0.33	0	0.33	0.33
$p_3$	0	0.5	0.5	0
$p_4$	0	0.5	0	0.5

Table 3: Prepositions in gold standard.

	$g_1$	$g_2$	$g_3$	$g_4$	$\Sigma$
$c_1$	0.83	0.5	0.33	0.33	= 2
$c_2$	0	1	0.5	0.5	= 2

Table 4: Evidence for clusters.

mass across the classes of which it is a member. Thus, Equation 11 becomes:

$$\hat{p}(c, g) = \frac{\mu(c \cap g)}{M}, \quad (12)$$

where  $\mu(c \cap g)$  is the total mass of the prepositions shared by  $c$  and  $g$ , and  $M$  is the total mass of the clustering. Note that  $M$  will only be equal to  $N$  if each preposition belongs to exactly as many clusters as classes.

Example: The prepositions  $p_1, p_3$  and  $p_4$  each belong to two classes, while preposition  $p_2$  belongs to three classes (cf. Table 3). Assuming cluster  $c_1$  contains  $p_1$ , and  $p_2$ , and  $c_2$  contains  $p_3$  and  $p_4$ , the contingency table for the clusters  $c_1$  and  $c_2$  is given as in Table 4. Thus, while both  $c_1$  and  $c_2$  each share two prepositions with the gold-standard classes  $g_1$  and  $g_2$  respectively, the higher ambiguity of  $p_2$  in the first case means there is less evidence for  $c_1$  given  $g_1$  than  $c_2$  given  $g_2$ , namely:  $\hat{p}(c_1|g_1) = .83/2 < 1/2 = \hat{p}(c_2|g_2)$ .

In addition to being applicable to ambiguous data on the side of the classes themselves, our adaptation of the V-Measure also allows for the application to soft clusterings. In this case, the data points may be present in multiple clusters and simply add their respective mass to the cells in the contingency table.

## 5 Detecting Polysemy

This section applies the evaluation measures to our cluster analyses, in order to detect polysemous prepositions, and to identify their spatial properties. Our hypothesis is that polysemous prepositions are outliers, and thus represent either (i) singletons or (ii) marginals of the clusters within a

cluster analysis. We present a series of assumptions regarding this main hypothesis, and check them according to our hard and soft clusterings.

**Singletons represent polysemy.** Our first analysis applies to the hard cluster analyses. The assumption here is that clusters that represent singletons contain polysemous prepositions, because singletons contain objects that do not belong to any of the other clusters. Figure 1 plots the number of polysemous singletons (i.e., those singletons whose only cluster member is a polysemous preposition) against the total number of singletons, for each SOM map. The baseline is provided by 51% of the total number of singletons, as 24 out of our 47 preposition types (51%) are polysemous, so the baseline corresponds to a random assignment of preposition types to singletons.

For SOM maps with up to  $k = 13$  clusters, there is maximally one singleton in the cluster analyses (except for  $k = 4$  and a grid of  $2 \times 2$ , which contains two singletons), so it is difficult to judge about the correctness of our prediction. For  $14 \leq k \leq 26$ , in most cases the number of polysemous singletons clearly outperforms the baseline. For  $k = 22$  with a grid of  $22 \times 1$  and  $k = 26$  with a grid of  $13 \times 2$ , the difference to the baseline is even significant ( $\chi^2$ ,  $p < 0.1$ ). For  $k > 27$ , the number of polysemous singletons outperforms the baseline in fewer cases than for smaller  $k$ . In sum, our prediction that singletons represent polysemy holds for a restricted subset of our SOM maps, most strongly for  $22 \leq k \leq 26$ .

Figure 1: Number of (ambiguous) singletons.

**Polysemous prepositions are misclassified.** Our second analysis also applies to the hard cluster analyses. Figure 2 exploits the Silhouette Value to predict polysemous prepositions. Since prepositions with several senses are expected to represent marginals in a cluster analysis, they

should be comparably far away from all cluster centroids, and thus their silhouette value  $sil$  should be low, i.e., misclassify them. Figure 2 plots the correlation values of Kendall's  $\tau$ -b<sup>4</sup> between the silhouette value  $sil(p)$  and the ambiguity rate  $amb(p)$  as defined by the gold standard, across all hard cluster analyses. According to our hypothesis,  $\tau$  should be negative: the higher the ambiguity rate, the lower the silhouette value.

The plot demonstrates that our assumption is only partly correct: There are cluster analyses where we find a weak negative correlation, but most clusterings do not exhibit a noticeable correlation, and some clusterings even have a moderate positive correlation. For  $k = 24$  with a grid of  $24 \times 1$  and  $k = 27$  with a grid of  $27 \times 1$ , we however find cluster analyses with a moderate negative correlation,  $\tau = -0.30$  and  $\tau = -0.32$ .

Figure 2: Correlation between  $sil(p)$  and  $amb(p)$ .

**General evaluation of soft clusterings.** Before we move on to exploring a further hypothesis regarding polysemous prepositions, we present a general evaluation of our two types of softening approaches. Figures 3 and 4 plot the *homogeneity*, *completeness* and *fuzzy v* scores after applying centroid-based and preposition-based softening to  $k$  hard clusters, respectively. The soft cluster analyses depend on the threshold  $t$  that controls the assignment of prepositions to clusters. We chose  $t = 0.7$  as a medium threshold for the two figures. Since the various  $k$  cause strong differences in the coverage of the preposition types in the soft cluster analyses, we also plot the *coverage*, and the harmonic mean of *fuzzy v* and *coverage*.

The best *fuzzy v* scores for the centroid-based soft clusters were obtained with  $k = 16$  and a  $8 \times 2$  grid (0.380),  $k = 12$  with a  $6 \times 2$  grid (0.379) and  $k = 10$  with a  $10 \times 1$  grid (0.377).

<sup>4</sup>Kendall's  $\tau$ -b is a measure of association based on concordant and discordant pairs, adjusted for the number of ties.

Figure 3: Centroid-based softening: evaluation.

Figure 4: Preposition-based softening: evaluation.

If we take the coverage into account, the best results were obtained with  $k = 20$  with a  $20 \times 1$  grid (0.534),  $k = 22$  with a  $11 \times 2$  grid (0.530) and  $k = 25$  with a  $5 \times 5$  grid (0.521). For the preposition-based soft clusters the respective *fuzzy v* scores were  $k = 12$  with a  $6 \times 2$  grid (0.396),  $k = 16$  with a  $8 \times 2$  grid (0.376) and  $k = 29$  with a  $29 \times 1$  grid (0.372); taking coverage into account, the respective scores were  $k = 20$  with a  $20 \times 1$  grid (0.547),  $k = 29$  with a  $29 \times 1$  grid (0.536) and  $k = 25$  with a  $5 \times 5$  grid (0.530). In sum, the best *fuzzy v* scores for both types of soft cluster analyses were in most cases obtained for  $k$  being similar to the number of gold standard classes. Taking coverage into account, the best results were obtained for cluster analyses with  $20 \leq k \leq 29$ .

A threshold of  $t = 0.7$  seemed appropriate for our descriptions, since lower and also higher values of  $t$  resulted in less clear preferences for  $k$ , and the threshold appeared like a useful compromise between low coverage in assigning prepositions to clusters, and highly ambiguous clusters.

**Correlation of cluster membership rate with ambiguity rate.** This final analysis investigates the relationship between the cluster membership rate of a preposition and its ambiguity rate. Our assumption is that the more clusters a specific preposition is assigned to, the more ambiguous it is. As

basis for this analysis we used both the centroid-based and the preposition-based soft clusters, with varying  $t$ . Figures 5 and 6 present the correlation results, again relying on *Kendall's tau-b*. For presentation reasons, we restrict the plots to  $10 \leq k \leq 30$  with grid shapes  $k \times 1$  only, and  $t = 0.6, 0.7, 0.8, 0.9$ .

Both plots demonstrate that the highest threshold  $t = 0.9$  corresponding to highly ambiguous cluster analyses exhibits the best correlations with the ambiguity rates of the prepositions. For the centroid-based softening, this is true for  $12 \leq k \leq 20$ , for the preposition-based softening, this is true for all but two values of  $k$ . For lower thresholds, it seems that  $t = 0.8 > t = 0.7 > t = 0.6$ , but the differences are not at all clear but rather vary depending on  $k$ . Overall, we reached moderate correlation values, the best correlation being  $\tau = 0.45$ . Interestingly, the best correlation values in the two types of softening approaches were obtained for similar values of  $k$ , and with  $k$  being very similar to the number of gold standard classes (12): the prediction of the centroid-based softening was best with  $k = 13$  and  $k = 12$  ( $\tau = 0.453$  and  $\tau = 0.449$ , respectively), and the prediction of the preposition-based softening was best with  $k = 12$  and  $k = 14$  ( $\tau = 0.439$  and  $\tau = 0.368$ ).

Figure 6: Preposition-based softening: ambiguity.

## 6 Discussion

In the previous section, we performed a series of analyses to investigate the spatial properties of polysemous prepositions in vector space models. Our main hypothesis is that polysemous prepositions are outliers, and thus represent either (i) singletons or (ii) marginals of the clusters within a cluster analysis. Concerning option (i), we showed that for specific values of  $k$ , there were significantly more polysemous prepositions in the singletons of the hard clusterings than there would be by chance. The relationship did not hold across  $k$ , however. Concerning option (ii), we performed two analyses. First, we checked whether the silhouette value of a preposition in a hard clustering correlated with its ambiguity rate, based on the assumption that the silhouette value identifies cluster marginals. Again, we found a strong correlation for specific values of  $k$ , but not across  $k$ . Second, relying on the soft clusterings we checked whether the cluster membership rate of a preposition correlated with its ambiguity rate: Especially in highly ambiguous cluster analyses there were strong correlations in both types of soft clusterings, for  $k$  similar to the number of gold standard classes.

In sum, our analyses confirmed our hypothesis, but (a) with regard to specific  $k$  only, and (b) the  $k$  varied across the analyses. This might partly be due to our clustering approaches (SOMs for hard clustering, and our two versions of softening approaches), so we are currently experimenting with alternatives. Furthermore, the *fuzzy v* measure that we developed in order to evaluate soft clusterings still seems to provide sub-optimal evidence of clustering quality: The magnitude of the score depends on the threshold, so it is difficult to decide which threshold performed best.

On the other hand, several of our analyses pointed towards similar numbers for an optimal  $k$ , and these optimal  $k$  values were reasonable, as they were close to the number of gold standard classes. Last but not least, we looked into a range of clusterings that performed well according to our *fuzzy v*, and it turned out that within a certain magnitude of  $k$ , the clusterings were very similar to each other, with similar strengths and weaknesses. We thus conclude this paper with a qualitative analysis of the centroid-based soft clustering with  $k = 16$  and a  $8 \times 2$  grid, the best clustering according to the general evaluation.

The clustering actually contained only 15 clus-

ters (so one cluster was an empty cluster). Three of the clusters were singletons, one with a 3-way ambiguous preposition (*nach*: local, modal, temporal), one with a 2-way ambiguous preposition (*unter*: local, modal), and one with a monosemous preposition (*samt*: modal). From the remaining 12 clusters, 8 could unambiguously be assigned a major sense according to the gold standard classes, and 4 clusters contained prepositions from various gold standard classes.

Overall, we found 27 local preposition senses, 24 modal senses, 21 temporal senses, 5 causal and 3 replacement senses. The minor senses (according to the sizes of the gold standard classes), i.e., final, creator, distributive, partitive, conditional, copulative and restrictive, were not found in the clustering. So there was a clear bias towards the assignment of majority senses. This bias might well be due to the very different sizes of the gold standard classes, so in future work we will experiment with sub-classifications of the large classes.

## 7 Conclusion

In this paper, we presented a methodology to identify polysemous German prepositions by exploring their vector spatial properties in hard and soft clusterings. The analyses demonstrated that – when looking at clusterings with a similar or slightly larger number of clusters than the gold standard – (a) singletons have a tendency to contain polysemous prepositions; and (b) misclassification and cluster membership rate exhibit a moderate correlation with ambiguity rate.

## Abstract

In Chinese abbreviation prediction, prior studies are limited on positive full forms. This lab assumption is problematic in real-world applications, which have a large portion of negative full forms (NFFs). We propose solutions to solve this problem of generalized abbreviation prediction. Experiments show that the proposed unified method outperforms baselines, with the full-match accuracy of 79.4%. Moreover, we apply generalized abbreviation prediction for improving web search quality. Experimental results on web search demonstrate that our method can significantly improve the search results, with the search F-score increasing from 35.9% to 64.9%. To our knowledge, this is the first study on generalized abbreviation prediction and its application on web search.

## 1 Introduction

Abbreviations increase the ambiguity in a text. Associating abbreviations with their fully expanded forms is important in various natural language processing applications (Pakhomov, 2002; Yu et al., 2006; HaCohen-Kerner et al., 2008). Chinese abbreviations represent fully expanded forms (e.g., the left side of Figure 1) through the use of shortened forms (e.g., the right side of Figure 1). Chinese abbreviations are derived via a generative lexical process. Although native speakers may possess intuitions of the generative process, it cannot be adequately explained by any linguistic theory (Chang and Lai, 2004; Chang and Teng, 2007).

Abbreviation prediction (i.e., predicting abbreviation of a given full form) is important in Chinese natural language processing applications. For example, it is helpful for information retrieval if we can estimate the abbreviation of a query. For

Full Form	Abbr.

European Economic and Monetary Union	

Figure 1: An example of abbreviation prediction.

the data of one month's People's Daily, only 17% of the documents contain the full form in Figure 1, while more than 70% of the articles contain only the abbreviation in Figure 1. It is expected that abbreviation prediction can improve the recall in information retrieval. In addition, (Yang et al., 2009b) in speech studies showed that Chinese abbreviation prediction can improve voice-based search quality.

The study of Chinese abbreviation prediction is still in an early stage. Chinese abbreviation prediction is quite different from English ones, because of its specific characteristics (Sun et al., 2008; Huang et al., 1994; Chang and Teng, 2007; Yang et al., 2009b; Yang et al., 2009a). For example, Chinese abbreviations are not necessarily from the initials of words. They frequently take non-initial characters from the words in the full form. In addition, the Chinese full form does not have word boundaries.

To our knowledge, all of the prior studies of Chinese abbreviation prediction (Sun et al., 2008; Sun et al., 2009; Sun et al., 2013; Huang et al., 1994; Chang and Teng, 2007; Yang et al., 2009b; Yang et al., 2009a) have focused on positive full forms with valid abbreviations. This implicit lab assumption is quite limited in real-world applications, because real-world Chinese full forms contain a large portion of negative full forms (NFFs), which have no abbreviation at all. Abbreviation prediction becomes more difficult by considering NFFs, because of the strong noise. This difficulty is one of the reason of the lab setting on considering only positive full forms. Another reason is

probably the difficulty of data collection. To our knowledge, there is no existing collection of abbreviation prediction data with NFFs.

We aim at solving this abbreviation prediction problem with generalized assumption (hereinafter *generalized abbreviation prediction*). We manually collected a large dataset for this study, which contains 10,786 entries including NFFs. To deal with the strong noise from NFFs, we propose a variety of solutions. We also apply generalized abbreviation prediction for web search and we show that it can significantly improve web search quality.

## 2 Proposed Method

### 2.1 Preprocessing

The preprocessing step includes word segmentation and part-of-speech tagging for the input abbreviation prediction full forms. The word segmentation and part-of-speech tagging is done via the tool ICTCLAS<sup>1</sup>.

### 2.2 Abbreviation Prediction

#### 2.2.1 Simple Heuristic System

The simple heuristic system means always choosing initial characters of words in the segmented full form. This is because the most natural abbreviating heuristic is to produce the first character of each word in the original full form. This is just the simplest baseline.

#### 2.2.2 Unified System

We present a unified system for generalized abbreviation prediction with NFFs. The unified system can conduct the abbreviation prediction with a single step. We cast abbreviation prediction as a sequential labeling task. Following (Sun et al., 2013), each character in the full form is tagged with a label,  $y \in \{P, S\}$ , where the label  $P$  produces the current character and the label  $S$  skips the current character.

As for NFFs, we need a special encoding of labeling  $E$  to represent “no valid abbreviation”. Since there is no prior work, we need to study this “no valid abbreviation” issue. Given a full form  $F$ , its valid abbreviation  $A$  should have the character number constraints:  $0 < |A| < |F|$ . On the other hand, we can assume that a negative full form has an “invalid abbreviation”  $A$  with  $|A| = 0$

<sup>1</sup><http://ictclas.org/>

or  $|A| = |F|$ . Those two kinds of interpretations actually represent two different answers to the question “why some full forms do not have valid abbreviations”:

- Assumption-1 with  $|A| = 0$ : It assumes that a negative full form  $F$  is “abbreviated” to nothing, i.e., with the abbreviation  $A = NULL$ .
- Assumption-2 with  $|A| = |F|$ : It assumes that a negative full form  $F$  is “abbreviated” to itself, i.e., with the abbreviation  $A = F$ .

We want to find out which assumption leads to better performance.

With those interpretations, invalid abbreviations are treated as special forms of abbreviations, thus positive and negative full forms can be modeled in a unified framework via sequential labeling. For simplicity, we use the well-known conditional random fields (CRFs) (Lafferty et al., 2001) for sequential labeling. Assuming a feature function that maps a pair of observation sequence  $\mathbf{x}$  (characters of a full form) and label sequence  $\mathbf{y}$  (label encoding based on abbreviations) to a feature vector  $\mathbf{f}$ , the probability function is defined as follows:

$$P(\mathbf{y}|\mathbf{x}, \mathbf{w}) = \frac{\exp[\mathbf{w}^\top \mathbf{f}(\mathbf{y}, \mathbf{x})]}{\sum_{\forall \mathbf{y}'} \exp[\mathbf{w}^\top \mathbf{f}(\mathbf{y}', \mathbf{x})]}, \quad (1)$$

where  $\mathbf{w}$  is a parameter vector.

Given a training set consisting of  $n$  labeled sequences,  $(\mathbf{x}_i, \mathbf{y}_i)$ , for  $i = 1 \dots n$ , parameter estimation is performed by maximizing the objective function,

$$\mathcal{L}(\mathbf{w}) = \sum_{i=1}^n \log P(\mathbf{y}_i|\mathbf{x}_i, \mathbf{w}) - R(\mathbf{w}). \quad (2)$$

The second term is a regularizer, typically an  $L_2$  (Gaussian) norm,  $R(\mathbf{w}) = \frac{\|\mathbf{w}\|^2}{2\sigma^2}$ .

We use features as follows:

- Character feature This feature records the input characters  $x_{i-1}$ ,  $x_i$  and  $x_{i+1}$ .
- Character bi-gram The character bi-grams starting at  $(i-2) \dots i$ .
- Numeral Whether or not the  $x_i$  is a numeral.

- Organization name suffix Whether or not the  $x_i$  is a suffix of traditional Chinese organization names.
- Location name suffix Whether or not the  $x_i$  is a suffix of traditional Chinese location names.
- Word segmentation information After the word segmentation step, whether or not the  $x_i$  is the beginning character of a word.
- Part-of-speech information The part-of-speech tag information of  $x_i$ .

$i$  denotes the current position for extracting features.

The character unigram and bi-gram feature is to capture character-based information in the abbreviating process. For example, some special characters are more likely to be chosen in abbreviating. The named entity suffix features are used because a named entity suffix character is more likely to be chosen in abbreviating. The word segmentation information is also important because the beginning character of a word is more likely to be chosen in abbreviating.

### 2.3 Label Encoding with Global Information

As a common practice to reduce complexity, only local information based on Markov assumption is used for sequential labeling. Nevertheless, the Chinese abbreviation generation process is highly dependent on global information. An example of global information is the number of characters of the generated abbreviations.

For better performance, we try to model global information to make the system be “aware” of the number of characters being generated. We use a simple, effective, and tractable solution for modeling global information in abbreviation prediction: label encoding with global information (GI) (Sun et al., 2013).

In this approach, the label  $y_i$  at position  $i$  will be encoded with the global information of its previous labels,  $y_1, y_2, \dots, y_{i-1}$ . Note that, while directly increasing the Markov order is untractable, the GI label encoding is tractable. More detailed description of the GI method is in (Sun et al., 2013).

Category	Portion (%)

### 2.4 Abbreviation Prediction for Web Search

Abbreviation prediction should be helpful for information search, but we find there is almost no prior work on this. It is probably because the traditional abbreviation prediction is not so applicable in real-world data, which includes lots of NFFs. Since we have solved this problem via generalized abbreviation prediction, we hope to apply generalized abbreviation prediction on improving information search.

In particular, we apply generalized abbreviation prediction for “query expansion” in Chinese web search. In this method, the original queries are treated as full forms (with NFFs) for generating abbreviations. Given a query as an input, the generalized abbreviation prediction system outputs an abbreviation candidate or a NULL string. If the output is an empty string, it means the query is an NFF. Finally, the derived abbreviations, together with the original query terms, are used for web search, and their search results (web pages) are simply added together. For the negative full forms, only the original full forms are used for the web search. The simple architecture of the query expansion system is summarized in Figure 2.

In addition, to make clear the role of the predicted abbreviations in web search, we can remove the full form information in web search and check the difference. In this way, the method turns to a “query alternation” method, which uses the predicted abbreviation to *replace* the positive full form for the web search. For a negative full form, the query alternation acts the same like the query expansion.

## 3 Experiments

Here we describe our collected data for generalized abbreviation prediction. First, we extract long phrases and terms from Chinese natural language processing corpora, including People’s Daily cor-

Figure 2: Generalized abbreviation prediction for improving web search.

Figure 3: Samples of the collected data with NFFs. The “X” means no valid abbreviation.

pora<sup>2</sup> and SIGHAN word segmentation corpora<sup>3</sup>. Then, we classify the collected phrases and terms into positive and negative full forms. For the negative full forms, no further annotation is required. For the positive full forms, their abbreviations are annotated.

We build a dataset containing 10,786 full forms, including 8,015 positive full forms and 2,771 negative full forms. Samples of the data are shown in Figure 3. The dataset is made up of phrases and terms, including noun phrases, verb phrases, organization names, location names, and so on. The distribution is shown in Table 1. For experiments, we randomly sampled 8,629 samples (80% of the full dataset) for training and 2,157 (20% of the full dataset) for testing.

For experiments on web search, we simply use the 2,157 testing samples as query terms for web

search. The evaluation is on the news domain<sup>4</sup> of the well-known web search engine “baidu.com”<sup>5</sup>. The Baidu news search engine has two alternative options: “title search” and “full content search”. Since abbreviations are more common in news titles, we adopt the option of title search.

### 3.1 Experimental Settings

For evaluating abbreviation prediction quality, the systems are evaluated using the following two metrics:

- **All-match accuracy (All-Acc):** The number of correct outputs (i.e., label strings) generated by the system divided by the total number of full forms in the test set.<sup>6</sup>
- **Character accuracy (Char-Acc):** The number of correct labels (i.e., a classification on a character) generated by the system divided by the total number of characters in the test set.

For evaluating web search quality based on a given query, the following metrics are used:

- **Precision  $P$ :** The number of correct search results returned by the query divided by the total number of search results returned by the query.
- **Recall  $R$ :** The number of correct search results returned by the query divided by the total number of existing correct search results based on the query.
- **F-Score  $F$ :**  $F = 2PR / (P + R)$ .

<sup>4</sup>We choose news domain because abbreviations are mainly from named entities, and named entities are important in news domain.

<sup>5</sup><http://news.baidu.com>

<sup>6</sup>There is only one label string for a full form, and a label string corresponds to a unique abbreviation candidate. A label string is deemed as correct if and only if *all* of the labels are correct.

<sup>2</sup>[http://ic1.pku.edu.cn/ic1\\_res](http://ic1.pku.edu.cn/ic1_res)

<sup>3</sup><http://www.sighan.org/bakeoff2005>

Method	Discriminate Acc (%)	Overall All-Acc	Overall Char-Acc
Heuristic System	73.20	25.77	65.79
Unified-Assum.1 (Perc)	87.48	54.89	87.02
Unified-Assum.1 (MEMM)	86.97	50.16	85.92
Unified-Assum.1 (CRF-ADF)	87.80	56.69	87.20
Unified-Assum.1-GI (Perc)	91.93	75.42	90.23
Unified-Assum.1-GI (MEMM)	88.59	70.32	88.21
Unified-Assum.1-GI (CRF-ADF)	91.05	<b>79.46</b>	<b>91.61</b>
Unified-Assum.2 (Perc)	86.83	55.86	82.20
Unified-Assum.2 (MEMM)	87.52	56.18	82.27
Unified-Assum.2 (CRF-ADF)	87.11	56.97	82.54
Unified-Assum.2-GI (Perc)	90.35	71.85	88.04
Unified-Assum.2-GI (MEMM)	87.99	63.74	83.77
Unified-Assum.2-GI (CRF-ADF)	90.77	74.78	89.19

Table 2: Results on comparing different methods on generalized abbreviation prediction. *Assum.1* and *Assum.2* represent the two assumptions on NFFs discussed in Section 2.2.2. *GI* means the integration with global information. As we can see, the *Unified-Assum.1-GI (CRF)* system has the best performance.

For evaluating web search quality based on a set of queries, we use the macro-averaging and micro-averaging of the precision, recall, and F-score based on a single query. Hence, we finally have six metrics: macro-precision, macro-recall, macro-F-score, micro-precision, micro-recall, and micro-F-score. We use the novel training method, adaptive online gradient descent based on feature frequency information (ADF) (Sun et al., 2012), for fast and accurate training of the CRF model.

To study the performance of other machine learning models, we also implement on other well-known sequential labeling models, including maximum entropy Markov models (MEMMs) (McCallum et al., 2000) and averaged perceptrons (Perc) (Collins, 2002).

### 3.2 Results on Abbreviation Prediction

The experimental results are shown in Table 2. In the table, the *overall accuracy* is most important and it means the final accuracy achieved by the systems in generalized abbreviation prediction with NFFs. For the completeness of experimental information, we also show the *discriminate accuracy*. The *discriminate accuracy* checks the accuracy of discriminating positive and negative full forms, without comparing the generated abbreviations with the gold-standard abbreviations.

As we can see from Table 2, first, the best system is the system *Unified-Assum.1-GI (CRF)*. Results demonstrate that incorporating global information can always improve the accuracy for

the unified methods. Second, the unified system with *assumption-1* has better accuracy than the one with *assumption-2*. This result suggests that *assumption-1* works better in practice. It is interesting that *assumption-1* is more useful. A probable reason is that those negative full forms have no similar patterns with the real abbreviations. For example, the number of characters in NFFs is very different compared with that of real abbreviations. Also, the NFFs contain more formal word units. Real abbreviations contain much less word units. Thus, *assumption-2* will have the inconsistency problem between abbreviations generated from NFFs and real abbreviations. As a result, *assumption-2* works worse than *assumption-1* which gives no abbreviations. Finally, the CRF model outperforms the MEMM and averaged perceptron models. To summarize, the unified system with *assumption-1*, global information, and CRF model has the best performance.

### 3.3 Results on Web Search

We use the 2,157 testing samples as query terms for web search. We test the original query terms, the query alternation, and the query expansion methods. Some search results actually do not match the query. For example, given a query *abc*, some search results do not contain *abc*, but with the expression “*ab...c*” or “*a...bc*”, where “*...*” means other characters. In this case, the search results are incorrect. Since the number of the search results is massive, we need to evaluate the web

Method	Micro Prec	Micro Rec	Micro F1	Macro Prec	Macro Rec	Macro F1
Original query	48.51	18.14	26.41	47.84	28.76	35.92
Query alternation	47.73	54.04	50.69	62.84	61.12	61.97
Query expansion	47.93	72.18	<b>57.60</b>	53.70	82.02	<b>64.90</b>

Table 3: Results on comparing different methods on web search quality.

Method	Micro Prec	Micro Rec	Micro F1	Macro Prec	Macro Rec	Macro F1
Original query	48.51	18.14	26.41	47.84	28.76	35.92
Query alternation (gold-standard)	72.31	81.86	76.79	83.07	79.11	<b>81.04</b>
Query expansion (gold-standard)	66.40	100.00	<b>79.81</b>	65.56	100.00	79.19

Table 4: Results on comparing different methods on web search quality.

search quality in an efficient way. The correctness of the search results is evaluated by an automatic postprocessing scoring system, which crawls the search results from the `baidu.com` site. Then, the system runs text matching analysis to check if the search query matches the retrieved web pages.

In traditional web search studies, many queries are phrases (e.g., NP+VP) with ambiguous senses. In this case, improving search precision via a contextual information is important. However, for abbreviation processing, most abbreviations are from named entities (the data contains phrases but most of them are NFFs), and the major problem of named entities is variational expressions. In this case, the search recall is more important. To calculate the recall rate in web search, we need to estimate the total number of correct web pages  $N$  relating to a query  $Q$  and its abbreviation  $A$ . We can estimate  $N$  via summing up the correct web pages of  $Q$  and the correct web pages of the gold-standard abbreviation  $A$ .

The precision, recall, F-scores are shown in Table 3. As we can see, the query expansion method based on generalized abbreviation prediction achieves significantly better F-scores on web search quality than using the original queries. We find the major improvement is from the recalls. As expected, the query alternation has lower recall rate than the query expansion method, because the full form information is removed. Nevertheless, the query alternation method is also better than using the original queries. This result emphasizes that the abbreviations are helpful in title-based news search.

Finally, we check the “up-bound” of the performance of generalized abbreviation prediction for web search. The up-bound is achieved by the 100% correct “gold-standard” system, in which

gold-standard abbreviations labeled in the data are used. The results are shown in Table 4. As we can see, the up-bound of the micro-F-score and the macro-F-score is 79.81% and 81.04%, respectively. Thus, the web search quality of automatic generalized abbreviation prediction still has a large space to be improved, possibly via a larger training data set in the future.

## 4 Conclusions and Future Work

This paper is dedicated on generalized abbreviation prediction and its application on improving web search. Experiments demonstrate that the unified system based on global information outperforms the baselines. Experiments also demonstrate that generalized abbreviation prediction can improve web search qualities. As future work, we try to improve the performance via collecting more training data or via semi-supervised learning methods.

## Abstract

This paper presents a graph-based model that integrates prosodic features into an unsupervised speech summarization framework without any lexical information. In particular it builds on previous work using mutually reinforced random walks, in which a two-layer graph structure is used to select the most salient utterances of a conversation. The model consists of one layer of utterance nodes and another layer of prosody nodes. The random walk algorithm propagates scores between layers to use shared information for selecting utterance nodes with highest scores as summaries. A comparative evaluation of our prosody-based model against several baselines on a corpus of academic multi-party meetings reveals that it performs competitively on very short summaries, and better on longer summaries according to ROUGE scores as well as the average relevance of selected utterances.

## 1 Introduction

Automatic extractive speech summarization (Hori and Furui, 2001) has garnered considerable interest in the natural language processing research community for its immediate application in making large volumes of multimedia documents more accessible. Several variants of speech summarization have been studied in a range of target domains, including news (Hori et al., 2002; Maskey and Hirschberg, 2003), lectures (Glass et al., 2007; Chen et al., 2011) and multi-party meetings (Banerjee and Rudnicky, 2008; Liu and Liu, 2010; Chen and Metze, 2012b).

Research in speech summarization – unlike its text-based counterpart – carries intrinsic difficulties, which draw their origins from the noisy nature of the data under consideration: imperfect

ASR transcripts due to recognition errors, lack of proper segmentation, etc. However, it also offers some advantages by making it possible to leverage extra-textual information such as emotion and other speaker states through an incorporation of prosodic knowledge into the summarization model.

A study by Maskey and Hirschberg (2005) on the relevance of various levels of linguistic knowledge (including lexical, prosodic and discourse structure) showed that enhancing a summarizer with prosodic information leads to more accurate and informed results.

In this work we extend the model proposed by Chen and Metze (2012c), where a random walk is performed on a lexico-topical graph structure to yield summaries. They exploited intra- and inter-speaker relationships through partial topic sharing for judging the importance of utterances in the context of multi-party meetings. This paper, on the other hand, enriches the underlying graph structure with prosodic information, rather than lexico-topical knowledge, to model speaker states and emotions.

Also different from Maskey and Hirschberg (2005), we model the multimedia document structure as a graph, which allows for flexibility as well as expressive power in representation. This graph structure provides the easy incorporation of targeted features into the model as well as in-depth analyses of individual feature contributions towards representing speaker information.

To the best of our knowledge this paper presents the first attempt at performing speech summarization using no lexical information in a completely unsupervised setting. Maskey and Hirschberg (2006) use an HMM to perform summarization by relying solely on prosodic features. However, their model – unlike ours – is supervised. The only requirement of the model in this paper is a pre-processing step that segments the audio into “ut-

terances”.

While utterance segmentation may be a non-trivial problem, the possibility of an unsupervised speech summarization model that relies solely on acoustic input is advantageous. Importantly, it does not rely on any training data and circumvents the primary difficulties that plague most speech summarization techniques — namely the noise introduced into the system by imperfect speech recognition.

We evaluate our model on a dataset consisting of multi-party academic meetings (Chen and Metze, 2012b; Banerjee and Rudnicky, 2008). We perform evaluation using the ROUGE metric for automatic summarization, which counts  $n$ -gram overlap between reference and candidate summaries. We also run a post-hoc analysis, which measures the average relevance score of utterances in a candidate summary.

Evaluation results indicate that our model outperforms a number of baselines across varying experimental settings in all but the shortest summaries. We hence claim that our model is a robust, flexible, and effective framework for unsupervised speech summarization.

The rest of the paper is organized as follows. Section 2 describes the prosodic features encoded in the model and how they are extracted. Section 3 presents the construction of the two-layer graph and mutually reinforced random walk for propagating information through the graph. Section 4 shows experimental results of applying the proposed model to the dataset of academic meetings and discusses the effects of prosody on summarization. Section 5 concludes.

## 2 Prosodic Feature Extraction

As previously stated, the only pre-requisite of the model proposed in this paper is a segmentation of the input document into chunks that are dictated by some meaningful notion of utterances. Once the audio has been segmented utterance-wise, the rest of the pipeline is effectively agnostic to all but its acoustic properties.

Given a set of pre-segmented audio files, we extract the following prosodic features from them using PRAAT scripts (Huang et al., 2006).

- Number of syllables and number of pauses.
- Duration time, – which is the speaking time including pauses – and the phonation time, –

Figure 1: A simplified example of the two-layer graph considered, where a type of prosody  $P_i$  is represented as a node in prosody-layer and an utterance  $U_j$  is represented as a node in utterance-layer of the two-layer graph.

which is the speaking time excluding pauses.

- Speaking rate and articulation rate, which are the number of syllables divided by the duration time and phonation time, respectively.
- The average, maximal and minimal fundamental frequencies measured in Hz (which objectify the perceptive notion of pitch).
- The energy measured in  $\text{Pa}^2/\text{sec}$  and the intensity measured in dB.

The inclusion of the features above into the model was motivated by their possible contribution to the notion of “important utterances” in a dialogue. For example, intuitively, pitch is a vocal channel for emotions, such as anger, or embarrassment. It may thus contribute, via the emotional investment of the speaker to the importance of her utterances. Similarly, the variation of energy over an utterance results in its perceived loudness, thus possibly permitting the inference of emphasis or stress to particular utterances by speakers. Again, speech rate often acts as a latent channel for communication of information, where excitement or emphasis is implicitly conveyed by a speaker.

## 3 Two-Layer Mutually Reinforced Random Walk

In this section we describe our method for modelling speech data as a two-layered interconnected graph structure and run the mutually reinforced random-walk algorithm for summarization.

Given an input speech document that is suitably segmented into utterance chunks, we construct a linked two-layer graph  $G$  containing an utterance set  $V_U$  and a prosody set  $V_P$ . Each node of the graph  $U_i \in V_U$  corresponds to a single utterance as obtained from the pre-processing ‘‘chunking’’ step. Every node  $P_i \in V_P$  illustrates a single prosodic features incorporated into the model.

Figure 1 shows a simplified example of such a two-layered graph.  $G = \langle V_U, V_P, E_{UP}, E_{PU} \rangle$ , where  $V_U = \{U_i\}$ ,  $V_P = \{P_i\}$ ,  $E_{UP} = \{e_{ij} \mid U_i \in V_U, P_j \in V_P\}$ , and  $E_{PU} = \{e_{ij} \mid P_i \in V_P, U_j \in V_U\}$ . Here,  $E_{UP}$  and  $E_{PU}$  represent the sets of directional edges between utterances and prosodic nodes with different directions (Cai and Li, 2012).

Based on these sets of directional edges we further define  $L_{UP} = [w_{i,j}]_{|V_U| \times |V_P|}$  and  $L_{PU} = [w_{j,i}]_{|V_P| \times |V_U|}$ . The matrices  $L_{UP}$  and  $L_{PU}$  effectively encode the directional relationship between utterances and prosodic features. More concretely, for example, the entry  $w_{i,j}$  of  $L_{UP}$  is the value of the prosodic feature  $P_j$  extracted from the utterance  $U_i$ . Row-normalization is performed on  $L_{UP}$  and  $L_{PU}$  (Shi and Malik, 2000). It may be noted that, as a consequence,  $L_{UP}$  is different from  $L_{PU}^T$ .

Traditional random walk only operates on a single layer of the graph structure and integrates the initial similarity scores with the scores propagated from other utterance nodes (Chen et al., 2011; Chen and Metze, 2012a; Hsu et al., 2007). The approach adopted in this paper, however, considers prosodic information by propagating information between layers based on external mutual reinforcement (Chen and Metze, 2012c).

Effectively the working of the algorithm stems from two interrelated intuitions. On the one hand, utterances that evidence more pronounced signs of important prosodic features should themselves be judged as more salient. On the other hand, prosodic features in salient utterances that are recorded with higher values should themselves be deemed as more important.

The advantage of the algorithm is that it is entirely unsupervised and allows for the integration of knowledge-rich target specific features. The mathematical formulation of the algorithm is presented as follows.

Given some initial scores  $F_U^{(0)}$  and  $F_P^{(0)}$  for utterance and prosody nodes respectively, the update

rule is given by:

$$\begin{cases} F_U^{(t+1)} = (1 - \alpha)F_U^{(0)} + \alpha \cdot L_{UP}F_P^{(t)} \\ F_P^{(t+1)} = (1 - \alpha)F_P^{(0)} + \alpha \cdot L_{PU}F_U^{(t)} \end{cases} \quad (1)$$

Here  $F_U^{(t)}$  and  $F_P^{(t)}$  integrate the initial importance associated with their respective nodes with the score obtained by between-layer propagation at a given iteration  $t$ .

Hence, the scores in each layer are mutually updated by the scores from the other layer, iteratively. In particular, utterances that exhibit more pronounced signs of important prosodic feature are progressively scored higher. At the same time, prosodic features that appear with higher values in salient utterances become progressively more important.

For the utterance set, the update rule increments the importance of nodes with the combination  $L_{UP}F_P^{(t)}$ . This latter term can be considered as the score from linked nodes in the prosody set, weighted by prosodic feature values. Finally, an  $\alpha$  value encodes the trade-off between initial utterance weight and information sharing via propagation. The algorithm converges satisfying (2).

$$\begin{cases} F_U^* = (1 - \alpha)F_U^{(0)} + \alpha \cdot L_{UP}F_P^* \\ F_P^* = (1 - \alpha)F_P^{(0)} + \alpha \cdot L_{PU}F_U^* \end{cases} \quad (2)$$

Additionally  $F_U^*$  has an analytical solution which is given by:

$$\begin{aligned} F_U^* &= (1 - \alpha)F_U^{(0)} \\ &+ \alpha \cdot L_{UP} \left( (1 - \alpha)F_P^{(0)} + \alpha \cdot L_{PU}F_U^* \right) \\ &= (1 - \alpha)F_U^{(0)} + \alpha(1 - \alpha)L_{UP}F_P^{(0)} \\ &+ \alpha^2 L_{UP}L_{PU}F_U^* \\ &= \left( (1 - \alpha)F_U^{(0)} e^T + \alpha(1 - \alpha)L_{UP}F_P^{(0)} e^T \right. \\ &+ \left. \alpha^2 L_{UP}L_{PU} \right) F_U^* \\ &= MF_U^*, \end{aligned} \quad (3)$$

where  $e = [1, 1, \dots, 1]^T$ . The closed-form solution  $F_U^*$  of (3) is the dominant eigenvector of  $M$  (Langville and Meyer, 2005).

It may be noted that for the practical implementation of the algorithm, we set the initial scores of utterance nodes  $F_U^{(0)}$  and prosodic nodes  $F_P^{(0)}$  to have equal importance. Also we empirically set  $\alpha = 0.9$  for all our experiments because several studies have shown that  $(1 - 0.9)$  is a proper damping factor (Hsu et al., 2007; Brin and Page, 1998).

## 4 Experiments

### 4.1 Pre-processing – Time Alignment

We have previously stressed that while our model is independent from the lexical representation of an audio document, it does rely on a pre-processing step that chunks the document into individual utterances. It is noted that this may not be a trivial task.

Speaker diarization (Tranter and Reynolds, 2006) and utterance segmentation (Christensen et al., 2005; Geertzen et al., 2007) are open areas of research in the NLP community. Systems developed for these purposes may be used to produce the initial chunking required by our model. In this paper, however, we do not explore these methods and instead rely on segmentation obtained from manually produced textual transcripts. This is to study the efficacy of our model in isolation.

A second reason for using textual transcripts is the presentation of experimental evaluation. This form of data allows for tangible results that are obtained through evaluation metrics such as ROUGE, which rely on measuring  $n$ -gram overlap between reference and candidate summaries. Furthermore, the resulting textual surface form and summaries are more “semantically” interpretable as well.

To associate prosodic information with the textual realization of each utterance in a manual transcript, a preprocessing step requires time alignments between the audio and the corresponding text of each utterance. Note that this step is unnecessary in the case when manual transcripts are not present, and utterance chunking is obtained from some other, automatic means. The time alignment is then implicitly obtained in the process of utterance segmentation.

To accomplish the alignment in our experimental framework, a speech recognizer is first used to produce an ASR output of the audio document. A by-product of this step is that each recognized token contains an inherent time signature. Using Viterbi alignment between the ASR output and manual transcription the time signatures from the audio is projected onto each manually transcribed utterance.

We experimented with Viterbi alignment at a number of different levels of granularity including token level, character level, and phoneme level (via conversion of text to phonetic representation using the CMU pronunciation dictionary (Weide,

1998)). The latter was empirically found to produce the most fine-grained and precise alignments, and was consequently used in all our experiments.

### 4.2 Corpus

The dataset used in our evaluation is the same one previously employed by Chen and Metze (2012b). It consists of 10 meetings held between April and June 2006, with largely overlapping participants and topics of discussion. There were a total of 6 unique participants, with each meeting involving between 2 and 4 individual speakers. SmartNotes (Banerjee and Rudnicky, 2008) was used to record both the audio and the notes for each meeting.

The average duration of a meeting in the dataset was approximately 28 minutes, and the total number of utterances was 7123. We only use the manual transcripts of the meetings to actually evaluate our model, although ASR transcripts were used for time alignment.

The reference summaries are produced by selecting the set of the most “noteworthy” utterances. Two annotators manually labelled the degree of “noteworthiness” (on a relevance scale of 1 to 3) for each utterance. We extract all the utterances with a “noteworthiness” level of 3 to form the reference summary of each meeting.

### 4.3 Baselines

Several baselines were used for comparison against our model and are described below.

1. **Longest:** The first baseline simply selects the longest utterances to form a summary of a document (where the length of the extracted summary is based on the desired ratio). We define the length of utterances by the number of tokens they contain.
2. **Begin:** A second variant of this baseline selects the utterances that appear in the beginning of the document.
3. **LTE:** The third baseline is a summary produced by using Latent Topic Entropy (LTE) (Kong and Lee, 2011). This measure essentially estimates the “focus” of an utterance. Hence, theoretically, a lower topic entropy relates to a more topically informative utterance, which in turn translates into a noteworthy utterance to include in a summary.
4. **TF-IDF** The final baseline uses basic TF-IDF to measure the importance of utterances, by

F-measure		ROUGE-1			ROUGE-L		
		10%	20%	30%	10%	20%	30%
Baseline	Longest	34.05	52.48	61.11	33.66	52.10	60.77
	Begin	<b>35.45</b>	54.42	64.63	<b>35.28</b>	54.18	64.37
	LTE	35.16	54.67	64.97	35.03	54.54	64.76
	TFIDF	32.01	51.33	63.11	31.89	51.08	62.84
This Paper		35.33	<b>55.17</b>	<b>65.60</b>	35.09	<b>54.90</b>	<b>65.36</b>

Table 1: ROUGE scores (%) on multi-party meeting dataset

taking the averaged TF-IDF score over each of its individual words.

It may be noted that the topic distribution of words as well as their IDF scores were obtained by computing statistics over all ten meetings in our experimental dataset.

#### 4.4 Evaluation Metrics

Our automated evaluation utilizes the standard DUC (Document Understanding Conference) evaluation metric, ROUGE (Lin, 2004), which measures recall over various  $n$ -gram statistics between a system-generated summary and a set of summaries produced by humans. F-measures for ROUGE-1 (unigram) and ROUGE-L (longest common subsequence) can be evaluated in exactly the same way.

We also use a post-hoc evaluation metric to measure the average “importance” of utterances in a summary. This metric associates a relevance score to a summary by taking the averaged noteworthiness score of each utterance, as obtained from human annotators.

#### 4.5 Results and Discussion

We ran each of the baseline summarizers as well as the system proposed in this paper to produce 10%, 20% and 30% summaries of each of the meetings in the dataset. The percentage of a summary was determined by selecting the top  $k$  utterances (as determined by a given system) until the desired ratio between the number of tokens in the summary to the total length of its corresponding meeting was met.

Evaluation results on the ROUGE metric are presented in Table 1. They reveal that the performance of our prosody-based model is competitive with the other baselines on the shortest 10% summaries. In fact it ranks second, only scoring lower than the baseline that considers the beginning of a document as a summary. Additionally, on the

longer 20% and 30% summaries, the system outperforms all the baselines.

We believe that in the case of very short summaries, the nature of the data under consideration biases the evaluation of the “begin” baseline. This is because the meetings generally commence with a presentation of an agenda which contains key terms that are likely to be discussed during the course of the rest of the session. In this scenario a metric such as ROUGE – which effectively measures  $n$ -gram overlap – would reward the “begin” summary for including key terms that appear several times in the gold standard summaries.

However for longer summaries, where lexical variation is more pronounced, prosodic information provides a robust source of intelligence to select noteworthy utterances. In fact we are surprised that it outperforms the lexically derived LTE and TF-IDF baselines in all evaluation configurations.

Overall, these results seem to suggest that our model is able to capture latent speaker information and incorporate it effectively into the process of extractive summarization.

We further test this conclusion by conducting a post-hoc analysis, where we examine the average “importance” of utterances in the summary produced by a particular system. More specifically, we measure the average relevance score – ranging on a scale of 1 to 3 – of the utterances, where the score of each utterance is derived from its noteworthiness level as judged by human annotators (Banerjee and Rudnicky, 2008). The results of this analysis are presented in Table 2.

While the “begin” baseline is able to produce summaries with the highest relevance score for the shortest 10% summaries, our model outperforms all other systems on the longer 20% and 30% summaries. Moreover, it is competitive with the “begin” baseline even on the shortest summaries and scores higher than the other baselines. These re-

Avg. Relevance		10%	20%	30%
Baseline	Longest	2.299	2.272	2.283
	Begin	<b>2.464</b>	2.402	2.398
	LTE	2.334	2.369	2.367
	TFIDF	2.355	2.363	2.375
This paper		2.454	<b>2.422</b>	<b>2.411</b>

Table 2: Avg. relevance scores on multi-party meeting dataset

sults align with the findings in Table 1.

As an auxiliary analysis we also extract the converged scores of prosody nodes and rank them in order to analyze their effectiveness. The ranking reveals that the number of pauses in an utterance, its minimum and average pitch, and its intensity tend to be the most predictive features. In the context of academic meetings the number of pauses may be indicative of the time a speaker takes to formulate and articulate his/her thoughts. Thus more pauses may indicate utterances that have been more carefully crafted and therefore include more relevant content. Pitch and intensity are generally good measures of important information, because speakers tend to use them to express emotion. This fact has previously been successfully leveraged for key term extraction (Chen et al., 2010).

Conversely the duration time of the utterance, the number of syllables, and the energy are the least predictive features. With the exception of energy, the other two features can be considered as a surrogate measure for the length of utterances. This parallels what the “longest” utterance baseline performs lexically. The finding corresponds to the results from Tables 1 and 2, which show that this baseline does not produce particularly relevant summaries.

## 5 Conclusion

Our paper proposes a novel approach to integrating speaker-state information, through the incorporation of prosodic knowledge into an unsupervised model for extractive speech summarization. We have also shown the first attempt at performing unsupervised speech summarization without using lexical information.

We have presented experiments on a dataset of academic meetings involving spoken interactions between multiple parties. Evaluation results indicate that our model extracts relevant utterances

as summaries, both from the perspective of automatic evaluation metrics such as ROUGE as well as a post-hoc metric that measured the average relevance score of utterances within summaries. In addition our model compared favorably with a number of heuristic and lexically derived baselines outperforming them in all but one scenario. This substantiates its claim to a robust and viable method for completely unsupervised speech summarization.

## Abstract

The problem of text summarization for a collection of documents is defined as the problem of selecting a small subset of sentences so that the contents and meaning of the original document set are preserved in the best possible way. In this paper we present a linear model for the problem of text summarization<sup>1</sup>, where a summary preserves the information coverage as much as possible in comparison to the original document set. We reduce the problem of finding the best summary to the problem of finding the point on a convex polytope closest to the given hyperplane, and solve it efficiently with the help of fractional (polynomial-time) linear programming. The experimental results show the superiority of our approach over most of the systems participating in the generic multi-document summarization task (MultiLing) of the TAC 2011 competition.

## 1 Introduction

Automated text summarization is an active field of research in various communities like Information Retrieval (IR), Natural Language Processing (NLP), and Text Mining (TM).

Some authors reduce summarization to the maximum coverage problem (Takamura and Okumura, 2009; Gillick and Favre, 2009) that, despite a great performance, is known as NP-hard (Khuller et al., 1999). Linear Programming helps to find an accurate approximated solution to this problem and became very popular in summarization field in the last years (Gillick and Favre, 2009; Woodsend and Lapata, 2010; Hitoshi Nishikawa and Kikui, 2010; Makino et al.,

<sup>1</sup>This work was partially funded by U.S. Department of Navy, Office of Naval Research.

2011). However, most mentioned works use exponential number of constraints or Integer Linear Programming which is an NP-hard problem.

Trying to solve a trade-off between summary quality and time complexity, we propose a novel summarization model solving the approximated maximum coverage problem by linear programming in polynomial time. We measure information coverage by terms<sup>2</sup> and strive to obtain a summary that preserves the optimal value of the chosen objective function as much as possible in comparison to the original document. Various objective functions combining different parameters like term's position and its frequency are introduced and evaluated.

Our method ranks and extracts significant sentences into a summary and it can be generalized for both single-document and multi-document summarization. Also, it can be easily adapted to cross-lingual/multilingual summarization.

Formally speaking, in this paper we introduce (1) a novel text representation model expanding a classic Vector Space Model (Salton et al., 1975) to Hyperplane and Half-spaces, (2) re-formulated extractive summarization problem as an optimization task and (3) its solution using linear or quadratic programming. The main challenge of this paper is a new text representation model making possible to represent an exponential number of extracts without computing them explicitly, and finding the optimal one by simple minimizing a distance function in polynomial time.

## 2 Our Method

### 2.1 Definitions

We are given a set of sentences  $S_1, \dots, S_n$  derived from a document or a cluster of related documents. Meaningful words in these sentences are entirely described by terms  $T_1, \dots, T_m$ . Our goal is to find a

<sup>2</sup>normalized meaningful words

subset  $S_{i_1}, \dots, S_{i_k}$  consisting of sentences such that (1) there are at most  $N$  terms in these sentences, (2) term frequency is preserved as much as possible w.r.t. the original sentence set, (3) redundant information among  $k$  selected sentences is minimized.

We use the standard sentence-term matrix,  $A = (a_{ij})$  of size  $m \times n$ , for initial data representation, where  $a_{ij} = k$  if term  $T_i$  appears in the sentence  $S_j$  precisely  $k$  times. Here, columns of  $A$  describe sentences and rows describe terms. Since we are not interested in redundant sentences, in the case of multi-document summarization, we can initially select meaningful sentences by clustering all the columns as vectors in  $\mathbb{R}^n$  and choose a single representative from each cluster. In this case columns of  $A$  describe representatives of sentence clusters. The total number of words (term appearances) in the document, denoted by  $S$ , can be computed from the matrix  $A$  as

$$S = \sum_i \sum_j a_{ij} \quad (1)$$

**Example 1.** Given the following text of  $n = 3$  sentences and  $m = 5$  (normalized) terms:

$S_1 = A \text{ fat cat is a cat that eats fat meat.}$   
 $S_2 = My \text{ cat eats fish but he is a fat cat.}$   
 $S_3 = All \text{ fat cats eat fish and meat.}$

Matrix  $A$  corresponding to the text above has the following shape:

$$\begin{array}{l} T_1 = \text{"fat"} \\ T_2 = \text{"cat"} \\ T_3 = \text{"eat"} \\ T_4 = \text{"fish"} \\ T_5 = \text{"meat"} \end{array} \begin{bmatrix} S_1 & S_2 & S_3 \\ a_{11} = 2 & a_{12} = 1 & a_{13} = 1 \\ a_{21} = 2 & a_{22} = 2 & a_{23} = 1 \\ a_{31} = 1 & a_{32} = 1 & a_{33} = 1 \\ a_{41} = 0 & a_{42} = 1 & a_{43} = 1 \\ a_{51} = 1 & a_{52} = 0 & a_{53} = 1 \end{bmatrix}$$

where  $a_{ij}$  are term counts. The total count of terms in this matrix is

$$S = \sum_{i=1}^5 \sum_{j=1}^3 a_{ij} = 16$$

Our goal is to find subset  $i_1, \dots, i_k$  of  $A$ 's columns so that the chosen submatrix represents the best possible summary under some constraints. Since it is hard to determine what is the best summary mathematically (this task is usually left to human experts), we wish to express summary quality as a linear function of the underlying matrix. We strive to find a summary that gives an optimal value once the function in question has been determined.

## 2.2 Text Preprocessing

In order to build the matrix and then the polytope model, one needs to perform the basic text preprocessing including sentence splitting and tokenization. Also, additional steps like stopwords removal, stemming, synonym resolution, etc. may be performed for resource-rich languages. Since the main purpose of these methods is to reduce the matrix dimensionality, the resulted model will be more efficient.

## 2.3 Polytope as a document representation

We represent every sentence by a hyperplane, and all sentences derived from a document form a hyperplane intersections (polytope). Then, all possible extracts can be represented by subplanes of our hyperplane intersections and as such that are not located far from the boundary of the polytope. Intuitively, the boundary of the resulting polytope is a good approximation for extracts that can be generated from the given document. We view every column of the sentence-term matrix as a *linear constraint* representing a hyperplane in  $\mathbb{R}^m$ . An occurrence of term  $t_i$  in sentence  $S_j$  is represented by variable  $x_{ij}$ . The maximality constraint on the number of terms in the summary can be easily expressed as a constraint on the sum of these variables.

**Example 2.** This example demonstrates variables corresponding to the  $5 \times 3$  matrix  $A$  of Example 1.

$$\begin{array}{l} T_1 \\ T_2 \\ T_3 \\ T_4 \\ T_5 \end{array} \begin{bmatrix} S_1 & S_2 & S_3 \\ x_{11} & x_{12} & x_{13} \\ x_{21} & x_{22} & x_{23} \\ x_{31} & x_{32} & x_{33} \\ x_{41} & x_{42} & x_{43} \\ x_{51} & x_{52} & x_{53} \end{bmatrix}$$

Every sentence in our document is a hyperplane in  $\mathbb{R}^m$ , defined with columns of  $A$  and variables representing terms in sentences:

$$\begin{aligned} A[[j]] &= [a_{1j}, \dots, a_{mj}] \\ \mathbf{x}_j &= [x_{1j}, \dots, x_{mj}] \text{ for all } 1 \leq j \leq n \end{aligned}$$

We define a system of linear inequalities

$$\begin{aligned} A[[j]] \cdot \mathbf{x}_j^T &= \sum_{i=1}^m a_{ij} x_{ij} \leq \\ &\leq A[[j]] \cdot \mathbf{1}^T = \sum_{i=1}^m a_{ij} \end{aligned} \quad (2)$$

Every inequality of this form defines a hyperplane  $H_i$  and its lower half-space specified by equation (2):

$$A[[j]] \cdot \mathbf{x}_j^T = A[[j]] \cdot \mathbf{1}^T$$

Figure 1: Two-dimensional projection of hyperplane intersection.

and with normal vector  $\mathbf{n} = (\mathbf{n}_{xy})$

$$\mathbf{n}_{xy} = \begin{cases} a_{xy} & 1 \leq x \leq m \wedge y = j \\ 0 & \text{otherwise.} \end{cases} \quad (3)$$

To say that every term is either present or absent from the chosen extract, we add constraints  $0 \leq x_{ij} \leq 1$ . Intuitively, entire hyperplane  $H_i$  and therefore every point  $p \in H_i$  represents sentence  $S_i$ . Then a subset of  $r$  sentences is represented by intersection of  $r$  hyperplanes.

**Example 3.** Sentence-term matrix  $A$  of Example 1 defines the following hyperplane equations.

$$H_1: 2x_{11} + 2x_{21} + x_{31} + x_{51} = 2 + 2 + 1 + 1 = 6$$

$$H_2: x_{12} + 2x_{22} + x_{32} + x_{42} = 5$$

$$H_3: x_{13} + x_{23} + x_{33} + x_{43} + x_{53} = 5$$

Here, a summary consisting of the first and the second sentence is expressed by the intersection of hyperplanes  $H_1$  and  $H_2$ . Figure 1 shows how a two-dimensional projection of hyperplanes  $H_1, H_2, H_3$  and their intersections look like.

## 2.4 Summary constraints

We express summarization constraints in the form of linear inequalities in  $\mathbb{R}^{mn}$ , using the columns of the sentence-term matrix  $A$  as linear constraints. Maximality constraint on the number of terms in the summary can be easily expressed as a constraint on the sum of term variables  $x_{ij}$ .

$$\sum_{i=1}^m \sum_{j=1}^n x_{ij} \leq T_{\max} \quad (4)$$

**Example 4.** Equation (4) for Example 1,  $T_{\max} = 11$  has the form

$$\begin{aligned} 0 \leq x_{ij} \leq 1, \forall i, j \\ \sum_{i=1}^5 \sum_{j=1}^3 x_{ij} \leq 11 \end{aligned}$$

Additionally, we may have constraints on the maximal  $W_{\max}$  number of words in the summary. We take into account only words that remain in the text after stop-word removal and stemming. The difference between the number terms and the number of words in a summary is that a single term can appear more than once in a sentence. Therefore, the total number of words in the text is expressed by summing up the elements of its term-count matrix. Therefore, maximality constraints for words are expressed by the following linear inequality.

$$\sum_{i=1}^m \sum_{j=1}^n a_{ij} x_{ij} \leq W_{\max} \quad (5)$$

**Example 5.** Equation (5) for the sentence-term matrix of Example 1 for  $W_{\max} = 11$  has the form

$$\begin{aligned} 2x_{11} + 2x_{21} + x_{31} + x_{51} + \\ + x_{12} + x_{22} + 2x_{32} + x_{42} + \\ + x_{13} + x_{23} + x_{33} + x_{43} + x_{53} \leq 11 \end{aligned}$$

## 2.5 The polytope model

Having defined linear inequalities that describe each sentence in a document separately and the total number of terms in sentence subset, we can now look at them together as a system:

$$\begin{cases} \sum_{i=1}^m a_{i1} x_{i1} \leq \sum_{i=1}^m a_{i1} \\ \dots \\ \sum_{i=1}^m a_{in} x_{in} \leq \sum_{i=1}^m a_{in} \\ \sum_{i=1}^m \sum_{j=1}^n x_{ij} \leq T_{\max} \\ \sum_{i=1}^m \sum_{j=1}^n a_{ij} x_{ij} \leq W_{\max} \\ 0 \leq x_{ij} \leq 1 \end{cases} \quad (6)$$

First  $n$  inequalities describe sentences  $S_1, \dots, S_n$ , the next two inequalities describes constraints on the total number of terms and words in a summary, and the final constraint determines upper and lower boundaries for all sentence-term variables. Since every inequality in the system (6) is linear, the entire system describes a convex polyhedron in  $\mathbb{R}^{mn}$ , which we denote by  $\mathbf{P}$ . Faces of  $\mathbf{P}$  are determined by intersections of hyperplanes defined in (6).

## 2.6 Objectives and summary extraction

We assume here that the surface of the polyhedron  $\mathbf{P}$  is a suitable representation of all the possible sentence subsets (its size, of course, is not polynomial in  $m$  and  $n$  since the number of vertices of  $\mathbf{P}$  can reach  $O(2^n)$ ). Fortunately, we do not need to scan the whole set of  $\mathbf{P}$ 's surfaces but rather to find

Function	Formula	Description
Maximal Weighted Term Sum ( <i>OBJ</i> <sub>1</sub> )	$\max \sum_{i=1}^m w_i t_i,$ $t_i = \sum_{j=1}^n x_{ji}$	Maximizes the information coverage as a weighted term sum. We used the following types of term weights $w_i$ . (1) POS_EQ, where $w_i = 1$ for all $i$ ; (2) POS_F, where $w_i = \frac{1}{app(i)}$ and $app(i)$ is the index of a sentence in the document where the term $T_i$ first appeared; (3) POS_B, where $w_i = \max\{\frac{1}{app(i)}, \frac{1}{n-app(i)+1}\}$ ; (4) TF, where $w_i = tf(i)$ and $tf(i)$ is the term frequency of term $T_i$ ; (5) TFISF, where $w_i = tf(i) * isf(i)$ and $isf(i)$ is the inverse sentence frequency of $T_i$
Distance Function ( <i>OBJ</i> <sub>2</sub> )	$\min \sum_{i=1}^m (\hat{t}_i - p_i)^2,$ (1) $\hat{t}_i = t_i = \sum_{j=1}^n x_{ji}$ and $\forall i p_i = 1$ , or (2) $\hat{t}_i = \frac{t_i}{\sum_{j=1}^n t_j}$ and $p_i = tf(i)$	Minimizes the Euclidian distance between terms $t = (t_1, \dots, t_m)$ (a point on the polytope $\mathbf{P}$ representing a generated summary) and the vector $p = (p_1, \dots, p_m)$ (expressing document properties we wish to preserve and representing the "ideal" summary). We used the following options for $t$ and $p$ representation. (1) MTC, where $t$ is a summary term count vector and $p$ contains all the terms precisely once, thus minimizing repetition but increasing terms coverage. (2) MTF, where $t$ contains term frequency of terms in a summary and $p$ contains term frequency for terms in documents.
Sentence Overlap ( <i>OBJ</i> <sub>3</sub> )	$\min \sum_{j=1}^n \sum_{k=j+1}^n ovl_{jk},$ $ovl_{jk} = \frac{ S_j \cap S_k }{ S_j \cup S_k } = \frac{\sum_{i=1}^m w(a_{ij}, a_{ik})(x_{ij} + x_{ik})}{\sum_{i=1}^m (a_{ij} + a_{ik})}$	Minimizes the Jaccard similarity between sentences in a summary (denoted by $ovl_{jk}$ for $S_j$ and $S_k$ ). $w(a_{ij}, a_{ik})$ is 1 if the term $T_i$ is present in both sentences $S_j$ and $S_k$ and is 0 otherwise.
Maximal Bigram Sum ( <i>OBJ</i> <sub>4</sub> )	$\max \sum_{i,j} bi_{ij},$ where $\forall i, j, 0 \leq bi_{ij} \leq 1$	Maximizes the information coverage as a bigram sum. Variable $bi_{ij}$ is defined for every bigram $(T_i, T_j)$ in the text.

Table 1: Objective functions for summarization using polytope model.

the point on  $\mathbf{P}$  that optimizes the chosen objective function. Table 1 contains four different objective functions<sup>3</sup> that we used for summarization, along with descriptions of the changes in the model that were required for each function.

Since the LP method not only finds the minimal distance but also presents an evidence to that minimality in the form of a point  $x = (x_{ij})$ , we use the point's data to find what sentences belong to the chosen summary. We check which equations of  $H_i$  the point  $x$  satisfies as equalities. If an equality holds,  $x$  lies on  $H_i$  and therefore the sentence  $S_i$  is contained in the summary. This test is straightforward and takes  $O(mn)$  time. In a case of insufficient summary length, the sentences nearest to the point  $x$  are extracted to a summary in a greedy manner.

### 3 Experiments

In order to evaluate the quality of our approach, we compared our approach to multiple summarizers participated in the generic multi-document summarization task of the TAC 2011 competition (Giannakopoulos et al., 2011) and human

<sup>3</sup>Since our approach is unsupervised, there is no possibility and meaning to use ROUGE, that needs Gold Standard, as an objective.

performance as well. Our software was implemented in Java using Ipsolve (Berkelaar, 1999)<sup>4</sup>. We used the following objective functions, described in Table 1.

- (1) Maximal weighted term sum  $OBJ_1^{weight\_type}$ , where  $weight\_type$  is one of POS\_EQ, POS\_F, POS\_B, TF, TFISF;
- (2) Minimal distance  $OBJ_2^{vector\_type}$ , where  $vector\_type$  is either MTC (Maximal Term Coverage) or MTF (Maximal Term Frequency);
- (3) Minimal sentence overlap  $OBJ_3$ ;
- (4) Maximal bigram sum  $OBJ_4$ .

We conducted the experiments on the MultiLing 2011 (Giannakopoulos et al., 2011) English dataset. MultiLing dataset consists of 10 document sets, 10 documents each one, in seven languages. The original news articles in English were taken from WikiNews<sup>5</sup>, organized into 10 sets, and then summarized. According to the MultiLing summarization task, all systems must generate summaries in size of 250 words at most. Eight systems (ID1-ID8) participated in the pilot and compared to the global baseline (ID9) and the global topline (ID10) systems. Systems A,B and C de-

<sup>4</sup>The software is available upon request.

<sup>5</sup><http://en.wikinews.org/wiki/>

note summaries manually created by human experts. The choice of this dataset is argued by future plans to adapt and evaluate the introduced system to multiple languages.

The automatic summarization evaluation package, ROUGE (Lin, 2004), is used to evaluate the effectiveness of our approach vs. 10 summarizers participated in the MultiLing pilot of the TAC 2011 competition. For fair comparison, only first 250 words<sup>6</sup> were considered in ROUGE statistics. The recall scores of ROUGE- $N$  for  $N \in \{1, 2, 3, 4\}$ , ROUGE- $W$ -1.2, and ROUGE- $SU4$  which are based on  $N$ -gram, Weighted Longest Common Subsequence (WLCS), and Skip-bigram plus unigram, with maximum skip-distance of 4, matching between system summaries and reference summaries, respectively, are reported in Table 2 below.

### 3.1 Experimental Results

As it can be seen from Table 2, our model using unweighted term sum ( $OBJ_1^{POS.EQ}$ ) as an objective function outperforms most of the systems – 6 systems in terms of ROUGE-1, ROUGE-2, ROUGE- $SU4$  and ROUGE- $W$ -1.2, and 8 systems in terms of ROUGE-3 and ROUGE-4. Conversely to our expectations, adding any type of weights to  $OBJ_1$  reduces its performance. Minimizing repetition while increasing terms coverage ( $OBJ_2^{MTC}$ ) shares the same rank with  $OBJ_1^{POS.EQ}$  for most ROUGE metrics. Minimizing distance to a document term frequency vector ( $OBJ_2^{MTF}$ ) performs worse – it outperforms 3, 4, 5, 6, 5 and 3 systems in terms of ROUGE-1, ROUGE-2, ROUGE-3, ROUGE-4, ROUGE- $SU4$  and ROUGE- $W$ -1.2, respectively. Sentence overlap ( $OBJ_3$ ) and maximal bigram sum ( $OBJ_4$ ) have very close scores, outperforming 3, 5, 5, 6, 5 and 3 systems in terms of ROUGE-1, ROUGE-2, ROUGE-3, ROUGE-4, ROUGE- $SU4$  and ROUGE- $W$ -1.2, respectively. Generally, optimizing the most of introduced functions generates the near-quality summaries. All functions perform better than the baseline (ID9) system.<sup>7</sup>

## 4 Conclusions and Future Work

In this paper we present a linear programming model for the problem of extractive summariza-

<sup>6</sup>ROUGE.pl -a -x -2 4 -u -c 95 -e data -r 1000 -n 4 -f A -p 0.5 -t 0 -d -l 250

<sup>7</sup>We did not perform tests of statistical significance due to too many comparisons (10 systems vs. 10 objective functions), leaving it as a future work.

tion. We represent the document as a set of intersecting hyperplanes. Every possible summary of a document is represented as an intersection of two or more hyperplanes. We consider the summary to be the best if the optimal value of objective function is preserved during summarization, and translate the summarization problem into a problem of finding a point on a convex polytope which is the closest to the hyperplane describing the "ideal" summary. We introduce multiple objective functions describing the distance between a summary (a point on a convex polytope) and the best summary (the hyperplane).

Since linear programming problem can be solved in polynomial time (see (Karmarkar, 1984), (Khachiyan, 1996; Khachiyan and Todd, 1993)), the time complexity of our approach is polynomial (quadratic, being more precise).

The results of experiments show that our method outperforms most of the systems participated in the MultiLing pilot in terms of various ROUGE metrics. In future, we intend to (1) improve the system's performance by introducing more objective functions and their combinations, (2) adapt our system to multiple languages, and (3) extend our model to query-based summarization.

## Acknowledgments

Authors thank Igor Vinokur for implementing the introduced approach and performing experiments.

# Detecting Domain Dedicated Polar Words

Raksha Sharma, Pushpak Bhattacharyya

Dept. of Computer Science and Engineering

IIT Bombay, Mumbai, India

{raksha,pb}@cse.iitb.ac.in

## Abstract

There are many examples in which a word changes its polarity from domain to domain. For example, *unpredictable* is positive in the movie domain, but negative in the product domain. Such words cannot be entered in a “universal sentiment lexicon” which is supposed to be a repository of words with polarity invariant across domains. Rather, we need to maintain separate domain specific sentiment lexicons. The main contribution of this paper is to present an effective method of generating a *domain specific sentiment lexicon*. For a word whose domain specific polarity needs to be determined, the approach uses the Chi-Square test to detect if the difference is *significant* between the counts of the word in positive and negative polarity documents. We extract 274 words that are polar in the movie domain, but are not present in the universal sentiment lexicon. Our overall accuracy is around 60% in detecting movie domain specific polar words.

## 1 Introduction

Sentiment analysis (SA) has attracted a great deal of attention in recent times (Hatzivassiloglou and McKeown, 1997; Wiebe, 2000; Pang et al., 2002; Turney, 2002; Yu and Hatzivassiloglou, 2003; Hu and Liu, 2004; Esuli and Sebastiani, 2005; Breck et al., 2007). The SA task is to predict the sentiment orientation of a text (document/para/sentence) by analyzing the polarity of words present in the text. A lexicon of sentiment bearing words is of great help in such tasks.

Sentiment lexicons are of two types: universal and domain specific. Words like ‘good’ and ‘bad’ have uniform polarity across all domains,

and so are members of universal sentiment lexicon. A word like ‘unpredictable’, on the other hand, is positive in the movie domain (‘unpredictable plot’), but negative in the car domain (‘unpredictable steering’). Such a word should be entered as positive in the sentiment lexicon of the movie domain and as negative in the sentiment lexicon of the car domain.

There are many “universal sentiment lexicons” like SentiWordNet<sup>1</sup>, subjectivity lexicon<sup>2</sup> by Wiebe, list of positive and negative opinion words<sup>3</sup> by Liu. These lexica contain only those polar words which have the same polarity in all domains. In this paper, we use the universal sentiment lexicon published by Wiebe.

Using resources like Wikipedia and SentiWordNet to determine polarity of a domain specific word may lead to wrong sentiment detection. The motivation for our work comes from addressing this problem. We would like to create domain specific sentiment lexicons.

Our technique for detecting domain specific polar words is inspired by the work done by Cheng and Zhulyn (2012). They used the Pearson’s Chi-Square test to find the top 200 words most indicative of positive sentiment and the top 200 words most indicative of negative sentiment from the corpus itself. They used these words as the lexicon for the hitting 2-gram language model. They observed that the hitting 2-gram model achieves far greater accuracy than other language models. In their work, they used the categorical Chi-Square test to determine the score of a word with positive sense and negative sense. Their Chi-Square test gives weightage also to those documents in which the word is absent while calculating the score. However, their idea of selecting hitting words, considers multiple occurrences of a word in a single doc-

<sup>1</sup><http://sentiwordnet.isti.cnr.it/>

<sup>2</sup><http://mpqa.cs.pitt.edu/>

<sup>3</sup><http://www.cs.uic.edu/liub/FBS/sentiment-analysis.html>

ument as one. This leads to loss of information that can help in deciding the correct polarity of a word from the corpus. We use the *goodness of fit Chi Square* test, that takes into account the total occurrences of a word in the corpus to assign the score. This test allows us to compare a collection of categorical data with some theoretical expected distribution<sup>4</sup>.

Our proposed method identifies sentiment words from the corpus. Wiebi (2000) observes that the probability of a sentence being subjective given that there is at least one adjective in the sentence is 55.8%. So we presently focus on adjectives. The key idea is that if a word can have both positive or negative polarity, then it should be uniformly distributed between positive and negative files. For this purpose, we take an equal number of positive and negative reviews from the same domain. So, the expected count of the word in positive and negative reviews is half of the total count in the corpus. This is the null hypothesis.

If the word satisfies the Chi-Square test, it indicates that there is a significant difference between the expected and observed count of the word. Hence, the null hypothesis should be rejected and it should be considered that this deviation from expected value is not by chance, but because of the domain specific polarity of the word, which makes the word more frequent in one of positive or negative reviews.

The road map for the rest of the paper is as follows: Section 2 describes the previous work done in the direction of sentiment lexicon. Section 3 elaborates on the generation of domain specific polar words through the Chi-Square test. Section 4 gives the experimental set up. In section 5, we present results along with discussions. We conclude the paper with points for future work in section 6.

## 2 Related Work

Extensive work has been done in the area of universal sentiment lexicon using corpora based approaches. Wiebe (2000) focused on the problem of identifying subjective adjectives with the help of the corpus. They proposed an approach to find subjective adjectives using the results of a method for clustering words according to their distributional similarity, seeded by a small number of simple adjectives. These adjectives were extracted

from a manually annotated corpus. The basic idea is that subjective words are similar in distribution as they share pragmatic usages. However, the approach is unable to predict sentiment orientations of the found subjective adjectives.

Some evidence exists in the area of domain specific sentiment lexicon. The work of Kanayama and Nasukawa [2006], demonstrates the extraction of domain specific sentiment words in Japanese text. They exploited clause level context coherency to find candidate words for domain specific sentiment lexicon from sentences that appear successively with sentences containing a word from the seed set. The seed set is the set of strong universally polar words. The intuition is that sentences appearing in contexts tend to have the same polarities, so if one of them contains sentiment words, the other successive sentences are expected to contain sentiment words too, with the same polarity. Then, they use a statistical estimation based method to determine whether the candidates are appropriate sentiment words. However, the idea of using a seed set to extract purely domain dependent words may lead to wrong polarity.

Qiu et al. (2009) exploited the relationship between sentiment words and product features that the sentiment words modify in a domain dependent corpus. They used sentiment words and product features to extract new sentiment words. The extraction rules are designed, based on relations described in dependency trees. Their method also begins with a seed set. They proposed that a feature should receive the same polarity in a review and the words extracted by this feature will receive polarity of feature. However, the reviewer may associate polarity with a feature of time. If time changes, his views for a feature may change in the same review. To understand this fact consider the following example.

*“When I purchased this camera, the battery was good, but now it is disastrous”.*

Qui et al. (2009) considered ‘camera’, ‘DVD player’, and ‘MP3 player’ as one domain. However, *grainy* and *blurred* are negative in the camera domain, but neutral for ‘DVD’ and ‘MP3 player’. Our work is independent of features and the seed list. It only needs a sufficient equal number of positive and negative review files written by a reliable source.

<sup>4</sup><http://math.hws.edu/javamath/ryan/ChiSquare.html>

### 3 The Proposed Method

In this paper, we focus on finding sentiment words for the movie domain with their polarity as positive or negative. Finding movie domain specific polar words is an appealing task for several reasons. First, providing polarity information about movie reviews is a useful service. Its proof is the popularity of several film review websites<sup>5</sup>. Second, movie reviews are harder to classify than reviews of other products (Turney, 2002) and so is the classification of sentiment words. Our data contains 1000 positive and 1000 negative reviews, all written before 2004<sup>6</sup>. Movie reviews are accompanied by plot descriptions and plot is not a part of the reviewer's opinion of the movie. So presence of polar words in plot description can mislead the Chi-Square test. To solve this problem, we clean the corpus by removing the plot description from reviews, before giving it as an input to the Chi-Square test. Cleaning of the corpus is done automatically by finding patterns for plot description in movie reviews. In this paper, we perform the Chi-Square test with adjectives extracted from both cleaned and non cleaned corpus. The orientation of polarity of the output sentiment words are predicted simultaneously.

#### 3.1 Sentiment Word Extraction and Polarity Assignment

The key idea is that if a word does not belong to a particular class, then it should be uniformly distributed among all classes. So, before starting the test, we consider a null hypothesis. A null hypothesis states that if a given word is neutral, its chance to occur in positive and negative documents is equal. The value of a null hypothesis is equal to the arithmetic mean of the word count in positive and negative documents. This can also be considered as the expected count of words in both the classes of documents. We apply the Chi-Square test on the expected count and the actual observed count of the word. Deciding the polarity of words, that are used very rarely in corpus, is not worth considering. Since, if a word is polar, then it will occur frequently in polar documents. So we give only those words as input to the Chi-Square test, whose mean value is greater than 6. If the Chi-Square test results in a value, which is

greater than the threshold value, then there is a significant difference between the expected and the observed count of the word. At this moment we reject the null hypothesis and consider the possibility that there is some other factor causing the observed count to differ from the expected count of words. This factor is nothing but the polarity of adjectives, which makes it appear in a particular type of documents, frequently. If the word has positive sentiment, then it will occur more frequently in positive documents. Consider the following example.

*mesmerizing, unpredictable, thrilling, non-stop*

Negatively polar words occur more frequently in negative documents. Consider the following example.

*juvenile, predictable, underwritten, murky*

The extraction approach is best described in Algorithm 1.

The Bidirectional Stanford POS tagger<sup>7</sup> is used to tag words from the corpus with parts of speech. Experiments are performed with different thresholds for the Chi-Square value of the adjective.

#### 3.2 Cleaning of Corpus

In the movie domain, reviewers feel free to describe the plot of the movie as part of the review for a better understanding of it. So, in the movie domain, the *cleaning of the corpus* is mandatory because the polar words which are present in the plot part may mislead the classifier. However, cleaning of the corpus is not required in other domains, for example, *Camera* and *Cell Phones*. We find patterns that represent plot description in the corpus.

- Some reviewers have explicitly divided reviews into two parts - one for review and another for the movie plot - under different titles. It is shown in table 1.
- Some reviewers have specified that the *review contains spoilers*.
- We are performing experiments with the *English* movie review corpus, so movie names

may overlap with adjectives, for example, *unhappy birthday*, *13th warrior*. In a few places in reviews, movie names are given inside *double quotes*.

We find such files that match the pattern described above automatically and delete the found pattern.

## 4 Experimental Setup and Discussion

We use customer review collection as input data. The collection contains 1000 positive reviews and 1000 negative reviews. Experiments are done with cleaned and non cleaned corpora. We perform experiments with three threshold values 1.07, 2.45, 3.84. The threshold value specifies the minimum

Plot Part	Review Part
Plot	Critique
Synopsis	Comment
Synopsis	Reviews
Ingredient	Opinion

Table 1: Parts of a Review

probability<sup>8</sup> to accept a null hypothesis. For example, a threshold value of 1.07 indicates that there must be more than a 30% probability, to accept a null hypothesis. If the Chi-Square value of a word is greater than 1.07, we can conclude from the Pearson Chi-Square probability table that there is less than 30% probability, to accept a null hypothesis. Hence, reject the null hypothesis and consider word as candidate for sentiment lexicon.

1.07 also classifies boundary words, whose sentiment is not very clear from the corpus. Boundary words are those words that have almost equal occurrence in positive and negative documents, since they occur less frequently in the whole corpus. So such words fail to qualify the Chi-Square test with higher threshold values, but are actually polar. With threshold values, 2.45, 3.84 we get an increment in precision at the cost of leaving some boundary words unclassified.

In one of the experiments, we were able to retain words with poor Chi-Square value and higher threshold, that is-3.84, with the help of universal sentiment lexicon. Universal sentiment lexicon contains words which are strongly polar independent of the domain(Wilson et al., 2005). If a word has been rejected by the Chi-Square test with a threshold of 3.84, and it belongs to universal sentiment lexicon, then the correct polarity of the word can be derived from universal sentiment lexicon. Consider the following examples.

*Distracting* gets a Chi-Square value 2.0 but certainly negative in all domains.

*Monotonous* gets a Chi-Square value 2.25 but certainly negative in all domains.

## 5 Results and Discussion

Since there is no gold standard sentiment lexicon for the movie domain, the quality of output obtained through the Chi-Square test is confirmed by the inter annotators agreement. We ex-

<sup>8</sup><http://faculty.southwest.tn.edu/jwilliams/probab2.gif>

tracted 11,828 adjectives from corpus as candidates for lexicon. Among them 932 adjectives fulfill the Chi-Square test on non-cleaned corpus with threshold 1.07. **476 adjectives** are marked as true positives by **inter annotators agreements**. Table 2 shows the precision obtained with non cleaned corpus. With a threshold of 1.07, we get a precision of 51%. This result is affected by the words that occur in the plot description. Words which are part of the plot description mislead the classifier, causing low precision. Table 3 shows an improvement in precision with the cleaning of the corpus. The Chi-Square test with a threshold of 3.84, and universal sentiment lexicon gives a very high precision, that is 69.1%.

With a small threshold of 1.07, we are able to fetch almost all the words from the corpus that can be candidates for sentiment lexicon in the movie domain. With this intuition, we use true positives (476) and false positives (456) extracted by the Chi-Square test with threshold of 1.07 on the non cleaned corpus as a gold standard data to calculate recall and accuracy for experiments whose results are shown in table 3.

Data Set	Threshold	Precision
Non-Cleaned Corpus	1.07	51.07%
Non-Cleaned Corpus + Universal Sentiment Lexicon	3.84	69.1%

Table 2: Precision of the Chi-Square test with a non-cleaned Corpus

Table 3 shows results of precision, recall with increasing threshold values for the Chi-Square test.

Threshold	Precision	Recall
1.07	54%	100%
2.45	59%	82%
3.84	61%	65%

Table 3: Precision of the Chi-Square test with a cleaned Corpus

Table 3 shows that, as the value of the threshold increases, the precision increases. However, recall decreases. Figure 1 shows the accuracy obtained with different Chi-Square threshold values. The words which have a good Chi-Square score

are strong candidates for sentiment lexicon. But the words which are actually polar in the movie domain, but have been used very occasionally by reviewer, get rejected with an increase in the value of the threshold.

Figure 1: Chi-Square Test Accuracy with Different Thresholds

From figure 1, we can observe that accuracy is highest with a threshold of 2.45. When we move towards a higher threshold values, accuracy starts decreasing because of the higher fall in recall.

## 6 Conclusion

In this paper, we proposed a scheme to detect domain-dedicated sentiment words from the corpus. Our algorithm identifies polar words through an innovative application of Chi-Square test on the difference in the counts of the word in positive and negative documents. We extract a list of words that are polar in the movie domain, but cannot be in a universal sentiment lexicon. Our work is important because without incorporation of such domain specific polar words, the recall of a sentiment analysis system deteriorates. Experimental results show that our proposed method is promising and can be implemented for any domain. Our future work will focus on improving the precision by incorporating the effects of conjunction and negation.

## Abstract

Text mining studies have started to investigate relations between positive and negative opinions and patients' physical health. Several studies linked the personal lexicon with health and the health-related behavior of the individual. However, few text mining studies were performed to analyze opinions expressed in a large volume of user-written Web content. Our current study focused on performing sentiment analysis on several medical forums dedicated to Hearing Loss (HL). We categorized messages posted on the forums as *positive*, *negative* and *neutral*. Our study had two stages: first, we applied manual annotation of the posts with two annotators and have 82.01% overall agreement with kappa 0.65 and then we applied Machine Learning techniques to classify the posts.

## 1 Introduction

Natural language statements can be divided into two categories: factual and emotional. Factual statements can be expressed with a few topic keywords, while emotional statements express sentiments of the statement's author and require a more complex analysis than the factual ones.

Sentiment Analysis is often regarded as classifying and identifying the subjective information in the natural language text. In its application, Sentiment Analysis aims to detect the sentiments (e.g., opinions and emotions) of the speaker of the statement. Sentiments are characterized by polarity, intensity, strength and immediacy.

In the current study, we focus on the polarity of sentiments that are expressed in messages posted on medical forums. Polarity can be binary (e.g., positive vs. negative) or multi-categorical (e.g., positive, negative and unknown). Below we list examples found in online discussions about hearing aids.

## Positive<sup>1</sup>

*This has the beneficial effect of making the quieter sounds audible but not blowing your head off with the louder sounds.*

## Neutral/Unknown

*Now, you'll hear some people saying that compression is bad, and linearity is good, especially for music.*

## Negative

*Someone with 50 DB hearing aid gain with a total loss of 70 DB may not know that the place is producing 107 DB since it may not appear too loud to him since he only perceives 47 DB.*

In this work, we classified the subjective sentences into positive, negative and neutral. We have identified different syntactic features, i.e., patterns / rules (Yi and Nasukawa, 2003) which can indicate subjectivity and polarity of the sentences. The dataset of 3515 sentences from 26 threads were manually annotated by two annotators having overall agreement of 82.01% and kappa 0.65 which indicates substantial agreed data.

Our experiments with different combinations of features using different classifiers have shown significant improvement in performance over the baseline. For example, with the Naïve Bayes classifier, the F1-score was 10.5% better.

The rest of the paper is organized as follows: we discuss the sentiment analysis of health-related online messages, then we introduce our data; next we discuss the Subjectivity Lexicon and the features we use to represent the data, the analysis of the manual annotation and the machine learning classification results, before we conclude the presentation.

---

<sup>1</sup>All textual examples keep the original spelling and grammar.

## 2 Related Work

Very little work has been done in sentiment analysis on health-related forums. In (Goeuriot et al., 2012), the authors have built a medical domain lexicon in order to perform classification on a dataset that they collected from a website called Drug Expert. The dataset contains user reviews on drugs with ratings from 0 to 10 (Negative to positive) and they achieved F-score of 0.62 for the positive class, 0.48 for the negative class and 0.09 for the neutral class. The authors have performed the polarity detection on this dataset which already contains subjective information (opinions) about users' experience with particular drugs. However, in our case, we have extracted messages from health forums which contain mixed subjective and non-subjective information.

Users express their sentiments differently on forums compared to the way they express opinions when providing reviews or sharing messages on social networks. Bobicev et al. (2012) have analyzed sentiments in Twitter messages using some statistical features based on the occurrence and correlation among words with the class labels of the training set. However, we have identified the correlation of phrases within sentences for predicting subjectivity and polarity.

## 3 Building the Dataset

Surgeries related to HL are the most common surgeries in North America; thus, they affect many patients and their families.

However, there are only a few health forums dedicated to Hearing Loss (HL). Hence, we did not have an access to a high volume of data. Also, we need forum discussions, i.e., threads, which consist of more opinionated messages rather than questions and answers about the medical problems.

For the sentiment analysis, we have chosen a critical domain of HL problems: opinions about Hearing Aids. To the best of our knowledge, no relevant previous work was done in this area. For our dataset, we have collected individual posts from 26 different threads on three health forums<sup>2</sup>.

### 3.1 Data Description

The initial collection of data contains about 893 individual posts from 34 threads. They were

extracted using the XPath query by using the Google Chrome extension "XPathHelper".

This data was filtered and reduced to 607 posts in 26 threads (Table 1), by removing the threads where people discussed the factual information about a specific problem or disease and which do not contain any sentiments or opinions. Statistics, like average posts per person, were measured for filtering the data. For example, threads with more than 100 posts were removed, as threads with a large number of posts deviated from the main topic of discussion.

	Threads	Posts	Avg. posts per person
www.hearingaidforums.com	7	185	2.9
www.medhelp.org	9	105	2.77
www.alldeaf.com	10	317	1.93
Total	26	607	2.53

**Table 1. Filtered dataset collection statistics**

We split the data from individual threads into sentences using our version of a regular expression-based sentence splitter. We partly removed noise from the text by removing sentences containing very few words (i.e., less than 4 in our case). The remaining sentences from the 26 threads were manually annotated by two independent annotators into three classes (Positive, Negative and Neutral/Unknown).

## 4 Subjectivity Lexicon

For our experiments, we used the Subjectivity Lexicon (SL) built by Wilson, Wiebe, and Hoffman (2005). The lexicon contains 8221 subjective expressions manually annotated as strongly or weakly subjective, and as positive, negative, neutral, or both. We have chosen this lexicon over other large automatically-generated dictionaries like SentiWordNet (Baccianella, Esuli, and Sebastiani, 2010), as it has been manually annotated and provides rich information with the subjectivity strength and prior polarity for each word considering the context of the word in the form of part of speech information.

The quality of this Subjectivity Lexicon is higher than the quality of other large automatically generated dictionaries; for example, SentiWordNet includes more than 65,000 entries. Some papers (Taboada et al., 2011) have shown that larger dictionaries contain information which is not detailed and include more words which may lead to more noise.

<sup>2</sup> <http://www.medhelp.org>, <http://www.alldeaf.com>, <http://www.hearingaidforums.com>

Below is a sample entry from the lexicon:

*type=weaksubjen=1 word1=ability pos1=noun stemmed1=n priorpolarity=positive*

This entry contains the term *ability*, which is a noun. Its length is 1 (single term); it is not stemmed; it is weakly subjective and positive.

	Posi- tive	Nega- tive	Neu- tral	Bot h	Total	Per- cent
Adjec- jec- tive	1171	1838	235	5	3249	39.52
Noun	677	1346	144	3	2170	26.40
Verb	380	869	68	8	1325	16.12
any- pos	362	676	104	5	1147	13.95
Ad- verb	128	183	19	0	330	4.01
Total	2718	4912	570	21	8221	100
Per- cent	33.06	59.75	6.93	0.26	100	

**Table 2. Distribution of prior polarities within Subjectivity Lexicon**

The Subjectivity Lexicon contains only single term expressions. Table 2 shows that about 60% of the words are negative and 33% are positive. Also, this resource contains 40% adjectives, 26.4% nouns, 16.12% verb, 13.95% anypos (could be in any part of speech) and only 4% adverbs. Table 3 shows that about 67.74% of the words are strong subjective and the rest of 32.2% are weak subjective in nature.

	Strong Subj	Weak Subj	Total	Percent
Adjective	2006 (61.74%)	1243 (38.25%)	3249	39.52
Noun	1440 (25.85%)	730 (33.6%)	2170	26.40
Verb	861 (15.46%)	464 (35.01%)	1325	16.12
Anypos	1043 (18.72%)	104 (9.06%)	1147	13.95
Adverb	219 (3.93%)	111 (33.6%)	330	4.01
Total	5569	2652	8221	100
Percent	67.74	32.26	100	

**Table 3. Distribution of subjectivity clue within the Subjectivity Lexicon**

The lexicon contains only 21 words having polarity “both”. Out of these 21, only 10 words

were found unique with their part of speech. As these both polarity words are neutral in our case, we decided to merge them with the neutral words. Table 4 shows the relation between strong and weak subjectivity with the polarity lexicon.

	Strong Subj	Weak Subj	Total	Percent
Positive	1717 (30.8%)	1001 (37.74%)	2718	33.06
Negative	3621 (65%)	1291 (48.6%)	4912	59.75
Neutral	231 (4.14%)	360 (13.57%)	591	7.18
Total	5569	2652	8221	100
Percent	67.74	32.26	100	

**Table 4. Distribution among subjectivity and polarity in the lexicon**

## 5 Methodology

In this work, we have used several different features for the sentiment analysis of the sentences. Section 4.2 lists all these features. These features are computed and presented for each sentence in a data file format used by the WEKA tool (Hall et al., 2009). Classification is performed based on the computed features and accuracy is measured using different combinations of features in order to improve the classification performance.

### 5.1 Parts of Speech in Lexicon Matching

Words can have different polarity when they represent different parts of speech; e.g., novel is positive when it is in adjective form; however it is a neutral as a noun. To minimize this problem, we have matched the words in the lexicon with their part-of-speech information. That helped us to use the correct polarity and subjectivity indication considering the correct part of speech.

#### Nouns

In our lexicon, nouns have the second most coverage, with 26.4%.

#### Verbs

Verbs are the next common in the lexicon and give good indication of subjectivity. However, as verbs are used in many different forms and have many meanings, just relying on the verb polarity will misguide the prediction in cases where the verbs are used in some other senses, e.g., *he uses a car* is neutral, when *he was used* has a negative sense.

## Lemmatization

For all nouns and verbs, we have used the lemmatization from the GATE<sup>3</sup> morphological plugin, which provides the root word. In case of nouns, the root word is the singular form of the plural noun, e.g., *bottles* become *bottle*, etc. In the case of verbs, the plugin provides the base form for infinitive, e.g., *helping* becomes *help*, and *watches* become *watch*. After performing lemmatization, we found 158 more words that were detected with the same part of speech considered as the original. There were still 175 words which were found with the root word in the lexicon, but with different part of speech, e.g., *senses* was used as noun in the data; after lemmatization it becomes *sense*, which exists as verb in the lexicon. Therefore it cannot be matched, as the context and meaning of the word is different.

## Adjectives

Early research in sentiment analysis focused mainly on adjectives and phrases containing adjectives, e.g., *what a blessed relief*. Adjectives are good indicators for the positivity or negativity of the sentences, but they are not sufficient for identifying the subjectivity in the sentences, as we will see in the experiments.

## Adverbs

Adverbs are words that modify the verbs, adjectives and other phrases or clauses, e.g., *I am usually a contributing adult, and am happily sane and I say whoa how did that happen?* Adverbs have the lowest concentration in the lexicon, only 4%, and as many adverbs are identified by their characteristic "ly" suffix, we have removed the suffix-ly and then matched the new word in the lexicon by considering it as adjective. In English, most of the adverbs with suffix -ly such as *badly, softly, carefully, extremely* are forms of adjectives; therefore considering these provides better results in predicting the polarity of words in their correct senses.

## Features

All the features considered for the experiment are based on sentence level. Table 5 shows the final features selected for the experiments. The most common features were pronouns, followed by weak subjective clues, adjectives, and adverbs. There were more words that matched with the lexicon's positive words than those that

matched with the lexicon's negative words. This led to classifier's performance become slightly better for positive in the experiments.

STRONGSUBJ	# of words found as strong subjective in current sentence
WEAKSUBJ	# of words found as weak subjective in current sentence
ADJECTIVE	# of adjectives
ADVERBS	# of adverbs
PRONOUN	# of pronouns
POSITIVE	# of words found having prior polarity as positive
NEGATIVE	# of words found having prior polarity as negative
NEUTRAL	# of words found having prior polarity as neutral
PRP_PHRASE	# of phrases containing pronouns found in current sentence

**Table 5. Final features considered for the experiments**

## 6 Sentiment Categories

The dataset of 3515 sentences from 26 threads were manually annotated by two annotators. The annotators were asked to tag each sentence into positive, negative and neutral (where both positive and negative sentiments are discussed). All the sentences which do not contain any opinions are left blank and they are removed, as we focus on sentences containing sentiments. According to Table 6, annotator1 and annotator2 did not label a large number of sentences, i.e., 2939 and 2728, respectively; therefore these sentences are removed. Due to the large number of unlabeled sentences, the data is reduced, as we consider only those sentences labeled as positive, negative and neutral. Since the positive and negative dataset is already balanced, no data balancing is performed.

Annotator 2	Annotator 1				Total
	Pos	Neg	Neut	No Label	
Pos	226				329
Neg		214			296
Neutral			117		162
No Label				2720	2728
Total	230	218	128	2939	3515

**Table 6. Annotations statistics of Sentences between the two annotators**

<sup>3</sup><http://gate.ac.uk/sale/tao/splitch21.html#x26-52600021.11>

The overall agreement for the two datasets is computed through the commonly used kappa statistic to evaluate the agreement ratio between the two annotators, in the same form used in (Sokolova & Bobicev, 2011):

$$\text{kappa} = \frac{\frac{a+d}{N} - \frac{f_1g_1+f_2g_2}{N^2}}{1 - \frac{f_1g_1+f_2g_2}{N^2}}$$

The overall percentage agreement between the annotators for the positive/negative dataset was 82.01% and kappa was 0.65. This indicates a substantial agreement between the taggers.

Positive / Negative dataset									
	Naïve Bayes			SVM			Logistics-R		
	P	R	F-1	P	Re	F-1	P	R	F-1
<b>positive, negative</b>	0.656	0.65	<b>0.644</b>	0.661	0.641	<b>0.625</b>	0.649	0.645	<b>0.641</b>

**Table 8. Comparison of performance with lemmatization between different features among three classifiers for both datasets**

## 7 Experiments

The output files generated by the system for the dataset are classified using the WEKA tool (Hall et al., 2009). For our evaluation, we used 10-fold cross validation which is a standard classifier selection for classification purpose. Experiments were performed using three different classifiers: Naïve Bayes, because it is known to work well with text, support vector machine (SVM) because of its high performance in many tasks, and logistic regression (logistic-R), in order to try one more classifier based on a different approach.

Performance was evaluated using the F1-measure between the three classifiers on the given datasets. We found that the performance of logistics regression was the best on the features selected for our evaluation.

For the baseline, the feature vector of bag of words is considered for both the datasets. We have not considered the unique words for the bag

of words because eliminating the words that appeared only once halves the size of the vectors, thus it makes it easier for the classifier to handle bag-of-words; also the unique words do not contribute much in classification since they appear only once, in one class. Table 7 shows significant improvement with positive, and negative features over the baseline and the difference was much higher with Naïve Bayes and SVM than with logistic-R, i.e., 10.5%, 3.9% and 5.7%, respectively.

In Table 8, for the positive/negative dataset, the classifiers Naïve Bayes and SVM underperformed with the lemmatization and their best performance decreased by 3.7% and 4.7%, respectively. However, the performance of logistic-R increased significantly, by 4.4%, and its F1-measure reached 68.5%, which indicates the benefit of lemmatization in matching within the lexicon.

## 8 Analysis

The results from the experiments have provided several insights about the sentiment analysis in health-related forums. Note that the bag-of-word representation (BOW) is a high baseline that is hard to beat in many texts classification problems. The Subjectivity Lexicon clues for polarity such as positive, negative and neutral have shown significant improvement for the identification of positive and negative sentences. As a result, the performance has increased by 4.2% on average among the three classifiers.

We have noticed that for the semantic orientation of the sentences, the combination of lexicon clue features with other basic counting features such as the number of adjectives, the number of adverbs, etc., decreased the performance of classification, as all the three classifiers have performed best with only positive and negative features.

Our results are comparative to other related studies for sentiment classification of medical forums. Sokolova & Bobicev (2011) achieved the best F-score of 0.708 using SVM; similarly Goeuriot et al. (2012) for drug reviews achieved F-score of 0.62 for the positive class, 0.48 for the negative class and 0.09 for the neutral class.

In general, for consumer reviews, opinion-bearing text segments are classified into positive and negative categories with Precision 56%–72% (Hu & Liu 2004). For online debates, the complete texts (i.e., posts) were classified as positive or negative stance with F-score 39%–67% (Somasundaran & Wiebe, 2009); when those posts were enriched with preferences learned from the Web, the F-score increased to 53%–75%.

It is also noted that the classification for semantic orientation depends heavily on the quality of the lexicon used, rather than the size of the lexicon, as the results show that the classification of the sentences into positive and negative reached 70% by using only the polarity clues for individual words within the lexicon.

## 9 Conclusion and Future Work

In this work, we performed the sentiment analysis of sentiments expressed in online messages related to Hearing Loss.

We used several lexicon-based features together with rule-based features like pronoun phrases for our classification of the dataset for detecting semantic orientation within the subjective data us-

ing different features based on the subjective lexicon.

The dataset of 3515 sentences from 26 threads were manually annotated by two annotators and achieved 82.01% overall agreement with kappa 0.65. Evaluations have been made for the classification of the substantial agreed data using three different supervised learning-based classifiers and it is shown that our proposed features outperformed the baseline of bag-of-word features by 10.5% with Naïve Bayes, 3.9% with SVM and 5.7% with logistic-R.

In future work, we could consider several directions. The lexicon could be improved, as the domain lexicon created in (Goeuriot et al., 2012) has shown better results over other dictionaries for polarity detection of the sentences.

Also, techniques and features presented in (Taboada et al., 2011), (Kennedy and Inkpen, 2006) such as intensification (e.g., *very good*) increase the polarity of *good* and negation (e.g., *not good*) which reverses the polarity of *good*, can be used for the semantic orientation or polarity detection of the sentences.

Another direction for future work could be to investigate changes of sentiments in threads. We want to analyze what linguistic events may prompt polarity to reverse (e.g., from *positive* to *negative*) and under what conditions the same polarity is sustained. To the best of our knowledge, this task was not addressed before.

## Acknowledgments

This work in part has been funded by a Natural Sciences and Engineering Research Council of Canada Discovery Research Grant and by a Children's Hospital of Eastern Ontario Department of Surgery Research Grant.

## Abstract

Emotion is an instinctive state of mind aroused by some specific objects or situation. Exchange of textual information is an important medium for communication and contains a rich set of emotional expressions. The computational approaches to emotion analysis in textual data require annotated lexicons with polarity tags. In this paper we propose a novel method for constructing emotion lexicon annotated with Ekman's six basic emotion classes (anger, disgust, fear, happy, sad and surprise). We adopt the Potts model for the probability modeling of the lexical network. The lexical network has been constructed by connecting each pair of words in which one of the two words appears in the gloss of the other. Starting with a small number of emotional seed words, the emotional categories of other words have been determined. With manual checking of top 200 words from each class an average precision of 85.41% has been achieved.

## 1 Introduction

Sentiment analysis and classification from electronic text is a hard semantic disambiguation problem (Das and Bandyopadhyay, 2010). Many recent researches have been conducted in the fields of sentiment extraction (Kim et al., 2012; Taboada et al., 2011), opinion mining, summarization (Aman and Szpakowicz, 2007; Das et al., 2012; Yang et al., 2007; Quan and Ren, 2010) and each of which has a variety of potentially valuable applications. For example, we can efficiently collect people's opinion on a new rule

enforced by the Government from Blog sites and at the same time be able to grasp their emotion without having to read their comments. An imperative resource for such kind of emotional analysis is an emotion lexicon annotated with several emotional classes like *happy*, *sad*, *fear*, *anger*, *surprise* and *disgust*. In the previous example, frequent appearance of words from the *happy* class in a blog document would imply that the writer of the comment is quite happy with the new rule proposed by the Government.

Several works have been conducted on building emotional corpora in different languages such as in English (Aman and Szpakowicz, 2007), Chinese (Yang et al., 2007; Quan and Ren, 2010), and Bengali (Das and Bandyopadhyay, 2010) etc. All these works have focused on developing sentiment lexicon with three sentiment classes. For instance, Takamura et al. (2005) have developed a lexicon of emotion words tagged with the classes *desirable* and *undesirable* using Spin model. A number of other polarity sentiment lexicons are available in English such as SentiWordNet 3.0 (Esuli et al., 2010), Subjectivity Word List (Wilson et al., 2005), WordNet-Affect list (Strapparava et al., 2004), Taboada's adjective list (Taboada et al., 2006). On the other hand, several polarity sentiment lexicons have been developed in different languages like Hindi, Bengali and Telegu (Das and Bandyopadhyay, 2010), Japanese (Torii et al., 2012) etc.

Among all these publicly available sentiment lexicons, SentiWordNet is one of the well-known and widely used ones (number of citations is higher than other resources<sup>1</sup>), having been uti-

---

<sup>1</sup> <http://citeseerx.ist.psu.edu/index>

lized in several applications such as sentiment analysis, opinion mining and emotion analysis.

Undoubtedly, manual compilation is the best way to create such an emotion lexicon but is much expensive in terms of time and human effort. Thus, the objective of the present paper is to develop a method for automatically creating such a list of words from the glosses of a dictionary, as well as from a thesaurus and a corpus. For this purpose, we have used the *Potts model*, a probabilistic model for lexical network. In the lexical network, each node has one of the three orientation values and the neighboring nodes tend to have the same value. For each of the emotion classes, we estimate the states of the nodes indicating the semantic orientation of each class. However, the proposed method does not deal with words that do not appear in the lexical network.

We have classified the words into six emotion classes using Potts model. First, the manual evaluation has been done to get the accuracies. Then we have automatically calculated accuracies comparing with the WordNet Affect list. We have also classified the words into two classes (positive and negative) and the accuracy is evaluated using the SentiWordNet. The generated emotion lexicon in English also contains the parts of speech (adjective, adverb, noun and verb) information of the emotion words as well as their emotional classes.

The rest of the paper is organized in the following manner. Section 2 discusses briefly the resources available till date. Section 3 provides an overview on Potts model. Section 4 describes the implementation of Potts Model for the construction of our emotion lexicon. Section 5 presents the experiments with detail analysis. Finally, conclusions are drawn and future directions are presented in Section 6.

## 2 Related Work

Takamura et al. (2005) extracted semantic orientation of words according to the spin model, where the semantic orientation of words propagates in two possible directions like electrons. Electrons propagate their spin direction to neighboring electrons until the system reaches a stable configuration. They have constructed a lexical network by connecting pairs of words. In each pair either word appears in the gloss of the other. They have applied spin model iteratively till energy of the system is minimized.

Esuli and Sebastiani's (2006) approach to develop the SentiWordNet is an adaptation to synset classification based on the training of ternary classifiers for deciding positive and negative (PN) polarity. Each of the ternary classifiers is generated using the Semi-supervised rules.

Strapparava and Valitutti (2004) developed the WORDNET-AFFECT, a lexical resource that assigns to a number of WORDNET synsets one or more affective labels such as emotion, mood, trait, cognitive state, physical state, behavior, attitude and sensation etc. They have prepared a preliminary resource named as AFFECT, then projected part of the affective information from the AFFECT database onto the corresponding senses of WORDNET-AFFECT.

Das and Bandyopadhyay, (2010) created the SentiWordNet for Indian Languages like Hindi, Bengali and Telegu by multiple computational approaches like WordNet based, dictionary based, corpus based or generative approaches. They have used the Bilingual corpus and generated the SentiWordNet(s) for the Indian languages from the English sentiment lexicon merged from the English SentiWordNet and the Subjectivity Word List.

Das et al., (2012) presented a task of developing an emotion lexicon. A lexical network has been developed on the freely available ISEAR dataset using the co-occurrence threshold. They classified words into seven categories, i.e., *anger, disgust, fear, guilt, joy, sadness* and *shame*. SVM and Fuzzy C-mean classifier have been used for the classification. They also computed the precision of top 100 words and reported 95% precision for seven emotion classes.

## 3 Potts Model

We have employed the Potts model which is a generalization of Ising model (Nishimori, 2001). If a variable has more than two values and there is no ordering relation between the values, such network is called a Potts Model (Wu, 1982). Potts model has been a subject of increasing research interest in the recent years. In this section we present the mathematics of Potts model. Potts model has been used in several applications such as extraction of semantic orientations of phrases from dictionary (Takamura et al., 2007).

It has been observed that the types of similarity or prior polarity scores do not completely solve the problem of classifying emotional words. In fact, finer details are revealed by so-called contextual polarity classification, because

the same textual content can be presented with different emotional slants (Grefenstette et al., 2005). For example, the word ‘succumb’ can trigger a mix of multiple emotions: ‘fear’ as well as ‘sad’. Considering word-wise emotion identification as a multi-label text classification problem, we deploy a Potts model based classification technique.

### 3.1 Introduction to Potts Model

Suppose a network of nodes and weighted edges is given. The states of the nodes are collectively represented by  $n$ . The weight between nodes  $i$  and  $j$  is represented by  $w_{ij}$ .

The energy function is represented as  $H(n)$ , which indicates the state of the whole network:

$$H(n) = -\beta \sum_{ij} w_{ij} \delta(n_i, n_j) + \alpha \sum_{i \in L} -\delta(n_i, a_i)$$

where  $\beta$  is a constant called *the inverse-temperature*,  $L$  is the set of the indices for the observed variables,  $a_i$  is the state of each observed variable indexed by  $i$ , and  $\alpha$  is a positive constant representing a weight on labeled data. Function  $\delta$  returns 1 if two arguments are equal to each other, 0 otherwise. The state is penalized if  $n_i$  ( $i \in L$ ) is different from  $a_i$ . Using  $H(n)$ , the probability distribution of the network can be represented as  $P(n) = \exp\{-H(n)\}/Z$ , where  $Z$  is a normalization factor.

However, it is computationally difficult to exactly estimate the state of this network. We resort to a mean-field approximation method. In the method,  $P(n)$  is replaced by factorized function  $\rho(n) = \prod_i \rho_i(n_i)$ . Then we can obtain the function with the smallest value of the variational free energy:

$$\begin{aligned} F(n) &= \sum_n P(n)H(n) - \sum_n -P(n) \log P(n) \\ &= -\alpha \sum_i \sum_{n_i} \rho_i(n_i) \delta(n_i, a_i) \\ &\quad -\beta \sum_{ij} \sum_{n_i, n_j} \rho_i(n_i) \rho_j(n_j) w_{ij} \delta(n_i, n_j) \\ &\quad - \sum_i \sum_{n_i} -\rho_i(n_i) \log \rho_i(n_i) \end{aligned}$$

By minimizing  $F(n)$  under the condition that  $\forall_i, \sum_{n_i} \rho_i(n_i) = 1$ , we obtain the following fixed point equation for  $i \in L$ :

$$\rho_i(n) = \frac{\exp(\alpha \delta(n, a_i) + \beta \sum_j w_{ij} \rho_j(n_j))}{\sum_m \exp(\alpha \delta(m, a_i) + \beta \sum_j w_{ij} \rho_j(m))}$$

The fixed point equation for  $i \notin L$  can be obtained by removing  $\alpha \delta(n, a_i)$  from above.

This fixed point equation is solved by an iterative computation. After the computation, we obtain the function  $\prod_i \rho_i(n_i)$ . When the number of classes is two, the Potts model in this formulation is equivalent to the mean-field Ising model (Nishimori, 2001).

## 4 Potts Model for Construction of Emotional Lexicon

In this section we describe the methodologies adopted to develop the emotional lexicon wherein words are classified into six emotional classes.

### 4.1 Constructing Lexical Networks

We have constructed a lexical network which has been termed as gloss network (Takamura et al., 2005). This network is developed by linking two words if one appears in the gloss of other word. Each link belongs to one of the two groups: same orientation links (SL) and different orientation links (DL). If at least one word precedes a negation word (e.g., not) in the gloss of the other word, the said link is considered as a different-orientation link. Otherwise the link is a same-orientation link. Lexical Network contains 88015 words collected from the dictionary. Statistics of the lexical network is shown in Table 1. Next, we assign weights  $W = (w_{ij})$  to links as follows:

$$w_{ij} = \begin{cases} \frac{1}{\sqrt{d(i)d(j)}} & (e_{ij} \in SL) \\ -\frac{1}{\sqrt{d(i)d(j)}} & (e_{ij} \in DL) \\ 0 & otherwise \end{cases}$$

where  $e_{ij}$  denotes the link between word  $i$  and word  $j$ , and  $d(i)$  denotes the degree of word  $i$ , which is actually the number of words linked with word  $i$ . Two words without a connection are regarded as connected by a link of weight 0.

Class	No. of words
Adjective	20497
Adverb	3751
Noun	55285
Verb	8482

Table 1. Statistics of Lexical network

We have also constructed another network, *the gloss thesaurus network (GT)*, by linking syno-

nyms, antonyms and hypernyms, in addition to the above linked words. Only antonym links are in DL.

We enhanced the gloss-thesaurus network with co-occurrence information extracted from corpus. Hatzivassiloglou and McKeown (1997) focused on conjunctive expressions such as “simple and well-received” and “simplistic but well-received”, where the former pair of words tend to have the same semantic orientation, and the latter tend to have the opposite orientation. Following their method, we connect two adjectives if the adjectives appear in a conjunctive form in the corpus. If the adjectives are connected by “and”, the link belongs to SL. If they are connected by “but”, the link belongs to DL. We call this network the *gloss-thesaurus-corpus network (GTC)*. We have used *gloss-thesaurus-corpus network* in our experiments.

## 4.2 Classification of Words

Takamura et al., (2007) used the Potts model for extracting semantic orientation of phrases (pair of adjective and a noun): positive, negative or neutral. In contrast to that, we have used the Potts model for identifying the emotional class (es) of a word.

We have used one seed word from each class to start with the experiment. Each seed word is assigned a class manually. We therefore estimate the state of nodes in the lexical network for each class of emotions. The only drawback is that, it could not assign any emotional class to a word which is not present in the lexical network. These words may be referred to as *unseen words*.

The reason of choosing Potts model over Ising model is that Ising model is helpful for modeling a system involving two classes only (i.e. positive and negative), whereas Potts model can be modeled for more than two classes.

## 5 Evaluation

We performed our experiments with different values of  $\beta$ , ranging from 0.5 to 1 with an interval of 0.1 and achieved best result for  $\beta = 0.9$ . We also performed experiments with different set of seed words. Fixed seed words are used with different  $\beta$  values. We prepared three lists of seed words containing 6, 12 and 18 words respectively. They were prepared by picking 1, 2 or 3 words from each emotional class respectively.

We have classified the words into six emotional classes with different seed words and dif-

ferent values of  $\beta$ . Then the accuracies were computed manually as well as using the WordNet Affect lexicon. We also classified the words into two classes, i.e. positive and negative. The accuracies of two classes were calculated using the SentiWordNet.

Classes (Manually checked)	Precision (in %age)
Happy (200)	80.0
Sad (200)	80.5
Surprise (200)	82.0
Angry (200)	92.5
Fear (200)	92.0
Disgust (200)	85.5
Average	85.41

Table 2. Precision (under manual checking of each class)

## 5.1 Classification Results

Before discussing the accuracy, we would like to make some interesting observations. There are some words that cannot be classified by the classifier, i.e., for these words the probabilities of each class is the same. The number of these words varies with the change of  $\beta$  values and the number of seed words. We also observed similar change in the number of words put into each class.

We have manually checked top 200 words from each class having highest probability and reported the precision in Table 2. We have achieved maximum precision of 92.5% and 92.0% *angry* and *fear* classes respectively. It has been observed that the *happy* class has lowest precision and is about 80%. The precisions of *sad*, *surprise* and *disgust* classes are 80.5%, 82% and 85.5% respectively. We also performed several experiments by changing the values of  $\beta$  and the varying the number of seed words. The highest precision is achieved with  $\beta = 0.9$  and number of seed word kept at 18, i.e., three words from each group.

We observed that the accuracy of *happy* class is low. The reason may be that many words in this class do not have any relation to happy class and such words are basically neutral words or tough words, i.e. these words do not contain any emotions. For example, “*handel*” and “*olivier*” are identified as *happy* words, whereas they do not have any relation with the *happy* class. We also observed that *happy* emotion class contains

	Happy	Sad	Surprise	Angry	Fear	Disgust	Neutral
Happy	160	0	4	0	0	0	36
Sad	0	161	1	13	8	15	2
Surprise	5	6	164	2	8	12	3
Anger	0	7	1	185	1	5	1
Fear	0	9	1	1	184	3	0
Disgust	0	11	2	12	3	171	1
Neutral	0	0	0	0	0	0	0

Table 3. Confusion matrix for manual precision checking.

Classes	Precision (in %age)
Happy	50.8
Sad	52.3
Surprise	46.8
Angry	56.0
Fear	51.4
Disgust	35.5
Average	48.8

Table 4. Precision of each class collected by WordNet-Affect.

Classes	Precision (in %age)
Happy	58.9
Sad	65.4

Table 5. Accuracy of each class based on SentiWordNet.

some words from the *surprised* class. For example, the word “*fortuitous*” means happening by a lucky chance. Another example is “*stunning*”, which is classified as happy class, but it belongs to surprise class. In case of *sad* word class, we found some words from *fear*, *angry* and *disgust* classes. *Angry* class comprises some words from *sad*, *fear*, *disgust* and *neutral* classes. For example, the word “*stink*” is classified as *sad* class where as it belongs to *disgust* class. It does not contain any word from *happy* class. *Fear* and *disgust* classes contain word from all other classes except *happy* class. The details can be found from confusion matrix given in the Table 3.

There are some words which could belong to more than two classes depending on the context/situation. For example, “*shiver*” falls under the class *sad* and *fear*. We have removed these words while calculating the accuracy of the system.

We have also cross checked the accuracies of our system using the WordNet Affect. Here we have classified the words in six emotion classes and the precision is computed by comparing with WordNet-Affect. As WordNet-Affect contains less numbers of emotion words, so we just checked top 100 words from each emotion classes and the precision is given in Table 4. The average precision calculated is 48.8%. This is due to the fact that WordNet-Affect contains less number of words.

We have also classified the words into two classes, i.e. positive and negative. Then we have computed the accuracy of the output using the SentiWordNet 3.0 (Esuli et al., 2010). Approximately 25000 words occur with same probability and those words are removed at the time of testing. The accuracy is given in the Table 5. We have achieved 58.9 % accuracy in positive class or happy class, whereas 65.4% in negative class or sad class.

A shortcoming of this system is that it cannot handle those words which are not present in the lexical network. Error occurs when a non-emotional word is assigned a class.

## 6 Conclusion and Future Work

A method has been proposed for extracting emotional orientations of words with high accuracy using Potts model. The major contribution in the task is to prepare the emotional lexicon.

There are several directions for future works. One of them is to incorporate the syntactic information. Since importance of each word in a gloss depends on its syntactic role, syntactic information in glosses should be useful for classification.

A single word could belong to multiple classes. So, the identification of those words and representing them in fuzzy classes is one of the crucial research goals to be achieved in future.

Reducing the number of words having same probability in each emotion classes may be another research work. New words that are not listed in the Lexical Network can be updated in later works.

Finally, we are of the opinion that the proposed model is applicable to other tasks in computational linguistics.

## Abstract

Can natural language processing be used to predict the likelihood that a musician will commit or has committed suicide? In order to explore this idea, we built a corpus of songs that includes a development set, a training set, and a test set, all consisting of different lyricists. Various vocabulary and syntactic features were then calculated in order to create a suicide/non-suicide song classifier. The features were input into the Weka machine learning suite and tested with an array of algorithms. We were able to achieve up to a 70.6% classification rate with the SimpleCart algorithm, a 12.8% increase over the majority-class baseline. Our findings suggest that syntactic and vocabulary features are useful indicators of the likelihood that a lyricist will commit or has committed suicide.

## 1 Introduction

Recently, research into the application of NLP to the detection of health illnesses has proved fruitful. For instance, in their study of the effects of dementia on writers, Le et al. (2011), guided by previous research, explored various hypotheses in the novels of three British writers. Their research found a decline in the type-token ratio of the novelists suffering from dementia. The use of passive constructions was also explored since it is generally believed that it represents a syntactic structure that is particularly complex and likely would be used less often by writers suffering from dementia. Indeed, they found that authors with dementia use less passives than their healthy peers. Their results indicate the potential for natural language processing in the language of mental illness. Similarly, much research into the application of NLP to depression and suicide prediction has been con-

ducted in recent years (Pestian et al. 2012; Sohn et al. 2012).

While one might not expect depression or a suicidal tendency to affect language in the same way as an illness such as dementia, it is reasonable to assume that there will be textual indications of these mental illnesses also. In Stirman and Pennebaker (2001), word use is treated as an indicator of the mental states of suicidal and non-suicidal poets. Stirman & Pennebaker developed the Linguistic Inquiry and Word Count program to analyze over 70 language dimensions, including: polarity, affect states, death, sexuality, tense, etc. Their research found a correlation between the likelihood of a poet committing suicide and his/her disengagement from society based on the suicidal poets' heavy use of first-person singular pronouns and decreased use of the first-person plural pronouns. Interestingly, they also noted that poets who had committed suicide generally used more sexual words and references to death than their non-suicidal counterparts. Additionally, latent semantic analysis has been used to detect depression in free texts (Neuman et al. 2010). By creating a semantic field from the words commonly associated with the concept of depression, Neuman et al. were able to accurately identify depressed people through their writing. Finally, other pertinent research involves the use of concrete nouns and the lack of abstract concepts in professionally-written poetry (Kao & Jurafsky, 2012).

Based on the prior research, we anticipated that the suicidal lyricists' use of first-person singular pronouns would differ from that of the non-suicidal lyricists, possibly being significantly higher. We also hypothesized that certain features like the usage of sensual and morbid words and the passive construction would be more prevalent in the works of suicidal lyricists. Additionally, we were interested in exploring the differences among other features, such as TTR, the degree to which

a text is polar and in which direction, the n-gram profiles of songs in relation to the n-gram profiles of suicide/non-suicide lyricists in general, and the semantic fields of other target emotions and affect states of the two groups.

## 2 Methods

First, a corpus of songs by male suicide and non-suicide lyricists was constructed, which consists of training, development, and test sets. The training set is comprised of 533 songs, of which 253 were written by four lyricists who have not committed suicide and 280 by five lyricists who did commit suicide. The test set consists of 63 songs by 5 non-suicidal lyricists and 46 songs by 4 suicidal lyricists. Finally, the development set consists of 168 songs, 94 from 5 non-suicidal lyricists and 74 from 6 suicidal lyricists. Finally, the test set contains 63 songs written by five non-suicide artists and 46 songs written by 4 suicide artists. Table 1 displays the composition of the sets.

In our search for lyricists who committed suicide, we looked for lyricists who met the following prerequisite: the suicide had to be relatively unambiguous. This requirement constrained the size of the corpus a great deal. In addition, we attempted to distribute the lyricists across the different sets in an even manner such that each set would be comprised of lyricists of a range of times and nationalities. For these reasons, it was a source of difficulty trying to create sets with unique lyricists. Although we did not require that each song be solely written by the lyricist in question due to the fact that it is often murky concerning to whom the lyrics should be attributed, we did make an attempt to exclude songs written entirely by bandmates or other musicians. Due to the lack of female lyricists who committed suicide, we were forced to consider exclusively male lyricists.

48% of the non-suicide corpus consists of songs written by one artist, Bob Dylan. Removal of 35% of those Dylan songs (and thus evening out the distribution of songs) did not significantly alter the classifier’s results. The other non-suicide lyricists contributed between 32-45 songs each. The training set of suicide songs is slightly over-represented by Elliott Smith (about 33% of the songs). The four remaining suicide artists each contributed between 11% and 20% of all songs in this set. We additionally used a development set of five non-suicide lyricists (94 songs) and six suicide lyricists

(74 songs), which was used to compute n-gram features.

Each song considered was searched for in on-line lyrics databases and was cleaned by hand, the lines being joined into punctuated sentences or phrases so that a POS-tagger and lemmatizer could be used. The lyrics were then tokenized using the OpenNLP tokenizer and lemmatized. Features were computed using Python and with some help from the UAM corpus tool (O’Donnell 2008)(which uses the Stanford Parser), especially for grammatical analysis.

### 3 Features

In order to create the suicide/non-suicide lyrics classifier, similar features to those used in the previous research were explored in conjunction with a set of original features. In all, there were 87 features that we explored.

#### 3.1 Vocabulary Features

While a few of our features were based on raw counts of types, tokens, and time of song (in seconds) alone, such as TTR (type-token ratio), they are mostly used to normalize many of the features in the following two sections. Below are the vocabulary features we explored:

- by type: type/token ratio (TTR) and type/time ratio
- by token: token/time ratio

#### 3.2 Syntactic Features

As in Le et al. (2011) and Stirman & Pennebaker (2001), we expected to find differences in the use of the passive construction and in the proportions of the first-person pronouns to the rest of the pronouns. We expected a greater use of passive constructions in the lyrics of the suicide lyricists in comparison to the non-suicide lyricists since it might signify a greater sense of disengagement from the external world. Additionally, we hypothesized a higher proportion of first-person pronouns to other pronouns in the suicidal lyrics since a common perception about suicide cases and depressive people in general is that they are more self-centered or that they are less concerned with others.

In addition to the exploration of the first-person pronouns and passive constructions, we also looked at the differences in the usage of mental-state verbs co-occurring with the first-person singular pronoun, including the use of verbs like *think* and *feel*. Our expectation here was that the suicide writers might use such constructions more often due perhaps to a preoccupation with thoughts and feelings and an inclination to think and feel more often than act.

These features were computed using the UAM corpus tool, which allows one to create autocoding rules and presents annotation statistics on the text level. Most of these count features were normalized by type, token, and time, but a few of them

consist of ratios between features, such as first-person singular pronouns to all other pronouns. Since the latter features were occasionally affected by data sparsity, we chose to deal with undefined values resulting from zeroes in the denominator by adding 0.01 to each count so that the resulting value would not be undefined.

#### 3.3 Semantic Class Features

Our expectations about the content of the suicide lyrics in comparison to the non-suicide lyrics was that they might deal with more negative, depressing subjects than positive ones. We also hypothesized that, as in Pennebaker & Stirman (2001), we would see a difference in the use of sexual words in the suicide lyrics (specifically, a heightened rate of sexual and death-related word usage). For these and other "semantic classes", we built word-lists consisting of terms relating to the target semantic classes.

The semantic classes considered were sensuality, action (specifically, verbs that signified some particular action), concreteness (specifically, nouns that represented concrete objects), death, love, depression, and drugs. We used the MPQA prior polarity word lexicon (Wiebe et al. 2005) to measure negative, positive, and neutral word usage. We counted the number of occurrences of these words in each song-text, normalizing the raw counts by type, token, and time. We also computed a number of features that consisted of ratios between raw counts, such as sensual words to positive words. Where applicable, we dealt with data sparsity using the same method described above, adding 0.01 to avoid undefined values.

Additionally, we used the AFINN (Nielsen, 2011) word-valence dictionary, which is a list of nearly 2,500 polar terms with associated polarity values (ranging from 5 to -5), to calculate the total and average polar value of each song. The total polar value was calculated by summing the polarity values for each polar term in a song-text while the average polar value was calculated by dividing the total polar value by the number of polar terms in a text.

#### 3.4 N-Gram Features

A Python script was written to build unique n-gram (for  $n = 1$  to  $n = 6$ ) profiles for the classes in the development set. (This set was used exclusively for this purpose and was not needed for any other features.) These unique n-gram profiles for

suicide and non-suicide lyricists were compared to the corresponding n-gram profiles of each song in the training and test sets to find out to what extent the n-grams in a given song overlapped with either n-gram profile.

In addition to percentage of overlapping n-grams, a number of features composed of the overlapping percentages were computed. The difference between overlapping n-gram percentages for each class was calculated for each value of n. For example, if a song's bigram profile overlapped with the non-suicide bigram profile at a rate of 6% and with the suicide bigram profile at a rate of 4%, the difference would be 2%. We also computed the average overlapping n-gram percentage for each class across all values of n. Finally, we calculated the difference between the average percentages of overlap for the non-suicide n-gram profiles and that for the suicide n-gram profiles.

## 4 Results

All features were input into Weka and a number of different ML algorithms were run to create a classifier. As a baseline for comparison, we used the majority-class prediction rate of 57.7%. The classifier was trained on the training set and then tested on the test set of different artists' songs. The most successful algorithm was the SimpleCart algorithm, which correctly classified the songs as either suicide or non-suicide 70.6% of the time and which achieved a 0.39 Cohen's kappa value. The correct classification rate represents an increase of 12.9% over the baseline. The SimpleCart algorithm achieved a precision, recall, and F-measure of 0.71, and an ROC Area value of 0.70. In Table 4 above, we report the confusion matrix for the test set.

While our classification statistics do not reach a satisfactory level, we believe that they indicate that we are on the right track and that this task can be tackled using NLP. Of the 87 features that were calculated, a number stood out as being most useful across numerous algorithms. Included among these features are the various n-gram features, the first-person singular + mental verb features, the concrete nouns, neutral terms, sensual words, and total polar value semantic class features, and the first-person singular and passive construction syntactic features.

a	b	<- classified as
29	17	a = suicide
15	48	b = non-suicide

Table 2: Confusion Matrix.

## 5 Discussion

The construction of a corpus for this type of task is beset by problems on all sides. Perhaps one of the largest issues is with the seemingly non-suicidal lyricists: whether these lyricists have passed away already or are still alive, there is no certainty that they would not have committed/will not commit suicide at some point after the point at which they are classified as non-suicidal. Perhaps one could try to use only those lyricists who died from non-suicidal causes late in life (say, after 60) since such lyricists might represent fairly safe cases, but even then there still would not be any certainty. Furthermore, there could be a situation in which a lyricist tried to commit suicide, but did succeed and news of the attempt was kept secret. Such lyricists might then be classified as non-suicides even though the amount of separation between them and the lyricists who were successful at committing suicide is next to nill. Although we acknowledge that this is a serious consideration, we believe that 1) it is a risk that we have to take in order to do this task since there seems to be no solution that guarantees 100% certainty and 2) the likelihood of committing suicide appears to be so low (even for artists) that it might not be such a bad course of action to assume that any given lyricist will not commit suicide unless he/she already has.

Though the vast majority of lyricists do not commit suicide, this fact leads directly to some of the other problems that afflicted the construction of our corpus. Since the number of lyricists who committed suicide is constrained, this leads to issues beyond the collection of as many songs as possible from such lyricists, which is a necessity. For example, the corpus of songs cannot simply be randomly split into sets because the we need to ensure that the songs we test on were not written by lyricists who composed songs that we trained on lest we merely learn the tendencies of those artists and not the abstract suicidal tendency that we are actually seeking. The same issue goes for the development set. However, even if we figured out a way to split the corpus into sets of the appropriate numbers of songs while taking into consideration

that the artists for each set must be unique, there are further factors that could skew the results. For example, we would ideally want the composition of each set of songs to be consistent from set to set in terms of the range of composition dates, the genres represented, etc. Although we attempted to take all of these factors into consideration in order to partition the data into sets, we realize that our method for doing so and the product of our labors leave much to be desired. In the future, we hope to work on refining our method so that it might optimize the partitioning of our corpus.

## 6 Further Research

Besides expanding the corpus to include many more non-suicide lyricists and (at the very least) to include more songs from each of the suicide artists, it would perhaps be fruitful to extend the analysis to other types of features and new lexicons since it has been demonstrated that this task could be solved using NLP.

## Acknowledgments

We would like to take this space to acknowledge again the use of the UAM corpus tool, which proved valuable to our analysis, the MPQA prior polarity lexicon, the AFINN word valence dictionary, the Weka machine learning suite, and the many online contributors of lyrics and word-lists. We would also like to thank Michael Flor for letting us use his own personal lemmatizer.

tb@ldwin.net

## Abstract

In this study we investigate how we can learn both: (a) syntactic classes that capture the range of predicate argument structures (PASs) of a word and the syntactic alternations it participates in, but ignore large semantic differences in the component words; and (b) syntactico-semantic classes that capture PAS and alternation properties, but are also semantically coherent (a la Levin classes).

We focus on Indonesian as our case study, a language that is spoken by more than 165 million speakers, but is nonetheless relatively under-resourced in terms of NLP. In particular, we focus on the syntactic variation that arises with the affixing of the Indonesian suffix *-kan*, which varies according to the kind of stem it attaches to.

## 1 Introduction

This research was motivated by the desire to semi-automatically develop a lexicon for a wide-coverage, precision grammar of Indonesian. Although these linguistically-motivated grammars are invaluable resources to the NLP community, the biggest drawback is the time required for the manual creation and curation of the lexicon. Our work aims to expedite this process by automatically assigning syntactic information to stems that make up the verbal elements, on the basis of predicting syntactico-semantic clusters based on distributional similarity.

However, one minor point becomes one major obstacle in this task: Indonesian is a relatively under-resourced language in terms of NLP. Therefore, many of the techniques that have been deemed successful in the inferring of syntactic information or inducing syntactico-semantic classes

are not available to us. Even studies that are considered lightweight minimally employ a part-of-speech (POS) tagger and chunker (Joanis et al., 2008), with many studies benefiting from the richness of the features that a syntactic parser provides (Schulte im Walde, 2006). In the case of Indonesian, there exist POS taggers (Pisceldo et al., 2009; Wicaksono and Purwarianti, 2010)<sup>1</sup> but no chunker or syntactic parser, and the reliance on such pre-processing tools is unrealistic.

We adhere to the notion that semantic similarity begets syntactic similarity as per Levin (1989), and so employ a distributional similarity method to learn our syntactic classes, based on a non-parametric Bayesian model. We experiment with learning both: (a) syntactic classes that capture the range of predicate argument structures (PASs) of a word and the syntactic alternations it participates in, but ignore large semantic differences in the component words; and (b) syntactico-semantic classes that capture PAS and alternation properties, but are also semantically coherent (a la Levin classes).

Here, we focus on the syntactic variation that arises with the affixing of the Indonesian suffix *-kan*. The specific morpho-syntactic behaviour of the *kan*-affixed verb is very much determined by the type of stem it attaches to, and its resulting behaviour varies from stem type to stem type (Kroeger, 2007; Vamarasi, 1999; Arka, 1993). The spectrum of variation induced by the affixing of *-kan* is not observed on all types of stems, and so being able to identify these superordinate types, representing the same morpho-syntactic variation, would assist greatly in accelerating lexicon development. It has been shown that Levin classes can be successfully induced employing unsupervised methods (Schulte im Walde, 2006; Kipper et al., 2006). We investigate the viability of automati-

<sup>1</sup>Although no POS tagger has been released for public use.

cally inducing coarser-grained types that represent morpho-syntactic variation, and we test whether the method we define is suited to such a task. Specifically, we focus on a case study detailed in Section 2 on the syntactic and semantic variation that arises with the affixing of the Indonesian suffix *-kan*. In Section 3 we outline our criteria in creating our gold standard data. Section 4 gives technical details of our methodology, and our interpretation of distributional similarity expressed in soft clusters derived using the hierarchical Dirichlet process (HDP). We present our results comparing our method employing HDP with a simpler benchmark system using hierarchical agglomerative clustering in Section 5, and also find that the method we employ in this study is better suited to discovering Levin-style classes rather than detecting morpho-syntactic variation, even though we had accommodated for syntactic structure in our model, by including functional words as structural indicators. We finally conclude with how we may extend this preliminary investigation.

Our contributions in this work are: (1) the demonstration that hierarchical Dirichlet processes are a highly effective way of modelling word similarity, outperforming simpler strategies; (2) the successful application of the syntax-semantic hypothesis of Levin to an under-resourced language based on distributional similarity analysis; (3) the finding that conflating semantic classes into superordinate types may be useful for annotating the lexicon, but when performing clustering tasks that employ distributional semantics, having a more semantically-oriented classification, such as Levin classes, are best suited for such methods, even when approximations are made to account for syntactic information; and (4) the demonstration that clustering based on semantic properties is a relatively strong predictor of deep syntactic lexical properties, and can be of great assistance in semi-automatically constructing a deep lexical resource for an under-resourced language

## 2 Background

Indonesian is an Austronesian language spoken by more than 165 million speakers in Indonesia (where it is the national language) and around the world (Gordon, 2005). Even with this status it still is an under-resourced language when it comes to NLP. For our case study, we aim to discover

groups of like stems that, when used predicatively in the same morphological context, give rise to the same syntactic behaviour. That is, we aim to induce classes of stems that exhibit the same syntactico-semantic behaviour when they have the same morphological marking.

Predictions on syntactico-semantic properties of stems via morphological processes have also been explored for English (Grimshaw, 1990). Although Grimshaw's account of nominalisation restrictions with the English suffix *-ing* can be explained with a more general theory of argument structure, she also shows that the nominalisation of certain predicates in this way exclude certain lexical classes, namely psychological predicates as shown in Example (1).

- (1) a. \*The (movie's) depressing**ing** of the audience.
- b. \*The worry**ing** of the public.

The morpho-syntactic study presented in this paper is specific to Indonesian, but these lexical changes initiated by morphological processes can be a source of investigation into syntactico-semantic properties of lexemes for a variety of languages including English. For our case study we look into the Indonesian suffix *-kan*, which is generally described as a morpheme that triggers a lexical rule that increases valency. It can introduce a benefactive object, form a causative construction, or apply other semantic changes. Examples (2) and (3) show the benefactive, and causative uses, respectively:

- (2) a. *Dia membeli buku itu untuk Mary.*  
s/he AV+buy book this for M  
“(S)he bought a book for Mary.”
- b. *Dia membelikan Mary buku itu.*  
s/he AV+buy+KAN M book this  
“(S)he bought Mary a book.”
- (3) a. *Orang-orang mengungsi.*  
person-person AV+take-refuge  
“The people took refuge.”
- b. *PBB mengungsikan orang-orang.*  
U.N. AV+refuge+KAN person-person  
“The U.N. evacuated the people.”

In the second line of each of these glossed examples, AV stands for *actor voice*, which means that the verb is active. This is marked by the prefix *me-* plus a homorganic nasal, which can be realised

as  $m$ ,  $n(g|y)$  or  $\emptyset$ . This verb behaves in a similar fashion to English verbs in an active sentence. We limit the examination of verbs in this study to those that exhibit the actor voice (AV) marking.

Linguists have tried to characterise stems according to their behaviour when affixed with *-kan* (Dardjowidjojo, 1971; Arka, 1993; Vamarasi, 1999). In particular, Vamarasi (1999) claims that *kan* is a good diagnostic for separating unaccusative from unergative stems, which predicts their morphosyntactic behaviour. However the facts of *-kan* seem more intricate than this characterisation. Even though the causative and benefactive constructions uses of *kan* are the most commonly cited, its usage is much more varied and nuanced, as shown by Kroeger (2007), which is why we chose this morpho-syntactic construction as our case study.

Since the early '90s, the tools and resources employed in valency acquisition tasks have become increasingly sophisticated and linguistically-rich. One of the earlier examples of this is by Brent (1993), who employs a system based on deterministic morphological cues to identify predefined syntactic patterns from the Brown Corpus. Manning (1993) employs a shallow parser or chunker in order to acquire subcategorisation frames from the New York Times. Schulte im Walde (2002) induces subcategorisation information for German with the use of a lexicalised probabilistic context free grammar (PCFG), and O'Donovan et al. (2005) employ the richly-annotated Penn Treebank in achieving this endeavour. In terms of resources, our work most closely resembles Brent (1993), in that we rely mainly on linguistic knowledge based on simple lexical features. However, the way linguistic knowledge is learned and applied is quite different, as we will see in Section 3

In terms of the methodology, the studies that we look to are those systems that are built to disambiguate and/or discover syntactico-semantic Levin-style classes, rather than systems that aim to induce valency or syntactic frame information from corpora. These can be built in a supervised fashion as in Lapata and Brew (2004) or tackled as a clustering task as in Schulte im Walde (2006) or Bonial et al. (2011). Lapata and Brew (2004) develop a semi-supervised system that generates, for a given verb and its syntactic frame, a probability distribution over the Levin verb classes. They then use this system to disambiguate tokens using collocation information. Our system, like Schulte

im Walde (2006), uses an unsupervised clustering approach. In her approach, Schulte Im Walde employs hierarchical agglomerative clustering over parse features to discover word classes in German, and evaluates using manually-created gold-standard data.

### 3 Evaluation Data

This section describes how we arrive at the two evaluation sets we use in our experiments.

#### 3.1 Forming Levin Classes

We use VerbNet 3.2<sup>2</sup> as our guide for forming Levin classes for Indonesian, and rely on their translation to determine membership for the class, for a particular sense of that verb.

We have 30 stems that we group into 16 Levin classes. Unlike the types we form in Section 3.2, which have unique membership, a lexical item can appear in multiple classes as appropriate. For example *baca* “read” has membership in both VerbNet classes **say-27.7** and **learn-14**. We show a subset of Indonesian Levin classes we develop based on VerbNet 2.3 in Table 1.

#### 3.2 Forming Superordinate Levin Types

These superordinate types combine Levin classes to form groups of stems that behave in the same way syntactically, but may not all be synonyms of each other. In determining the coarse-grained superordinate types, we did not simply want to group stems according to intuition. Rather, we were after an explicit description of the syntax and semantics of grouped stems that all behave in the same way when affixed with *-kan*. Stems that are grouped together should exhibit the same semantic shifts. That is, if affixing *-kan* to a stem gives rise to a causative meaning, then its corresponding group member will also produce a causative meaning when *-kan* is applied to the stem. Also, if adding a *-kan* does not increase the valency for a stem in a particular group, then its corresponding group member will also exhibit the same syntactic behaviour.

In order to achieve this, we map out the different behaviour of verb stems when they occur in the morphological patterns (a) and (b):<sup>3</sup>

<sup>2</sup><http://verbs.colorado.edu/~mpalmer/projects/verbnet/downloads.html>

<sup>3</sup>As mentioned earlier in Section 2, AV stands for *actor voice*, and can be likened to an English verb in an active sentence.

Indonesian Members	VerbNet Class
<i>beri</i> “give” <i>jaja</i> “hawk/sell”, <i>pinjam</i> “lend”	give-13.1
<i>kenang</i> “think” <i>kenal</i> “know” <i>ingat</i> “remember”	consider-29.9
<i>mati</i> “die”, <i>tewas</i> “perish”	disappearance-48.2
<i>susup</i> “duck down”, <i>singkir</i> “get out of way”	avoid-52
<i>timpa</i> “hit” <i>hantam</i> “hit/blow” <i>tabrak</i> “hit”	hit-18.1
<i>baca</i> “read” <i>tulis</i> “write”	say-37.7
<i>baca</i> “read” <i>hafal</i> “memorize”	learn-14

Table 1: Subset of the mapping of Levin classes into Indonesian

- (a) ME  $N$ +stem  
AV+stem
- (b) ME  $N$ +stem+KAN  
AV+stem+KAN

We map out the variation of arguments for pattern (a) with only the AV prefix, i.e. ME  $N$ +stem, and then note the changes when the stem has both the actor AV and *-kan* affixes, i.e. pattern (b) ME  $N$ +stem+KAN. We also track the semantic changes relative to the stem for these two patterns and found that 25 verb stems found their way into 8 verb types.<sup>4</sup> This formed one of our evaluation sets in our experiments (see Mistica (2013) for further details on forming these superordinate types).

In the interests of space, we only present two out of the 8 manually-induced verb types in Table 2. Below each of the types, we show the syntactic and semantic changes that determine our verb types or subclasses.

## 4 Method

We define our features in terms of the context of occurrence of our target lexeme, and employ hierarchical agglomerative clustering (HAC) over these features in two ways: (1) directly over the raw word frequencies; and (2) over extracted semantic features learned via the contexts of occurrence, which are represented as topic probabilities.

We use Indonesian Wikipedia<sup>5</sup> as our text collection, and remove mark-up with Wikiprep,<sup>6</sup> then tokenise with the English-trained models of OpenNLP.<sup>7</sup> The total word count of the text collection is approximately 26 million words. In the

<sup>4</sup>We had also manually grouped stems from other word classes: 48 noun stems were grouped into 13 subclasses; and 27 adjective stems were grouped into 5, giving us a total of 100 stems with the 25 verbs, but we only report on the verb experiments.

<sup>5</sup><http://dumps.wikimedia.org/idwiki/>

<sup>6</sup><http://www.cs.technion.ac.il/~gabr/resources/code/wikiprep>

<sup>7</sup><http://opennlp.apache.org/> Our experiments showed that OpenNLP’s English models performed better than a rule-based Malay sentence tokeniser (Baldwin and Awab, 2006).

next section we summarise the features we use in our experiments, in addition to outlining our clustering method.

### 4.1 Feature Engineering

Our features determine how we collect unigrams from the text collection. We collect these unigram features from 735 lexemes that we were able to identify as possible *-kan* hosts. These 735 lexemes had stems that belonged to any of the open class categories in Indonesian (noun, adjective or verb).

In our preparation of the Wikipedia data, we include function words as a means to infer structural information. Because we do not use a parser to explicitly obtain syntactic features, this is how we approximate this kind of information.

We use three main feature types in our task: (1) **morph**  $\in$  ‘k’, ‘mk’, ‘smk’; (2) **win**  $\in$  1 to 5; and (3) **context**  $\in$  ‘+’ (forward), ‘-’ (backward).

**Morphological features (morph):** These are contextual features for different morphological forms of the target lexeme, where: ‘s’ stands for *stem*, i.e. the unaffixed lexeme; ‘m’ stands for the AV variant of the lexeme, based on pattern (a) from Section 3.2; and ‘k’ stands for the KAN suffixed form of the AV variant of the lexeme, based on pattern (b) from Section 3.2. An example of the ‘s’, ‘m’ and ‘k’ variants of *beli* “buy” are *beli*, *membeli*, and *membelikan*, respectively. These morphological features determine whether the unigram features we collect for a lexeme are based on instances of ((s)m)k forms found in the text. We experiment with the context features based on these morphological variants in isolation and also in combination. For example, ‘mk’ would capture context features for the *membeli* and *membelikan* variants of the stem *beli* “buy”.

**Window Size (win):** This stipulates the context window size, relative to individual occurrences of the target lexeme, and can take a value of 1–5.

<b>Example Type A:</b> <i>acuh</i> “to heed”, <i>terjemah</i> “translate”, <i>mandi</i> “bathe”		
MEN+V <sub>1</sub>	–	–
MEN+V <sub>1</sub> +KAN	<NP <sub>a</sub> , NP <sub>b</sub> >	DO <sub>to</sub> ( [NP <sub>a</sub> ], [V <sub>1</sub> TO( [NP] ) ] )
<b>Example Type B:</b> <i>dengar</i> “hear”, <i>kenang</i> “think of”		
MEN+V <sub>3</sub>	<NP <sub>a</sub> , NP <sub>b</sub> >	HAPPEN <sub>to</sub> ( [NP <sub>b</sub> ], [ V <sub>3</sub> TO([NP <sub>a</sub> ] ) ] )
MEN+V <sub>3</sub> +KAN	<NP <sub>a</sub> , NP <sub>b</sub> >	DO <sub>to</sub> ( [NP <sub>a</sub> ], [ V <sub>3</sub> TO( [NP <sub>b</sub> ] ) ] )

Table 2: Manually generated verb Types (‘–’ = no attested word form in the text; ‘{...}’ = optional)

**Context Features (context):** We look at backward (‘–’) or forward (‘+’) context unigrams.

## 4.2 Clustering Stems

We employ hierarchical agglomerative clustering (HAC) in two ways: (1) over the raw frequencies of words based on the feature representations defined in Section 4.1; and (2) over the output of the distributional semantic modelling (HDP) discussed in Section 4.3. The output of this step produces topic models. In other words, we perform HAC over raw unigram frequencies and induced topic models from these raw frequencies to ascertain the usefulness of the HDP step.

To compute the distance between a pair of patterns, we use Squared Euclidean, and for the linkage criterion for merging clusters we use weighted linkage clustering (WPGMA). We compare the output of HAC with the flat-structured gold-standard classes. In order to induce flat clusters from the hierarchical output of HAC, we apply a similarity threshold  $t = 0.825$  to determine which instances should be grouped together.

## 4.3 Modelling Distributional Similarity

Distributional semantic models are commonly employed in the induction and disambiguation of word senses (McCarthy and Carroll, 2003; Lapata and Brew, 2004; Brody and Lapata, 2009; Lau et al., 2012), and to a lesser extent, in learning syntactic classes and diathesis alternation behaviour (Parisien and Stevenson, 2011; Bonial et al., 2011). We infer lexical similarity and soft word clusters using topic modelling, based on a hierarchical Dirichlet process (HDP: Teh et al. (2006)), a non-parametric extension of latent Dirichlet allocation (LDA: Blei et al. (2003)). LDA is a Bayesian generative topic model that learns *latent* topics for a collection of documents

based on the *observable* words. Our definition of a document is a target lexeme and the observable words that surround the target lexeme (based on the window size in the parameter settings).

Formally, in LDA a topic is associated with a multinomial distribution of words, and each document (i.e. lexeme) in the collection is associated with a multinomial distribution of topics. HDP relaxes the constraint in LDA where the number of topics  $T$  is fixed, and learns  $T$  based on the training data using Dirichlet processes (DPs).

## 4.4 Evaluation

We develop two baseline systems to compare our results against: (1) majority class; and (2) random class assignment based on a uniform class distribution. The random scores reported are based on the median of 11 random assignments.

We use pairwise precision ( $pP$ ), recall ( $pR$ ), and F-score ( $pF_1$ ) to evaluate our generated clusters, relative to the gold-standard word classes, as described by Schulte im Walde (2006).

## 5 Results

We perform two experiments. First, we apply the hierarchical Dirichlet process (HDP) to produce topic probabilities, over which we perform HAC. Second, we perform HAC over the raw unigram features (NoHDP), as our benchmark system, a method also employed by systems such as Schulte im Walde (2002) for German and Jurgens and Stevens (2010) for English word sense induction. In both cases, we base our experiments on the 735 lexemes identified as being able to be affixed with *-kan*, and the unigram features from Section 4.1. Note, however, that evaluation is based on the subset of the 735 lexemes which were manually classified into classes and types in Section 3.

We employ a *bagging* approach (sampling with

System	Maj.	Rand.	ON-ALL	ON-VERBS
LEVIN-HDP			<b>.174</b>	<b>.367</b>
LEVIN-NOHDP	.114	.065	.057	.111
TYPES-HDP			<b>.281</b>	.261
TYPES-NOHDP	.271	.140	.026	.152

Table 3:  $pF_1$  score comparing benchmark system NOHDP with our HDP system for Levin Classes (LEVIN) and our coarser-grained TYPES

A	<i>main</i> “play”, <i>nyanyi</i> “sing”, <i>gesek</i> “scrape”
B	<i>irim</i> “send”, <i>hantar</i> “place”
C	<i>dapat</i> “get”, <i>menang</i> “win”, <i>terima</i> “receive”

Table 4: Induced groups with no known categorised words

replacement) to ascertain the best parameters to apply to our 735 lexemes in terms of the unigram features we define in Section 4.1.

Given the discovered parameters, we report our results in Table 3. The label ON-ALL for all HDP systems are systems that have had topics induced from all 735 stems (made up of not only verbs, but also nouns and adjectives), while ON-VERBS only induces topics from a subset of the 735 lexemes whose stems are also verbs, even though we only evaluate on verbs in these experiments.

We observe in Table 3 that HDP consistently outperforms NO-HDP systems. Furthermore, the LEVIN-HDP system outperforms the Random (“Rand.”) and the Majority Class (“Maj.”) baselines, as well as the benchmark NOHDP system. The TYPES-HDP system, on the other hand, barely exceeds the Majority Class baseline with the ON-ALL experiment, and fails to do so with the ON-VERBS experiment.

## 6 Discussion

For our error analysis, we examine a sample of the resulting stem groups from the Levin Class experiments. Table 4 shows membership of all stems found in four separate clusters. The lexemes from these particular groups do not have membership into any of the gold standard Levin classes, unlike the groups formed in Table 5. In this table, the top half are groups that match our Levin classes, part of which is presented in Table 1, and the bottom half are groups that do not match Levin classes.

Group A from Table 4 has 3 verbs — *main*

D	<i>singkir</i> “get out of way”, <i>susup</i> “duck down”
E	<i>baca</i> “read” <i>hafal</i> “memorise”
F	<i>terjemah</i> “translate” <i>tulis</i> “write”, <i>muat</i> “insert/contain”
G	<i>paksa</i> “force” <i>pinjam</i> “lend” <i>hapus</i> “wipe off/vanish/blot out”

Table 5: Induced groups with known categorised words

“play”, *nyanyi* “sing”, and *gesek* “scrape” — which may initially seem not to form a semantically coherent group, however they all are associated with producing music: *main* “play” is used to describe the playing of most musical instruments, and *gesek* “scrape/rub” is used for string instruments, such as violins or cellos. Group B has members that describe movement from one place to another, as does Group C.

Groups D and E in Table 5 faithfully replicate the Levin Classes **avoid-52**, and **learn-14** from Table 1. However, Groups F and G seem to not form coherent semantic groups.

## 7 Conclusion

We have explored the question of whether distributional similarity models can be used to learn deep syntactic features for an under-resourced language, namely Indonesian. Our results demonstrate that hierarchical Dirichlet processes are a highly effective way of modelling word similarity, and outperform a simpler strategy of simply applying HAC over raw frequencies. We have also shown that learning classes geared toward the potential morpho-syntactic alternations of stems, while conflating the semantics of the stem are too coarse for this particular method. The experiments that used true Levin classes to evaluate against performed much better in comparison to the baselines, than did the experiments where we induced our manually constructed coarse-grained types. Although resources and tools are limited for Indonesian NLP, we would need to model syntactic structure more effectively to gain success in predicting lexical types rather than Levin classes.

## Abstract

Supervised training of models for semantic relation extraction has yielded good performance, but at substantial cost for the annotation of large training corpora. Active learning strategies can greatly reduce this annotation cost. We present an efficient active learning framework that starts from a better balance between positive and negative samples, and boosts training efficiency by interleaving self-training and co-testing. We also studied the reduction of annotation cost by enforcing argument type constraints. Experiments show a substantial speed-up by comparison to the previous state-of-the-art pure co-testing active learning framework. We obtain reasonable performance with only 150 labels for individual ACE 2004 relation types.

## 1 Introduction

Relation extraction aims to discover the semantic relationship, if any, between a pair of entities in text. This structured information can be used to build higher-level applications such as question answering and other text mining applications.

Relation extraction was intensively studied as part of the multi-site ACE [Automatic Content Extraction] evaluations conducted in 2003, 2004, and 2005. For 2004, six major relation types were defined. Each relation mention takes two entity mention arguments in the same sentence. In annotating text, each entity mention pair within one sentence will be labeled if it involves one of the relation types. As part of ACE, substantial hand-annotated corpora marked with entities and relations were produced. For example, the ACE 2004 corpus had in total about 5,000 relation instances (and about 45,000 same-sentence entity pairs not bearing one of these relations). These large training corpora stimulated research on the supervised training of relation extractors, with

considerable success: the best systems, when given hand-tagged entities, correctly identify and classify relations with an F score above 70% (Jiang and Zhai 2007).

Although supervised methods were effective, annotating a corpus of this size is too expensive in practice to serve as a model for developing new extractors: it requires consideration of 50K instances, of which only a small portion involve the target relation type. In consequence, most research has focused on reducing the annotation cost through semi-supervised learning methods such as bootstrapping systems. However, with limited labeled data, those semi-supervised systems failed to come close to the supervised level of performance. Their performance also varies with the distribution of seeds.

Recent studies have proposed new ways of reducing the annotation cost by using active learning. The advantage of active learning is that it can achieve reasonable performance, and even performance comparable to the supervised version, with few labeled examples, due to its ability to selectively sample unlabeled data for annotation.

To further reduce the annotation cost and provide an efficient framework for rapidly developing relation extraction models, we combine active learning with semi-supervised methods, provide solutions to the imbalanced seed set and uneven co-testing classifiers, and optionally incorporate argument type constraints. Most relation types now achieve reasonable performance with only 150 labeled instances. Section 2 gives more related work in detail. Section 3 describes the enhancements we have made. Section 4 reports the experimental results and the improvement in performance when only a few instances have been labeled. Section 5 concludes the paper.

## 2 Related Work

For reducing the cost of annotation in the task of relation extraction, most prior work used semi-

supervised learning. (Uszkoreit 2011) introduced a bootstrapping system for relation extraction rules, which achieved good performance under some circumstances. However, most previous semi-supervised methods have large performance gaps from supervised systems, and their performance depends on the choice of seeds (Vyas et al., 2009; Kozareva and Hovy, 2010).

Recent studies have shown the effectiveness of active learning for this task. (Zhang et al., 2012) proposed a unified framework for biomedical relation extraction. They used an SVM as the local classifier and tried both uncertainty-based and density-based query functions and showed comparable results for the two methods. They also proposed using cosine-distance to ensure the diversity of queries.

(Roth and Small 2008) used a dual strategy active learner (Donmez, Carbonell, & Bennett 2007) in their pipeline models of segmentation, entity classification and relation classification at the same time. They also adopted a regularized version of the structured perceptron (Collins 2002) instead of SVM and reported better results in active learning. Their work simulated the whole pipeline in active learning to achieve relation extraction, but had no specific research on the stage of relation extraction in the pipeline.

(Zhang 2010) proposed multi-task active learning with output constraints as a generalization of multi-view learning. The multi-task method relied on constraints on output between different tasks; this might be extended to situations where we need to learn relation sub-types as well as types, but was not applicable when relation extraction is an individual task.

Multi-view learning in a co-testing framework was used in (Sun and Grishman 2012). This paper proposed an LGCo-testing framework in which the local view is a maximum-entropy model with local features, and the global view is based on the distributional similarity in a large unlabeled corpus of the phrases between the two entity mentions of a relation. Extractor training was faster than with alternative active learning methods – much faster than with sequential annotation.

There has been research on combining different learning methods with active learning to obtain further improvement. (Song et al. 2011) used variants of SVM to apply semi-supervised learning after active learning in protein-protein interaction extraction.

The current paper adopts the earlier co-testing framework (Sun and Grishman 2012) and exam-

ines some of the design issues in order to achieve substantial further speed-ups.

### 3 Method

#### 3.1 Framework

In active learning, users are asked to judge whether a particular sentence expresses the target relation between two entity mentions. For a fixed number of queries (fixed annotation cost), active learning aims to achieve the highest performance possible. The work described here builds on a state-of-the-art co-testing based active learning algorithm (Sun and Grishman 2012). Our framework starts with a better initial setting (section 3.2), and then interleaves self-training with querying (section 3.3). We adjust for imbalanced classifiers (section 3.4) to improve query selection. By enforcing entity type constraints (section 3.5), the annotation cost could be further reduced. This framework is able to build a bridge between labeled data and unlabeled data more rapidly than previous pure co-testing based active learning.

The overall procedure is as follows:

```

Let:
U: unlabeled data
V: labeled data
(Labeled positive [relation] or negative [non-relation])
L: Local classifier
G: Global classifier

BEGIN
  // Initial set, section 3.2
  V = seed set
  Add Non-relations to V [see text]
  Train L, G on V
  REPEAT
    //Co-testing based on L and G, section 3.3
    P = {x ∈ U | G(x) = pos & L(x) = neg}
    N = {x ∈ U | G(x) = neg & L(x) = pos}
    Q = 5 queries selected from P ∪ N, preferring P;
    FOR each q ∈ Q
      //Entity type rules, section 3.5
      IF q violates entity type constraints
        THEN V += <q, neg>
        ELSE V += <q, user-assigned label>
    END IF
  END FOR
  Retrain L, G on V
  //Interleaved self-training, section 3.4
  Self-Train using both L, G

```

```
    to obtain positives and negatives and add to V
  Retrain L, G on V
END REPEAT
END
```

### 3.2 Non Relation Approximation

To initiate active learning, we require a small number of seeds (5 in our experiments) for the target relation type. To train the initial model, we also need negative samples. If a small set of negative samples were sufficient, we could ask the user to provide them. However, a small negative set would not be representative of the entire data space, which has far more negative instances than positive ones.<sup>1</sup> As a result, such an initial model gives poor performance; queries in early iterations appear irrelevant to the target relation. Better approximating the negative background by adding a certain number of high-confidence negative samples automatically will give the model the ability to distinguish most negative samples from the very beginning, thus accelerating initial learning.

Random sampling could be used to obtain the negative examples because of the sparsity of positives. However, there is the risk that random sampling may introduce too many false negatives, which is not acceptable for the initial set, even though active learning can deal with a certain degree of noise. To overcome this problem, we train an initial model by incrementally adding more probable non-relations. Since every relation is defined under entity type constraints, we have a subset of the unlabeled data in which the mention pair violates these constraints on the target relation. The instances in this subset are strongly assured not to be target relations if the entity types are hand-labeled, and somewhat more weakly assured if labeled by a NE tagger. By sampling from this subset of non-relations, we safely approximate the non-relation background of the unlabeled data and foster the early learning of the entity type rules. Thus the queries will also be more meaningful to users even at the beginning of the active learning process.

In implementing the sampling, we use the metric of how much of the non-relation subset we have learned instead of specifying a fixed number of instances. We train the model (a basic local feature classifier, the same as that in co-

testing, section 3.3) on the labeled instances, apply the classifier to the so-far-unlabeled instances of this subset, and rank the instances by their uncertainty. We repeatedly select the five most uncertain instances, add them to the labeled set, and retrain the model until the model gives mostly correct predictions on classifying the non-relations in this subset. In the experiments, it is tuned to be 99% accurate on non-relations when the model has roughly balanced precision versus recall on target relations. The balanced model will be a better initial model for later active learning. Meanwhile, the way we add non-relations also enforces early learning of entity type constraints.

### 3.3 Co-testing based query selection

When the initial set is ready, we can start selective sampling and pose queries to improve the model. We use a co-testing method similar to LGCo-Testing (Sun and Grishman 2012), the state-of-the-art active learning algorithm for relation type extension, but give preference to the weaker classifier to get some additional benefit in the early iterations.

LGCo-Testing uses co-testing based on the local view and the global view to select queries. The local classifier uses a rich set of lexical and syntactic features (from both constituent and dependency parses) as well as semantic type information for the arguments. (Zhou et al. 2005; Jiang and Zhai 2007) studied the effectiveness of different features. The global classifier relies on the similarity of relation phrases (the words between the entity mentions), computed based on the shared contexts of these phrases across a large news corpus. The global classifier returns the relation type of the labeled instances to which the unlabeled instance is most similar (a  $k$ -nearest-neighbor strategy, with  $k=3$ ).<sup>2</sup> The instances on which the two classifiers disagree is the contention set, from which queries are selected. Elements of the contention set are ranked by the KL-divergence, and elements with greater divergence are preferred as queries (because they are likely to be more informative in updating one of the models). Because of the additional knowledge from the global view, this method outperforms other methods in active learning for relation extraction, and thus we choose this method as our query selection function.

---

<sup>1</sup> The number of non-relation instances (mention pairs that are not the target type) is usually much larger than the number of target relations. In ACE 2004, it's about 25 times larger than the most frequent relation, EMP-ORG.

---

<sup>2</sup> We closely followed the classifier design in (Sun and Grishman 2012) so that our results would be comparable; the reader is referred there for more details.

While the global view provides valuable additional knowledge, the global classifier, in practice, gives few positive predictions. In principle, when the two classifiers are evenly matched, co-testing should work quite well at selecting informative instances. In this case, their settings favor instances with a positive prediction from the local classifier and a negative prediction from the global classifier, thus influencing the selection of queries. However, in terms of diversity of queries, the global classifier is more capable of discovering unseen instances in the local feature space.

Active learning systems that are based on co-testing may have a similar problem. So we tried to compensate for this by giving preference to the global classifier. In the contention set, the system will first pick as queries instances that the global classifier believes to be positive, and then pick instances that the local classifier predicts to be positive (this may result in selecting queries only from the global classifier in one iteration). The contention set works based on uncertainty. Giving priority to the global classifier is similar to the preference for density in active learning, which usually works better at few labels (Donmez, Carbonell, & Bennett 2007). To save computing time, the selection is only made from the top entropy instances (1000 in our experiments). When there is a substantial amount of annotated data, the local feature model will be able to cover the diversity from the global view. At this point, the contention set will only have examples that the local classifier predicts positive among the top entropy instances, and the priority to the global classifier will not make changes to query selection. We naturally transition to the original uncertainty-based co-testing. This actually gives a kind of mixture of uncertainty-based and density-based methods, which is expected to give better overall performance.

### 3.4 Interleaving Self-training

At each iteration of co-testing, the contention set from the local and global classifiers will be the candidate set for queries to be given to the user (section 3.3). We would also like to make use of the agreement set – the elements on which the classifiers agree – to further improve the model. We can do so by applying a semi-supervised method, akin to bootstrapping. To integrate this with active learning, we propose to automatically label selected elements of the agreement set at

each iteration, thus extending the knowledge directly provided by the user.

We employed the same models as those in active learning for estimating the confidence. In this task, positives are sparse, while negatives are frequent, so we distinguish the strategies for bootstrapping the two classes in the agreement set. For positives in the agreement set, we set a threshold on the local classifier to select sufficiently confident instances in order to avoid errors even when the model is small. We picked the threshold (0.8) based on our observation of early iteration self-training results. The global classifier works as a constraint to avoid semantic drift. (Sun and Grishman 2011) showed that clusters in the global view could be effective constraints in semi-supervised relation extraction. The global classifier, based on the similarity to the few labeled instances, provides a much stricter constraint on predicting an instance to be positive, so no threshold was required. Among those positive agreement instances satisfying the local classifier threshold, we select the most confidently classified instances to label.

In using those instances which both classifiers agree to be negative, we tend to be greedy. In fact, this is again selecting non-relations from unlabeled data, just as in the initial set setting. In the middle of the active learning, the model is more robust to noisy data, and this negative agreement set is also closer to a pure non-relation set. We employ random sampling on this set to emphasize the diversity since we are less concerned about accuracy. To maintain the balance of positives and negatives in the model, we let self-training produce the same number of positives and negatives. To avoid semantic drift away from human annotation, for each class (positive and negative), we limit the number of self-trained instances to be the same as the number of queries (5) at each iteration.

### 3.5 Entity Type Constraints

Relations are defined within entity type constraints. For instance, the EMP-ORG relation is limited to the types (PER – ORG), (PER – GPE), (ORG – ORG), (ORG – GPE), and (GPE – ORG) in ACE 2004.<sup>3</sup> In supervised learning, this is usually not a big problem.

---

<sup>3</sup> PER = person, ORG = organization, GPE = geo-political entity: a location with a government.

	30 iterations		stopping point: iterations	at stopping point		supervised learning
	baseline	our system		baseline	our system

Overall	37.97	52.98	103	48.29	60.25	67.69

Table 1. Comparison with baseline (F1 score). The overall F score is the direct average of 6 types

Type	# queries in total	#queries that filters apply	Ratio
EMP-ORG	1000	91	9.1%
PHYS	1000	106	10.6%
GPE-AFF	590	84	14.2%
PER-SOC	234	64	27.3%
ART	151	54	35.8%
OTHER-AFF	105	56	53.3%

Table 2. Instances auto-labeled by type constraints

When the number of instances is large enough, the statistical model will effectively incorporate these entity type constraints as long as entity types are extracted as features. However, in active learning, even with suitable training examples, we will select and present to the user some instances violating these constraints. Applying explicit type filters would save a certain amount of human labeling effort. In practice, this still depends on the quality of the NE tagger. In the experiment section, we show that we can save a certain amount of annotation by using these simple constraints on hand-annotated entities. Since the savings is substantial, especially on some sparse types, it will be still helpful when using an imperfect NE tagger. A similar rule can be constructed to reject candidate relations where the two arguments are co-referential.

## 4 Experiments

### 4.1 Experimental settings

We use the ACE 2004 corpus to simulate active learning. We treat each of the relation types in turn as the target type to be learned. We collect all pairs of entity mentions appearing in the same sentence to be the candidates for querying. Our task is to find the target relations and obtain reasonable performance using limited hand-labeled data. We use the original tags in the corpus to answer the queries during the active learning process, which simulates hand-labeling. We take

Figure 1. Improvement by different components.

B: Baseline, N: Non relations, S: Interleaving Self-Training, G: Preference for the Global View

randomly selected 4/5 of the corpus as the sampling space for active learning, and the remaining 1/5 as the test set.

### 4.2 Evaluation

We compare our work to the pure co-testing based active learning (Sun and Grishman 2012), and show the F1 measure given the same number of iterations (5 queries per iteration). For random selection of target seeds, we use the same random sequence for both the baseline and our framework for fair comparison. In the co-testing framework, the contention set will be empty at some point, which gives the final model of active learning. We report the overall improvement when the system achieves a reasonable performance with limited human annotation (30 iterations) and the final performance (Table 1). The overall result is the average of the F1 measure of all types.

Even though the initial non-relation selection led to early learning of entity type constraints, during the active learning process, there remain queries that could be answered automatically by entity type and co-reference rule filters. The hand-labeling cost could thereby be further reduced (Table 2). For some sparse types, the reduction by these filters is substantial. In practice, this has to deal with noise from the NE tagger, but is still helpful as long as there is a decent NE tagger.

On the whole, our system substantially outperforms the baseline with a small number of labeled examples (150 instances, at the 30<sup>th</sup> iteration) and also after a relatively large amount has been annotated (the final model)

To show the effectiveness of each component of our framework, we display the overall performance comparison including random sampling, over the first 30 iterations (Figure 1). At this point, most of the six relations have not reached their stopping point, and so the benefits of the individual components are more evident.

The overall F1 score is the direct average of the F1 scores of the six types. Non-relation approximation gives an improvement since auto-labeling a certain number of non-relations saves quite a few queries, and the better initial balance of positive and negative examples also makes the model select more informative queries from the beginning. Self-training boosts the system further as it incorporates more instances (especially positives) automatically. After these, the preference for the global view also gives improvement after 10 iterations. As a trade-off strategy between density and uncertainty, it is common that such methods only outperform the baseline for a certain duration.

With these components and auto-labeling with type constraints (Table 2), we provide a quite reasonable relation extraction system given only 150 labels.<sup>4</sup> With more labels, we can approximate supervised learning. So we can build a relation extraction system quickly when there is no relation annotation in a new corpus. If we need more relations in this new corpus, we can start the framework again, treating previously acquired relations as labeled negative instances of the new target relation. Experiments on this multiple relation type extension also show similar gains over the baseline system using our methods.

---

<sup>4</sup> Keep in mind that the best systems, trained on thousands of examples, only achieve F scores in the low 70's.

## 5 Conclusion

We present a more practically efficient way to do active learning than a pure co-testing based algorithm. The improvement is most pronounced initially, for small numbers of annotations. We can now achieve reasonable performance for extracting relations with very little annotation. Adding a new relation in an hour now seems within reach.

Each component in the framework is still worth further study. We can consider further efforts to enlarge and balance the initial set from the view of non-relation approximation. We can also try more adaptive semi-supervised algorithms to interleave with co-testing. The quality of the global classifier in the co-testing also remains a constraint, so we will be investigating alternative similarity metrics. While the experiments reported here involve simulated active learning, we are now planning real, human-in-the-loop active learning trials.

## Abstract

Mentions of event-argument relations, in particular dependency paths between event-referring words and argument-referring words, can be decomposed into meaningful components arranged in a regular way, such as those indicating the type of relations and the others allowing relations with distant arguments (e.g., coordinate conjunction). We argue that the knowledge about arrangements of such components may provide an opportunity for making event extraction systems more robust to training sets, since unseen patterns would be derived by combining seen components. However, current state-of-the-art machine learning-based approaches to event extraction tasks take the notion of components at a shallow level by using n-grams of paths. In this paper, we propose two methods called pseudo-count and Bayesian methods to semi-automatically learn PCFGs by analyzing paths into components from the BioNLP shared task training corpus. Each lexical item in the learned PCFGs appears in 2.6 distinct paths on average between event-referring words and argument-referring words, suggesting that they contain recurring components. We also propose a grounded way of encoding multiple parse trees for a single dependency path into feature vectors in linear classification models. We show that our approach can improve the performance of identifying event-argument relations in a statistically significant manner.<sup>1</sup>

## 1 Introduction

Event extraction tasks can be viewed as identifying event-argument relations between tokens by mapping events onto tokens, to be called henceforth *triggers*, even though events may have oth-

er events as arguments in contrast to average relation extraction tasks, leading to interdependencies between events. On looking into mentions of event-argument relations, in particular the shortest dependency path between triggers and arguments, one may find that they can be decomposed into intuitively meaningful components arranged in a regular way, such as *core components* indicating the type of relations and *subordinate components* making it possible for events to take arguments further away from triggers (e.g., coordinate conjunction). We anticipate that the knowledge about arrangements of components provides an invaluable opportunity for making event extraction systems more robust to the choice of training sets, for example by assembling seen components into unseen patterns. Towards this goal, we propose in this paper a way of automatically learning and exploiting internal structures of dependency paths for a robust extraction of biological events from the biological literature with the corpora provided by a series of BioNLP shared tasks (Kim et al., 2009 and Kim et al., 2011).

For example, the following sentence has annotated positive regulation events, including the induction of IP-10 by IFN, in the training corpus.

- (1) IL-10 preincubation resulted in the inhibition of gene expression for several IFN-induced genes, such as IP-10, ISG54, and intercellular adhesion molecule-1. (PMID: 10029571)

From this sentence, we may formulate the pattern “X-induced genes, such as Y” with slots X and Y to detect the THEMES of positive regulation events based on the underlined expression. This pattern can also be decomposed into a core component “X-induced Y” and a subordinate component “genes such as Y”. These two components have different roles. That is, the core component

<sup>1</sup> All the datasets and codes used in this study are available at <http://www.biopathway.org/ijcnlp2013>

alone can be used to detect the THEMES of positive regulation events (e.g., “IFN-induced IP-10”), but the subordinate component alone cannot. Core components may not appear together in a pattern, but subordinate components may (e.g., there are two other involved subordinate components “genes such as Y” and “[PROTEIN] and Y”, where “[PROTEIN]” would be replaced with any protein or gene name, in “IFN-induced genes, such as IP-10, ISG54 and intercellular adhesion molecule-1”). From this observation it is possible to come up with an unseen pattern “X-induced Y and Z”.

However, current state-of-the-art machine learning-based approaches exploit the notion of components of patterns only at a shallow level using n-grams encoding partial structures of dependency graphs (including unigrams used in bag-of-words models), not to mention the notion of regularity in arrangements of components (e.g., Björne et al., 2009; Miwa et al., 2010; Riedel et al., 2011). Therefore, their approaches would be biased towards dependency paths that contain a number of components even overlapping with one another, even though such paths may have undesired meanings due to the arrangements of components.

In this paper, we propose two methods (called *pseudo-count* and *Bayesian* methods) to semi-automatically learn three types of probabilistic context-free grammars (PCFGs) that assume different internal structures of paths, with the help of which dependency paths will be analyzed into components. All the learned PCFGs contain lexical items covering an average of about 2.6 distinct paths between triggers and arguments in the training corpus, suggesting that the methods successfully identified recurring components. To exploit multiple parse trees derived from a single path, we also propose a linear classification model whose output score approximates the difference between the log probabilities of the path being derived from positive and negative relations. We find that the use of PCFGs learned by our pseudo-count method improves the performance of classifiers in a statistically significant manner, compared to a baseline classifier with n-grams encoding partial structures of paths.

## 2 Related Work

The literature on information extraction (IE) contains a number of studies in which dependency paths are found to play a significant role (Johansson and Nugues, 2008; Miwa et al., 2010b; Qiu

et al., 2011). Likewise, the biological event extraction research, a branch of information extraction, stresses the importance of the role of dependency paths in identifying event-argument relations due to the resemblance of event-argument relations to dependency relations (Björne et al., 2008). For this reason, most of the event extraction studies have to use dependency path features, such as n-grams ( $n=1\sim 4$ ) of dependencies and words, the length of dependency paths and so on, in identifying event-argument relations (Björne et al., 2009 and Miwa et al., 2010b).

It is thus not surprising that while there are many studies on dependency paths in the IE literature, most of them focus on identifying the type of dependency graph representations that is most suitable to their problem (cf. Johansson and Nugues, 2008, Miwa et al., 2010a), with few exceptions including Kilicoglu and Berger (2009) and Joshi and Penstein-Rosé (2009). In particular, Kilicoglu and Bergler (2009) manually constructed a total of 27 dependency path patterns by examining dependency paths between triggers and arguments. Joshi and Penstein-Rosé (2009) first generated sequences of triples of dependency relations and the baseform/POS of their tokens and then generalized the sequences by concealing one of the elements of the triples. They find that the use of such generalized sequences improves the performance of the task of identifying opinions from product reviews. However, there are no studies on automatically learning and using the internal structure of the dependency paths that express semantic relations between tokens, as addressed in this paper, to the best of our knowledge.

## 3 Problem Setting

Our proposal is tested on the event extraction task as defined in the 2009 BioNLP shared task 1 (Kim et al., 2009), which was later renamed as GENIA Event Task 1 and extended to cover full papers in the 2011 Bio-NLP shared task (Kim et al., 2011). Their task is to extract structured information on events from sentences in the biological literature, including their event type and participants encoded with a controlled vocabulary that has nine event types and two role types (“THEME” and “CAUSE”). This task can be considered to consist of two sub-tasks, one of identifying triggers and another of identifying event-argument relations. In this study, we focus on the latter and use the gold-standard annota-

tions of triggers in the training and development corpora (including full papers) to generate dependency paths for training and testing.

In order to identify event-argument relations, we use twelve binary classifiers for all the possible combinations of event and role types. One may argue that multi-class classifiers are more suitable for this setting than binary classifiers, but there is no conclusive evidence for their advantage (cf. Baek and Park, 2012). Note also that our present focus is on assessing the benefit from the use of the knowledge about internal structures of dependency paths and not on assessing the whole event extraction systems.

## 4 Method

### 4.1 Preparation of Training Sequences

The shortest dependency paths between triggers and argument candidate words (e.g., “-induced” and “IP-10” in (1)) over basic Stanford dependency graphs<sup>2</sup> (de Marneffe et al., 2006) are first computed, from which the three types of sequences are extracted in turn: *token sequences*, or a sequence of the surface forms of the visited tokens (e.g., “induced gene as IP-10”), *dependency sequences*, or a sequence of the visited dependencies (or more precisely, their type and direction; e.g., “-amod +prep +pobj”), and *combined sequences*, or a sequence of the visited tokens and dependencies (e.g., “induced -amod genes +prep as +pobj IP-10”).

Training sequences are derived from the extracted sequences by preprocessing them as follows. First, the last tokens of sequences, namely arguments, are dropped, because of the observation that this makes it easy to convert the components of patterns into sequences and their subsequences in a systematic way. For example, the two components “-induced Y” and “genes, such as Y” of the pattern “-induced genes, such as Y” can be converted into the sequences “-induced -amod” and “genes +prep as +pobj”, which are combined into a sequence corresponding to the pattern, namely, “induced -amod genes +prep as +pobj”. Second, protein names are replaced with a special token “[PROTEIN]” to help learn generalized patterns, since there are a considerable amount of different types of proteins. Third, the first occurrence of each word in the training corpus is replaced with a special token “[UN-

KNOWN]” to simulate encounters with unknown words in the test corpus during learning. Its downside is that all the tokens in the first training sequence are replaced with “[UN-KNOWN]”.

Note that it is a natural extension of our work to additionally generate other types of sequences, for example by replacing the surface forms of tokens with their other attributes (e.g., POSs and surface forms concatenated with POSs) in sequences mentioned above and by dropping functional tokens (e.g., prepositions) within token sequences, even though we do not consider them here.

### 4.2 PCFG Induction

A PCFG consists of production rules (of the form  $A \rightarrow x$ ), each indicating that a nonterminal symbol  $A$  (a *parent symbol*) is replaced with a sequence  $x$  of symbols (*child symbols*) with a predefined probability. Our PCFGs have two types of production rules, those that produce a sequence of nonterminal symbols (*non-lexical production rules*) and the others that produce a lexical item (*lexical production rules*). In our PCFGs, non-lexical production rules are crafted manually and lexical production rules are learned. The probability of each rule is determined by maximum-likelihood estimation (MLE), which divides the total number of the occurrences of the rule in training parse trees by the total number of the occurrences of its parent symbol in training parse trees.

We build two sets of non-lexical rules, one generating positive sequences and another generating negative sequences, together with the following two non-lexical rules, where “S” stands for the start symbol and “Positive” and “Negative” symbols are the ones to be expanded into positive and negative sequences, respectively.

- (2)  $S \rightarrow \text{Positive}$
- (3)  $S \rightarrow \text{Negative}$

We come up with the following three types of non-lexical rules for positive sequences, where the underlined symbols are *lexical symbols*, or the ones to be expanded into single lexical items, and asterisks indicate that the marked symbols may occur zero or more times in a row.

- (4) Unigram Rules  
Positive  $\rightarrow$  Component Component\*
- (5) Uni-directionally Growing Rules  
Positive  $\rightarrow$  Core Component\*

<sup>2</sup> Since arguments and triggers may be hyphenated, we preprocess dependency graphs, so that hyphenated words are separated into their component words.

(6) Bi-directionally Growing Rules  
Positive  $\rightarrow$  Component\* Core Component\*

These rules assume that sequences consist of components that may appear independently of one another (*independence constraint*), but also that they cannot overlap with one another (*non-overlapping constraint*). The second and third types of rules assume that sequences should have core components as indicated by the “Core” symbols. The independence constraint may not capture the nature of dependency paths, but makes it cheaper to learn lexical rules. We leave the question about the effect of the independence constraint open for future research. The uni-directionally growing rules are most consistent with our observation that triggers and their dependencies play a significant role in determining the type of event-argument relations.

Since lexical items are allowed to span across more than one element in positive sequences but are not annotated on training sequences, we need to make a guess at parse trees for each sequence to count the occurrences of rules. To address this problem, we propose two methods. One is called a *pseudo-count method* that assigns all possible parse trees for each training sequence an equal probability (i.e., one divided by the number of all possible parse trees) of the sequence being generated from them, and accumulates the assumed probability (i.e., pseudo-count) of parse trees containing each rule.

Another is called a *Bayesian method* that converts our non-lexical rules into an adaptor grammar, or a description of non-parametric Bayesian models with Chinese Restaurant Processes (CRP) and Pitman-Yor Processes (PYP) (Johnson et al., 2007), by adding production rules, to be called *lexical item production rules*, that replace lexical symbols with a sequence of terminal symbols, such as tokens and dependencies (e.g., “Tokens  $\rightarrow$  Token Token\*”), and by labeling lexical symbols as an *adaptor symbol*, whose expansion to terminal symbols is collected during learning. One advantage of this method is to penalize lengthy lexical items, and as a result, to facilitate analyzing sequences into more than one lexical item, since producing a lengthy lexical item requires the use of many lexical item production rules with a probability below one. In practice, we use the adaptor grammar inference program (Johnson et al., 2007), which samples analyses of input sequences (i.e., sequences of dependency types). We assume that all production rules in our adaptor grammars have the same probability.

We ran two thousand iterations of sampling analyses, but ignored samples during the first half, as these may not be significantly different from randomly assigned initial analyses. Afterwards, we counted the occurrences of lexical items and rules. As a result, 1,000 samples are taken for each sequence.

Since negative training sequences can convey a variety of semantic types, it is unlikely that a training corpus contains all possible negative training sequences covering such semantic types, suggesting the risk of over-fitting of learned PCFGs to negative training sequences (cf. Li et al., 2010). To avoid it, we use a simple grammar, which is expected to be able to learn from a relatively small amount of training instances, as shown below, where “NComponent” symbols produce single token and dependency types. In contrast to the positive sequences, it is straightforward to construct parse trees for negative sequences and to count production rules, since all negative sequences have only one possible parse tree.

(7) Negative  $\rightarrow$  NComponent NComponent\*

Finally, we filter out infrequent and lengthy lexical items, which may have the same form as the sequences from which they are learned, to prevent models from memorizing training sequences as they are (e.g., “induced -amod genes +prep as +pobj”), that is, assigning a high weight to them and to teach instead models ways of analyzing positive sequences into relatively small lexical items (e.g., “induced -amod” and “genes +prep as +pobj”). For each lexical symbol, we remove the least probable lexical items whose occurrences form a predefined percentage<sup>3</sup> of the occurrences of the lexical symbol. Note that it is apparently a more reasonable option to learn PCFGs and linear classification models on two different disjoint subsets of randomly selected sequences. We leave this option for future work.

### 4.3 Linear Classification Model

Using the CKY algorithm with beam search, we generate the most probable  $k$  parse trees for three types of sequences extracted from a dependency path with the help of the learned PCFGs, each of which explicitly has a favorite label. One way to

---

<sup>3</sup> The predefined percentage is 1% if the ratio of the number of distinct sequences to the number of sequences is below a third, 5% if the ratio is between a third and two third, and 10% otherwise.

combine their opinions is to let respective classifiers  $S$  for the types of sequences vote for their favorite label  $z_s(x)$  (+1 or -1) of a path  $x$  and to count their vote with a different weight proportionate to their reported confidence  $w_s(x)$  and their credibility  $c_s$ , as follows:

$$y = \sum_S c_s z_s(x) w_s(x) = \sum_S c_s y_s(x)$$

If the output score  $y$  is positive, our classifier makes a final decision of labeling  $x$  as being positive. The term  $z_s(x)w_s(x)$  can be regarded as the output score  $y_s(x)$  given by a classifier  $S$ .

We define  $y_s(x)$  as follows, where the capital letters stand for random variables:

$$y_s(x) = \log\left(\frac{P(Z = +1, X = x)}{P(Z = -1, X = x)}\right)$$

The log probability  $\log(P(Z, X))$  is written in terms of the probability  $P(Z, T)$  of our PCFGs generating  $T_z$  parse trees supporting a value  $z$  of  $Z$ :

$$\log(P(z, x)) = \log(T_z \times \overline{P(z, T_x)})$$

where  $\overline{P(z, T_x)}$  is the average of the probability of parse trees generating  $x$  and supporting  $z$ . Using Jensen's inequality, it is easy to show that its lower bound  $l(z, x)$  is:

$$\log(P(z, x)) \geq l(z, x) = \overline{\log P(z, T_x)} + \log T_z$$

where the first term is the average of the log probability of parse trees under consideration. One thing to note is that the equality always holds for  $P(Z = -1, X = x)$ , since our PCFGs for negatively labeled sequences produce at most one parse tree for each sequence. For this reason, the lower bound  $y_s^{low}(x)$  of  $y_s(x)$  is:

$$y_s^{low}(x) = \sum_z \left( \sum_{t \rightarrow x|z} \frac{z \log P(T = t)}{T_z} + z \log T_z \right)$$

Instead of  $y_s(x)$ , we use  $y_s^{low}(x)$  at risk of the deterioration of the performance of the resulting model, since it is apparently easier to handle than  $y_s(x)$ .

In the worst case, the difference between  $\log P(Z, X)$  and  $l(z, x)$  can be:

$$|\log(P(z, x)) - l(z, x)| \leq \log \frac{\overline{P(z, T_x)}}{P_{min}(z, T_x)}$$

where the denominator is the least probability of parse trees under consideration. It indicates that with a wide beam width the estimated value of  $y_s^{low}(x)$  may be significantly lower than the true value of  $y_s(x)$ , while with a narrow beam width the estimated value of  $y_s^{low}(x)$  is likely to be similar to the estimated value of  $y_s(x)$ , which may be significantly higher than its true value. Thus the success of the use of  $y_s^{low}(x)$  is dependent on the beam width.

Expanding the log probability  $\log P(T = t)$ ,  $y_s^{low}(x)$  is rewritten:

$$\sum_r \sum_z z \log(p_r) \left( \sum_{t \rightarrow x|z} \frac{\text{count}(r \text{ in } t)}{T_z} \right) + \left( \sum_z z \log T_z \right)$$

where  $p_r$  is the probability of rule  $r$ , which is given by PCFGs, and  $\text{count}(r \text{ in } t)$  is the number of the occurrences of rule  $r$  in parse tree  $t$ . Introducing coefficients  $w_r$ ,  $w_1$  and  $w_0$  into the equation,  $y_s^{low}(x)$  can be generalized to a linear model as shown below.

$$\sum_r w_r \left( \sum_{t \rightarrow x|z} \frac{\text{count}(r \text{ in } t)}{T_z} \right) + w_1 \left( \sum_z z \log T_z \right) + w_0$$

Being their linear combination of the linear models  $y_s^{low}(x)$ , the output score  $y$  is also a linear model. In this paper, we train our linear classifiers using LIBLINEAR (Fan et al., 2008)<sup>4</sup>.

Finally, we note that as in the re-ranking parsers (e.g., Charniak and Johnson, 2005), it is possible to use *global features*, or features not allowed in the CKY algorithm, to calculate the log probability  $\log P(T = t)$ . In this paper, we leave the effect of the use of such global features for future research.

## 5 Experiments

We generated labeled training dependency paths for each event-argument relation type from the BioNLP training corpus with the help of the Charniak-Johnson parser (Charniak and Johnson, 2005) with a self-trained biomedical parsing model (McClosky and Charniak, 2008). There are 7,009 positive paths and 10,603 negative paths. The ratio of the number of positive paths

<sup>4</sup> Our linear classifiers are trained using the L2 regularized logistic regression solver with cost constants that are chosen among 0.01, 0.1, 1 and 100 with the help of five-fold cross validation.

to the number of negative paths is 0.66. We found that a majority of the relation types would have a balanced set of training instances, except for a few relation types with the imbalance between positive and negative instances. One way of correcting the imbalance is to give more weight to positive instances, but we leave out the imbalance in this experiment.

We extracted three types of sequences from them. We found that most distinct negative sequences appear once in the training corpus as shown in Table 1, where the bracketed figures are the ratios of the number of distinct sequences to the number of sequences, justifying the use of a simple grammar for negative sequences.

Sequence	Positive	Negative	Total
Combined	3,703 (1.89)	9,781 (1.08)	13,484 (1.31)
Token	3,366 (2.08)	9,270 (1.14)	12,636 (1.39)
Dependency	1,816 (3.86)	7,419 (1.43)	9,235 (1.91)

Table 1. Distinct Training Sequences

We use the pseudo-count and Bayesian methods to learn grammars. The learned PCFGs contain the mentioned example lexical items, “-induced -amod”, “genes +prep as +pobj” and “[PROTEIN] +conj”. They contain a number of intuitively correct core and subordinate components. The learned subordinate components include “genes +prep like +pobj”, “[PROTEIN] +abbrev” and “[PROTEIN] +appos”.

With three different beam widths, we parse sequences to generate feature vectors for our linear classification models and evaluate the resulting models in terms of accuracy, as shown below.

Grammar	Beam Width		
	k=1	k=10	k=100
Pseudo-Count			
Unigram	<b>86.43%</b>	85.97%	86.07%
Uni-direct	86.94%	<b>87.05%</b>	87.03%
Bi-direct	<b>86.48%</b>	86.43%	86.25%
Bayesian			
Unigram	82.72%	<b>83.39%</b>	83.27%
Uni-direct	82.95%	<b>83.70%</b>	82.88%
Bi-direct	82.70%	<b>83.45%</b>	83.26%

Table 2. Accuracy of Our Classifiers

For each grammar, the best reported accuracy is set in bold. With PCFGs learned by the pseudo-count method, the use of multiple parse trees does not affect or even decrease the performance of classifiers. One possible explanation is that the wider the beam is the more erroneous parse trees are likely to affect the final decision of classifiers. In contrast, the classifiers with PCFGs learned by

the Bayesian model would slightly benefit from the use of multiple parse trees, even though their performance also drops when using the widest beam. To explain that we get only a slight benefit from a wide beam width, we looked at feature vectors, noticing that many positive training sequences have only a small number of possible parse trees. We also observed that as expected, classifiers with the uni-directionally growing PCFGs outperform the other classifiers, with one exception of classifiers with the widest beam and the ones learned by the Bayesian method.

To compare with our classifiers, we implement *linear baseline classifiers* that use as features all n-grams (n=1~4) of token, dependency and combined sequences extracted from the training instances. They first replace unknown words in an input sequence with a special token “[UNKNOWN]” and count the occurrence of n-grams in the sequence. Like our classifiers, they are also trained by LIBLINEAR (Fan et al., 2008).

The accuracy of the baseline classifiers is 85.76%, which is lower than that of the pseudo-count classifiers with any beam width in use, but higher than that of the Bayesian classifiers with any used beam width. The superiority of the pseudo-count classifiers with any beam width over the baseline classifiers is statistically significant at the 10% significance level in terms of their accuracy (p-value=5.6~8.4%), according to the one-sided paired Student’s *t*-test with the accuracy of classifiers for each relation type.

## 6 Conclusion

In this paper we proposed a way of exploiting internal structures of dependency paths for the extraction of biological events from the biological literature with the BioNLP shared task corpora. We proposed pseudo-count and Bayesian methods to learn three types of PCFGs that assume different internal structures of paths from dependency paths. To use multiple parse trees for a single path, we also developed a linear classification model whose output score approximates the difference between the log probabilities of the path being derived from positive and negative relations. Finally, we have shown that our approach can improve the performance of identifying event-argument relation in a statistically significant manner.

## Abstract

Paraphrase extraction relying on a single factor such as distribution similarity or translation similarity might lead to the loss of some linguistic properties. In this paper, we propose a paraphrase extraction framework, which accommodates various linguistically motivated factors to optimize the quality of paraphrase extraction. The major contributions of this study lie in the augmentable paraphrasing framework and the three kinds of factors conducive to both semantic and syntactic correctness. A manual evaluation showed that our model achieves more successful results than the state-of-the-art methods.

## 1. Introduction

Paraphrasing provides an alternative way to express an idea using different words. Early work on paraphrase acquisition has been mainly based on either distributional similarity (e.g., Lin and Pantel, 2001) or the pivot-based approach (e.g., Bannard and Callison-Burch, 2005). Both methods have their strengths and limitations. Distributional similarity is capable of extracting syntactically correct paraphrases, but may risk including antonymous phrases as paraphrases. On the other hand, the pivot approach has the advantage of preserving semantic similarity among the generated paraphrases; however, the quality and quantity of the paraphrases closely correlates with the techniques of bilingual phrase alignment.

Considering single factors, existing paraphrasing methods could lose some linguistic properties. In view of this, we attempt to differentiate the importance of the paraphrase

candidates based on various factors. In this paper, we take a graphical view of the paraphrasing issue. To achieve the goal mentioned above, we adopt the Weighted PageRank Algorithm (Xing and Ghorbani, 2004). English phrases are treated as nodes. The edge weights are determined by various factors such as semantic similarity or syntactic similarity between nodes. It means that the performance of the ranked paraphrase candidates depends on the factors we selected and added. In other words, our framework is augmentable and is able to accommodate various factors to optimize the quality of paraphrase extraction.

In this case, we propose three linguistically motivated factors to improve the performance of the paraphrase extraction. Lexical distributional similarity is used to ensure that the contexts in which the generated paraphrases appear are similar whereas syntactic distributional similarity is adopted for the purpose of maintaining the syntactic correctness. Translation similarity, one more factor, is capable of preserving semantic equivalence. These three selected factors adopted together effectively achieve better performance on paraphrase extraction. The evaluation shows that our model achieves more satisfactory results than the state-of-the-art pivot-based methods and graph-based methods.

## 2. Related Work

Several approaches have been proposed to extract paraphrases. Earlier studies have focused on extracting paraphrases from monolingual corpora. Barzilay and Mckeown (2001) determine that the phrases in a monolingual parallel corpus are paraphrases of one another only if they appear in similar contexts. Lin and Pantel (2001) derive

paraphrases using parse tree paths to compute distributional similarity. Another prominent approach to paraphrase extraction is based on bilingual parallel corpora. For example, Bannard and Callison-Burch (2005) propose the pivot approach to extract phrasal paraphrases from an English-German parallel corpus. With the advantage of its parallel and bilingual natures of such a corpus, the output paraphrases preserve semantic equivalence. Callison-Burch (2008) further places syntactic constraints on extracted paraphrases to improve the quality of the paraphrases. Chan et al. (2011) use monolingual distributional similarity to rank paraphrases generated by the syntactically-constrained pivot method.

Recently, some studies take a graphical view of the pivot-based approach. Kok and Brockett (2010) propose the Hitting Time Paraphrase algorithm (HTP) to measure the similarities between phrases. Chen et al. (2012) adopt the PageRank algorithm to find more relevant paraphrases that preserve both meaning and grammaticality for language learners. In this paper, we, similarly, present the state-of-the-art approach as a graph. However, unlike Kok and Brockett (2010), we treat English phrases (instead of multilingual phrases) as nodes. On the other hand, different from Chen et al. (2012), our model is augmentable by involving varied linguistic information or domain knowledge.

### 3. Method

Typically, the state-of-the-art paraphrase extraction models only deal with single factors such as distribution similarity or translation similarity. However, different linguistic factors could facilitate the paraphrase extraction in various ways. With this in mind, we propose an augmentable paraphrase extraction framework based on a graph-based method, which can be modeled with multiple linguistically motivated factors.

In the following section, we describe the graph construction (Section 3.1). Then the paraphrase extraction framework is outlined in Section 3.2. Section 3.3 introduces the three factors we proposed for optimizing the quality of paraphrase extraction. Finally, we utilize the grid search method to fine-tune the parameters of our model.

### 3.1 Graph Construction

We transform the paraphrase generation problem into a graph-based problem. First, we generate a graph  $G \equiv (V, E)$ , in which an English phrase is a node  $v \in V$  and two nodes are connected by an edge  $e \in E$ . A set of paraphrase candidates  $CP = \{cp_1, cp_2, \dots, cp_n\}$  is generated for a query phrase  $q$  from a bilingual corpus based on the pivot method (Bannard and Callison-Burch, 2005). We further generate a set of transitive paraphrases  $CP' = \{cp'_1, cp'_2, \dots, cp'_m\}$  of the phrase  $q$ , namely, paraphrases  $cp_i$  and their paraphrases  $cp'_j$  in the same manner. We truncate the paraphrase candidates whose translation similarities are smaller than the threshold  $\varepsilon'$ ; we also exclude  $cp_i$  that consists only of a stopword or contains  $q$  or is contained in  $q$ . Thus, some noisy paraphrases are easily eliminated.

Consider the example graph for the query phrase “*on the whole*” shown in Figure 1. We first find its set of candidate paraphrases  $CP$ , including “*generally speaking*”, “*in general*”, “*in a nutshell*”, using the pivot-based method mentioned above. Then for each phrase in  $CP$ , we extract the corresponding paraphrases respectively. For example, “*in brief*”, “*broadly speaking*”, “*in general*” are paraphrases of the first phrase “*generally speaking*” in  $CP$ . During the process, we keep the extracted paraphrases whose translation similarities are larger than  $\delta^2$ . By linking the phrases with their transitive paraphrases, the graph  $G$  is created.

### 3.2 Augmentable Paraphrase Extraction Framework

In this sub-section, we propose an augmentable paraphrase extraction framework, which can be modeled by multiple factors. Considering a graph  $G \equiv (V, E)$ , the PageRank algorithm assigns a value  $PR$  to each node as their importance measurement. We further adopt the Weighted PageRank algorithm (Xing and Ghorbani, 2004) to state the relatedness between nodes. We calculate the weight  $W$  of the edge which links node  $v$  to node  $u$  using various factor functions  $\mathcal{F}_i$ , the weight function is described as follow,

$$W(u, v) = \sum_{i=1}^N \lambda_i \mathcal{F}_i(u, v, q)$$

<sup>1</sup> We set  $\varepsilon=0.01$ .

<sup>2</sup> We set  $\delta = 0.0001$ .

where  $q$  is a query phrase,  $\mathcal{F}_i(u, v, q)$  is a factor function and  $\lambda_i$  is the weight of the factor. The weighted  $PR$  value of a certain node  $u$  is defined iteratively as:

$$PR(u) = \sum_{v \in R(v)} PR(v)W(u, v)$$

where  $R(v)$  is a set of nodes that point to  $u$ .

**Figure 1.** Example graph for the phrase “on the whole”.

### 3.3 Linguistically Motivated Factors

Our model enables linguistically motivated factors to optimize the performance of paraphrase extraction. In this sub-section, we introduce three decisive factors: lexical distributional similarity, syntactic distributional similarity and translation similarity.

#### Lexical distributional similarity factor

Lexical distributional information is to ensure that the contexts in which the generated paraphrases appear are similar. For each phrase  $p$  in  $G$ , we extract three kinds of context vectors,  $v_L$ ,  $v_R$ ,  $v_{LR}$  and calculate vector similarities. Vectors  $v_L$  and  $v_R$  represent two sets of adjacent words which occur in the left and right of  $p$  respectively. Words appear simultaneously in both left and right sides of  $p$  are also extracted as the feature vector  $v_{LR}$ . Each item in vectors is an associated score calculated by pointwise

mutual information of the phrase  $p$  (Cover and Thomas, 1991).

Given the query phrase  $q$ , for each paraphrase candidate  $u$  in  $G$ , we calculate the cosine similarity of the context vectors,  $v_L$ ,  $v_R$ ,  $v_{LR}$  between  $q$  and  $u$ . That is, three factors  $\mathcal{F}_{v_L}$ ,  $\mathcal{F}_{v_R}$  and  $\mathcal{F}_{v_{LR}}$  are described as a cosine similarity function:

$$\mathcal{F}_k = \frac{v_{u_k} \cdot v_{q_k}}{|v_{u_k}| |v_{q_k}|}$$

where  $v_{u_k}$  denotes a context vector of  $u$ , and  $v_{q_k}$  a context vector of  $q$  and  $k \in \{L, R, LR\}$ .

#### Syntactic distributional similarity factor

Calculating the extrinsic syntactic similarity between nodes is used to maintain the syntactic correctness of the generated paraphrases. For each phrase  $p$ , we extract three vectors  $s_L$ ,  $s_R$ ,  $s_{LR}$ , which represents the <POS tag, frequency> pairs that appear on the left, right and both left and right sides of the phrase  $p$ . We use the GENIA tagger to obtain POS tags surrounding the phrase  $p$ . Each item in vectors is paired with the frequency of the corresponding tag. For each paraphrase candidate  $u$  of the query phrase  $q$ , we calculate the similarities  $\mathcal{F}_{s_L}$ ,  $\mathcal{F}_{s_R}$  and  $\mathcal{F}_{s_{LR}}$  between the vectors of  $u$  and  $q$  using cosine similarity.

$$\mathcal{F}_k = \frac{s_{u_k} \cdot s_{q_k}}{|s_{u_k}| |s_{q_k}|}$$

where  $s_{u_k}$  denotes a vector of  $u$ , and  $s_{q_k}$  a vector of  $q$ , and  $k \in \{L, R, LR\}$ .

#### Translation similarity factor

Next, we calculate the intrinsic translation similarity which is capable of preserving semantic equivalence. Translation similarity factor for an edge connecting node  $v$  and  $u$  is defined as:

$$\mathcal{F}_{tran} = \sum_{f \in T(v)} P(f|v)P(u|f)$$

where  $u$  is one paraphrase of phrase  $v$ ,  $T(v)$  denotes a set of the foreign-language alignment of  $v$ , and  $P(\cdot)$  the translation probability. Both of the alignment and translation probability are described in Och and Ney (2003).

### 3.4 Parameter Optimization

Once the factors are selected, we have to determine the weights of the factors, (i.e.,  $\lambda_i$  in Section 3.2). In other words, we train the weights of factors such that the performance is optimal for a given developing data set. We use Discounted Cumulative Gain (DCG) (Järvelin and Kekäläinen, 2002) to measure the quality of paraphrases. From the top to the bottom of the result list, the DCG score is accumulated with the gain of each result discounted at lower ranks. The DCG score is defined as:

$$DCG(r, c) = \sum_{i=1}^k \frac{2^{score_i} - 1}{\log_2(i + 1)}$$

where  $r$  represents a set of manually labeled paraphrase scores,  $c$  is a set of paraphrases to be evaluated, and  $score_i$  is the paraphrase score at rank  $i$  of  $c$ .

The parameters<sup>3</sup> are selected in order to maximize the DCG scores in a total of  $S$  query phrases from the developing data set:

$$\hat{\lambda}_1^N = arg \max_{\lambda_1^N} \left\{ \sum_{s=1}^S DCG(r_s, \hat{c}(p_s, \lambda_1^N)) \right\}$$

where  $\hat{c}$  is a set of paraphrases of the query phrase  $p_s$ , extracted from our model under the parameter values  $\lambda_1^N$ .

In the process, we first assign each parameter a random value ranging from 0 to 1 and use a grid-based line optimization method to optimize the parameters. While optimizing a parameter, we maximize the parameter of certain dimension while the parameters of other dimensions are fixed. The process stops when the values of the parameters do not change in two iterations.

## 4. Results

### 4.1 Experimental Setting

In this paper, we adopted the Danish-English section (containing 1,236,427 sentences) of the Europarl corpus, version 2 (Koehn, 2002) for computing distributional similarity and translation similarity. Word alignments were

<sup>3</sup> In this paper, the parameters are  $\lambda_{v_L} = 0.03$ ,  $\lambda_{v_R} = 0.01$ ,  $\lambda_{v_{LR}} = 0.99$ ,  $\lambda_{s_L} = 0.00001$ ,  $\lambda_{s_R} = 0.00001$ ,  $\lambda_{s_{LR}} = 0.18$  and  $\lambda_{tran} = 0.06$ .

produced by Giza++ toolkit (Och and Ney, 2003). We randomly selected 50 phrases as the developing set for optimizing parameters. For each phrase, three distinct sentences which containing the phrase are randomly sampled. A total of 6073 paraphrases have been labeled score 0 (incorrect), 1 (partially correct), and 2 (correct) by considering the fluency of each sentence for developing optimization.

We compared our augmentable paraphrase extraction framework (**APF**) with three baselines: the syntactically-constrained pivot method (**SBiP**) (Callison-Burch, 2008), syntactically-constrained pivot method using monolingual distributional similarity (**SBiP-MonoDS**) (Chan et al., 2011) and the graph-based method (**GB**) (Chen et al., 2012). To assess the contribution of the parameter optimization, we built another model based on APF with identical weights of factors (**APF-avgW**).

We evaluated the paraphrase quality through a substitution test. We randomly selected 133 most commonly used phrases from 30 research articles. For each phrase, we extracted the corresponding paraphrase candidates and evaluated its top 5 candidates. At the same time, three or less distinct sentences containing the phrase were randomly sampled (a total of 398 sentences were evaluated) from the New York Times section of the English Gigaword (LDC2003T05) to capture the fact that paraphrases are valid in some contexts but not others (Szpektor et al., 2007). Two native speaker judges evaluated whether the candidates are syntactically and semantically appropriate in various contexts. They assigned two values corresponding to the semantic and syntactic considerations to each sentence by score 0, (not acceptable), 1 (“acceptable”) and 2 (“acceptable and correct”). The inter-annotator agreement was 0.67.

It is worth noting that we include two measurement schemes for comprehensive analysis. The strict scheme considers a paraphrase as “correct” if and only if both of the two judges scored 2 points, whereas the other one considers a paraphrase as “acceptable” if it is given scores of 1 or 2.

### 4.2 Experimental Results

We compared the performance of the five models, **SBiP**, **SBiP-MonoDS**, **GB**, **APF-avgW** and **APF**, using the precision, coverage, MRR and DCG. Because the number of paraphrases generated by **SBiP**, **SBiP-DS** (101 phrases) and **GB**, **APF-avgW**, **APF** (131 phrases) are varied, we

decided to analyze the results of 99 phrases involving 295 sentences which were generated by all five models. Top- $k$  precision indicates the percentage of the sentences in which correct paraphrase(s) appear in the top- $k$  paraphrase candidates. The coverage was measured by the number of sentences in which at least one out of five paraphrases is correct within all 398 sentences.

Table 1 shows the results of precision and coverage in overall consideration. As can be seen, the **APF** achieved higher precision and coverage than the other four methods.

Additionally, we evaluated the results using MRR. MRR is defined as a measure of how much effort needed for a user to locate the first appropriate paraphrase for the given phrase in the ranked list of paraphrases. As shown in Table 2, the **APF** model performed better than the other models in both correct and acceptable measures. Moreover, Table 3 showed that the **APF** model outperformed the other models in both correct and acceptable measures based on either overall or individual consideration. DCG comprehensively considers both the number of good quality paraphrases and the ranking of these paraphrases. Overall, the **APF** model achieved better performance in paraphrase extraction.

	Top-1 precision	Top-5 precision	Coverage
SBiP	0.13/0.29	0.29/0.59	0.22/0.45
SBip-DS	0.15/0.36	0.32/0.57	0.25/0.44

**Table 3.** DCG scores of the five models. Note that the former value indicates **correct** measures and the **latter** acceptable measures.

## 5. Conclusion

In this paper, we propose a paraphrase extraction framework. Accommodating various linguistically motivated factors, the framework is capable of extracting better paraphrases carrying linguistic features. The results of the manual evaluation demonstrated that the proposed methods achieved performance improvement in terms of precision, coverage, MRR and DCG. The optimized parameters show that the lexical and syntactic distributional similarity factors make a substantial contribution to our model. Specifically, the words as well as the POS tags appear in both left and right sides show satisfactory performance.

However, some further analyses could be conducted in the future. Although the weights of parameters carry the linguistic properties, the proposed factors could be considered separately for examining and comparing the individual effectiveness in our framework. On the other hand, other factors could be taken in consideration. For example, parsing information could be added to the framework to investigate whether or to what extent it contributes to the paraphrasing task.

## Abstract

We propose a supervised classification approach for automatically determining the polarities of medical sentences. Our polarity classification approach is context-sensitive, meaning that the same sentence may have differing polarities depending on the context. Using a set of carefully selected features, we achieve 84.7% accuracy, which is significantly better than current state-of-the-art for the polarity classification task. Our analyses and experiments on a specialised corpus indicate that automatic polarity classification of *key* sentences can be utilised to generate evidence-based recommendations.

## 1 Introduction

Evidence Based Medicine is a practice that requires practitioners to rely on the best available medical evidence when answering clinical queries. While this practice improves patient care in the long run, it poses a massive problem of information overload to practitioners because of the large volume of medical text available electronically (e.g., MEDLINE<sup>1</sup> indexes over 22 million articles). Research has shown that the act of searching for, appraising, and synthesising evidence from multiple documents generally requires more time than practitioners can devote (Ely et al., 1999). As a result, practitioners would benefit from automatic systems that help perform these tasks and generate *bottom-line recommendations*.

In this paper, we take the first steps towards the generation of bottom-line, evidence-based summaries. Our analyses reveal that the polarities of *key* sentences in medical documents can be utilised to determine final recommendations associated with a query. *Key* sentences refer to the

<sup>1</sup><http://www.ncbi.nlm.nih.gov/pubmed>

most important sentences in a medical abstract that are associated with a posed query. In our work, we use the sentences extracted by a domain-specific, query-focused text summariser. Consider the following sentence for example:

*A significant body of evidence supports the use of long-acting bronchodilators and inhaled corticosteroids in reducing exacerbations in patients with moderate to severe COPD.*

The sentence is taken from a medical abstract, and clearly recommends the use of *bronchodilators and inhaled corticosteroids*, which are the context interventions in this case. In other words, it has a positive polarity for this task. Since positively polarised *key* sentences generally represent the recommendations, we attempt to automatically identify the polarities of medical sentences as the first step towards generating bottom-line recommendations. We show that sentence-level polarity classification is a useful approach for generating evidence-based recommendations. We model the problem of sentence polarity classification as a binary classification problem, and we present a supervised machine learning approach to automatically classify the polarities of *key* sentences. Our classification approach is context dependent, i.e., the same sentence can have differing polarities depending on the context.

## 2 Related Work

Research work most closely related to ours is that by Niu *et al.* (2005; 2006). In their approach, the authors attempt to perform automatic polarity classification of medical sentences into four categories, and apply supervised machine learning to solve the classification problem. In contrast, our approach takes into account the possibility of the same sentence having multiple polarities. This can happen when multiple interventions are mentioned

in the same sentence, with differing results associated with each intervention. Keeping the end-use of this task in mind, we model the problem as a binary classification problem. We use the approach proposed by Niu *et al.* (2005) as a benchmark approach for comparison, and also use some of the features proposed by them.

The majority of the work related to polarity classification has been carried out outside the medical domain, under various umbrella terms such as: sentiment analysis (Pang *et al.*, 2002; Pang and Lee, 2004), semantic orientation (Turney, 2002), opinion mining (Pang and Lee, 2008), subjectivity (Lyons, 1981) and many more. All these terms refer to the general method of extracting polarity from text (Taboada *et al.*, 2010). The pioneering work in sentiment analysis by Pang *et al.* (2002) utilised machine learning models to predict sentiments in text, and their approach showed that SVM classifiers (Vapnik, 1995) trained using bag-of-words features produced good accuracies. Following this work, such classification approaches have been applied to texts of various granularities: documents, sentences, and phrases. Research has also focused on classifying polarities relative to contexts (Wilson *et al.*, 2009). However, only limited research has taken place on applying polarity classification techniques on complex domains such as the medical domain (Niu *et al.*, 2005; Sarker *et al.*, 2011).

Our aim is to investigate the possibility of using sentence-level polarity classification to generate bottom-line, evidence-based summaries. While there has been some research on automatic summarisation in this domain (Lin and Demner-Fushman, 2007; Niu *et al.*, 2006; Sarker *et al.*, 2013; Cao *et al.*, 2011), to the best of our knowledge, there is no system that currently produces bottom-line, evidence-based summaries that practitioners can utilise at point of care.

### 3 Data, Annotation and Analysis

We use the corpus by Mollá and Santiago-Martinez (2011), which consists of 456 clinical questions, sourced from the Journal of Family Practice<sup>2</sup> (JFP). Each question is associated with one or more bottom-line answers (multi-document summaries) authored by contributors to JFP. Each bottom-line answer is in turn associated with detailed explanations provided by the JFP contrib-

<sup>2</sup><http://www.jfponline.com>

utors; these detailed explanations are generally single-document summaries. The corpus also contains abstracts of source documents that provide the evidence of the detailed explanations.

The bottom-line summaries in the corpus present final recommendations in response to the queries. For example, a bottom-line summary may or may not recommend an intervention in response to a disorder. Thus, the bottom-line summaries can be considered to be polarised — when an intervention is recommended, the polarity is positive, and when it is not recommended, the polarity is non-positive. The bottom-line summaries are generated by synthesising information from individual documents. Therefore, it is likely that the polarities of the individual documents, or their summaries, agree with the polarities of the associated bottom-line summaries.

For the preliminary annotation and analysis, we used the same data as the task-oriented coverage analysis work described in (Sarker *et al.*, 2012). The data consists of 33 manually identified questions. All these questions are treatment questions and the bottom-line summaries mention one or more interventions, some of which are recommended while the others are not. We first annotated the polarities of the bottom-line answers relative to the interventions mentioned. We used two categories for the annotation — recommended/not recommended (positive/non-positive). Figure 1 presents a question, the associated bottom-line summary, and our contextual polarity annotation. All the answers to the 33 questions were annotated by the first two authors of this paper. In almost all the cases, there was no disagreement between the annotators; the few disagreements were resolved via discussion.

Next, we collected the *key* (summary) sentences from the abstracts associated with the bottom-line summaries. To collect the *key* sentences from the documents, we used the QSpec summariser (Sarker *et al.*, 2013), which has been shown to generate content-rich, extractive, three-sentence summaries. We performed polarity annotation of these summary sentences. Similar to our bottom-line summary annotation process, for a sentence, we first identified the intervention(s) mentioned, and then categorised their polarities. We came across sentences where two different interventions were mentioned and the polarities associated with them were opposite. Consider the following sentence

**Question:** *What is the most effective beta-blocker for heart failure?*

**Bottom-line answer:** *Three beta-blockers-carvedilol, metoprolol, and bisoprolol-reduce mortality in chronic heart failure caused by left ventricular systolic dysfunction, when used in addition to diuretics and angiotensin converting enzyme (ACE) inhibitors.*

**Contextual Polarities:** *carvedilol – recommended; metoprolol – recommended; bisoprolol – recommended.*

Figure 1: Sample bottom-line summary and an example of polarity annotation.

fragment, for example:

*The present study demonstrated that the combination of cimetidine with levamisole is more effective than cimetidine alone and is a highly effective therapy ...*

For this sentence, the combination therapy is recommended over monotherapy with *cimetidine*. Therefore, the polarities are: *cimetidine with levamisole* – recommended; *cimetidine alone* – not recommended. At the same time, in a number of cases, although a sentence is polarised, it does not mention an intervention. Such sentences were annotated of this paper without adding any intervention to the context. In this manner, we annotated a total of 589 sentences from the QSpec summaries associated with the 33 questions. If a sentence contained more than one intervention, we added an annotated instance for each intervention.

A subset of the QSpec sentences, 124 in total, were annotated by the second author of this paper and these annotations were used to measure agreement among the annotators. We used the Cohen’s Kappa (Carletta, 1996) measure to compute inter-annotator agreement. We obtained an agreement of  $\kappa = 0.85$ , which can be regarded as almost perfect agreement (Landis and Koch, 1977).

Following the annotation process, we compared the annotations of the single document summary sentences with the bottom-line summary annotations. Given that a summary sentence has been annotated to be of positive polarity with an intervention in context, we first checked if the drug name (or a generalisation of it) is also mentioned in the bottom-line summary. If yes, we checked the polarity of the bottom-line summary. In this

manner, we collected a total of 177 summary sentence – bottom-line summary pairs. Among these, in 169 (95.5%) cases, the annotations were of the same polarity. In the rest of the 8 cases, the QSpec summary sentence recommended a drug, but the bottom-line summary did not.

We also manually examined the 8 cases where there were disagreements. In all the cases, this was either because individual documents presented contrasting results, i.e., the positive findings of one study were negated by evidence from other studies; or because a summary sentence presented some positive outcomes, but side effects and other issues were mentioned by other summary sentences, leading to an overall negative polarity.

If automatic sentence-level polarity classification techniques are to be used for generating bottom-line summaries in a two-step summarisation process, the first step (QSpec summaries) also needs to have very good recall. The QSpec summary sentences contained 99 out of the 109 unique interventions, giving a recall of 90.8%. We examined the causes for unrecalled interventions and found that of the 10 not recalled, 4 were due to missing abstracts from the corpus, and 2 drug names were not mentioned in any of the referenced abstracts. Thus, the actual recall is 96.1%. Considering the high recall of interventions in the summary sentences, and the high agreement among the summary sentences and bottom-line summary sentences, it appears that automatic polarity classification techniques have the potential to be applied for the task of bottom-line summary generation in a two-step summarisation process.

## 4 Automatic Polarity Classification

We model the problem of sentence level polarity classification as a supervised classification problem. We utilise the annotated contexts in our supervised polarity classification approach by deriving features associated with those contexts. We annotated a total of 2362 *key* sentences (QSpec summaries) from the corpus (1736 non-positive and 626 positive instances). We build on the features proposed by existing research on sentence level polarity classification and introduce some context-specific and context-independent features. The following is a description of the features.

### (i) Word n-grams

Our first feature set is word n-grams ( $n = 1$  and  $2$ ) from the sentences. Cues about the polarities

of sentences are primarily provided by the lexical information in the sentences (e.g., words and phrases). We lowercase the words, remove stopwords and stem the words using the Porter stemmer (Porter, 1980). For each sentence that has an annotated context, we replace the context word(s) using the keyword ‘\_CONTEXT\_’. Furthermore, we replace the disorder terms in the sentences using the keyword ‘\_DISORDER\_’. We used the MetaMap<sup>3</sup> tool (Aronson, 2001) to identify broad categories of medical concepts, known as the UMLS<sup>4</sup> *semantic types*, and chose terms belonging to specific categories as the disorders<sup>5</sup>.

#### (ii) Change Phrases

We use the Change Phrases features proposed by Niu *et al.* (2005). The intuition behind this feature set is that the polarity of an outcome is often determined by how a change happens: if a *bad* thing (e.g., mortality) was *reduced*, then it is a positive outcome; if a *bad* thing was *increased*, then the outcome is negative. This feature set attempts to capture cases when a *good/bad* thing is *increased/decreased*. We first collected the four groups of *good*, *bad*, *more*, and *less* words used by Niu *et al.* (2005). We augmented the list by adding some extra words to the list which we expected to be useful. In total, we added 37 *good*, 17 *bad*, 20 *more*, and 23 *less* words. This feature set has four features: MORE-GOOD, MORE-BAD, LESS-GOOD, and LESS-BAD. The following sentence exhibits the LESS-BAD feature, indicating a positive polarity.

*Statistically and clinically significant improvement, including a statistically significant reduction in mortality, has been noted in patients receiving ...*

To extract the first feature, we applied the approach by Niu *et al.* (2005): a window of four words on each side of a MORE-word in a sentence was observed. If a GOOD-word occurs in this window, then the feature MORE-GOOD is activated. The other three features were activated in a similar way. The features are represented using a binary vector with 1 indicating the presence of a feature and 0 indicating absence.

<sup>3</sup><http://metamap.nlm.nih.gov/>

<sup>4</sup><http://www.nlm.nih.gov/research/umls/>

<sup>5</sup>Semantic types in this category: pathological function, disease or syndrome, mental or behavioral dysfunction, cell or molecular dysfunction, virus, neoplastic process, anatomic abnormality, acquired abnormality, congenital abnormality and injury or poisoning

#### (iii) UMLS Semantic Types

We used all the UMLS *semantic types* (identified using MetaMap) present in a sentence as features. Intuitively, the occurrences of *semantic types*, such as *disease or syndrome* and *neoplastic process*, may be different in different polarity of outcomes. Overall, the UMLS provides 133 *semantic types*, and we represent this feature set using a binary vector of size 133 – with 1 indicating the presence and 0 indicating the absence of a *semantic type*.

#### (iv) Negations

Negations play a vital role in determining the polarity of the outcomes presented in medical sentences. To detect negations, we apply three different techniques. In our first variant, we detect the negations using the same approach as (Niu *et al.*, 2005). In their simplistic approach, the authors use the *no* keyword as a negation word and use that for detecting negated concepts. To extract the features, all the sentences in the data set are first parsed by the Apple Pie parser<sup>6</sup> to get phrase information. Then, in a sentence containing the word *no*, the noun phrase containing *no* is extracted. Every word in this noun phrase except *no* itself is attached a ‘NO’ tag. We use a similar approach, but instead of the Apple Pie parser, we use the GENIA Dependency Parser (GDep)<sup>7</sup> (Sagae and Tsujii, 2007), since it has been shown to give better performance with medical text.

For the second variant, we use the negation terms mentioned in the BioScope corpus<sup>8</sup> (Vincze *et al.*, 2008), and apply the same strategy as before, using the GDep parser again. For the third variant, we use the same approach using the negation terms from NegEx (Chapman *et al.*, 2001).

#### (v) PIBOSO Category of Sentences

Our analysis of the QSpec summary sentences suggested that the class of a sentence may be related to the presence of polarity in the sentence. For example, a sentence classified as *Outcome* is more likely to contain a polarised statement than a sentence classified as *Background*. Therefore, we use the PIBOSO classifications of the sentences as a feature. The sentences are classified using the system proposed by Kim *et al.* (2011) into the categories: Population, Intervention, Background, Outcome, Study Design and Other.

<sup>6</sup><http://nlp.cs.nyu.edu/app/>

<sup>7</sup><http://people.ict.usc.edu/~sagae/parser/gdep/>

<sup>8</sup><http://www.inf.u-szeged.hu/rgai/bioscope>

#### (vi) Synset Expansion

Certain terms play an important role in determining the polarity of a sentence, irrespective of context (e.g., some of the *good* and *bad* words used in the *change phrases* feature). Certain adjectives, and sometimes nouns and verbs, or their synonyms, are almost invariably associated with positive or non-positive polarities. Thus, for each adjective, noun or verb in a sentence, we use WordNet<sup>9</sup> to identify the synonyms of that term and add the synonymous terms, attached with the ‘SYN’ tag, as features.

#### (vii) Context Windows

This is the first of our context sensitive features. We noticed that, in a sentence, the words in the vicinity of the context-intervention may provide useful information regarding the polarity of the sentence relative to that drug. Thus, we collect the terms lying inside 3-word boundaries before and after the context-drug term(s). This feature is useful when there are direct comparisons between two interventions. We tag the words appearing before an intervention with the ‘BEFORE’ tag and those appearing after with the ‘AFTER’ tag, and use these as features.

#### (viii) Dependency Chains

In some cases, the terms that influence the polarity of a sentence associated with an intervention do not lie close to the intervention itself, but is connected to it via dependency relationships, and to capture them, we use the parses produced by the GDep parser. For each intervention appearing in a sentence, we identify all the terms that are connected to it via specific dependency chains using the following rule:

1. Start from the intervention and move up the dependency tree till the first VERB item the intervention is dependent on, or the ROOT.
2. Find all items dependent on the VERB item (if present) or the ROOT element.

All the terms connected to the context term(s) via this relationship are collected, tagged using the ‘DEP’ keyword and used as features.

#### (ix) Other Features

We use a number of simple binary and numeric features, which are: context-intervention position, summary sentence position, presence of modals, comparatives, and superlatives.

## 4.1 Classification, Results and Discussion

In our experiments, we use approximately 85% of our annotated data (2008 sentences) for training and the rest (354 sentences) for evaluation. We performed preliminary 10-fold cross validation experiments on the training set using a range of classifiers and found SVMs to give the best results, in agreement with existing research in this area. We use the SVM implementation provided by the Weka machine learning tool<sup>10</sup>.

Table 1 presents the results of our polarity classification approach. The overall accuracy obtained using various feature set combinations is shown, along with the 95% confidence intervals<sup>11</sup>, and the f-scores for the positive and non-positive classes. The first set of features shown on the table represent the features used by Niu *et al.* (2006); we consider the scores achieved by this system as the baseline scores. The second row presents the results obtained using all context-free features. It can be seen from the table that the two context-free feature sets, expanded synsets and PIBOSO categories, improve classification accuracy from 76% to 78.5%. This shows the importance of these context-free features. All three negation detection variants give statistically significant increases in accuracy compared to the baseline.

The non-positive class f-scores are much higher than the positive class f-scores. The highest f-score obtained for the positive class is 0.74, and that for the non-positive class is 0.89. This is perhaps due to the fact that the number of training examples for the latter class is more than twice to that of the positive class. We explored the effect of the size of training data on classification accuracy by performing more classification experiments. We used different sized subsets of the training set: starting from 5% of its original size, and increasing the size by 5% each time. To choose the training data for each experiment, we performed random sampling with no replacement. Figure 2 illustrates the effect of the size of the training data on classification accuracies.

As expected, classification accuracies and f-scores increase as the number of training instances increases. The increase in the f-scores for the positive class is much higher than the increase for the non-positive class f-scores. This verifies that the

<sup>10</sup><http://www.cs.waikato.ac.nz/ml/weka/>

<sup>11</sup>Computed using the `binom.test` function of the R statistical package (<http://www.r-project.org/>)

Feature sets	Accuracy (%)	95% CI	Positive f-score	Non-positive f-score
i,ii,iii, and iv (Niu et al., 2006)	76.0	71.2 – 80.4	0.58	0.83
Context-free (i-vi)	78.5	73.8 – 82.8	0.64	0.85
All (Niu)	83.9	79.7 – 87.6	0.71	0.89
All (Bioscope)	84.7	80.5 – 88.9	0.74	0.89
All (NegEx)	84.5	80.2 – 88.1	0.73	0.89

Table 1: Polarity classification accuracy scores, 95% confidence intervals, and class-specific f-scores for various combinations of feature sets.

Figure 2: Classification accuracies, and positive and non-positive class f-scores for training sets of various sizes.

positive class, particularly, suffers from the lack of available training data. The increasing gradients for all three curves indicate that if more training data were available, better results could be obtained for both the classes. This is particularly true for the positive class, which is also perhaps the more important class considering our goal of generating bottom-line recommendations for clinical queries. The highest accuracy obtained by our system is 84.7%, which is significantly better than the baseline system for this domain.

To conclude this investigation, we performed manual evaluation to validate the suitability of the polarity classification approach for the generation of bottom-line recommendations. We used the 33 questions from our preliminary analysis for this. We ran 10-fold cross validation on the whole

data set, collected all the sentences associated with these 33 questions, and computed the precision and recall of the automatically identified polarities of the interventions by comparing them with the annotated bottom-line recommendations. The results obtained by the automatic system were: recall - 0.62, precision - 0.82, f-score - 0.71. Understandably, the recall is low due to the small amount of training data available for the positive class, and the f-score is similar to the f-score obtained by the positive class in the polarity classification task.

## 5 Conclusion and Future Work

We presented an approach for automatic, context-sensitive, sentence-level polarity classification for the medical domain. Our analyses on a specialised corpus showed that individual sentence-level polarities agree strongly with the polarities of bottom-line recommendations. We showed that the same sentence can have differing polarities, depending on the context intervention. Therefore, incorporating context information in the form of features can be vital for accurate polarity classification. Our machine learning approach performs significantly better than the baseline system with an accuracy of 84.7%, and an f-score of 0.71 for the bottom-line recommendation prediction task.

Post-classification analyses showed that the most vital aspect for improving performance is the availability of training data. Research tasks specific to a specialised domain, such as the medical domain, can significantly benefit from the presence of more annotated data. Due to the promising results obtained in this paper, and the importance of this task, future research should focus on annotating more data and utilising them for improving classification accuracies. Our future research will also focus on implementing effective strategies for combining the contextual sentence-level polarities to generate bottom-line recommendations.

# Clustering Microtext Streams for Event Identification

Jie Yin

Computational Informatics

CSIRO, Australia

Jie.Yin@csiro.au

## Abstract

The popularity of microblogging systems has resulted in a new form of Web data – microtext – which is very different from conventional well-written text. Microtext often has the characteristics of informality, brevity, and varied grammar, which poses new challenges in applying traditional clustering algorithms to analyze microtext. In this paper, we propose a novel two-phase approach for clustering streaming microtext, in particular Twitter messages, into event-based clusters. In the online phase, an incremental process is applied to discover base clusters and maintain detailed summary statistics. Upon demand for any user-specified time horizons, an offline phase is triggered to merge related clusters together. We demonstrate that our proposed approach can achieve better clustering accuracy than state-of-the-art methods.

## Introduction

Microtext is a newly emerging type of Web data which is generated in enormous volumes with the proliferation of online microblogging systems. These systems, such as Twitter and Facebook, provide a light-weight, easy form of communication that enables individuals around the globe to share information and express their opinions in fluid and less formal ways. Microtext streams generated from these sites offer a rich source of real-time information about a wide variety of real-world events, ranging from planned occurrences such as political campaigns or sports games, to unexpected incidents such as earthquakes or terrorist riots. To provide insight into user-generated content broadcast in microtext streams, clustering approaches have demonstrated great potential for

identifying what topics people are talking about and tracking how events unfold over time.

Clustering microtext streams poses a number of new challenges, due to short, noisy and informal nature of microtext [Ellen, 2011]. First, clustering techniques should be scalable to the sheer volume of data generated in microblogging systems. Twitter, for example, generates over 400 million tweets per day in early 2013. Thus, it is crucial to develop efficient clustering algorithms that can handle such massive amounts of streaming data. Second, microtext often has the characteristic of informality, brevity, varied grammar, and free-style. Depending on various personal style or background knowledge, people tend to use different words to convey the same or similar meanings, when writing about a particular event. Therefore, it is highly desirable to design effective clustering algorithms that can discover event-based clusters over time.

To cope with the sparsity and brevity of microtext, different methods have been proposed for microtext clustering in recent years. The majority of previous work has primarily focused on clustering a static collection of short documents [Rangrej et al., 2011, Tsur et al., 2012], or on using surface features to compute pairwise similarity between microtext [Reuter et al., 2011, Li et al., 2012]. However, the challenge of how to effectively cluster microtext in dynamic data streams has not been well addressed.

In this paper, we propose a novel framework for automatically grouping streaming microtext, in particular Twitter messages, into a set of event-based clusters; it intelligently divides the clustering process into an online component which maintains summary statistics, and an offline component which uses these compact statistics to discover event-based clusters. In the online phase, an incremental process is applied to discover base clusters and maintain detailed summary statistics about the clusters. This process can be efficiently

performed for the purpose of online social media monitoring. The generated base clusters serve as an intermediate statistical representation of the stream. Upon request, an offline phase is thereafter utilized to perform more computational analyses which merge similar clusters together in a bottom-up manner within a given time horizon. Experimental results show that our proposed clustering algorithm improve the clustering quality of other state-of-the-art approaches.

## Related Work

This section reviews two primary related research areas: first, short text clustering which deals with very short and informal text; and second, studies that address event identification in social media.

### Short Text Clustering

Although document clustering is well studied in the past decade, clustering very short, noisy and informal text has remained a challenging task. Rosa et al. [2010] studied the problem of clustering tweets into several pre-specified categories. They used hashtags as indicators of topics and argued that the clusters produced by traditional unsupervised methods can often be incoherent from a topical perspective. Rangrej et al. [2011] compared the performance of three document clustering techniques on Twitter data, and found that graph-based approach using affinity propagation performs best in clustering tweets. To cope with the sparsity of tweets, Tsur et al. [2012] constructed a virtual document by concatenating all micro-messages having the same hashtag, and then applied  $k$ -means algorithm to cluster virtual documents. Existing research has primarily focused on clustering a static collection of short text, while the challenge of continuously clustering microtext streams has not been well addressed.

### Event Identification in Social Media

In recent years, identifying events from social media has attracted much attention. Petrović et al. [2012] applied a  $k$ -nearest neighbor approach to detect the first message talking about an event in a stream of Twitter messages, and used locality-sensitive hashing to speed up the computational process. Reuter et al. [2011] formulated the event identification problem as a record linkage task, in which a blocking strategy was used to reduce the number of pairs of documents consid-

ered for computing pairwise similarity. Becker et al. [2011] proposed an incremental clustering approach to group Twitter messages into clusters, which was similar to the method developed for detecting events in streams of text documents [Allan et al., 1998]. This approach determines the assignment of a message based on its similarity to textual centroids of existing clusters. Li et al. [2012] proposed to first detect bursty tweet segments as event segments and then use graph-based clustering to cluster event segments into events. Most of these works have either relied on computing pairwise similarity between static messages, or considered only the textual features of messages. In our work, however, we focus on developing an efficient framework for clustering a continuous stream of microtext, which groups clusters in a single pass and has the flexibility to merge clusters upon demand to identify event-based clusters.

### Microtext Stream Clustering

We aim to design an effective microtext stream clustering algorithm that can meet three requirements: (1) The ability to handle massive volumes of microtext (*i.e.*, tweets) under the one-pass constraint of streaming scenarios; (2) The ability to employ temporal information in the clustering process, because tweets published within a certain time interval are more likely to correspond to the same event in the stream; (3) The ability to merge related clusters together when necessary. To meet these needs, we propose a new clustering framework which works in two phases, *i.e.*, an online discovery phase and an offline cluster merging phase. The basic idea is to carefully balance the computational load between the online component and the offline component. In the online phase, the Twitter stream is processed in a single pass to maintain sufficient summary statistics about the evolving stream. The offline phase provides the flexibility for an analyst to perform queries about clusters and retrieve event-based clusters upon demand over different time horizons.

Below, we detail the two phases in the following two subsections.

#### Online Discovery Phase

The main task of the online phase is to provide a one scan algorithm over the incoming Twitter stream for identifying base clusters, with each cluster consisting of a set of similar tweets. For

this purpose, we design an efficient single-pass clustering algorithm which clusters the stream of tweets in an incremental manner.

To represent textual information of tweets, we employ a traditional vector-space model which uses the bag-of-words representation. A tweet is represented using a vector of words (terms or features), which are weighted using the term frequency (TF) and the inverse document frequency (IDF) [Salton and Buckley, 1988]. Using this model, a tweet represents a data point in  $d$ -dimensional space,  $\mathbf{m}_i = (v_1, v_2, \dots, v_d)$ , where  $d$  is the size of the word vocabulary and  $v_j$  is the TF-IDF weight of  $j^{\text{th}}$  word in tweet  $m_i$ . However, in a dynamic microtext stream, word vocabulary changes and the number of tweets increases over time, making it computationally expensive to recalibrate the inverse document frequency of TF-IDF. Therefore, we resort to using term frequency as the term weight and adopting a sparse matrix representation of tweets to deal with dynamically changing vocabulary in our clustering algorithm.

To discover meaningful clusters, one important factor is defining an effective similarity measure. In our work, we use cosine similarity to measure textual similarity between two tweets, which is defined as

$$\text{sim}_{\text{text}}(\mathbf{m}_i, \mathbf{m}_j) = \frac{\mathbf{m}_i \cdot \mathbf{m}_j}{\|\mathbf{m}_i\| \times \|\mathbf{m}_j\|}, \quad (1)$$

where  $\mathbf{m}_i \cdot \mathbf{m}_j$  indicates the dot product of vectors  $\mathbf{m}_i$  and  $\mathbf{m}_j$ . Besides,  $\|\mathbf{m}_i\|$  and  $\|\mathbf{m}_j\|$  denotes the norm of vectors  $\mathbf{m}_i$  and  $\mathbf{m}_j$ , respectively.

Since real-world events typically span a limited time interval, tweets that largely differ on their publication times are much less likely to belong to the same event. Therefore, in order to cluster tweets into temporally-related groups, we also exploit a time similarity measure defined as

$$\text{sim}_{\text{time}}(\mathbf{m}_i, \mathbf{m}_j) = \exp\left(-\frac{|t_{\mathbf{m}_i} - t_{\mathbf{m}_j}|}{\lambda}\right), \quad (2)$$

which is based inversely on the distance between tweets' publication dates/times.  $|t_{\mathbf{m}_i} - t_{\mathbf{m}_j}|$  indicates the time difference between tweets  $\mathbf{m}_i$  and  $\mathbf{m}_j$ , represented as the number of days, and  $\lambda$  is the number of days of one month, whose value is application dependent. In our case, if  $t_{\mathbf{m}_i}$  and  $t_{\mathbf{m}_j}$  are more than one month apart, we consider time similarity between  $\mathbf{m}_i$  and  $\mathbf{m}_j$  to be very small.

Putting together, our clustering algorithm uses a

combined similarity measure defined as:

$$\text{sim}(\mathbf{m}_i, \mathbf{m}_j) = \text{sim}_{\text{text}}(\mathbf{m}_i, \mathbf{m}_j) \cdot \text{sim}_{\text{time}}(\mathbf{m}_i, \mathbf{m}_j). \quad (3)$$

This similarity measure not only captures the similarity between the textual vectors of tweets, but also penalizes the similarity between tweets if their publication dates/times are far away.

To maintain sufficient information about clusters, we represent each cluster  $C_i$  using a cluster feature vector  $\psi(C_i)$ , defined as follows:

- Textual centroid  $C_i^w$ : which is a vector in which each element represents the average weight of the corresponding words for all tweets in cluster  $C_i$ .
- Time centroid  $C_i^t$ : which is the average publication time of all tweets that form cluster  $C_i$ .
- Cluster size  $|C_i|$ : which is defined as the number of tweets belonging to cluster  $C_i$ .

Now we describe the process of the incremental clustering algorithm. Given a Twitter stream in which the tweets are sorted according to their published times, the algorithm takes the first tweet from the stream, and uses it to form a cluster. As a new tweet  $\mathbf{m}$  arrives, we calculate the similarity between tweet  $\mathbf{m}$  and any existing clusters  $C_i$  as

$$\text{sim}(\mathbf{m}, C_i) = \text{sim}_{\text{text}}(\mathbf{m}, C_i^w) \cdot \text{sim}_{\text{time}}(t_{\mathbf{m}}, C_i^t). \quad (4)$$

Let  $C$  be the cluster that has the maximum similarity with  $\mathbf{m}$ . If  $\text{sim}(\mathbf{m}, C)$  is less than a similarity threshold  $\delta_{\text{sim}}$ , which is to be determined empirically, a new cluster is created to include  $\mathbf{m}$ ; Otherwise, the tweet  $\mathbf{m}$  is assigned to the closest cluster  $C$ . By adjusting the threshold  $\delta_{\text{sim}}$ , we can obtain clusters at different levels of granularity. Once a new tweet  $\mathbf{m}$  is added to cluster  $C_i$ , we update the corresponding cluster representatives  $\psi(C_i)$  using the following equations:

$$\hat{C}_i^w = \frac{C_i^w \times |C_i| + \mathbf{m}}{|C_i| + 1}, \quad (5)$$

$$\hat{C}_i^t = \frac{C_i^t \times |C_i| + t_{\mathbf{m}}}{|C_i| + 1}, \quad (6)$$

$$|\hat{C}_i| = |C_i| + 1. \quad (7)$$

This incremental algorithm is efficient as it considers each tweet at once, and can thus scale to a growing amount of tweets. To further improve efficiency, we maintain a list of active clusters over

time in the online phase. If no more tweets are added to a cluster for a period of time, which is determined based on application needs, the cluster is considered inactive and it is removed from the active list. The algorithm considers only those clusters in the active list as candidates to which a new tweet can be added. The output of the algorithm is a list of clusters  $C_1, \dots, C_H$ , together with their cluster representatives  $\psi(C_1), \dots, \psi(C_H)$ .

### Offline Cluster Merging Phase

The base clusters generated by the online phase serve as an intermediate statistical representation, which can be maintained in an efficient way even for a large volume of tweets. The subsequent offline phase is utilized to merge a list of clusters into event-based clusters. There is no need to process the voluminous microtext stream, but the compactly stored summary statistics of clusters.

For a particular event, since users tend to convey the same or a similar meaning using different words depending upon their own personal style, the online phase would organize the tweets that report the same event, but expressed using different words, into different base clusters. Therefore, we propose to merge together the clusters that are related with respect to the same event in the offline phase. Concretely, we calculate a cluster merge criterion,  $link(C_i, C_j) = sim_{text}(C_i^w, C_j^w) \cdot sim_{time}(C_i^t, C_j^t)$ , which captures the inter-similarity between two clusters  $C_i$  and  $C_j$ . The principle is to merge a pair of clusters that have a larger inter-cluster similarity. When two clusters are merged, we merge a smaller cluster into the larger one and in this way, larger clusters are retained which can better represent significant events of interest.

The offline clustering phase provides the flexibility to query the clustering results at any time horizon. Given a list of clusters generated during the online phase, we consider iteratively merging two clusters  $C_{j^*}$  and  $C_{i^*}$  such that  $link(C_{i^*}, C_{j^*})$  is maximized. Accordingly, cluster representatives for cluster  $C_{i^*}$  are updated as follows:

$$\hat{C}_{i^*}^w = \frac{C_{i^*}^w \times |C_{i^*}| + C_{j^*}^w \times |C_{j^*}|}{|C_{i^*}| + |C_{j^*}|}, \quad (8)$$

$$\hat{C}_{i^*}^t = \frac{C_{i^*}^t \times |C_{i^*}| + C_{j^*}^t \times |C_{j^*}|}{|C_{i^*}| + |C_{j^*}|}, \quad (9)$$

$$|\hat{C}_{i^*}| = |C_{i^*}| + |C_{j^*}|. \quad (10)$$

To determine an optimal number of clusters,

we use the notion of *separation* to measure the clustering quality, which is defined as the average inter-cluster similarity over all the clusters, that is,  $S(k) = \frac{1}{N(N-1)} \sum_i \sum_j link(C_i, C_j)$ , where  $C_1, \dots, C_N$  are the clusters obtained at step  $k$ . The smaller value this metric has, the better clusters are separated from each other. Based on this metric, we design a criterion to decide whether or not to stop the merging process. At each step  $k$ , given two candidate clusters to be merged, we compute a validation index as

$$\Delta_k = \frac{S(k+1) - S(k)}{S(k)}, \quad (11)$$

which represents the relative change in inter-cluster similarity after a merge is made. If  $\Delta_k < 0$ , that means a cluster merge can improve the separation of clusters. We thus proceed with merging the two clusters. Otherwise, if  $\Delta_k \geq 0$ , we stop the cluster merging process. In this way, the optimal number of clusters can be automatically determined during the cluster merging process.

## Experiments

We carry out experiments to evaluate the effectiveness of our proposed algorithm, and compare its performance with other baseline methods.

### Dataset

The dataset we used is an annotated corpus of tweets collected from the beginning of July 2011 to September 2011 [Petrović et al., 2012]. The corpus was distributed as a set of tweet IDs, together with their annotations. We re-retrieved the tweets using Twitter search API<sup>1</sup> and obtained a set of 2,633 tweets. Each tweet was annotated as one out of 27 events, which cover a variety of real-world events, such as London riots, terrorist attacks in Norway, Earthquake in Virginia, and NASA's announcement about discovery of water on Mars. The annotations are used as the ground truth for evaluating the clustering algorithms.

We preprocessed the tweets by removing stopwords, user mentions (@username), and embedded links, because such elements in tweets may not be useful for indicating the topics. We compiled a list of stopwords that specifically suited Twitter content. It includes formal English stopwords such as *is*, *am*, informal English stopwords

<sup>1</sup><https://dev.twitter.com/docs/using-search>

such as *gonna*, *arent*, and Twitter specific stop-words such as *RT* that indicates a retweet. We also performed a shallow lexical normalization on tweets and stemmed words using Porter Stemmer. For lexical normalization, we only considered words that were emphasized by repeating one or more letters. If a letter was repeated more than three times, it was normalized to one instance of that letter. For example, the word *crazyyyyy* was turned to *crazy*.

For our clustering task, we constructed a Twitter stream by sorting all tweets according to their publication times. The stream was taken as input to the clustering algorithms. For each tweet, we mainly used bag-of-words and specific hashtags (words preceded with a # sign) as features to construct a vector model.

### Baselines

Our proposed algorithm is referred to as **MSC** (Microtext Stream Clustering). For comparison, we use two other methods as baselines:

- **IC**: which is a standard incremental clustering algorithm adopted by Becker et al. [2011]. It determines the assignment of a message solely based on its similarity to the textual centroids of existing clusters.
- **IC-Time**: which differs from our proposed algorithm in that it only uses the first on-line phase to discover clusters. By comparing with this baseline, we show how much gain in clustering quality can be achieved with the offline cluster merging.

In our experiments, we set parameter  $\lambda$  in Eq.(2) to be 30. In addition, we set the similarity threshold  $\delta_{sim} = 0.2$  for all the algorithms.

### Evaluation Metrics

Let  $\mathcal{C} = \{C_1, \dots, C_K\}$  denote the clustering result produced by one clustering algorithm, and  $\mathcal{G} = \{G_1, \dots, G_L\}$  denote the desired ground truth. We use two evaluation metrics: F-measure [Yin and Yang, 2005] and normalized mutual information (NMI) [Strehl and Ghosh, 2003], to validate the effectiveness of the clustering algorithms. we observe that the results are strongly correlated on the two metrics.

### Experimental Results

We first performed experiments to evaluate the performance of three clustering algorithms on the

entire stream. Since hashtags are considered as good indicators of topics in the tweets, we investigated two different ways of using hashtags as features: first, considering hashtags in the same way as words, and second, removing the # symbol and treating hashtags as normal words. Table 1 reports the clustering accuracy using the three algorithms on the two settings.

		F-measure	NMI
<i>Hashtags</i>	IC	0.892	0.897
	IC-Time	0.905	0.907
	MSC	<b>0.958</b>	<b>0.955</b>
<i>Hashtags without #</i>	IC	0.899	0.907
	IC-Time	0.910	0.913
	MSC	<b>0.966</b>	<b>0.962</b>

Table 1: Comparison of clustering algorithms on F-measure and NMI metrics

The top part of the table compares the performance of the three algorithms using bag-of-words and original hashtags as features. We can see that, our proposed MSC algorithm is superior to the other two baselines, while IC-time performs slightly better than IC. This is because, IC only relies on the cosine similarity between textual features of tweets to form clusters, while IC-Time enforces a time constraint in the similarity measure to reflect the time locality of events, which thus leads to better clustering accuracy. By explicitly merging related clusters, MSC achieves the highest accuracy on both two metrics.

The bottom part of the table shows the clustering results by removing the # symbol and treating hashtags as normal words. We can observe that, this improves the clustering accuracy for all three algorithms. We believe that this improvement is because removing the # symbol contributes to increasing the term frequency of the same topic word in the tweets. It thus translates to yielding better clustering accuracy. This can be illustrated using the examples as follows.

*Bold move as Google Buys Motorola for 12.5 Billion, and paid cash #google #motorola.*

*5.8 earthquake happened in Virginia just moments ago. #Earthquake #Virginia.*

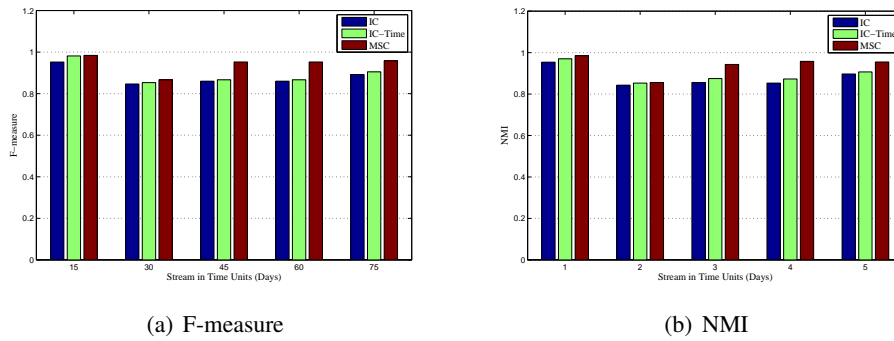

Figure 1: Clustering accuracy over different time horizons

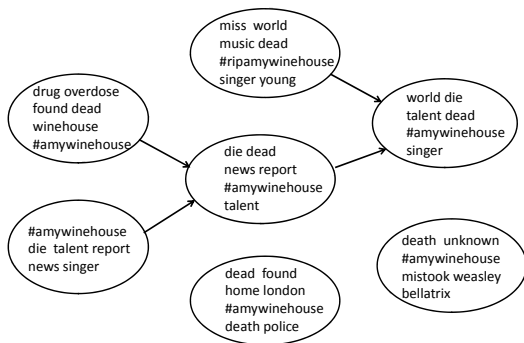

Figure 2: Illustration of the cluster merge process

If we remove the # symbol, hashtags *#google* and *#motorola* are turned into words *google* and *motorola*, in the first tweet, and *#Earthquake* and *#Virginia* are into *Earthquake* and *Virginia*, in the second tweet. In both cases, this increases the term frequencies of the topic words or main entities of events, thus highlighting their contributions to forming the clusters.

To better understand how our MSC algorithm performs cluster merges, Figure 2 illustrates the cluster merging process for the topic talking about the death of Amy Winehouse<sup>2</sup>. There are seven clusters generated from the online phase, each of which is represented using top-ranked keywords in the figure. In the offline phase, the clusters are merged based on their similarity and relatedness in a bottom-up manner, and finally three clusters remain after two rounds of cluster merges.

The other important feature of our proposed MSC algorithm is that it can merge related clusters upon demand for any user-specified horizon. Therefore, we carried out experiments to compare the clustering quality of the three algorithms at dif-

<sup>2</sup>[http://en.wikipedia.org/wiki/Amy\\_Winehouse](http://en.wikipedia.org/wiki/Amy_Winehouse)

ferent time horizons. Figure 1 shows the clustering accuracy with respect to F-measure and NMI at different time units in the stream. We can see that, our proposed MSC algorithm consistently outperforms the other two baselines over time. This indicates that, MSC has the ability to retain sufficient statistics required for effective cluster merging in the offline phase.

## Conclusions and Future Work

In this paper, we proposed a new approach for clustering microtext streams into event-based clusters. Our proposed approach intelligently divides the clustering process into an online component which maintains summary statistics, and an offline component which uses these compact statistics to discover event-based clusters. Therefore, it has the advantage of processing and scaling to large volumes of microtext streams. Experiments and comparisons demonstrated that our proposed approach achieves better clustering accuracy than state-of-the-art methods, and merging similar clusters can improve the performance of short text clustering.

This work can be extended in several directions. We will further evaluate the effectiveness of our clustering algorithm in the ESA (Emergency Situation Awareness) system [Yin et al., 2012] in larger-scale datasets. In particular, we will test its performance together with the burst detection module for identifying significant event-based clusters from the real-time Twitter stream. Moreover, since short, informal microtext has high degree of lexical variations, we will explore paragraphing techniques to uncover hidden semantic relatedness between microtext. Such information can be leveraged to group clusters that talk about the same event, but expressed using different words, and thus improve the clustering quality.

## Abstract

Since the machines become more and more intelligent, it is reasonable to expect the automatic construction of text classifiers by given just the objective categories. As trade-off solutions, existing researches usually provide additional information to the category terms to enhance the performance of a classifier. Unique from them, in this paper, we construct the standard corpora from the web by just providing text categories. Since there are millions of manually constructed websites, it is hopeful to find out proper text categorization (TC) knowledge. So we directly go to the web and use the hierarchies implied in navigation bars to extract and verify TC resources. By addressing the issues of navigation bar recognition and text filtering, the corpora are constructed for given text categories and the classifiers are trained based on them. We conduct our experiments on the large scale of webpages collected from the 500 top English websites on Alexa. The Open Directory Project (ODP) is used as testing corpus. Experimental results show that, being compared with the classifier based on manually labeled corpus, the classifier trained on auto-constructed corpora reaches comparable performance for the categories that are well covered by the training corpus.

## 1 Introduction

As one of the key techniques in web information processing, text classification has been studied for a long time (Aas and Eikvil, 1999; Wang and Li, 2011; Yang and Pedersen, 1997). A growing number of machine learning techniques have been applied to text classification and some of them

have proven to be successful (Miao and Kamel, 2011; Sebastiani, 2002). In the machine learning approach, the learning process is an instance of supervised or semi-supervised learning because classifier can be built automatically by learning from adequately pre-labeled training documents and then classified unseen documents (Feldman and Sanger, 2007). However, the task of manually labeling a large amount of documents is time-consuming and even impractical. Given a general classification task, people usually construct training data in two ways. One is augmenting a small number of labeled documents with large amounts of unlabeled ones to guide the learning model iteratively, so that the new classifier can label the unlabeled documents (Jiang, 2009; Nigam et al., 2000). In such studies, the bootstrapping technique is often used to label the unlabeled documents and refine the initial classifier (Gliozzo et al., 2009; Ko and Seo, 2009). The other is collecting training corpora from the Web. Such works use the class name and its associated terms to collect training corpora iteratively (Huang et al., 2005). Cheng (2009) and Day et al. (2009) firstly sample the Web with a set of given class names, and then query the keywords manually populated from each class by search engines for retrieving quality training documents. Huang et al. (2004) proposed a LiveClassifier system which also makes use of search engines for automatically constructing training classifier.

Though reached encouraging performance, above methods have some limitations in organizing training corpora. For the first method, although some algorithms just use a small set of labeled documents, which still require much time and effort for complicated categories (Chen et al., 2009); And the second method depends on several external resources, which greatly limits its flexibility and reliability. For example, manually given keywords or terms for a class are easily affected by

different persons; different search engines may also bring different results with various type of noises contained in search results (Huang et al., 2004).

Inspired by these issues, we design a new system to automatically acquire training corpora. Given a class hierarchy, our basic idea is to collect corpora merely based on class names. Firstly, we crawl the webpages starting with several selected websites and identify the navigation bars of these websites. Then each navigational item in the navigational bars is matched with the class names. The valid subpages from a navigational item are labeled with the matched class name. After extracting contents from these subpages, the initial candidate corpora are constructed. Finally clustering algorithm is used to remove noises from the corpora. In latter parts of paper, we denote the automatic constructed corpora as ACC.

The main contributions of this paper are:

(1) An automatic system for constructing classification corpora is built. It is a new way to collect large-scale, high quality corpora; moreover, it is completely adaptive to any kind of class hierarchy;

(2) To improve the ACC quality, text clustering based automatic noise filtering approaches are proposed and analyzed;

(3) The proposed system and methods are evaluated on large scale standard corpora and encouraging results are reached.

The remainder of this paper is organized as follows. Section 2 described the architecture of the automatic corpora construction system; Section 3 and 4 present experimental settings and results respectively. The paper is closed with conclusion and future work in section 5.

## 2 Automatic Corpora Construction

In this paper, we propose a novel system that can automatically acquire effective training data through web mining. The architecture of the system is given in Fig 1. It is composed of four modules: data collection, navigational processing, candidate corpora construction and corpora denoising. The data collection module crawls webpages from the given URL seeds. The navigational processing module is to extract the navigational bars from downloaded web pages, and to make category judgments for each navigational item. The candidate corpora construction module is to get the candidate corpora by performing content extraction for the valid links from the navigational item-

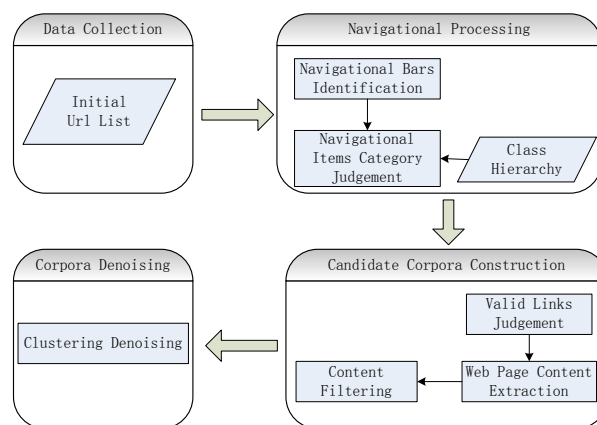

Figure 1: Architecture of the ACC System.

s. The corpora denoising module makes clustering for all texts in the candidate corpora and removes the noisy web pages for each category.

### 2.1 Navigational Bars Processing

Generally, the navigational bars locate in one block or several blocks of a web page. Thus it is necessary to split the web page into blocks for identifying the navigational bars. In this paper, we use the approach proposed by (Keller and Nussbaumer, 2012) for segmentation and simplify it by three rules as follows.

- (1) Remove leaf nodes which are not link nodes;
- (2) If the node is the only child of its parent node, delete the parent node and directly connect the node with its ancestor node;
- (3) If the node has two children nodes, and the first child node is the link node, while the other is not, then delete the node and connect the two children nodes with its ancestor node.

In latter parts of this paper, the set of blocks after segmentation is denoted as PageSec.

#### 2.1.1 Navigational Bars Identification

The approaches for navigational bars identification can be divided into two categories, i.e., rule-based and graph-based filtering respectively. In this paper, we compared two different approaches for the navigational bars identification.

**Rule-based Identification:** Firstly, we conduct filtering for each block in PageSec. The filtering conditions include link type, link uniqueness etc. Then a ranking formula is constructed to calculate the score for each blocks. The features used in the formula are listed as follows.

- (1) **Consistent degree of link depth between the anchor texts within block:** Each anchor text

within the block will point to a link. The depth of a link is represented by its slashes' number. The consistent degree of link depth between the anchor text within block is calculated by formula (1).

$$Dep(Sec) = \frac{-\sum_{i=1}^n (P(AcD_i) \ln(P(AcD_i)))}{\ln(n)} \quad (1)$$

Where  $n$ : The number of anchors with different depth within the block.

$P(AcD_i)$ : The proportion of anchors with the  $i$ th anchor depth within the block.

**(2) Consistent degree of word number between the anchor texts within block:** Generally, the word number of each navigational item is consistent. The more tidy appearance of the items, the more likely to belong to the same navigational bar. The consistent degree of word number between the anchor texts within block is calculated in the same way with the consistent degree of link depth.

**(3) The proportion of the remaining anchor texts within block.**

Integrating the three features above, we construct a linear weighted summation formula to rank for the blocks. Finally, the top-ranking blocks with score bigger than a threshold are added to the candidate of the navigational bars.

**Graph-based Identification:** Firstly, we construct the relationship graph of links and find the maximum complete subgraph by the Bron-Kerbosch algorithm. Then we use a discriminant algorithm to extract the final navigational bars.

**(1) Construction of Links Relationship Graph:** Each web page is represented with a node, if page A has a link pointing to page B, a directed edge from A to B is generated. We deleted single directional edges and preserved bi-directional edges; moreover, the directed graph is transformed to be undirected for simplification. In this paper, the Bron-Kerbosch algorithm is used to get the maximum complete subgraph.

**(2) Extraction of Navigational Bars:** For extracting navigational bars, we need to take advantage of maximum complete subgraphs to conduct filtering on the block structure of the web page. The pseudo code is listed in algorithm1. In addition, as the vertex number increases to a value, the running time of searching for the maximum subgraphs becomes unacceptable. Thus we apply an approximate algorithm to extract the navigational

bars when the vertex number is more than 100.

## 2.1.2 Navigational Items Category Judgment

After identifying the navigational bars, we need to match the navigational items with each class of the given class hierarchy. The cosine similarity in the vector space model is used for calculating the matching degree. Moreover, in order to get a better result, we apply stemming for the navigational items and word expansion for the class names. Given a navigational item, we firstly calculate its similarities with all classes and sort those classes in descending order of the similarities. If the maximum similarity in the rank is unique and greater than a given threshold, label the navigational item with the corresponding class. Otherwise, we use the URL information to make further judgment.

---

### Algorithm1: Navigational bars extraction

**Input:** Maximum complete subgraph MCSQueue  
Block set of homepage PageSec

**Output:** Candidate navigational bars CandNav

Step1: Label all the elements in MCSQueue with unprocessed.

Step2: Select an unprocessed subgraph SGraph from MCSQueue. If all processed, turn to step 4.

Step3: Filter on all the elements in PageSec, remove the elements not in SGraph and save the result in CandNav, turn to step 2.

Step4: Sort all blocks in CandNav from more to less by the number of elements.

Step5: Traverse CandNav from the beginning and delete Sec if current block contains all the elements of block Sec which is at the position behind.

Step6: End

---

## 2.2 Candidate Corpora Construction

### 2.2.1 Valid Links Judgment

A navigational item within the navigational bar usually points to a hub web page that is mainly composed of a set of links, which makes it difficult to extract relevant web pages for a given topic. In general, the links that point to external websites are treated as invalid links and can be directly filtered. Since some kind of invalid links, such as the *Login*, *Sitemap* etc, occur many times in the website and the times of category assignment to the invalid links are significantly more than the valid links. In this paper, we regard the links with the times of category assignment more than a threshold as invalid links. Since there are multiple nav-

igational paths that can lead to a web page, each valid link may have multiple category labels and the voting strategy is used to label the valid link.

### 2.2.2 Web Page Content Extraction

Extracting content from webpages has been researched for decades and numerous methods have been proposed. Tim proposes a method to extract content text from diverse web pages by using the HTML documents tag ratios (Weninger et al., 2010). Sun presents Content Extraction via Text Density (CETD) to extract content and also proposes a method called DensitySum to extract integral content. Moreover, CETD-DS has shown that it is an effective and robust content extraction algorithm (Sun et al., 2011). In this paper, we apply Tim’s tag ratio to extract content.

**Tag Ratio:** Tim’s tag ratio is the ratio of HTML tags characters and Non-HTML tags characters at each row of the HTML source code. It can be described by formula (2) as follows:

$$TagRatio_i = \frac{NonTagChars_i}{TagNum_i} \quad (2)$$

Where  $NonTagChars_i$ : The number of Non-HTML tags characters at the  $i$ th row.

$TagNum_i$ : The number of HTML tags at the  $i$ th row. For the hyperlink tag, multiply it by 2.

Since the comments, scripts and CSS tags do not contain the text content, we remove them from the HTML code while calculating the tag ratio. For the tag ratio, we apply the standard gaussian approach to make smoothing. Firstly we construct a gaussian kernel (Keerthi and Lin, 2003) with radius of 1 and variance of 2 by formula (3).

$$k_i = \sum_{j=-[\sigma]}^{[\sigma]} e^{-\frac{j^2}{2\sigma^2}}, 0 \leq i \leq 2[\sigma] \quad (3)$$

After normalization, we get (4):

$$k'_i = \frac{k_i}{\sum_{j=0}^{2[\sigma]} k_j}, 0 \leq i \leq 2[\sigma] \quad (4)$$

Then we make the convolution operation with this filter and tag ratio to get the smoothing tag ratio.

**Content Extraction:** Most of the methods for content extraction try to use different threshold selection strategies for different features, but the generalization performance of these algorithms are still not satisfactory. Therefore, we adopt the K-means clustering with two-dimensional features

to get the final content. The first dimensional feature is the smoothing tag ratio, the second one is the approximate derivative of the tag ratio.

### 2.3 Corpora Denoising

Ideally, web pages with the same category label in the candidate corpora belong to the same topic. However, because of the different website authority and management level, some web pages which do not belong to the category topic are also classified into this category. In addition, some irrelevant web pages are preserved owing to the weakness of the valid links judgment. These noisy web pages greatly reduce the quality of the candidate corpora. Therefore, we apply K-means clustering algorithms to conduct corpora denoising. After clustering, the large clusters are preserved while the smaller ones are removed as the noises.

## 3 Experimental Settings

### 3.1 Databases

**Self-collected Data:** A universal crawler is implemented for the automatic corpora construction task. In addition to the general crawler task, it records the jumping information between web pages for locating the target web pages and the orders of visiting each page in the crawling process. The initial seed links of the crawler are collected from the Alexa<sup>1</sup> top 500 websites of each category on May 26, 2012. After removing the duplicated websites, there are 5593 ones left. Take them as the starting links and perform crawling, finally we crawled a total of 783035 web pages.

**ODP (Open Directory Project):** ODP is one of the largest corpora for web page classification. We download the ODP corpus on April 22, 2012. There are totally 4066266 web page links in which 2144930 web page links are downloaded.

**Dataset Split:** In our experiments, both the automatic constructed data and ODP are randomly split into three near equal scale of subsets with two parts for training and the remaining for testing.

### 3.2 Experimental Settings

**Preprocessing:** The class hierarchy of ODP is used for the automatic corpora construction. Libxml2 is used to parse the web pages into the DOM trees. For the web pages that cannot be directly parsed, tidy is applied to correct the syntax mistakes. The Porter algorithm (Jongejan and

<sup>1</sup>Alexa:<http://www.alexa.com/>

Dalianis, 2009) is used for stemming. Generally, there are two kind of ways to make word expansion. One is based on WordNet (Fellbaum, 1998) and the other is to obtain the description words for categories by search engine or other external resources. In this paper, the description words for each category come from its secondary classification keywords under the ODP class hierarchy.

**Classification and Clustering:** Expected Cross Entropy is selected for feature selection. 8000 dimensional features are selected out. LibSVM<sup>2</sup> is used for classification where the linear kernel and default settings are applied. K-means is used for clustering where K is set to 8.

## 4 Experimental Results

### 4.1 Performance of ACC system

**Navigational Bars Identification:** To evaluate the performance of navigational bars identification, we randomly select five websites from the initial seed links for human label. The results of rule-based and graph-based navigational bars identification are shown in Table 1.  $N_{nb}$  denotes the number of navigational bars.  $A_{nr}$  and  $R_{nr}$  denote the accuracy and recall of rule-based identification approach.  $A_{ng}$  and  $R_{ng}$  denote the accuracy and recall of graph-based identification approach. We can see that both methods reach high accuracy and relatively lower recall without significant difference. The reason is that some external links are filtered while some navigational bars are composed of items from different domains.

**Navigational Items Category Judgment:** We randomly sampled 100 websites for human label from the initial seeds of the crawler. The performance of navigational items category judgment is demonstrated in Table 2. Since the accuracy of category judgment is very high, a navigational identification method with higher recall is selected to increase the size of the final corpora.

**Web Page Content Extraction:** We evaluate the performance of web page content extraction on seven standard corpora: CleanEval-Eng, NY Times, Yahoo!, Wikipedia, BBC, Arts Technica and Chaos. Table 3 shows that the web page content extraction algorithm performs well on accuracy for all the seven corpora, but the recall is not satisfactory on corpora like Wikipedia and Yahoo!

Website	$N_{nb}$	$A_{nr}(\%)$	$A_{ng}(\%)$	$R_{nr}(\%)$	$R_{ng}(\%)$
CNN	49	65	81.3	53.1	53.1
Yahoo!	41	36.2	52.9	51.2	22.0
EatingWell	81	87.2	78.5	43.6	79.5
Adobe	39	97.5	65.5	36.4	17.8
Cornell	38	100	51.6	65.8	42.1

Table 3: Performance of web page content extraction on 7 corpora

**Corpora Accuracy:** In Table 4, we demonstrate the performance of ACC on each category.  $N_p$  denotes the number of crawled web pages.  $A$  denotes the accuracy before clustering and  $A_c$  denotes the accuracy after clustering. This table shows that the macro-average accuracy can reach 68.18%. Furthermore, the applying of simple text clustering method contributes up to 2.73% accuracy performance gains, which demonstrates the effectiveness of our denoising method.

### 4.2 Performance of Classification

**Size of ACC and ODP:** The number of crawled web pages and left web pages after content extrac-

<sup>2</sup>Liblinear:<http://www.csie.ntu.edu.tw/~cjlin/liblinear/>

tion in ACC and ODP denoted by  $N_p$  and  $N_{cp}$  respectively are given in Table 5. From this table we can see that only a little part of crawled web pages in both data sets contain effective contents. It is because that most of the web pages in ODP are the homepages of websites, and many web pages mainly contain pictures rather than effective contents in ACC.

**Classification Results of ACC and ODP:** In Table 6, we show the overall SVM classification performance of each category on ODP and ACC. The macro-F1 is approximately 72.3% and 79.8% respectively. By comparing the classification results of ODP and ACC on each category, we can see that the performance of ACC is better than ODP on accuracy and recall.

Table 6: SVM classification performance of each category on ODP and ACC

in Table 7. The results show that the classification performance is relatively poor. The main reason is that the coverage of ACC is inadequate, which leads to a big distribution difference between the training and testing data. The factors that influence the coverage of corpora include the size of initial URL seeds, the crawling depth, the recall of navigational bars etc.

Category	Accuracy	Recall	F1

## 5 Conclusion

In this paper, we proposed a new automatic approach which makes use of web resources to construct the corpora. An automatic system for constructing classification corpora is built. Experiments conducted on ACC and ODP show that the automatic corpora construction approach is effective, although the cross-test result is not satisfactory. Future research will focus on solving the coverage problem of ACC.

## Abstract

The wealth of information present in the World Wide Web has made internet search a de-facto medium for obtaining any required information. Users typically specify short and/or ambiguous queries and expect the answer to appear at the top. Hence, it can be extremely important to produce a diverse but relevant set of results in the precious top  $k$  positions. This calls for addressing two types of needs: (i) producing relevant results for queries that are often short and ambiguous and (ii) selecting a set of  $k$  diverse results to satisfy different classes of information needs. In this paper, we present a novel technique using a Biconvex optimization formulation as well as adaptations of existing techniques from other areas, for addressing these two problems simultaneously. We propose a graph based iterative method to choose diversified results. We evaluate these approaches on the QRU (Query Representation and Understanding) dataset used in SIGIR 2011 workshop as well as on the AMBIENT (Ambiguous Entities) dataset and present results on generating diversified query interpretations. We also compare these approaches against other online systems such as *Surf Canyon*, *Carrot2*, *Exalead* and *DBpedia* and empirically demonstrate that our system produces competitive results.

## 1 Introduction

The growth of internet has resulted in the proliferation of electronic documents on the World Wide Web. Every search engine, be it generic or application and domain specific, serves as a portal to access these documents. User queries, in general, are

short and often tend to be ambiguous and/or under-specified. In addition, a query can have multiple *concealed interpretations*. For example, *Sun* could be interpreted as “The sun as a star”, “Composition of Sun”, “Sun Micro systems company”, “Sun news paper”, “Sun Record music company”, and so on. We believe that, in addition to these concealed interpretations, *related interpretations* are also equally important. As examples, “Solar Cells” and “Photosynthesis”, could be interpretations related to this query. To improve user interaction and to guide him/her in further refining the query, it could help if the search engine generated these relevant interpretations as well. Due to the sheer size of online information and its diversity, the possible interpretations to a short query are enormous. In addition, users expect their intended answer to be present in the top few search results. This calls for presenting a diversified but relevant set of results in the top  $k$  positions. Note that, in this paper we consider the diverse search results produced by the search system as *interpretations* of the query in some sense. In addition, we consider each search result is a document describing some aspect related to the query. Hence we restrict our notion of interpretation to each such *document* in the search result.

We present an original method as well as adaptations of some existing methods to solve this problem. As for our proposed method, we construct an interpretation graph with potential interpretations as its nodes and edges indicating their similarity. Inspired by the works on GCD (Dubey et al., 2011) and MMR (Carbonell and Goldstein, 1998), we develop a new technique for diversity ranking of interpretations. As part of this technique, we propose an algorithm (Rel-Div) to learn the node and edge weights of the interpretation graph iteratively by solving a biconvex optimization (Gorski et al., 2007) problem. At query time, we solve a convex optimisation problem to choose

$k$  diverse nodes and present them as interpretations to the user query. We identify interpretations relevant to the query using a publicly available internet encyclopedia. Though we used Wikipedia as the source, we believe that the repository can be easily extended to accommodate other catalogs like YAGO and Freebase.

We compare our diversification approach with other diversification approaches (which were applied not necessarily to solve the same problem as ours) such as variants of GCD (Dubey et al., 2011), Affinity Propagation (Frey and Dueck, 2006),(Frey and Dueck, 2007). We evaluated results on benchmark queries from the SIGIR 2011 workshop’s QRU (Query Representation and Understanding) dataset and the AMBIENT data sets. In addition, we compare the diversity of interpretations generated by these approaches against those of other online systems such as Surf Canyon, Carrot2, Exalead and DBpedia (URLs of all these systems listed under References)

We summarize our contributions as: 1) Top-K diversity ranking using a graph based approach. 2) Iterative Graph weight learning technique - A new iterative technique for learning the node and edge weights for an interpretation graph by solving a biconvex optimisation problem.

The rest of the paper is organized as follows: In Section 2 we present related work. In Section 3 we describe our technique of iterative graph weight learning and diversity ranking. In Section 4 we demonstrate the utility of our technique by applying it to the interpretation generation task from Wikipedia. In Section 5, we present experimental evaluations. We conclude our work in the subsequent section.

## 2 Prior work

Most of the prior research has focused on generating diversified result urls. The approach presented by (Swaminathan et al., 2009) filters initial search results and covers diversified topics based on bag of words measures. Yisong and Joachims (Yue and Joachims, 2008) train a model using Struct SVM and encode diversity as a penalty function (this is penalty for not covering certain topics). Most recently, Brandt et al.(Brandt et al., 2011) and Raman *et. al.* (Raman et al., 2011) proposed an approach for *dynamic ranking* and then group URLs with similar intentions.(Dubey et al., 2011) formulate the problem of ensuring diversity as that of

identifying relevant urls which are most likely to be visited by the random surfer. We propose a new approach for interpretation generation. The report (Hearst, 2006) by M.A Hearst claims that clustering based on similarity measure may not always result in meaningful interpretations or labels. So, instead of dynamically generating labels, we pick labels or relevant interpretations for a query from the pool of labels. We use Wikipedia as a primary source to capture these interactions along with their semantic relations. (Hahn et al., 2010),(Ben-Yitzhak et al., 2008) produce Wikipedia pages as search results and align the search results along a set of fine grained attributes/facets. In our work, facets (which we refer to as interpretations) are neither predefined nor necessarily fine grained. Moreover, as we will see, our interpretations need not be restricted to Wikipedia entities. Closest to our approach is the approach of (Ma et al., 2010). They apply page ranking technique on the graph constructed using query log statistics to obtain diversified interactions.

## 3 Diversified Interpretation Generation

### 3.1 Our Problem

Given a large corpus  $U$  of documents and a short user query  $q$ , we define a function  $H(q, U)$  that returns a subset of documents  $S = \{e_1 \dots e_n\} \subseteq U$ , satisfying the query  $q$ . The function  $H(q, U)$  acts as a filtering function to retrieve the documents  $S$  that are syntactically and/or semantically related to the query  $q$ . In its simplest form,  $H(q, U)$  can just return  $U$  without performing any filtering, which is not generally useful. It is important to design an  $H(q, U)$  (*e.g.*, keyword based lookup, semantics matching, *etc.*) that can help reduce the search space in a meaningful manner. Our goal is to choose a set of  $k$  documents from  $S$  and we assume that to best satisfy the user intention, these  $k$  documents presented to the user should be diverse yet highly relevant to the query  $q$ .

### 3.2 The Training Algorithm

We expect groups of documents in  $S$  to be related to each other via some semantic relations. We initially construct a document-relation graph using  $e_1 \dots e_n$ . We refer to this graph as an *Interpretation Graph*, since the documents in this graph are obtained as various interpretations of the query. While the nodes are documents from  $S$ , each edge is a relation between the documents. A relation

could be one of synonymy, hyponymy, meronymy, homonymy, *etc.*. These relations could be obtained from external catalogs such as Wikipedia, Wordnet, *etc.*

Each node in the graph is assigned a score which represents the relevance of the node to the query. We use the notation  $b_q$  to represent the column vector (of size  $n \times 1$ ) containing all the node relevance scores. The weight on an edge represents the degree of similarity between the two nodes connected by that edge. We use the notation  $C_q$  (of size  $n \times n$ ) to represent the matrix of edge scores reflecting similarity between pairs of nodes. Note that, each column  $C_q^i$  of the matrix  $C_q$  represents a document  $e_i$  and the cell values in that column indicate the similarity of document  $e_i$  with other documents. The scores in  $b_q$  are used to ensure that the subset of  $k$  interpretations are relevant to  $q$ , whereas the similarity scores in  $C_q$  are used to ensure diversity in the subset of  $k$  interpretations.

We assume that we are provided training data, consisting of queries and their correct interpretations. Our goals in training are to 1) develop a model for the node score  $b_q$ , 2) develop a model for the edge potentials  $C_q$  and 3) learn parameters of these models such that the set of  $k$  relevant yet diverse nodes obtained from the graph using  $b_q$  and  $C_q$  are consistent with the training data. Thus, implicit in our third goal is the following subproblem, which is also our query time inference problem: 4) compute a subset of  $k$  best interpretations using  $b_q$  and  $C_q$ , that represent  $k$  diverse, but relevant interpretations. A part of the graph for the query "sun" is depicted in Figure 1

Figure 1: Interpretation Graph for the query *Sun*

### 3.2.1 Modeling node potentials ( $b_q$ )

In order to build a learning model for  $b_q$ , it is important to define a good set of features that characterize the node's relevance to the query. Let  $N_{1..|N|}(q, S)$  be a set of  $|N|$  query independent node features. Each feature  $N_f(q, S)$  evaluates the relevance of documents in  $S$  to the query  $q$  and returns a vector of scores. These feature functions are problem specific and crafted carefully to bring

out the relevance between query and documents (such as term overlaps, n-gram matches, etc). In Section 4 we provide some practical examples of node features.

The node potential vector  $b_q$  is obtained by combining the scores returned by individual feature functions  $N_f(q, S)$ . One of the obvious choices is to use Logistic Regression (Yan et al., 2003). *i.e.*  $b_q[i] = \frac{1}{1+e^{-\sum_{f=1}^{|N|} w_f N_f(q, S)[i]}}$ . The weight vector  $W^T = [w_1 \dots w_{|N|}]$  is learnt through supervised training explained in Section 3.2.3.

### 3.2.2 Modeling edge potentials ( $C_q$ )

To learn the edge potentials, it is important to define a good set of features that measure the similarities between every pair of nodes and return similarity scores. Higher the score, more similar are the nodes. Let  $C_{1..|C|}(S)$  be the set of  $|C|$  edge features that evaluate similarities between documents in  $S$  and each returns a  $n \times n$  matrix of scores. These feature functions are problem specific and crafted carefully to bring out the similarities between the documents. In Section 4 we provide some practical examples of edge feature construction using Wikipedia.

The edge potential matrix  $C_q$  is obtained as  $C_q = \sum_{f=1}^{|C|} \lambda_f C_f(S)$  where  $0 \leq \lambda_f \leq 1$  and  $\sum \lambda_f \geq 1 \forall f$ . The weight vector  $\lambda^T = [\lambda_1 \dots \lambda_{|C|}]$  is learnt through supervised training explained in Section 3.2.3.

### 3.2.3 Learning feature weights $W^T, \lambda^T$

Proposition 1:

$$b_q \approx \sum_{j=1}^k \tilde{C}_q^{i_j} \quad (1)$$

for sufficiently large  $k$  diverse documents, where,  $\tilde{C}_q$  is the matrix  $C_q$  with the columns scaled so that the diagonal cell values match the relevance value, *i.e.*,  $\tilde{C}_q(i, i) = b_q(i)$ . The values  $i_1 \dots i_k$  represent indices of  $k$  columns of matrix  $\tilde{C}_q$ . Hence,  $\tilde{C}_q^{i_j}$  is the  $i_j$ th column of matrix  $\tilde{C}_q$ .

The intuition behind this approximated equality comes from the fact that, two similar documents should have similar relevance score with the query and we are interested in selecting  $k$  diverse documents. Let  $e_i$  be one of these  $k$  diverse documents. If the documents  $e_{j_1} \dots e_{j_p}$  are similar to  $e_i$ , then,  $b_q[i] \approx b_q[j_1] \approx \dots \approx b_q[j_p]$  and  $C_q[i, i] \approx C_q[i, j_1] \approx \dots \approx C_q[i, j_p] \approx 1$  and  $C_q[t] \approx 0, t \notin j_1 \dots j_p$ . But, we already know that  $\tilde{C}_q[i, i] = b_q[i]$ . That implies,  $b_q[j_1] \approx \tilde{C}_q[i, j_1]$ ,

$b_q[j_2] \approx \tilde{C}_q[i, j_2], \dots, b_q[j_p] \approx \tilde{C}_q[i, j_p]$ . When we take the summation on all diverse  $k$  documents, the Equation 1 holds.

Based on the above proposition, we present an algorithm to learn weights  $W^T$  and  $\lambda^T$  iteratively in a supervised learning setup. The training data is provided in a vector  $r_q$  (of size  $n \times 1$ ) such that  $r_q[i] = 1$  if the document  $e_i$  is relevant to the query (and one of diverse documents), otherwise,  $r_q[i] = 0$ . Note that, the quantity  $\tilde{C}_q r_q$  represents the sum of  $k$  columns (assuming  $k$  number of 1s in  $r_q$ ) and is the RHS of Equation 1.

Our training objective is to learn  $\lambda^T$  and  $W^T$  such that Equation 1 holds. Formally, the problem being solved is:

$$\underset{\lambda_1, \dots, \lambda_{|C|}, w_1, \dots, w_{|N|}}{\operatorname{argmin}} D \left( \frac{1}{1 + e^{-\sum_g w_g N_g}}, \sum_f \lambda_f \tilde{C}_f r_q \right) \quad (2)$$

where  $D(x, y)$  is a distance measure between  $x$  and  $y$ . (for e.g., KL Divergence, Euclidean, etc.);  $\tilde{C}_f$  is the normalized  $C_f$  as in Proposition 1.

Applying the coordinate descent technique, we learn the weights  $W^T$  and  $\lambda^T$  iteratively using two steps outlined in Equation 3 and Equation 4, each of them convex in the respective optimization variables, hence our optimisation problem is biconvex.

div-step: Learn  $\lambda_1^{(t)}, \lambda_2^{(t)}, \dots$  holding  $w_1^{(t-1)}, w_2^{(t-1)}, \dots$  constant, by solving:

$$\underset{\lambda_1, \lambda_2, \dots}{\operatorname{argmin}} D \left( \frac{1}{1 + e^{-\sum_g w_g^{(t-1)} N_g}}, \sum_f \lambda_f^{(t)} \tilde{C}_f r_q \right) \quad (3)$$

rel-step: Learn  $w_1^{(t)}, w_2^{(t)}, \dots$  holding  $\lambda_1^{(t-1)}, \lambda_2^{(t-1)}, \dots$  constant, by solving:

$$\underset{w_1, w_2, \dots}{\operatorname{argmin}} D \left( \frac{1}{1 + e^{-\sum_g w_g^{(t)} N_g}}, \sum_f \lambda_f^{(t-1)} \tilde{C}_f r_q \right) \quad (4)$$

In *div-step*, we learn  $\lambda^T$  by holding  $W^T$  fixed and honoring Equation 1. In *rel-step*, we learn  $W^T$  by holding  $\lambda^T$  fixed. The relevance and divergence is enforced during training through the vector  $r_q$ .

We learn node and edge feature weights iteratively by recognizing and assigning weights to prominent node and edge features that satisfy queries of different types. Having all statistically driven computation of weights for edge features can minimize the side effect of poor node features and likewise computing weights for node features can decrease the consequences of poor edge features.

Algorithm 1 outlines the training procedure.  $I_q^+, I_q^-$  are the set of relevant and irrelevant documents for each query  $q$  in the ground truth that is used for training.

### 3.3 Query-time Inference

For a new user query  $q$ , inference problem is to choose  $k$  diversified results. Using  $H(q, \mathcal{C})$  we reduce the search space drastically and get the set  $\mathcal{S}$ . Otherwise, we need to run our inference on entire set  $U$ , which is very expensive. We then compute the node and edge feature matrices for all defined node and edge features. These individual feature matrices are then combined (using  $\lambda^T$  and  $W^T$ ) to obtain vector  $b_q$  and matrix  $C_q$ . Based on Proposition 1, our inference objective is to choose  $k$  columns from the matrix  $\tilde{C}_q$  such that their sum is as close as possible to  $b_q$ . Formally, the problem being solved is:

$$\underset{i_1, \dots, i_k}{\operatorname{argmin}} D \left( b_q, \sum_{j=1}^k \tilde{C}_q^{i_j} \right) \quad (5)$$

where  $i_1, \dots, i_k$  are indices of  $k$  columns of  $\tilde{C}_q$ .

Determining the exact solution (i.e.  $i_1, \dots, i_k$  columns) to the above optimization problem turns out to be computationally infeasible. Hence, we have to resort to an approximate solution. Algorithm 2 describes a greedy inference procedure. At each step we pick one column from  $\tilde{C}_q$  that minimizes the distance in Equation 5 most. However, we also ensure that the picked column is most diverse from the already selected columns in the previous steps. At the end of  $k$  steps we will have  $k$  diverse, but relevant documents.

#### Algorithm 1 Training

- 1: **Input:** Set of training data instances  $\{q, I_q^+, I_q^-, N_f, C_f, r_q\}$
- 2: **Output:**  $W^T$  and  $\lambda^T$
- 3: initialize variables  $W^T$  and  $\lambda^T$
- 4: learn initial  $W^T$  using Logistic Regression  $\triangleright$  uses  $\{q, I_q^+, I_q^-, N_f\}$   
 $\triangleright \tilde{C}_q, \tilde{C}_f$  used below are normalized  $C_q, C_f$  as in Proposition 1
- 5: **while** not converged( $|b_q - \tilde{C}_q r_q|$ ) **do**
- 6:  $b_q =$  compute relevance matrix using  $W^T$  and  $I_q^+$
- 7: find  $\lambda^T$  so that  $D(b_q, \sum_f \lambda_f \tilde{C}_f r_q)$  is minimized  $\triangleright W^T$  is fixed
- 8:  $p_q = \sum_f \lambda_f \tilde{C}_f r_q$
- 9: find  $W^T$  so that  $D\left(\frac{1}{1 + e^{-\sum_f w_f N_f}}, p_q\right)$  is minimized  $\triangleright \lambda^T$  is fixed
- 10: **end while**  
**return**  $(W^T, \lambda^T)$

#### Semantic relations and values from Wikipedia page excerpts

1. **Synonym:** All redirected names of the Wikipedia page.
2. **Association:** All valid hyperlinks of a Wikipedia page.
3. **Frequent:** All phrases occurring more than two times within a Wikipedia page section.
4. **Synopsis:** All nouns, verbs, adjectives from the abstract and titles of the sections in a Wikipedia page
5. **Hyponym:** All pages/sub categories of selected categories ending with Wikipedia page title. Ex: For Sony: robotics at Sony.
6. **Meronym:** All phrases which occur both in wordnet meronyms and with in Wikipedia pages.
7. **Hypernym:** All parent categories of selected categories.
8. **Homonym:** Pages referring to one or more disambiguation page.
9. **Sibling:** Siblings are the sub categories/pages which do not follow hyponym pattern. Ex: For Sony: list of sony trademarks

Table 1: Semantic Relations

#### Algorithm 2 Inference

- 1: **Input:** User query  $q$ , Corpus  $U$ ,  $\lambda^T$ ,  $W^T$ ,  $N_f, C_f$
- 2: **Output:**  $k$  diverse interpretations
- 3: Generate  $S = H(q, C)$  and build a graph using documents in  $S = \{e_1, \dots, e_n\}$
- 4: Compute  $b_q$  using  $W^T$  and node features  $N_{1..|N|}(q, S)$
- 5: Compute  $C_q = \sum_f \lambda_f C_f(S)$  and normalize as in Proposition 1
- 6:  $R = \{i_i \in Q\}$  ▷ set of selected indices
- 7:  $Q = \{i_1, \dots, i_n\}$  ▷ indices to select
- 8: **for**  $i = 1$  to  $k$  **do**
- 9: 
$$\underset{c_k \in Q/R}{\operatorname{argmin}} \left\{ D \left( b_q, \sum_{r \in R \cup \{c_k\}} (C_q^r) \right) \times \left( 1 - \frac{1}{2} \min \left( D(C_q^{R1}, C_q^{c_k}), \dots, D(C_q^{R|R|}, C_q^{c_k}) \right) \right) \right\}$$
▷ (query match)  $\times$  (dissimilar to selected),  $z$  is normalizer
- 10:  $R = R \cup \{c_k\}$
- 11: **end for**  
**return**  $k$  interpretations representing  $k$  columns  $R_1, \dots, R_{|R|}$

## 4 An example using Wikipedia

In this section we apply our Rel-Div technique to generate diverse but relevant results to a short and/or ambiguous user query using Wikipedia. For e.g. *Beagle*, *Laptop Charger*, *Sony Camera*, etc. We do not support queries which are highly rich in semantics like *Who invented music*, *Earn money at home* or very specific in nature like *DB2 error code 1064*.

In this case,  $U$  is a set of all Wikipedia entities (a.k.a. pages/articles). Note, in the context of Wikipedia, every document is treated as an entity. We defined  $H(q, U)$  as a set of filters which return Wikipedia entities  $S$ , called candidate interpretations, relevant to the user query. In order to build this filter function, we made use of prominent Wikipedia attributes (Title, Infobox entries, Frequently occurring words, etc) and different semantic relations between Wikipedia entities (Association via hyperlinks, Page Redirects, See Also links, etc). Table 1 summarizes these Wikipedia signals, which are captured for every entity.

## 4.1 Node Features

**Query Match:** Calculates the term overlap between query terms and the semantic relation terms of an interpretation. For e.g., for the query *Sony*, *PlayStation 2* is one of the interpretations, which has multiple occurrence of term *Sony* in one or more semantic relations.

**No. of Semantic Relation match:** Total number of semantic relations that contain the query terms. For e.g., for the query *Sony*, *PlayStation 2* interpretation may have 3 semantic relations (Synonym, Association and Frequent) containing term *Sony*.

**Title score:** Captures the interpretation title match to the query terms.

## 4.2 Edge Features

**Interpretation Content Overlap:** This feature measures the similarity between two interpretations by considering the amount of overlap between the words in these interpretation title and content.

**Decaying Recursive Similarity:** We considered neighborhood of an interpretation (hyperlinked entities, parent categories, subcategories, and grand parent pages) in the similarity measurement. However, an appropriate weight which decays with distance is set to avoid influence of farther neighborhood nodes.

**Link based proximity:** Determined by the depth  $D(lca)$  of the least common ancestor (LCA) of interpretations  $I_i$  and  $I_j$  from the root of Wikipedia category structure and the hop distance  $len(I_i, I_j)$  from  $I_i$  to  $I_j$  through LCA. Link proximity is defined as  $LP(I_i, I_j) \propto D(lca) * len(I_i, I_j)$ . When multiple LCAs exist, we define the proximity as  $\max(LP(I_i, I_j))$ .

## 5 Experimental Evaluation

We used Wikipedia as our knowledge source. We captured different signals shown in Table 1 for every Wikipedia entity.

### 5.1 Dataset

The QRU dataset used in SIGIR 2011 contains 100 TREC queries with various interpretations. We restricted our space of interpretations to Wikipedia entities. We also experimented with ambiguous queries from the AMBIENT dataset which contains 40 one word queries.

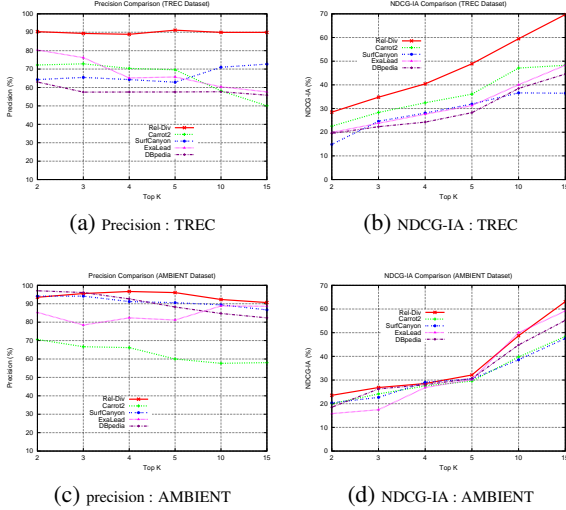

Figure 2: Comparison with external systems

		Precision(%)			Recall(%)			NDCG-IA(%)		
		@5	@10	@10	@5	@10	@10	@5	@10	@10
TREC	Rel-Div	<b>91.13</b>	<b>89.93</b>	<b>89.83</b>	<b>7.02</b>	<b>13.85</b>	<b>20.4</b>	48.9	59.47	<b>69.7</b>
	M-Div	89.87	84.27	84.32	6.74	12.71	18.88	<b>49.71</b>	<b>62.68</b>	67.39
	M-Div-NI	83.75	80	80	6.83	12.81	19.35	42.48	60.88	66.52
	AFP	78.3	76.9	80.7	6.3	12.4	18.1	34.2	38.8	47.6
AMBIENT	Rel-Div	96.05	92.3	90.67	7.33	<b>14.57</b>	<b>21.61</b>	<b>32.12</b>	<b>48.72</b>	<b>63.1</b>
	M-Div	96.15	<b>94.15</b>	<b>93.56</b>	<b>7.43</b>	14.37	21.61	32.41	47.49	58.09
	M-Div-NI	<b>96.2</b>	93.58	93.19	7.33	13.87	21.11	22.93	43.59	55.84
	AFP	88.4	90.9	92.3	6.9	13.6	21.47	32.09	45.9	55.1

Table 2: Results of different approaches

## 5.2 Evaluation methodology

Manually, interpretations for each query are marked as relevant or irrelevant and each interpretation is assigned one or more topics. The system is trained on 30 and tested on the rest. We evaluated results on queries of length one or two. The relevance of any interpretation to the query is measured using precision at different positions and the diversity is estimated using NDCG-IA (Agrawal et al., 2009). Recall measurement is tricky. It is practically not possible to manually inspect all Wikipedia entities and determine how many are actually relevant for a query. Hence we based our recall on the candidate interpretations generated. We manually counted number of relevant interpretations present in the candidate interpretations and measured how many of these relevant interpretations appeared in the top  $k$  interpretations.

In our experiments, we also consider a couple of other approaches to diversification, which have been reported in literature, though used in other problem settings. These include variants of GCD and affinity propagation (Frey and Dueck, 2006; Frey and Dueck, 2007).

**M-Div** : Uses page rank matrix  $M$  as in GCD instead of the  $C_q$  matrix.

**M-Div-NI** : Similar to M-Div, but node and edge weights are learnt independently, without any iter-

ations. This acts as GCD implementation.

**AFP:Exemplar** nodes of Affinity propagation are taken as interpretations.

## 5.3 Comparison with other approaches

While experimenting with our proposed approach, we found best performance when  $D$  in div-step was chosen to be KL-divergence and  $D$  in rel-step was chosen as the Euclidean distance. In Table 2, we compare the proposed diversification algorithm against M-Div, M-Div-NI and AFP on precision, recall and NDCG-IA measures.

We observed that our Ranking algorithm Rel-Div performs at par with (and sometimes even better than) M-Div and M-Div-NI. However, one of the major advantage of our method compared to M-Div and M-Div-NI is that, we need not calculate the inverse of  $C_q$  matrix, which is a computationally intensive process for a large dimension matrices. We conclude from the results that the Rel-Div performs consistently better than other approaches when both relevance and diversification are considered across all types of queries.

## 5.4 Comparison against other systems

We compare the diversity in search result using our approach against those from four other systems, viz., carrot2, SurfCanyon, Exalead and DBPedia to demonstrate that the Rel-Div approach produces high diversity in the search results, which is evident from the Figure 2.

## 6 Conclusion

We presented a body of techniques for generating top  $k$  interpretations to a user query using some internet encyclopedia, (in particular, Wikipedia was used in the experiments that were reported). Our approach is hinged on catering to two needs of the user, viz., that all the interpretations are relevant and that they are as diverse as possible. We addressed this using a bunch of node features and edge features based on semantic relations and learn these feature weights together iteratively. We present experimental evaluations and find that our approach performs well on both the fronts (diversity and relevance) in comparison to existing techniques and publicly accessible systems. We believe technique can be improved for better handling of multiword queries by adopting deep NLP parsing techniques, which will form part of our future work.

## Abstract

This paper presents our research on automatic question classification for Vietnamese using machine learning approaches. We have experimented with several machine learning algorithms utilizing two kinds of feature groups: bag-of-words and keywords. Our research focuses on two most important tasks which are corpus building and features extraction by crawling data from the Web to build a keyword corpus. The performance of our approach is promising where our system's precision outperforms the state-of-the-art Tree Kernel approach (Collins and Duffy, 2001) on a Vietnamese question corpus.

## Keywords

keyword collection, machine learning, Vietnamese question classification corpus.

## 1 Introduction

Question Classification (QC) is a task that, given a question, maps it to one of the predefined  $k$  classes, which indicates a semantic constraint on the sought-after answer (Li and Roth, 2006).

In a question answering system, before finding an answer of a question, the system has to identify which category it is asking about, and this is the obligation of question classification. Then, based on the identified category, we can narrow the space of answers that we have to find. Let us consider some examples:

- **Q:** *"Ai là người phụ nữ đầu tiên hy sinh trong chiến tranh Việt Nam?"* ("Who was the first woman killed in the Vietnam War?"), we expect to know that the target of this question is a **person**, thus reducing the number of possible answers significantly.

- **Q:** *Tại sao nắng màu vàng?* (*Why is the sunshine yellow?*) indicates that this question wants to get information about **reason**, thus in next steps our system just concerns about reason answers space rather than human or number categories.

The problem is that if the number of categories is more and the categories are more specific, the question answering system will spend more time classifying questions but its performance will be better. Let consider another example, in the next two questions, they are both asked to get information about **location**:

- **Q:** *Thành phố nào ở Canada có nhiều dân nhất?* (*What Canadian city has the largest population?*)
- **Q:** *Đất nước nào trao tặng Mỹ tượng nữ thần tự do?* (*Which country gave New York the Statue of Liberty?*)

More particularly, we can see that the target of the first question is a city and the other one is a country, both city and country are locations. In this case, location is considered a coarse-grained class and city and country are fine-grained classes. Naturally, the more fine-grained classes we have, the more difficult it is to tell them apart. For hierarchical categories, we adopted a two-level learning approach: first we solve the problem of classifying questions in the coarse-grained classes then based on this predicted label we continue with the fine-grained categories.

Our main contributions are building a Vietnamese corpus, collecting and using a kind of important features, which is keyword, for Vietnamese question classification. We tackle the corpus building by translating an existing well known English question corpus to Vietnamese. To the best of our knowledge, there is no publicly available Vietnamese questions corpus. As a result of

this work, we will share our newly built corpus to the research community. Collecting and using keywords is another important contribution of our work, which indicates that keyword extracted from Web is the most effective feature for Vietnamese question classification task. In this paper, we are going to present how we collect and extract keyword features for Vietnamese question classification.

The paper is organized as follows: Section 2 describes the related works and section 3 presents the process we take to build the Vietnamese data corpus. In section 4 we describe our Vietnamese question classification system, especially the features extraction step which involves crawling data from the Internet to create keyword features. In section 5 we show our experiments when using different machine learning algorithms with the set of features we extracted on our data corpus to classify questions in Vietnamese. Finally, section 6 provides some conclusions.

## 2 Related Works

There are many different approaches to resolve the question classification problem. Zhang and Lee (Zhang and Lee, 2003) with SVM (Cortes and Vapnik, 1995) using Tree Kernel, Li and Roth (Li and Roth, 2006) with SNoW model are two state-of-the-art approaches for English question classification. In Zhang and Lee's approach, the input question for this method is parsed into a syntax tree and converted to a vector in a multi-dimensional space. They introduced a new kernel function for SVM, Tree Kernel, constructed by dynamic programming to derive the similarity between two different syntax trees. This method achieved a precision of 90% with coarse-grained classification on TREC but there isn't any published results with fine-grained classification. In Li and Roth's approach, a set of features they used not only include syntactic features such as chunking but also include semantic features by using WordNet for English and building class-specific related words. Using semantic features, this method achieved a high precision of 92.5% with coarse-grained class and 85% with fine-grained class classification on a set of data including 21500 training questions from TREC 8, 9 (Voorhees, 1999; Voorhees, 2000), USC (Hovy et al., 2001), and 1000 testing questions from TREC 10, 11 (Voorhees, 2001; Voorhees, 2002).

## 2.1 Question Classification in Vietnamese

Question Classification in English is a classical problem but in Vietnamese, it is still a relatively new problem. To the best of our knowledge, there is not any research which works on open-domain Vietnamese question classification using learning based approach is published. In a research about question answering system for Vietnamese (Tran et al., 2009), the authors used machine learning approach for question classification module, however, the questions are only on travelling domain. Moreover, there is another research also working on question answering in Vietnamese (Dat et al., 2009). This system also focuses on answering questions on a specific domain and the authors used rule-based approach to resolve question classification module.

Combining the strengths of many solutions applied for English and the idea of (Tran et al., 2009), we started our research and experiment in Vietnamese question classification using machine learning approaches. Our main contributions are building a question set and a class-specific related word (keywords) set for Vietnamese.

## 3 Corpus Building

### 3.1 Question Hierarchy

From 1999, to support competitive research on question answering, The Text Retrieval Conference (TREC) has launched a QA track (TREC 8). Because the TREC QA track builds a fully automatic open-domain question answering system, there are many researches using TREC as experimental data sets. Importantly, the question type taxonomies of TREC can be used for any language. Besides there is not any standard for Vietnamese question classification yet, so we decide to use the question type taxonomies of TREC in our research.

TREC defined a two-layered taxonomy, which represents a natural semantic classification for typical answers. The hierarchy contains 6 coarse-grained classes (ABBREVIATION, ENTITY, DESCRIPTION, HUMAN, LOCATION and NUMERIC VALUE) and 50 fine-grained classes. Table 1 shows the hierarchy of these classes in nearly 5500 training and 500 testing questions of TREC 10. Each coarse-grained class contains a non-overlapping set of fine-grained classes.

Coarse	Fine-Grained
ABBR	abbreviation, expansion
DESC	definition, description, manner, reason
ENTY	animal, body, color, creation, currency, disease/medical, event, food, instrument, language, letter, other, plant, product, religion, sport, substance, symbol, technique, term, vehicle, word
HUM	description, group, individual, title
LOC	city, country, mountain, other, state
NUM	code, count, date, distance, money, order, other, percent, period, speed, temperature, size, weight

**Table 1: The TREC coarse and fine-grained question classes.**

### 3.2 Question Translation

From the English question corpus, we translated them into Vietnamese and use them for Vietnamese question classification based on following rules:

- The content of Vietnamese question must correspond to its label.
- Some named entities can be changed without keeping the semantic meaning. For example, Washington can be changed to be Hà Nội or White House can be changed to Hồ Gươm.
- Given an English question, we can translate it into many Vietnamese questions with the same meaning but different in syntactic structures. As a result, our classifier can detect many kinds of Vietnamese questions.

In this project, we allocated 5 students who have TOEFL score > 500 for translating 6000 TREC English questions into Vietnamese in about 2 months. Every member of our group not only has to translate but also review the translated Vietnamese questions from other members to find mistakes to correct them and assure the quality of the translated data.

With our Vietnamese question classification problem, there is no publicly available Vietnamese corpus, when our corpus is made publicly available, it can be used for many works in the future.

## 4 Vietnamese Question Classification System (VnQCS)

### 4.1 Vietnamese Question Classification System Architecture (VnQCS - Architecture)

There are two main components in our system, the Feature Extractor and the Classifier (Figure 1). Source code of our system and the data corpus were made publicly available at: <https://code.google.com/p/vn-qcs/>

The Classifier contains two levels, the coarse-grained classification and the fine-grained one. In the first step, questions are classified into the coarse-grained classes, then taking result of the first step as a feature, we continue classifying questions to the fine-grained classes.

With a classification problem using machine learning approaches, the feature extraction is a key step. The quality of the set of features extracted directly impacts the classification precision. The Feature Extractor module consists of two components: Vietnamese Word Segmenter and Keyword Collector. Among them, Keyword Collector plays an important role in feature extraction method and it is the highlight of this research.

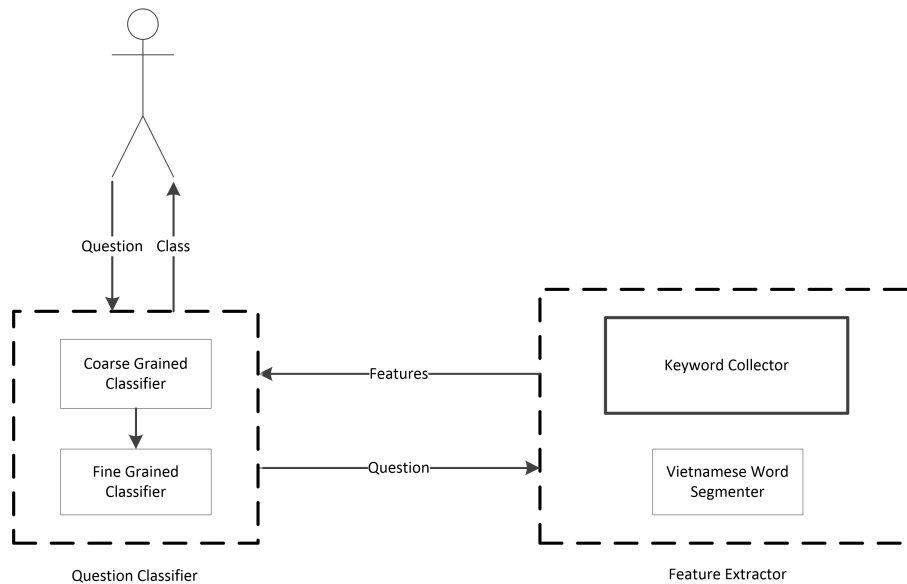

### 4.2 Feature Extraction in VnQCS

First, it is known that the linguistic characteristics of Vietnamese is different from English. Unlike English, in Vietnamese, one word may contain more than one token. For example, *mobile* (English) is translated into *điện thoại* (Vietnamese) and *mobile* is a word but *điện thoại* is a word which includes two tokens (*điện, thoại*). So, to match the characteristics of Vietnamese grammar, we will use words as a feature of algorithm in question classification.

We divide the features we extracted into three groups: bag-of-words, keywords and syntactic trees.

With **bag-of-words**, to get a set of features of Vietnamese words, we use a VnWordSegmenter tool<sup>1</sup> to extract them from Vietnamese training questions. With VnWordSegmenter tool, a question, for instance, "Bốn hình thức tồn tại của vàng là gì? (What four forms does gold occur in ?)", will be segmented into a sequence of words, as "Bốn hình\_thức tồn\_tại của vàng là\_gì?".

<sup>1</sup>Developed tool of iTim Company, website: <http://coccoc.com/about/>

**Figure 1: Architecture of VnQCS.**

With **keywords**, there are many keywords for a question class. In Li and Roth (Li and Roth, 2006), they used WordNet for English and built a set of class-specific words as semantic features and achieved the high precision (see section 2). But for Vietnamese, there isn't any lexical database like WordNet, so we have to develop an algorithm which collect keywords from the Internet which are lists of class-specific words for a smaller scale and useful enough for question classification (see Section 4.2.1). Moreover, we also manually collect keywords by observing the set of training questions. For examples, in reason class, with a why-question, we usually use "tại sao (why)" to start the question, or in abbreviation class, we usually use "viết tắt (abbreviation)". Most of classes have some specific words. This really has a significant impact when we use these lists of words as semantic features in question classification using machine learning.

With **syntactic trees**, the reason we extract this kind of features is that in Zhang and Lee (Zhang and Lee, 2003), the SVM algorithm using Tree Kernel method is the state of art for English question classification. So, we intend to answer the following question: "Does this method still outperforms the other methods in Vietnamese?". To use Tree Kernel, the questions must have corresponding syntax tree forms. For this, we used a parser tool for Vietnamese, Coltech-Parser (Le et al., 2009). The Coltech-Parser requires word segmentation for each input sentence. So, before using

the parser, we used the VnWordSegmenter tool to segment input questions.

#### 4.2.1 Keyword Collection from Web in VnQCS

Keywords are important semantic features though collecting them is not an easy task. Since the Internet contains a great number of web pages, this huge resource will help us to address the above-mentioned problem. The algorithm 1 describes how we collect keywords from Web and we hope it will be the basis for building semantic lexicons for other language processing tasks in Vietnamese.

- Firstly, we manually collect websites from the Internet which focus their content to one of our classes. Note that these websites should totally contain web content about one kind of class we want. As a result, our keywords from these will correspond to that class only and good for training features.
- In the next step, we crawl all links in these websites, note that we use only internal links since some external links will lead to other websites which are not related to the class we are interested in. Besides, in some cases all links that we want are only part of a website, we have to detect the format of them to get good content for training data.
- Base on links from previous step, we segment their text content. However, the words that we get in this step may contains some

**Input:** Set of websites which their contents focus on specific fine-grained class input

**Output:** Good keywords set for fine-grained class input

```
setOfPages = {};  
foreach website in websitesInputSet do  
    foreach internalLink in website do  
        | setOfPages = setOfPages + pageOfThisInternalLink;  
    end  
end  
  
setOfKeywords = {};  
foreach page in setOfPages do  
    remove all tags from page to get pageContent;  
    segment pageContent to get listOfWords;  
    foreach word in listOfWords do  
        | setOfKeywords = setOfKeywords + word;  
        | wordFrequency[word] = wordFrequency[word] + 1;  
    end  
end  
  
sort all words in decreasing order of wordFrequency and save result to sortedWords;  
eliminate all words which have low IDF index from sortedWords;  
choose top words from sortedWords and save result to keywordsResult;
```

**Algorithm 1:** Collect Keywords of a Specific fine-grained Class

trivial words like "là" (is), "và" (and), "hoặc" (or)... Since these stop words have low meaning, we can threshold their  $IDF^2$  index and eliminate small value ones. Besides, we count the frequency of each word in each class and choose top N words with biggest frequencies. Finally, reviewing these N words and removing unsuitable ones for target class are necessary works that we have to do.

## 5 Experiments

This section describes our experiments on the Vietnamese corpus that we built. These experiments will help us find out the most suitable combination of algorithms and features for this task on this dataset. The results of experiments indicate that the semantic features, especially keywords, are really useful.

We designed three experiments to test the precision of our classifiers on Vietnamese questions corpus which we built. The corpus consists of two data sets: a training data set which includes nearly 5500 questions and a testing data set which includes 500 questions translated from TREC 10 and all of questions are in 6 coarse-grained classes or 50 fine-grained classes. To evaluate the experi-

mental results, we use two main measures: weight average precision and weight average recall, which are all micro-average values.

- The first experiment evaluates the individual contribution of different feature types to question classification precision. In particular, we use Weka (Hall et al., 2009) to run machine learning algorithms namely Decision Tree (DT) (Quinlan, 1986), Naive Bayes (NB) (Bayes, 1763), SVM and Voting (Parhami, 1994), which are trained from our data we built using the following feature set: bag-of-words.
- In the second experiment, both bag-of-words and keyword features will be used together on machine learning algorithms on Weka. The goal is to verify the contribution of keyword features to question classification precision.
- Finally, we experiment with syntactic tree features set on SVM-Light-TK (Moschitti, 2004). This test will show us different affection of syntactic features between English and Vietnamese to question classification precision, and the important role of semantic features in Vietnamese question classification.

<sup>2</sup><http://en.wikipedia.org/wiki/Tf%E2%80%93idf>

## 5.1 Bag-of-words

	6 class		50 class	
	Precision	Recall	Precision	Recall
<b>Decision Tree</b>	87.3%	87%	78.2%	76.2%
<b>Naive Bayes</b>	84.4%	83.6%	78.2%	73%
<b>SVM</b>	<b>91.2%</b>	<b>91%</b>	<b>83.1%</b>	<b>82.4%</b>
<b>Majority Voting</b>	91%	90.6%	81.1%	79.4%

**Table 2: The question classification results using different machine learning algorithms, with same kind of feature: bag-of-words.**

Like results in (Zhang and Lee, 2003), table 2 shows us that in Vietnamese question classification, SVM still outperforms other methods with the same kind of features. With bag-of-words features, SVM model achieves the highest precision with 91.2% on coarse-grained class and 83.1% on fine-grained class classification.

## 5.2 Bag-of-words + Keywords

	6 class		50 class	
	Precision	Recall	Precision	Recall
<b>Decision Tree</b>	86.2%	86.2%	80.3%	77.4%
<b>Naive Bayes</b>	87.4%	86.2%	81.1%	78.4%
<b>SVM</b>	<b>94.1%</b>	<b>94%</b>	<b>85.4%</b>	<b>83.8%</b>
<b>Majority Voting</b>	94.1%	94%	83.5%	81.8%

**Table 3: The question classification results using different machine learning algorithms, with same kind of features: bag-of-words and keywords.**

If only using bag-of-words, we can not fully exploit the semantic elements of the language in Vietnamese. As we expected, with both bag-of-words and keyword features used together, although the precision of classification using DT or NB only increases slightly, it increases significantly if we use SVM. In particular, with 6 coarse-grained classes, the precision increases from 91.2% (table 2) to 94.1% (table 3), and with 50 fine-grained classes, it increases from 83.1% (table 2) to 85.4% using SVM (table 3). So, keyword features have an important role to increase the precision of question classification.

## 5.3 Tree Kernel

We experimented SVM-Light-TK to using SVM combined Tree Kernel for Vietnamese question classification since this state of the art method is successful for English data. However, SVM-Light-TK can only classify binary label, we use one-vs-all strategy for problems of 6 coarse-grained

	6 class		50 class	
	Precision	Recall	Precision	Recall
<b>Tree Kernel</b>	88.4%	88%	75.1%	67.4%
<b>Bag-of-words</b>	91.2%	91%	83.1%	82.4%
<b>Bag-of-words + Keywords</b>	<b>94.1%</b>	<b>94%</b>	<b>85.4%</b>	<b>83.8%</b>

**Table 4: The question classification results using SVM algorithm with some different kinds of features.**

classes and 50 fine-grained classes. The precision of this taxonomy is 88.4% for coarse-grained classes but only 75.1% for fine-grained classes (see table 4).

## 6 Conclusion

There are two main contributions of this paper. Firstly, we created a corpus for Vietnamese question classification (section 3). All the English questions in TREC 10 were translated into Vietnamese not only for this research but also many works in the future. This corpus will be made publicly available. Secondly, we extracted several feature groups and found out that the semantic features (bag-of-words and keywords) are really helpful to Vietnamese question classification meanwhile syntactic ones (syntactic tree) don't contribute so much to taxonomy precision. So we propose a method for collecting keywords from the Internet in a large scale. There isn't any WordNet for Vietnamese but with this method, we still have enough training data features for classifying a large range of Vietnamese questions.

Though Vietnamese question classification is a new challenge and there is not any work done on this, our experimental results indicate that the Vietnamese question classification can be addressed with relatively high precision using machine learning approaches. The result of classification can achieve a high precision of 94.1% with coarse-grained class classification and 85.4% with fine-grained class classification.

## Acknowledgments

We wish to thank The Vietnam National Foundation for Science and Technology Development (NAFOSTED) for financial support. Thanks also to NLP group at University of Engineering and Technology for partially supporting us in building the corpus. Finally, we thank the anonymous reviewers for helping us improve the presentation.

## Abstract

Ubuntu’s Internet Relay Chat technical support channel has bots that output specific messages in response to command words from other channel users. These messages can be used to answer frequently-asked questions instead of requiring an expert to (repeatedly) type a lengthy reply. We describe an approach to automatically distinguish bot-answerable questions, which would mitigate this problem. To the best of our knowledge, this is the first work on investigating question answering in a multiparticipant chat domain. Our results indicate that for some types of questions, supervised learning algorithms perform well on this task and, in addition, that character  $n$ -grams are a better representation than traditional bag-of-words for this task and domain.

## 1 Introduction

Ubuntu (a Linux-based operating system) maintains multiple Internet Relay Chat (IRC) channels for technical support. Some of these channels contain bots, which are automated agents pre-programmed to perform certain tasks. One of the bots can output pre-written messages, called *factoids*, in response to command words. For example, if a user types “!flash”, then the bot would output “To install Flash see <https://help.ubuntu....mats/Flash> - See also !Restricted and !Gnash”. These factoids are used to answer common questions, enforce channel guidelines, direct non-English speakers (in their native tongue) to Ubuntu’s foreign language support channels, and query Ubuntu’s repository of packages. While useful, this bot must be manually invoked. Automating the bot to self-detect and answer questions that it can answer could reduce

the workload for knowledgeable experts trying to help other users. This is applicable to not only Ubuntu’s technical support channels, but to other IRC channels providing technical support (e.g., Debian’s support channels) and to channels that use similar bots (e.g., Eggdrop and Infobot) for other purposes.

We describe initial steps on a self-invoking bot. We begin by investigating the multi-classification task of which questions are bot-answerable questions (BAQ) and which are human-answerable questions (HAQ), which requires a human to answer due to the question’s complexity. We implemented a baseline non-learning approach and supervised support vector machines (SVM) and  $k$ -nearest neighbor ( $k$ -NN) algorithms. Our results show that a bot can answer with confidence some types of questions, especially those directing users to more appropriate channels for help on certain topics.

Our contributions are as follows:

- **Problem:** We identified a real-world problem that has not been investigated, despite bots having been around for years on IRC channels.
- **Data:** We created an annotated multiparticipant chat corpus that is publicly available.
- **Empirical study:** We report on our investigation of applying supervised learning algorithms and leveraging different feature representations, whose results will be used as a foundation for a larger case-based reasoning approach.
- **Discussion:** We describe how some types of automatically-answerable questions can be easy or difficult to classify.

## 2 Related Work

Chat is a difficult medium to analyze: its characteristics make it difficult to apply traditional natural language processing techniques. It has uncommon features such as frequent use of abbreviations, acronyms, missing subject pronouns, emoticons, abbreviated nicknames, words stripped of vowels to reduce number of keystrokes, and entangled conversation threads (Uthus and Aha, 2013a).

In the multiparticipant chat domain, there has been some work in creating a bot that can answer questions with Cobot (Isbell et al., 2006). This bot was limited in capability – it could only respond to questions directed at it. Another recent work resulted in a bot which could respond to utterances through word matching and used templates for output (Shaikh et al., 2010).

Also related in this domain are a few military research efforts that have focused on classifying chat messages. One examined profile-driven information extraction from chat using regular expressions and entity classes (Berube et al., 2007). Another examined identifying uncertainty and urgency within a chat message using rule-based approaches and statistical analysis (Budlong et al., 2009). A third, whose work is most similar to ours, compared several supervised algorithms for classifying chat utterances (Dela Rosa and Ellen, 2009). Using an artificial chat log, they classified messages as either non-important filler messages or as messages containing Navy ship updates. Their results showed  $k$ -NN and SVM performed best for this task. Our task differs from these previous investigations in that we are applying supervised learning algorithms to a multi-labeled corpus composed of real chat messages.

This problem is also related to the larger field of question answering, such as pertaining to discussion boards (Hong and Davison, 2009; Kim et al., 2007), frequently asked question files (Burke et al., 1997), and community-based question answering (Zhou et al., 2012). An important difference between this body of related work and what we are investigating is the medium. Multiparticipant chat is more difficult to work with compared to other mediums due to entangled conversation threads – a researcher cannot easily automatically analyze the messages of a single conversation. In prior work, researchers could usually isolate individual conversations automatically, making it possible to identify (to some extent) the question and

Figure 1: The volume of messages in the IRC channel #ubuntu during 2011.

the answer. Another important difference is the temporal scale – chat is in real-time, and a chat user expects to receive an answer quickly. A chat user can only see messages while they are logged in (in the case where there is no archive being stored offline). Both of these differences results in new challenges not seen in other mediums for question answering.

## 3 Ubuntu’s IRC Channels

The IRC channel #ubuntu is Ubuntu’s primary technical support channel. It provides support for those who have problems using Ubuntu; it is not used for socializing or for receiving help with other Linux distributions (e.g., Debian, Linux Mint, Fedora) or software.

The channel’s traffic level varies throughout the year and day (see Figure 1). During the year, it experiences heavy traffic during Ubuntu’s semi-annual new releases in April and October and generally experiences heavy traffic during the North American and European evening hours. Heavy traffic creates difficulties for users trying to get answers to their questions.

ubottu<sup>1</sup> is the bot that can access 1234 factoids, corresponding to 2324 commands (some factoids are mapped to multiple commands). It can also provide information about any software package found in Ubuntu’s software repository. A channel user (oftentimes an expert) can task ubottu to answer another user’s question (see

```

Figure 2: Example of `ubottu` being invoked with a command word (in this case “!unr”) to answer a question.

Figure 2). Automating `ubottu` would allow experts to focus their valuable time on responding to more challenging requests.

## 4 Corpus

We created an annotated corpus by pulling questions from the Ubuntu Chat Corpus, specifically from the `#ubuntu` channel logs (Uthus and Aha, 2013b). This corpus has 4577 messages, including 2002 HAQs and 2575 BAQs from 68 factoid categories. These messages were taken from chat logs from 28 April 2011 (the day Ubuntu 11.04 was released) to 13 October 2011 (the day before Ubuntu 11.10 was released).

We looked for messages in which a question is answered with a factoid, or a question required a human to answer. To judge between these two types, we relied on the expertise of users and how they answered the questions. To reduce noise, we limited HAQs to conversations in which the first reply came from a user who invoked `ubottu` frequently (i.e., experts). These `ubottu` invokers are considered a better judge of what is a BAQ or HAQ compared to someone who rarely invokes `ubottu` to answer questions. For the BAQs, we restricted questions to those with at least ten examples mapped to a factoid. Figure 3 shows the distribution of BAQs to factoids in our corpus.

Some of the corpus’ messages are not in English. In such cases, users will be directed to one of Ubuntu’s foreign-language support channels (though a user can re-ask their question in English). Some languages present in the corpus include Spanish, French, Chinese, Russian, German, Polish, and Portuguese. Additionally, some of these messages are written with non-Latin characters, such as Chinese and Russian.

Figure 3: Distribution of the sixty-eight factoid invocations in our corpus.

## 5 Approach

We are using  $k$ -NN and SVM algorithms for classifying messages. This builds on results by Dela Rosa and Ellen (2009), who had found these two supervised learning algorithms to work best on chat messages. Implementation of these algorithms were obtained from Scikit-learn (Pedregosa et al., 2011).

For preprocessing, text was normalized by lowering the case for each term.

We examined different representations for encoding the questions. These include bag-of-words, bigrams, and character  $n$ -grams. With the character  $n$ -grams, we examined  $n$ -grams which overlap words and  $n$ -grams which are restricted to within word boundaries. We used  $tf - idf$  to weigh the features and  $\chi^2$  for feature selection.

## 6 Empirical Study

We have two hypothesis we are testing:

**H1:** Supervised learning algorithms will outperform a non-learning baseline approach for classifying BAQs.

**H2:** Using character  $n$ -grams for this domain will allow for better precision and recall when compared to more traditional representations of bag-of-words and bigrams.

Our intuition for H2 is that we believe that character  $n$ -grams will allow for better representation of misspelled words commonly seen in chat messages when compared to bag-of-words and bigrams.

### 6.1 Baseline

Our non-learning baseline algorithm maps questions to factoids by checking if the question contains the factoid command as a word token. As a reminder, multiple factoids can map to the same response. If a question contains multiple factoids, then the most frequently invoked factoid is applied (ties are broken by alphabetical ordering). If a

Representation	$\chi^2$ Feature Size	Precision	Recall	F <sub>0.5</sub> Score
Non-learning baseline				
–	–	0.44	0.24	0.37
SVM				
Character 3-grams, WB	4000	0.67	0.42	0.60
Character 3-grams	3200	0.67	0.38	0.59
Character 4-grams, WB	3600	0.63	0.40	0.57
Bag-of-words	1600	0.62	0.40	0.56
Character 4-grams	4000	0.58	0.35	0.51
Bigrams	1200	0.51	0.20	0.39
<i>k</i> -NN				
Character 4-grams, WB	800	0.55	0.34	0.49
Character 3-grams, WB	800	0.55	0.32	0.48
Character 4-grams	1200	0.57	0.30	0.48
Character 3-grams	800	0.54	0.41	0.47
Bag-of-words	400	0.54	0.31	0.47
Bigrams	400	0.44	0.15	0.32

Table 1: Results for the baseline, SVM and *k*-NN algorithms. WB means the character *n*-grams were bounded within word boundaries.

question contains no factoids, then it is considered a HAQ.

## 6.2 Metrics

We used a 10-fold cross evaluation protocol and precision, recall, and the F<sub>0.5</sub> score as our evaluation metrics. For this work, we consider precision to be more important than recall because a bot that frequently answers questions incorrectly could anger chat users and cause them to ignore the bots. Therefore, F<sub>0.5</sub> is more appropriate here than the standard F score because it places more emphasis on precision. Additionally, as these are multi-classification problems, we used the macro version of these metrics to average over the different labels.

When calculating precision, recall, and F<sub>0.5</sub>, we omit the HAQ scores when calculating the macro scores for this multi-classification problem. We also omitted any questions that are incorrectly labeled as HAQ for calculating precision and recall scores because a HAQ can be answered by a human expert. Essentially, we do not penalize for erring on the side of caution.

## 6.3 Results

Table 1 summarizes the results of the application of our baseline and learning algorithms. We ap-

plied all variations of the two learning algorithms, testing on all combinations of representations and  $\chi^2$  feature size limits. For the feature size limits, we tried values between [400:4000] in steps of 400. The results display the best configuration for each representation.

As shown, the learning algorithms outperformed the baseline for all three metrics, supporting hypothesis H1. This shows that some questions cannot be easily distinguished by simply looking for factoid commands within the questions.

In regards to the second hypothesis, both learning algorithms performed best when using character *n*-grams, especially when restricted by word boundaries, thus supporting H2. We believe this is due to the character *n*-grams being able to better handle noisy nature of chat, especially with the misspellings and abbreviations.

We next examine what *type* of questions do these learning algorithms perform well on, especially when compared to our baseline. For this, we focus on the results of applying SVMs. Figure 4 compares the difference of F<sub>0.5</sub> scores between SVM and the baseline. For most factoids, SVMs performed better or had similar performance to the baseline. The small number of factoids it performed worse on were generally factoids both

Figure 4: Comparison of  $F_{0.5}$  scores between SVM and baseline.

SVM and the baseline performed poorly, finding low  $F_{0.5}$  scores.

Figure 5 shows the  $F_{0.5}$  scores achieved by SVM for each individual factoid category. These are ordered by their distribution in the corpus (see Figure 3). One fact shown by this figure is that there is not a strong correlation between the distribution size and the result achieved by the SVM. While having more examples within a category does help, there are plenty of factoids where SVM performed poorly. This shows that it is the difficulty of the questions themselves, and not the amount of examples, which causes difficulty for the SVMs, let alone learning algorithms for this domain.

One set of questions SVMs performs well on are questions where users are subsequently directed to another channel. This includes Ubuntu’s non-English channels and channels that provide support for other Linux distributions. SVMs did well on all the non-English factoids, with  $F_{0.5}$  scores ranging between 0.88 (for Chinese) and 0.99 (for Russian). This is probably due to these questions having uncommon features, such as non-English words or software that is not supposed to be discussed in `#ubuntu`.

One similar pair of questions, which are addressed by two factoids, caused some confusion for the learners – asking for permission to ask a question (e.g., “Can I ask a question?”) or asking if anyone can help without stating their problem (e.g., “Can anyone help me?”). This commonly happens with first time visitors to the channel, as they do not know the channel guidelines and will then ask for permission to ask a question or if someone could help them. The channel operators try to encourage users to just ask their question – this happens frequently enough that there are two factoids (labels *ask* and *anyone* in the corpus)

Figure 5:  $F_{0.5}$  scores for each factoid when applying SVM, ordered by distribution.

to answer these similar questions. Unfortunately, there is a lack of consistency in invoking these two factoids, and as such the learning algorithms we tested had difficulty with these questions.

Some other types of questions that SVMs struggle with are those that cover a wide-range of possible questions. For example, `#ubuntu` can be used either in cases to explain what the channel topic is (for those asking), or to get users on topic (with the possible off-topic message types being wide-ranging); *details*, which can be used whenever someone asks a question or for help without providing enough details for anyone to begin to help; and *wine* to help users with problems running any type of Windows program under Linux. These types of questions may require a human to aid in answering, as it would be difficult to learn all possible types of questions that are covered by these factoids.

## 7 Conclusions

We have investigated applying supervised learning algorithms to classify questions as HAQ or BAQ, and our results show that these algorithms can outperform a non-learning baseline approach. We also show that character  $n$ -grams are a better representation than traditional bag-of-words for our task. More importantly, the learning algorithms can answer some types of questions well, indicating that a self-invoking bot can be created that can answer common questions with confidence.

Future work to extend this is to apply unsupervised methods for finding additional questions to match with the factoids. This would greatly extend what we have presented, as we were restricted to the manually-labeled messages to match questions with answers. We plan on applying a case-based reasoning framework (Richter and Weber, 2013) to achieve such a goal.

A final area to investigate is an extension of `ubottu` that can learn to update its knowledge. Currently, only a few users are allowed to edit or add new factoids to `ubottu`. It would be advantageous if it could add new commands and factoids itself by summarizing common answers, or update outdated factoids should it see a common pattern of answers conflicting with its knowledge.

## Abstract

This work aims at constructing a corpus to satisfy such requirements to support research towards professional writing assistance. Our corpus is a collection of scientific work written by non-native speakers that has been proofread by native English experts. A new annotation scheme, which is based on word-alignments, is then proposed that is used to capture all types of inarticulations and their corrections including both spelling/grammatical error corrections and paraphrases made by proofreaders. The resulting corpus contains 3,485 pairs of original and revised sentences, of which, 2,516 pairs contain at least one articulation.

## 1 Introduction

Detection and correction of misspellings and grammatical errors have been recognized as key techniques for writing assistance, and have extensively been studied in natural language processing (NLP) (Whitelaw et al., 2009; Gamon, 2010; Tetreault et al., 2010; Park and Levy, 2011). However, correcting misspellings and grammatical errors, which can be performed by normal English native speakers, does not satisfy all the requirements of professional writing (Futagi, 2010). The core of the proofreading process, in reality, is paraphrasing inarticulations, which can only be done by expert proofreaders. Considering the two paraphrased sentences (1a) and (1b) below, we can see that sentence (1b) is likely to be considered better by most people (Williams and Colomb, 2010), although neither of them contains any misspellings or grammatical errors.

(1a) *The outsourcing of high-tech work to Asia by corporations means the loss of jobs for many middle-class American workers.*

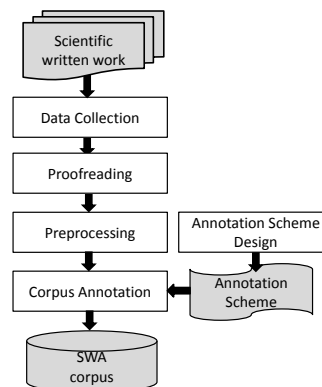

Figure 1: Methodology for corpus annotation

(1b) *Many middle-class American workers are losing their jobs, because corporations are outsourcing their high-tech work to Asia.*

(Williams and Colomb, 2010)

Most of the existing corpora are designed to capture errors in spelling and grammar, but they have not paid enough attention to paraphrasing.

We constructed a corpus that we called scientific writing assistance corpus (SWA), to support research on assistance with scientific-writing that captures all types of inarticulations, including those in both misspellings/grammar and paraphrasing. We have used the term *inarticulation* and *inarticulation correction* instead of *error* and *error correction* in this paper, to include in our task the paraphrasing, which is actually not errors.

Figure 1 overviews the methodology we proposed to construct the corpus. Scientific work written by non-native researchers or graduate students are collected (i.e., data collection, see Section 3), and this was then proofread by English native experts (i.e., proofreading). After that, we preprocessed the documents to convert them into a predefined format (i.e., preprocessing, see Section 3). Annotators with linguistic backgrounds were asked to strictly follow our annotation scheme, which had been designed to capture all types of

inarticulations (i.e., annotation scheme design, see Section 2).

Our corpus construction had several substantial advantages in comparison to the existing corpora such as the NUCLE (Dahlmeier and Ng, 2011), NICT\_JLE (Izumi et al., 2004) and KJ corpora (Nagata et al., 2011). First, the proofreading process is separated from the annotation process. By doing this, both the writer and the proofreader were unaware of the construction of the corpus, so it could capture real articulations and corrections to these. Second, the alignment-based annotation scheme was employed in annotations to capture all types of articulation correction. This allowed us to annotate discontinuous paraphrasing patterns, which were not neatly handled in other corpora. Third, paraphrases were captured, and were proved to be an important type of articulation correction for advanced learners.

The main contributions of this work are in the annotation of paraphrasing and its annotation method, in context of professional proofreading. Statistics for the SWA corpus was given in Section 4). We compared the grammatical errors annotated in the obtained corpus with those in the KJ corpus and NUCLE corpus, two popular corpora often used for research on grammatical error correction (Section 5), and performed an analysis of the paraphrases annotated (Section 6). Our analyses also show the potential of NLP research toward professional text revision.

## 2 Annotation scheme design

We extended the alignment-based paraphrase annotation scheme of Cohn et al. (2008) by categorizing the alignments into more fine-grained types (see Figure 2) to capture all types of inarticulation corrections. Figure 3 outlines example annotations to illustrate our annotation scheme. The alignments at the top level, are divided up into four broad types: Preserved, Metadata, Inarticulation Bi-alignment and Inarticulation Mono-alignment.

The Preserved type of alignments is the most trivial type that connects words with the same surface and function, e.g., *the*, *efficiency*, *various*, *methodologies* in Figure 3(A). Still, there are many cases where two words have the same surface form, but do not have the same functions in the original and the proofread sentences. For instance, the word *of* in the above example appears in both the sentences, but the two occurrences are

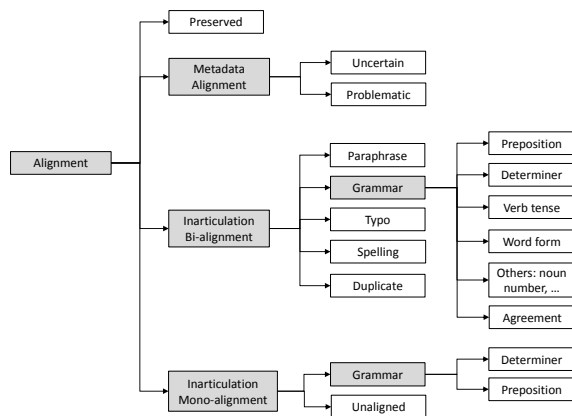

Figure 2: Proposed tagset. Categories in gray are used for classification but not for tagging.

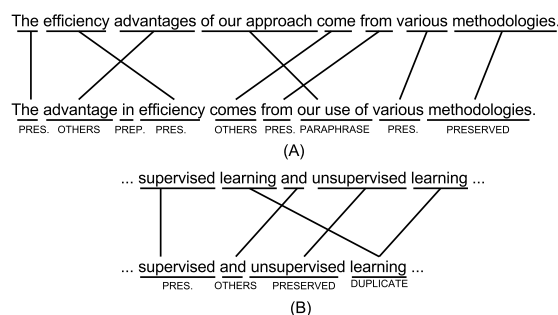

Figure 3: Annotations using our annotation scheme. Top has original texts, and bottom has the proofread text.

not aligned, because they modify different words, i.e., *approach* and *methodologies* in this case.

Inarticulation alignments including mono-alignments and bi-alignments are for capturing inarticulations and their corrections. The Grammar subtype of inarticulation alignments is not used for all types of grammatical errors as in the other annotation scheme, but is limited to some well-defined types of grammatical errors, which will be explained later in Section 2.1. The other subtypes are Duplicate, Spelling, Typo, and Unaligned, which will be explained in the following.

- **Duplicate:** A duplicate alignment connects words that appear once in the original sentence, but more than once in the proofread sentence, or vice versa. This tag captures the correction for articulations like the word *learning* in the example in Figure 3(B).
- **Spelling:** A spelling alignment is used for misspellings, e.g., *occured*→*occurred*<sup>1</sup>. This also includes the use of hyphens, e.g., *state of*

<sup>1</sup>The expression to the right of the arrow (→) is the preferred expression within context of writing

*the art*→*state-of-the-art*.

- **Typo:** The expression typo is a short form of typographical error, which refers to errors caused by typing mistakes. If annotators judge that the error is likely to be caused by a typing mistake, they should mark the errors as typo. Typo may be considered to be less important in writing assistance.
- **Unaligned:** An unaligned mono-alignment is used for words in the original sentence that have no correspondences in the proofread sentence, or vice versa.

Reordering of words are naturally captured by cross alignments, so we do not create a type for this. Punctuation marks are not annotated.

Besides, alignments have additional features to capture information that is specific to proofreading by humans. The current features are: Uncertain and Problematic. An alignment is marked as *uncertain* when the proofreader is not confident in the correction. This type is specific to the proofreading process. When the native proofreader is doubtful about his/her understanding of the original sentence, he/she will comment on it by stating “*I do not understand this,*” or “*This correction is a guess*”. An alignment is classified as *Problematic* when the annotators discover that the proofreader has made an erroneous correction. This happens when the proofreader misunderstands the author’s intention. Although such situations can be rare, this tag is designed to offer a mechanism for annotators to provide feedback.

## 2.1 Grammar

Grammar-typed alignments connect a grammatical error in the original sentence with its correction in the proofread sentence. Grammatical errors in our annotation scheme are comprised of errors with determiners, prepositions, verb tenses, word forms, agreement, and others. They are tagged with the corresponding tags called Determiner, Preposition, Verb tense, Word form, Agreement, and Others. The Others type merges several specific subtypes of grammatical errors, including noun number, verb number, wh-word choice, or conjunction choice. Note that we do not use Others as a catch-all type. Except for Agreement, most of the subtypes of the Grammar type can be aligned well with the error types in the error taxonomies used by the existing corpora. The Agreement type is used to capture the number agree-

ments of articles and nouns, genitives and nouns, or nouns and verbs, when a change in the number of one word forces us to change the number and form of another word.

## 2.2 Paraphrase

Any type of correspondence that cannot be classified into these types above is marked Paraphrase. In other words, Paraphrase is used as a catch-all type. Those errors that require complex corrections, i.e., corrections to phrase structures or sentence structures, which are not classified into the Grammar type, are captured with Paraphrase. We have followed the definition of paraphrases in the guidelines for paraphrase annotation by Callison-Burch et al. (2006): “*paraphrases convey the same meaning but are worded differently*”. We have two rules of thumb for the boundary of paraphrases: (1) shorter paraphrases are preferable (similar to (Callison-Burch et al., 2006)), and (2) a paraphrase alignment should not contain an alignment of other types in it.

## 3 Data collection and preprocessing

We collected scientific works that were written by seven authors with two language backgrounds Japanese and Vietnamese. The collected documents included different types of scientific publications such as short papers, full papers, and book chapters. We will use the terminology *document* to refer to a written work of any type. The collected documents belonged to two domains or fields of studies, which were computer vision (11 documents) and natural language processing (7 documents); and all were proofread by native English experts.

We then preprocessed these documents to convert them into a standard format. Non-text information such as figures and tables were removed. Format tags such as LaTeX’s tags were also removed. We separated the original text and the proofread text for each document, and aligned the sentences in these two texts, so that a line in the original text corresponded to a line in the proofread text. We found that there were cases where a sentence in the original text should have been aligned with more than one sentence in the proofread text or vice versa. We allowed two or more sentences to be aligned in such cases.

## 4 Corpus annotation and results

We made use of Yawat, a web-based word-alignment annotation tool (Germann, 2008) to annotate the corpus. Yawat accepts text files containing pairs of aligned sentences as input. We applied a simple string-matching algorithm to produce default Preserved and Unaligned alignments for the corpus to save annotation time and effort.

The corpus was annotated by two annotators with linguistics background. The agreement between them was measured using the F1-score formula similarly to that by Cohn et al. (2008). *Atom-alignments*, or one-to-one alignments, were generated from the bi- and mono-alignments. An  $M \times N$  multiple alignment would result in  $M \times N$  atom alignments. We removed the preserved atom-alignments that were annotated by both annotators, because they occupied the majority of atom alignments but were not a meaningful indicator of inter-annotator agreement. Considering annotations by one annotator as gold annotations, we then calculated recall, precision, and F1-score over all the annotated alignments in the two versions of the SWA corpus. The overall F-scores with and without considering alignment types were 0.637 and 0.716 respectively. It can be seen that our inter-annotator agreement measure without considering alignment classification is comparable to those reported by Cohn et al. (2008) (0.71, 0.74, and 0.76, for the three datasets of MTC, Leagues, and News, respectively). This is reasonable because when alignment classification is taken into account, the annotation task is more difficult, so the inter-annotator agreement is lower.

A total of 4,686 Inarticulation alignments were annotated for 2,516 pairs of sentences in 18 documents. 69,738 (91.8%) of the total of 75,968 words in the corpus were annotated with Preserved alignments. Table 1 lists the ratios (%) of broad types of alignments. We can see that the Grammar errors, both in bi- and mono-alignments, occupy 58.1% of the total errors, which is not a surprise. Paraphrase alignments occupy a significant part, i.e., 29.3% of the total. These figures indicate that paraphrasing is an essential type for scientific writing; therefore, research on writing assistance should pay more attention to error correction by using paraphrasing.

The ratios of the subtypes of Grammar alignments are listed in the column named SWA (the

Alignment Type	Count	Ratio (%)
Paraphrase	1,372	29.3
Bi-Grammar	1,511	32.2
Typo	68	1.5
Spelling	308	6.6
Duplicate	13	0.3
Preserved	2	0.0
Mono-Grammar	1,212	25.9
Unaligned	200	4.3
TOTAL	4,686	100.0

Table 1: Statistics for all alignments (except for the Preserved type) annotated in the corpus

name of our corpus) in Table 2. Out of all grammatical errors, determiners caused a lot of troubles for non-native writers from the Japanese and Vietnamese language backgrounds, even though the authors of the collected documents all had an advanced level of proficiency in English. This may be because of the difference between the characteristics of their background languages and the English language.

## 5 Cross-corpora comparison for grammatical errors

This section compares the grammatical-error annotations (Grammar alignments) in our corpus with those annotated in the KJ and NUCLE corpora. The Grammar types of errors in our scheme are restricted to well-defined types of grammatical errors. It would be interesting to analyze the differences in grammatical errors made by writers of the three corpora. The writers for our SWA corpus were graduate students and researchers in the field of computer vision and natural language processing, who could be considered to be advanced learners. The writers for the KJ and NUCLE were Japanese and Singaporean students, respectively.

As the three corpora used different annotation schemes, we created a mapping between compatible tags in the three tagsets to compare our corpus with theirs. This mapping is summarized in Table 3. The annotation scheme used for the KJ corpus, called KJ annotation scheme, was a simplified version of the NICT\_JLE annotation scheme (Nagata et al., 2011). The definitions of types and marking schemes are basically similar in the two annotation schemes, but the KJ annotation scheme merges several subtypes into one type, for example, the

Type	KJ Count ( $\times\alpha$ )	KJ (%)	NUCLE Count ( $\times\beta$ )	NUCLE (%)	SWA Count	SWA (%)
Determiner	543 (726)	18.7	6,004 (641)	12.9	1,176	25.1
Preposition	377 (504)	13.0	7,312 (781)	15.7	547	11.7
Others	404 (540)	13.9	5,486 (543)	10.9	427	9.1
Verb tense	249 (333)	8.6	3,288 (351)	7.1	369	7.9
Word form	317 (423)	10.9	2,241 (239)	4.8	151	3.2
Agreement	146 (195)	5.0	1,578 (168)	3.4	53	1.1
TOTAL of Grammar	2,036 (2,723)	70.0	25,509 (2,723)	54.7	2,723	58.1
Total of all types	2,907	100.0	46,597	100.0	4,686	100.0

Table 2: Statistics for Grammar alignments in SWA in comparison with KJ corpus and NUCLE corpus with  $\alpha = \text{TOTAL}_{SWA} / \text{TOTAL}_{KJ}$ ,  $\beta = \text{TOTAL}_{SWA} / \text{TOTAL}_{NUCLE}$

KJ	NUCLE	SWA
at	ArtOrDet	Determiner
prp	Wcip	Preposition
n_num, rel	Nn, Vform	Others
v_tns	Vt	Verb tense
aj, v_lxc	Wform	Word form
v_agr	SVA	Agreement

Table 3: Tagset mapping of KJ, NUCLE, and SWA for comparison. Note that only corresponding tags are mapped.

*noun inflection*, *noun case*, *noun countability* and *complement of noun* of the NICT\_JLE annotation scheme, are merged into one type, the *noun lexical*. The KJ tagset contains 19 tags, fewer than the total number of 45 error tags in the NICT\_JLE tagset (Izumi et al., 2004). The NUCLE tagset has more fine-grained tags than the KJ tag set (27 tags).

The four types Determiner, Preposition, Verb tense, and Agreement in our tagset have counterparts in the KJ tagset, which are *at* (article), *prp* (preposition), *v\_tns* (verb tense), and *v\_agr* (verb agreement) tags, and in the NUCLE tagset, which are *ArtOrDet* (article or determiner), *Wcip* (wrong collocation/idiom/preposition), *Vt* (verb tense), and *SVA* (subject-verb agreement). Note that subject-verb agreement is only part of the Agreement type in our annotation scheme (see Section 2). The counts for the Others type were sums of the *n\_num* (noun number) and *rel* (relative) types for the KJ corpus, and of the *Nn* (noun number) and *Vform* (verb form) types for the NUCLE corpus. The Word-form figure of the KJ corpus was a sum of the *aj* (adjective), and *v\_lxc* (verb lexical) types. As NUCLE has the exactly corresponding type called *Wform* (word form), so we used the count of this type in our comparison.

The comparison statistics are summarized in Ta-

ble 2. We can see in this table that the ratios (%) of the totals of basic grammatical types over the totals of all annotated inarticulations, are significantly different for the three corpora, which correspond to 70.0%, 54.7%, and 58.1% for KJ, NUCLE, and SWA. The differences probably reflect the actual proficiency levels of the writers. Texts in KJ and NUCLE are written by college students, but they are not the same. This can be explained by the fact that NUCLE’s college students are studying in Singapore, where English is used as an official language, while KJ’s students are living in Japan, where English is not usually heard in daily life. The SWA’s writers are also not living in an English-speaking environment, but they made fewer basic grammatical errors than KJ’s students, which is reasonable because they have a higher proficiency level.

We normalized the count of each error type by using  $\alpha$  and  $\beta$  listed in Table 2 to directly compare the three corpora in more detail. The normalized counts are in parentheses, next to the actual counts. To our surprise, the SWA’s writers, who were scientific writers, make numerous determiner errors: 1,176 errors, compared to 726 (KJ) and 641 (NUCLE). KJ’s students made fewer errors of this type than SWA’s writers. This is possibly due to the difference in the complexity of the sentence structures used by the three groups of writers. KJ’s students wrote very short sentences, while advanced learners tended to write those that were longer and more complex. Additional analyses of the sentence lengths and structures would clarify this further.

## 6 Analysis for paraphrase alignments

We carried out an analysis of the annotated Paraphrase alignments for understanding the challenges and possible solutions for research toward automatic proofreading (Table 4). For this anal-

Type	Examples of annotation	Count	%
1.Short-form ↔ Long-form	<i>PCA</i> → <i>principle component analysis</i>	2	0.6
2. Verb ↔ Prepositional phrase	<i>to collect</i> → <i>of collecting</i>	13	3.6
3.Relative clause ↔ Participle	<i>needed</i> → <i>that need</i>	5	1.4
4.Active ↔ Passive	<i>has not ... studied</i> → <i>has not ... been ... studied</i>	13	3.6
5.Anaphoric pronoun ↔ Referent	<i>this</i> → <i>the result</i>	22	6.1
6.Selection	<i>have</i> → <i>provide</i> <i>on the contrary</i> → <i>on the other hand</i> <i>frontal</i> → <i>the front of</i>	131	36.4
7.Mis-use/ Ad- dition	<i>good point</i> → <i>advantage</i>	55	15.3
8.Unknown/ Simplification	<i>It is better if ... are used</i> → <i>Using ... is better</i>	32	8.9
9.Complex		87	24.2
TOTAL		360	100.0

Table 4: Subtypes of Paraphrase alignments representing different confusing patterns of writers.

ysis, we randomly picked 20 Paraphrase alignments from each annotated document, and manually categorized them into nine subtypes that approximately represented different confusing patterns of writers.

The first five subtypes in the table are rather well-defined types. They were used for such transformations as between short- and long-form of acronyms, or relative clauses and their reduced forms, and so on. These well-defined paraphrases occupy 20.8 percent of all the total samples. The transformation between active and passive forms, and between anaphoric pronouns and their concrete forms could be challenging, because it requires correct interpretation of the event or entity being mentioned. For not-well-defined paraphrases, we classified them based on the number and the part-of-speech of the inclusive words.

The Selection subtype is for the replacement of a word with another word of the same part-of-speech, or an idiom with another idiom. There were several causes of this type of inarticulation. One cause was that the writers used less-formal or ambiguous words, which were inappropriate for scientific writing style. Another cause was that they selected a word which did not precisely describe the intended meaning, due to the interference by the writer’s background-language or other reasons. The latter reason would be more challenging for automatic proofreading applications.

Selection-typed paraphrasing is very important for writing assistance, not only because of its frequency but also it is a representative example of the increasing fluency of texts.

The Mis-use/Addition subtype is applied when a word in the original text is replaced with a sequence of several words in the proofread text. This often happens when the original words do not provide enough details, or mis-describe what the writers mean. Unknown/Simplification is the reverse subtype of Mis-use/Addition. This subtype indicated that non-native writers sometimes used long descriptions instead of compact words, such as *good point* instead of *advantage*. These two subtypes reveal the demand for techniques to simplify, or to provide more information to the text.

The Complex subtype is for many-to-many alignments. While the changes made by the other subtypes above are rather local, this subtype often required global changes at high levels of a sentence structure, such as those in the example *it is better if ... are used* → *using ... is better*. Previous studies on text revision have suggested that such changes are necessary for the coherence of a bigger discourse such as a paragraph or whole document (Williams and Colomb, 2010). How to make use of discourse information in automatic proofreading is an interesting issue of NLP studies using our corpus.

## 7 Conclusion

We described the SWA corpus, which was constructed to support studies on assistance techniques for professional writing. The traditional problem of error annotation was reformulated as a paraphrase annotation of pairs of the original and proofread sentences. This view inspired us to extend the alignment-based annotation scheme to be used for our annotation process. The comparison with two existing popular corpora revealed that grammatical errors made by different types of writers varied a great deal. The advanced writers tended to make more inarticulations that require paraphrasing.

The SWA corpus can be used as benchmark data for different tasks including grammatical error correction, paraphrase extraction, and automatic alignment, in context of proofreading. Further research should be carried out for paraphrasing techniques. The corpus is made available for research community on request basis.

## Abstract

The metalinguistic facilities of natural language are crucial to our ability to communicate, but the patterns behind the appearance of metalanguage—and thus the clues for how we may instruct computers to detect it—have remained relatively unknown. This paper describes the first results on the feasibility of automatically identifying metalanguage in English text. A core metalinguistic vocabulary has been identified, supporting intuitions about the phenomenon and aiding in its detection and delineation. These results open the door to applications that can extract the direct, salient information that metalanguage encodes.

## 1 Introduction

In linguistic communication it is sometimes necessary to refer to features of language, such as orthography, vocabulary, structure, pragmatics, or meaning. *Metalanguage* enables a speaker to select a linguistically-relevant referent over (or in addition to) other typical referents (Audi, 1995). Metalanguage is illustrated in sentences such as

- (1) *Graupel* refers to a kind of precipitation.
- (2) The name is actually *Rolla*.
- (3) *Keep tabs on* is a colloquial phrase.
- (4) He wrote “**All gone**” and nothing more.

The roles of the bold substrings in the above sentences contrast with those in (5)-(8) below:

- (5) **Graupel** fell on the weary hikers.
- (6) **Rolla** is a small town.
- (7) **Keep tabs on** him, will you?
- (8) They were **all gone** when I returned.

Conventional stylistic cues, such as italics in (1), (2), and (3) and quotation marks in (4), sometimes help the audience to recognize metalinguistic statements in written language. In spoken language or in written contexts where stylistic cues are not used, the audience is expected to identify metalinguistic statements using paralinguistic cues (such as intonation, when speaking) or context and meaning.

Metalanguage is both pervasive and, paradoxically, the subject of limited attention in research on language technologies. The ability to produce and understand metalanguage is a core linguistic competence that allows humans to converse flexibly, unrestricted by domain (Anderson et al., 2002). Humans use it to establish grounding, verify audience understanding, and maintain communication channels (Anderson et al., 2004). Metalanguage encodes direct and salient information about language, but many typical examples thwart parsers with novel word usage or arrangement (Wilson, 2011a). Metalanguage is difficult to classify through the interpretive lens of word senses, given that conventional word senses have little relevance when a word appears chiefly “as a word”. The roles of metalanguage in L2 language acquisition (Hu, 2010), expression of sentiment toward others’ utterances (Jaworski et al., 2004), and irony (Sperber and Wilson, 1981) have also been noted.

This paper describes the results of the first effort to automatically identify instances of metalanguage in English text. *Mentioned language*, a common variety of metalanguage, is focused upon for its explicit, direct nature, which makes its structure and meaning easily accessible once an instance is identified. Section 2 reviews a prior project by Wilson (2012) to create a corpus of instances of metalanguage, a necessary resource for the present effort. Section 3 describes an approach to distinguishing sentences that contain

---

\* This research was performed during a prior affiliation with the University of Maryland at College Park.

metalanguage from those that do not, a task referred to as *detection* for brevity. Results show that the performance of this approach roughly matches an implied performance ceiling of inter-annotator agreement. Section 4 describes an approach to *delineate* sequences of words that are directly mentioned by a metalinguistic statement; although the results are preliminary, its accuracy shows promise for future development. Together, these results on detection and delineation show the feasibility of enabling language technologies to extract the salient information about language that metalanguage contains.

## 2 Background

The reader is likely to be familiar with the concept of metalanguage, but a discussion is appropriate to ground the concept and connect to previous work. Section 2.1 summarizes a prior study (Wilson, 2012) to collect instances of metalanguage, and 2.2 reviews some related efforts.

### 2.1 Prior Work

A diverse variety of phenomena in natural language satisfy the intuitive criteria that we associate with metalanguage. The prior study focused on identifying sentences that contained *mentioned language*, a phenomenon defined below:

*Definition: For T a token or a set of tokens in a sentence, if T is produced to draw attention to a property of the token T or the type of T, then T is an instance of mentioned language.*<sup>1</sup>

Here, a *token* is an instantiation of a linguistic entity (e.g., a letter, symbol, sound, word, phrase, or other related entity), and a *property* is an ostension of language (García-Carpintero, 2004; Saka, 2006), such as spelling, pronunciation, meaning (for a variety of interpretations of *meaning*), structure, connotation, or quotative source. Generally attention is drawn to the *type* of T (for example, in Sentences (1)-(4)), but it can be drawn to the *token* of T for self-reference, as in Sentence (9):

(9) “The” appears between quote marks.

Although constructions like (9) are unusual and carry less practical value, the definition accommodates them for completeness.

Mentioned language is a common form of metalanguage, used to perform the full variety of

language tasks discussed in the introduction. However, other metalinguistic constructions draw attention to tokens *outside of* the referring sentence. Some examples of this are (10)-(12) below. Supporting contexts are not shown for these sentences, though such contexts are easily imagined:

- (10) Disregard the last thing I said.
- (11) That spelling, is it correct?
- (12) People don’t use those words lightly.

In each of the above three sentences, a linguistic entity (an utterance, a sequence of letters, and a sequence of words, respectively) is referred to, but the referent is contained in a separate sentence. The referent may have been produced by a different utterer or appeared in a different medium (e.g., speaking aloud while referring to written text). These “extra-sentential” forms of metalanguage have clear value to understanding discourse and coreference. The focus on mentioned language is a limitation to the present work, to utilize an existing corpus and to apply tractable boundaries to the identification tasks.

The mentioned language corpus of the prior study<sup>2</sup> was constructed by filtering a large volume of sentences with a heuristic, followed by annotation by a human reader. A randomly selected subset of articles from English Wikipedia was chosen as a source for text because of its representation of a large sample of English writers (Adler et al., 2008), the rich frequency of mentioned language in its text, and the frequent use of stylistic cues in its text that delimit mentioned language (i.e., bold text, italic text, and quotation marks). Sentences were sought that contained at least one of these stylistic cues and a *mention-significant* word in close proximity. Mention-significant words were a set of 8,735 words and collocations with potential metalinguistic significance (e.g., *word*, *symbol*, *call*), extracted from the WordNet lexical ontology (Fellbaum, 1998). Phrases highlighted by the stylistic cues were considered *candidate instances*, and these were labeled by a human reader, who determined that 629 sentences were *mention sentences* (i.e., containing instances of mentioned language) and the remaining 1,764 were not. Mention sentences were categorized based on functional properties that emerged during categorization. Table 1 shows some examples of collected mention sentences in each category.

<sup>1</sup> This definition was introduced by Wilson (2011a) along with a practical rubric for evaluating candidate sentences. For brevity, its full justification is not reproduced here.

<sup>2</sup> The corpus is available at [http://www.cs.cmu.edu/~shomir/um\\_corpus.html](http://www.cs.cmu.edu/~shomir/um_corpus.html).

Category	Examples
Words as Words	The IP Multimedia Subsystem architecture uses the term <b>transport plane</b> to describe a function roughly equivalent to the routing control plane. The material was a heavy canvas known as <b>duck</b> , and the brothers began making work pants and shirts out of the strong material.
Names as Names	<b>Digeri</b> is the name of a Thracian tribe mentioned by Pliny the Elder, in The Natural History. Hazrat Syed Jalaluddin Bukhari's descendants are also called <b>Naqvi al-Bukhari</b> .
Spelling or Pronunciation	The French changed the spelling to <b>bataillon</b> , whereupon it directly entered into German. Welles insisted on pronouncing the word apostles with a hard <b>t</b> .
Other Mentioned Language	He kneels over Fil, and seeing that his eyes are open whispers: <b>brother</b> . During Christmas 1941, she typed <b>The end</b> on the last page of Laura.

Table 1: Examples of mentioned language from the corpus. Instances of the phenomenon appear in bold, with the original stylistic cues removed.

To verify the reliability of the corpus and the definition of mentioned language, three additional expert annotators independently labeled a shuffled set of 100 sentences, consisting of 54 randomly selected mention sentences and 46 randomly selected non-mention sentences. All three agreed with the primary annotator on 46 mention sentences and 30 non-mention sentences, with an average pairwise Kappa of 0.74. Kappa between the primary annotator and a hypothetical “majority voter” of the additional annotators was 0.90. These results were seen as a moderate indication of reliability and a potential performance ceiling for automatic identification.

## 2.2 Related Work

The present effort is believed to be the first to automatically identify a natural variety of metalanguage in English text. Aside from the corpus described above, the only other significant corpus of metalanguage was created by Anderson et al. (2004), who collected metalinguistic utteranc-

es in conversational English. A lack of phrase-level annotations in their corpus as well as substantial noise made it suboptimal for the present effort. However, it is possible (if not likely) that indicators of metalanguage differ between written and spoken English, lending importance to the Anderson corpus as a resource.

Metalanguage has a long history of theoretical treatments, which chiefly explained the mechanics of selected examples of the phenomenon. Many addressed it through the related topic of *quotation* (Cappelen and Lepore, 1997; Davidson, 1979; Maier, 2007; Quine, 1940; Tarski, 1933), and others previously cited in this paper discussed it directly as *metalanguage* or the *use-mention distinction*. The definition of mentioned language in Section 2.1 was a synthesis of the most empirically-compatible theoretical treatments, and the present effort to automatically identify metalanguage builds on that synthesis.

## 3 Detection of Mentioned Language

The corpus-building effort used a heuristic to accelerate the collection of mentioned language, but its low precision is impractical for automatic identification. Moreover, the stylistic cues that the heuristic relied upon are often inconsistently applied (or entirely absent in informal contexts), and they are sometimes unavailable for the writer to use or for the audience to extract. This section presents an approach to the *detection* task, to discriminate between mention and non-mention sentences. Early examination of the corpus suggested that mention sentences tend not to have distinct structural differences from non-mention sentences, so a lexical approach was first taken, although combinations of lexical and structural approaches are later explored indirectly through the delineation task. In this section a sentence is assumed to be a sequence of words without stylistic cues for mentioned language.

### 3.1 Approach

To establish performance baselines, a matrix of feature sets and classifiers was run on the corpus with ten-fold cross validation. The feature sets were bags of the following: stemmed words (SW), unstemmed words (UW), stemmed words plus stemmed bigrams (SWSB), and unstemmed words plus unstemmed bigrams (UWUB). Classifiers were chosen to reflect a variety of approaches to supervised learning; as implemented in Weka (Hall et al., 2009), these were Naive Bayes (John and Langley, 1995), SMO (Keerthi

Figure 1. Cumulative coverage over sentences by the most common words before (top) and after (bottom) instances of mentioned language.

et al., 2001), J48 (Quinlan, 1993), IBk (Aha and Kibler, 1991), and Decision Table (Kohavi, 1995).

Prior observations suggested that a small set of approximately ten words significant to metalanguage (“metawords”, informally) appear near most instances of mentioned language (Wilson, 2011b). The metalanguage corpus described in Section 2 provided an opportunity to explore this observation. The sentences in the corpus were part-of-speech tagged and stemmed (using NLTK (Bird, 2006)). Sets were collected of all unique (stemmed) words in the three-word phrases directly preceding and following candidate instances, and (respective of position) these were ranked by frequency. The appearance or non-appearance of these words was then determined over all mention and non-mention sentences. Figure 1 shows the cumulative coverage (i.e., appearance at least once) over sentences for the top ten words appearing before and after candidate instances. For example, *call*, *word*, or *term* were the three most common words before candidate instances; they appear at least once in 36% of mention sentences, but they appear in only 1.6% of non-mention sentences.

The high frequencies of intuitive metawords, combined with their difference in coverage over

mention and non-mention sentences, informed the approach taken to the detection task. To attempt to improve over the baseline, the SW feature set was ranked by information gain, and all features except the top ten were discarded to create the metawords feature set (MW). Feature selection was done using the training set for each cross-validation fold, and the testing data for each fold was pruned correspondingly. The five selected classifiers were then applied to the data.

### 3.2 Results and Discussion

The combination of five feature sets and five classifiers produced 25 sets of annotations, for which precision, recall and F1 were calculated for detecting mentioned language. For brevity, we present the highlights and contrast the metawords approach with baseline performances.

Table 2 compares classifier performances using MW with SW, its closest relation. MW produced improvement for all classifiers except Naive Bayes<sup>3</sup>. The J48-MW combination had the highest F1 and recall of any feature set-classifier combination, though some combinations exceeded its precision. For all feature set-classifier pairs, precision was higher than recall, by as little as 0.024 (IBK-MW) and as much as 0.22 (Decision Table-UW). For the baseline feature sets, the best classifier was consistently SMO, with F1 scores of 0.70, 0.70, 0.73, and 0.71 for SW, UW, SWSB, and UWUB, respectively. J48 was consistently the second best, with F1 scores within 0.01 of SMO for each feature set.

Table 3 lists differences between F1 scores using the MW feature set and each baseline feature set. MW resulted in improvements over the baseline feature sets for nearly all classifiers, and statistically significant improvements (using one-tailed T-tests across the populations of validation folds,  $p < 0.05$ ) were observed for eleven of the sixteen combinations. IBk appeared to benefit the most, with significant improvements over all baseline feature sets, and Naive Bayes the least. In general, recall benefited more than precision.

Examining the MW features confirmed that most were intuitive metawords. Nine words appeared in all ten folds of MW: *name*, *word*, *call*, *term*, *mean*, *refer*, *use*, *derive*, and *Latin*. The last two words are perhaps artifacts of the encyclopedic nature of the source text, but the rest generalize easily. Future research using additional

<sup>3</sup> It seems likely that the method used to create the MW feature set aggravated the Naive Bayes assumption of feature independence.

Classifier	Precision	Recall	F1
Naive Bayes	.76 / <b>.75</b>	.63 / <b>.60</b>	.69 / <b>.66</b>
SMO	.74 / <b>.75</b>	.67 / <b>.70</b>	.70 / <b>.73</b>
IBk	.69 / <b>.74</b>	.64 / <b>.72</b>	.66 / <b>.73</b>
Decision Table	.76 / <b>.74</b>	.61 / <b>.68</b>	.67 / <b>.71</b>
J48	.72 / <b>.75</b>	.69 / <b>.73</b>	.70 / <b>.74</b>

Table 2. The performances of classifiers using the SW and MW (in bold) feature sets.

Classifier	SW	UW	SWSB	UWUB
Naive Bayes	-.024	-.018	.005	.007
SMO	<b>.023*</b>	<b>.026*</b>	.000	.015
IBk	<b>.067*</b>	<b>.088*</b>	<b>.07*</b>	<b>.108*</b>
Decision Table	<b>.038*</b>	<b>.047*</b>	.027	<b>.052*</b>
J48	<b>.037*</b>	<b>.046*</b>	.025	.034

Table 3. Differences between F1 scores from using the MW feature set and baseline feature sets. Statistically significant improvements are starred.

text sources will be necessary to fully verify whether the MW approach and these specific metalinguistic terms are widely applicable.

It also appears that 20% to 30% of instances of mentioned language resist identification using word and bigram-based features alone. Many of the false negatives from this experiment appeared to lack the common metawords that the detection approach relied upon. The sentences below (taken from the corpus) illustrate this lack:

(13) Other common insulting modifiers include “dog”, “filthy”, etc.

(14) To note, in the original version the lyrics read “Jim crack corn”.

While *modifier* in (13) and *read* in (14) have intuitive metalinguistic value, they also have common non-metalinguistic senses. This suggests that an approach incorporating word senses may further improve upon the MW performances, and such an approach is preliminarily explored in the following section.

Finally, it is notable that the best MW performances approach the Kappa score observed between the additional annotators. Although this is an indication of some success, the higher “majority vote” Kappa score of 0.90 remains a meaningful goal for future research efforts.

#### 4 Toward Delineation

After identifying a mention sentence, the task remains to determine the specific sequence of

words subject to direct reference (e.g., the bold words in Sentences (1) through (4) and in other examples throughout this paper). This task, in addition to detection, is necessary to ascribe the information encoded in a metalinguistic statement to a specific linguistic entity.

#### 4.1 Approach

Manual examination of the corpus showed two frequent relationship patterns between metawords and mentioned language. The first was *noun apposition*, in constructions like (15) and (16), where the metaword-noun appears in italics and the mentioned word in bold:

(15) The *term* **auntie** was used depreciatively.

(16) It comes from the root *word* **conficere**.

The second pattern was the appearance of mentioned language in the *semantic role of a meta-word-verb*, as in (17) below:

(17) We sometimes *call* it **the alpha profile**.

Notably these patterns do not guarantee the correct delineation of mentioned language, but their applicability made them suitable for the task.

To assess the applicability of phrase structures and semantic roles to the automatic delineation of mentioned language, case studies were performed on the sets of sentences in the corpus containing the nouns *term* and *word* and the verb *call*. All sentences containing these three metawords (appearing as their respective targeted parts of speech) were examined, including those that did not contain mentioned language, since it was believed that methods of delineation could indirectly perform detection as well. Because of the limited data available, formal experiments were not possible, although the results still have illustrative value.

The noun apposition pattern described above was formalized for *term* and *word* using TRegex search strings (Levy and Andrew, 2006). The 91 sentences in the corpus containing *term* and the 107 containing *word* were parsed using the Stanford Parser (Marneffe et al., 2006), and the TRegex strings were applied to each sentence; when a match occurred, the result was a prediction that a specific sequence of words was mentioned language (delineation), as well as a prediction that the sentence contained mentioned language (detection). The semantic role pattern for *call* was explored similarly using the Illinois Semantic Role Labeler (SRL) (Punyakanok et al., 2008). Each of the 158 sentences in the corpus containing *call* as a verb was processed by

SRL, and when the output contained the appropriate semantic role (i.e., SRL’s “attribute of arg1”) with respect to the metaword, the phrase fulfilling that role was considered a predicted delineation of mentioned language. By proxy, such matching also implied a prediction that the phenomenon was present in the sentence.

## 4.2 Results and Discussion

Delineation was evaluated with respect to the correctness of *label scope*: that is, for a sentence that contained an instance of mentioned language, whether the predicted word sequence exactly matched the sequence labeled in the corpus, overlabeled it (i.e., included the instance of mentioned language plus additional words), or underlabeled it (i.e., did not include the entire instance). To avoid confounding detection and delineation, the statistics on label scope do not include instances when the appropriate pattern failed to annotate *any* phrase in a sentence that contained mentioned language, or annotated a phrase when no mentioned language was present. Such instances are instead represented through *pattern applicability* statistics: when one of the sought relationships between a chosen metaword and a phrase appeared in a sentence, it was considered a positive prediction of the presence of mentioned language. Table 4 shows performance metrics from each of the three case studies.

Noun apposition with either *term* or *word* appeared to be adept at predicting scope, with perfect labels for 97% and 89% of instances, respectively. The instances of overlabeling and underlabeling for these two were mostly due to parsing errors, which occurred prior to applying the TRegex pattern. Overlabeling was a greater problem for *call*, for which 80% of labels were perfect and nearly the rest were overlabeled. Manual examination revealed that the prediction often would “spill” far past the actual end of mentioned language, due to the boundaries of the semantic role in SRL’s output. For example, the entire phrase in bold in (18) below was erroneously predicted to be mentioned language, instead of simply *snow-eaters*:

(18) Winds of this type are called ***snow-eaters*** for their ability to make snow melt or sublime rapidly.

Re-examining the detection task through pattern applicability, noun appositions with *term* and *word* exhibited perfect precision. The false negatives that lowered the recall were again mostly due to parse errors. Precision and recall

Metaword	Label Scope		
	Overlabeled	Underlabeled	Exact
<i>term</i> (n)	0	2	57
<i>word</i> (n)	3	4	57
<i>call</i> (v)	16	1	68

Metaword	Pattern Applicability		
	Precision	Recall	F1
<i>term</i> (n)	1.0	0.89	0.90
<i>word</i> (n)	1.0	0.94	0.97
<i>call</i> (v)	0.87	0.76	0.81

Table 4: Performance statistics for delineation (in the form of label scope) and detection (pattern applicability) for the case studies.

for *call* suffered from two sources of errors: incorrect applications of the semantic role and applications of it that, while valid, did not involve mentioned language.

For the selected metawords, it appeared patterns in noun apposition and semantic roles were moderately effective at delineating as well as detecting mentioned language. However, the accuracy of these patterns was a reflection of the dependability of the underlying language tools, and the case studies in aggregate covered only 33% of the sentences containing mentioned language in the corpus. To create a comprehensive method for delineation, more relationships must be identified between metawords and mentioned language. A perusal of the corpus suggests that these patterns are small in variety but large in quantity: metawords are diverse, and some have non-metalinguistic senses that must be accounted for, as shown by Sentences (13) and (14) and others that resisted detection.

## 5 Conclusion

The detection and delineation methods presented in this paper demonstrate the feasibility of identifying metalanguage in English text. The next goals of this project will be to assimilate metalanguage from additional text sources and integrate the detection and delineation tasks. This will improve performance and provide a richer structural knowledge of metalanguage, which will enable practical systems to incorporate processing of the phenomenon and exploit the linguistic information that it encodes.

## Abstract

This paper is concerned with the problem of automatic essay grading, where the task is to grade student written essays given course materials and a set of human-graded essays as training data. Latent Semantic Analysis (LSA) has been used extensively over the years to accomplish this task. However, the major limitation of LSA is that it only retains the frequency of words by disregarding the word sequence, and the syntactic and semantic structure of texts. As a remedy, we propose the use of syntactic and shallow semantic tree kernels for grading essays. Experiments suggest that syntactic and semantic structural information can significantly improve the performance of the state-of-the-art LSA-based models for automatic essay grading.

## 1 Introduction and Related Work

To evaluate the content of free texts is a challenging task for humans. Automation of this process is useful when an expert evaluator is unavailable in today's Internet-based learning environment. Research to automate the assessment of free texts, such as grading student-written essays, has been carried out over the years (Kakkonen et al., 2006; Kakkonen and Sutinen, 2004; Kanejiya et al., 2003; Persing et al., 2010; Yannakoudakis et al., 2011). Some notable essay scoring systems currently available are *AutoScore* by American Institutes for Research (AIR), *Bookette* by CTB/McGraw-Hill, *Project Essay Grade* by Measurement, Inc. and *Intelligent Essay Assessor* by Pearson Knowledge Technologies. The approaches such as Project Essay Grade and e-rater were solely based on some simple surface features that took essay-length, number of commas etc. into consideration (Page and Petersen,

1995; Powers et al., 2000). The major drawback of these systems is that they ignore the creativity factor by only dealing with the simple measures. To overcome this limitation, recent researches tend to focus on understanding the inner meaning of the texts. Latent Semantic Analysis (LSA) (Landauer et al., 1998; Deerwester et al., 1990) has been shown to fit well in addressing this task (Kakkonen et al., 2006; Kakkonen and Sutinen, 2004; Lintean et al., 2010; Kanejiya et al., 2003).

LSA uses a sophisticated approach to decode the inherent relationships between a context (typically a sentence, a paragraph or a document) and the words that they contain. This approach is based on Bag-Of-Words (BOW) assumption that uses the frequency of occurrence of each word in the context to construct a word-by-context co-occurrence matrix (Kanejiya et al., 2003). The major limitation of LSA is that it only retains the frequency of the words and does not take into account the sequence of them (word ordering). It ignores the syntactic and semantic structure of the context and thus, cannot distinguish between "The police shot the gunman" and "The gunman shot the police". Traditionally, information extraction techniques are based on the BOW approach augmented by language modeling. But when the task like *automated essay grading* requires the evaluation of more complex syntactic and semantic structures, the approaches based on only BOW are often inadequate to perform fine-level textual analysis. For example, in the basic LSA model for automated essay grading, a student essay can obtain a good grade by having a very small number of highly representative words that correlates the golden essays. This also means that the repetition of important terms without having any syntactic/semantic appropriateness can lead to an overstated grade (Jorge-Botana et al., 2010).

Several improvements on BOW have been shown by the use of dependency trees and syntac-

tic parse trees over the years (Hirao et al., 2004; Punyakanok et al., 2004; Kim and Kim, 2010). Kakkonen et al. (2006) used an enhanced LSA approach by incorporating parts-of-speech (POS) information to improve the performance of the basic LSA model for automatic essay grading. The augmentation of POS information into the basic LSA model enabled it to exploit a sufficient amount of local information about internal relations among the words. In this manner, the enhanced LSA model could disambiguate the meaning between the words having the same base forms but different POS tags. Kanejiya et al. (2003) proposed a similar model called *Syntactically Enhanced LSA* by considering a word along with its syntactic neighborhood (obtained from the part-of-speech tag of its preceding word). Wiemer-Hastings and Zipitria (2001) showed that a sentence comparison metric that combines structure-derived information with vector-based semantics has a better correlation to human judgements than the LSA model alone. This motivates us to propose the use of syntactic and semantic structural information (by means of syntactic and shallow semantic tree kernels) with a LSA-based model to automatically grade essays. The effectiveness of using various text-to-text semantic similarity measures, and dependency graph alignment techniques have been also shown to improve upon the BOW approaches for a similar task of short answer grading (Mohler et al., 2011; Mohler and Mihalcea, 2009).

The importance of syntactic and semantic features in finding textual similarity is described by Moschitti et al. (2007), and Moschitti and Basili (2006). An effective way to integrate syntactic and semantic structures in different applications is the use of *tree kernel* functions (Collins and Duffy, 2001), which has been successfully applied to other Natural Language Processing (NLP) tasks such as question classification (Moschitti and Basili, 2006). In this paper, we use the tree kernel functions and to the best of our knowledge, no other study has used tree kernel functions before to encode syntactic/semantic information for more complex tasks such as computing the relatedness between the contexts for automatic essay grading. Our experiments on an occupational therapy dataset show that the addition of syntactic and semantic information can improve the performance of the BOW-based and POS enhanced state-of-the-art LSA models significantly.

## 2 LSA Model for Essay Grading

LSA can determine the similarity of the meaning of words and the context based on word co-occurrence information (Kakkonen et al., 2006). Our grading model is most closely related to the approach described in Kakkonen and Sutinen (2004) where the experiments were conducted in the Finnish language. However, in this work, we experiment with the essays and course materials written in the English language. The main idea is based on the assumption that a student's knowledge is largely dependent on learning the course content; therefore, the student's knowledge can be computed as the degree of semantic similarity between the essay and the given course materials. An essay will get a higher grade if it closely matches with the course content.

The grading process includes three major steps. In the first step, we build a semantic space from the given course materials by constructing a word-by-context matrix (WCM). Here we use different local and global weighting functions to build several LSA models (for baseline selection). In the next step, a set of pre-scored (human-graded) essays are transformed into a query-vector form similar to each vector in the WCM and then their similarity with the semantic space is computed in order to define the threshold values for each grade category. The similarity score for each essay is calculated by using the traditional cosine similarity measure. In the last step, the student-written to-be-graded essays are transformed into the query-vector forms and compared to the semantic space in a similar way. The threshold values for the grade categories are examined to specify which essay belongs to which grade category.

As discussed previously, the basic LSA model for automatic essay grading lacks sensitivity to the context in which the words appear since it is solely based on the BOW assumption. It ignores the internal structure of the sentences and does not consider word orders. Our aim in this paper is to propose a similarity measure in which syntactic and/or semantic information can be added to enhance the basic LSA model by encoding the relational information between the words in sentences. We claim that for a complex task like evaluating student-written essays, where the relatedness between the sentences of an essay and the given course materials is an important factor, our grading model would perform more effectively if

we could incorporate the syntactic and semantic information with the standard cosine measure (i.e. done in basic LSA) while calculating the similarity between sentences. In the next sections, we describe how we can encode syntactic and semantic structures in calculating the similarity between sentences.

### 3 Syntactic Similarity Measure (SYN)

Inspired by the potential significance of using syntactic measures for finding similar texts, we get a strong motivation to use it as a similarity measure in essay grading framework. The first step to calculate the syntactic similarity between two sentences is to parse the corresponding sentences into syntactic trees using the Charniak parser (Charniak, 1999). Once we build the syntactic trees, our next task is to measure the similarity between the trees. For this, every tree  $T$  is represented by an  $m$  dimensional vector  $v(T) = (v_1(T), v_2(T), \dots, v_m(T))$ , where the  $i$ -th element  $v_i(T)$  is the number of occurrences of the  $i$ -th tree fragment in tree  $T$  (Moschitti et al., 2007). The tree kernel of two trees  $T_1$  and  $T_2$  is actually the inner product of  $v(T_1)$  and  $v(T_2)$  (Collins and Duffy, 2001), which computes the number of common subtrees between two trees to provide the similarity score between a pair of sentences. Each course material sentence contributes a score to the essay sentences. The average syntactic similarity scores of the essay sentences are combined to get an overall similarity score for an essay with respect to the course material sentences.

### 4 Semantic Similarity Measure (SEM)

Shallow semantic representations can prevent the weakness of cosine similarity based models (Moschitti et al., 2007). Since the textual similarity between a pair of sentences relies on a deep understanding of the semantics of both, applying semantic similarity measurement in our essay grading framework is another noticeable contribution of this paper. To calculate the semantic similarity between two sentences, we first parse the corresponding sentences semantically using the Semantic Role Labeling (SRL) system, ASSERT<sup>1</sup>. We represent the annotated sentences using tree structures called semantic trees (ST). In the tree kernel method (Section 3), common substructures cannot

<sup>1</sup>Available at <http://cemantix.org/assert>

be composed of a node with only some of its children. Moschitti et al. (2007) solved this problem by designing the Shallow Semantic Tree Kernel (SSTK) which allows to match portions of a ST. The SSTK function yields the similarity score between a pair of sentences based on their semantic structures. An overall semantic similarity score for each essay is obtained similarly as the syntactic measure.

## 5 Experiments and Evaluation

### 5.1 Data

We use a dataset obtained from an occupational therapy course where 3 journal articles are provided as the course materials. The students are asked to answer an essay-type question. The dataset contains 91 student-written essays, which are graded by a professor<sup>2</sup>. The length of the essays varied from 180 to 775 characters. We use 3-fold cross-validation for our experiments.

### 5.2 System Settings

Initially, we split the course materials into 64 paragraphs and built the word-by-paragraph matrix by treating the paragraphs as contexts. Our preliminary experiments suggested that this scheme shows worse performance than that of using individual sentences as the contexts. So, we tokenized the course materials (journal articles) into 741 sentences and built the word-by-sentence matrix. We do not perform word stemming for our experiments. We use a stop word list of 429 words to remove any occurrence of them from the datasets. In this work, C++ and Perl are used as the programming languages to implement the LSA models and encode the syntactic and shallow semantic structures. The GNU Scientific Library (GSL<sup>3</sup>) software package is used to perform the SVD calculations in LSA. During the dimensionality reduction step of LSA, we have experimented with different dimensions of the semantic space. Finally, we kept 100 as the number of dimensions since we got better results using this value. We experiment with six variations of the LSA model based on different local and global weighting functions according to Chali and Hasan (2012). The best performing LSA model is used as the baseline for comparison purposes.

<sup>2</sup>Each essay is graded on a scale from 0 to 6.

<sup>3</sup><http://www.gnu.org/software/gsl/>

### 5.2.1 Variations of the LSA Model

Inspired by the work of Jorge-Botana et al. (2010), we experiment with different local and global weighting functions applied to the WCM. The main idea is to transform the raw frequency cell  $x_{ij}$  of the WCM into the product of a local term weight  $l_{ij}$ , and a global term weight  $g_j$ . Given the term/document frequency matrix (WCM), a weighting algorithm is applied to each entry that has three components to make up the new weighted value in the term/document matrix. This looks as:  $w_{ij} = l_{ij} * g_j * N_j$ , where  $w_{ij}$  is the weighted value for the  $i^{th}$  term in the  $j^{th}$  context,  $l_{ij}$  is the local weight for term  $i$  in the context  $j$ ,  $g_j$  is the global weight for the term  $i$  across all contexts in the collection, and  $N_j$  is the normalization factor for context  $j$ .

**Local Weighting:** We use two local weighting methods in this work: 1) *Logarithmic*:  $\log(1 + f_{ij})$ , and 2) *Term Frequency (TF)*:  $f_{ij}$ , where  $f_{ij}$  is the number of times (frequency) the term  $i$  appears in the context  $j$ .

**Global Weighting:** We experiment with three global weighting methods: 1) *Entropy*:  $1 + \left(\frac{\sum_j (p_{ij} \log(p_{ij}))}{\log(n)}\right)$ , 2) *Inverse Document Frequency (IDF)*:  $\log\left(\frac{n}{df_i}\right) + 1$ , and 3) *Global Frequency/Inverse Document Frequency (GF/IDF)*:  $\frac{\sum_j f_{ij}}{df_i}$ , where  $p_{ij} = \frac{f_{ij}}{\sum_j f_{ij}}$ ,  $n$  is the number of documents in our word by context matrix, and  $df_i$  is the number of contexts in which the term  $i$  is present.

**Different Models:** By combining the different local and global weighting schemes, we build the following six different LSA models: **1) LE:** logarithmic local weighting and entropy-based global weighting, **2) LI:** logarithmic local weighting and IDF-based global weighting, **3) LG:** logarithmic local weighting and GF/IDF-based global weighting, **4) TE:** TF-based local weighting and entropy-based global weighting, **5) TI:** TF-based local weighting and IDF-based global weighting, and **6) TG:** TF-based local weighting and GF/IDF-based global weighting.

### 5.2.2 Systems for Evaluation

To study the impact of syntactic and semantic representation introduced earlier (in Section 3 and Section 4) for the essay grading task, we build six systems as defined below:

**(1) Baseline:** Our baseline is the best performing

LSA model among the six variations (discussed in Section 5.2.1) that uses the standard cosine similarity measure based on BOW assumption and does not consider syntactic/semantic information.

**(2) SYN:** This system measures the similarity between the sentences using the *syntactic tree* and the *general tree kernel* function defined in Section 3.

**(3) SEM:** This system measures the similarity between the sentences using the *shallow semantic tree* and the *shallow semantic tree kernel* function defined in Section 4.

**(4) LSA+SYN:** This system measures the similarity between the sentences using both standard cosine similarity measure and the syntactic tree kernel.

**(5) LSA+SEM:** This system measures the similarity between the sentences using both standard cosine similarity measure and the shallow semantic tree kernel.

**(6) LSA+SYN+SEM:** This system measures the similarity between the sentences using standard cosine similarity measure, syntactic tree kernel, and shallow semantic tree kernel.

We use an equally weighted linear combination by summing the similarity scores obtained by **LSA**, **SYN** and **SEM** (when multiple similarity measures are used) as we believe that the word distribution, syntactic and semantic similarity between a pair of texts are all equally important. The average value of the similarity scores of the representative essays (with comparison to the course materials) of a certain grade category is considered as the threshold for that particular grade. For example, if we have five pre-scored essays of grade 6, we obtain five similarity scores corresponding to the course materials. The average of these scores are considered as the minimum score (threshold) that should be obtained by a non-graded student-written essay in order to assign it the grade 6. For a more robust evaluation, we also implement a state-of-the-art part-of-speech (POS) enhanced LSA model (**POS+LSA**) for essay grading according to Kakkonen et al. (2006) by considering the POS tag of the current word.

### 5.3 Evaluation Results

In Table 1, we present the results of our baseline selection step. The first column stands for the weighting model used ("N" denotes no weighting method applied). The "Correlation" column

presents the Spearman rank correlation between the scores given by the professor and the systems. The “Accuracy” column stands for the proportion of the cases where the professor and the system have assigned the same grade whereas the next column shows the percentage of essays where the system-assigned grade is at most one point away or exactly the same as the professor. From these results, we can see that the performance of the systems varied (having correlation from 0.32 to 0.68) with respect to the weighting scheme applied. We observe that the combination of the logarithmic local weighting with the entropy-based global weighting scheme performs the best for our dataset. Hence, we use this model as our baseline system.

In Table 2, we present the results of different systems. The columns denote the same meaning as Table 1. We can see that for the **SYN** system, the correlation is decreased by 7.93% from the baseline and 12.69% from the **POS+LSA** system. The **SEM** system improves the correlation over the baseline system by 2.94%, but decreases by 1.42% from the **POS+LSA** system. The **LSA+SYN** system improves the correlation over the baseline system by 7.35% and over the **POS+LSA** system by 2.81% whereas the **LSA+SEM** system improves the correlation by 11.76%, and 7.04% respectively. Lastly, the **LSA+SYN+SEM** system improves the correlation over the baseline system by 10.29% and over the **POS+LSA** system by 5.63%. Analysis of these results reveals that the proposed systems (that encode the syntactic and/or semantic information with the basic LSA model) considerably outperform both the standard cosine similarity based and the state-of-the-art POS enhanced LSA approaches. The results also denote that encoding the syntactic and/or semantic information on top of the standard cosine similarity measure often outperform the systems that consider only syntactic and/or semantic information.

**Statistical Significance:** We use Student’s t-test to compute whether the differences between the correlations of different systems are statistically significant. For this computation, we have one measurement variable, “correlation”, and one nominal variable, “system”. We had three runs and the observations were the set of correlations for each of the systems in consideration. We find that the differences between the correla-

tions are statistically significant at  $p < 0.05$  except for the differences between the **SEM** system and the **POS+LSA** system, and between the **LSA+SYN+SEM** system and the **LSA+SEM** system. We also compute the statistical significance of the correlations themselves. In Table 1, the reported correlations are statistically significant ( $p < 0.05$ ) except for “TE” and “N” models. The correlations reported in Table 2 are statistically significant ( $p < 0.05$ ).

Model	Corr.	Accuracy (%)	Close (%)
LE	0.68	40.2	73.1
LI	0.49	27.1	51.8
LG	0.40	21.3	42.2
TE	0.34	19.2	36.4
TI	0.52	32.6	58.6
TG	0.38	20.4	38.9
N	0.32	17.8	32.9

Table 1: Variations of LSA model

System	Corr.	Accuracy (%)	Close (%)
Baseline	0.68	40.2	73.1
POS+LSA	0.71	42.6	70.8
SYN	0.63	34.8	60.1
SEM	0.70	41.5	76.2
LSA+SYN	0.73	43.2	78.1
LSA+SEM	0.76	48.3	82.5
LSA+SYN+SEM	0.75	46.7	79.6

Table 2: Evaluation results

## 5.4 Discussion

### 5.4.1 Is Thresholding Adequate?

Our experiments showed that the formation of the thresholds were adequate as we could obtain different thresholds for different grade categories. However, in a few cases, the difference between two subsequent thresholds was found to be small. This might be because the grades were not evenly distributed among the given human-graded corpus. Ideally it is desirable to have the representative training essays across the spectrum of possible grades to set the thresholds on by using the SVD generated from the training materials. We also believe that the use of a larger dataset while defining the thresholds might improve the overall performance. Our further experiments (shown in the next subsection) support this claim. The length of the essays is another issue since longer essays tend to capture more information in their representative vectors which provides the scope for a better similarity matching with the semantic space.

### 5.4.2 Can We Automate Data Generation?

To experiment with an LSA-based model we require a number of student-written essays. It is often hard to collect a huge number of raw student-written essays and process them into the machine-readable format. To reduce the human intervention involved in producing a large amount of training data, we propose to automate this process by using the ROUGE (Lin, 2004) toolkit. We assume each individual sentence of the course material as the candidate extract sentence and calculate its ROUGE similarity scores with the corresponding golden essay. Thus an average ROUGE score is assigned to each sentence of the course content. We choose the top 50% sentences based on ROUGE scores to have the label +1 (candidate essay sentences) and the rest to have the label -1 (non-essay sentences), and thus, we generate essays up to a predefined word limit considering different levels of expertise of the students. The sentences having the label +1 are further sorted in descending order of their assigned scores. A collection of sentences (upto length 775 characters) having the highest scores are considered to have the grade 6, the next collection of sentences to grade 5 and so on. In this manner, we have generated 216 essays from the given course materials. We have used 20 golden essays in this experiment. We treated the essays that got the full score of 6 as the golden essays. The automatically generated essays appeared to be similar in content to that of the original student-written essays.

We run further experiments using the automatically generated dataset in order to make sure that the proposed methods are useful for the essay grading task. For this purpose, we build a corpus containing 147 essays (that include both human-written and automatic essays), where the grade categories are evenly distributed. We use 3-fold cross-validation for our experiments. In Table 3, we present the results of different systems. A relative comparison of these results with the results of Table 2 yields that there is a marginal improvement in the overall performance of all the systems except for the **LSA+SYN** system. This phenomenon suggests that the even distribution of the grade categories in a larger corpus of essays is useful in general to achieve better grading performance. The results also reveal the effectiveness of our proposed method for automatic training data generation. The differences between

the correlations are statistically significant at  $p < 0.05$  (using Student's t-test) except for the differences between the **LSA+SYN** system and the baseline, and between the **LSA+SYN+SEM** system and the **LSA+SEM** system. The reported correlations are also found to be statistically significant ( $p < 0.05$ ).

System	Corr.	Accuracy (%)	Close (%)
Baseline	0.71	42.6	75.4
POS+LSA	0.73	45.2	72.5
SYN	0.65	35.2	63.5
SEM	0.75	48.5	79.7
LSA+SYN	0.72	42.8	77.5
LSA+SEM	0.80	52.3	84.2
LSA+SYN+SEM	0.78	50.1	81.6

Table 3: Evaluation results (second corpus)

## 6 Conclusion and Future Work

We proposed to encode the syntactic and semantic information for measuring sentence relationships to automatically grade student-written essays and demonstrated that adding syntactic and/or semantic information on top of the standard cosine measure improves the performance over the BOW based and state-of-the-art POS enhanced LSA models. To the best of our knowledge, no other study has used syntactic and shallow semantic tree kernels for the task of automatic essay grading to improve the basic LSA model's performance. Our approach to automate the data generation process is also unique and novel in this problem domain. Experimental results revealed the effectiveness of the proposed approach. Our experiments also suggested that the overall syntactic/semantic similarity between a pair of texts can be effectively captured using the aggregated tree kernel scores of all possible sentence pairs. In the future, we plan to focus on other important metrics in terms of creativity, novelty, etc. for the essay grading task which we believe would further enhance the overall grading performance given that the major limitation of the basic LSA model is overcome.

### Acknowledgments

The research reported in this paper was supported by the Mitacs-Accelerate internship program, the Natural Sciences and Engineering Research Council (NSERC) of Canada – discovery grant and the University of Lethbridge. The authors are grateful to Colin Layfield and Laurence Meadows for their assistance.

# Little by Little: Semi Supervised Stemming through Stem Set Minimization

Vasudevan N, Pushpak Bhattacharyya

Dept. of Computer Science and Engg.

IIT Bombay, Mumbai

{vasudevan,pb}@cse.iitb.ac.in

## Abstract

In this paper we take an important step towards completely unsupervised stemming by giving a scheme for semi supervised stemming. The input to the system is a list of word forms and suffixes. The motivation of the work comes from the need to create a root or stem identifier for a language that has electronic corpora and some elementary linguistic work in the form of, say, suffix list. The scope of our work is suffix based morphology, (*i.e.*, no prefix or infix morphology). We give two greedy algorithms for stemming. We have performed extensive experimentation with four languages: English, Hindi, Malayalam and Marathi. Accuracy figures ranges from 80% to 88% are reported for all languages.

## 1 Introduction

Stemming is critical for many NLP, IR and IE problems (Hull, 1996). In the current paper, we report construction of a semi supervised stemmer that does stemming by *minimizing the total number of distinct stems*. The input to the system is the word list along with the legal suffix list of the language. Even if a language does not have an elaborate linguistic tradition and exhaustive body of linguistic work, the language is expected to have at least the legal suffix list for nouns and verbs.

To get the intuition behind our work, consider the word list {*boy, boys, moss, mosses*}. The splitting (the *split* is formally defined later) that generate the minimum number of stems (*viz.*, 2) from the above word list is {*boy+ $\phi$ , boy+s, moss+ $\phi$ , moss+es* }, where  $\phi$  is the null suffix. The minimum stem set is {*boy, moss*}. Any other splitting, say *mosse+s* will increase the number of stems.

This work is applicable to languages with concatenative morphology where suffixes stack one after another. However, problems arise when there are phonemic changes in the boundaries of the stems and suffixes (*sandhi*). In such situation, existence of fused, composite suffixes in the suffix list is assumed.

The roadmap of the paper is as follows. Related work in morphology learning is explained in section 2. Notations and terminologies used in this paper are defined in section 3. In section 4 we defined the stemming problem addressed in this work. Two models for this stemming are proposed in section 5 and section 6. In section 7, we described various experiments conducted. The conclusions and future works are presented in section 8.

## 2 Related Work

Morphology learning is one of the widely attempted problems in NLP. A recent survey by Harald Hammarström (2011) gives an overall view of unsupervised morphology learning. The Linguistica (Goldsmith, 2001) model based on minimum description length (MDL) principle is one of the benchmark works of unsupervised stemming. In the Linguistica model, the authors defined a signature structure. The objective of their stemming approach is the minimization of total description length, *i.e.*, the description length of stem list, suffix list, signatures and corpus.

Maximum a posteriori model (Creutz and Lagus, 2007) is a generalization of the Linguistica model, in the sense of being a recursive MDL. This probabilistic approach is more suitable for languages with more than one suffix. Stochastic transducer based model (Clark, 2001) and generative probabilistic model (Snover et al., 2002) are other relevant probabilistic models for stemming.

A Markov Random Field by Dreyer (2009) is also a useful probabilistic approach related to unsupervised morphology.

Graph based model (Johnson and Martin, 2003), lazy learning based model (van den Bosch and Daelemans, 1999), clustering based same stem identification model (Hammarström, 2006a; Hammarström, 2006b), ParaMor system for paradigm learning (Monson et al., 2008) and full morpheme segmentation and automatic induction of orthographic rules (Dasgupta and Ng, 2007; Dasgupta and Ng, 2006) are also a relevant.

### 3 Terminology and Notation

Let us define some terms and notations used throughout this paper.

$w$ : word

$W$ : input word list

$N$ : number of words in the input word list

$X$ : input suffix list

$x$ : suffix candidate of  $w$  (possible suffix)

$\phi$ : null suffix, *i.e.*, the suffix with zero length.

$t$ : stem candidate of  $w$  (possible stem)

$T$ : the set of possible stems from the word list

$|\cdot|$ : overloaded for the cardinality of a set and the length of a string

‘+’: splitting (breakage) of string

‘.’: concatenation of strings

*Stem*: the longest common prefix of the inflected words of a lexeme. The stem from the set of inflections of the lexeme *play* ( $\{plays, playing, played\}$ ) is *play*. Note that while a lexeme has to be a meaningful word in the language, the stem need not to be so. *E.g.*, stem of the words *lady* and *ladies* is *lad*, but the lexeme is *lady*.

*Suffix*: the portion(s) of the word after removing its stem. *E.g.*, the suffix of *boys* is *s*. The suffix can be a null string ( $\phi$ ) or chain of suffixes (Words in agglutinative languages can have multiple suffixes. In this case, chain of suffixes is taken as a single suffix.).

*Split*: the outcome of the process of segmentation (null strings permitted). A word can be segmented in multiple ways, giving rise to multiple *splits*. *E.g.*, a *split* of *boys* can be *b+oys*, *bo+ys*, *boy+s* or *boys+φ*. The *correct split* is the *split* that

separates a word in to its correct stem and correct suffix. *E.g.*, the *boy+s* is the *correct split* of *boys*.

*Splitset*: a set of *splits* obtained from the whole input word list. For every word in the word list, exactly one *split* will be there in the *splitset*. In other words,  $splitset = \{t + x \mid t \cdot x \in W \text{ and for any } t' + x' \in splitset, t \cdot x = t' \cdot x' \rightarrow t = t' \text{ and } x = x'\}$ . *E.g.*,  $\{bo+ys, girl+\phi, play+ing\}$  is a *splitset* of  $\{boys, girl, playing\}$ . The *correct splitset* is defined as the set of *correct splits* of all the words from the given word list. The *correct splitset* of  $\{boys, girl, playing\}$  is  $\{boy+s, girl+\phi, play+ing\}$ .

$T_s(splitset)$ : the set of stems from the *splitset*. *E.g.*,  $T_s(\{bo+ys, girl+\phi, play+ing\}) = \{bo, girl, play\}$ .

$X_s(splitset)$ : the set of suffixes from the *splitset*. *E.g.*,  $X_s(\{bo+ys, girl+\phi, play+ing\}) = \{ys, \phi, ing\}$ .

### 4 Problem Definition

The stemming problem addressed in this paper is defined as follows. Given a list of word forms  $W$  and a list of suffixes  $X$ , the problem is to find the *correct splitset*.

The suffix list of a language plays a crucial role in this problem. The suffix list considered in this problem should contain all atomic suffixes (*E.g.*, *s, es, ing*) and its orthographic variants (*E.g.*, *iness* in *happiness*). The suffix list also should contain chain of suffixes in case of agglutination. *E.g.*, the concatenated form of Malayalam<sup>1</sup> plural marker  $\text{കാല}(kal)$  and genitive case marker  $\text{ഉടെ}(ude)$  is  $\text{കാലുടെ}(kalude)$ . This concatenated form should be in the suffix list since it is the suffix (as per our definition) of the word  $\text{കുട്ടികളുടെ}(kuttikalude)$ (of children).

The suffix list  $X$  should be as large as possible and  $X$  should be a superset of all suffixes in the word list, *i.e.*,  $X_s(correct\ splitset) \subseteq X$ . *E.g.*, for the sample word list  $W = \{boy, boys, moss, mosses\}$ , the set  $X_s(correct\ splitset)$  is  $\{\phi, s, es\}$ , where  $\phi$  is the null suffix. So the suffix list should contain at least  $\phi, s$  and *es*.

The desired output of the above input is its *correct splitset*, *i.e.*,  $\{boy+\phi, boy+s, moss+\phi,$

<sup>1</sup>A morphologically rich language of India belonging to the Dravidian family.

*moss+es*}. Two computational models for this stemming problem is proposed in the section 5 and section 6.

## 5 Minimum Stem Set Model for Stemming

Consider the sample word list  $\{boy, boys, moss, mosses\}$  and suffix list  $\{\phi, s, es\}$ . Out of all possible *splitsets* of this input, the *correct splitset*,  $\{boy+\phi, boy+s, moss+\phi, moss+es\}$  produces the minimum number of distinct stems. This intuition leads to the Minimum Stem Set model for stemming. The Minimum Stem Set model (MSS) identifies the *correct splitset* by minimizing the number of distinct stems. In other words, this model identifies the *splitset* with the minimum number of distinct stems as the *correct split*.

Core of the MSS model is an optimization problem (MSS problem). The MSS problem is formally stated as follows,

*Input:* A list of word forms ( $W$ ) and a set of suffixes ( $X$ ) such that  $X_s(\text{correct splitset}) \subseteq X$

*Output:* 
$$\underset{\text{splitset}: X_s(\text{splitset}) \subseteq X}{\text{argmin}} \left\{ |T_s(\text{splitset})| \right\}$$

### 5.1 Greedy Algorithm for MSS

Since the complexity of computing the MSS problem is NP-Hard (Vasudevan and Bhattacharyya, 2012), we designed an approximation algorithm by utilizing similarity between our problem and the set cover problem. Set cover problem is a well known NP-Hard problem, which has a simple greedy approximation algorithm with approximation factor of  $\log(N)$  (Chvatal, 1979). This approximation factor is the best attainable factor for the set cover problem (Feige, 1998). The corresponding greedy algorithm for MSS problem is the best polynomial time approximation algorithm. This greedy approximation algorithm for the MSS problem (Approx-MSS) is described below.

Input of the Approx-MSS algorithm is a word list  $W$  and a suffix list  $X$ . The algorithm first initializes a set of all possible stems  $T$ . This can be done by stripping suffixes in  $X$  from end of each word in  $W$ . Then it initialize sets of all possible inflections of each  $t$  in  $T$ , let's call  $Infl(t)$ .  $Infl(t)$  can be initialized by appending suffixes from  $X$  to  $t$ . If a word created by appending a suffix  $x$  in  $X$  to

$t$  is in  $W$ , then add that word into  $Infl(t)$ . Set of all possible stems ( $T$ ) and  $Infl(t)$  of the running example is shown in Table 1.

After the initialization, the algorithm start the iterations with an empty *splitset*. In the first step, it chooses a stem  $t$  from  $T$  that has maximum  $|Infl(t) \cap W|$ . I.e., it finds a  $t^* = \underset{t \in T}{\text{argmax}} \{|Infl(t) \cap W|\}$ . In the next step, for all words ( $w$ ) in  $Infl(t^*) \cap W$ , the *split*  $t^* + x$  is added to *splitset*, where  $x$  is the suffix of word  $w$  after the stem  $t^*$ . Then it removes all words from  $W$  whose *splits* are added to *splitset*. This process is repeated until the *splitset* is complete, i.e., for all words there is a *split* in the *splitset*. The complexity of this approximation algorithm is  $O(|W||X|)$  and approximation factor is  $\log(|W|)$ .

Consider the example shown in Table 1. Initially both *boy* and *moss* have highest  $|Infl(t) \cap W|$ . So the greedy algorithm chooses either one of them in the first step as  $t^*$ . In the next step it chooses the other one. By these two steps, the greedy algorithm identifies the *correct split* of all four words.

T	<i>mosses</i>	<i>mosse</i>	<i>moss</i>	<i>mos</i>	<i>boys</i>	<i>boy</i>
$Infl(t)$	{ <i>mosses</i> }	{ <i>mosses</i> }	{ <i>mosses</i> , <i>moss</i> }	{ <i>moss</i> }	{ <i>boys</i> }	{ <i>boys</i> , <i>boy</i> }

Table 1: Possible Stems, their  $Infl()$

## 6 Weighted Minimum Stem Set (WMSS) Model

MSS problem uses the information from other words to identify the stem of each word. If the word list doesn't have any other inflections of a word, then MSS cannot choose the stem properly. In this case MSS randomly selects one of the possible stems. This is one of the main drawbacks of MSS. Languages with poor morphology have a lesser number of inflections than that of language with rich morphology. So in a word list with fixed number of words, the above problem is more serious for morphologically poor languages.

We extended the MSS model to a Weighted Minimum Stem Set (WMSS) model, which reduces the number of distinct stems and the number of splits with non empty suffixes. Output of this model is also a *splitset*. Consider a small word list  $\{boy, boys, moss, mosses\}$  and a suffix list  $\{\phi, s, es, ses\}$ . In this case both  $\{boy+\phi, boy+s, moss+\phi,$

$moss+es$ } and  $\{boy+\phi, boy+s, mos+s, mos+ses\}$  are optimum solutions for MSS problem. In such a tie situation, the WMSS model prefer the *splitset* with more number of null suffix ( $\phi$ ), *i.e.*, the first one. From our knowledge about English language, we can see that the first one is the *correct splitset*.

In the WMSS model, a weight function  $wg(t)$  is defined for each and every possible stem  $t$  as  $wg(t) = 1 + \frac{[t \notin W]}{|W|}$ . Where  $[t \notin W]$  is the Iverson bracket (Weisstein, Online 30 04 2010), *i.e.*, it is 1 if  $t \notin W$ , 0 otherwise. WMSS will find out a *splitset* such that the total weight of all stems in  $T_s(splitset)$  is minimum. Let's define the problem in WMSS model formally.

*Input:* A list of word forms ( $W$ ) and a set of suffixes ( $X$ ) such that  $X_s(correct\ splitset) \subseteq X$

$$\text{Output: } \underset{splitset: X_s(splitset) \subseteq X}{\operatorname{argmin}} \left\{ \sum_{t \in T_s(splitset)} wg(t) \right\}$$

In this extended problem formulation,  $wg(t)$  contain two terms. The first term, the constant 1 is for reducing the number of distinct stems and the second term,  $\frac{[t \notin W]}{|W|}$  is for reducing the number of *splits* with non empty suffixes. If there is no second term then  $wg(t) = 1$  and it is exactly the same as MSS problem.

Since the maximum value of the second term in WMSS is  $\frac{1}{|W|}$  and maximum number of stems in any  $T_s(splitset)$  is less than  $|W|$ ,  $|T_s(splitset)| < \sum_{t \in T_s(splitset)} wg(t) < |T_s(splitset)| + 1$ . Therefore any solution of WMSS should be a solution of MSS, but the reverse is false. Relevance of this WMSS problem comes only if there are multiple solutions for MSS problem.

Since the solution of WMSS problem is a solution of MSS problem, the reduction from MSS to WMSS is trivial. Suppose WMSS have a polynomial time algorithm, then we can use that algorithm for MSS problem also. Since MSS is NP-Hard we can say that, WMSS is also NP-Hard.

### 6.1 Greedy Algorithm for WMSS

The WMSS problem can be solved effectively by utilizing its similarity with weighted set cover problem. Weighted set cover problem is also an NP-Hard problem, and its greedy approximation have a bound of  $\log(N)$ . The greedy algorithm for weighted set cover problem is adapted for WMSS

problem. The corresponding greedy algorithm for WMSS (Approx-WMSS) is explained below.

The Approx-WMSS is similar to Approx-MSS. The only difference is in the first step. While Approx-MSS algorithm selects a stem with maximum  $|Infl(t) \cap W|$  in the first step, Approx-WMSS algorithm selects a stem with maximum  $\frac{|Infl(t) \cap W|}{wg(t)}$ . Note that, when  $wg(t)$  is 1 then both terms are the same. All remaining steps are the same for both algorithms. Similar to Approx-MSS algorithm, the complexity of this approximation algorithm is  $O(|W||X|)$  and approximation factor is  $\log(|W|)$ .

Consider the  $W = \{boy, boys, moss, mosses\}$  and  $X = \{\phi, s, es, ses\}$ . The set of all possible stems and its corresponding  $Infl()$  and  $wg()$  are shown in Table 2. Initially *boy* has the highest  $\frac{|Infl(t) \cap W|}{wg(t)}$ . So this greedy algorithm chooses the stem *boy* and add *boy+ $\phi$*  and *boy+s* to *splitset* in the first step. In the next step it chooses *moss* and add *moss+es* and *moss+ $\phi$*  to *splitset*. By these two steps, this greedy algorithm terminate by identifying *correct splitset*.

T	<i>mosses</i>	<i>mosse</i>	<i>moss</i>	<i>mos</i>	<i>boys</i>	<i>boy</i>
$Infl(t)$	{ <i>mosses</i> }	{ <i>mosses</i> }	{ <i>mosses</i> , <i>moss</i> }	{ <i>moss</i> }	{ <i>boys</i> }	{ <i>boys</i> , <i>boy</i> }
$wg(t)$	1	$1 + \frac{1}{4}$	1	$1 + \frac{1}{4}$	1	1

Table 2: Possible Stems, their  $Infl()$  and  $wg()$

## 7 Experimentation

Two new stemming systems based on the greedy algorithms for MSS problem and WMSS problem are implemented. Performances of these systems are evaluated for four languages from Indo-European family and Dravidian family. The selected languages are English, Hindi, Marathi and Malayalam, in the increasing order of morphological complexity. First three languages are from Indo-European family while the fourth language, Malayalam is a highly agglutinative language from Dravidian family. These spectrum of languages from different families with different morphological richness is necessary for the evaluation of the suitability of proposed models.

Performance of proposed models are compared with different baselines. The first baseline is a random stem selection, which randomly selects a *split* for each word such that the suffix in this *split* is in the input suffix list. The length of the suffix (or

stem) is another information that can provide second and third baselines. The second one selects a *split* for each word form that has the smallest stem, albeit with the suffix in the input suffix list. Similarly the third one selects the *split* with the largest stem.

Linguistica is an MDL based system that identifies stem of each word in a word list without using any other input. One of the heuristics used in Linguistica model is modified to make the fourth baseline. In the Linguistica heuristics, a probability is assigned to every *split* for every word. Then iteratively it learns the best probability distribution by optimizing a figure of merit, which is a function of length and frequency of morphemes. Since there is no need to consider any *split* with a suffix which is not in the input suffix list, the sample space can be minimized. Probability distribution after this modification is learned using the same iterative procedure as in Linguistica. We implemented this modified Linguistica algorithm and considered it as fourth baseline.

## 7.1 Data Analysis

Word list of size 10,000 distinct words in Unicode format were selected for English, Hindi, Marathi and Malayalam. English words are taken from Brown and BNC corpora (Francis and Kucera, 1964; Edition, 2007). Selected Hindi words are from tourism and news corpus. The source of Marathi words for experimentation is the corpora from the Indian Language Corpora Initiative (ILCI) project, which is a Government of India effort (<http://www.tdil.mit.gov.in>). Malayalam words are obtained from IITMK<sup>2</sup> and from various blogs and newspapers. For each words the correct stem as per the definition, *i.e.*, the largest prefix of all inflected forms of the lexeme, is identified for the evaluation. Suffix lists are mainly created from the words in the word list. By adding available suffixes from web, the suffix lists are expanded as big as possible.

Counts and frequencies of stems and suffixes are relevant statistics to reflect the nature of word list for stemming. So the number of distinct stems (*StCount*) and suffixes (*SfCount*) are counted from each word list. The average stem frequencies (*StFreq*) and average suffix frequencies (*SfFreq*)

<sup>2</sup>Indian Institute of Information Technology and Management-Kerala

are also measured from word lists of all four languages. These measured values are shown in Table 3.

Language	<i>StCount</i>	<i>StFreq</i>	<i>SfCount</i>	<i>SfFreq</i>	<i>X</i>
English	4974	2.01	43	232.58	436
Hindi	4792	2.09	134	74.63	726
Marathi	4086	2.45	604	16.56	1958
Malayalam	1077	9.29	762	13.12	26248

Table 3: Statistics of Word List and Suffix List (*X*)

Number of distinct stems in the word form list decreases and average stem frequencies increases along with morphological complexity of language. Similarly the number of distinct suffixes in the word list increases and average suffix frequencies decreases along with morphological complexity. We can also see that the number of suffixes in a language also increases with morphological complexity. Since these patterns are quite intuitive, the data taken for experiments seems to be proper samples that represents the languages.

## 7.2 Results and Discussion

The accuracy of four baselines and two newly proposed systems for four languages are tabulated in Table 4. The results indicates the effectiveness of the new systems over baseline systems across various languages. Improvement in the performance of WMSS over MSS is also clearly visible in the table. Above 80% accuracies for all languages are obtained by using the WMSS model. English, Hindi, Marathi and Malayalam are the languages in the increasing order of morphological complexity. We can observe that the accuracies are decreasing along with the morphological complexity of language. This indicates stemming is difficult for morphologically complex languages.

Language	Random Stem	Largest Stem	Smallest Stem	Modified Linguistica	MSS	WMSS
English	44.98	47.39	49.36	53.82	84.44	88.86
Hindi	50.68	43.04	57.44	62.74	80.71	83.98
Marathi	41.66	30.44	69.766	59.33	78.28	80.19
Malayalam	19.31	3.51	57.58	65.86	78.32	80.06

Table 4: Stemming Accuracies in Percentage

For all four languages, the baseline which selects stems with maximum length have a lesser score than the baseline which selects stems with minimum length. This shows, if there are more

than one stem candidate, then smaller stems is preferred. Since null suffix is present in the suffix list, maximum stem length baseline always selects the word itself as its stem. So the low score for maximum stem length baseline for Malayalam indicates, most of the Malayalam words are in the inflected form. To get better insight about the remaining issues an error analysis of the output sample is required.

### 7.3 Error Analysis

To get better insight about the remaining issues, erroneous samples generated by the best performing system, *i.e.*, WMSS, are categorized in to under stemming<sup>3</sup>, over stemming<sup>4</sup> and weight error. The weight error is the case where the correct stem is in the word list but the identified incorrect stem is not. Such errors can be corrected by modifying the weight function in the WMSS formulation. Percentage of errors in various categories are tabulated in Table 5.

If the number of suffixes in the word list is very small compared to the total number of suffixes in the suffix list, then there is a high chance for overstemming. So the ratio between total number of suffixes and the number of suffixes in the word list (suffix ratio), for all four languages are also included in Table 5.

Language	Under-Stemming	Over-Stemming	Weight-Error	Suffix ratio
English	2.76	8.38	3.74	10.0
Hindi	3.90	12.12	5.94	5.42
Marathi	8.36	11.45	5.57	3.24
Malayalam	0.93	19.01	0.24	34.5

Table 5: Percentage of Errors and Suffix ratios

Suffix ratio of English is high (10). It decreases in Hindi, and further decreases in Marathi. According to this pattern, the under stemming errors are very few (only 3%) in English and it increases in Hindi and Marathi. The suffix ratio of Malayalam is higher than English so the under stemming errors are negligibly small (less than 1%). The relation between suffix ratio and under stemming errors are clearly visible from these numbers. So to reduce the under stemming errors, we need to increase the number of input suffixes.

<sup>3</sup>identified stem is longer than correct stem, *e.g.*, *mosse* in *mosses*

<sup>4</sup>identified stem is shorter than correct stem, *e.g.*, *s* in *sing*

The over stemming errors increases from English to Malayalam. This indicates that the over stemming errors are more sensitive to morphological complexity than the suffix ratio. From the table we can see that, weight errors are significant except in Malayalam. This indicates the requirement of weight modification. Also, we can see that the weight errors are high in Hindi and Marathi, and hence the weight modification is crucial for these languages.

After the analysis, the main observation is about the importance of weight modification. Some sample words from all four languages are shown in Figure 1.

Language	Word	Identified Stem	Correct Stem (in case of erroneous sample)
English	pretenses halfways rhodes.	pretenses halfway rhodes	pretense
Hindi	मच्छर (machhar) (mosquito) चूर्ण (choornom) सोफे (sophe)	मच्छ (machha) चूर्ण (choorn) सोफ (sofa)	मच्छर (machhar)
Marathi	छेडतील (chhedtheel) (to provoke) सांभाळतात (saambhaalthaath) (to look after) दिव्य (divya) (magnificent)	छेड (chhed) सांभाळ (sambhaal) दिव (diva)	दिव्य (divya)
Malayalam	കൂണിലുമുല്ലം (koonilumellam) (also in mushroom) പാമ്പിനുള്ളിൽ (paampinullil) (inside snake) അണുക്കൾ (anukkalum) (and atoms)	കൂണ (koona) പാമ്പ (paampa) അണ (ana)	അണു (anu)

Figure 1: Output Samples (WMSS)

## 8 Conclusion

Two algorithms for stemming, that produces a mapping from words to stems by minimizing the number of stems upto a limit, given a word list and a suffix list are proposed and implemented. Stemming systems that use these algorithms are evaluated using languages from Indo European and Dravidian families. Moderate to high accuracies of stemming are obtained in case of for all four languages: English, Hindi, Malayalam and Marathi.

Collecting a word list is relatively an easy task for a new language. But, collecting a complete list of suffixes is a much more involved task since detailed linguistic work is required. So completely unsupervised stemming is our future work. Stems will be produced from only the word form list.

# What information is helpful for dependency based Semantic Role Labeling

Yanyan Luo    Kevin Duh    Yuji Matsumoto

## Abstract

Semantic Role Labeling (SRL) is an important task since it benefits a wide range of natural language processing applications. Given a sentence, the task of SRL is to identify arguments for a predicate (target verb or noun) and assign semantically meaningful labels to them. Dependency parsing based methods have achieved much success in SRL. However, due to errors in dependency parsing, there remains a large performance gap between SRL based on oracle parses and SRL based on automatic parses in practice. In light of this, this paper investigates what additional information is necessary to close this gap. Is it worthwhile to introduce additional dependency information in the form of N-best parse features, or is it better to incorporate orthogonal non-dependency information (base chunk constituents)? We compare the above features in a SRL system that achieves state-of-the-art results on the CoNLL 2009 Chinese task corpus. Our findings suggest that orthogonal information in the form of constituents is much more helpful in improving dependency based SRL in practice.

## 1 Introduction

In recent years, SRL has become an important component in many kinds of deep natural language processing applications, such as question answering (Narayanan and Harabagiu, 2004), event extraction (Riedel and McCallum, 2011), document categorization (Persson et al., 2009). SRL aims at identifying the semantic relations between predicates in a sentence and their associated arguments, with these relations drawn from a pre-specific list of possible semantic roles for

corresponding predicates. Syntax information is essential in SRL systems. To date, both constituent parsing and dependency parsing based SRL have been investigated (Xue, 2008; Johansson and Nugues, 2008), with dependency based systems giving superior results in CoNLL 2008 (Surdeanu et al., 2008) and CoNLL 2009 shared tasks (Hajič et al., 2009).

However, the performance gap is still quite large between SRL systems using oracle "perfect" dependency parses and SRL systems using automatic dependency parses. We observe as much as 10% F-score difference in our experiments. Clearly, errors in the 1-best dependency parse affects SRL prediction. This leaves an open question: in order to improve dependency based SRL, is it more worthwhile to incorporate more dependency information (in the form of N-best parse), or to incorporate an entirely separate source of information, such as base phrase chunks? We perform such an analysis in this paper, using a state-of-the-art Chinese SRL system.

Our findings suggest that constituent information such as chunking nicely complements dependency based SRL, achieving more improvements compared to N-best dependency information. Finally, we also report the best results to date on the CoNLL 2009 Chinese shared task.

## 2 Related Work

The bulk of previous work on automatic SRL has primarily focused on using full constituent parse of sentences to define argument boundaries and to extract relevant information for training classifiers. However, there have been some attempts at relaxing the necessity of using syntactic information derived from full parse trees. Sun et. al (2009) and Hacioglu et. al (2004) addressed the SRL problem on the basis of shallow syntactic information at the level of phrase chunks. In their approach, SRL is formulated as a sequence label-

ing problem, performing IOB2 decisions on the syntactic chunks of a sentence. However, this method ignores the full syntactic parsing information entirely, and we believe that even the accuracy of full syntactic parsing is not ideal, it is still helpful for SRL. Moreover, their method is inapplicable to dependency based SRL since a chunk usually consists of successive words.

A substantial amount of research has focused on dependency-based SRL (Meza-Ruiz and Riedel, 2009; Luo et al., 2012) since the CoNLL-2009 shared task and rich linguistic features (Zhao et al., 2009) are applied. For dependency related features, most studies focused on extracting them from the best dependency result. Johansson and Nugues (2008) tried to use N-best dependency parsing results. In their work, they applied 16-best dependency trees to generate predicate-argument structures and applied both syntactic trees and predicate-argument structures to a linear model. This model reranks the predicate-argument structures and the top 16 dependency trees at the same time. Though their work suggests that N-best dependency parsing can enhance the SRL, little is known about how the N-best dependency parsing related features perform on SRL.

### 3 Dependency based SRL Model

First, we define an instance as a predicate word and its corresponding argument words. If there are  $m$  predicates in a sentence, then there will be  $m$  instances. Given an instance  $X = \{x_1, \dots, x_p, \dots, x_n\}$  with the predicate position  $p$ , we want to find the corresponding sequence of argument labels and predicate sense  $S = a_1, a_{p-1}, P, a_{p+1}, \dots, a_n = \langle P, A \rangle$ . Each  $a_i$  for the  $i$ -th word in the instance  $X$  is drawn from a set of tags  $T(A)$  which contains all the semantic role labels in the corpus and which follows the definition criteria in Chinese PropBank. In addition, the special label *NONE* is added to  $T(A)$ . Words, labeled as *NONE*, are not arguments for the predicate. As for  $P$ , this is a member of a sense set  $T(x_p)$  which contains all possible senses of predicate word  $x_p$ . We propose two sorts of label assignment models  $Pr_{local}$  and  $Pr_{global}$ . The former can incorporate local features only; the latter can incorporate also global features. We use three types of local feature sets:  $F_P$ ,  $F_A$ ,  $F_{PA}$  and one global feature set  $F_G$ . These type definitions are the same as those in Watanabe et. al (2010).

### 3.1 Predicate Sense Disambiguation and SRL with a Local Model

Since the predicate cannot be an argument of itself for Chinese, we define the following local probabilistic model for argument classification and predicate sense disambiguation.

$$Pr_{local}(S|X) = \prod_{i=1(i \neq p)}^n Pr(a_i|P, X, i, p) \cdot Pr(P|X, p) \quad (1)$$

where  $Pr(a_i|P, X, i, p)$  and  $Pr(P|X, p)$  are estimated according to the following equation:

$$Pr(a_i|P, X, i, p) = \frac{1}{Z^A(X)} \exp\left\{ \sum_{f_{A_j} \in F_A} \lambda_{f_{A_j}} f_{A_j}(a_i, X) + \sum_{f_{PA_k} \in F_{PA}} \lambda_{f_{PA_k}} f_{PA_k}(a_i, X, p, P) \right\},$$

$$Pr(P|X, p) = \frac{1}{Z^P(X)} \exp\left\{ \sum_{f_{P_l} \in F_P} \lambda_{f_{P_l}} f_{P_l}(X, p, P) \right\},$$

where  $Z^A$  and  $Z^P$  are normalization functions, i.e.,

$$Z^A = \sum_{a_i \in T(A)} \exp\left\{ \sum_{f_{A_j} \in F_A} \lambda_{f_{A_j}} f_{A_j}(a_i, X) + \sum_{f_{PA_k} \in F_{PA}} \lambda_{f_{PA_k}} f_{PA_k}(a_i, X, p, P) \right\};$$

$$Z^P = \sum_{P \in T(x_p)} \exp\left\{ \sum_{f_{P_l} \in F_P} \lambda_{f_{P_l}} f_{P_l}(X, p, P) \right\};$$

$f$  are the features with associated weight  $\lambda$  learned via training.

### 3.2 Predicate Sense Disambiguation and SRL with the Global Model

Global information is known to be useful in SRL (Nakagawa, 2007). We propose a global probabilistic model  $Pr_{global}$  here for SRL as follows:

$$Pr_{global}(S|X) = \frac{1}{Z} Pr_{local}(S|X) \cdot \exp\left\{ \sum_{f_{G_m} \in F_G} \lambda_{f_{G_m}} f_{G_m}(S, X) \right\} \quad (2)$$

where  $Z$  is a normalizing factor over all candidate sequences  $S(X, p)$  (set of possible configurations of semantic tags and predicate senses given  $X$  and predicate location  $p$ ). To get the whole sequence of  $S$ , we need to perform a computationally expensive search. As done in previous work (Watanabe et al., 2010), we use a simple approach,

Type	%Error	#Error/#Occurrence
C	49.4%	7,162/14,497
G	88.62%	109/123
O	80.71%	3,175/3,934

Table 1: The distribution of SRL errors on development corpus by the joint model.

n-best relaxation. Unlike the  $Pr_{local}(S|X)$ , the product of probability distributions of each word, the probability distribution  $Pr_{global}(S|X)$  is calculated by feature functions  $f_G$  defined on an instance  $X$  with assignment  $S$ . Thereby, we can use any information in an instance without the independence assumption for assignments of words in it.

### 3.3 Error Analysis for Dependency-based SRL

Using the gold parse of dependency relations between a predicate and its arguments and according to these relations, we classified SRL errors into following three types.

- **C**: children of a predicate should be arguments but they are tagged incorrectly.
- **G**: grand children of a predicate should be arguments but they are tagged incorrectly.
- **O**: others

Table 1 shows the distribution of three errors observed in the development corpus after tagging by our joint model. For example, there are a total of 14,497 arguments that are children of predicates and among them, and 7,162(49.4%) are errors.

## 4 Results and Discussion

### 4.1 Experimental Setting

We used the Chinese dataset provided by CoNLL-2009 shared task for experiments. For comparison, two kinds of dependency parsing results are provided, the first is from MALT parser, the second is from second-order MST parser.

As for chunking information, we used the chunk definition presented in (Chen et al., 2006) to extract chunks from Chinese Tree Bank as training corpus. The line  $CH$  in Figure 1 shows the definition of chunks. In this example, "金融工作"(finance work) is a noun phrase and is composed by two nouns.

With the Inside/Outside representation for proper chunks and the following feature templates, where  $x_0$  is the current word, a CRF++<sup>1</sup> is trained for Chinese chunking task.

- Uni-gram word/POS tag features:  $x_{-2}$ ,  $x_{-1}$ ,  $x_0$ ,  $x_{+1}$  and  $x_{+2}$ .
- Bi-gram word/POS tag features:  $x_{-2}x_{-1}$ ,  $x_{-1}x_0$ ,  $x_0x_{+1}$  and  $x_{+1}x_{+2}$ .

### 4.2 Features

Most of features templates are "standard" which have been widely used in previous dependency-based SRL research (Johansson and Nugues, 2008; Luo et al., 2012). We do not explain "standard" features, however, we give a detailed description of the features used in this work.

#### 4.2.1 Base Phrase Chunking Related Features

In Figure 1, obviously, words in chunks do not have equal importance for SRL. Headwords represent the main meaning of the chunks. The base phrase chunking related features shown in Table 2 are only applied to these headwords. For other words in chunks, only lemma and POS information is used. The rules described in Sun and Jurafsky (2004) are used to extract headwords. Verb class in Table 2 is represented similarly as  $Verb.C1C2$ , which means this *verb* has two senses. For its first sense, it has one core argument and for its second sense, it has two core arguments. These verb classes are extracted from Chinese PropBank (Xue, 2008).

#### 4.2.2 Features from N-best Dependency Parsing

According to the statistics of development corpus, it is found that about 78.13% arguments are children of predicates. Even if its error percentage shown in Table 1 is less than 10%, the total error number is also considerable. If we can reduce the head errors for dependents, the  $C$  errors caused by dependency parsing errors should be decreased, and SRL tagging results would be improved. Under this hypothesis, we simply extracted the following features from every parse tree in the N-best list which are generated using second-order MST parser. These features are also included in the "standard" feature set when  $N = 1$ .

<sup>1</sup><http://crfpp.sourceforge.net/>

WORD	去年	西藏	金融	工作	取得	显著	成绩
POS	NN	NR	NN	NN	VV	JJ	NN
CH	[NP]	[NP]	[ NP ]	[VP]	[ADJP]	[NP]	
TAG	B-NP	B-NP	B-NP	I-NP	B-VP	B-ADJP	B-NP
SRL	TMP	NONE	NONE	A0	取得.01	NONE	A1

Figure 1: Chunking information for a predicate-argument structure.

Feature Name	Description
Chunk features	<p>chunk tag of headword with IB representation (e.g. <math>B - NP</math>)</p> <p>chunk tag of the chunk where the headword belongs to</p> <p>the number of words in a chunk</p> <p>the POS sequence of words in a chunk, for example, "金融工作" (finance work) is "NN_ NN"</p> <p>the position of the chunk with respect to the predicate(Position). There are three possible values: "before", "after" and "here".</p> <p>the conjunctions of Position and headword, predicate and verb class</p> <p>the conjunctions of Position and POS of headword, predicate and verb class</p> <p>lemma/POS of one word immediately before/after of the chunk</p>
Path features	<p>a chain of chunk types between the headword and the predicate.</p> <p>the length of the chunk chain between the headword and the predicate</p> <p>For example, chain of chunk types between headword "工作" and predicate "取得" is "NP-VP" and the length of the chunk chain is 2.</p>

Table 2: Chunking related feature template for experiments.

*Arguments'heads*: lemma/pos; lemma and pos; dependency label; whether they are predicates.

*Position*: position of the argument candidates with respect to the predicate positions in the tree; position of the heads of the argument candidates with respect to the predicate position in the sentence.

*Chain*: the left-to-right chain of the dependency labels of the predicate's dependents.

### 4.3 SRL Performance

The overall performance of SRL is calculated using the semantic evaluation metric of the CoNLL-2009 shared task scorer<sup>2</sup>. Table 3 gives the comparison of SRL performance before and after adding the proposed base phrase chunking related features on the test data. Lines with  $-/+$  show the SRL performance without/with base phrase chunking related features. As seen in this table, without gold dependency parse, the best SRL is up to 80.52 in  $F_1$  score. To the best of author's knowledge, there are few Chinese SRL results more than

<sup>2</sup><http://ufal.mff.cuni.cz/conll2009-st/eval09.pl>

	P(%)	R(%)	$F_1$ (%)
Gold parsing -	88.68	86.30	87.47
Gold parsing +	<b>90.03</b>	<b>87.71</b>	<b>88.86</b>
MALT -	82.64	72.68	77.34
MALT +	<b>84.17</b>	<b>74.67</b>	<b>79.13</b>
MST-2 -	83.01	75.39	79.02
MST-2 +	<b>84.49</b>	<b>76.92</b>	<b>80.52</b>

Table 3: SRL results without/with base phrase chunking information.

80%.

Although comparing the lines with  $-$ , it shows dependency parsing play the central role in Chinese SRL as expected. Comparing their corresponding lines with  $+$ , Chinese SRL can still benefit a lot from shallow parsing information. An example from the corpus is shown in Figure 2. Figure 2a shows the gold dependency parsing result and the gold predicate argument structure; Figure 2b shows the dependency parsing result from MALT parser and the predicate argument structure as a result of the predicted parse; Figure 2c shows the predicate argument structure which is predicted after adding base phrase chunking re-

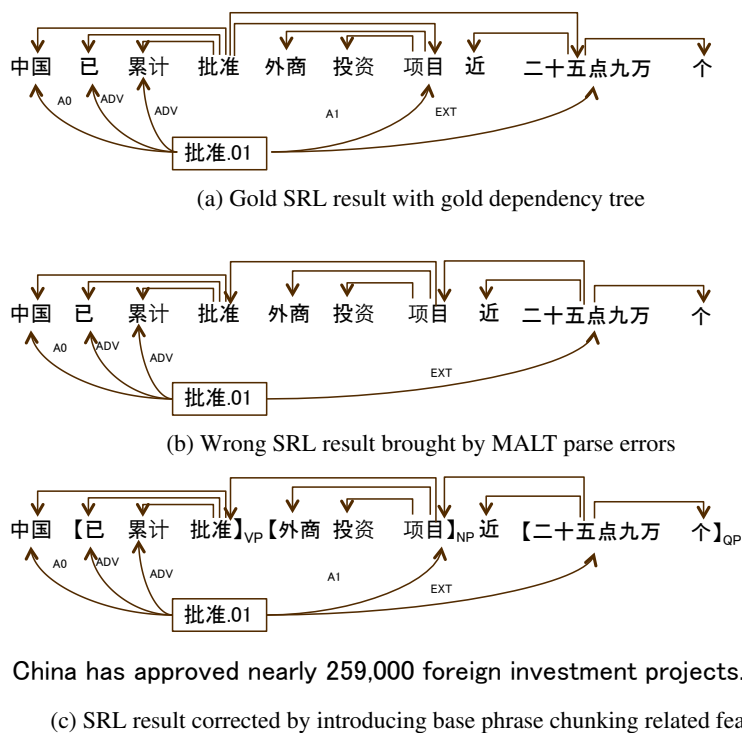

Figure 2: An example that the argument prediction error brought by MALT parse errors is corrected by introducing base phrase chunking related features.

	N-best	P (%)	R (%)	F <sub>1</sub> (%)
MST-2-	1	<b>83.01</b>	75.39	79.02
MST-2-	3	82.52	<b>77.16</b>	79.75
MST-2-	5	82.74	77.10	<b>79.82</b>
MST-2-	10	82.44	76.98	79.62

Table 4: SRL results with N-best dependency parsing related features.

N-best	Correct (#)	Error(#)	Noise(#)
1	18,428	3,176	-
3	19,071	2,533	4,636
5	19,392	2,212	5,667
10	19,738	1,866	7,699

Table 5: Dependency accuracy and the noise changes with different N.

lated features. In Figure 2c, the subscripts stand for chunk types. From Figure 2b, it can be seen that the argument A1 is not identified by the dependency based SRL because of dependency errors. Comparing Figure 2b and 2c, we can see that after adding the base phrase chunking related features, this SRL error brought by dependency parsing errors is corrected.

Line MALT+ and line MST-2- show that even the dependency parsing result from MALT is not better than that from second order MST, with the aid of chunking related features, Chinese SRL can still get comparable results.

Table 4 shows the Chinese SRL results after adding the N-best dependency parsing related features. It is not surprising that SRL can get better performance when  $N > 1$ , because the larger N, a more accurate dependency parsing results can be

likely obtained. When  $N = 5$ , SRL gets the best performance 79.82 in  $F_1$  with 0.8 point improvement.

However, the improvement declines when  $N = 10$ . A larger N may result in adding more accurate dependency parsing, however, it can also result in including more noises. For the MST parser using second order algorithm, Table 5 shows how the choice of the value of N affects the dependency parsing. The Correct(#) column represents the number of cases where the correct parent of an argument is predicted within the N-best. For example, in 3-best, it counts the number of arguments where their parents are correctly predicted in at least one of the 3 predictions. In the case where the parent is not predicted in any tree, they are counted as an error, as listed in the second column. The third column (Noise), is defined under

	N-best	P(%)	R (%)	F <sub>1</sub> (%)
[Björkelund, 2009]	-	82.42	75.12	78.60
[Meza-Ruiz, 2009]	-	82.66	73.36	77.73
[Zhao, 2009]	-	80.42	75.20	77.72
MST-2 +	1	<b>84.49</b>	76.92	80.52
MST-2 +	3	83.81	<b>78.51</b>	<b>81.07</b>
MST-2 +	5	83.71	78.40	80.97

Table 6: SRL results with base phrase chunking information and N-best parsing related features.

a hypothesis: correct dependency relations generate correct SRL results, wrong dependency relations generate incorrect SRL results. It represents the number of wrong dependency relations in Correct case which can cause bad influence on SRL results. For example, if 3 best heads for an argument are top-1, top-2, top-3 respectively, and top-1 is the correct one, then this case is a Correct case and the number of noise are 2; if none of the three results are correct, then this case is an Error case, and no noise. From this table, it obviously indicates that the benefit for dependency parsing brought by a larger N is less than the noise brought by the N.

With Tables 3 and 4, it can be seen that SRL benefits more from chunking related features than from N-best parse related features.

Table 6 shows the the results of Chinese SRL after adding base phrase chunking information and N-best parsing related features and gives the comparison with the previous work. From Tables 4 and 6 we can see that after adding the chunking related features, the impact of N-best parsing related features is a little reduced.

#### 4.4 Discussion

In Section 4.3, we see that both chunking and N-best parsing related features are helpful for Chinese SRL to some extent. In order to understand how they affect SRL, we analyze the results from three types of errors introduced in Section 3.3. Table 7 shows the error changes when different features are added.

Since accurate dependency information is not always available, the three types of errors should become larger when automatic dependency parsers are used. From Tables 1 and 7, the *C* and *O* errors increased as expected, while *G* de-

	N-best	C(%)	G(%)	O(%)
MST-2-	1	25.37	86.93	59.06
MST-2-	3	22.83	78.43	56.84
MST-2-	5	22.83	78.43	57.36
MST-2+	1	23.93	86.93	54.70
MST-2+	3	21.5	76.47	53.05
MST-2+	5	21.66	76.47	53.38

Table 7: SRL error changes with different features

creased. The main reason is that arguments, that are grandchildren of predicates, are relocated in the dependency trees because of dependency errors, and these locations make them easier to be tagged. From the first and fourth rows, they suggest that shallow parsing information are helpful to reduce the *C* and *O* errors. Comparing the fourth line with second and third rows, they explain why SRL achieves more improvements from chunking than from N-best dependency. When *N* changed from 1 to 3, the errors decreased obviously, however, when the *N* = 5, there are no obviously different changes.

## 5 Conclusions and Future Work

In this paper, we introduce additional information: base phrase chunking and N-best dependency parsing related features to a dependency based SRL system and investigate the benefit that our Chinese SRL model can get from them. Evaluations on the CoNLL 2009 Chinese corpus show that chunking information well complements dependency based SRL, achieving more improvements compared to N-best dependency information. With those additional features, our dependency based SRL achieves the best result on the same Chinese corpus to our knowledge. Furthermore, while all our experiments are for Chinese, it is possible to design experiments for other languages with our models.

Our experiment results show that we are not limited to increase SRL performance via more accurate syntactic parsing, but that we can explore other information, which is easier to get and is helpful for SRL. This also guides our future work. In our future work, we would like to explore more features and their influence on SRL.

## Abstract

Natural language generation systems rely on taxonomic thesauri for tasks such as lexical choice and aggregation. WordNet is one such taxonomy, but it is limited in size. Motivated by the needs of a generation system in the scientific literature domain, we present a method for building a taxonomic thesaurus from Wikipedia articles, where each article represents a potential concept in the taxonomy. We propose framing the problem of creating a taxonomy as a classification task of the potential relations between individual Wikipedia article pairs, and show that a supervised algorithm can achieve high precision in this task with very little training data.

## 1 Introduction

Thesauri are useful resources for many NLP applications. In particular, taxonomic thesauri which contain synonymy and hypernymy relations are important for natural language generation (NLG) systems which must make decisions regarding lexical choice and aggregation. WordNet (Fellbaum, 1998) is one such thesaurus which has many uses in generation (Jing, 1998), but its set of concepts (called *synsets*) is quite limited. It does not contain many domain-specific concepts, nor does it contain technical concepts that emerged very recently. This work is motivated by the needs of a NLG system in the scientific literature domain, where these missing concepts are absolutely necessary for any practical application. Our goal is to generate a thesaurus containing synonymy and hypernymy relations between scientific terms which a generation system can use to select the most appropriate term given a context.

The English Wikipedia has over 4 million articles, and over 8.6 million titles if *redirects*, which

are alternative titles for the articles, are included. These titles are essentially lexical terms referring to concepts. Crucially, it contains articles describing many domain-specific concepts, and, in particular, scientific and technological concepts. For example, Wikipedia contains articles with titles such as *Supersymmetric String Theory*, *Gorilla Glass* and *Sentiment Analysis*, all of which are missing from WordNet. While there have been attempts to build ontologies from Wikipedia, these tended to focus (in their optimization and evaluation) on entities such as people, places and events. There is still a need for a WordNet-like taxonomy which would contain accurate synonymy and hypernymy relations for highly specialized terms from various scientific domains (for our purposes) and other specialized domains.

Unlike previous approaches, which tend to rely on WordNet's hierarchy and/or on Wikipedia's pseudo-hierarchy of *categories*, we frame the problem as a binary classification task for a pair of Wikipedia article titles - deciding whether the term representing the concept in the first article is a hypernym of the term representing the second or not. This enables us to handle specialized concepts which are far from the established concepts in the WordNet hierarchy.

WordNet-like taxonomies behave in some ways as a dictionary, in others as an ontology. To avoid confusion, we define the main terms we use in this paper and what they correspond to:

- A *concept* in computational ontologies is a unique semantic entity. We assume that WordNet synsets correspond to concepts. Another assumption we make is that each Wikipedia article describes something analogous to a concept; this assumption does not work for some types of articles (e.g. Template articles), and we remove such articles before processing, as explained in section 3.

- A *term* is a lexical entity (word or combination of words) used to refer to a concept. Each WordNet synset contains multiple terms (synonyms) which all refer to the concept represented by the synset. We treat Wikipedia article titles as terms referring to the concept described in the article. In addition to the main title, Wikipedia has multiple additional *redirect titles* referring to each article. We do not *a priori* treat these as synonyms, as they are often hypernyms, hyponyms or even terms referring to distinct (though related) concepts (for example, at the time of this publication, *Disambiguation* redirects to *Word Sense Disambiguation*; *nano-SIM* redirects to *Subscriber Identity Module (SIM)*; and *Sheep Sounds* redirects to *Sheep*).
- *Relations* in this work are semantic relations between pairs of terms - specifically, synonymy and hypernymy. This is in contrast to the use of the word in ontologies where relations occur between pairs of concepts.

The following are a few examples of relations that do not appear in WordNet and which our method correctly finds:

- *Gene Silencing* is a hypernym of *RNA Interference*
- *Graph Property* is a hypernym of *Clustering Coefficient*
- *Conditional Random Field* and *CRF* are synonyms

We will use these examples to illustrate the limitations of other methods in the next section.

## 2 Related Work

There have been many attempts to extend WordNet with concepts from Wikipedia. Because WordNet has some of the properties of an ontology, most work on extending WordNet with Wikipedia concepts was in the context of creating an ontology. Although our work is different in that we focus on extending only the taxonomic relations between the terms, this related work is still very relevant. There have also been attempts to create ontologies directly from Wikipedia in various ways, and we discuss those as well.

Yago (Suchanek et al., 2007) is a large ontology (over 10 million concepts) based on WordNet

and extended with concepts from Wikipedia and other resources. Its hypernymy hierarchy (a relation called *subClassOf*) is derived by matching articles with existing WordNet synsets using the lexical and syntactic properties of the title. This approach works well for some complex entities: a title like “American people in Japan” contains the head compound *people* which matches the WordNet synset *Person/Human*. It does not work as well for scientific concepts, where titles tend to be less clearly related. For example, Yago contains the concepts *Clustering Coefficient* and *RNA Interference*, because they are titles of Wikipedia articles; but these concepts are not part of the *subClassOf* hierarchy, because their titles are not lexically similar to *Graph Property* and *Gene Silencing*, respectively.

Ponzetto and Navigli (2009) link Wikipedia *categories* to existing WordNet synsets, leveraging the category structure to enrich WordNet with concepts from Wikipedia. Wikipedia categories are mostly thematic, with no strict hierarchical structure and do not represent a taxonomy, but they do tend to be somewhat hierarchical for concepts low in the hierarchy (i.e., more specific concepts). For example, *Public transport in Stockholm* is in the category *Public transport in Sweden* which is in the category *Public transport*, and the latter corresponds to a synset in WordNet. However, this is not true for many scientific concepts, where even the more general concept does not appear in WordNet. For example, *Clustering coefficient* is in the category *Graph invariants*, but the categories above that are purely thematic, and WordNet does not contain a synset for *Graph invariant*. Similarly, the term *CRF* is the title of a disambiguation page, which does not belong to any categories and so would not be linked to *Conditional Random Field*.

Syed and Finin (2010) match each Wikipedia article to a WordNet synset as a hypernym-like superclass. Their method relies on the synset-category mappings of (Ponzetto and Navigli, 2009), extending it with information obtained from the hyperlink structure of the Wikipedia articles. However, this approach is still limited by the choice of categories for each article. In addition, it does not work as well for articles with a small number of hyperlinks, which is typical of the more specialized scientific articles.

There have also been attempts (Auer et al.,

2007; Wu and Weld, 2008) to build ontologies from the *infoboxes* of Wikipedia articles, which commonly occur in articles of (e.g.) people and places but not in the articles of most domain-specific concepts.

There has also been work mapping words from Wikipedia articles to particular senses within WordNet using WSD techniques (Mihalcea, 2007; Milne and Witten, 2008). Our work is different in that we attempt to create a thesaurus specifically containing terms that are not in WordNet.

## 2.1 Contrast to Related Work

In addition to not being optimal for the scientific domain, these approaches all have in common that in attempting to extend WordNet using Wikipedia they rely on the structural information in WordNet directly. This generally means that the further down the hierarchy a term is (that is, the further it gets from the most specific hypernym available in WordNet) the less accurate the constructed taxonomy becomes with regard to its relations. This again works well for some entities, where WordNet contains reasonably specific concepts (e.g., occupations and nationalities for people, industries for organizations) but not too well for specialized concepts in specific domains.

In contrast, in our approach, WordNet is only used to provide the labels for very few relations (5,000) that are used in training and (separately) in evaluation. However, these relations are all considered individually. We do not rely on the WordNet hierarchical structure as a whole; instead, we learn to classify the relation between a pair of terms using only information from their Wikipedia article content. This makes our method more robust with regard to very specific concepts. Evaluating other methods using gold data from WordNet may be biased, because concepts from WordNet (even if they are not used directly in ontology construction) are inevitably close to other concepts in WordNet. It can be expected that for more highly specialized concepts, these methods will not perform as well. In our approach, there is nothing special about a relation whose concepts appear in WordNet, and performance on those should give a good indication of performance on other relations (perhaps with the caveat that concepts which appear in WordNet may have larger corresponding articles on average).

## 3 Data and Definitions

Since we want our terms from Wikipedia to refer to concepts, we remove from the Wikipedia corpus all the pages whose title begins with a wikipedia special prefix. These prefixes are single words followed by a colon, and denote a special type of wikipedia page, such as Template, Category or File. We also remove all pages whose title does not contain at least one English letter character.

We define a Wikipedia term as any Wikipedia article title and any redirect title which passes the filters above. This lexical definition is motivated by the need to find synonymy and hypernymy. It also makes evaluation (which we do using WordNet) more straightforward. To make things even simpler, we completely ignore senses. While word sense disambiguation has been a major part of some related work, it is less crucial for our purposes since specialized terms are less likely to be ambiguous than general terms. We hypothesize that the Wikipedia article itself describes the concept that is referred to by the term.

We define a WordNet term as any term (synonym) participating in any noun synset in WordNet. Wikipedia terms are matched to WordNet terms lexically, with some pre-processing: we lowercase the titles, replace underscores with spaces, remove diacritics from unicode characters and remove text in parentheses (which are commonly used in Wikipedia to disambiguate senses).

Using our definition, there are 117,092 WordNet terms. The total number of potential terms from Wikipedia is 9,096,022, which covers 73.62% of the WordNet terms. WordNet has 494,892 hypernym and synonym relations between all terms. The set of all potential relations from the Wikipedia term set (which is 9,096,022<sup>2</sup> in size) covers 63.71% of those.

We define our task as a binary classification over all potential relations from the Wikipedia term set. For each ordered pair of terms, we want to decide whether the first is a hypernym of the second or not. If two terms are determined to both be hypernyms of each other we treat them as synonyms. We evaluate on a dataset sampled from that subset of the Wikipedia terms which also exist in WordNet.

To determine the relations for all Wikipedia terms, the space of potential relations must first be dramatically reduced from its current size of over 82 trillion data points. In this paper, we present

results on sampled subsets.

## 4 Features

We extract fourteen features of four general types. For most of these, it is essential that each term in the pair corresponds to a Wikipedia article. Each term matches either the article title, or a redirect title that redirects to the article.

### 4.1 Features from the hyperlink structure of Wikipedia

We utilize the graph structure of hyperlinks between articles to build the following eight features:

1. First article links to second (yes or no)
2. Second article links to first (yes or no)
3. The cosine similarity between the outgoing links of the articles
4. The ratio of outgoing links in the first article shared by the second article
5. The ratio of outgoing links in the second article shared by the first article
6. The cosine similarity between the incoming links of the articles
7. The ratio of incoming links in the first article shared by the second article
8. The ratio of incoming links in the second article shared by the first article

One of the powerful aspects of Wikipedia is its hyperlink structure. Based on the simple assumption that article A links to article B only if the information in B is related to or somehow assists in understanding the information in A, the intuition is that two articles having a semantic relation will more often link to one another, and will in general link to more similar (additional) articles than will two unrelated articles. The Wikipedia hyperlink structure has been used to compute similarity between articles, for example in (Syed and Finin, 2010) and (Yazdani and Popescu-Belis, 2010).

Wikipedia links contain two bits of information: the title of the article they link to, and the text of the hyperlink as it appears in the referring article. For features (1) and (2), we allow both: that is, even if a hyperlink links to a third article, but uses the relevant article's title in the text,<sup>1</sup> we count that as a link to the relevant article. For the other features, we use only the title of the actual linked articles. The reason is that in features (1) and (2) we

<sup>1</sup>For example, a link for the article *New York City* may have only *New York* in the text, which is the title of an article about the state

want to measure something different than in the rest: whether or not one of the articles mentions the other directly (hyponyms often mention their hypernyms, while hypernyms sometimes list their hyponyms). An article being mentioned by name in a hyperlink, even when the link goes elsewhere, answers that criteria. The other features are intended to capture the similarity of the two articles based on how related the links to/from them are, and so using the text is less relevant (and that information would be captured to some extent by the feature in the next category instead).

### 4.2 Features from the text of the articles

For each article, we build a bag-of-words vector. These vectors are used to compute the cosine similarity between the two articles of a pair, which we use as a feature.

The intuition behind this central feature is that articles having a semantic similarity will also have a higher lexical similarity. This is the same intuition behind distributional similarity (Church and Hanks, 1990), which is that terms surrounded by similar context tend to be semantically related. In this case, the context does not surround the terms but is in the body of the articles corresponding to them. Lexical similarity between Wikipedia articles has been used successfully to link articles, for example in (Yazdani and Popescu-Belis, 2010).

### 4.3 Features from the redirect structure of Wikipedia

The Wikipedia dump contains a list of redirects from multiple alternative titles to each article. We use those to build three boolean features:

1. The first term redirects to the second term's article (yes or no)
2. The second term redirects to the first term's article (yes or no)
3. Both terms redirect to the same, third article (yes or no)

As mentioned earlier, redirect titles are often synonyms, hypernyms or hyponyms of the main title of the article they redirect to. While it is not consistent enough to use as a strict rule, this structure can be taken advantage of in features.

### 4.4 Features from the terms (i.e. the article titles)

In some cases, the terms themselves can point at the relation among them. In particular, hyper-

nyms are sometimes lexical subsets of their hypernyms (*String Theory* is a hypernym of *Super String Theory*; *Leukemia* is a hypernym of *lymphocytic leukemia* which in turn is a hypernym of *B-cell chronic lymphocytic leukemia*).

We therefore derive two features from the terms themselves (which correspond to article titles or redirect titles): the difference between the number of words in the two terms, and the number of words which overlap in the two terms.

## 5 Method and Evaluation

Our training, development and test data sets all consist of ordered pairs of terms from Wikipedia where both terms also appear in WordNet. The label is positive if the first term in the pair is a hypernym (or a synonym) of the second. The positive samples (which consist of pairs exhibiting either hypernymy or synonymy) are sampled from the relations in WordNet. To get negative samples we randomly pair terms from WordNet that have no relation between them.

We train two SVM classifiers: one on a small training set of 5,000 labeled pairs, and the other on a much larger set of 100,000 pairs. In both cases, the training sets are balanced and we used a balanced development set of 186,000 pairs. We then evaluate on a large unbalanced test dataset of 10 million pairs. Using the number of WordNet's total potential relations ( $117,092^2$ ) and the number of its true relations (494,892), we estimate the ratio of real relations in the natural set of all potential relations to be around 0.0036%. Estimating the factor by which we aim to reduce the size of the total space (of 82 trillion) as 1,000, the test set is then built using 360,000 sampled true relations from WordNet, while the rest are randomly paired concepts (which appear in WordNet but have no relation between them).

To illustrate our performance specifically on the science domain, we constructed a second data set using Wikipedia's category hierarchy. In this data set, we included only terms such that their corresponding articles are in a category which is a descendent of the *Science* category with a depth of no more than 20, but are *not* descendents of one of the following categories with a depth of 5 or less: *People*, *Places*, *History*, *Chronology*, *Music*, *Film* and *Sports*. These exclusions are required because descendents of the *Science* category include articles for entities such as scientists and

universities, certain historical dates/eras, and expansions of the technologies used in the music, film and sports industries to include entities from these fields (songs, bands, movies...) which then completely overwhelm the data set in size. The depth restrictions are necessary because the category graph is cyclic. In addition to illustrating performance in our intended domain, this test set is important in that it features negative samples that are not entirely random, since they are at least thematically related. The size of this set is 258,971, and it is unbalanced with about 10% positive samples. Note that we use the same classifier (trained on the same unrestricted training set) when evaluating on all test sets, including this one.

To illustrate our approach's advantage over naive methods, we include the results for two baselines. The first uses only the term names and makes predictions based on the Levenshtein distance between them (predicting synonym for distance  $< 8$ , hypernym for distance  $< 12$ , and none otherwise). The second predicts the relation type based on the lexical cosine similarity between the articles (predicting synonym for similarity  $> 0.1$ , hypernym for  $> 0.05$ , and none otherwise). The thresholds in both baselines were manually tuned to optimize f-measure on the development set.

In addition, we compare our performance with that provided by querying two leading publicly available ontologies that were constructed using Wikipedia's category hierarchy and infoboxes: Yago (Suchanek et al., 2007) and DBPedia (Auer et al., 2007).

We show two binary evaluations for each data set. The main evaluation, where a positive answer means the (ordered) pair has a hypernymy relation, is shown in Table 1. *SynonymOrNot*, in Table 2, is an additional evaluation over those pairs that were judged as having a relation in the first evaluation, and a positive answer means the pair is a synonym. Recall that we mark as synonyms those pairs that are determined to have both directional hypernyms. We found the results to be statistically significant using a standard t-test.

## 6 Discussion

The first thing to notice is that the SVM classifiers operate as high-precision, lower-recall systems for both tasks. On the *SynonymOrNot* task, precision is extremely high while retaining a reasonable recall even on the unbalanced test set. This is impor-

	Bal. P	Bal. R	Bal. F	Un. P	Un. R	Un. F	Sci. P	Sci. R	Sci. F

SVM (trained on 100K samples)	99.92	29.92	46.05	99.62	44.46	61.48	97.75	58	<b>72.8</b>

Table 2: **Precision, Recall and F-measure** obtained for each data set for **SynonymOrNot**. **Bal.** stands for **balanced**, the balanced development data set, **Un.** stands for **unbalanced**, the unbalanced test data set, and **Sci.** stands for **science**, the science-only filtered test set.

tant, since a high precision is crucial to maintaining coherence in tasks such as lexical choice.

The classifiers beat both baselines on the main task. The lexical baseline does quite well on the *SynonymOrNot* task, but its performance deteriorates on the unbalanced test sets while the classifiers’ performance actually significantly increases due to its high-precision nature.

While the ontologies (Yago and DBPedia) offer incredibly high precision in all cases, their recall is very low (often less than 1% in DBPedia). This is because they focus on entities that are well defined through the category hierarchy and/or infoboxes, which most Wikipedia articles are not.

Overall, the classifiers beat both baselines and both ontologies in both tasks on both test sets. Most importantly, we achieve a relatively high performance on the science domain test set, which is our main goal in this paper.

Finally, it is interesting to note that there is little difference in performance between the SVM when trained on a small training set and when trained on a much larger training set. It seems that whatever can be learned about the data using these features (which is quite a bit, given the performance and especially the precision using this simple approach on a highly unbalanced test set) is learned very quickly, even from a small sampled set.

## 7 Conclusion and Future Work

We described a simple supervised method of classifying pairs of Wikipedia article titles in terms

of the relation among them, covering synonymy and hypernymy. Our approach significantly outperforms the baselines on simulated target data, and achieves very high precision. Unlike previously described approaches, it does not rely on the WordNet hierarchy as a whole, but only on the properties of the individual pair.

In order to use this method in building a taxonomic thesaurus from Wikipedia, we must first reduce the space of potential articles, which is tens of trillions in size. We leave this task and the task of building a full thesaurus to future work. Even without the full thesaurus, our approach can be used to make on-line decisions about the relation between any arbitrary pair of terms.

## Abstract

Chinese time entity is quite complex. In this paper, we give a comprehensive linguistic study on it. Based on the analysis, we present a rule system which only considers the inner structure of Chinese time entities for the recognition. Experiments on Sinica and TempEval-2 corpus show that the rule system performs much better than the CRFs model. When using the rules as features within a CRFs model, the performance could be further improved.

## 1 Introduction

In SemEval-2010 competition, there is a sub task for temporal entity identification, which includes a Chinese corpus. The final goal of the task is to associate a temporal expression to a certain event. It is very important to extract all the elements for events in that it will be useful for event tracking. By identifying the time information of events will enable us to make inference on the temporal relation of different events.

In this paper, we will make a comprehensive study on Chinese time entities from a linguistic perspective and then present a rule system for recognizing them. Chinese temporal entity is very complex due to the flexible grammar of Chinese and the existence of many different time systems, such as Gregorian system, the Chinese lunar system, the Chinese tian-gan & di-zhi (GZ) time system.

Based on our linguistic analysis, we formalize a set of temporal elements that are the blocks used to construct time entities, such as *century*, *year*, *month*, *day*, *hour* etc. We then build a rule system that actually describe the topology of the temporal elements. For example, *year* follows *century*; *month* follows *year*. So, the model of our system is a directed graph, while a

valid temporal expression is a path from one certain node to another node. The longer the path is, the more confident the recognition will be.

CTEMP (Wu et al., 2005) also used linguistic rules for Chinese temporal entity recognition. However, the focus of this work differs from them in that we aims to identify Chinese time entities which could be described with a limited set of rules and can be easily translated into a structured format, such as TIMEX3(Pustejovsky et al., 2010) standard. For this part, the set of rules in this work are more comprehensive than (Wu et al., 2005). However, we don't include events that are used as time entities, since events intrinsically are not time entities. According to the Generative Lexicon Theory (Pustejovsky, 1995), this is a case of type coercion.

In Section 2, we will give a linguistic study on Chinese time entity expressions. In Section 3, we will construct a rule system which is mainly based on our linguistic study. In Section 4, we test rule system on Sinica and TempEval-2 corpora and give a discussion on the experimental result. Section 5 is the conclusion.

## 2 Chinese time entity: A linguistic study

We refer to Y.R. Chao's book (Chao, 1968) as a starting point of our study. In China, there are different time systems, including the lunar system, TianGan-DiZhi (GZ) system, etc. In ancient China, people used the emperor's reign to count time. When a new emperor appeared, a new period would then started.

In another perspective, people try to divide the time axis by different levels of granularity. Roughly, the whole axis can be divided into three periods: *guo-qu* (past), *xian-zai* (present) and *jiang-lai* (future). Smaller granularity includes century (*shi-ji*), year (*nian*), season (*ji-jie*), month (*yue*), day (*ri*), hour (*shi*), minute (*fen*), second (*miao*). Week (*zhou*) is a granularity that is independen-

t to year, season and month. In China, there are also jie-qi (JQ) that divides one year into 24 different periods. One month can also be divided into 3 periods (XUN): the first ten days (shang-xun), the second ten days (zhong-xun) and the left days (xia-xun). One day can also be divided into different vague phases (DP), e.g. before dawn (ling-chen), early morning (zao-shang), morning (shang-wu), noon (zhong-wu), afternoon (xia-wu), evening and night (wan-shang), midnight (wu-ye).

To compile rules for the automatic recognition of Chinese time entities, one important issue is to find out the construction regularity for each temporal element and the relations among the elements, which is also the inner structure of Chinese time entities.

## 2.1 Gregorian system and Chinese lunar system

Gregorian system starts from the year of Christ's birth. Before this year, B.C. (gong-yuan-qian) is used with a number to denote time on the time axis. After this year, A.D. (gong-yuan) is used, which is also the default value. Chinese supports this system. For example, 2013-08-08 09:01:01 is said in Chinese (gong yuan) *er-ling-yi-san-nian ba-yue ba-ri jiu-dian ling-yi-fen ling-yi-miao*.

One hour can also be divided into four quarters (ke). However, only *yi-ke* (fifteen) and *san-ke* (forty five) are valid expressions. For the half of an hour, *ban* (half) is used. *zheng* (right) will be used as the right start of an hour. So, *zheng, yi-ke, ban, san-ke* are the four possible values for the *KE* element.

One year can be divided into four quarters (ji-du:JD) or (ji-jie:season). An ordinal number will be used to refer to a certain JD, such as *di-yi ji-du* (the first quarter). The ordinal marker *di* could be omitted. So, *yi ji-du* is also a valid expression. Each season has its own name: spring (chun-ji), summer (xia-ji), autumn (qiu-ji) and winter (dong-ji).

For hours, day phases (DP) could be added before them. The DP is usually placed before *hour*, such as *ling-chen san-dian* (3:00am), *wu-ye shi-er-dian* (0:00). However, the boundaries of different phases are not clear, such as *xia-wu/wan-shang liu-dian* (6:00 in the afternoon/evening).

Century (shi-ji) can be followed by decade (nian-dai), such as *er-shi-shi-ji jiu-shi-nian-dai*

(the 90s of 20th century). The first decade is usually called *ling-ling-nian-dai* (00s) or *tou-shi-nian* (first ten years).

If *gong-yuan* (A.D.) or *gong-yuan-qian* (B.C) is used before *century* or *year*, then the numbers will be written as the pronunciation of the number rather than a sequence of digits. For example, *gong-yuan liang-qian-ling-yi-shi-san nian* is similar to be said as two thousand and thirteenth years A.D. in English. Otherwise, year 2013 will be written as *er-ling-yi-san-nian* (two-zero-one-three year).

Chinese lunar time system uses a similar way to denote time as the Gregorian system. However, it refers to the movement of the moon to count months. So the start of one year in lunar system is different from the Gregorian system. We can use a flag '&' (nong-li) to denote the lunar system, such as *& 2013-08-08*. In addition, the lunar system uses *chu* before the day number for the first ten days of a month in order to make up of two syllables, while the day marker *ri* is usually omitted. For example, Aug. 8th is said *ba-yue chu-ba*, Aug. 11th is said *ba-yue shi-yi*. The lunar label *nong-li* can also be placed before the subsequence of *year-month-day*, such as *nong-li wu-yue chu-wu (& 05-05)*, *nong-li chu-wu (& 05)*' etc.

## 2.2 TianGan-DiZhi system

This system was invented in Ancient China based on a the Chinese traditional philosophical theory. There are ten heavenly stems (tian gan: TG): *jia, yi, bing, ding, wu, ji, geng, xin, ren, gui* and twelve mundane branches (di zhi: DZ): *zi, chou, yin, mao, chen, si, wu, wei, shen, you, xu, hai*. Then, one year is denoted by a combination of two different elements circularly, which generates sixty different denotations. If we use a sequence number to denote the two elements, i.e.  $TG_{0-9}$  and  $DZ_{0-11}$ , then the  $i$ th year of a circulation is defined as  $y_i = TG_{i\%10}DZ_{i\%12}$ , where  $0 \leq i < 60$  and  $\%$  is the *mod* operation. For example, *gui-si-nian* (2013) can be formally denoted as year  $TG_9DZ_5$ , or simply  $GZ_{9,5}$ . Similarly, month, day and the Chinese hour can also be denoted like this.

The twelve DZ items are also associated with twelve animals (sheng xiao: SX): *shu* (mouse), *niu* (cattle), *hu* (tiger), *tu* (rabbit), *long* (dragon), *she* (snake), *ma* (horse), *yang* (sheep), *hou* (monkey), *ji* (chick), *gou* (dog), *zhu* (pig). So, one year can also be simplified as [*animal*] *nian*. For example,

year 2013 can be also called as *she-nian* (year of snake), or formally denoted as  $SX_5$ . However, this kind of expression can only be said alone. It can rarely be said with month and day, such as *\*she-nian wu-yue* (the 5th month of year of snake).

### 2.3 Jie-Qi

As we have mentioned, there are also twenty four Jie-Qi (JQ) within one year: *li-chun, yu-shui, jing-zhe, chun-fen, qing-ming, gu-yu, li-xia, xiao-man, mang-zhong, xia-zhi, xiao-shu, da-shu, li-qiu, chu-shu, bai-lu, qiu-fen, han-lu, shuang-jiang, li-dong, xiao-xue, da-xue, dong-zhi, xiao-han, da-han*. Every six JQs corresponds to and divide one season. The JQs are actually time words and included in Chinese dictionaries. *JQ* usually follows *year* element, such as *er-ling-yi-san-nian qiu-fen* (qiu-fen of 2013).

### 2.4 Regnal year system

Ancient Chinese people have seen a new emperor as a starting point of a new period. A number is used to count the following years after that year. The first year is called *yuan-nian*, the second year is called *er-nian* (2nd year), etc. For example, *QianLong yuan-nian* stands for the year when QianLong became the emperor. However, there are hundreds of emperors in the history of China, and many of them are not recorded at all. So, the list of emperors is hard to be complete. Usually, the most used regnal years refer to the Qing Dynasty.

### 2.5 Weekdays

Weekdays (*xing-qi*) are expressed by *xing-qi* plus a number from one to six. Sunday doesn't use seven, but *ri/tian* (day). Formally, they can be written as  $XQ_{0-6}$ . *xing-qi* is also called *zhou* (week) or *li-bai* (go to church) that is borrowed from religious activities. However, when we use *zhou*, Sunday cannot be said as *\*zhou-tian*. Week days are usually placed after *day* and before *hour* as a parenthesis, such as *2013-10-15 (Tuesday) 3:00pm*.

### 2.6 Festivals and Events

Some days or day sequences are named as festivals. Festivals are usually based on Gregorian system, such as the national day (*guo-qing*). In China, there are some festivals that are based on lunar system, such as the autumn day (*zhong-qiu*), which is & *08-16*. Some JQs are also regarded as festivals, especially when there are vacations for them, such

as *qing-ming festival*. Festivals are usually used independently to other temporal elements. Meanwhile, most of the festivals have been lexicalized and included in dictionaries.

Some festivals' dates are dynamic. For example, Thanksgiving is the fourth Thursday of November in the United States. For such festivals, we need to construct a function to automatically select a certain day in the year of context, e.g. *select(Thursday, 4, November, \$Year)*. From this point of view, we need to build ontology for translating festivals into the TIMEX3 standard.

An event can denote a time, such as *hun-qian* (before marriage), *shi fa dang tian* (the day when it happened) etc. Sometimes, a time operator can explicitly change the event into a time entity, such as *qian* (before), *hou* (after) etc. However, such expressions are hardly to be complete, and we don't deal with events in this system.

### 2.7 Referential time

The demonstrative, such as *zhe* (this) and *na* (that), can be placed before some temporal elements to form a referential time (ref). For example, *zhe-yi-nian* (this one year), *ben-shi-ji* (this century). The general pattern of such construction is  $[zhe/na]+[number]+[classifier]$ . There are also some lexicalized referential time expressions, such as *jin-nian* (this year), *ming-tian* (tomorrow) etc.

### 2.8 Durations

Duration is an interval of two time spots, i.e. the starting time and the ending time, connected by *dao/zhi* (to). *cong* (from) can also be placed in front. For example, *(cong) shi-yue shi-wu-ri dao shi-yue shi-qi-ri* (Oct. 15th - Oct. 17th). When there is only one temporal element in the starting and ending time, which means that their parent elements are the same, the first time marker can be omitted. For example, *shi-yue shi-wu-(ri) dao shi-qi-ri* (Oct. 15-17). Sometimes, only the length information is expressed, such as *liang-nian* (two years), which is made up of a Chinese number plus a classifier.

### 2.9 Period phases

When talking about a specific time period, we can refer to its different phases, e.g. its starting period (*chu-qi*), middle period (*zhong-qi*) and final period (*mo-qi/hou-qi*). Period is different from duration

in that duration emphasizes the length, while period not. So, '\*liang-nian chu-qi' (the start of two years) is an invalid expression.

### 3 A rule system for Chinese time entity recognition

So far, we have discussed 24 temporal elements: *century, decade, year, month, day, hour, minute, second, season, XUN, JQ, JD, DP, SX, lunar, GZyear, SXyear, GZmonth, GZday, GZhour, regnalyear, weekday, festival, periodphase*. Since festivals are lexical time expressions and it is hard to provide a complete list of festivals, we don't recognize festivals in this version. However, it is possible to build festival ontology which could be used to translate them into Gregorian calendar. We also add a limited set for the referential time expressions such as *jin-tian* (today), *ben-shi-ji* (this century) etc. This introduces 9 elements: *refcentury, refyear, refmonth, refday, refhour, refminute, refsecond, refJD, refdecade*.

The rule system is actually trying to describe the topological relations of the elements. The final model is a directed graph, containing 32 nodes and 50 edges. Table 1 shows a subset of the edges as demonstration. There are three different symbols in the rules. *A-B* means *B* follows *A*. *>* and *<* means 'stick to'. For example, *A > B* means *A* follows and depends on *B*. In other words, *A* cannot be used alone. *A <> B* means that they stick to each other. We should note that *<>* doesn't mean that they must appear together. For example, if there is another rule *A <> C*, then *A* can appear together either with *B* or *C*.

century - decade	refcentury - decade
year - jq	refyear - jq
year - jd	refyear - jd
year - month	refyear - month
month - xun	refmonth - xun
month - day	refmonth - day
hour<ke	gzhour<ke
lunar>year	lunar>month
lunar>gzyear	gzyear - gzmonth
day - dp	dp - hour
hour<minute	minute<second

Table 1: Topological Relation of Temporal Elements.

The recognition of time expressions includes two phases: identify the temporal elements and then concatenate the elements to get sequences based on the topological relations of them and the constraints described in Table 1. The recognition of temporal elements are implemented by regular expressions. The topological relation could be modeled as an acyclic graph.

#### 3.1 Convert to TIMEX3 format

In Chinese, the numbers in each temporal element can be a sequence of either Chinese or Arabic digits. For example, *er-ling-ling-san-nian* (year 2003) can also be written as *2003-nian*. For this kind of expressions, we need a parser to get the Chinese numbers first, which has been embedded in our system. Meanwhile, it can also parse them into machine readable integers.

In Chinese, we can also use Arabic numbers. In our system, we build a parser that could translate both Arabic and Chinese number into machine readable integers. However, due to the space limitation, we will not describe the parser here. Once we get numbers for each element. Some heuristic rules can be used to filter some false positive examples. For instance, *er-shi-san-dian* (23:00) is a legal time expression, while *er-shi-wu-dian* (25:00) is illegal. It appears in text because it can also mean (25 points). We add constraint on the value of *month*(1, 12), *day*(1, 31), *hour*(0, 24) etc.

Based on our rule system, the converting to TIMEX3 format is quite straightforward since the rules are based on the inner structures of Chinese time entities. In cases of referential temporal elements, such as *refyear, refday*, we can first place a variable for further processing, since the resolution of such references is an independent task. However, this will be our future work. For festivals, as we mentioned that most festivals have fixed date. So, a festival dictionary will be needed.

Nevertheless, translating time entities into machine readable format is a great advantage of rule systems. Even though static methods can give higher performance on recognition, there is no obvious way how to convert the time entities into machine readable format unless conversion rules are compiled, which then will resort to the inner structure of the entities which is then the work done by our rule system.

Corpus	#Words	#Entity
Sinica	10M	88K
TempEval-2 Training	23K	766
TempEval-2 Test	10K	191

Table 2: Corpus Information.

## 4 Experiments

We use two different corpora: Sinica (Chen et al., 1996) and TempEval-2 from SemEval-2010 competition (Pustejovsky and Verhagen., 2009). Sinica Corpus contains 10M words and the total number of time entity is 88K as shown in Table 2. The time words are tagged as ‘Nd’. However, there is no entity information. So, when an entity is recognized by our system, we first separate it into elements and then calculate the performance. Durations are labeled as *number + classifier* in Sinica, which are not time words. So, we don’t recognize durations in Sinica. For regnal year system, we only include a list of emperors of the Qing dynasty. We don’t deal with festivals as most of them are already lexicalized and are beyond the scope of entities. In other words, they can be recognized with a dictionary in a general word segmentation task.

TempEval-2 corpus includes training and test parts, as shown in Table 2 We analyse the annotation scheme based on training data and then add some additional rules on durations, such as *shinian* (ten years), *shi-tian* (ten days), and some approximate expressions, e.g. *shi-ji-nian* (more than ten years) and so on. Meanwhile, we add three new elements: *past* (guo-qu), *present* (xian-zai), *future* (jiang-lai). Each element includes a list of Chinese words.

### 4.1 Experimental results and Discussion

Table 3 shows the overall performance on Sinica and TempEval-2 corpora. Our rule system gives a high performance. Table 4 shows the precision and the number of recalled entities for some selected frequent patterns from 91 patterns identified from Sinica. Some long patterns give 1.0 precision. Some patterns are quite ambiguous, such as *hour-minute*. This is due to fact that *dian* means both the point in float numbers and time hour, and *fen* means both minute and score point in Chinese. For example, *san dian wu fen* means both 3:05 and 3.5 points. Regarding the different performances of different patterns, we can assign a confidence

Corpus	Precision	Recall	F1

day	0.8571	6
year-month-day	0.8571	6
present	0.848	106
past	0.625	15

Table 5: Performance of the rule system on TempEval-2 training corpus.

mainly due to the annotation errors that have split certain temporal elements into number-classifier construction in Sinica Corpus. For example, *er-shi-wu-ri* (the 25th) is annotated as *er-shi-wu* (25) plus *ri* (day).

Most ambiguous patterns contain one element, such as *year* and *day*. They can be both a date and a duration when the number is expressed in Chinese or Arabic digits. For example, *13 nian* (13 year: year 2013) could also be thirteen years. In Sinica, durations are labeled as *number + classifier*, which are not time words. In TempEval-2 corpus, both date and duration are entities. So, it will not be a problem for detection on this corpus. The ambiguity of such patterns introduced most of the false positive examples.

Table 5 and Table 6 show the identified patterns and their precision and the number of recalled entities. Compared to Sinica corpus, TempEval-2 corpus is quite sparse, and the element *refyear* such as *jin-nian* (this year) and *present* such as *mu-qian* (currently), take up a large part of the entities. This problem will affect the evaluation result in that the identification of time words e.g. *refyear* and *present* will be important to the overall performance.

In order to compare our rule system with the state-of-the-art statistical models. We also built a

CRFs classifier with CRF++<sup>1</sup> on TempEval-2 corpus. The features used are shown in Table 7. To study whether the rule system could help the statistical model, we also use the recognition results of our rule system as pattern features. The result is shown in Table 8. We can see that the rule system gives a much higher performance than CRFs without using the patterns as features, i.e. 0.8564 v.s. 0.7787.

we also conduct experiment to test the statistical model based on characters with features shown in Table 9. This setting is actually more reasonable than word based, since word segmentation and entity recognition are overlap tasks. The result is shown in Table 10. We can see that, compared to word based setting, the performance increased

Table 10: Performance of time entity extraction with CRFs based on characters on TempEval-2 corpus.

from 0.7787 to 0.7831. This may due to the fact that with the segmentation information, the context features will be more sparse. When combining the patterns in CRFs model, the performance could be slightly improved. Overall, we can say that the inner structure of Chinese time entity is more important than context features.

**The false negative examples of the rule system in Sinica** includes some patterns that are not included in our system, some of which we think is not normal constructions of time expressions. For example, an Arabic digit sequence without the year marker *nian*, such as 2013, is also possibly a year element. Another one is the regnal year pattern, i.e. the *min-guo* period established in 1912 after Qing dynasty. However, there are many examples like *ba-shi-ba-nian* (88th years) with *min-guo* omitted.

**The false negative examples of the rule system in TempEval-2** includes some time word-

s that are not encoded in the rules. Some entities contains weekdays as a parenthesis, such as *jin-ri (xing-qi-er)* meaning *today (Tuesday)* will be treated as two entities. Some durations such as *san-[pause punctuation]-wu-nian* (three to five years). These are also not included in our system. The bare-number year is also a problem in this corpus.

## 5 Conclusion

In this paper, we made a linguistic study on Chinese time entities and presented a rule system for automatic recognition. We compare our system with CRFs model and the experiments on two different corpora showed that it gave a higher performance than the baseline system based on a CRFs model. When combining the rules with CRFs, the performance could be improved.

## Abstract

This paper attempts to identify the importance of sentiment words in financial reports on financial risk. By using a finance-specific sentiment lexicon, we apply regression and ranking techniques to analyze the relations between sentiment words and financial risk. The experimental results show that, based on the bag-of-words model, models trained on sentiment words only result in comparable performance to those on origin texts, which confirms the importance of financial sentiment words on risk prediction. Furthermore, the learned models suggest strong correlations between financial sentiment words and risk of companies. As a result, these findings are of great value for providing us more insight and understanding into the impact of financial sentiment words in financial reports.

## 1 Introduction

Sentiment analysis is the task of finding the attitudes of authors about specific objects. In recent years, because of the explosion of sentiment information from social web sites (i.e., Twitter and Facebook), blogs, and online forums, sentiment analysis has become one of the popular research areas in computational linguistics, such as (Narayanan et al., 2009; Mohammad and Turney, 2010).

The growing importance of Sentiment Analysis applied to finance brings forth many research and practical issues to minds like “Why Sentiment Analysis is important?” In finance, there have been several studies (Loughran and McDonald, 2011; Price et al., 2012; Garca, 2013) using textual analysis to examine the sentiment of numerous news items, articles, financial reports, and tweets about public companies. Then, the examined sentiments can be used to reflect the correlations with other fi-

ancial measures, such as stock returns and volatilities. For most sentiment analysis algorithms, as mentioned in (Feldman, 2013), the sentiment lexicon is the most important resource. In (Loughran and McDonald, 2011), the Harvard Psychosociological Dictionary, a common dictionary for general sentiment analysis, is extended to be a finance-specific sentiment lexicon.

In this study, we attempt to use the finance-specific sentiment lexicon to model the relations between sentiment information and financial risk. In specific, we formulate the problem as two different prediction tasks: regression and ranking. For the regression task, we aim to use sentiment information to predict a company’s future risk, which is usually characterized by its real-value volatility. Instead of predicting the real-value volatility, in the ranking task, we try to employ sentiments to rank companies according to their relative risk levels. From the two tasks, we observe that, trained on the finance-specific sentiment lexicon only, both the regression models and ranking models can obtain comparable performance to those trained on original texts, even though the word dimension is largely reduced from hundreds of thousands to only one and half thousand. In addition, we also conduct some analyses on the learned models, which can provide more insight into the financial sentiments.

The remainder of this paper is organized as follows. Section 2 introduces the financial risk measure and describes the problem formulations. In Section 3, we describe the details of our experimental settings and then report the experimental results. Some discussions and analyses on the learned models are provided in Section 4. Section 5 concludes.

## 2 Methodology

### 2.1 Stock Return Volatility

In finance, volatility is a common risk metric measured by the standard deviation of a stock’s returns

over a period of time. Let  $S_t$  be the price of a stock at time  $t$ . Holding the stock for one period from time  $t - 1$  to time  $t$  would result in a simple net return:  $R_t = S_t/S_{t-1} - 1$  (Tsay, 2005). Therefore, the volatility of returns for a stock from time  $t - n$  to  $t$  can be defined as follows:

$$v_{[t-n,t]} = \sqrt{\frac{\sum_{i=t-n}^t (R_i - \bar{R})^2}{n}}, \quad (1)$$

where  $\bar{R} = \sum_{i=t-n}^t R_i / (n + 1)$ .

## 2.2 Financial Sentiment Lexicon

For most sentiment analysis algorithms, a sentiment lexicon is the most crucial resource. As mentioned in (Loughran and McDonald, 2011), a general purpose sentiment lexicon might misclassify common words in financial texts. As shown in their paper, almost three-fourths of the words in the 10-K financial reports from year 1994 to 2008, which are identified as negative by the widely used Harvard Psychosociological Dictionary, are typically not considered negative in financial contexts.

In this paper, we use a finance-specific lexicon that consists of the 6 word lists provided by (Loughran and McDonald, 2011) to analyze the relations between these sentiment words and financial risk. The six lists are shown as follows:<sup>1</sup>

1. Fin-Neg: negative business terminologies (e.g., *deficit*, *default*).
2. Fin-Pos: positive business terminologies (e.g., *achieve*, *profit*).
3. Fin-Unc: words denoting uncertainty, with emphasis on the general notion of imprecision rather than exclusively focusing on risk (e.g., *appear*, *doubt*).
4. Fin-Lit: words reflecting a propensity for legal contest or, per our label, litigiousness (e.g., *amend*, *forbear*).
5. MW-Strong (Strong Modal Words): words expressing strong levels of confidence (e.g., *always*, *must*).
6. MW-Weak (Weak Modal Words): words expressing weak levels of confidence (e.g., *could*, *might*).

<sup>1</sup>All these lists are available at [http://www.nd.edu/mcdonald/Word\\_Lists.html](http://www.nd.edu/mcdonald/Word_Lists.html).

## 2.3 Problem Formulation

### 2.3.1 Regression Task

Given a collection of financial reports  $D = \{\mathbf{d}_1, \mathbf{d}_2, \dots, \mathbf{d}_n\}$ , in which each  $\mathbf{d}_i \in \mathbb{R}^p$  and is associated with a company  $c_i$ , we seek to predict the company's future risk, which is characterized by its volatility  $v_i$ . Such a prediction can be defined by a parameterized function  $f$  as follows:

$$\hat{v}_i = f(\mathbf{d}_i; \mathbf{w}). \quad (2)$$

The goal is to learn a  $p$ -dimensional vector  $\mathbf{w}$  from the training data  $T = \{(\mathbf{d}_i, v_i) | \mathbf{d}_i \in \mathbb{R}^p, v_i \in \mathbb{R}\}$ .

Support Vector Regression (SVR) (Drucker et al., 1997) is a popular technique for training such a regression model. SVR is trained by solving the following optimization problem:

$$\begin{aligned} \min_{\mathbf{w}} V(\mathbf{w}) &= \frac{1}{2} \langle \mathbf{w}, \mathbf{w} \rangle \\ &+ \frac{C}{n} \sum_{i=1}^n \max(|v_i - f(\mathbf{d}_i; \mathbf{w})| - \epsilon, 0), \end{aligned}$$

where  $C$  is a regularization constant and  $\epsilon$  controls the training error. More details about SVR can be found in (Schölkopf and Smola, 2001).

### 2.3.2 Ranking Task

For the ranking task, our goal is to rank companies by using their financial reports according to the volatilities of stock returns. Following the work in (Tsai and Wang, 2013), we split the volatilities of company stock returns within a year into different risk levels, which can be considered as the relative difference of risk among the companies.

After classifying the volatilities of stock returns (of companies) into different risk levels, the ranking task can be defined as follows: Given a collection of financial reports  $D$ , we aim to rank the companies via a ranking model  $f : \mathbb{R}^p \rightarrow \mathbb{R}$  such that the rank order of the set of companies is specified by the real value that the model  $f$  takes. In specific,  $f(\mathbf{d}_i) > f(\mathbf{d}_j)$  is taken to mean that the model asserts that  $c_i \succ c_j$ , where  $c_i \succ c_j$  means that  $c_i$  is ranked higher than  $c_j$ ; that is, the company  $c_i$  is more risky than  $c_j$ . In this paper, we adopt Ranking SVM (Joachims, 2006) for the ranking task.

## 3 Experiments

This section first describes the details of our experimental settings. Then, we report the experimental results of the models trained on the finance-specific

sentiments only and those on original texts for the regression and ranking tasks.

### 3.1 Experimental Settings

#### 3.1.1 Corpora and Preprocessings

In the United States, the federal securities laws require publicly traded companies to disclose information on a regular basis. A Form 10-K, an annual report required by the Securities and Exchange Commission (SEC), provides a comprehensive overview of the company’s business and financial conditions, and includes audited financial statements. In this paper, the 10-K Corpus (Kogan et al., 2009) is used to conduct our experiments, in which only Section 7 “management’s discussion and analysis of financial conditions and results of operations” (MD&A) is used because the section contains the most important forward-looking statements about the companies.

For the preprocessing, in our experiments, all documents and the 6 financial sentiment word lists were stemmed by the Porter stemmer, and some stop words were also removed. Table 1 lists the statistics of documents and unique terms in each year. Table 2 shows the statistics before and after

stemming in each of the 6 financial word lists. Note that some words occur in more than one word list, so the number of unique stemmed sentiment words is 1,546 rather than 1,664.

In addition, the twelve months before/after the report volatility for each company (denote as  $v^{-(12)}$  and  $v^{+(12)}$ , respectively) can be calculated by Equation (1), where the price return series can be obtained from the Center for Research in Security Prices (CRSP) US Stocks Database. For the ranking task, in order to obtain the relative risks among companies, we categorize the companies of each year into 5 risk levels by following the work in (Tsai and Wang, 2013).

#### 3.1.2 Feature Representation

In our experiments, for the bag-of-words model, two word features are used to represent the 10-K reports. Given a document  $\mathbf{d}$ , two word features (i.e., TFIDF and LOG1P) are calculated as follows:

- $\text{TFIDF}(t, \mathbf{d}) = \text{TF}(t, \mathbf{d}) \times \text{IDF}(t, \mathbf{d}) = \text{TC}(t, \mathbf{d})/|\mathbf{d}| \times \log(|D|/|\mathbf{d} \in D : t \in \mathbf{d}|)$ ,
- $\text{LOG1P} = \log(1 + \text{TC}(t, \mathbf{d}))$ .

Above,  $\text{TC}(t, \mathbf{d})$  denotes the term count of  $t$  in  $\mathbf{d}$ ,  $|\mathbf{d}|$  is the length of document  $\mathbf{d}$ , and  $D$  denotes the set of all documents in each year. Note that IDF is computed from the documents in a single year because the document frequency of a specific word may vary across different years. Following (Kogan et al., 2009), we also use the logarithm of the twelve months before the report volatility (i.e.,  $\log v^{-(12)}$ ) as an additional feature. We denote these trained models as TFIDF+ and LOG1P+ hereafter.

#### 3.1.3 Evaluation Metrics

For the regression task, the performance is measured by the Mean Squared Error (MSE) between the predicted ( $\hat{v}_i^{+(12)}$ ) and true log-volatilities ( $v_i^{+(12)}$ ).

$$\text{MSE} = \frac{1}{n} \sum_{i=1}^n \left( \log \left( v_i^{+(12)} \right) - \log \left( \hat{v}_i^{+(12)} \right) \right)^2,$$

where  $n$  is the number of tested companies.

For the ranking task, two rank correlation metrics are used to evaluate the performance in our experiments: Spearman’s Rho (Myers and Well, 2003) and Kendall’s Tau (Kendall, 1938). Given two ranked lists  $X = \{x_1, x_2, \dots, x_n\}$  and  $Y =$

Task (Features)		2001	2002	2003	2004	2005	2006	Mirco-avg
Regression (LOG1P+)	Mean Squared Error							
	ORG	<b>0.18082</b>	0.17175	0.17157	0.12879	0.13038	0.14287	0.15271
	SEN	0.18506	<b>0.16367</b>	<b>0.15795</b>	<b>0.12822</b>	<b>0.13029</b>	<b>0.13998</b>	<b>0.14894</b>
Ranking (TFIDF+)	Kendall's Tau							
	ORG	0.62173	<b>0.63626</b>	0.58528	<b>0.59350</b>	0.59651	0.57641	0.59965
	SEN	<b>0.63349</b>	0.62280	<b>0.60527</b>	0.59017	<b>0.60273</b>	<b>0.58287</b>	<b>0.60458</b>
	Spearman's Rho							
	ORG	0.65271	<b>0.66692</b>	0.61662	<b>0.62317</b>	0.62531	0.60371	0.62939
SEN	<b>0.66397</b>	0.65303	<b>0.63646</b>	0.61953	<b>0.63133</b>	<b>0.60999</b>	<b>0.63403</b>	

Table 3: Experimental Results of Using Original Texts and Only Sentiment Words.

$\{y_1, y_2, \dots, y_n\}$ ,

$$\text{Rho} = 1 - \frac{6 \sum (x_i - y_i)^2}{n(n^2 - 1)},$$

$$\text{Tau} = \frac{\#\text{concordant pairs} - \#\text{discordant pairs}}{0.5 \cdot n \cdot (n - 1)}.$$

For the measure of Kendall's Tau, any pair of observations  $(x_i, y_i)$  and  $(x_j, y_j)$  is concordant if the ranks for both elements agree; that is, if both  $x_i \succ x_j$  and  $y_i \succ y_j$  or if both  $x_j \succ x_i$  and  $y_j \succ y_i$ . In contrast, it is discordant if  $x_i \succ x_j$  and  $y_j \succ y_i$  or if  $x_j \succ x_i$  and  $y_i \succ y_j$ . If  $x_i = x_j$  or  $y_i = y_j$ , the pair is neither concordant nor discordant.

### 3.1.4 Parameter Settings

For the regression task, linear kernel is adopted with  $\epsilon = 0.1$  and the trade-off  $C$  is set to the default value of SVM<sup>light</sup>,<sup>2</sup> which are the similar settings to those in (Kogan et al., 2009). For ranking, linear kernel is adopted with  $C = 1$ , all the other parameters are set as the default values of SVM<sup>Rank</sup>.<sup>3</sup>

## 3.2 Experimental Results

Table 3 tabulates the experimental results, in which the training data is composed of the financial reports in a five-year period, the following year of which is the test data. For example, the reports from year 1996 to 2000 constitute a training data, and the learned model is tested on the reports of year 2001.

We compare the performance of the models trained on the original texts (denoted as ORG hereafter) with those on only sentiment words (denoted

as SEN hereafter). In our experiments, the word feature LOG1P is chosen for the regression task and TFIDF for the ranking one, as suggested in (Kogan et al., 2009) and (Tsai and Wang, 2013). Note that in these two studies, their models are trained on the original texts and the results are listed in the row denoted as ORG in Table 3. The bold face number in the table denotes the best result between ORG and SEN. As shown in the table, for the two tasks, the results of using only sentiment words, in most cases, perform better than those of using the original texts.

## 4 Analysis

### 4.1 Ranking vs. Regression

Figure 1 shows the top 10 learned words from both the ranking (TFIDF+) and regression (LOGP+) models trained on sentiment words only (SEN); in addition, the figure also lists the accumulated numbers of these words appearing in the 6 corresponding regression or ranking models.

Observe that the words learned from the ranking models are much more consistent than those from the regression ones. For example, the words "amend," "deficit," "forbear" appear in all of the 6 ranking models; in addition, there are 7 words from the ranking models get the majority vote with more than 4 occurrences, whereas only 3 words from the regression ones occur more than 4 times. On the other hand, there are 11 words from the ranking models and 20 words from the regression ones that occur only one time. The results shown in Figure 1 correlate with the findings in (Tsai and Wang, 2013), which states that adopting the ranking models to analyze the relations between financial risk

<sup>2</sup><http://svmlight.joachims.org/>

<sup>3</sup>[http://www.cs.cornell.edu/people/tj/svm\\_light/svm\\_rank.html](http://www.cs.cornell.edu/people/tj/svm_light/svm_rank.html)

Figure 1: Number of Occurrences of the Top 10 Weighted Terms Learned via the Ranking and Regression Tasks. The notation \* denotes that except the term “concern” there are other terms that occur only one time among 6 ranking models, which are listed as follows: *breach, profit, violat, regain, uncomplet, accid, abl, integr, doubt, grantor*; similarly, for the notation ^, the terms are: *incorrectli, fault, nondisclosur, misus, breakag, defalc, excit, unclear, sentenc, overdu, omit, inforc, irrevoc, unencumb, further, variant, precipit, libel, loss*.

and text information might be a more reasonable way than the regression models.

## 4.2 Financial Sentiment Terms Analysis

As shown in Section 4.1, the ranking models can obtain more consistent results than the regression ones. Therefore, in the following discussions, we conduct some analyses on the words learned from the ranking models.

Figure 2 plots the words learned from our ranking models. In the figure, the single-outline circle denotes that only sentiment words are used as the training data; the double-outline circle denotes that all words in the original texts are considered when training. Moreover, the color filled in a circle with a term denotes which the sentiment word lists the

term belongs to; the circle with 2-mixed colors indicates the term belongs to two word lists. Note that the circle area is proportional to the average weight of each term.

In Figure 2, the top 5 average weighted words for the results of each kind of training data are marked by numbers from 1 to 5. For the case of training on sentiment words only (SEN), the top 5 average weighted words are *amend, deficit, forbear, delist, default*, whereas those under case ORG are *ceg, nasdaq, gnb, coven, forbear*; only one word *forbear* overlaps. An interesting finding is that when the models are trained on the original texts, some less informative terms like *ceg* (a company name, Co-Energy Group), *nasdaq* (an American stock exchange), *gnb* (a company name, GNB Technologies), are highly ranked; however, the relation is weak between these words and financial risk. In contrast, as only sentiment words are used for training, it is more reasonable that the terms are highly related to financial risk. In addition, since the terms in the figure have been stemmed, one term may correspond to one or more words. We also list the original words from the sentiment lexicon for each top 5 average weighted sentiment term in Figure 2. For example, the top 1 weighted term “*amend*” will have the list containing the words “*amend,*” “*amendable,*” “*amendatory,*” and so on.

Below we provide some original descriptions from 10-K reports that contain the top 2 weighted sentiment words in Figure 2. Note that the term with a higher weight is associated with higher financial risk. First, the term “*amend*” from the Fin-Lit list is considered. One piece of paragraph quoted from the original report is listed as follows:

(from AGO, 2006 Form 10-K)

On March 22, 2005, we *amended* the term loan agreements to, among other reasons, lower the borrowing rate by 25 basis points from LIBOR plus 2.00% to LIBOR plus 1.75%.

In finance, the *amend* usually means “to change by some formal processes.” This top-ranked term indicates that companies amending their policies frequently are associated with relative high risk.

We then discuss the term “*deficit*” from the Fin-Neg list, which means an excess of liabilities over assets, of losses over profits, or of expenditure over income in finance. Therefore, it is natural to say that a company associated with higher deficit might

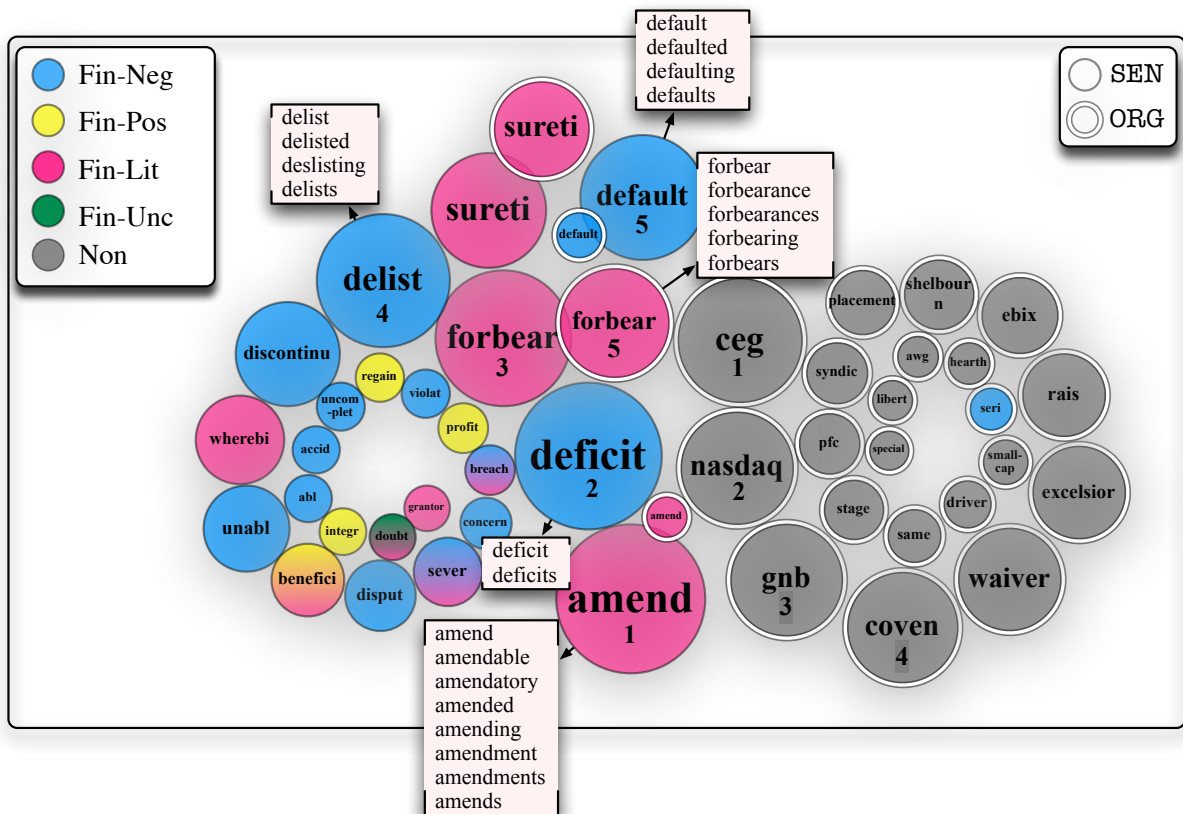

Figure 2: Highly-Weighted Terms Learned from the 6 Ranking Models of Using Original Texts (ORG) and Only Sentiment Words (SEN). The color filled in a circle with a term denotes which the sentiment word lists the word belongs to; the circle with 2-mixed colors indicates the term belongs to two word lists. The single-outline circle denotes that only sentiment words from the 6 dictionaries (see Table 2) are used as the training data; the double-outline circle denotes that the original texts are considered when training. Top 5 terms for the results of each kind of training data are marked by numbers from 1 to 5; the original words from the sentiment lexicon for each top 5 average weighted sentiment terms are also provided.

have higher risk. One piece of paragraph quoted from the original report is listed as follows:

(from AXS-One Inc., 2006 Form 10-K)  
 At December 31, 2005, we had cash and cash equivalents of \$3.6 million and a working capital *deficit* of \$3.6 million which included \$8.2 million of deferred revenue. The increase of the working capital *deficit* from \$3.3 million at December 31, 2004 is primarily the result of a decrease in cash and decreased accounts receivable offset partially by a decrease in deferred revenue.

## 5 Conclusions and Future Work

This paper identifies the importance of sentiment words in financial reports associated with financial risk. With the usage of a finance-specific sentiment lexicon, regression and ranking techniques are applied to analyze the relations between the sentiment words and financial risk. The experimental results

show that, based on the bag-of-words model, the models trained on sentiment words only can result in comparable performance to those on origin texts, which attests the importance of the financial sentiment words on risk prediction. In addition, the learned models also suggest strong correlations between financial sentiment words in financial reports and the risk of companies. As a result, these findings provide us more insight and understanding into the impact of financial sentiment words on companies' future risk. There are several future work, such as how to use even further information (i.e., syntactic information) for analysis, and how to conduct more fine-grained analysis.

## Abstract

This paper addresses the open problem of mathematical term sense disambiguation. We introduce a method that uses a MathML parallel markup corpus to generate relevant training and testing datasets. Based on the dataset generated, we use Support Vector Machine classifier to disambiguate the sense of mathematical terms. Experimental results indicate we can generate such data automatically and with reasonable accuracy.

## 1 Introduction

Word-sense disambiguation (WSD) refers to the process of identifying the correct sense or meaning of a word in a sentence when the word has multiple meanings. WSD remains a difficult open problem in natural language processing. Current WSD systems are based on supervised, unsupervised, and knowledge-based approaches (Navigli, 2009). This paper focuses on the problem of disambiguating the sense of mathematical terms occurring within normal text, an aspect little discussed to date.

The problem of achieving automated understanding of mathematical expressions can be illustrated quite clearly. For instance, depending on context, the mathematical term  $\delta$  can be interpreted to refer to Kronecker Delta, Dirac Delta, Discrete Delta, or simply to a variable  $\delta$ . Another example is  $i$ , which can be interpreted to mean the imaginary constant, the index variable, or the bound variable of an operation. Other examples include  $\alpha$ ,  $\beta$ ,  $\sigma$ ,  $\phi$ ,  $\omega$ ,  $\Phi$ ,  $B$ ,  $H$ ,  $x$ ,  $y$ , *sim*. In many such cases, disambiguation can play a crucial role in the automated understanding, translation, and calculation of mathematical expressions.

One major issue in early research on machine understanding of mathematical terms found in text was the lack of evaluation datasets. A previous study (Wolska et al., 2011) was based on a small evaluation set of 200 mathematical expressions annotated by experts. Clearly, large samples of sense-tagged data would require significant human annotation and labor. Fortunately, then, Ide et al. (2002) showed that sense distinctions derived from cross-lingual information are at least as reliable as those made by human annotators. The novel research described in our paper presents a fully automated method for generating large samples of mathematical terms with sense-tagged data.

As part of the effort described here to address mathematical term sense disambiguation (MTSD), we first propose a method that uses a MathML parallel markup corpus to generate training and testing datasets. Second, we propose heuristics that improve alignment results for the parallel markup corpus. Third, we present a classification-based approach to the MTSD problem. To the best of our knowledge, this study is the first to make use of parallel corpora to address MTSD.

The rest of this paper is organized as follows: Sections 2 and 3 provide a brief overview of the background and related work; Section 4 presents our methods; Section 5 describes the experimental setup and results; Section 6 concludes the paper and points to directions for future research.

## 2 Background

Web pages and documents represent mathematical expressions in many formats: images,  $\text{\TeX}$ , MathML (Ausbrooks et al., 2010), OpenMath (Buswell et al., 2004), OMDoc (Kohlhase, 2006), or the ISO/IEC standard Office Open XML (Miller et al., 2009). This paper uses MathML markup, a format recommended by the W3C Math Working Group, as a standard for rep-

representing mathematical formulas. MathML uses presentation markup to capture notational structures and content markup to capture mathematical structures and mathematical meaning. MathML parallel markup provides both forms of markup for the same mathematical expression. Figure 1 shows the MathML presentation and content markup for the expression  $\arctan(0) = 0$ <sup>1</sup>.

#### Presentation MathML

```
<mrow>
  <mrow>
    <msup>
      <mi>tan</mi>
      <mrow>
        <mo>-</mo>
        <mn>1</mn>
      </mrow>
    </msup>
    <mo>(</mo>
    <mn>0</mn>
    <mo>)</mo>

  <apply>
    <arctan/>
    <cn>0</cn>
  </apply>
  <cn>0</cn>
</apply>
```

Figure 1: MathML presentation and content markup for the expression  $\arctan(0) = 0$

Natural language sentences and presentation mathematical expressions have several key similarities and differences. A token element in a mathematical expression can be regarded as a word in a sentence. In presentation markup, token elements are divided into four main types: identifiers ( $\langle \text{mi} \rangle x \langle \text{mi} \rangle$ ), operators ( $\langle \text{mo} \rangle + \langle \text{mo} \rangle$ ), numbers ( $\langle \text{mn} \rangle 2 \langle \text{mn} \rangle$ ), and text ( $\langle \text{mtext} \rangle \text{non zero} \langle \text{mtext} \rangle$ ). A sentence may contain certain layout elements, such as subscripts or superscripts, while a mathematical expression may contain numerous layout elements, such as  $\langle \text{mrow} \rangle$ ,  $\langle \text{msup} \rangle$ ,  $\langle \text{munderover} \rangle$ , and  $\langle \text{mfrac} \rangle$ . As noted by Ausbrooks et al. (2010), mathematical notation, while more rigorous than natural language, is ambiguous and context-dependent.

<sup>1</sup><http://functions.wolfram.com/01.14.03.0001.01>

### 3 Related Work

Several studies have shown encouraging results for WSD based on parallel corpora (Diab and Resnik, 2002; Tufiş et al., 2004; Chan and Ng, 2005; Carpuat and Wu, 2007; Padó and Lapata, 2009; Lefever and Hoste, 2010; Lefever et al., 2011). Ide et al. (2002) used translation equivalents derived from parallel aligned corpora to determine sense distinctions applicable to automatic sense-tagging. They evaluated their work using a subset of 33 nouns covering a range of occurrence frequencies and degrees of ambiguity (Ide et al., 2001), with results indicating no significant difference in agreement rates for the algorithm and for human annotators. The main limitation of this study is its dependence on aligned corpora, which are not easily obtainable.

Wolska et al. (Wolska and Grigore, 2010; Wolska et al., 2011) presented a knowledge-poor method for identifying the denotation of simple symbolic expressions in mathematical discourse. Based on statistical co-occurrence measures, the system sorted a simple symbolic expression under one of seven predefined concepts. Here, the authors found that lexical information from the linguistic context immediately surrounding the expression improved results. This approach achieves 66% agreement with the gold standard of manual annotation by experts. From our perspective, the predefined concepts are closely related to syntactic function, not the semantics of the terms.

### 4 Our Approach

#### 4.1 Generating the Datasets

We compiled our MTSD data using parallel MathML markup expressions gathered from the Web. First, using a set of heuristic rules, we pre-processed the parallel MathML markup expressions. We then used the GIZA++ toolkit to obtain node-to-node aligned data. Based on the node-to-node aligned data, we created subtree-to-subtree aligned data. Finally, we extracted ambiguous terms from the subtree-to-subtree aligned data to obtain data for MTSD. Figure 2 gives the steps taken to generate the data.

A crucial step in generating MTSD data is achieving alignment between the Presentation side and the Content side of the expressions. Given a set of several MathML parallel markup expressions, we used the automated word alignment

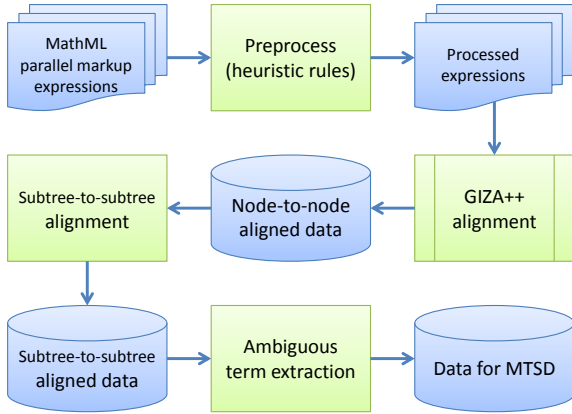

Figure 2: Steps for generating the data for MTSD.

GIZA++ (Och and Ney, 2003) to obtain alignment between the Presentation terms and Content terms. Developed to train word-based translation models, the GIZA++ toolkit is not directly applicable to a tree-based corpus. One common solution is to convert the tree into a sentence by extracting the leaf nodes of the tree and to form a sequence (Sun et al., 2010). While this approach works well for natural language text, it is less effective with mathematical expressions, since the intermediate nodes of these expressions contain layout information.

Before using GIZA++, to enhance alignment precision, we apply two heuristic rules to the presentation tree based on information on its structure. The first heuristic rule converts the intermediate layout nodes (except `msrow`) to leaves on the tree by moving them to the position of their first child. When moving an intermediate layout node, we create a temporary (‘temp’) node to replace the moved node and to keep the other child nodes intact. Unnecessary parentheses, which indicate that the expressions in the parentheses belong together, are also removed. Figure 3 illustrates an example of this heuristic. In this example, we moved the `msup` node to a leaf of the tree and removed a pair of parentheses, `<mo> (</mo>` and `<mo> ) </mo>`, near `<mn>0</mn>` node.

The second heuristic rule moves operator (`mo`) nodes to the beginning of the subtree if that subtree contains operator nodes. This rule reduces cross alignments, since most notations in content MathML are prefix notations and placed in leaf nodes. In Figure 3, the `<mo>=</mo>` node is moved to the first position of the tree. The `<mo>-</mo>` node is not moved because it is already the first child of its parent node. This figure also shows alignment results for GIZA++ before

and after applying heuristic rules for the expression  $\arctan(0)=0$ .

To extract more complex mathematical terms, we expand the node-to-node alignments to subtree-to-subtree alignments. In this study, we expanded the subtree alignment only to the parent of the `mi` nodes. The criteria used here to achieve subtree aligned pair are similar to that used by Tinsley et al. (2007). First, a node can be linked only once. Second, descendants of a presentation node can link only to descendants of its content counterpart. Third, ancestors of a presentation node can link only to ancestors of its content counterpart (a node counts as its own ancestor).

If one presentation node links to more than one content node, we keep only the link with the highest alignment score, as given by Equation 1. The number of alignments between the presentation tree  $tree_P$  and the content tree  $tree_C$  is the sum of (1) the number of alignments from the leaf children of  $tree_P$  to the leaf children of  $tree_C$  and (2) the number of alignments from the leaf children of  $tree_P$  to the leaf children of  $tree_C$ . For more accurate results, we removed node-to-node alignments if alignment probabilities fell below a certain threshold (0.2). In Equation 1,  $P_{child}$  and  $C_{child}$ , respectively, refer to the child nodes of  $tree_P$  and  $tree_C$ . The blue lines in Figure 3 represent the expanded alignments between subtrees.

$$score(tree_P, tree_C) = \frac{\# \text{alignments}}{\# P_{child} + \# C_{child}} \quad (1)$$

Based on the alignment results, we extracted pairs of presentation mathematical terms and their associated content terms. A mutually aligned presentation subtree and content subtree form a pair. This paper will consider only mathematical terms containing `mi` (e.g.  $\tan^{-1}$ ,  $A_i$ ,  $A_i(0)$ ,  $\Gamma$ ,  $\Gamma(\frac{2}{3})$ ). Only terms associated with ambiguous mapping are retained to generate training and testing data.

## 4.2 Disambiguating Mathematical Terms

We created a labeled training set, then used Support Vector Machines (SVM) to learn a classifier from this labeled data. Assume that a presentation term  $e$  has  $n$  ways of translating to content MathML term. Then, for each mathematical expression, we create one positive instance by combining  $e$  and its correct translation. We also create  $n-1$  negative instances by combining  $e$  and its incorrect translations. We will assign each instance

Figure 3: Example of alignment results for GIZA++ before and after applying the heuristic rules for the expression  $\arctan(0)=0$ . Red lines represent alignments from presentation nodes to content nodes; green lines represent alignments from content nodes to presentation nodes; blue lines represent expanded alignments between subtrees.

to one of two classes, depending on the candidate translation: The class is ‘true’ if the content term is the correct translation of the presentation term; otherwise, the class is ‘false.’

We can divide the features used in SVM disambiguation into two main groups: presentation MathML and text features. Presentation MathML features are extracted from the presentation MathML markup of the mathematical expressions. Mathematical compendium websites often group expressions into several categories. The only text feature we use here is the name of the category to which a mathematical expression belongs. Table 1 shows the features we used for classification.

Table 1: Features used for classification

Feature	Description
Only child	Is it the only child of its parent
Preceded by mo	Is it preceded by an $m_o$ node
Followed by mo	Is it followed by an $m_o$ node
mo’s name	The name of the followed $m_o$
Parent’s name	The name of its parent node
Node name	The name of the node
Identifier’s name	The name of the first $m_i$ child
Category	Relation between category name & candidate translation

Our experiment involved seven presentation MathML features. The first determines whether the term is the only child of its parent. The next three features encode the relationship between the term and the surrounding  $m_o$  elements. The last three features represent the parent’s name, the term’s own name, and the first  $m_i$  child’s name. Since mathematical terms differ from natural language words, the features differ as well.

## 5 Evaluation

### 5.1 Evaluation Setup

For these experiments, we collected parallel MathML markup expressions from the Wolfram Functions Site<sup>2</sup> (WFS), the world’s largest collection of formulas and graphics related to mathematical functions. All mathematical expressions on WFS are available in MathML parallel markup. For simplicity, we excluded long expressions containing more than 30 leaf nodes. We collected a total of 20,314 mathematical expressions.

### 5.2 Evaluation Results

We began by investigating the quality of the generated MTSD data. Using WFS data, we generated 2,925 different mathematical terms. There are 390 distinct ambiguous terms and 2,535 distinct

<sup>2</sup><http://functions.wolfram.com/>

unambiguous terms. Of the ambiguous terms, 90 distinct terms are single  $mi$  elements. There are 67,987 instances contain all the ambiguous terms in our data. Table 2 shows the generated data.

Table 2: Generated data

Type	Distinct term
Ambiguous $mi$ terms	90
Other ambiguous terms	300
Unambiguous terms	2,535

The table shows that only 14% of the extracted mathematical terms are ambiguous. One possible explanation: In WFS data, people tend to use one meaning for a fixed notation. Another: The system depends on the quality of the alignment output. The aligner may ignore an alignment if the probability of the alignment is low. This also causes errors in sense extraction if a sub-tree is aligned with a single term but the links are not fully connected: for example,  $\tan^{-1}$  (Presentation) and  $\arctan$  (Content).

Within the scope of this paper, we focused on the single  $mi$  element terms. (The same method can be expanded to encompass additional ambiguous terms.) We manually verified these single  $mi$  element terms to assess the quality of the generated MTSD data. Of 247 extracted senses, 197 were correct, an accuracy rate of 79.76% for the generated data. Each  $mi$  element term has an average of 2.74 senses. The term with the most senses was  $\langle mi \rangle C \langle /mi \rangle$ , which had six senses: Catalan, CatalanNumber, C, GegenbauerC, Cyclo-tomic, and FresnelC.

Next, we set up an experiment using libSVM<sup>3</sup> in the Weka toolkit (Hall et al., 2009) to examine sense disambiguation results for each presentation MathML term. The data we used contained the 90 distinct ambiguous  $mi$  terms. In this evaluation, we compared the results for systems using different training data: automatically extracted data and manually verified data. We also compared the results of our approach to the ‘most frequent’ method, which chooses the interpretation of highest probability. Since in the real world not every mathematical expression is associated with its category name, we also set up another experiment to assess the performance of our approach with and without the ‘category’ feature.

We built two models using nine-tenths of the au-

<sup>3</sup><http://www.csie.ntu.edu.tw/~cjlin/libsvm/>

tomatically extracted data and nine-tenths of the manually verified data. Both systems set aside one-tenth of the verified data for testing. Classification accuracies were computed over the set of binary decisions. We used the default libSVM parameters. Table 3 gives the disambiguation accuracy for ambiguous  $mi$  terms.

Table 3: Sense disambiguation accuracy for ambiguous  $mi$  terms

Method	Extracted data	Verified data
All feature	<b>91.40</b>	<b>93.94</b>
Without ‘category’ feature	91.22	92.41
Most frequent	85.01	89.76

The results in Table 3 indicate reasonable results for the automatically extracted data. We gained improvements ranging from 1.2 to 2.5 percent by building a model using manually verified data. The classifier with ‘category’ feature slightly outperformed the classifier without the ‘category’ feature. Overall, the results here were approximately 4 to 7 percent more accurate than for the ‘most frequent’ method. The explanation for the relatively high scores for the ‘most frequent’ method is that mathematical elements often have a preferred meaning.

The results suggest we can make direct use of automatically generated data when working on the MTSD problem. For mathematical expressions in MathML parallel markup, the generated data is good enough without manual checking. The results also show that the text feature-i.e., the category of the mathematical term-contributes to system performance. While this improvement is modest, it suggests that features aside from the mathematical term itself can be helpful. However, the system works well even without this feature.

## 6 Conclusion

This paper presents an approach to creating training data for the mathematical term sense disambiguation problem. Combining word-to-word alignment models and heuristic alignments, this approach shows that we can generate reasonably accurate MTSD data using parallel corpora. The data generated can then be used to train a classifier that allows automatic sense-tagging of mathematical expressions.

In contrast to natural language text, mathematical expressions require specific processing methods. More work needs to be done to establish the features best-suited to mathematical terms in a larger dataset. An extension of the model with more text and context features, in addition to the category feature, should prove interesting. Since the alignments between presentation and the content tree affect the generated data, improving alignment accuracy may boost system performance.

## Abstract

In this paper we present our work on adapting a state-of-the-art anaphora resolution system for a resource poor language, namely Bengali. Performance of any anaphoric resolver greatly depends on the quality of a high accurate mention detector. We develop a number of models for mention detection based on heuristics and machine learning. Our experiments show that, a language-dependent system can attain reasonably good performance when re-trained on a new language with a proper subset of features. The system yields the MUC recall, precision and F-measure values of 57.80%, 79.00% and 66.70%, respectively. Our experiments with other available scorers show the F-measure values of 59.47%, 49.83%, 31.81% and 70.82% for BCUB, CEAFM, CEAFE and BLANC, respectively.

## 1 Introduction

Anaphora/co-reference resolution is the task of identifying noun phrases that are used to refer to the same entity in a text. More precisely, let us assume that C1 and C2 are occurrences of two noun phrases (NPs) and both have a unique referent in the context in which they occur. Here C2 refers to C1 in the context. C1 is called antecedent and C2 is called anaphor. The noun phrases that may participate in co-reference relation are called mentions/markables. Various practical tasks require language technology; for example, information extraction and text summarization, can be performed more reliably if it is possible to automatically find parts of the text containing information about a given topic. Anaphoric information is also needed to solve several other such kinds of Natural Language Processing (NLP) problems.

Most of these works on supervised machine learning co-reference resolution have been developed for English (Soon et al., 2001; Ng and Cardie, 2002; Yang et al., 2003; Luo et al., 2004), due to the availability of large corpora such as ACE (Walker et al., 2006) and OntoNotes (Weischedel et al., 2008). BART, the Beautiful Anaphora Resolution Toolkit (Versley et al., 2008), (Ponzetto and Strube, 2006), (Poesio and Kabadjov, 2004), is the resultant of the project titled "Exploiting Lexical and Encyclopedic Resources For Entity Disambiguation" carried out at the Johns Hopkins Summer Workshop 2007. It can handle all the preprocessing tasks to perform automatic coreference resolution. A variety of machine learning approaches are used in BART; it mainly uses several machine learning toolkits, including WEKA, MaxEnt and Support Vector Machine (SVM).

Literature shows the significant amount of works in the area of anaphora resolution. But these (Pradhan et al., 2012; Ng, 2010; Poesio et al., 2010) are mainly in non-Indian languages. The works related to anaphora resolution in Indian languages are still at the nascent stage due to the following facts: Indian languages are resource constrained, i.e. corpus, annotated corpus, morphological analyzers, Part-of-Speech (PoS) taggers, named entity (NE) taggers, parsers etc. are not readily available. There have been few attempts for anaphora resolution in Indian languages. In 2011 a shared task on NLP Tools Contest on Anaphora Resolution in Indian Languages was organized in association with 9th International Conference on Natural Language Processing (ICON 2011)<sup>1</sup>. Four teams participated in this contest with the varying approaches (Chatterji et al., 2011; Dakwale and Sharma, 2011; Senapati and Garain, 2011; Ghosh et al., 2011).

In this paper we propose our work on anaphora

---

<sup>1</sup><http://ltrc.iit.ac.in/icon2011/contests.html>

resolution in Bengali, a resource poor language. We develop a number of models for mention detection. The mention detector developed with the supervised classifier, Conditional Random Field (Lafferty, 2001) performs best for the anaphora resolution. We identify and implement several features for mention detection as well for anaphora resolution. Detailed experiments were carried out on the development set to identify the most relevant set of features. Later on we use that particular configuration to report the final evaluation results on test data.

## 2 Brief Description of BART System Architecture

Our starting point of anaphora resolution system is the toolkit from (Versley et al., 2008), originally conceived as a modularized version of previous efforts from (Ponzetto and Strube, 2006; Poesio and Kabadjov, 2004; Versley, 2006; Broscheit et al., 2010). BART’s final aim is to bring together state-of-the-art approaches, including syntax-based and semantic features. The state-of-the-art anaphora resolution system, BART has five main components: preprocessing pipeline, mention factory, feature extraction module, decoder and encoder. In addition, an independent language plugin module handles all the language specific information and is accessible from any component. Each module can be accessed independently and thus adjusted to leverage the system’s performance on a particular language or domain. The preprocessing pipeline converts an input document into a set of linguistic layers, represented as separate XML files. The mention factory uses these layers to extract mentions and assign their basic properties (number, gender etc). The feature extraction module describes pairs of mentions  $M_i, M_j, i < j$  as a set of features. The decoder generates training examples through a process of sample selection and trains a binary classifier. Finally, the encoder generates testing examples through a (possibly distinct) process of sample selection, runs the classifier and partitions the mentions into coreference chains.

### 2.1 Models for Mention Detection

Robust mention detection is an essential component of anaphora resolution system in any language. BART supports different pipelines for mention detection. The choice of a pipeline de-

pends crucially on the availability of linguistic resources for a given language. The very first step of anaphora resolution process tries to identify the occurrence of mentions in the documents. In our original experimental datasets, three information were provided for each token: Part-of-Speech (PoS), phrase (or, chunk) and Named Entity (NE). We develop the following mention detection models:

1. **First Model:** In our first model we consider each noun phrase(NP) as a possible candidate of mention. Results of this model are shown in Table 1.
2. **Second Model:** In our second model we consider each Named Entity (NE) or pronoun (PRP) as a mention and its results are shown in Table 1.
3. **Third Model:** In the third model we take only person name or pronoun (PER/PRP) as a candidate of mention. Results in Table 1 show a little improvement in the performance for one document, however the performance for the other documents decrease.
4. **Fourth Model:** Here we use Conditional Random Field (CRF) based supervised classifier to detect mentions from a given text. We formulate the mention detection as a classification problem by assigning each token in the text a label, indicating whether it is a mention or not. Hence to learn a classifier at first we have to create a training data and have to derive the class values (either B-mention/I-mention/Others)<sup>2</sup> of all the tokens from the annotated data. We create a training set for mention detection based on the mentions present in the original training data. Evaluation results in Table 1 clearly show that this mention detection system is the best compared to the other three models. Details of this systems are mentioned in the following subsection.

### 2.2 Conditional Random Field(CRF) based Mention Detection System

To formulate the problem of mention detection using CRF(Lafferty, 2001), we consider the token

<sup>2</sup>Here B, I and O denote the beginning, internal and outside the entity mention

of a sentence as an element of the observation sequence and the corresponding class label as an element of its state sequence. We have used the C++ based CRF++ package <sup>3</sup>.

### 2.2.1 Features for Mention Detection

We train CRF with the following set of features.

1. **Context word:** The contextual information of a target entity plays a significant role to decide whether it is a potential candidate for being a mention (or markable). We use the preceding and following few tokens as the features.
2. **Word suffix and prefix:** Fixed length (say,  $n$ ) word suffixes and prefixes are used as the features for mention detection. These are the fixed length character strings stripped either from the rightmost (for suffix) or from the leftmost positions (for prefix) of the words. We included this feature with the observation that mentions, in general, share some common character sequences either at the beginning or at the end.
3. **Part-of-Speech (PoS) information:** PoS information of the token is effective for mention detection. We consider the PoS classes like NN (Common noun), NNP (Proper noun), PRP (Pronoun) etc. as important for mention detection.
4. **Chunk information:** Each mention belongs to the noun phrase and so its boundary identification is important. We use the chunk information provided with the datasets.
5. **Suffix list:** Variable length suffixes of a word are matched with the predefined list of useful suffixes which are helpful to detect person (e.g., *-bAbu*, *-der*, *-dI*, *-rA* etc.) and pronoun (e.g., *-tI*, *-ke*, *-der* etc.) names <sup>4</sup>. We prepared such lists from the training data. A binary valued feature is defined that fires if the current word contains any of these suffixes.
6. **Noun phrase preceding pronoun:** We observed that in many cases the pronoun appears immediately after the potential markable candidate. We define a binary-valued

<sup>3</sup><http://crfpp.sourceforge.net>

<sup>4</sup>Henceforth all the Bengali glosses are written in ITRANS notations available at <http://www.aczoom.com/itrans/>

Sr.	Mentions	DevData	precision	recall	F-measure
1	NP	Doc-1 Doc-2	26.08 25.76	99.16 99.62	41.30 40.93
2	NE /PRP	Doc-1 Doc-2	72.02 47.18	33.80 25.86	46.01 38.35
3	PER /PRP	Doc-1 Doc-2	82.47 92.47	13.13 25.86	22.65 40.42

Table 1: Results of different approaches for mention detection on development data

feature that is set to 1 for a pronoun (PRP) if it follows a noun phrase (NP).

7. **Named entity information:** The Named Entity (NE) class is used for identifying mentions. This is a very useful feature as the majority of the mentions belong to the different NE categories.
8. **Pronoun list:** We manually prepare a list of pronoun names (e.g., *jeMon*, *kAro*, *tAhole*, *onnyoKe* etc.) that do not participate in anaphora resolution. This discards pronouns that are not co-referent mentions.
9. **First word:** Noun phrases often appear at the beginning for the particular datasets that we have used, and these can most likely be the mentions. This feature is used to define whether the token is the first word in the sentence or not.
10. **Morphological features:** We extract morphological features from the shallow parser available at <sup>5</sup>. The features include *lemma* and number *information* (singular/plural) of the words.
11. **Fine-grained noun information:** The fine-grained information of nouns are extracted from the PoS tags. The feature checks whether the token is definite noun or demonstrative noun, and decides accordingly.

We present the results of mention detection module in Table 1. It shows that CRF based classifier attains the best performance. Inspired by these results, we identify mentions in test data using this CRF based classifier. We merge the development

<sup>5</sup>[http://lrc.iit.ac.in/showfile.php?filename=downloads/shallow\\_parser.php](http://lrc.iit.ac.in/showfile.php?filename=downloads/shallow_parser.php)

data with the training data and create a new training dataset for CRF. Results on the test data are reported in Table 2.

### 3 Methods for Anaphora Resolution

In this work we extend BART to perform anaphora resolution for Bengali, a resource poor language. We perform systematic study to identify most suitable configuration of BART for anaphora resolution in Bengali. We identify and implement several features for this task. We design and evaluate our system using the Bengali datasets obtained from the NLP Tools Contests on Anaphora Resolution in Indian Languages, organized in ICON-2011<sup>6</sup>. The Bengali corpus contains three types of datasets- training, development and test.

#### 3.1 Preprocessing and Markable Extraction

For the anaphora resolution system, mentions are identified from the datasets based on the gold annotations. These are treated as the markables. Thereafter we convert the markables to the data format used by BART, namely MMAX2s standoff XML format.

#### 3.2 Features for anaphora resolution

We view coreference resolution as a binary classification problem. We use the learning framework proposed by (Soon et al., 2001) as a baseline. Each classification instance consists of two markables, i.e. an anaphor and its potential antecedent. Instances are modelled as feature vectors and are used to train a binary classifier. The classifier has to decide, given the features, whether the anaphor and the candidate antecedent are coreferent or not. To improve the performance we define some features specific to the language. Given BART’s flexible architecture, we explore the contribution of some features implemented in BART for co-reference resolution in Bengali. Given a potential antecedent  $RE_i$  and an anaphor  $RE_j$ , we compute the following features:

1. **String match:** This feature compares between the two mentions. The value of this feature is true if the candidate anaphor ( $RE_j$ ) and antecedent ( $RE_i$ ) have the same surface strings forms, otherwise false.
2. **Sentence distance:** A non-negative integer feature capturing the distance between anaphor and antecedent; if they are in the same sentence, then value of 0 is produced else if their sentence distance is 1 the value of 1 is produced.
3. **Markable distance:** This is also a non-negative integer feature that captures the distance in terms of the number of mentions between the two markables.
4. **First person pronoun:** This feature is defined based on the direct and indirect speech. For a given anaphor-antecedent pair ( $RE_j, RE_i$ ) a feature is set to high if  $RE_j$  is a first person pronoun found within a quotation and  $RE_i$  is a mention immediately preceding it within the same quote. If  $RE_i$  is outside the quote and appears either in the same sentence or in any of the previous three sentences and is not first person then the corresponding feature is also set to high. The feature also behaves in a similar way if the pair ( $RE_j, RE_i$ ) appears outside the quotation.
5. **Second person pronoun:** This feature checks whether the pair ( $RE_j, RE_i$ ) is in the same quote and fires the feature accordingly. It is true if  $RE_j$  is second person and  $RE_i$  is other than the first person. If  $RE_j$  is inside the quotation, and  $RE_i$  ends with the suffix "ke" and is outside the quote then the feature fires.
6. **Third person pronoun:** This feature checks whether the pair ( $RE_j, RE_i$ ) appears inside or outside the quotation. It feature fires if both the mentions either appear within or outside the quotation.
7. **Reflexive pronoun:** For a given pair ( $RE_j, RE_i$ ), this feature checks whether  $RE_j$  is a reflexive pronoun and fires accordingly. This means if any antecedent is immediately followed by a reflexive pronoun then the feature is true, otherwise false.

<sup>6</sup><http://ltrc.iit.ac.in/icon2011/contests.html>

8. **Number agreement:** If both anaphor( $RE_j$ ) and antecedent( $RE_i$ ) agree in their number information then the feature value is set to true, otherwise false. We extract this feature from the shallow parser available at <sup>7</sup>. The parser was not able to take longer sentences as inputs and so we had to pre-process the data before running the parser.
9. **Semantic class feature:** If both  $RE_j$  and  $RE_i$  agree in their semantic classes then this feature is set to true, otherwise false. In particular this feature checks whether the pair either belongs to *person class* or *organization class* or *location class*.
10. **Alias feature:** It checks whether  $RE_j$  is an alias of  $RE_i$  or not.
11. **Appositive feature:** If  $RE_j$  is in apposition to  $RE_i$  then the value of this feature is set to true, otherwise it is false.
12. **String kernel:** String kernel similarity is used to estimate the similarity between two strings based on the string subsequence kernel.
13. **Mention type:** Following (Soon et al., 2001), we have encoded mention types (name, nominal or pronoun) of the anaphor and the antecedent. In addition, we check whether the anaphor  $RE_j$  is a definite pronoun or demonstrative pronoun or merely a pronoun. We also check whether each of the entities in the mention pair denotes proper name.

### 3.3 Learning algorithm

In order to learn coreference decisions, we experiment with WEKA's (Witten and Frank, 2005) implementation of the C4.5 decision tree learning algorithm (Quinlan, 1993), with the above mentioned feature combinations. Instances are created following (Soon et al., 2001). We generate a positive training instance from each pair of adjacent coreferent markables. Negative instances are created by pairing the anaphor with any markable occurring between the anaphor and the antecedent. During testing, we perform a closest first clustering of instances deemed coreferent by the classifier. Each text is processed from left to right: each

<sup>7</sup>[http://ltrc.iiit.ac.in/showfile.php?filename=downloads/shallow\\_parser.php](http://ltrc.iiit.ac.in/showfile.php?filename=downloads/shallow_parser.php)

Dataset	#sentences	#tokens
Training	881	10,504
Development	598	5,785
Test	572	6,985

Table 3: Statistics of the datasets

markable is paired with any preceding markable from right to left, until a pair labelled as coreferent is output, or the beginning of the document is reached.

### 3.4 Decoding

In the decoding step, the coreference chains are created by the best-first clustering. Each mention is compared with all of its previous mentions with a probability greater than a fixed threshold value, and is clustered with the highest probability. If none has probability greater than the threshold, the mention becomes a new cluster.

## 4 Evaluation

### 4.1 Dataset

For our experiments we use the data sets provided in the ICON NLP Tools Contest on Anaphora Resolution in Indian Languages. The datasets were taken from the Bengali literature (mostly from the short stories). All the datasets were provided with PoS, chunk and NE information. For training and development datasets, anaphoric annotations were provided by the organizers. However for test set there was no annotation available. In line with the annotations of training and development datasets, we manually annotated test dataset. Some statistics of the datasets are presented in Table 3.

### 4.2 Evaluation metrics and results

In order to evaluate the anaphora resolution system we use different scorers such as MUC (Vilain et al., 1995), B<sup>3</sup> (Bagga and Baldwin, 1998), CEAF (Luo, 2005) and BLANC (Recasens and Hovy, October 2011). We experiment with the different mention detectors for anaphora resolution. Table 4 shows the MUC recall, precision and F-measure values of the system trained using the training data and evaluated using the development data. Experiments were carried out on a high performance computing facility with the following configuration: Dell machine, 216 cores, 2.66 GHZ Intel Xeon processors, 4 GB RAM/core, and 10 TB storage.

Mentions	recall	precision	F-measure
NP	52.50	40.40	45.60
NE/PRP	45.20	69.40	54.80
PER/PRP	45.20	66.30	53.80
CRF Classifier	52.20	78.80	62.80

Table 4: Results with MUC scorer on development data

Scorers	recall	precision	F-measure
MUC	57.80	79.00	66.70
BCUB	51.02	71.27	59.47
CEAFM	49.83	49.83	49.83
CEAFE	48.88	23.58	31.81
BLANC	70.66	70.99	70.82

Table 5: Overall results on test data

Results of Table 4 reveal the fact that the proposed anaphora resolution system achieves the best performance when CRF based classifier is used for mention detection. Based on these results on development data, we evaluate the system for the test data using the mentions extracted by the CRF based machine learner. Results on the test data are reported in Table 5. Results show the F-measure values of 66.70%, 59.47%, 49.83%, 31.81% and 70.82% for MUC, BCUB, CEAFM, CEAFE and BLANC, respectively.

### 4.3 Discussion

We explore different models for mention detections. We observed that the mention detection performs best with the supervised machine learner, CRF. These system mentions are then used for the encoding and decoding modules in BART. Experimental results shown in Table 4 show that mention detection plays an important role in anaphora resolution. We implement the baseline model using a subset of the features reported in (Soon et al., 2001). These include number agreement, alias, string matching, semantic class agreement, sentence distance, appositive and several features (c.f. Section 3.2). This model showed the MUC recall, precision and F-measure values of 38.8%, 67.4% and 49.3%, respectively. This is clearly much less compared to our proposed model. Comparisons with the available related works (specific to the language) show that our proposed system achieves state-of-the-art accuracy.

## 5 Conclusion

We present an anaphora resolution system for Bengali, a resource-poor language based on BART, a state-of-the-art coreference resolution model originally developed for English. We explore many models for markable identification, and observed that a supervised CRF based classifier produces the best results. The main focus of this work is to build a machine learning based anaphora resolution system for a resource-poor Indian language. Our system attains the state-of-the-art accuracy level. Currently our focus is on developing methods for capturing the missing markables; and identifying more syntactic and semantic features. Future work will also concentrate on porting the systems to other Indian languages, e.g. Hindi and Telugu, as well as investigating the portability and usefulness of more syntactic, morphological and semantic information across different languages. We also aim to perform systematic feature selection for mention detection and anaphora resolution.

# Chinese Event Coreference Resolution: Understanding the State of the Art

Chen Chen and Vincent Ng

Human Language Technology Research Institute

University of Texas at Dallas

Richardson, TX 75083-0688

{yzcchen, vince}@hlt.utdallas.edu

## Abstract

Given the relatively small amount of work on event coreference resolution, our understanding of the task is arguably fairly limited. This makes it difficult to determine how to improve an event coreference resolver. We seek to gain a better understanding of the state of the art in event coreference resolution by performing the first publicly available analysis of a Chinese event coreference resolver.

## 1 Introduction

Event coreference resolution is the task of determining which event mentions in a text refer to the same real-world event. Compared to entity coreference (the task of determining which entity mentions in a text refer to the same real-world entity), there is much less work on event coreference.

Given the lesser amount of work on event coreference, our understanding of the task is arguably fairly limited. Specifically, while it is not surprising that the performance of an event coreference resolver depends heavily on the quality of the output of its preprocessing components, it is not clear *to what extent* the noise inherent in the output of each preprocessing component is limiting the performance of a resolver. Note that this issue is more serious for event coreference than for entity coreference: since an event coreference resolver lies towards the end of the information extraction pipeline, it has to rely on the noisy output produced by more upstream components than its entity counterpart. The lack of understanding of this issue makes it difficult to identify the components that need most attention. Moreover, when analyzing the errors made by a resolver, it is not clear which types of errors can be fixed by improving the resolution algorithm and which ones can be fixed by improving the preprocessing com-

ponents. This makes it difficult to precisely determine how to improve the resolution algorithm. Taken together, these two issues make it difficult to understand how an event coreference resolver should be improved.

Our goal in this paper is to better understand the state of the art in event coreference and provide directions for further work on this task by addressing the aforementioned issues, which are summarized by the following two questions. First, to what extent is the noise inherent in the output of *each* of its upstream components limiting its performance? Second, what are the major types of errors that are attributable to (and therefore can be fixed by improving) the resolution algorithm?

We address these two questions by presenting a systematic analysis of a state-of-the-art Chinese event coreference resolver. Our decision to focus on Chinese can be attributed in part to the lack of publicly available results on Chinese event coreference resolution. In particular, to our knowledge, almost all recent work on event coreference has reported results for English (e.g., Humphreys et al. (1997), Chen et al. (2009), Bejan and Harabagiu (2010), Chen et al. (2011), Lee et al. (2012)).<sup>1</sup> Hence, the results in the paper can serve as a baseline against which future work on Chinese event coreference can be compared.

It is worth mentioning that similar questions were faced by entity coreference researchers, who have reached a point where it is crucial to answer these questions in order to make further progress. For that reason, a number of recent research papers have focused on these questions via analyzing the inner workings of entity coreference resolvers (e.g., Stoyanov et al. (2009), Recasens and Hovy (2010), Chen and Ng (2012a)). On the other hand, no attempts have been made to address these questions in the context of event coreference.

<sup>1</sup>A notable exception is Zinmeister et al.'s (2012) work, which reports results for both German and English.

## 2 ACE Event Coreference

As mentioned in the introduction, event coreference is the task of determining which event mentions in a text refer to the same real-world event. The ACE 2005 event coreference task, which is the version of the event coreference task we focus on, requires that an event coreference resolver performs coreference only on event mentions belonging to one of the ACE event types.

More specifically, an ACE event mention has a *type* and a *subtype*. In ACE 2005, eight types are defined, which are further subcategorized into 33 subtypes. Not surprisingly, two event mentions that have different subtypes cannot be coreferent.

To better understand the ACE 2005 coreference task, consider the sentence in Figure 1, which is taken from the ACE 2005 corpus. This example contains three event mentions: 砍 (stabbed), 伤 (injured) and 行凶 (criminal). 砍 and 行凶 have type CONFLICT and subtype ATTACK, whereas 伤 has type LIFE and subtype INJURE. In this example, 砍 and 行凶 are coreferent because they refer to the same real-world event.

---

(张家荣)(昨天傍晚)在(路上)骑自行车运动时遭到了(两名歹徒)持(刀)[砍][伤]。(歹徒)的[行凶]动机可能和(张家荣)的问证有关联。

(Zhang Jiarong) was cycling on (the road) (yesterday evening) and was [injured] when (two men) [stabbed] (him) with (a knife). (The thugs)' [criminal] motivation may have something to do with (Zhang Jiarong)'s testimony in a criminal case.

---

Figure 1: An example. Event mentions are bracketed and entity mentions are parenthesized.

## 3 Six Upstream Components

Our event coreference resolver adopts a fairly standard ACE event coreference system architecture, relying on six components. As we will see, the first four components have a direct influence on event coreference, meaning that their output will be used to create features for use by the event coreference model. On the other hand, the last two components only have an indirect influence on event coreference through other components.

**Component 1: Event mention boundary identification and subtyping.** This component (1) provides the event mentions for event coreference resolution, and (2) labels each event mention with its event subtype. Since two event mentions with different subtypes cannot be coreferent, subtypes

can be used to create useful features for event coreference. To implement this component, we use our Chinese event extraction system (Chen and Ng, 2012c), which jointly learns these tasks.

**Component 2: Event mention attribute value computation.** This component takes as input a set of event mentions (provided by Component 1) and computes for each mention its attributes, including its POLARITY, MODALITY, GENERICITY and TENSE. Since two event mentions that differ with respect to any of these attributes cannot be coreferent, they can be used to create useful features for event coreference. Following Chen et al. (2009), we train a classifier to compute the value of each attribute of each event mention (see Chen et al. for details on the implementation of these classifiers).

**Component 3: Event argument and role classification.** This component takes as input a set of event mentions (provided by Component 1) and a set of candidate arguments (provided by Component 5). For each event mention *em*, it (1) identifies those candidate arguments that are the true arguments of *em* (e.g., the participants, time, and place of *em*), and then (2) assigns a *role* (e.g., VICTIM, PLACE, TIME-WITHIN) to each of its true arguments. Since two events involving different times, places, or participants cannot be coreferent, the arguments and their roles can be used to create useful features for event coreference. To implement this component, we use our Chinese event extraction system (Chen and Ng, 2012c), which jointly learns these two tasks.

**Component 4: Entity coreference resolution.** This component takes as input a set of entity mentions (provided by Component 5) and creates a coreference partition in which each cluster contains all and only those entity mentions that refer to the same real-world entity. Since two event mentions having coreferent arguments are likely to be coreferent, the output of this component can be used to create useful features for event coreference. To create a coreference partition from a set of entity mentions, we employ our Chinese entity coreference resolver (Chen and Ng, 2012b).

**Component 5: Entity mention boundary identification.** This component provides the candidate arguments and the entity mentions needed by the aforementioned components, so it only has an indirect influence on event coreference. Since candidate arguments can be entity mentions, time ex-

pressions, and value expressions<sup>2</sup>, we train one CRF (using CRF++<sup>3</sup>) to extract each of these three types of candidate arguments.

#### Component 6: Entity typing and subtyping.

This component takes a set of entity mentions (provided by Component 5) and determines the semantic type and subtype of each entity mention. Knowing the semantic type and subtype of an argument is helpful for classifying the role of event arguments. For example, we can assign the role VICTIM only to those arguments with entity type PERSON. To determine semantic type and subtype, we train two SVM multiclass classifiers using SVM<sup>multiclass</sup> (Tsochantaridis et al., 2004).

### 4 Chinese Event Coreference Resolver

Underlying our learning-based Chinese event coreference resolver is a mention-pair model (Soon et al., 2001) trained using the SVM<sup>light</sup> package (Joachims, 1999). Training instances are created as follows. For each anaphoric event mention  $em$ , we create one positive instance between  $em$  and its closest antecedent. To create negative instances, we pair  $em$  with each of its preceding event mentions that is not coreferent with it.

Each instance is represented using 32 features, which are modeled after a state-of-the-art English event coreference resolver (Chen and Ji, 2009; Chen et al., 2009) (see the Appendix for a detailed description of these features). After training, the resulting mention-pair model is used in combination with a closest-first single-link clustering algorithm to impose a coreference partition on the event mentions in a test text (Soon et al., 2001).

### 5 Empirical Analysis

Next, we address our first question: to what extent is the noise inherent in the output of *each* of the upstream components limiting a resolver's performance? To answer this question, we start with a resolver where all of its upstream components are assumed to be oracle components, and then replace each of them with its real (i.e., imperfect) version one after the other, as described below.

#### 5.1 Experimental Setup

For evaluation, we report five-fold cross-validation results over the 633 Chinese documents

<sup>2</sup>See the ACE 2005 task definition (<http://www.itl.nist.gov/iad/mig/tests/ace/2005/doc/ace05-evalplan.v2a.pdf>).

<sup>3</sup><http://crfpp.googlecode.com/svn/trunk/doc/index.html>

in the ACE 2005 training corpus. Results, expressed in terms of recall (R), precision (P), and F-measure (F), are obtained by applying three commonly-used coreference scoring programs, MUC (Vilain et al., 1995), B<sup>3</sup> (Bagga and Baldwin, 1998), and CEAF<sub>e</sub> (a.k.a.  $\phi_4$ -CEAF) (Luo, 2005), to the coreference partitions produced by our resolver after singleton event mentions are removed. Stanford's Chinese NLP and Speech Processing tool<sup>4</sup> is used for word segmentation, syntactic parsing, and dependency parsing.

#### 5.2 Results and Analysis

As mentioned above, we start with an event coreference resolver that assumes that all the six upstream components are error-free (see row 1 of Table 1 for its performance), and then replace each oracle component with its *system* (i.e., machine-learned) counterpart one after the other (rows 2-7 of Table 1). Therefore, the results in the last row of Table 1 correspond to the performance of an *end-to-end* event coreference resolver that relies solely on system components. Below, we discuss the impact of each component on coreference performance. Note that these components can be considered in a different order than what we show in this section. Here, we show one ordering in which the parent(s) of a component are considered *after* the component itself.

**Component 2 (Event mention attribute value computation).** First, we replace the oracle event mention attribute predictors with their system counterparts. Since there are four event mention attributes, namely, POLARITY, MODALITY, GENERICITY and TENSE, we trained four classifiers to predict the attribute values of an event mention. Our results suggest that each of these four classifiers is only marginally better than a simple majority baseline.<sup>5</sup> We then used the values predicted by these classifiers to compute features for the *test* instances for the event coreference resolver. Note that the features for the *training* instances for the resolver are computed based on gold rather than system event attribute values.

<sup>4</sup><http://nlp.stanford.edu/projects/chinese-nlp.shtml>

<sup>5</sup>Chen et al. (2009) trained classifiers to predict the attribute values of English event mentions. While their POLARITY, MODALITY, and GENERICITY classifiers perform only slightly better than a majority baseline, their TENSE classifier has reasonably good performance. This is perhaps not surprising: tense classification for English verbs is easier than for Chinese verbs since Chinese verb forms do not change according to tense.

	MUC			B <sup>3</sup>			CEAF <sub>e</sub>			Avg F
	R	P	F	R	P	F	R	P	F	
1. All oracle	80.4	70.0	74.8	88.4	79.7	83.8	57.3	66.8	61.7	73.4
2. + System event mention attribute values										
2a. system event mention attributes on test only	59.9	60.8	60.3	76.8	78.5	77.6	53.3	52.5	52.9	63.6
2b. no event mention attribute features	72.8	63.4	67.8	84.2	76.6	80.2	52.1	60.0	55.8	67.9
2c. system event mention attributes on train & test	72.5	64.5	68.3	83.8	77.4	80.5	53.1	59.9	56.3	68.3
3. + System event arguments and roles	71.2	61.2	65.8	83.9	74.9	79.1	49.9	58.0	53.6	66.2

6. + System entity mention boundaries	63.3	57.4	60.2	80.2	74.4	77.2	48.2	52.8	50.4	62.6
7. + System entity mention boundaries & subtypes	37.4	36.7	37.1	72.8	71.1	71.9	40.6	41.1	40.8	49.9

Table 1: Results when oracle components are replaced with system components one after the other.

Given the poor performance of these attribute predictors, we hypothesize that coreference performance will drop considerably when the oracle attribute predictors are replaced with their system counterparts. Results of this experiment, shown in row 2a, are consistent with this hypothesis: in comparison to row 1, the Avg F-score (unweighted average of the MUC, B<sup>3</sup>, and CEAF<sub>e</sub> F-scores)<sup>6</sup> drops significantly by nearly 10%.<sup>7</sup> A natural question is: do these results represent an unnecessary amplification of the impact of event mention attributes on event coreference performance? To answer this question, we consider two alternative ways of employing the system event mention attribute values for event coreference resolution. One way is to simply discard all features created from these attributes when training and testing the event coreference resolver. Results of this experiment are shown in row 2b. Somewhat interestingly, we can see by comparing rows 2a and 2b that discarding these features does yield a less considerable drop in performance than employing them. Another way is to employ system attribute values to generate features for both the training and test instances for the event coreference resolver. Results of this experiment are shown in row 2c. In comparison to row 2b, we see that there is a slight, but insignificant, improvement in coreference performance. Consequently, we assume in the rest of our experiments that we employ system event mention attribute values on both the training set and the test set (i.e., the configuration in row 2c), since it seems to more accurately reflect the impact of event mention attributes on event coreference performance.

**Conclusion 1:** Improving the four event attribute classi-

<sup>6</sup>For ease of exposition, we follow the CoNLL 2011 and 2012 shared tasks and use Avg F when discussing results.

<sup>7</sup>All statistical significance test results reported in this paper are conducted using the paired *t*-test ( $p < 0.05$ ).

fiers could significantly improve event coreference.

**Component 3 (Event argument and role classification).** Next, we replace the oracle event argument and role classification component with its system counterpart. Results on the test set indicate that when gold event mentions and subtype, gold entity type and subtype, and gold entity mention boundaries are used, the F-scores of system argument classification and role classification are 76.9% and 68.2% respectively. Replacing the oracle component with this system counterpart, we see that the Avg coreference performance drops slightly, though still significantly, by 2.1%.

**Conclusion 2:** Event argument classification and role classification have a small, but significant, impact on event coreference performance.

**Component 4 (Entity coreference).** Next, we replace oracle entity coreference with system entity coreference. As noted before, event coreference directly depends on entity coreference. Our system entity coreference resolver achieves a MUC F-score of 78.0% when gold entity mentions are used. Comparing rows 3 and 4, we see that replacing oracle entity coreference with system entity coreference incurs nearly a 4% drop in coreference performance according to Avg F-score. These results suggest that employing a better entity coreference resolver can improve event coreference. Joint learning of event and entity coreference may help to improve both tasks.

**Conclusion 3:** Improving entity coreference could significantly improve event coreference.

**Component 6 (Entity typing and subtyping).** Next, we replace oracle entity typing and subtyping with its system counterpart. Recall that this component has only an indirect impact on event coreference but a direct impact on event argument and role classification, since the entity type and subtype of a mention are used to create features for training the event argument and role classifier. Our

system entity type and subtype classifiers achieve F-scores of 90.1% and 81.6%, respectively, when gold entity mentions are used. Using system rather than gold entity types and subtypes, the F-scores of the event argument classifier and the event role classifier drop by 2.8% and 4.3% respectively, but comparing rows 4 and 5, coreference performance does not drop.

**Conclusion 4:** Improving entity type and subtype classification is unlikely to improve event coreference.

**Component 5 (Entity mention boundary detection).** Next, we replace gold entity mention boundary detection with its system counterpart. The performance of our system mention boundary detection component is reasonably good: it achieves an F-score of 84.7%. Comparing rows 5 and 6, we see that replacing gold mention boundary detection with its system counterpart does not alter event coreference performance.

**Conclusion 5:** Improving entity mention boundary detection may not improve event coreference.

**Component 1 (Event mention boundary identification and subtyping).** Finally, we replace the oracle event mention boundary identification and subtyping component with its system counterpart. Our learned event mention boundary identifier achieves an F-score of 65.1%, while our event subtype classifier achieves an F-score of 61.30%. Comparing rows 6 and 7, we see that replacing oracle with system event mention boundary identification and subtyping causes Avg F-score to drop by 12.7%, even though the event extraction system we employ for event mention boundary identification and subtype classification is a state-of-the-art system. Furthermore, MUC recall decreases more abruptly than MUC precision, which suggests that the low recall of event mention boundary identification severely harms system performance.

**Conclusion 6:** Event mention boundary identification and subtyping is the upstream component that has the largest impact on event coreference. There is a lot of room for improving this component, especially its recall.

We conclude this section with two noteworthy points. First, the *cumulative* study we conducted in this section is just one possible way to examine the extent to which the noise inherent in the output of each of the upstream components limits a resolver's performance. Another way is to conduct an *ablation* study: we start with a resolver where all of its upstream components are assumed to be oracle components, and then replace exactly one

oracle upstream component with its real (i.e., imperfect) version in each ablation experiment. Since the conclusions that can be drawn from the ablation study and the cumulative study are similar, we will omit the description of the ablation experiments and their results for the sake of brevity.

Second, although we discuss the results in this section in terms of Avg F, it turns out that in these experiments Avg F exhibits the same performance trends as those of MUC, B<sup>3</sup>, and CEAF<sub>e</sub>. In particular, the significance test results that we obtained using Avg F remain unchanged when Avg F is replaced with any of the three scoring metrics.

## 6 Error Analysis

Next, we address our second question: what are the major types of errors that are attributable to (and therefore can be fixed by improving) the resolution algorithm? To answer this question, we perform a qualitative error analysis on the output produced by the resolver where all six upstream components are gold. This ensures that all the errors are attributable to the resolution algorithm.

### 6.1 Three Major Types of Precision Errors

**Lack of event timestamping.** Only those events that occur at the same time can be coreferent. We use the TENSE event attribute as a feature to enforce TENSE consistency, essentially employing TENSE as a very rough approximation of the timestamp of an event. Perhaps not surprisingly, many events having the same tense are not coreferent. For example, consider the following pair of sentences, where the *triggers* (i.e., the words/phrases corresponding to the event mentions) are enclosed in brackets.

去年三月间杨光南在上海首度 [被捕]

In last March, Yang Guangnan was [arrested] in Shanghai for the first time

杨光南在上海再度 [被捕]

Yang Guangnan was [arrested] again in Shanghai

It is fairly easy to see that the first *arrest* occurred before the second one and therefore the two event mentions should not be coreferent. However, our resolver incorrectly posits them as coreferent, since they have the same PERSON and PLACE arguments (i.e., 杨光南 (Yang Guangnan) and 上海 (Shanghai)) and the same tense (i.e., *past*). If we could assign a timestamp to each event, our resolver might fix this type of precision error.

**Incompatible triggers.** As coreference between arguments is a strong indicator that the corresponding event mentions are coreferent, our resolver tends to link two event mentions with coreferent arguments together even when the triggers are not semantically compatible. The following pair of sentences illustrates this type of error.

萨姆·努乔马 28 日乘专机抵达平壤开始对朝鲜进行正式友好 [访问]

On the 28th, Sam Nujoma arrived in Pyongyang by plane for an official goodwill [visit] to the DPRK

纳米比亚总统萨姆·努乔马 28 日乘专机 [抵达] 平壤  
Namibian President Sam Nujoma [arrived] in Pyongyang by plane on the 28th

As we can see, the triggers are 访问 (visit) and 抵达 (arrived). Since both their ARTIFACT arguments (i.e., 萨姆·努乔马 (Sam Nujoma)) and their VEHICLE arguments (i.e., 专机 (plane)) are coreferent, our resolver wrongly posits the two event mentions as coreferent, although the corresponding triggers, 访问 and 抵达, are semantically incompatible. If we had access to a semantic dictionary from which we can derive the fine-grained semantic type of these triggers, our resolver might fix this type of error.

**Incompatible important arguments.** Our resolver has the tendency to posit two *largely compatible* event mentions as coreferent, i.e., they have only a small number of incompatible arguments but many features that suggest that they are coreferent (e.g. same trigger word, some coreferent arguments). Consider the example below.

代表团 [访问] 了瑞典

The delegation [visited] Sweden

[访问] 丹麦期间, 中国基督教代表团举行记者招待会

During their [visit] in Denmark, the Chinese Christian delegation held a press conference

Note that the two event mentions have identical triggers 访问 (visited) and ARTIFACT arguments 代表团 (The delegation). Given these positive evidences, our resolver posits the event mentions as coreferent despite the fact that their DESTINATION arguments are incompatible: one is 瑞典 (Sweden) and the other is 丹麦 (Denmark). To fix this kind of error, we may employ human knowledge to mark each argument role of each event subtype as *important* or *unimportant*, and enforce the constraint that two event mentions cannot be coreferent if their arguments in an *important* argument role are incompatible. In our example, we would mark both ARTIFACT and DESTINA-

TION as important argument roles for the MEETING event subtype (i.e., the subtype for *visited*), meaning that we will disallow the two event mentions in the example to be coreferent unless both the ARTIFACT and DESTINATION arguments are compatible.

## 6.2 Two Major Types of Recall Errors

**Coreferent mentions with synonymous triggers.** Our resolver fails to link some event mentions that have synonymous but lexically different trigger words. Consider the following example.

犹太人针对阿拉伯人的 [暴力]

Jewish [violence] against the Arabs

[冲突] 双方

Two parties of [conflict]

While the event mentions corresponding to the two synonymous triggers, 暴力 (violence) and 冲突 (conflict), are coreferent, our resolver fails to identify them as coreferent because the triggers are lexically different. We could fix this type of error if we had access to a semantic dictionary that can suggest that *violence* and *conflict* have similar meaning.

**Coreferent mentions with compatible arguments.** Some arguments are not coreferent but compatible. Consider the following sentences.

南斯拉夫国家元首第一次对波黑进行这样的 [访问]

Yugoslavia's head of state [visited] Bosnia-Herzegovina for the first time

科什图尼察 [访问] 波黑首都萨拉热窝

Kostunica [visited] Sarajevo, the capital of Bosnia-Herzegovina

Here, the triggers are 访问 (visited). Our resolver does not posit these two event mentions as coreferent since their arguments are not coreferent. However, if we had the world knowledge to recognize 波黑 (Bosnia and Herzegovina) and 萨拉热窝 (Sarajevo) are compatible arguments, then our resolver might be able to discover the coreference link between the two event mentions.

## 7 Conclusion

We conducted the first empirical analysis of an ACE-style Chinese event coreference system, focusing on the questions of (1) the extent to which event coreference performance is affected by errors made by upstream components in the information extraction pipeline, and (2) the types of errors made by the resolution algorithm. We hope our analysis will help direct future research.

## Acknowledgments

We thank the four reviewers for their insightful comments. This work was supported in part by NSF Grants IIS-1147644 and IIS-1219142.

## Appendix: Event Coreference Features

The 32 features used by our event coreference resolver can be divided into five groups. Group  $i$  ( $1 \leq i \leq 4$ ) contains the features computed based on Component  $i$ 's output, and Group 5 contains the remaining features. For convenience, we use  $em_2$  to refer to an event mention to be resolved and  $em_1$  to refer to one of its candidate antecedents.

**Group 1 (4):** Whether  $em_1$  and  $em_2$  agree w.r.t. event type; whether they agree w.r.t. event subtype; the concatenation of their event types; the concatenation of their event subtypes.

**Group 2 (8):** The four event mention attributes of  $em_2$ ; whether  $em_1$  and  $em_2$  are compatible w.r.t. each of the event mention attributes.

**Group 3 (4):** The roles and number of the arguments that only appear in  $em_1$ ; the roles and number of the arguments that only appear in  $em_2$ .

**Group 4 (6):** The roles and number of arguments between  $em_1$  and  $em_2$  that have the same role and are also in the same entity coreference chain; the roles and number of arguments between  $em_1$  and  $em_2$  that have same role but are in different coreference chains; the roles and number of arguments between  $em_1$  and  $em_2$  that have different roles but are in the same coreference chain.

**Group 5 (10):** The sentence distance between  $em_1$  and  $em_2$ ; the number of event mentions intervening them; the number of words between them; whether they have the same trigger word; whether they are in a coordinating structure; whether they have same basic verb; whether they agree in number if they are nouns; whether they have incompatible modifiers if they are nouns; the concatenation of the part-of-speech tags of their heads; the concatenation of their trigger words.

## Abstract

Named entity recognition in queries is the task of identifying sequences of terms in search queries that refer to a unique concept. This problem is catching increasing attention, since the lack of context in short queries makes this task difficult for full-text off-the-shelf named entity recognizers. In this paper, we propose to deal with this problem in a two-step fashion.

The first step classifies each query term as token or part of a named entity. The second step takes advantage of these binary labels for categorizing query terms into a pre-defined set of 28 named entity classes. Our results show that our two-step strategy is promising by outperforming a one-step traditional baseline by more than 10%.

## 1 Introduction

Search engines are key players in serving as interface between users and web resources. Hence, they started to take on the challenge of modelling user interests and enhance their search experience. This is one of the main drivers of replacing the classical document-keyword matching, a.k.a. bag-of-words approach, with user-oriented strategies. Specifically, these changes are geared towards improving the precision, contextualization, and personalization of the search results. To achieve this, it is vital to identify fundamental structures such as named entities (e.g., persons, locations and organizations) (Hu et al., 2009). Indeed, previous studies indicate that over 70% of all queries contain entities (Guo et al., 2009; Yin and Shah, 2010).

Search queries are on average composed of 2-3 words, yielding few context and breaking the grammatical rules of natural language (Guo et al., 2009; Du et al., 2010). Thus, named entity recognizers for relatively lengthy grammatically well-

formed documents perform poorly on the task of Named Entity Recognition in Queries (NERQ).

At heart, the contribution of this work is a novel supervised approach to NERQ, trained with a large set of manually tagged queries and consisting of two steps: 1) performs a binary classification, where each query term is tagged as token/entity depending on whether or not it is part of a named entity; and 2) takes advantage of these binary token/entity labels for categorizing each term within the query into one of a pre-defined set of classes.

## 2 Related Work

To the best of our knowledge, there have been a few previous research efforts attempting to recognize named entities in search queries. This problem is relatively new and it was first introduced by (Paşca, 2007). Their weakly supervised method starts with an input class represented by a set of seeds, which are used to induce typical query-contexts for the respective input category. Contexts are then used to acquire and select new candidate instances for the corresponding class.

In their pioneer work, (Guo et al., 2009) focused on queries that contain only one named entity belonging to four classes (i.e., movie, game, book and song). As for learning approach, they employed weakly supervised topic models using partially labeled seed named entities. These topic models were trained using query log data corresponding to 120 seed named entities (another 60 for testing) selected from three target web sites. Later, (Jain and Pennacchiotti, 2010) extended this approach to a completely unsupervised and class-independent method.

In another study, (Du et al., 2010) tackled the lack of context in short queries by interpreting query sequences in the same search session as extra contextual information. They capitalized on a collection of 6,000 sessions containing only queries targeted at the car model domain.

They trained Conditional Random Field (CRF) and topic models, showing that using search sessions improves the performance significantly. More recent, (Alasiry et al., 2012a; Alasiry et al., 2012b) determined named entity boundaries, combining grammar annotation, query segmentation, top ranked snippets from search engine results in conjunction with a web n-gram model.

In contrast, we do not profit from seed named entities nor web search results, but rather from a large manually annotated collection of about 80,000 open-domain queries. We consider search queries containing multiple named entities, and we do not benefit from search sessions. Furthermore, our approach performs two labelling steps instead of a straightforward one-step labelling. The first step checks if each query term is part of a named entity or not, while the second assigns each term to one out of a set of 29<sup>1</sup> classes by taking into account the outcome of the first step.

### 3 NERQ-2S

NERQ-2S is a two-step named entity recognizer for open-domain search queries. First, it differentiates named entity terms from other types of tokens (e.g., word and numbers) on the basis of a CRF<sup>2</sup> trained with manually annotated data. In the second step, NERQ-2S incorporates the output of this CRF into a new CRF as a feature. This second CRF assigns each term within the query to one out of 29 pre-defined categories. In essence, considering these automatically computed binary entity/token labels seeks to influence the second model so that the overall performance is improved.

Given the fact that binary entity/token tags are only used as additional contextual evidence by the second CRF, these labels can be reverted in the second step. NERQ-2S identifies 28 named entity classes that are prominent in search engine open-domain queries (see table 1). This set of categories was deliberately chosen as a means of enriching search results regarding general user interests, and thus aimed at providing a substantially better overall user experience. In particular, named entities are normally utilized for devising the lay-out and the content of the result page of a search engine.

<sup>1</sup>In actuality, we considered 29 classes: 28 regards named entities and one class for non-entity (token). For the sake of readability, from now on, we say indistinctly that the second step identifies 28 named entity classes or 29 classes.

<sup>2</sup>CRFsuite: <http://www.chokkan.org/software/crfsuite>

At both steps, NERQ-2S uses a CRF as classifier and a set of properties, which was determined separately for each classifier by executing a greedy feature selection algorithm (see next section). For both CRFs, this algorithm contemplated as candidates the 24 attributes explained in table 2. Additionally, in the case of the second CRF, this algorithm took into account the entity/token feature produced by the first CRF. Note that features in table 2 are well-known from other named entity recognition systems (Nadeau and Sekine, 2007).

## 4 Experiments

In all our experiments, we carried out a 10-fold cross-validation. As for **data-sets**, we benefited from a collection comprising 82,413 queries, which are composed of 242,723 terms<sup>3</sup>. These queries were randomly extracted from the query log of a commercial search engine, and they are exclusively in English. In order to annotate our query collection, these queries were first tokenized, and then each term was manually tagged by an editorial team using the schema adopted in (Tjong Kim Sang and De Meulder, 2003).

Attributes were selected by exploiting a **greedy** algorithm. This procedure starts with an empty bag of properties and after each iteration adds the one that performs the best. In order to determine this feature, this procedure tests each non-selected attribute together with all the properties in the bag. The algorithm stops when there is no non-selected feature that enhances the performance.

Figure 1: Attributes selected by the greedy algorithm and their respective contribution (baseline). See also table 2 for id-feature mappings.

As for a **baseline**, we used a traditional one-step approach grounded on CRF enriched with 13

<sup>3</sup>Due to privacy laws, query logs cannot be made public.

ID	Name	Example	ID	Name	Example
0	Airline Code	AA, LA, JJ	15	Food	Sushi, Bread, Dessert
1	Beverage	Cocktails, Beer	16	Food Ingredient	Honey, Avocado

14	File Name	msimn.exe, .htaccess			

Table 1: Named entity classes recognized by NERQ-2S.

out of our 24 features (see table 2), which were chosen by running our greedy feature selection algorithm. Figure 1 shows the order that these 13 features were chosen, and their respective impact on the performance. Regarding these results, it is worth highlighting the following findings:

1. The first feature selected by the greedy algorithm models each term by its non-numerical characters (id=11 in table 2). This attribute helps to correctly tag 80.42% of the terms when they are modified (numbers removed).
2. The third chosen feature considers the value of the following word, when tagging a term (id=2 in table 2). This attribute helps to correctly annotate 79.68%, 74.55% and 74.87% of tokens belonging to person, place and organization names, respectively.
3. Our figures also point out to the relevance of the three word features (id=0,1,2 in table 2). These features were selected in a row, boosting the performance from  $F(1) = 0.561$  to  $F(1) = 0.634$ , a 13.01% increase with respect to the previously selected properties.

In summary, the performance of the one-step baseline is  $F(1) = 0.659$ . In contrast, figure 2 highlights the 16 out of the 25 features utilized by the second phase of NERQ-2S. Note that the “new” bar indicates the token/entity attribute determined in the first step. Most importantly, NERQ-2S finished with an  $F(1) = 0.729$ , which means a 10.62% enhancement with respect to the one-step baseline. From these results, it is worth considering the following aspects:

1. In terms of features, 11 of the 13 attributes used by the one-step baseline were also exploited by NERQ-2S. Further, NERQ-2S profits from four additional properties that were also available for the one-step baseline.
2. The five more prominent properties selected by the baseline, were also chosen by NERQ-2S with just a slight change in order.
3. The “new” feature achieves an improvement of 23.51% ( $F(1) = 0.641$ ) with respect to the previous selected property. The impact of the entity/token attribute can be measure when compared with the performance accomplished by the first five features selected by the baseline ( $F(1) = 0.634$ ).

In light of these results, we can conclude that: a) adding the entity/token feature to the CRF is vital for boosting the performance, making a two-step approach a better solution than the traditional one-step approach; and b) this entity/token property is complementary to the list shown in table 2.

The confusion matrix for NERQ-2S shows that errors, basically, regard highly ambiguous terms. Some interesting misclassifications:

1. Overall, 17.38% of the terms belonging to place names were mistagged by NERQ-2S. From these, 72.11% were perceived as part of organization names.
2. On the other hand, 17.27% of the terms corresponding to organization names were mislabelled by NERQ-2S. Here, 15.52% and 12.84% of these errors were due to the fact that these terms were seen as tokens and parts of place names, respectively.

ID	Feature	Example
Word Features		
0	Current term ( $t_i$ )	abc123
1	Previous term ( $t_{i-1}$ )	before
2	Next word ( $t_{i+1}$ )	after
N-grams		
3	Bi-gram of $t_{i-1}$ and $t_i$	before abc123
4	Bi-gram of $t_i$ and $t_{i+1}$	abc123 after
Pre- & Postfix		
5	1 leftmost character from $t_i$	a
6	2 leftmost characters from $t_i$	ab
7	3 leftmost characters from $t_i$	abc
8	1 rightmost character from $t_i$	3
9	2 rightmost characters from $t_i$	23
10	3 rightmost characters from $t_i$	123
Reductions		
11	$t_i$ without digits	abc
12	$t_i$ without letters	123
Word Shape		
13	Shape of $t_i$ (“a” represents letters; “0” digits, “-” special characters)	aaa000
14	Shape of $t_i$ (same elements joined)	a0
Position & Lengths		
15	Position of $t_i$ from left	3
16	Position of $t_i$ from right	2
17	Character length of $t_i$	6
Boolean		
18	$t_i$ is a number? (only digits)	false
19	$t_i$ is a word? (only letters)	false
20	$t_i$ is a mixture of letters and digits?	true
21	$t_i$ contains “?”	false
22	$t_i$ contains apostrophe?	false
23	$t_i$ contains other special characters?	false

Table 2: List of used features. Examples are for the third term of query “*first before abc123 after*”.

Figure 2: Attributes selected by the greedy algorithm and their respective contribution (NERQ-2S). See also table 2 for id-feature mappings. The word “new” denotes the binary token/entity attribute determined in the first step.

Incidentally, NERQ-2S mislabelled 10.40% of the tokens (non-named entity terms), while the one-step baseline 17.57%. This difference signals the importance of first-step consisting of an specialized and efficient token/entity term annotator. With regard to the first step of NERQ-2S, nine out of the 24 properties were useful, and the first step finished with an  $F(1) = 0.8077$ . From these nine attributes, eight correspond to the top eight features used by our one-step baseline, and one extra attribute (id=20). Thus, the discriminative probabilistic model learned in this first step is more specialized for this task. That is to say, though the context of a term might be modelled similarly, the parameters of the CRF model are different.

The confusion matrix for this binary classifier shows that 11.44% of entity terms were mistagged as token, while 22.24% of tokens as entity terms. This means a higher percentage of errors comes from mislabelled tokens.

On a final note, as a means of quantifying the impact of the first step on NERQ-2S, we replaced the output given by the first CRF model with the manual binary token/annotations given by the editorial team. In other words, the “new” feature is now a manual input instead of an automatically computed property. By doing this, NERQ-2S increases the performance from  $F(1) = 0.729$  to  $F(1) = 0.809$ , which means 10.97% better than NERQ-2S and 22.76% than the one-step baseline. This corroborates that a two-step approach to NERQ is promising.

## 5 Conclusions and Further Work

This paper presents NERQ-2S, a two-step approach to the problem of recognizing named entities in search queries. In the first stage, NERQ-2S checks as to whether or not each query term belongs to a named entity, and in the second phase, it categorizes each token according to a set of pre-defined classes. These classes are aimed at enhancing the user experience with the search engine in contrast to previous pre-defined categories.

Our results indicate that our two-step approach outperforms the typical one-step NERQ. Since our error analysis indicates that there is about 11% of potential global improvement by boosting the performance of the entity/token tagger, one research direction regards combining the output of distinct two-sided classifiers for improving the overall performance of NERQ-2S.

# A Comparison of Centrality Measures for Graph-Based Keyphrase Extraction

Florian Boudin

LINA - UMR CNRS 6241, Université de Nantes, France

florian.boudin@univ-nantes.fr

## Abstract

In this paper, we present and compare various centrality measures for graph-based keyphrase extraction. Through experiments carried out on three standard datasets of different languages and domains, we show that simple degree centrality achieve results comparable to the widely used TextRank algorithm, and that closeness centrality obtains the best results on short documents.

## 1 Introduction

Keyphrases are the words and phrases that precisely and compactly represent the content of a document. Keyphrases are useful for a variety of tasks such as summarization (Zha, 2002), information retrieval (Jones and Staveley, 1999) and document clustering (Han et al., 2007). However, many documents do not come with manually assigned keyphrases. This is because assigning keyphrases to documents is very costly and time consuming. As a consequence, automatic keyphrase extraction has attracted considerable attention over the last few years.

Previous works fall into two categories: supervised and unsupervised methods. The idea behind supervised methods is to recast keyphrase extraction as a binary classification task (Witten et al., 1999). Unsupervised approaches proposed so far have involved a number of techniques, including language modeling (Tomokiyo and Hurst, 2003), clustering (Liu et al., 2009) and graph-based ranking (Mihalcea and Tarau, 2004). While supervised approaches have generally proven more successful, the need for training data and the bias towards the domain on which they are trained remain two critical issues.

In this work, we focus on graph-based methods for keyphrase extraction. Given a document, these

methods construct a word graph from which the most important nodes are selected as keyphrases. TextRank (Mihalcea and Tarau, 2004), a ranking algorithm based on the concept of eigenvector centrality, is usually applied to compute the importance of the nodes in the graph. Here, centrality is used to estimate the importance of a word in a document.

The concept of centrality in a graph has been extensively studied in the field of social network analysis and many different measures were proposed, see (Opsahl et al., 2010) for a review. Surprisingly, very few attempts have been made to apply such measures to keyphrase extraction. (Litvak et al., 2011) is one of them, where degree centrality is used to select keyphrases. However, they evaluate their method indirectly through a summarization task, and to our knowledge there are no published experiments using other centrality measures for keyphrase extraction. In this study, we conduct a systematic evaluation of the most well-known centrality measures applied to the task of keyphrase extraction on three standard evaluation datasets of different languages and domains<sup>1</sup>.

The rest of this paper is organized as follows. We first briefly review the previous work, followed by a description of the centrality measures. Next, we present our experiments and results and conclude with a discussion.

## 2 Related work

Graph-based keyphrase extraction has received much attention recently and many different approaches have been proposed (Mihalcea and Tarau, 2004; Wan and Xiao, 2008a; Wan and Xiao, 2008b; Liang et al., 2009; Tsatsaronis et al., 2010; Liu et al., 2010). All of these approaches use a graph representation of the documents in

<sup>1</sup>Code and datasets used in this study are available at [https://github.com/boudinfl/centrality\\_measures\\_ijcnlp13](https://github.com/boudinfl/centrality_measures_ijcnlp13)

which nodes are words or phrases, and edges represent co-occurrence or semantic relations. The importance of each node is computed using TextRank (Mihalcea and Tarau, 2004), a graph-based ranking algorithm derived from Google’s PageRank (Page et al., 1999). Words corresponding to the top ranked nodes are then selected and assembled to generate keyphrases.

Most previous studies focus on building a more accurate graph representation from the content of the documents (Tsatsaronis et al., 2010) or adding features to TextRank (Liu et al., 2010), but very few tried to use other existing centrality measures. The only works we are aware of are that of Litvak and Last (2008) that applied the HITS algorithm (Kleinberg, 1999), and Litvak et al. (2011) in which TextRank and degree centrality are compared. However, both works were evaluated against a summarization dataset by checking whether extracted keyphrases appear in reference summaries. This methodology is somewhat unreliable, as a word that occurs in a summary is not necessarily a keyphrase (e.g. experiments, results).

### 3 Keyphrase extraction

Extracting keyphrases from a document can be divided into three steps. First, a word graph is constructed from the document. The importance of each word is then determined using a centrality measure. Lastly, keyphrase candidates are generated and ranked based on the words they contain. The following sections describe each of these steps in detail.

#### 3.1 Graph construction

Given a document, the first step consists in building a graph representation from its content. An undirected word graph is constructed for each document, in which nodes are words and edges represent co-occurrence relations within a window of maximum  $N$  words. Words added to the graph are restricted with syntactic filters, which select only lexical units of a certain Part-of-Speech (nouns and adjectives). Edges are weighted according to the co-occurrence count of the words they connect. Following (Wan and Xiao, 2008b), we set the co-occurrence window size to 10 in all our experiments.

#### 3.2 Centrality measures

Once the word graph is constructed, centrality measures are computed to assign a score to each node. Let  $G = (V, E)$  be a graph with a set of vertices (nodes)  $V$  and a set of edges  $E$ . Starting with degree centrality, this section describes the ranking models we will be using in this study.

**Degree centrality** is defined as the number of edges incident upon a node. Applied to a word graph, the degree of a node  $V_i$  represents the number of words that co-occur with the word corresponding to  $V_i$ . Let  $\mathcal{N}(V_i)$  be the set of nodes connected to  $V_i$ , the degree centrality of a node  $V_i$  is given by:

$$C_D(V_i) = \frac{|\mathcal{N}(V_i)|}{|V| - 1} \quad (1)$$

**Closeness centrality** is defined as the inverse of farness, i.e. the sum of the shortest distances between a node and all the other nodes. Let  $\text{distance}(V_i, V_j)$  be the shortest distance between nodes  $V_i$  and  $V_j$  (in our case, computed using inverted edge weights to use co-occurrence information), the closeness centrality of a node  $V_i$  is given by:

$$C_C(V_i) = \frac{|V| - 1}{\sum_{V_j \in V} \text{distance}(V_i, V_j)} \quad (2)$$

**Betweenness centrality** quantifies the number of times a node acts as a bridge along the shortest path between two other nodes. Let  $\sigma(V_j, V_k)$  be the number of shortest paths from node  $V_j$  to node  $V_k$ , and  $\sigma(V_j, V_k|V_i)$  the number of those paths that pass through node  $V_i$ . The betweenness centrality of a node  $V_i$  is given by:

$$C_B(V_i) = \frac{\sum_{V_j \neq V_i \neq V_k \in V} \frac{\sigma(V_j, V_k|V_i)}{\sigma(V_j, V_k)}}{(|V| - 1)(|V| - 2)/2} \quad (3)$$

**Eigenvector centrality** measures the centrality of a node as a function of the centralities of its neighbors. Unlike degree, it accounts for the notion that connections to high-scoring nodes are more important than those to low-scoring ones. Let  $w_{ji}$  be the weight of the edge between nodes  $V_j$  and  $V_i$  and  $\lambda$  a constant, the eigenvector centrality of a node  $V_i$  is given by:

$$C_E(V_i) = \frac{1}{\lambda} \sum_{V_j \in \mathcal{N}(V_i)} w_{ji} \times C_E(V_j) \quad (4)$$

**TextRank** is based on the eigenvector centrality measure and implements the concept of “voting”. Let  $d$  be a damping factor (set to 0.85 as in (Mihalcea and Tarau, 2004)), the TextRank score  $S(V_i)$  of a node  $V_i$  is initialized to a default value and computed iteratively until convergence using the following equation:

$$S(V_i) = (1-d) + \left( d \times \sum_{V_j \in \mathcal{N}(V_i)} \frac{w_{ji} \times S(V_j)}{\sum_{V_k \in \mathcal{N}(V_j)} w_{jk}} \right) \quad (5)$$

### 3.3 Keyphrase selection

Selecting keyphrases is a two step process. First, keyphrase candidates are extracted from the document. Sequences of adjacent words, restricted to nouns and adjectives only, are considered as candidates. Extracting sequences of adjacent words instead of n-grams ensure that keyphrase candidates are grammatically correct but entail a lower recall.

The score of a candidate keyphrase  $k$  is computed by summing the scores of the words it contains normalized by its length + 1 to favor longer n-grams (see equation 6).

$$\text{score}(k) = \frac{\sum_{\text{word} \in k} \text{Score}(\text{word})}{\text{length}(k) + 1} \quad (6)$$

Keyphrase candidates are then ranked and redundant candidates filtered out. Two candidates are considered redundant if they have a same stemmed form (e.g. “precisions” and “precision” are both stemmed to “precis”).

## 4 Experimental settings

### 4.1 Datasets

As mentioned by (Hasan and Ng, 2010), it is essential to evaluate keyphrase extraction methods on multiple datasets to fully understand their strengths and weaknesses. Accordingly, we use three different datasets in our experiments. An overview of each dataset is given in Table 1.

The **Inspecc** dataset (Hulth, 2003) is a collection of abstracts from journal papers. We use the 500 abstracts designated as the test set and the set of uncontrolled keyphrases.

The **Semeval** dataset (Kim et al., 2010) is composed of scientific articles collected from the ACM Digital Library. We use the 100 articles of the test set and its set of combined author- and reader-assigned keyphrases.

The **DEFT** dataset (Paroubek et al., 2012) is made of French scientific articles published in social science journals. We use the 93 articles of the test set and its set of author-assigned keyphrases.

	<b>Inspecc</b>	<b>Semeval</b>	<b>DEFT</b>
Type	abstracts	articles	articles
Language	English	English	French
Documents	500	100	93
Tokens/document	136	5180	6970
Keyphrases/document	9.8	14.7	5.2
Tokens/keyphrase	2.3	2.1	1.6

Table 1: Overview of the three datasets we use in our experiments.

### 4.2 Pre-processing

For each dataset, we apply the following pre-processing steps: sentence segmentation, tokenisation and Part-of-Speech tagging. For the latter, we use the Stanford POS-tagger (Toutanova et al., 2003) for English and MELt (Denis and Sagot, 2009) for French. We use the networkx<sup>2</sup> package to compute the centrality measures.

### 4.3 Evaluation measures

The performance of each centrality measure is evaluated with precision, recall and f-score at the top 10 keyphrases. Candidate and reference keyphrases are stemmed to reduce the number of mismatches. Consistent with (Hasan and Ng, 2010), we also report the performance of each centrality measure in terms of precision-recall curves for the three datasets. To generate the curves, we vary the number of extracted keyphrases from 1 to the total number of keyphrase candidates.

## 5 Results

Table 2 presents the performance of each centrality measure on the three datasets. Overall, we observe that the best results are obtained using degree which is the simplest centrality measure both conceptually and computationally. Closeness obtains the best results on Inspecc and significantly outperforms TextRank. However, it yields the worst performance on the other two datasets. This suggests that closeness is best suited for short documents (Inspecc documents are 136 tokens long on average).

<sup>2</sup><http://networkx.github.io/>

Centrality	Inspec			Semeval			DEFT		
	P	R	F	P	R	F	P	R	F
Degree	31.4	37.6	32.2	<b>11.4</b>	<b>8.0</b>	<b>9.3</b>	<b>7.7</b>	<b>14.8</b>	<b>10.0</b>
Closeness	<b>32.8<sup>‡</sup></b>	<b>38.6<sup>†</sup></b>	<b>33.3<sup>‡</sup></b>	4.1	2.8	3.3	2.6	5.2	3.4
Betweenness	31.5	37.7	32.3	10.0	7.1	8.2	7.3	13.9	9.5
Eigenvector	29.5	35.0	30.2	10.7	7.4	8.7	6.2	12.1	8.1
TextRank	31.5	37.7	32.2	10.7	7.4	8.7	7.6	14.5	9.9

Table 2: Performance of each centrality measure in terms of precision, recall and f-score at the top 10 keyphrases on the three datasets (<sup>†</sup> and <sup>‡</sup> indicate a significant improvement over TextRank at the 0.05 and 0.01 levels respectively using Student’s t-test).

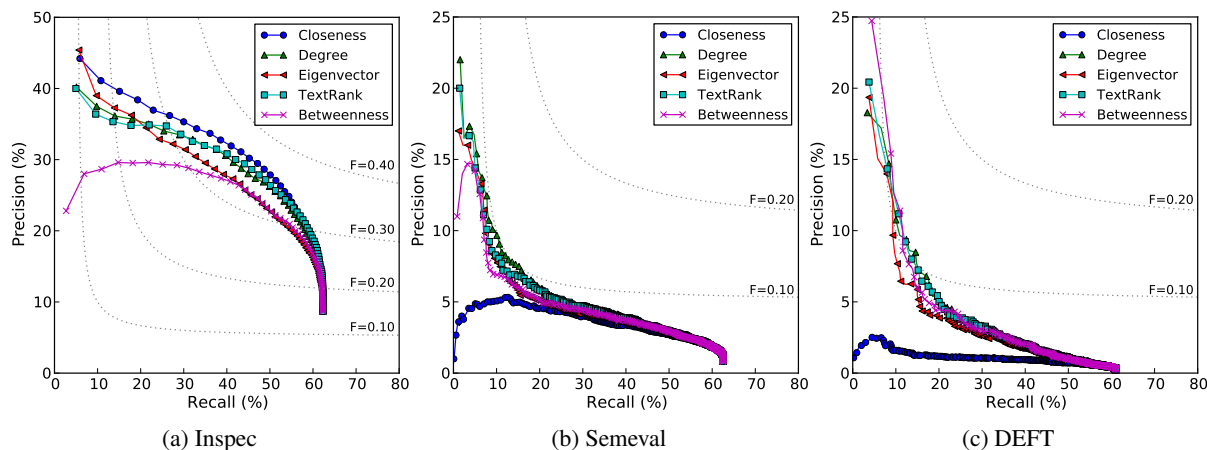

Figure 1: Precision-recall curves for each centrality measure on the three datasets.

To get a better understanding of the performance for each centrality measure, we report in Figure 1 their precision-recall curves for each of the three datasets. Moreover, to estimate how each measure performs in terms of f-score, we also plot the curves corresponding to different levels of f-score. Again, we observe that the best measure for the Inspec dataset is closeness. For the other two datasets, there is no centrality measure which overall performs best. We note that the maximum recall is almost the same for the three datasets.

Interestingly, degree and TextRank achieve similar performance on the three datasets. The reason for this is that TextRank is derived from PageRank which was shown to be proportional to the degree distribution for undirected graphs (Grolmusz, 2012). Degree centrality, whose time complexity is  $\Theta(V^2)$ , can therefore advantageously replace TextRank for keyphrase extraction.

## 6 Conclusion

In this paper, we presented a comparison of five centrality measures for graph-based keyphrase extraction. Using three standard datasets of different languages and domains, we showed that degree centrality, despite being conceptually the simplest measure, achieves results comparable to the widely used TextRank algorithm. Moreover, results show that closeness significantly outperforms the other centrality measures on short documents.

## Acknowledgments

The author would like to thank Emmanuel Morin and Solen Quiniou for their helpful comments on this work. We also thank the anonymous reviewers for their useful comments. This work was supported by the French Agence Nationale de la Recherche under grant ANR-12-CORD-0029 (TermITH project).

## Abstract

In this paper, we present a translation template model to translate Chinese unknown words. The model exploits translation templates, which are extracted automatically from a word-aligned parallel corpus, to translate unknown words. The translation templates are designed in accordance with the structure of unknown words. When an unknown word is detected during translation, the model applies translation templates to the word to get a set of matched templates, and then translates the word into a set of suggested translations. Our experiment results demonstrate that the translations suggested by the unknown word translation template model significantly improve the performance of the Moses machine translation system.

## 1 Introduction

Automatic translation of unknown words is still an open problem. As a result, most statistical machine translation (SMT) systems treat such words as unknown tokens and leave them untranslated. (Koehn et al., 2003; Chiang, 2005; Koehn et al., 2007)

The unknown word translation problem has generated considerable interest in recent years. Some works (e.g., Callison-Burch et al., 2006; Marton et al., 2009; Mirkin et al., 2009) focus on finding in-vocabulary paraphrases, which are then used as bridges to translate target unknown words. Li and Yarowsky (2008) proposed an unsupervised method for extracting the mappings from Chinese abbreviations and their full-forms. The method exploits the full-forms as bridges to translate the abbreviations. A prerequisite of the above methods is that the unknown words must have paraphrases (or full-forms). However, many

types of unknown words do not have paraphrases (full-forms) naturally.

In contrast to paraphrasing methods, Huang *et al.* (2011) developed a sublexical translation method that translates an unknown word by combining the translations of its sublexicals. However, to deal with the reordering problem, the model combines the translations of sublexicals by considering both *straight* and *inverse* directions and uses a language model to select the better one. The ordering is generally morphological structure dependent, but language models only select the most fluent order without considering morphological constraints.

In this paper, we propose a translation template model to translate Chinese unknown words. Our model has a number of advantages. First, the translation templates can be extracted automatically from a word-aligned parallel corpus. Second, the word order information is encoded in the templates, so we can compose the translation of an unknown word in a more reliable order. Finally, the expansion of the non-terminal symbol in the translation templates is flexible.

The remainder of this paper is organized as follows. In the next section, we introduce the proposed translation template model. In Section 3, we describe the experimental setup; and in Section 4, we evaluate the translations of unknown words derived by our model. Section 5 contains some concluding remarks.

## 2 Translation Template Model

The form of a translation template is similar to that of the *hierarchical phrase pair* rule (Chiang, 2005), except that the translation template is designed for translating unknown words, whereas the hierarchical phrase pair rule is designed for translating phrases. As a result, they differ in terms of the training process and rule fitting process.

---

$Na \rightarrow < [Na_1]業, [Na_1] industry >$   
 $Nc \rightarrow < [Nc_1]市, [Nc_1] city >$   
 $Na \rightarrow < 副[Na_1], deputy [Na_1] >$   
 $Nc \rightarrow < [Nv_1] 司, secretary for [Nv_1] >$

---

Figure 1. Examples of translation templates; the notations in brackets represent the non-terminal symbols.

As shown in Figure 1., a translation template is comprised of three parts: a non-terminal symbol ( $Na$ ) on the left-hand side, a source language template ( $[Na_1]業$ ) in the middle, and a target language template ( $[Na_1] industry$ ) on the right-hand side.

## 2.1 Definition of Translation Template

Based on the symbols used by Chiang (2005), we define a translation template as follows:

$$X \rightarrow < \gamma, \alpha, \sim > \quad (1)$$

where  $X$  is a left-hand side non-terminal symbol, which is usually a part-of-speech that constrains the part-of-speech of the target unknown word;  $\gamma$  is a translation template of the source language, and may contain terminal and non-terminal symbols;  $\alpha$  is a translation template of the target language, and may also contain terminal and non-terminal symbols; and  $\sim$  is a one-to-one correspondence between non-terminal occurrences in  $\gamma$  and non-terminal occurrences in  $\alpha$ .

## 2.2 Translation Process

The steps of the translation process for a given unknown word are as follows:

- Apply translation templates to the unknown word and return the matched templates.
- Translate the word based on the matched templates.
- Compute the scores for each translation candidate.

We take "出口業" (export industry) as an example to illustrate the translation process. First, translation templates are applied to the word and a set of templates are returned (shown as Figure 2).

---

$Na \rightarrow < [Nv_1]業, [Nv_1] industry >$   
 $Na \rightarrow < [Nv_1]業, [Nv_1] business >$

---

Figure 2. The matched translation templates.

Then, the non-terminal symbol of each rule is expanded with the translation equivalents of the

in-vocabulary word "出口" (export) and the following translation candidates are generated by the matched translation templates (shown as Figure 3).

---

$Na \rightarrow < 出口業, export industry >$   
 $Na \rightarrow < 出口業, exportation industry >$   
 $Na \rightarrow < 出口業, export business >$   
 $Na \rightarrow < 出口業, exportation business >$

---

Figure 3. Translation candidates.

In the final step, we compute each translation candidate's score, and then rank all the candidates to drive the top-n translations.

## 2.3 Translation Probability and Lexical Weighting

Most phrase-based SMT systems use the *translation probability* and the *lexical weighting* as the parameters of scoring functions for translated phrases (Koehn et al., 2003). The original SMT translation probability is defined as follows:

$$p(\mathbf{f} | \mathbf{e}) = \frac{freq(\mathbf{f}, \mathbf{e})}{freq(\mathbf{e})} \quad (2)$$

where  $\mathbf{e}$  denotes a phrase in the source language,  $\mathbf{f}$  denotes a phrase in the target language, and  $freq(\bullet)$  denotes the frequency function.

Due to the lack of unknown words in the training data, we approximate the translation probability by using the *rule fitting probability*, which is defined as follows:

$$p(\mathbf{f} | \mathbf{e}) \cong p(X \rightarrow < \gamma, \alpha, \sim > | \mathbf{e}) \quad (3)$$

In our experiments, we utilized the maximum entropy model (Berger et al., 1996) to model the *rule fitting probability*. It is also difficult to estimate the *lexical weighting* for the translation candidates of an unknown word. The original lexical weighting is defined as follows:

$$p_w(\mathbf{f} | \mathbf{e}, \mathbf{a}) = \prod_{i=1}^n \frac{1}{|\{j | (i, j) \in \mathbf{a}\}|} \sum_{\forall (i, j) \in \mathbf{a}} p(f_i | e_j) \quad (4)$$

where  $f_i$  denotes a word in the source phrase, and  $e_j$  denotes the words in the target phrase.

For convenience, we assume that the alignment units of the unknown words are Chinese characters, and that the alignments

between Chinese characters and English words are fully linked. Under this assumption, the lexical weighting can be simplified as follows:

$$p_w(\mathbf{f} | \mathbf{e}, a) \cong \prod_{\forall f_i \in \mathbf{f}} \frac{1}{|\mathbf{e}|} \sum_{\forall c_j \in \mathbf{e}} p(f_i | c_j) \quad (5)$$

where  $c_i$  denotes a character in the source phrase  $\mathbf{e}$  (a Chinese unknown word), and  $f_i$  denotes a word in the target phrase  $\mathbf{f}$  (an English phrase).

## 2.4 Extraction of Translation Templates

The translation templates are automatically extracted from a word-aligned corpus by the following steps:

- Mark the known translation equivalents in corresponding phrase pairs in the word-aligned corpus.
- Transform the marked translation equivalent pairs into the translation template form.
- Collect the translation templates derived in the previous step and compute the frequency for each rule.

In the first step, to mine translation templates from the word-aligned corpus, we utilized multi-syllabic Chinese compound words to derive translation templates by marking their translation equivalents in the word-aligned corpus, as shown in Figure 4.

POS	Chinese $\mathbf{f}$	Aligned English $\mathbf{e}$
Na	[旅遊]業	[tourism] industry
Na	副[廠長]	deputy [director]
Nc	[運輸]司	secretary for [transport]

Figure 4. Examples of word-aligned pairs ( $\mathbf{f}$ ,  $\mathbf{e}$ ) with marked translation equivalents in the square brackets.

In the second step, we transform the marked items into the translation template form by replacing the marked words/morphemes with non-terminal symbols. The symbols on the left-hand side are part-of-speech constraints on the unknown word. Figure 5 shows the translation templates derived from the word-aligned pairs in Figure 4.

Na	→	< [Na <sub>1</sub> ]業 , [Na <sub>1</sub> ] industry >
Na	→	< 副[Na <sub>1</sub> ] , deputy [Na <sub>1</sub> ] >
Nc	→	< [Nv <sub>1</sub> ] 司 , secretary for [Nv <sub>1</sub> ] >

Figure 5. The translation templates transformed from the word-aligned pairs in Figure 4.

Finally, we collect the translation templates from the translation template tagged corpus and remove low frequency templates from the list.

## 2.5 Rule Fitting Probability

We employ the Maximum Entropy Toolkit (Zhang, 2004) to construct the rule fitting probability model, which uses the features shown in Figure 6.

POS	POS of the word.
Prefix	First character of the word.
Suffix	Last character of the word.
Character	Each character of the word.
Length	Length of the word.
Has_surname	Does the word begin with a Chinese surname?
Has_number	Does the word contain a digital number?
POS-1	POS of the previous word.
POS+1	POS of the next word.
Word-1	Previous word.
Word+1	Next word.

Figure 6. The extra features used by the *rule fitting probability* model.

## 2.6 Morphological Translation Rules

Some unknown words cannot be composed with simple morphemes. For example, "百分之八十" (80 percent) has a numeric morpheme, "八十" (80), which is not enumerable. The template model is flexible to be extended to use morphological translation rules instead of translation table to generate the translations of morphemes. We use two types of morphological translation rules: *numerical* and *phonetic* morphological translation rules.

## 3 Experimental Setting

We evaluate the model on Moses (Koehn et al., 2007) by embedding the translations of the unknown words to test data as suggestion translations.

### 3.1 Baseline SMT System and Data Sets

We used the Hong Kong Parallel Text (LDC2004T08) as the training data for the Moses SMT system and our template model. The Chinese sentences were pre-processed by the CKIP Chinese word segmentation system (Ma and Chen, 2003). The language model was trained on the English Gigaword corpus (LDC2003T05). We randomly selected 340

sentences from the NIST MT08 test data as our development set, the NIST MT06 test data and the rest of the NIST MT08 as our test set.

### 3.2 Training

The parallel text was word-aligned by the GIZA++ toolkit (Och and Ney, 2003). Then, we utilized the word-aligned corpus to extract translation templates. This process yielded a set of translation templates and a translation template tagged corpus, which was used to train the fitting probability model. To evaluate the fitting probability model, the translation template tagged corpus was randomly split into two parts to obtain a translation template tagged training set (about 1,800,000 sentences) and a translation template tagged test set (about 200,000 sentences).

We used the translation template tagged training set to train the rule fitting probability model. Then, we used the translation template tagged test set as a pseudo gold standard to evaluate the performance of the rule fitting probability model.

We also rebuilt the experiments based on the FBIS Parallel Text (LDC2003E14), which contains about 300,000 parallel sentences to verify the stability of our model. The rebuilding process is the same as that for the Hong Kong Parallel Text.

## 4 Experimental Results

We evaluated the translation template model on the NIST MT06 test set and NIST 08 subset. During the evaluation, the test sets were translated by the Moses SMT system with/without the embedded translation suggestions derived by the translation template model. The parameters in Moses were tuned by *minimum-error-rate* training (Och, 2003) on the development set.

	MT06	MT08_sub
Baseline	23.36	19.36

Phonetic	23.83 (+0.47)	19.65 (+0.29)
Numeric	23.43 (+0.07)	19.44 (+0.08)
All	23.89 (+0.53)	19.80 (+0.44)

Table 1. Evaluation results based on the Hong Kong Parallel Text.

As mentioned in Section 2.6, the translation templates can be flexible expanded by translation table as well as by morphological translation

rules. In our experiments, we exploit phonetic and numerical morphological translation rules to generate translations of morphemes. Table 1 shows the performances of the translation results with/without unknown word translation suggestions. As it shows, all of the translation expansion methods significantly improved the underlying SMT system.

To verify the stability of this method, we also rebuilt a baseline system and an unknown word translation model based on the FBIS parallel corpus, as shown in Table 2.

	MT06	MT08_sub
Baseline	24.38	19.94
Trans. table	24.54 (+0.16)	20.21 (+0.27)
Phonetic	24.78 (+0.40)	20.28 (+0.34)
Numeric	24.64 (+0.26)	20.09 (+0.15)
All	25.09 (+0.71)	20.65 (+0.71)

Table 2. Evaluation results based on the FBIS parallel corpus.

The improvement in the BLEU score is statistically significant ( $p < 0.01$ ) under the paired bootstrap re-sampling test (Koehn, 2004). The experimental results show that the proposed translation template model significantly improves the performance of the statistical machine translation system.

## 5 Conclusion

We have proposed a method that utilizes a translation template model to translate Chinese unknown words. The translation templates can be automatically extracted from a word-aligned parallel corpus and evaluated without using extra information. Experimental results show that the model can suggest accurate unknown word translations for an existing SMT system and improve the translation quality.

# Multilingual Lexicon Bootstrapping - Improving a Lexicon Induction System Using a Parallel Corpus

Patrick Ziering<sup>1</sup> Lonneke van der Plas<sup>1</sup> Hinrich Schütze<sup>2</sup>

<sup>1</sup>Institute for NLP, University of Stuttgart, Germany

<sup>2</sup>CIS, University of Munich, Germany

{Patrick.Ziering, Lonneke.vanderPlas}@ims.uni-stuttgart.de

## Abstract

We address the task of improving the quality of lexicon bootstrapping, i.e., of expanding a semantic lexicon on a given corpus. A main problem of iterative bootstrapping techniques is the fact that lexicon quality degrades gradually as more and more false terms are added. We propose to exploit linguistic variation between languages to reduce this problem of semantic drift with a knowledge-lean and language-independent ensemble method. Our results on English and German show that lexicon bootstrapping benefits significantly from the multilingual symbiosis.

## 1 Introduction

High-quality semantic lexicons are an essential resource for many natural language processing (NLP) tasks like information extraction or anaphora resolution. Methods for automatically bootstrapping semantic lexicons given a seed list often struggle with lexicon accuracy decrease in higher iterations depending on corpus size (Igo and Riloff, 2009). One reason for this is *semantic drift*, which occurs when erroneous terms and/or contexts are introduced into and then dominate the iterative process (Curran et al., 2007). For instance, the ambiguity found in female names such as *Iris* and *Rose* may cause the induced terms to drift into flower names (McIntosh and Curran, 2009). Examples from the patent domain, that we are focusing on in this work, are PROCESSES that may drift into the semantic class of OBJECTS when terms such as *energy storage* and *spring coupling* are induced.

Previous work has used the cross-lingual correspondence between variations in linguistic structure and variations in ambiguity as a form of naturally occurring supervision in unsupervised learning for a number of tasks (Dagan et al., 1991;

Snyder and Barzilay, 2010). On the lexical level, cross-lingual variations proved to remedy problems related to polysemy for synonym acquisition (Van der Plas and Tiedemann, 2010) and word sense disambiguation (Lefever and Hoste, 2010).

We hypothesize that cross-lingual divergences will be preeminently suitable to remedy problems related to semantic drift in iterative bootstrapping, where lexical and structural ambiguity give rise to erroneous terms and/or contexts. Languages are not isomorphic: ambiguous terms and contexts are frequently language-specific. In our example above, the English term *energy storage* is ambiguous, however, in German, each reading has its own translation. *Energy storage* is translated with *Energiespeicher* in the OBJECT reading and *Energiespeicherung* in the PROCESS reading.

Our multilingual ensemble lexicon bootstrapping system is inspired by Basilisk (Thelen and Riloff, 2002). Previous work has addressed semantic drift in Basilisk by conflict resolution between several classes (Thelen and Riloff, 2002), by using web queries (Igo and Riloff, 2009) and by combining Basilisk in an ensemble with an SVM tagger and a coreference resolution system (Qadir and Riloff, 2012). These approaches are monolingual. Instead we use a multilingual ensemble method where the induced lexicons of several languages constrain each other.

Apart from addressing semantic drift, the multilingual setting we propose has several other advantages. First, one language may leave implicit what another expresses directly in linguistic forms. In German, common nouns are capitalized and compound nouns are written as one word. We propagate German noun information via word alignment to English and thereby learn both single words as well as most multiword expressions (MWEs) without the need for a noun chunker or MWE recognizer.

Second, as a result of the multilingual ensem-

ble method we are able to induce lexicons for any language given a parallel corpus. We do not need seed lists for all languages, which are often sparse. Translating<sup>1</sup> the English seed list automatically results in high-quality lexicons for all other languages.

Finally, many pattern-based lexicon bootstrapping methods use pre-defined patterns which require language- and domain-specific syntactic analyses. Our multilingual approach makes use of a parallel corpus and tools from phrase-based machine translation that substitute for the necessity of pattern definition and once more guarantees a knowledge-lean and language-independent process.

## 2 Multilingual Lexicon Bootstrapping

### Monolingual bootstrapping

```

1: lexicon ← seed
2: for int  $i = 0; i < m; i++$  do
3:   patterns ← patternsOf(lexicon)
4:   score(patterns)
5:   patterns ← return-top-k(patterns, 20 +  $i$ )
6:   terms ← termsOf(patterns) – lexicon
7:   score(terms)
8:   lexicon ← lexicon  $\cup$  return-top-k(terms,  $t$ )
9: end for
10: return lexicon

```

Figure 1: Basilisk (Thelen and Riloff, 2002)

Our basic algorithm is inspired by Basilisk (Thelen and Riloff, 2002), an algorithm developed for monolingual lexicon bootstrapping as shown in Figure 1. The starting point is a lexicon initialized with a given seed set. Then the lexicon is expanded iteratively. First Basilisk ranks all patterns containing terms from the lexicon (lexicon terms) (lines 3-4) based on the RlogF score:

$$\text{RlogF}(\text{pattern}_i) = F_i/N_i \log_2(F_i)$$

where  $F_i$  is the number of lexicon terms occurring in  $\text{pattern}_i$  and  $N_i$  is the total number of terms occurring in  $\text{pattern}_i$ . Then Basilisk ranks all non-lexicon terms that occur in the  $20+i$  highest-ranked patterns (where  $i+1$  is the number of performed iterations) (lines 5-7) based on the AvgLog score:

$$\text{AvgLog}(\text{term}_i) = 1/P_i \sum_{j=1}^{P_i} \log_2(F_j + 1)$$

<sup>1</sup>Potential ambiguity in translated seeds will be taken care of, because our ensemble learning prevents false terms resulting from erroneous seeds to be added to the lexicon.

where  $P_i$  is the number of patterns containing term $_i$ . Finally Basilisk adds the  $t$  (originally 5) highest-ranked terms to the lexicon (line 8) and process repeats.

### Multilingual ensemble framework

```

1: for  $L_i$  in  $\{L_1, \dots, L_n\}$  do
2:    $B_i \leftarrow$  initialize Basilisk for  $L_i$ 
3:    $B_i.\text{final} \leftarrow \{\}$ 
4: end for
5: while  $\exists i$  ( $\text{size}(B_i.\text{final}) < l$ ) do
6:   for  $B_i$  in  $\{B_1, \dots, B_n\}$  do
7:      $B_i.\text{iterate}(m, t)$ 
8:   end for
9:   consensusCheck( $\{B_1, \dots, B_n\}$ )
10: end while
11: return ( $B_1.\text{final}, \dots, B_n.\text{final}$ )

```

Figure 2: Multilingual bootstrapping

We adapted Basilisk to a multilingual setting as shown in Figure 2. Key to the framework is the multilingual consensus check. In the **consensusCheck**, for each Basilisk process  $B_i$  we intersect its lexicon with the translations of the lexicons of all other Basilisk processes  $B_k$ . We translated the lexicons from  $L_k$  to  $L_i$  using the bilingual dictionary  $\text{DICT}_{k \leftrightarrow i}$  extracted from the corresponding phrase table. If the lexicon intersection is non-empty, the consensus terms are added to the final list of  $B_i$  and the temporary lexicon is reset to the seed terms and the final list. If the intersection is empty, the lexicons are maintained completely leading to a higher chance of non-emptiness in the subsequent multilingual iteration.

We first initialize a Basilisk process  $B_i$  for each language  $L_i$  (Figure 1, line 1; Figure 2, lines 1-4). For each Basilisk process, we introduce a *final* list, that contains only lexicon terms that survived the consensus check. As long as at least one Basilisk process has a final list containing less than  $l$  terms, each Basilisk process performs  $m$  iterations of learning the top  $t$  terms<sup>2</sup> each (Figure 1, line 2-9; Figure 2, lines 6-8). Multilingual bootstrapping is finished, when all Basilisk processes have a final list of at least  $l$  terms (Figure 2, line 11).

<sup>2</sup>Thelen and Riloff (2002) originally set  $t = 5$  - this would be inefficient with our ensemble lexicon bootstrapping on state-of-the-art machines because most of the time, there would be no consensus terms. We set  $m = 2$  and  $t = 25$ , which seems to be a good trade-off between time and accuracy.

### 3 Experiments

Although our method is multilingual and language-independent we restrict our demonstration of its potential to two languages: German and English.

**The parallel corpus.** We use patent data distributed by the European Patent Office (EPO<sup>3</sup>) between 1998 and 2008. Most European patents provide their claims (the part of a patent defining the scope of protection) in German, English and French. We constructed a German-English parallel corpus out of 177,317 patent documents.

**Creation of Moses phrase table.** For each unordered language pair, we create a MOSES (Koehn et al., 2007) phrase table in several steps. We first apply sentence alignment (GARGANTUA Braune and Fraser (2010)), then word alignment (MGIZA++ Gao and Vogel (2008)) to the data. And finally, we apply the statistical machine translation tool MOSES to the parallel word-aligned data. The resulting data structure is a phrase table of word-aligned phrases in two languages as shown in Figure 3, where the third line indicates the word alignment.

Verfahren zur selektiven Flüssigphasenhydrierung
the process for selective liquid phase hydrogenation
0-0 0-1 1-2 2-3 3-4 3-5 3-6

Figure 3: Main content in a phrase table entry

**Extracting terms and patterns.** For term extraction, we define one language as the term-specifying language  $L_{term}$  (i.e., the language that specifies the set of candidate terms for all languages) – in our case, we choose German since it expresses term boundaries very directly in its linguistic forms (capitalized nouns, single word compounding). German terms are defined as a capitalized token with at least 4 letters. For each unordered language pair  $\{L_{term}, L_i\}$ , we define each term in  $L_i$  as a sequence of tokens that are aligned to a term in  $L_{term}$ . In Figure 3, “liquid phase hydrogenation” is defined as term since it is aligned to “Flüssigphasenhydrierung”.

For reducing errors due to poor word alignment<sup>4</sup>, we apply MATE (Bohnet, 2010) part of speech (PoS) tagger on phrases in languages other

<sup>3</sup>www.epo.org

<sup>4</sup>Since our corpus is not large enough for perfect word alignment, it can be supported by a part of speech tagger. To keep the process completely language-independent, this step may also be skipped.

than  $L_{term}$  and define a PoS filter that removes spurious tokens at the left and right boundaries. Figure 4 shows the PoS filter for English, that is adapted from Justeson and Katz (1995) to the task of filtering tokens. The aligned terms that pass the filtering are stored in a dictionary  $DICT_{term \leftrightarrow i}$ .

English (JJ|VBG|NN)\* NN (IN NN+)?

Figure 4: PoS pattern for term filtering

Patterns are extracted from the phrase tables as well. For each phrase in  $L_{term}$  and  $L_i$  we use the remaining tokens surrounding each term as bootstrapping pattern associated with this term (e.g., “Verfahren zur selektiven <X>” is defined as pattern for “Flüssigphasenhydrierung”).<sup>5</sup>

Our final data set contains roughly 19 million German and English term-pattern pairs. The dictionary  $DICT_{DE \leftrightarrow EN}$  comprises 1.8 million entries.

**Translating seed sets.** We define one corpus language as the seed-defining language  $L_{seed}$  – in our case, we choose English since it provides the richest lexical resources. Then, for all other languages  $L_i$  we translate each seed term from  $L_{seed}$  to  $L_i$  using the most frequent translation in  $DICT_{seed \leftrightarrow i}$ .

**Evaluation.** We evaluated the multilingual bootstrapping system on two semantic classes motivated by the technical field of patents: PROCESS and TECHNICAL QUALITY.

**PROCESS:** A method or event that results in a change of state (e.g., *stretching, molding process, redundancy control, ...*).

**TECHNICAL QUALITY:** A basic or essential attribute which is measurable or shared by all members of a group (e.g., *power consumption, piston speed, light reflection index, ...*).

The sources for the English seed sets have been WordNet lexicographer classes (Ciaramita and Johnson, 2003) and Wikipedia<sup>6</sup> word lists.

For each semantic class and language we induced lexicons of 2000 terms. For each lexicon we evaluated a sample of 200 terms. Two annotators first rated 50 terms for each language and class as TRUE or FALSE. Then they discussed disagreements. Afterwards, they rated the remaining terms in each lexicon sample. We achieved a total inter-annotator agreement of  $\kappa = .701$  (Cohen’s

<sup>5</sup>We remove unique patterns because they do not contribute to lexicon bootstrapping.

<sup>6</sup>www.wikipedia.org

Kappa). For the results, we used the labeled lexicons of the annotator that finalized the task first.

## 4 Results

In our experiments we compare two methods. The first is the monolingual bootstrapping method<sup>7</sup> and the second is the bilingual ensemble bootstrapping method. For a proper comparison both methods make use of the same data as described in Section 3. Table 1 shows the accuracy of the induced lexicons for German and English when learned separately (lines 1-2) and when induced with the bilingual ensemble bootstrapping method (line 3)<sup>8</sup>.

	Mode	Process	Technical Quality
1	DE	.730	.880
2	EN	.740	.895
3	DE / EN	.980† / .790	.960† / .955†

Table 1: Results of lexicon evaluation

Bilingual ensemble bootstrapping outperforms monolingual bootstrapping in both classes and languages. For the class TECHNICAL QUALITY there is a significant improvement in both languages (German: +.080; English: +.060). For the class PROCESS there is a significant improvement for German (+.250), whereas there is a nonsignificant improvement for English.

**Analysis and discussion.** To give the reader a better idea of how the bilingual ensemble method remedies semantic drift, we will comment on the asymmetric impact on performance, when high levels of ambiguity are present in one of the two languages.

We know from linguistic research (Ehrich and Rapp, 2000) that the German *ung*-ending is subject to sortal ambiguity. Words ending in *-ung* can be of various semantic types: processes, objects, events, and states. Many terms in the PROCESS class are described by nouns ending in *-ung*. Their sortal ambiguity gives rise to semantic drift from PROCESS to TECHNICAL QUALITY (e.g., *Belastung* can mean *charging* or *burden*), and to PROCESS-RELATED DEVICE (e.g., *Steuerung* can mean *steering* or *controller*). This sortal ambiguity of nouns in the PROCESS class does not have its

<sup>7</sup>Although the first method relies on a parallel corpus and multilingual preprocessing, we refer to it as the monolingual method because the learning is done monolingually.

<sup>8</sup>We mark each number with † if it significantly outperforms monolingual bootstrapping (z-test for proportions;  $p < .05$ ).

counterpart in the English lexicon. It is therefore not surprising that we see a large improvement in the quality of the German lexicons, when English is used in the ensemble bootstrapping method. We achieve an improvement in German of +.250, the largest improvement overall.

In the present bilingual setting, we cannot prevent the ambiguity found in the German terms to influence the English terms. We believe that this is the reason for the asymmetric impact of bilingual bootstrapping on the class PROCESS, where we see only a small improvement in English (+.060). The positive effects from ensemble learning for the English PROCESS class is partly wiped out by the influence of high levels of ambiguity in German. In future work, we plan to add several languages to be able to prevent ambiguity in one language to overshadow the multilingual ensemble.

## 5 Conclusion

We address the problem of semantic drift in iterative bootstrapping. We propose a multilingual ensemble learning method for lexicon bootstrapping, in which lexicons for several languages are induced in parallel and constrain each other. This method exploits linguistic variation between languages to reduce the impact of lexical and structural ambiguity within one language. In a case study on German and English and the two semantic classes TECHNICAL QUALITY and PROCESS, we show that bilingual lexicon bootstrapping outperforms monolingual bootstrapping in all classes and languages.

In addition, our multilingual approach to lexicon bootstrapping is particularly knowledge-lean and language-independent. A parallel corpus, language-independent machine translation tools and seed lists of one single corpus language suffice to extract patterns, determine term boundaries and provide seed lists for an in principle unlimited number of languages.

# Mining Japanese Compound Words and Their Pronunciations from Web Pages and Tweets

Xianchao Wu

Baidu Inc.

wuxianchao@gmail, baidu}.com

## Abstract

Mining compound words and their pronunciations is essential for Japanese input method editors (IMEs). We propose to use a chunk-based dependency parser to mine new words, collocations and predicate-argument phrases from large-scale Japanese Web pages and tweets. The pronunciations of the compound words are automatically rewritten by a statistical machine translation (SMT) model. Experiments on applying the mined lexicon to a state-of-the-art Japanese IME system<sup>1</sup> show that the precision of Kana-Kanji conversion is significantly improved.

## 1 Introduction

New compound words are appearing everyday. Person names, technical terms and organization names are newly created and used in Web pages such as news, blogs, question-answering systems. Abbreviations, food names and event names are formed and shared in Twitter and Facebook. Mining of these new compound words, together with their pronunciations, is an important step for numerous natural language processing (NLP) applications. Taking Japanese as an example, the lexicons containing compound words (in a mixture of Kanjis and Kanas) and their pronunciations (in a sequence of Kanas) significantly influence the accuracies of speech generation (Schroeter et al., 2002) and IME systems (Kudo et al., 2011). In addition, monolingual compound words are shown to be helpful for bilingual SMTs (Liu et al., 2010).

In this paper, we mine three types (Figure 1) of new (i.e., not included in given lexicons) Japanese compound words and their pronunciations: (1) *words*, which are combinations of sin-

<sup>1</sup>freely downloadable from [www.simeji.me](http://www.simeji.me) for Android and <http://ime.baidu.jp/type/> for Windows

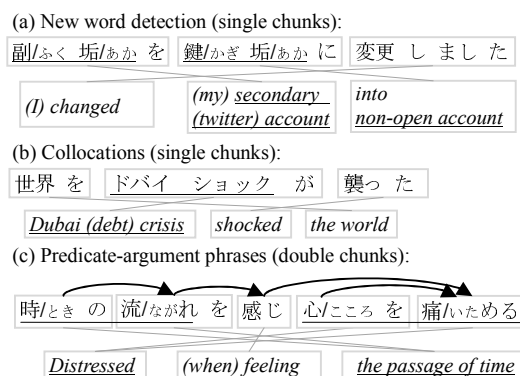

Figure 1: Examples of new (compound) words.

gle characters and/or shorter words; (2) *collocations*, which are combinations of words; and (3) *predicate-argument phrases*, which are combinations of chunks constrained by semantic dependency relations. The sentences were parsed by a state-of-the-art chunk-based Japanese dependency parser, Cabocha<sup>2</sup> (Kudo and Matsumoto, 2002a) which makes use of Mecab<sup>3</sup> with IPA dictionary<sup>4</sup> for word segmenting, POS tagging, and pronunciation annotating.

The first sentence in Figure 1 contains two new words which were not correctly recognized by Mecab. We call them “new words”, since *new* semantic meanings are generated by the combination of single characters. There is one Kana collocation in the second sentence. Different from many former researches (Manning and Schütze, 1999; Liu et al., 2009) which only mine collocations of two words, we do not limit the number of words in our collocation lexicon. The third sentence contains two predicate-argument phrases of noun-noun modifiers and object-verb relations.

The main contribution of this paper is that the

<sup>3</sup><http://mecab.googlecode.com/svn/trunk/mecab/doc/index.html>

<sup>4</sup><http://code.google.com/p/mecab/downloads/detail?name=mecab-ipadic-2.7.0-20070801.tar.gz>

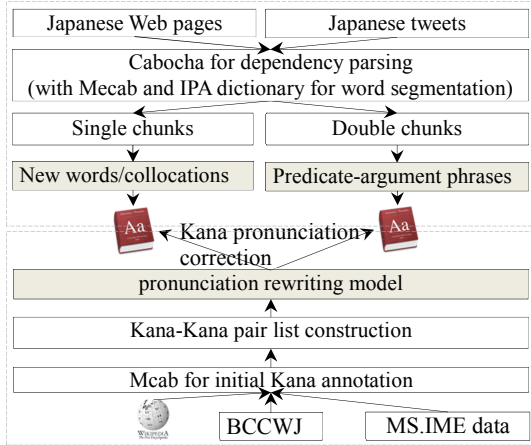

Figure 2: The lexicon mining processes.

well studied *chunk-level dependency technique* is firstly (as far as our knowledge) adapted to compound word mining. The proposed mining method has the following three parts. First, it explicitly utilize the chunk identification features and frequency information for detecting new words and collocations. Second, chunk-level semantic dependency relations are employed for determining predicate-argument phrases. Third, a Kana-to-Kana pronunciation rewriting model based on phrasal SMT framework is proposed for correcting Kana pronunciations of the compound words.

## 2 Compound Word Mining

Figure 2 shows our major lexicon mining process: lexicon mining in a top-down flow and pronunciation rewriting in a bottom-up flow.

### 2.1 Mining single chunks

**Definition 1 (Japanese chunk)** Suppose  $\mathbf{w}$  being the Japanese vocabulary set, a Japanese chunk is defined as a sequence of contiguous words,  $C = w_n^+ w_p^*$ , where  $w_n^+ \in \mathbf{w}$  is a sequence of notional words with no less than one  $w_n$ , and  $w_p^* \in \mathbf{w}$  contains zero or more particles  $w_p$ . New words and collocations come from  $w_n^+$  without  $w_p^*$ .

This mining idea is based on the fact that an Japanese morphological analyser (e.g., Mecab) tends to split one out-of-vocabulary (OOV) word into a sequence of known Kanji characters. The point is that, most of the known Kanji characters are annotated to be notional words such as nouns. Consequently, Cabocha, which takes words/characters and their POS tags as features for discriminative training using a SVM model (Kudo

	Frequency $\geq 20$	Frequency $\geq 500$
single chunk (web)	9,823,176	685,363
double chunks (web)	20,698,683	794,605
single chunk (twitter)	156,506	6,131
not in web	21,370 (13.7%)	492 (8.0%)
double chunks (twitter)	160,968	2,446
not in web	35,474 (22.0%)	443 (18.1%)

Table 1: The number of compound words mined.

and Matsumoto, 2002b), can still *correctly* tend to include these single-Kanji-character words into one chunk. Thus, we can re-combine the wrongly separated pieces into one (compound) word.

### 2.2 Mining predicate-argument phrases

**Definition 2 (Predicate-argument phrase)** A predicate-argument phrase is defined as a labelled graph structure,  $A = \langle w_h, w_n, \tau, \rho \rangle$ , where  $w_h, w_n \in \mathbf{w}$  are a predicate and an argument word (or chunk) of the dependency,  $\tau$  is a predicate type (e.g., transitive verb), and  $\rho$  is a label of the dependency of  $w_h$  and  $w_n$ . We append one constraint during mining:  $w_h$  and  $w_n$  are adjacent. That is, the phrases mined are all contiguous without gaps. The predicate-argument phrases mined in this way is helpful for context-based Kana-Kanji conversion of Japanese IME.

Japanese is a typical Subject-Object-Verb language. The direct object phrase normally appears before the verb. For example, for two input Kana sequences “やさいをいためる” (野菜/vegetables を/particle 炒める/cooking: stir-fried vegetables) and “こころをいためる” (心/heart を痛める/hurt: hurt ones heart), even “いためる” takes the similar keyboard typing, the first candidate Kanji words are totally different. The users will be angry to see the candidate of “心を炒める” (stir-fried heart) for “こころをいためる”. It is the pre-verb objects that determines the dynamic choosing of the correct Kanji verbs.

### 2.3 Experiments on compound word mining

We use two data sets for compound word mining. The first set contains 200G Japanese Web pages (1.9 billion sentences) which were downloaded by an in-house Web crawler. The second set contains 44.7 million Japanese tweets (28.8 words/tweet) which were downloaded by using an open source Java library twitter4j<sup>5</sup> which implemented the Twitter Streaming API<sup>6</sup>.

<sup>5</sup><http://twitter4j.org/ja/index.html>

<sup>6</sup><https://dev.twitter.com/docs/streaming-apis>

Lexicons	Frequency $\geq 20$	Precision
alignment method	2,562	76.5%
single chunk	16,673	93.0%
double chunks	9,099	91.5%

Table 2: The number of entries and precisions of the alignment method (Liu et al., 2009) and our approach, using 2M sentences.

Table 1 shows the statistics of the single/double chunk lexicons (of frequencies  $\geq 20$  or 500). We compared the novel entries included in the twitter lexicons but not the web. The ratio ranges from 8.0% to 22.0%, reflecting a special bag of compound words used in tweets instead of the traditional web pages.

We compare our lexicons with two baselines, one is the C-value approach (Frantzi and Ananiadou, 1999) with given POS sequences and the other is the monolingual word alignment approach (Liu et al., 2009). We ask Japanese linguists to give a POS sequence set with 128 rules for compound word mining. Applying C-value approach with these rules to the 200G web data yields a lexicon of 884,766 entries (frequency  $\geq 500$ ). Our single (double) chunk lexicon shares around 30% (7%) with this lexicon. This lexicon is used in our baseline Japanese IME system (Table 5).

During our re-implementation of the alignment approach, we found that the EM algorithm (Dempster et al., 1977) for word aligning the 1.9 billion sentences is too time-consuming. Instead, we only used the first 2M sentences (28.4 words/sentence) of the web data for intuitive comparison. The statistics are shown in Table 2. The precisions are computed by manually evaluating the top-200 entries (with higher frequencies) in each lexicon. The lexicons mined by our approach outperforms the baseline in a big distance, both precision and the number of entries successfully mined.

### 3 Pronunciation Rewriting Model

Our pronunciation rewriting model mapping from the compound words’ original pronunciations to their correct pronunciations. It is a generative model based on the phrasal SMT framework. We limit the model monotonically rewrite initial Kana sequences to their correct forms without reordering. We use Moses<sup>7</sup> (Koehn et al., 2007) to implement this model by setting the source and target sides to be Kana sequences.

<sup>7</sup><http://www.statmt.org/moses/>

The Kana-Kana rewriting model improves the traditional Kanji-Kana predication models (Hatori and Suzuki, 2011) in the following aspects. First, data sparseness problem of Kanji-Kana approach can be mitigated in a sense, since the number of Kanas in Japanese is no more than 50 yet the number of Kanjis is tens of thousands. Second, Kana-Kana pairs are easier to be aligned with each other, since most Kanjis are pronounced by no less than two Kanas and consequently the number of Kanas almost doubles the number of Kanjis in the experiment sets. Finally, the entries in the final lexicons contain two Kana pronunciations, before and after correcting. We argue this is helpful to improve the user experiences of IME systems where we need to cover the users’ typing mistakes.

#### 3.1 Mining Kanji-Kana entries from Wiki

For training the rewriting model, we mine a Kana-Kanji lexicon from parenthetical expressions in Japanese Wikipedia pages<sup>8</sup>, a high quality collection of new words. The only problem is to determine the pre-brackets Kanji sequence that exactly corresponds to the in-bracket Kana sequence.

Our method is inspired by (Okazaki and Ananiadou, 2006; Wu et al., 2009). They used a term recognition approach to build monolingual abbreviation dictionaries from English articles (Okazaki and Ananiadou, 2006) and to build Chinese-English abbreviation dictionaries from Chinese Web pages (Wu et al., 2009). For locating a textual fragment with a Kanji sequence and its Kana pronunciation in a pattern of “Kanji sequence (Kana sequence)”, we use the heuristic formula:

$$LH(c) = \text{freq}(c) - \sum_{t \in T_c} \text{freq}(t) \times \frac{\text{freq}(t)}{\sum_{t \in T_c} \text{freq}(t)}.$$

Here,  $c$  is a Kanji candidate (sub-)sequence;  $\text{freq}(c)$  denotes the frequency of co-occurrence of  $c$  with the in-brackets Kana sequence; and  $T_c$  is a set of nested Kanji sequence candidates, each of which consists of a preceding Kanji or Kana character followed by the candidate  $c$ .

Table 3 shows the number of entries mined by setting the LH score to be  $\geq 3, 4, \text{ or } 5$ . From the table, we observe that as LH threshold is added by one, the number of entries is cut nearly a half. For each entry set, we further randomly selected 200 entries and checked their correctnesses by

<sup>8</sup>All the Japanese pages until 2012.06.03 were used. Examples can be found in <http://ja.wikipedia.org/wiki/三日月>

LH $\geq$	# of Entries	Precision
3	42,423	95.0%
4	18,348	95.5%
5	10,234	96.0%

Table 3: Kanji-Kana entries mined from Wiki.

System	Prec.	BLEU-4	src/trg	Data	Train/Dev/Test
baseline	70.2%	0.8663	4.9/7.0	bcc-	25.3k/0.5k/0.5k
Ours	90.4%	0.9687	7.0/7.0	wj	
baseline	49.8%	0.6734	2.8/4.9	wiki	17.3k/0.5k/0.5k
Ours	62.2%	0.7380	4.9/4.9		
baseline	43.5%	0.9504	58.0/78.1	ms	5.6k/0.2k/0.2k
Ours	62.0%	0.9737	80.7/78.1		

Table 4: Pronunciation predication accuracies.

hand. The precisions ranges from 95% to 96%. Moreover, this mining approach can make use of parenthetical expressions appearing in not only Wikipedia but also the total Japanese Web pages.

### 3.2 Experiments on pronunciation rewriting

As shown in Figure 2, we use three data sets for training our pronunciation rewriting model. The first set is a Kanji-Kana compound lexicon collected from the 2009 Core Data of the Balanced Corpus of Contemporary Written Japanese (BC-CWJ) corpus (Maekawa, 2008). The second is the Microsoft Research IME data<sup>9</sup> (Suzuki and Gao, 2005). The third set is the Wikipedia Kana-Kanji lexicon with LH  $\geq$  4 (Table 3).

The precisions and BLEU-4 scores (Papineni et al., 2002) of the baseline system (Hatori and Suzuki, 2011) and our approach are shown in Table 4. The baseline system takes character-level translation units. From Table 4, we observe that the number of Kanas is larger than the number of Kanjis while the number of initial Kanas and corrected Kanas are almost the same. Our approach yield significant improvements ( $p < 0.01$ ) in both precisions and BLEU-4 scores.

## 4 Japanese IME Evaluation

As an application-oriented evaluation, we finally integrate the mined lexicons (as a cloud service) into a state-of-the-art Japanese IME system. The system is constructed based on the n-pos model (Mori et al., 1999; Komachi et al., 2008; Kudo et al., 2011). For training the n-pos model, we used 2.5TB Japanese Web pages as the training data. We run Mecab on Hadoop<sup>10</sup>, an open source soft-

<sup>9</sup><http://research.microsoft.com/en-us/downloads/AF99E662-B77B-4622-ADAA-7AB9F2842B20/default.aspx>

<sup>10</sup><http://hadoop.apache.org/>

IME	Top-1	Top-3	Top-5	Top-9	Test Set
baseline	38.93%	63.76%	70.47%	74.50%	twitter.net
+twitter	48.99%	70.47%	73.15%	75.17%	
baseline	50.16%	75.10%	82.99%	87.46%	JDMWE
+web	52.01%	78.61%	85.34%	89.07%	
baseline	56.23%	84.29%	91.18%	93.80%	Nagoya
+web	58.16%	84.65%	92.01%	94.35%	

Table 5: The top-n precision improvements of appending the mined twitter/web lexicons to a baseline IME system.

ware that implemented the Map-Reduce framework (Dean and Ghemawat, 2004), for parallel word segmenting and POS tagging the data.

For testifying the lexicons mined from the 200G Web data and from the tweets, we respectively use three test sets: (1) “twitter.net” with 149 entries which is a manually collected Twitter new word lexicon<sup>11</sup>; (2) partial “JDMWE” (Shudo et al., 2011) lexicon with 2,169 entries; and (3) “Nagoya” compound word lexicon<sup>12</sup> with 3,628 entries such as idioms.

The top-n (=1, 3, 5, 9) precisions are listed in Table 5. In the baseline system, we used the compound lexicon that was mined by the C-value approach using 128 POS sequences. For direct comparison, we replace this compound lexicon respectively by the web and twitter lexicons (frequency  $\geq$  500). In the twitter.net test set, the precision of the top-1 candidate significantly ( $p < 0.01$ ) improves from 38.93% to 48.99% (+10.06%). In the JDMWE and Nagoya test sets, the web lexicon can also significantly improve the top-1 precisions of around 2% ( $p < 0.05$ ). Through these numbers, we can say that the proposed approach is helpful for improving the accuracies of real-world Japanese IME application.

## 5 Conclusion

We have proposed an approach for mining new Japanese compound words from single/double chunks generated by a chunk-based dependency parser. Experiments show that the approach works well on mining new words, collocations and predicate-argument phrases from large-scale Web pages and tweets. We achieved significant improvements on top-n precisions when integrating the mined compound words together with their Kana pronunciations into a state-of-the-art Japanese IME system with million level users.

## Abstract

In this paper, we describe a Turkish factoid QA system which uses surface level patterns called answer patterns in order to extract the answers from the documents that are retrieved from the web. The answer patterns are learned using five different answer pattern extraction methods with the help of the web. Our novel approach to extract named entity tagged answer patterns and our new confidence factor assignment approach have an important role in the successful performance of our QA system. We also describe a novel query expansion technique to improve the performance. The evaluation results show that the named entity tagging in answer patterns and the query expansion leads to significant performance improvement. The scores of our QA system are comparable with the results of the best factoid QA systems in the literature.

## 1 Introduction

Question answering is the task of returning a particular piece of information in response to a natural language question. The aim of a question answering system is to present the required information directly, instead of documents containing potentially relevant information. Questions can be divided into five categories (Modolvan et al., 2002; Schone et al., 2005): factoid questions, list questions, definition questions, complex questions, and speculative questions. A factoid question has exactly one correct answer which can be extracted from short text segments. The difficulty level of factoid questions is lower than the other categories. In this paper, we present a Turkish factoid question answering system which retrieves the documents that contain answers, and extracts the answers from these retrieved documents with the help of a set of learned answer extraction patterns. List, defini-

tion, complex, and speculative questions are out of the scope of this paper.

At TREC-10 QA track (Voorhees, 2001), most of the question answering systems used Natural Language Processing (NLP) tools such as a natural language parser and WordNet (Fellbaum, 1998). However, the best performing system at TREC-10 QA track used only an extensive list of surface patterns (Soubbotin and Soubbotin, 2001). Therefore we have decided to investigate their potential for Turkish factoid question answering. Our factoid question answering system learns answer patterns that are surface level patterns, and it uses them in the extraction of the answers of new questions. Our answer patterns are learned from the web using machine learning approaches. In addition to the creation of raw string answer patterns, we tried different methods for answer pattern creation such as stemming and named entity tagging. Our novel answer pattern creation method using named entity tagging produces most successful results.

One of the important issues in the factoid question answering is the answer ranking. The correct answer for a question should be in the top of the produced answer list by a QA system. The learned answer patterns in our QA system are associated with confidence factors, and their confidence factors indicate their precision values for the training set. The confidence factors of the rules that extracted the answers are also used to rank the answers and this approach produces very good results.

The question answering systems that extract the answers from the retrieved web pages should be able to retrieve the web pages that contain the answers. These QA systems form a search engine query and submit this query to retrieve the related web pages containing the answers. The retrieved web pages may or may not contain the answers. The QA systems can only consider the first retrieved web pages in order to extract an-

swers from them, and the QA systems have a bigger chance to extract the correct answers if the first retrieved web pages contain the answers. In order to increase the chance that the first retrieved web pages contain the possible answers, we apply a novel query expansion approach using answer patterns. Our evaluation results indicate that our query expansion approach improves the performance of our factoid question answering system.

The factoid question answering system described here is the first successful Turkish factoid question answering system. Our new confidence factor assignment approach to the learned answer patterns has an important role in the success of our factoid QA system. The contributions of our paper also include the introduction of a novel query expansion approach and the creation of named entity tagged answer patterns. The performance results of our factoid question answering system are competitive with the results of the state of art QA systems in the literature.

The rest of the paper is organized as follows. Section 2 discusses our answer pattern extraction methods and confidence factor assignments to the extracted answer patterns. In Section 3, we describe the question answering phase of our QA system. Section 4 presents the detailed discussions about the evaluation results. Section 5 contains concluding remarks.

## 2 Answer Pattern Extraction

In the learning phase of our question answering system, a set of answer patterns are inferred for each question type using the training set of that question type and the web. For each question type, we prepared a set of training examples which consists of question and answer phrase pairs. A query is formed as a conjunction of question and answer phrases in each training example. This query is used to retrieve top documents (*DocSet1*) containing the question and answer phrases. The retrieved documents are used in the extraction of answer patterns without confidence factors. For each training example, we also form a query which only consists of the question phrase. The retrieved documents (*DocSet2*) using this query may or may not contain answer phrases. Two document sets are used in the calculation of the confidence factors of the learned answer patterns.

Although the retrieved documents in *DocSet1* contain both question and answer phrases, question and answer phrases may not appear together

in a sentence of a document. In order to determine answer pattern strings, the sentences that contain the question and the answer phrases together are selected from documents, and answer pattern strings are extracted from these sentences. An answer pattern string is a substring that starts with the answer phrase and ends with the question phrase, or starts with the question phrase and ends with the answer phrase. In addition, we extract an answer pattern string with a boundary word in order to determine the boundary of the answer phrase.

After an answer pattern string is extracted, we apply five different methods in order to learn answer patterns: Raw String (*Raw*), Raw String with Answer Type (*RawAT*), Stemmed String (*Stemmed*), Stemmed String with Answer Type (*StemmedAT*), and Named Entity Tagged String (*NETagged*). Raw string methods learn more specific rules than Stemmed string methods, and *NETagged* method learns more general rules.

In order to extract a raw string answer pattern using our *Raw* method, question phrase and answer phrase in an answer pattern string are replaced with appropriate variables QP and AP. QP is replaced with the given question phrase during question answering, and AP is bound to the answer phrase of the question if the pattern matches. The length of the found answer phrase is determined by the boundary word if the answer pattern contains a boundary word. Otherwise, a fixed size is used as its length.

There can be many strings that can match with an answer pattern that is learned using *Raw* method. One reason for this is that there is no type checking for the string to which AP binds. As long as the pattern matches, AP binds with a string. Our *RawAT* method associates AP variables with answer types. An answer type is a named entity type that is determined by our Turkish named entity tagger. During question answering, the found answer phrase is checked by our named entity tagger in order to make sure that it satisfies the type restriction. For this reason, an answer pattern with an answer type is more specific than the corresponding answer pattern without a type.

Answer patterns obtained by raw string methods contain surface level words, and they have to match exactly with words in extracted strings. Stemmed string methods replace words with their stems in answer patterns. In order to match a string with a stemmed answer pattern, all its words are stemmed first and its stemmed version matches with the stemmed answer pattern to ex-

tract the answer. The extracted answer patterns can be still more specific since they may contain specific words. *NETagged* method can further generalize answer patterns by replacing all named entities in the string by typed variables.

After all answer patterns are extracted from the training set, the confidence factors are assigned to these extracted answer patterns. A confidence factor of an answer pattern indicates its accuracy in the training set. In question answering phase, we use only the answer patterns whose confidence factors are above a certain threshold. From two document sets (*DocSet1* and *DocSet2*), the sentences containing the question phrase are collected as a training set for confidence factor assignment. The confidence factor of an answer pattern is the proportion of correct results to all results extracted by that pattern.

### 3 QA Using Answer Patterns

Our base question answering module uses the given question phrase as a search engine query. Using Bing web search engine top documents containing the given question phrase are retrieved. In these documents, the sentences containing the question phrase are extracted. The question phrases in the retrieved sentences are replaced by QP, and these sentences are used in the answer processing phase.

In the answer processing phase, the answer patterns of the given question type are applied to the selected sentences in order to extract answer phrases. The preprocessing of the sentences may be required depending on the method of the used answer pattern. If the applied method is a raw string method, there is no need for the preprocessing of the sentence, and the raw string answer pattern is directly applied to the sentence. If the answer pattern is a stemmed string answer pattern, all the words are stemmed first, and the answer pattern is applied to the stemmed version of the sentence. If the answer pattern is a NE tagged answer pattern, the sentence is analyzed by the named entity tagger in order to determine all named entities in the sentence, and the answer pattern is applied to the named entity tagged version of the sentence.

If the applied answer pattern matches the sentence, an answer phrase is extracted as a result. If the answer phrase in the applied answer pattern is named entity tagged, the extracted answer phrase must also satisfy conditions of that named entity. The confidence value of an extracted answer is the confidence factor of the matched an-

swer pattern. The top ranked answer is returned as the result of the question.

Our base QA algorithm creates a search engine query and that query only contains the given question phrase. The retrieved documents may be insufficient to extract the correct answer because the query is too general and the retrieved documents may not contain the answer. We want to retrieve documents that contain many sentences holding the question phrase and answer phrase together. Thus, there is a bigger chance that our answer patterns match those sentences, and the correct answer can be extracted. In order to retrieve the documents that are more likely to contain the answer, we use a query expansion approach. The answer patterns with high confidence factors are used to expand the query, so that the more related documents can be retrieved.

### 4 Evaluation Results

In order to evaluate the performance of our system, we prepared a training set and a test set and they do not contain any common item. Each of them contains 15 question-answer phrase pairs from seven different question types (Author, Capital, DateOfBirth, DateOfDeath, LanguageOfCountry, PlaceOfBirth, PlaceOfDeath). Since we obtained our best results, when we use the answer patterns higher than 0.75 confidence factors, we only used these answer patterns for evaluations. The answer patterns are tested with the question-answer phrase pairs in the test set.

We used four standard evaluation metrics: Precision, Recall, Fmeasure and MRR. Precision is the proportion of the number of correct answers to the number of returned answers, and Recall is the proportion of the number of correct answers to the number of test questions. Fmeasure is the harmonic mean of Precision and Recall. Mean Reciprocal Rank (MRR) considers the rank of the first correct answer in the list of possible answers (Voorhees, 2001).

	<i>MRR</i>	<i>Recall</i>	<i>Precision</i>	<i>Fmeas</i>
<i>Raw</i>	0.28	0.24	0.57	0.34
<i>RawAT</i>	0.31	0.30	0.86	0.44
<i>Stemmed</i>	0.29	0.26	0.57	0.36
<i>StemmedAT</i>	0.30	0.29	0.88	0.44
<i>NETagged</i>	0.45	0.45	0.94	0.61
<i>AllWithNE</i>	0.58	0.56	0.86	0.68

Table 1. Evaluation results

We evaluated each of our five methods separately and their best combination. The evaluation results are given in Table 1. The results in the

columns 2-5 of Table 1 are the average values of the results of the seven question types. The rows 2-6 give the results for individual methods and the last row gives the results of their best combination *AllWithNE* which contains the answer patterns that are learned from methods *RawAT*, *StemmedAT* and *NETagged*. According to the results, our best method is *NETagged* method which accomplishes the best scores for all four evaluation metrics. These results indicate that the usage of named entity tagged string answer patterns increases the performance. The results indicate that the effect of stemming is not as good as expected. The usage of answer types blocks the extraction of most of the incorrect answers.

In our query expansion method, we use the words appearing in the high confidence answer patterns. One way to test the effectiveness of our query expansion mechanism is to measure the change in the number of sentences containing both the question phrase and the answer phrase in the retrieved documents. According to our results, the number of such sentences is increased from 3227 to 6647 when the query expansion is employed. This means that our answer patterns have almost twice the chance to extract answers using query expansion. We applied our answer patterns in our best combination *AllWithNE* to the documents returned as a result of the query expansion. The highest increase (29%) occurred in Recall result because the answers of more questions are retrieved as a result of the query expansion. Precision result is also improved from 0.86 to 0.94 (9% increase). The increase in MMR result is 26% percent and the increase in Fmeasure result is 20%. As a conclusion, the query expansion is a useful tool to improve the performance since it leads to increases in all measures.

<i>QA System</i>	<i>MRR</i>
TREC-8 (max,avg,min)	0.66, 0.25, 0.02
TREC-10 (max,avg,min)	0.68, 0.39, 0.27

Our Best without query expansion	0.62
Our Best with query expansion	0.73

Table 2. Comparisons of QA systems

Although it is difficult to directly compare the results of our QA system with the published results of other factoid question answering systems, we still discuss the MRR results of our QA system and other factoid question answering

systems. Table 2 compares our best MRR results with the MRR results of the other systems (Voorhees, 1998; Voorhees, 2001; Schlaefter and Gieselmann, 2006; Ravichandran and Hovy, 2001; Amasyali and Diri, 2005). Although these scores may not give fair comparisons, they still show that our QA system is competitive to the best factoid QA systems.

## 5 Conclusion and future work

The answer pattern matching technique has been used successfully for English Factoid QA (Ravichandran and Hovy, 2001; Schlaefter and Gieselmann, 2006; Soubbotin and Soubbotin, 2001), we therefore decided to apply various answer pattern extraction methods for Turkish factoid QA. These methods are compared according to MRR, Fmeasure, Recall and Precision scores. The scores of stemmed string methods are slightly better than the scores of raw string methods, so stemming slightly improves the performance of the system. The scores of *RawAT* and *StemmedAT* methods are better than the scores of *Raw* and *Stemmed* methods, so checking the answer type improves the performance of the system significantly. *NETagged* method has the best scores. So, replacing words with their named entity tags improves the performance.

We have also implemented a novel query expansion approach using answer patterns. We use the most reliable raw string answer patterns to extend queries. The number of sentences containing the answer phrase increases when the query expansion is applied. The performance scores increase significantly when the query expansion is applied.

The question answering system described in this paper is the first successful Turkish factoid question answering system. The evaluation results indicate that the performance of our QA system is comparable with the performances of the state of the art factoid question answering systems.

Investigating the potential of more generic answer patterns is left as a future work. *Stemmed*, *StemmedAT* and *NETagged* methods extract more generic answer patterns compared to *Raw* and *RawAT* methods and they achieve better results. More generic answer patterns can be extracted by using linguistic techniques such as phrase chunking and morphological analysis. We believe that combining different answer processing techniques can improve the performance of the QA system significantly.

## Abstract

People are generating more and more short texts. There is an urgent demand to classify short texts into different domains. Due to the shortness and sparseness of short texts, conventional methods based on Vector Space Model (VSM) have limitations. To tackle the data scarcity problem, we propose a new model to directly measure the correlation between a short text instance and a domain instead of representing short texts as vectors of weights. We firstly draw domain knowledge for each user-defined domain using an external corpus of longer documents. Secondly, the correlation is calculated by measuring the proportion of the overlapping part of the instance and the domain knowledge. Finally, if the correlation is greater than a threshold, the instance will be classified into the domain. Experimental results show that the classifier based on the proposed model outperforms the state-of-the-art baselines based on VSM.

## 1 Introduction

In recent years, web services are generating more and more short texts including micro-blogs, customer reviews, chat messages and so on. However, a user is often only interested in very small part of these data. There is an urgent demand to classify incoming short texts into different domains, so that users are not overwhelmed by the raw data. As short texts do not provide sufficient word occurrences (i.e., the length of a micro-blog is limited to 140 characters), conventional text classifiers often cannot achieve high accuracy,

especially when the number of training examples is small.

Vector Space Model (VSM) is a very popular document representation model, where each document is represented as a vector of weights. Text classification methods based on VSM perform well when processing documents in regular length (Berry and Michael, 2004). But, the sparsity of VSM will reduce the classification accuracy when processing short texts.

There have been several studies that attempted to solve the problem of data sparseness in VSM. One way is to select more useful features using additional semantics from Wikipedia (Banerjee *et al.*, 2007), WordNet (Hu *et al.*, 2009) or HowNet (Liu *et al.*, 2010). Another way is to expand the coverage of classifier by using background knowledge drawn from much longer external data sources. Zelikovitz and Hirsh (2000) utilized a corpus of unlabeled longer documents as a “bridge”, to connect the test example with training examples. Phan *et al.* (2008) and Chen *et al.* (2011) integrated the original short text with hidden topics discovered from external large-scale data collections to add more meta-information. These researches have shown positive improvement by enriching the representation of feature vectors, but a disadvantage is the high computational complexity.

In this paper, we try to solve the sparse problem from another direction with lower computational complexity. We propose a new model to directly measure the correlation between a short text instance and a domain, using domain knowledge drawn from a labeled external corpus of related longer documents. We performed a careful evaluation for our model on micro-blog

classification task, and achieved consistent improvements over two baselines.

The overall framework of our approach is shown in Figure 1. We firstly draw domain knowledge for each user-defined domain using the external corpus. Secondly, the correlation between a short text instance and a domain is calculated by measuring the proportion of the overlapping part of this instance and the domain knowledge of this domain. Finally, if the correlation is greater than a threshold, the instance will be classified into the domain. The main advantages of our approach include the following points:

- Good generalization performance: domain knowledge learned from longer documents can cover lots of terms that do not exist in a small labeled training set.
- Easy to implement: No need to construct VSM to train classifiers. All we need to prepare is the domain knowledge.

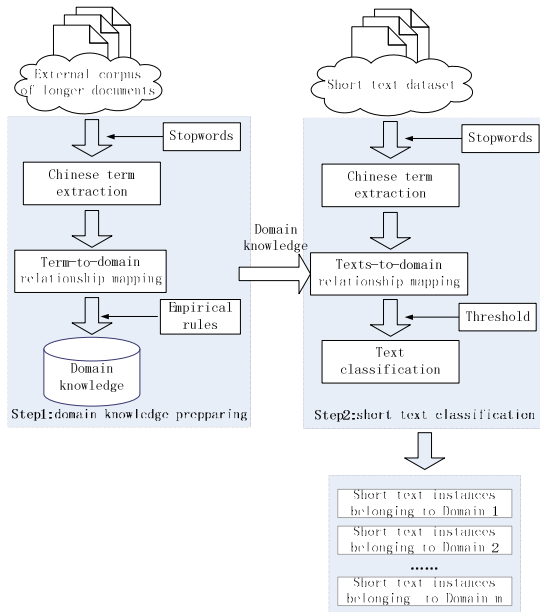

Figure 1. The framework of our approach

## 2 Our Approach

### 2.1 Domain knowledge preparing

To expand the coverage of our model, we utilize a labeled external corpus of longer documents to draw domain knowledge. Text documents in this corpus have been classified into user-defined domains. There are two main conditions that should be followed to choose an appropriate external corpus. First, the coverage of vocabulary should be sufficient. Second, the user-defined

domains should be consistent with the classification problem. In fact, the second condition will not be a problem, because a large number of web documents belonging to different domains can be crawled from portal sites such as Sina<sup>1</sup> and Sohu<sup>2</sup>.

After Chinese term extraction and removing stop words, we obtain an initial term list appearing in the corpus, denoted by  $T = \{t_1, t_2, \dots, t_n\}$ .

The aim of term-to-domain relationship mapping is to select  $K$ -number of most related terms for each domain from  $T$ . The set of selected terms is regarded as the domain knowledge of a domain. How terms are related to each domain is measured by applying Chi-square statistical term-to-domain independency measurement. The measurement is based on the co-occurrence frequencies of a term and a domain. We firstly assume that the term and the domain are statistically independent, and then compare the observed frequency and the expected frequency.

Let  $t_i (i = 1, 2, \dots, n)$  be a term in the initial term list  $T$ , and  $d_j (j = 1, 2, \dots, m)$  be a domain in the user-defined domain list  $D = \{d_1, d_2, \dots, d_m\}$ . The expected frequency is defined as:

$$E_{e_i e_c} = \frac{\sum_{p \in \{0,1\}} O_{pe_c} \sum_{q \in \{0,1\}} O_{e_i q}}{N}, e_i \in \{0,1\}, e_c \in \{0,1\} \quad (1)$$

where  $N = O_{11} + O_{01} + O_{10} + O_{00}$ ,  $O_{11}$  denotes the observed frequency of documents which contain  $t_i$  and belong to  $d_j$ ,  $O_{01}$  denotes the observed frequency of documents which do not contain  $t_i$  but belong to  $d_j$ ,  $O_{10}$  denotes the observed frequency of documents which contain  $t_i$  but not belong to  $d_j$ , and  $O_{00}$  denotes the observed frequency of documents that neither contain  $t_i$  nor belong to  $d_j$ .

The Chi value for  $t_i$  and  $d_j$  is defined as:

$$\chi^2(t_i, d_j) = \sum_{e_i \in \{0,1\}} \sum_{e_c \in \{0,1\}} \frac{(O_{e_i e_c} - E_{e_i e_c})^2}{E_{e_i e_c}} \quad (2)$$

Note that the greater the Chi value is, the closer the relationship between  $t_i$  and  $d_j$  is.

Let  $\overline{DK} = \{dk_1, dk_2, \dots, dk_m\}$  be the domain knowledge vector,  $dk_j$  be the domain knowledge of domain  $d_j$ ,  $\overline{tr}_i$  be the Chi value vector of term  $t_i$ , and  $\overline{dr}_j$  be the Chi value vector of do-

<sup>1</sup> <http://www.sina.com.cn/>

<sup>2</sup> <http://www.sohu.com/>

main  $d_j$ . The algorithm of term-to-domain relationship mapping includes three main steps:

**Step1:** For each term  $t_i$ , construct its Chi value vector  $\bar{tr}_i = \{\chi^2(t_i, d_1), \chi^2(t_i, d_2), \dots, \chi^2(t_i, d_m)\}$ .

**Step2:** For each  $\bar{tr}_i$ , find its largest item  $\chi^2(t_i, d_j)$  and put it into  $\bar{dr}_j$ .

**Step3:** Sort items in  $\bar{dr}_j$  in descending order. Select the corresponding terms of the first  $K$  - number of items, and put them in  $dk_j$ . All terms in  $dk_j$  are arranged in descending order under its Chi value.

## 2.2 Short text classification

In this section, we introduce an intuitive model to directly relate each short text instance to one or more specific domains. How a short text instance, denoted by  $g$ , is related to a domain  $d_j$  can be measured based on the correlation between them. The correlation is calculated by measuring the proportion of the overlapping part of  $g$  and the domain knowledge  $dk_j$  (Liu *et al*, 2012), see Figure 2.

Figure 2. The overlapping part of a short text instance and the domain knowledge

To measure the proportion of the overlapping part, we need to compute the score of domain knowledge  $dk_j$  and the score of the overlapping part of  $g$  and  $dk_j$ , and then normalize the latter by the former. Moreover, we introduce a weight, denoted by  $w_{jk}$ , to indicate the importance of a term in  $dk_j$ , when calculating the scores. As the Chi values of terms in different domain knowledge vary greatly, we define the weight of a term based on its ordering position in the domain knowledge. The weight is defined as:

$$w_{jk} = \frac{K+1-k}{K}, k=1,2,\dots,K \quad (3)$$

where  $k$  is the order of the term in  $dk_j$ , and  $K$  is the number of terms in  $dk_j$ .

Finally, the correlation between  $g$  and  $d_j$  is calculated based on scores as:

$$score_{dk_j} = \frac{1}{L} \sum_{k=1}^K w_{jk} \quad (4)$$

$$score_{overlapping} = \sum_{k=1}^K w_{jk} \times \frac{tf(t_{jk})}{len(g)} \quad (5)$$

$$correl(g, d_j) = \frac{score_{overlapping}}{score_{dk_j}} \quad (6)$$

where  $L$  is the average length of documents in the external corpus ( i.e. the average size of the term lists of documents),  $tf(t_{jk})$  is the frequency of term  $t_{jk}$  appearing in  $g$ , and  $len(g)$  is the length of  $g$ .

If  $correl(g, d_j)$  is greater than a threshold  $\delta$ ,  $g$  will be classified into  $d_j$ . The optimized value of  $\delta$  can be obtained by cross-validation.

## 3 Experiments and results

### 3.1 Data Sets

We collect short texts from Sina micro-blog<sup>3</sup>, and use an open corpus<sup>4</sup> collected by Sogou Lab from the Internet as the external corpus.

**External Corpus** Documents belong to 8 domains: Finance, IT, Health, Sports, Tour, Education, Film&TV, and Military. Each domain contains 600 documents. The vocabulary is 69909 terms. The average length of documents is 403 terms.

**Micro-blog Dataset** We manually choose training samples and test samples for each user-defined domain. Samples in the training set and the test set are totally exclusive. The average length of micro-blogs is 31 terms. There is a noise set in the test set containing micro-blogs which do not belong to any user-defined domain, see Table 1.

Domain	#Train data	#Test data
Finance	600	300
IT	600	300
Health	600	300
Sports	600	300
Tour	600	300
Education	300	150
Film&TV	600	300
Military	300	150
<b>Noise set</b>	0	10,000
<b>Total</b>	4200	12100

Table 1. Description of the micro-blog dataset

<sup>3</sup> <http://t.sina.com.cn>

<sup>4</sup> <http://www.sogou.com/labs/dl/c.html>

### 3.2 Measurement

We adopt the F1-measure as our performance criterion to balance the influence between precision and recall.

$$precision = \frac{TP}{TP + FP} \quad (7)$$

$$recall = \frac{TP}{TP + FN} \quad (8)$$

$$F1\text{-measure} = \frac{2 \times precision \times recall}{precision + recall} \quad (9)$$

where  $TP$  denotes the numbers of relevant samples classified as relevant,  $FN$  denotes the numbers of relevant samples classified as irrelevant, and  $FP$  denotes the number of irrelevant samples classified as relevant.

### 3.3 Experiment results and analysis

In order to obtain the optimized value of  $\delta$ , we randomly divided the training set into five equal partitions and performed 5-fold cross-validation. In Table 2, we can find that our classifier achieves the highest F1-measure when  $\delta = 0.2$  and  $K = 500$ . Thus in all following experiments, we employ  $\delta = 0.2$ .

$\delta$ $K$	0.1	0.2	0.3	0.4	0.5
100	0.8201	0.8847	0.9110	0.9189	0.9125
200	0.8635	0.9274	0.9476	0.9421	0.8821
300	0.8934	0.9506	0.9447	0.9235	0.7203
400	0.9187	0.9519	0.9417	0.7286	0.4537
500	0.9388	<b>0.9554</b>	0.8494	0.5463	0.2293
600	0.9453	0.9523	0.7545	0.4372	0.1120
700	0.9482	0.8938	0.6842	0.3213	0.0503

Table 2. 5-fold cross-validation on training set

The next experiment is to compare our method with two baselines based on VSM of TFIDF weights on the test set. Both the baselines are composed of 8 SVM (Support Vector Machine) classifiers (one for each domain to decide whether a test sample belongs to this domain). One of them uses terms in domain knowledge drawn from the external corpus as features to enrich the representation of VSM (“VSM with E” for short). The other one only uses terms in domain knowledge drawn from the training set as features to construct VSM (“VSM without E” for short). We use RBF kernel and optimized parameters which are chosen by grid-search in LIBSVM<sup>5</sup> to train SVM classifiers.

<sup>5</sup> <http://www.csie.ntu.edu.tw/~cjlin/libsvm/>

	VSM without E	VSM with E	Our Method
Optimized $K$	700	500	500
Optimized F1-measure	0.8965	0.9285	<b>0.9520</b>

Table 3. The overall optimized results of our method and VSM-based methods

Table 3 shows the overall optimized result of each method with its optimized  $K$  on the test set, and Figure 3 shows the optimized result of each domain in more details. We can find that our method achieves the highest overall F1-measure, and achieves 5.7%, 1.7%, 3.0%, 1.9%, 3.5%, 0.06%, 2.9% and 1.4% improvements over VSM with E for Finance, IT, Health, Sports, Tour, Education, Film&TV, and Military respectively.

Figure 3. Optimized results of each domain in more details

## 4 Conclusion

In this paper, we propose a new model based on domain knowledge to solve the data sparsity problem in short text classification. We validate through experiments that classifier based on our model outperforms classifiers based on VSM. In the future work, we will try to combine the external knowledge and the training set to further improve the performance of short text classification.

## Abstract

This paper proposes a keyword extraction process, based on the PageRank algorithm, to reduce noise of input data for measuring semantic similarity. This paper will introduce several features related to implementation and discuss their effects. It will also discuss experimental results which showed significantly improved document retrieval performance with this extraction process in place.

## 1 Introduction

To date, the most popular and well known approach to calculating semantic similarity of text documents has been utilizing Vector Space Models (VSM). The key idea of VSM is to map each document in a corpus or collection into a vector of a vector space, and interpret the distance between the query document's vector and the other texts' vectors as their degree of semantic relatedness (Salton, 1971; Salton et al., 1975; Turney and Pantel, 2010).

The VSM evolved from the SMART information retrieval system (Salton, 1971) and SMART pioneered many important terms and concepts that were adopted by modern search engines (Turney and Pantel, 2010). Many search engines are reported to use VSM to calculate the similarity between a query and a document (Manning et al., 2008).

A common problem of VSM is that documents often contain words with high frequency but little semantic significance. VSM usually deal with this obstacle using tf-idf weighting and singular value decomposition techniques (Turney and Pantel, 2010).

In order to improve retrieval systems that use the models, we suggest that employing keyword

extraction on a per document basis to help reduce the noise inherent in large texts. For this purpose, PageRank, a graph-based ranking algorithm, was used in this study. Graph-based analysis techniques represent a document or text as a graph consisting of nodes (terms or phrases) and edges (pre-defined relations). Along with Brin and Page (1998)'s PageRank, various modifications and other graph-based algorithms have been introduced and proved their usefulness in various natural language processing tasks (Erkan and Radev, 2004; Kurland and Lee, 2006; Mihalcea et al., 2004; Wang et al., 2007; Widdows and Dorow, 2002).

Graph-based extraction systems showed better performance over frequency-based systems on multiple-theme documents (Grineva et al., 2009). In this study, it was assumed that applications would benefit from being able to select important words from documents using the extraction system; not just for keyword extraction tasks, but also for any complex system that needs its input-data to be noise-reduced for future processes.

## 2 Theoretical Background

In this paper, typical core parts of VSM are applied to measure semantic similarity over documents. Therefore, instead of using raw frequencies tf-idf weighting is adopted and length normalization is performed on both queries and target documents (Salton and Buckley, 1988; Buckley, 2005). In addition, the traditional cosine similarity is used to calculate closeness scores between pseudo documents (queries) and documents (following Buckley, 2005). However, the vector space dimensionality reduction phase has been omitted to simplify the experiment process.

### 2.1 Representing Text as Graphs

Before applying the Graph-based approach, several preprocessing stages had to be implemented.

First of all, the words in the text were identified as vertices of the graph. In this study, only unigrams were considered as node candidates. These unigrams were then POS tagged and passed through a syntactic filter, which only allowed a particular subset of POS tags. Various syntactic filters were experimented with including nouns, verbs, and adjectives but the best results were obtained when only nouns were used.

## 2.2 Defining Relationship Between Vertices

The relationship between vertices was chosen to be a co-occurrence relationship. Two nouns of the text would be connected if they both occurred within a window of  $N$  pre-fixed words.  $N$  can be any integer from 2 to 10, but the number of vertices,  $V$  is always equal to or less than  $N$  because the words in the window must bear a relevant POS tag from a predefined set.

In English it is easy to determine which words are within a specific window since each word split by spaces usually corresponds to one POS tag. However, unlike English, Korean is an agglutinative language and most words consist of more than one morpheme, each with their own part of speech. The example below, (1) demonstrates this fact.

- (1) 그 여자가 학교에 갔다.  
 Ku nyeca-ka hakkyo-ey ka-ss-ta  
 The(ku) woman(nyeca)-Normative(ka)  
 school(hakyo)-Locative(ey) go(ka)-  
 PST(ss)-FinalSuffix(ta)  
 ‘The woman went to school’

If the sentence above is POS tagged, the number of tagged members would be eight, three tags more than the English equivalent. What this means is that the average distance between particular POS tagged items in Korean sentences is longer than in English sentences. Presumably, this would lengthen optimal window size in Korean when compared to English. According to the related result of Mihalcea et al. (2004), the best performance was achieved with the window of 2. In our case, it is natural to assume the span of the window would be wider.

However, it is also possible to consider the segments divided by whitespaces as the candidate nodes for the graph, and perform POS tagging after the separation. In this way, we can disregard the distance between any lexeme and functional prefix/suffix attached to it. Under this scheme the normative case ‘ka’ in the middle is

ignored and thus the words ‘woman’ and the ‘school’ in (1) have no distance between them.

This second approach is very similar to the way in which English text is translated as a graph, but it disregards information gained from grammatical relations between nouns and functional prefixes/suffixes glued to them. These two approaches were both experimented with and their results are compared in Section 4.1.

## 3 Experiment

### 3.1 System Framework

The components explained above were implemented in an integrated system, including text pre-processing, POS tagging, keyword extraction, term weighting, and finally calculating semantic similarity. The goal of this system was to retrieve semantically related documents using query documents from the collected corpus.

The general workflow of the system is presented in Fig. 1. The system is designed for easy addition or removal of any of the intermediate stages or processes for experimental purposes. Such configuration changes constituted the different experiment conditions of this research.

Text pre-processing indicates deletion of any special characters, emoticons, and foreign words to allow the sanitized text to be parsed safely during part of speech analysis. And the POS tagger assigns each morpheme one of 22 tag sets and the words given the tag of ‘noun’, excluding pronouns, are passed for later processing.

To establish the stop-word list, three reviewers examined all the nouns extracted from the 800 documents that were collected for this study and selected 192 lexical items manually only if at least two of the reviewers voted for the same word to be on the list.

The Graph-based Keyword Extraction, Frequency Counting, and tf-idf Weighting modules may vary or be absent across various experiment conditions (This is denoted by the dotted boxes in Fig. 1). Keyword extraction stage always follows after Graph analysis because it is the process for sorting and choosing the adequate number of keywords. If the graph analysis is not performed, there can be no keyword extraction.

The Graph-based Keywords Extraction and Frequency Counting are mutually exclusive and only one method is chosen for each experiment condition.

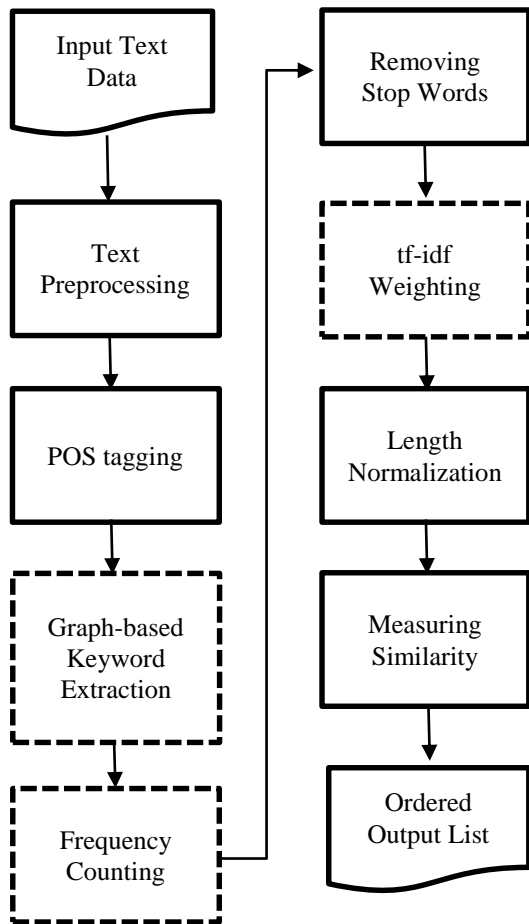

Figure 1. System workflow

### 3.2 Experiment Conditions

Three conditions in total were examined using the system. The first model, using graph-based ranking algorithm, adopted the tf-idf weighting method but omits the Frequency Counting stage. As such, the tf-idf module was supplied with the weighted values given by the Graph-based Keyword Extraction module as instead of the results of the Frequency Counting module. In this circumstance, tf and idf would not stand for term-frequency and inverse-document-frequency, but instead for term or inverse-document weighted scores. This condition can be regarded as a kind of integrated model of graph analysis and VSM.

The second model differed from the first in that the tf-idf weighting module received the frequencies for the keywords from the Frequency Counting module. This type of integration allowed the term-document matrix to be constructed in the way typical of tf-idf systems but the number of the rows was reduced because, same as in the first model, only a subset of the terms

were selected during the Keyword Extraction process.

The final experiment condition was a typical form of VSM and provided a control measure of semantic similarity by using the traditional method, as described in Section 2. This model did not implement the graph-ranking algorithm and skipped the Keyword Extraction stage.

### 3.3 Data

To collect the test data set, 30 famous objects on a list of Seoul cultural assets, each including some descriptive text, were selected for use as queries. For each query, 20 related documents were manually collected including Wikipedia documents, blog posts, and news articles written on the object. Two hundred texts unrelated to any of the queries were searched and stored. These texts consisted of articles, blogs, and web page texts on various topics but limited to social, economic or cultural contents. Hence, each of the cultural objects there would be 20 semantically related documents against 780 unrelated texts.

### 3.4 Evaluation Scheme

To estimate the performance of the models in this system, the well-known measure Mean Average Precision was used (Voorhees and Harman, 2005). This measure ranges from 0 to 1 where the maximum value 1 means that all target documents are placed higher than the non-related texts in the ordered output list.

## 4 Results

### 4.1 Morpheme vs. Word

For the 30 queries, given a word-window of 4 and a Proportion of Keywords of 0.4, the mean average of the precision (MAP score) for the morpheme-based criteria was 0.83 while the word-based criteria was 0.74.

Only four of the 30 queries showed higher MAP scores for the word-based separation method. Thus, in this study, the morpheme-based approach significantly outperforms the word-based approach.

### 4.2 Window Size

A Determining the length of word-window is related to the problem of morpheme/word based separation. In some languages, especially agglutinative languages like Korean, one word might be composed of more than three morphemes. Practically, this means that if there are two words both containing a noun and split by whitespace,

the probability of finding a morpheme between of them will be higher than in non-agglutinative languages such as English, widening the mean distance between any two nouns.

To confirm this prediction, an experiment manipulating the size of the window was conducted and the result is presented in Fig. 2. As one can see, the highest the MAP value (0.83) for the morpheme-based split method is obtained with a window length of 4. This pattern is what was expected given the discussion in Section 2.2. In contrast, using the word-based separation method, there does not seem to be any significant relationship between window size N and MAP score.

One easy interpretation of this result is that the word-based solution is not effective enough to capture the connective pattern of the terms in the network since it is missing the syntactic cues associated with words' stems.

Figure 2. Mean average precision score in terms of window of word N.

### 4.3 Proportion of Keywords

In Fig. 3, the window size was set to 4 and the highest performing experiment model was used (the comparison result for the different models will be provided in next section).

As one can see in the graph, a proportion of 4/10 recorded the highest score. However, after this point the MAP score rapidly dropped; in contrast with the period of gradual increase observed up to that point.

To understand this result, it is important to recall that the tf-idf weighting mechanism uses inverse document frequency to give weights to the terms that are found in only a small number of documents but are frequent within a particular document. Hence, removing too many terms from the text would artificially increase the value of the idf component of tf-idf as a word may be rarely selected as a keyword despite occurring in a large number of documents.

Figure 3. Mean average precision scores for the change of the keyword proportion (e.g., 9/10 means that 90 percent of the candidate nouns were accepted).

### 4.4 Comparison of Different Models

In Table 1, the notation [+/-] indicates whether the function was employed in the workflow of the experiment. Thus, Keyword extraction with plus sign means that the PageRank-based ranking algorithm was used for the keyword extraction process. Similarly, if the tf-idf module is displayed with minus sign then it means that frequencies per each term in the documents were replaced with the values from the graph-based analysis module.

Model	MAP score
Keyword extraction +, tf-idf -	0.81
Keyword extraction -, tf-idf +	0.80
Keyword extraction +, tf-idf +	<b>0.83</b>

Table 1. The MAP scores for different experiment conditions.

The results in Table 1 reveal that the full model (including all the sub-modules) outperforms the other two models, proving the research assumption that pre-filtering input texts would improve the quality of semantic similarity measurements based on VSM. The other modified condition employing the graph-analysis recorded the second highest, but the difference to the control condition was very small. These results were obtained using a window size of 4 and a keyword proportion of 4 out of 10; these values yielded the best outcome from the experiments.

In short, the comparative result of the experimental conditions suggest that drawing a bag of filtered words per document before tf-idf weighting could improve the process of computing semantic relatedness.

## Acknowledgments

The authors would like to thank the three anonymous reviewers for their helpful and valuable comments.

## Abstract

In this paper, we probe the problem of organization name disambiguation on twitter messages. This task is challenging due to the fact of lacking sufficient information in a tweet message. Instead of conventional methods based on mining external information from web sources to enrich information about organization, we propose to mine the relationship among tweets in data set to utilize context information for disambiguation. With a small scale of labeled tweets, we propose LP-based and TSVM-based semi-supervised methods to classify tweets. We aim to mine both related and non-related information for a given organization. The experiments on WePS-3 show that proposed methods are effective.

## 1 Introduction

Twitter is an online social networking and microblogging service, which rapidly gained worldwide popularity. How to retrieval, analyze and monitor Twitter information has been receiving a lot of attention in natural language processing and information retrieval research community (Kwak, *et al.*, 2010; Boyd, *et al.*, 2010; Tsagkias, *et al.*, 2011). One of the essential things of these researches is first to get the information which is related to the studied entity. This is caused by the ambiguity of entities. For example, the name of company “Apple” has a separate meaning referring to one kind of fruit. The word “Amazon” also could refer to river or company.

In this paper, we focus on finding related tweets for a given organization, which can be treated as a binary classification problem. Assuming that tweets are retrieved by a query, such as “apple”, the task is to classify whether each

retrieved tweet is relevant to the target organization (“Apple Inc.”) or not. However, constructing such a classifier is a challenging task, as tweets are short and informal. Additionally, the information about a given organization is limited, which is difficult to cover the word occurrences in the given organization related tweets.

Different from previous work on mining external information from web sources to enrich information about the given organization, we propose to mine the relationship among retrieved tweets in data set. With a small scale of labeled tweets, we propose semi-supervised methods to mine the relationships between labeled and unlabeled tweets for the given organization.

The remainder of the paper is organized as follows: Section 2 describes the related work on name disambiguation. Section 3 gives problem description and an overview of our approach. Section 4 and Section 5 present LP-based and TSVM-based semi-supervised methods to classify tweets. Section 6 gives the experiments and results. Finally section 7 summarizes this paper.

## 2 Related Work

Twitter contains little information in each tweet, with no more than 140 characters. This makes the tasks of analyzing Twitter messages more challenge, and attracts much interest from the research community in recent years (Meij *et al.*, 2012; Liu *et al.*, 2011; Sriram *et al.*, 2011).

The most related works are WePS-3 Online Reputation Management<sup>1</sup> held in 2010, which aims to identify tweets which are related to a given company (Amigó *et al.*, 2010).

In WePS-3, the research of (Yerva *et al.*, 2010) shows the best performance in the evaluation

---

<sup>1</sup> <http://nlp.uned.es/weps/>

campaign. They adopt SVM classifier with external resources, including Wordnet, metadata profile, category profile, Google set, and user feedback, to enrich the information of the given organization. Yoshida *et al.* (2010) classify organization names into “organization-like names” or “general-word-like names”. Kalmar (2010) adopts bootstrapping method to classify the tweets. The research of (García-Cumbreras *et al.*, 2010) shows the named entities in tweets are appropriate for certain company names.

There are some similar works. Perez-Tellez *et al.* (2011) adopt clustering technique to solve the problem of organization name disambiguation. Focus on identifying relevant tweets for social TV, Dan *et al.* (2011) propose a bootstrapping algorithm utilizing a small manually labeled dataset, and a large dataset of unlabeled messages.

Different from their works, we utilize semi-supervised methods to classify the tweets. We aim to transfer related or unrelated information of the given organization among tweets based on a small scale of labeled data.

Compared with bootstrapping algorithm, which is based on a local consistency assumption, LP algorithm is based on a global consistency assumption, and can effectively capture the natural clustering structure in both the labeled and unlabeled data to smooth the labeling function.

### 3 Overview

#### 3.1 Problem Statement

Given a set of tweets and an organization name, the goal is to decide whether each tweet in the set talks about the given organization or not.

In detail, the input information per tweet contains: the tweet identifier, the entity name, the query used to retrieve the tweet, the author identifier and the tweet content.

For each organization in the dataset, it gives the organization name and its homepage URL.

The output per tweet is True or False tag corresponding to related or non-related with the given organization.

#### 3.2 Our Method

In this paper, we propose semi-supervised methods to classify tweets for a given organization. This is considered from the following two points:

- Organization information automatically mined from web pages is limited, which could not cover the potentially infinite words occurred in tweets. However, how to

mine the high quality organization related information is also a problem.

- Both positive and negative samples are important for classification task. Though, it is possible to mine organization related information as positive sample from web by some key words or human input. However, it is difficult to obtain negative information about the other meanings of the given organization name which do not refer to the given organization.

Therefore, instead of mining external information from web sources to enrich information about organization, we propose to mine information directly from tweet set. The organization related information is extracted from the positive samples, which reflects keywords related to the given organization in tweets. The information extracted from the negative samples, gives the possible different interpretations of the given organization name.

With a small scale of labeled tweets for a given organization name, we utilize LP and TSVM based semi-supervised classifiers to mine unlabeled tweets, which will be described in the following section in detail.

### 4 LP Based Semi-supervised Classifier

Label Propagation (LP) is a graph-based semi-supervised algorithm, proposed by Zhu *et al.* (2002). The main idea of graph-based semi-supervised learning is to use pair-wise similarities between instances to enhance classification accuracy. It is a diffusion process on graphs, where the information is propagated from the labeled instances to the rest of unlabeled instances.

LP algorithm is to represent labeled (served as seeds) and unlabeled examples as nodes in a connected graph, then propagating the label information from any vertex to nearby nodes through weighted edges iteratively, finally get the labels of unlabeled examples after the propagation process converges. The labels of unlabeled examples are determined by considering both the similarity between labeled and unlabeled examples, and the similarity between unlabeled examples (Chen, *et al.*, 2008).

LP algorithm has achieved good performance in many applications, such as noun phrase anaphoricity in coreference resolution (Zhou, *et al.*, 2009), word sense disambiguation (Niu, *et al.*, 2005) and entity relation extraction (Chen, *et al.*, 2006).

## 4.1 Graph Building

Let  $X = \{x_i\}_{i=1}^n$  be a set of tweets for a given organization, where  $x_i$  represents  $i$ th tweet,  $n$  is the total number of tweets. The first  $l$  tweets are labeled  $(x_1, y_1) \dots (x_l, y_l)$ ,  $Y_L = \{y_1, \dots, y_l\}$  are labels. Here,  $y_i \in C$ ,  $C$  refers to two known classes (*True* or *False*) for this task. The others  $(x_{l+1}, y_{l+1}) \dots (x_{l+u}, y_{l+u})$  are the unlabeled tweets, where  $Y_U = \{y_{l+1}, \dots, y_{l+u}\}$  are unknown.

For the graph, the nodes represent both labeled and unlabeled tweets. The edge between any two nodes  $x_i$  and  $x_j$  is weighted by some distance measure. Based on assumption, the closer the two nodes are in some distance measure, the larger the weight  $w_{ij}$ , which is defined as follows:

$$w_{ij} = \exp\left(-\frac{s_{ij}^2}{\sigma^2}\right) = \exp\left(-\frac{\text{Cos}^2(x_i, x_j)}{\sigma^2}\right)$$

Where  $s_{ij}$  is the distance measure, we adopt cosine similarity to measure two nodes  $x_i$  and  $x_j$ .  $\sigma$  is a constant parameter to scale the weights.

For measuring the similarity of two nodes, we adopt two types of features to represent each tweet: one is the unigram word unit, the other is 4-gram character unit.

Unigram word: the words contain in a tweet after filtering stop words.

4-gram character unit: the possible 4-gram character for each unigram word.

The tweet is short and informal. There are little information contain in one tweet. One key-word missing may lead the change of the tweet's classification result. Therefore, we adopt character unit as feature to allow the mistake of spelling in some extent.

## 4.2 Algorithm

All nodes in graph have soft labels that can be interpreted as distribution over labels. The label of a node is propagated to all nodes through the edges. Larger edge weights allow labels to travel through easier. Define a  $n \times n$  probabilistic transition matrix  $T$ , ( $n = l + u$ ).

$$T_{ij} = P(j \rightarrow i) = \frac{w_{ij}}{\sum_{k=1}^{l+u} w_{kj}}$$

Here  $T_{ij}$  is the probability to jump from node  $j$  to node  $i$ . We define a  $(l+u) \times C$  label matrix  $Y$ , the  $i$ th row representing the label probability distribution of node  $x_i$ .

The label propagation algorithm is as follows:

- (1) Propagate  $Y \leftarrow TY$
- (2) Row-normalize  $Y$ , to maintain the label probability interpretation
- (3) Clamp the labeled tweets, replace the  $Y_L$  with the initial value
- (4) Repeat from step (1) to (3) until  $Y$  converges

Here, we make use of JUNTO Label Propagation toolkit<sup>2</sup> to implement this algorithm.

## 5 Transductive SVM

Transductive Support Vector Machines (TSVM) is a semi-supervised learning method, which can be treated as an extension of SVM by introducing unlabeled data. Similar with SVM, TSVM tries to label the unlabeled data, and find the maximum margin separation hypersurface that separates the positive and negative instances of labeled data and the unlabeled data. The basic idea of TSVM is to seek a decision surface away from the dense regions of unlabeled data.

For the given labeled tweets  $\{(x_i, y_i) | x_i \in R^n, y_i \in \{-1, +1\}\}_{i=1}^L$ ,  $y_i$  refers to two known classes (*True* or *False*) for this task, and unlabeled data  $\{x_j^* | x_j^* \in R^n\}_{j=1}^{L^*}$ . This can be written as minimizing

$$\arg \min_{w, b, \xi, y^*} \frac{1}{2} \|w\|^2 + C \sum_{i=1}^L \xi_i + C^* \sum_{j=1}^{L^*} \xi_j^*$$

Subject to

$$\forall i: y_i w \bullet \phi(x_i) + b \geq 1 - \xi_i$$

$$\forall j: y_j^* w \bullet \phi(x_j) + b \geq 1 - \xi_j^*$$

$$\forall i: \xi_i \geq 0$$

$$\forall j: \xi_j^* \geq 0$$

$$\forall j: y_j^* \in \{-1, +1\}$$

$$w \in R^m, b \in R$$

Similar with LP, we adopt two types of features to represent each tweet: one is the unigram word unit, the other is 4-gram character unit. Here, we make use of SVMLight tools to implement this algorithm.

## 6 Experiments and Results

### 6.1 Corpus and Evaluation Metric

We have conducted experiments on the WePS-3 task 2 data. The test data contain about 50 organization names with about 450 tweets for each organization.

<sup>2</sup> <http://code.google.com/p/junto/>

	<i>P+</i>	<i>R+</i>	<i>F+</i>	<i>P-</i>	<i>R-</i>	<i>F-</i>
LP	0.8097	0.5008	0.4120	0.8059	0.5593	0.5166
TSVM	0.6683	0.6969	<b>0.7144</b>	0.6942	0.6484	<b>0.6972</b>
Top_1	0.7108	0.7445	0.6264	0.8443	0.5195	0.5606
Top_2	0.7546	0.5409	0.4935	0.7413	0.6049	0.5651
Top_3	0.7410	0.6157	0.5062	0.7365	0.4911	0.4683
Baseline (NR)	1.0000	0.0000	0.0000	0.5652	1.0000	0.6563
Baseline (R)	0.4348	1.0000	0.5274	1.0000	0.0000	0.0000

Table 1. Performances of semi-supervised methods and other systems

The task is to classify the tweets related or non-related with the given organization, it belongs to classification task. Therefore, we measure the performance by *accuracy*, *precision*, *recall* and *F-measure*.

## 6.2 Results and Analysis

Based on the test data, we testify the performance of our proposed methods.

### Seed selection for semi-supervised classifiers

We random select 100 tweets as seeds from the test data for each organization name, which is about 20% for tweet set.

Decreasing the influence of seed selection for the performances of semi-supervised classifiers, we try out the experiments five times and get the average values for the final results.

### Performance of semi-supervised classifiers

For comparison, we select five system results as references, three of them are the top 3 systems in WePS contest, the other two systems are the baseline systems. Two baseline systems tag all tweets as related (Baseline (R)) or non-related (Baseline (NR)) to each organization.

Figure 1 and Table 1 show the performances of semi-supervised methods and other systems.

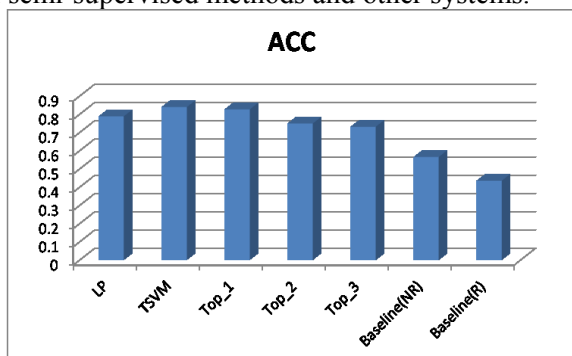

Figure 1. Accuracies of semi-supervised methods and other systems

In Figure 1, the *accuracy* of Baseline (NR) is higher than that of Baseline (R), which shows

there are more unrelated tweets in the whole test data, the disambiguation of tweets is necessary. The accuracies of our proposed methods and Top 3 systems are all much higher than those of two baselines. It proves that adopting some methods to disambiguate tweets is feasible.

The accuracies of our proposed semi-supervised methods based on LP and TSVM are both higher than that of Top\_2 system. The accuracy of TSVM is 0.8391, which is higher than that of Top\_1 (0.8267). It proves that semi-supervised methods are effective for this task. Instead of mining web sources, it is also effective to mine the information among tweets, especially which including both related and non-related information about the organization name.

In Table 1, it shows the performance of each system on *precision*, *recall* and *F-measure*. The values are calculated on the average performance for each organization name in test data set. Though *P+* and *R+* values of TSVM are not the highest ones, the *F+* value is highest among the five systems. *F-* value is also the highest one. it shows that TSVM-based classifier gets the best balance between precision and recall for classification. *F+* value is important to measure the ability of finding the related tweets to a given organization.

## 7 Conclusion

In this paper, we probe the problem of organization name disambiguation on twitter information. We utilize LP and TSVM based semi-supervised method to implement the disambiguation system. The experiments on WePS-3 show that both LP-based classifier and TSVM-based classifier are effective. Especially, TSVM-based classifier gets higher performance than that of the best result in WePS contest, which proves that semi-supervised method is a feasible way to classify the related tweets information for a given organization on Twitter.

## Abstract

Dictionary editing requires enormous time to discuss whether a word should be listed in a dictionary or not. So as to define a dictionary word, this study employs the number of word users as a novel metrics for selecting a dictionary word. In order to obtain the word user, we used about 0.25 billion tweets of approximately 100,000 people published for five months. This study compared the classification performance of various measures. The result of the experiments revealed that a word in a dictionary is used by numerous users.

## 1 Introduction

Dictionary editing requires numerous time to discuss whether a word should be listed in a dictionary or not. In order to define a dictionary word, this study assumes that the following two scales are essential than word frequency:

- (1) **Usage period:** a dictionary word has been used for larger period of time.
- (2) **User population:** a dictionary word has been used by more people.

The first scale is hard to measure in practice, because the usage period requires a longitudinal data. For the investigation, the second clue has more feasibility by social media resources, which enables to know the word usage for each user.

The objective of this study is to retrieve a dictionary word. This study approaches this problem by drawing on a binary classification task, which divides the words into two categories:

ries: a dictionary word (listed in a dictionary) and a out-of-dictionary word.

For the database, we have collected 0.25 billion tweets of 100,000 people from Twitter. The experimental results have revealed that a dictionary word is highly correlated with the number of word users. Although the experiment is conducted in Japanese language, the proposed method does not depend on a specified language.

## 2 Related Work

So far, a strong clue for dictionary editing is a word frequency. The relation between a word frequency and its coverage has been an interest for many researchers (Crowley 2003, Freeborn 2006, Burrige and Kortmann 2008). In English, the frequent 2,000 words cover 90% of spoken language (West 1953), and the most frequent 6,000 words cover 90% of written language (Francis, Kučera et al. 1982). The results in Japanese are similar to them. The frequent 10,000 words cover almost all vocabulary used in magazines (90 magazines) (NINJAL 1997), and 17,000 words cover the vocabulary spoken in television programs (Ishino 2000). Although the target media differs, they share the same findings that frequent words cover most of the corpus. This study presents another word measure.

## 3 Materials

This study has used two types of data: user corpus (Section 3.1), and a gold standard data (Section 3.2):

### 3.1 Corpus: 100,000 people tweets

This study employs Twitter as a fundamental database, because Twitter has two strong advantages for the purpose of this study: (1) it has numerous

users and (2) the author information is available for each tweet. This study sampled 0.25 billion tweets from 99,964 people, as described below.

- **Data collection period:** 143 days from November 3<sup>rd</sup> 2009 to March 25<sup>th</sup> 2010.
- **Number of users:** 99,964 people, as extracted based on the following three qualifications:
  - A user who posts at least 5 tweets per a month
  - Total posts contain over 5,000 words.
  - Japanese language users: at least one Japanese UTF code characters are used in the first tweet.
- **Total number of tweets:** 253,482,784 tweets (4,258,707,255 words): the words are analyzed by a morphological analyzer (Kurohashi, Nakamura et al. 1994)

### 3.2 Gold standard Data

The gold standard data of this study is a word listed in the *IWANAMI* Japanese Dictionary 7<sup>th</sup> edition (Nishio, Iwabuchi et al. 2009). This dictionary is one of the best selling dictionaries in Japanese.

## 4 Methods

The task of this study is to classify whether a word is listed in a dictionary or not. For the classification, this study employs four measures:

1.  $freq(w)$ : a word frequency of a word  $w$ .
2.  $R_{freq}(w)$ : a rank of  $freq(w)$ .
3.  $user(w)$ : the number of users of a word  $w$ .
4.  $R_{user}(w)$ : a rank of  $user(w)$ .

While the first two ( $freq(w)$  and  $R_{freq}(w)$ ) are conventional measures used among the many previous researches, the other two ( $user(w)$  and  $R_{user}(w)$ ) are newly introduced by this study.

### Baseline Approach

A easy approach is to select a word which has enough frequency (more than  $\alpha$  times). This approach is formalized as follows:  $freq(w) > \alpha$ .

### Proposed Approach

Instead of the frequency, the proposed approach relied on the number of users ( $user(w)$ ). This approach is formalized as follows:  $user(w) > \alpha$

### Another Proposed Approach

This approach makes balance between the number of users ( $user(w)$ ) and the word frequency ( $freq(w)$ ). If both measures stay in balance, the both ranks should equal, satisfying the following formula:

$$R_{user}(w) = R_{freq}(w) .$$

If a certain user prefers to use specific words, the rank of the frequency ( $R_{freq}$ ) become larger than that of users ( $R_{users}$ ):

$$R_{user}(w) > R_{freq}(w) .$$

In the same method, a widely used word could be extracted by using the following formula:

$$R_{user}(w) < R_{freq}(w) .$$

## 5 Experiment

### 5.1 Test-set: Wikipedia entry names

A test-set consists of 4,000 nouns, which are randomly sampled from Wikipedia entry names. Half of them (2,598 nouns) are listed in the dictionary (positive examples). The other 1,402 words are out-of-dictionary (negative examples).

### 5.2 Comparable Methods

We compared the following classification methods:

- **Rfreq:** this method selects the words whose frequency is in the top  $\alpha$  rank:  $R_{freq}(w) < \alpha$ .
- **Ruser:** this method selects the words whose user size is in the top  $\alpha$  rank:  $R_{user}(w) < \alpha$ .
- **Ruser' (weighted based):** this method is essentially based on the number of users. However, it is weighted by the frequency as follows:  $-\log(freq(w)) \cdot user(w) < \alpha$ .
- **Ruser/Rfreq:** this approach is based on the balance of two ranks:  $R-Ratio < \alpha$ . Here,  $R-Ratio = R_{user}(w) / R_{freq}(w)$ .

The evaluation is conducted in possible  $\alpha$  range ( $\alpha = 0 \sim \infty$ ).

### 5.3 Evaluation Metrics

The methods are evaluated using information retrieval metrics:

- **Precision (P):** # of correct outputs / # of system positive outputs.
- **Recall (R):** # of correct outputs / # of positive examples (=2,598).
- **F-measure (F):** harmonic mean between the precision and the recall.

## 5.4 Result

The precision-recall curve for each method is presented in Figure 1. The best F-measure points of all methods are the same (Recall=1; Precision=0.6). However, the accuracies differ in the low-recall area. Basically **Ruser** (partly **Ruser/Rfreq**) showed the best performance. **Rfreq** constantly showed poor performance rather than the others. These results indicated that the number of users is an essential factor.

Figure 2 shows the distribution of dictionary words plots in  $R_{freq}(w)$  and  $R_{user}(w)$ . Numerous words are distributed on the balanced line ( $X=Y$ ), indicating that  $R_{freq}(w)$  and  $R_{user}(w)$  correlated with each other.

We found several outliers in the TOP-LEFT area ( $Y \gg X$ ), suggesting that several words have the low number of users compared to the frequency metrics. The examples of such words are presented in Table 1 (b), consisting of many out-of-dictionary words.

## 5.5 Discussion

This study reveals that the number of users is an important clue to classify a dictionary word. This result has a number of applications; e.g., the popular vocabulary learning, a user number-based spell checking system, and so on.

However, this study has several limitations, which comes from the following factors:

- **User bias:** Most Twitter users are 20-30 years old. This population gap might bias the results.
- **Device bias:** The type of input device, such as keyboard typing, touch pad, and input suggestion, might bias the results.
- **Twitter bias:** The length limit of Twitter (140 characters) might prefers shorter words.

Reducing the above biases is one of the remaining problems.

## 6 Conclusion

This study proposes a method to classify a dictionary word. We assume that a dictionary word should be used by many users. To prove this point, we have obtained the 100,000 user texts from Twitter. Then, we have evaluated various measures: a frequency based, a user based, and the ratio based. The experimental result has revealed that the number of word users is an essential indicator for classifying a dictionary word.

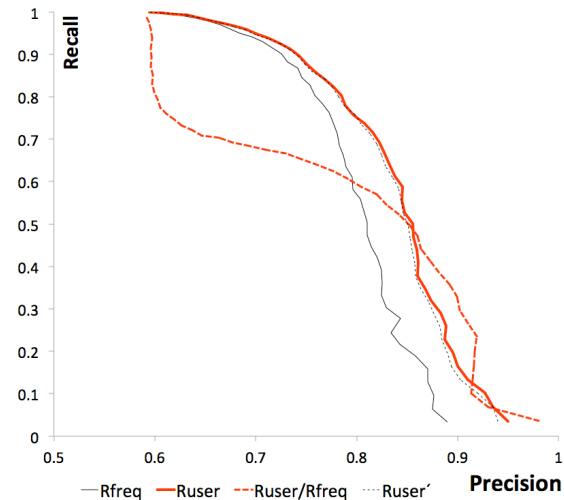

Figure 1: The precision-recall curve for each method.

Figure 2: The Rank of Word User ( $R_{user}$ ) and the Rank of Word Frequency ( $R_{freq}$ ).

The X-axis indicates the rank of word frequency ( $R_{freq}$ ); the Y-axis indicates the rank of word users. The dotted line indicates  $R_{freq}=2000$  and  $R_{user}=2000$ . The line indicates that the balanced line ( $R_{freq}=R_{user}$ ). The RIGHT-BOTTOM area contains words that are high user words. The LEFT-TOP area contains words that are low user words. As shown in the figure, most of low user words are out-of-dictionary words.

## Abstract

A fundamental issue in opinion mining is to search a corpus for opinion units, which typically comprise the evaluation by an author for a target object from an aspect, such as “This hotel is in a good location”. However, no attempt has been made to address cases where the validity of an evaluation is restricted on a condition in the source text, such as “for traveling with small kids”. In this paper, we propose a method to extract such conditions, namely evaluative conditions, from sentences including opinion units. Our method uses supervised machine learning to determine whether each phrase is a constituent of an evaluative condition. We propose several features associated with lexical and syntactic information, and show their effectiveness experimentally.

## 1 Introduction

Reflecting the rapid growth in the use of opinionated texts on the Web, such as customer reviews, opinion mining has been explored to facilitate utilizing opinions mainly for improving products and decision-making purposes. While in a broad sense opinion mining refers to a process to discover useful knowledge latent in a corpus of opinionated texts, in a narrow sense its purpose is to extract opinions from a corpus. In either case, fundamental issues involve modeling a unit of opinions and searching the corpus for those units, which typically comprise the evaluation by an author for a target object from an aspect.

We take the following review sentence as an example opinionated description.

“I think hotel A is in a good location for traveling with small kids”.

From the above example, existing methods (Pang and Lee, 2008; Seki et al., 2009; Jin et al., 2009; Zhao et al., 2010; He et al., 2011; Liu and Zhang, 2012) for opinion mining extract the following quintuple as an opinion unit.

Target = “hotel A”, Aspect = “location”,  
Evaluation (Polarity) = “good” (positive), Holder = “I (author)”, Time = N/A

Depending on the application, “Evaluation” can be any of a literal evaluation expression (e.g., “good”), a polarity (positive/negative), or a value for multipoint scale rating. However, because this difference is not important in our research, we usually use the term “evaluation”.

Given those structured items extracted from a corpus, it is easy to overview the distribution of values for each element or a combination of elements. Those who intend to improve the quality of hotel A may investigate the distribution of values for “Aspect” in the reviews with “Target=hotel A & Polarity=negative”, while those who look for accommodation may compare the distribution of values for “Aspect & Polarity” in reviews for more than one hotel.

However, no attempt has been made to address cases where the validity of an evaluation is restricted on a condition in the source text. We shall call such a condition “evaluative condition”. In the above example sentence, the evaluation for hotel A (“in a good location”) is valid only “for traveling with small kids”, and it is not clear whether this evaluation is valid irrespective of the situation. The existing methods, which do not analyze evaluative conditions, potentially overestimate or underestimate the utility of hotel A and the quality of opinion mining is decreased accordingly.

To alleviate this problem, we need to introduce evaluative conditions as an element in the opinion unit, such as Condition=“for traveling with small kids”, which enables us to perform deeper

and finer-grained analysis for opinion mining. To avoid any confusion, we consistently use the term “opinion unit” to refer to the traditional quintuple-based unit in which a few elements can be omitted.

Motivated by the above background, in this paper we propose a method to extract evaluative conditions from opinionated corpora. The contribution of our research is introducing the notion of evaluative conditions into opinion mining and proposing a method to extract evaluative conditions from opinionated corpora.

Currently, we target corpora of review text in Japanese. As the first step of research, we focus only on cases where an evaluative condition and an opinion unit are in the same sentence. In addition, we leave the following two research issues as future work.

First, compared with the existing opinion elements, such as Aspect, values for Condition tend to be long and thus it is important to standardize various expressions for the same condition, such as “for traveling with small kids” and “for a family trip with children”. It can be expected that existing methods for paraphrasing alleviate this problem.

Second, it can be useful to subdivide evaluative conditions into general or domain-specific categories, such as “purpose”, “user”, and “situation” in reviews for hotels. For example, those categories can be effective to refine user’s needs in retrieving or recommending products. We show example sentences for several categories, in which the evaluative condition and evaluation expression are in bold and italic faces, respectively.

The room is *large enough* **for a business trip**. (purpose)

The bed is *small* **for people who is 185cm tall**. (user)

**If you stay more than one day**, you will be *tired of* the breakfast. (situation)

I was *content* with the meal **if it was less expensive**. (counterfactual)

**Considering the class of this hotel**, the dinner is *acceptable*. (concession)

## 2 Related Work

Evaluative conditions are related to causes and reasons because all of them have an influence on the validity of the corresponding evaluation in an opinion.

Although causal relations can be divided into inter-sentential and intra-sentential, our current interest is more related to the extraction of intra-sentential relations (Girju, 2003; Chang and Choi, 2004; Inui et al., 2005). These methods generally identify two event-related components in a sentence and determine the type of the causal relationship between those components, if any, such as “precondition”, “cause-effect”, and “consequence”. An event-related component is usually a word, such as “cancer”, or a proposition, such as “he is a heavy smoker”.

However, the above existing methods focused only on specific syntactic patterns, such as “<Clause1, Marker (*tame* in Japanese), Clause2>” (Inui et al., 2005) and “<NP1, Verb, NP2>” (Girju, 2003; Chang and Choi, 2004). In Section 1, none of the example sentences including evaluative conditions matches to those patterns, irrespective of whether in English or in Japanese. Additionally, looking at the examples for “counterfactual” and “concession”, the relation between the evaluation and evaluative condition is different from the causal relation. Besides this, our research is the first attempt to extract cause-like relations in opinion mining.

Kim and Hovy (2006) proposed a method to identify a reason for the evaluation in an opinion, such as “the service was terrible because the staff was rude” and “in a good location close to the station”. However, their purpose is to identify grounds that justify the evaluation, which are different from evaluative conditions.

## 3 Proposed method

### 3.1 Overview

The purpose of our method is to extract one or more evaluative conditions in an opinionated sentence in Japanese. Currently, we assume that both an opinion unit and an evaluative condition are in the input sentence, and that the opinion unit has been identified by an existing automatic method.

Our extraction method follows the BIO chunking classifier, which labels each token in a sentence as being the beginning (B), inside (I), or outside (O) of a span of interest. However, because there is no specific characteristics at the beginning of evaluative conditions in Japanese, we do not use the “B” label. We regard Japanese bunsetsu phrases, which consists of a content word and one or more postpositional particles, as tokens, and ex-

tract a sequence of I-phrases as an evaluative condition. However, phrases in an opinion unit are always classified into O-phrases. We use Support Vector Machine (SVM) to train a binary classifier for bunsetsu phrases and propose several features associated with lexical and syntactic information.

### 3.2 Features for phrase classification

Figure 1 depicts an example of syntactic dependency analysis for a review sentence in Japanese. We used “CaboCha” (Kudo and Matsumoto, 2002) for the dependency analysis. In Figure 1, a rectangle and an arrow denote a phrase and a dependency between two phrases, respectively, and in each phrase we show Romanized Japanese words and their English translations in parentheses.

Looking at Figure 1, by definition the evaluative condition (phrases #3-6) modifies the evaluation expression (phrase #7), but does not modify other opinion elements including the aspect (phrase #2). Also, the evaluative condition ends with specific particles in phrase #6. These properties motivated us to propose the following five features for the binary phrase classification.

**Feature A:** Because an evaluative condition modifies the evaluation expression, they are usually in close proximity to each other. Thus, there should be a pass of dependencies between an I-phrase and the evaluation expression, and a phrase in closer proximity to the evaluation expression is more likely to be an I-phrase. We use the dependency distance (i.e., the number of dependencies) between a phrase in question and the evaluation expression as the value for feature A. The value for a phrase is -1 if there is no pass between that phrase and the evaluation expression. In Figure 1, values for phrases #1, #4, and #8 are 2, 3, and -1, respectively.

**Feature B:** Feature A is not robust against errors of the dependency analysis. To complement this weakness of feature A, we roughly estimate the dependency distance by a phrase distance. In practice, we use the difference between the phrase IDs between a phrase in question and the evaluation expression as the value for feature B. If the evaluation expression consists of more than one phrase, we take the minimum difference. Because Japanese sentence has a post modification structure, in which a modifier is followed by its head, a phrase with a negative value for feature B is usu-

ally an O-phrase. In Figure 1, unlike the case for feature A, the values for phrase #1 is 6.

**Feature C:** Because an evaluative condition does not modify any opinion elements other than the evaluation expression, for the value of feature C we take 0 if there is a pass of dependencies between a phrase in question and a non-evaluation opinion element; otherwise 1. In Figure 1, values for phrases #1, #4, and #8 are 0, 1, and 1, respectively.

**Feature D:** Because an evaluative condition often ends with one or more specific particles, we use the existence (1/0) of those particles in a phrase as the value for feature D. Example particles include “ga (the nominative case)”, “no (of)”, “nitottte (for)”, and “nara (if)”. In Figure 1, values for phrases #1 and #6 are 1 and those for the remaining phrases are 0.

**Feature E:** As in Figure 1, an evaluative condition often consists of a phrase whose value for feature D is 1 and one or more preceding phrases. We use the existence (1/0) of a pass of dependencies between a phrase in question and a phrase whose value for feature D is 1. In Figure 1, values for phrases #3-5 are 1 and those for the remaining phrases are 0.

## 4 Experiments

To evaluate the effectiveness of our method, we used the Rakuten Travel data<sup>1</sup>, which consists of approximately 348,564 reviews for hotels in Japanese. From this data set, we randomly selected 675 reviews and manually annotated quintuples for opinion units and evaluative conditions. We found that 182 reviews include evaluative conditions and decomposed those reviews into sentences. We collected 286 sentences including evaluative conditions and used those sentences as the corpus for experiments. The total number of bunsetsu phrases in our corpus is 2,472, which consists of 761 I-phrases and 1,126 O-phrases in which 585 phrases are elements in opinion units.

We performed 10-fold cross-validation and compared different methods in terms of precision (P), recall (R), and F-measure (F). In Table 1, while “Phrase” denotes the result of the binary classification for bunsetsu phrases, “Condition” denotes that of extracting evaluative conditions as a whole using the BIO classifier. The line “Rule” denotes the result of a rule-based method, which is

<sup>1</sup><http://www.nii.ac.jp/cscenter/idr/rakuten/rakuten.html>

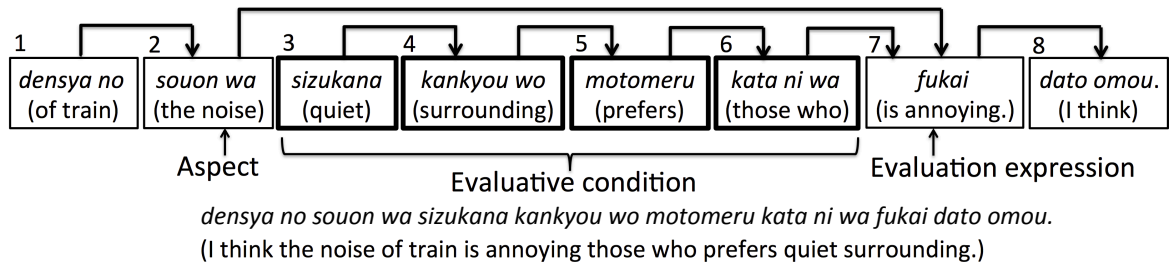

Figure 1: Example of dependency analysis for Japanese.

used as the baseline. This method extracts a bunsetsu phrase ending with one or more specific particles and all phrases from which there is a dependency path to that phrase. For example, in Figure 1 because phrase #6 ends with specific particles, the rule-based method extracts a sequence of phrases #3-#6 as an evaluative condition. The remaining lines denote different combinations of our five features in Section 3.2. While “w/o X” denotes our method without feature X, “All” denotes our complete methods using the five features.

Looking at Table 1, one can see that any variation of our method outperformed the rule-based method irrespective of the configuration, and that our complete method outperformed the remaining of our methods in terms of F-measure. We used the two-tailed paired t-test for statistical testing and found that the differences of “Rule” and “All” in F-measure for “Phrase” and “Condition” were significant at the 1% level. Thus, we conclude that each of our five features was independently effective for extracting evaluative conditions in review sentences and that when used together the improvement was even greater. At the same time, because values for P, R, and F in “Condition” were substantially smaller than those in “Phrase”, we need to improve methods to combine I-phrases and determine the final evaluative condition.

	Phrase			Condition		
	P	R	F	P	R	F
Rule	.539	.614	.553	.407	.412	.410
w/o A	.733	.797	.734	.505	.541	.517
w/o B	.598	.685	.609	.410	.460	.426
w/o C	.719	.789	.725	.490	.524	.500
w/o D	.732	.787	.732	.522	.554	.531
w/o E	.745	.756	.713	.456	.496	.468
All	.730	.792	.735	.538	.571	.548

Table 1: Results for experiments.

## 5 Conclusion

Although a number of methods have been proposed to search an opinionated corpus for opinion units, no attempt has been made to address cases where the validity of an evaluation in an opinion is restricted on a condition in the source text. We proposed a method to extract such conditions, namely evaluative conditions, from sentences including opinion units. Our method performed supervised binary classification to determine whether each phrase is a constituent of an evaluative condition. We proposed five features associated with lexical and syntactic information for Japanese, and show their effectiveness using reviews for hotels. Future work includes addressing research issues discussed in Section 1.

## Abstract

Cognates are words in different languages that are associated with each other by language learners. Thus, cognates are important indicators for the prediction of the perceived difficulty of a text. We introduce a method for automatic cognate production using character-based machine translation. We show that our approach is able to learn production patterns from noisy training data and that it works for a wide range of language pairs. It even works across different alphabets, e.g. we obtain good results on the tested language pairs English-Russian, English-Greek, and English-Farsi. Our method performs significantly better than similarity measures used in previous work on cognates.

## 1 Introduction

In order to improve comprehension of a text in a foreign language, learners use all possible information to make sense of an unknown word. This includes context and domain knowledge, but also knowledge from the mother tongue or any other previously acquired language. Thus, a student is more likely to understand a word if there is a similar word in a language she already knows (Ringbom, 1992). For example, consider the following German sentence:

*Die internationale Konferenz zu kritischen Infrastrukturen im Februar ist eine Top-Adresse für Journalisten.*

Everybody who knows English might grasp the gist of the sentence with the help of associated words like *Konferenz-conference* or *Februar-February*. Such pairs of associated words are called *cognates*.

A strict definition only considers two words as cognates, if they have the same etymological origin, i.e. they are genetic cognates (Crystal, 2011). Language learners usually lack the linguistic background to make this distinction and will use all similar words to facilitate comprehension regardless of the linguistic derivation. For example, the English word *strange* has the Italian correspondent *strano*. The two words have different roots and are therefore genetically unrelated. However, for language learners the similarity is more evident than for example the English-Italian genetic cognate *father-padre*. Therefore, we aim at identifying all words that are sufficiently similar to be associated by a language learner no matter whether they are genetic cognates. As words which are borrowed from another language without any modification (such as *cappuccino*) can be easily identified by direct string comparison, we focus on word pairs that do not have identical spelling.

If the two associated words have the same or a closely related meaning, they are true cognates, while they are called false cognates or false friends in case they have a different meaning. On the one hand, true cognates are instrumental in constructing easily understandable foreign language examples, especially in early stages of language learning. On the other hand, false friends are known to be a source of errors and severe confusion for learners (Carroll, 1992) and need to be practiced more frequently. For these reasons, both types need to be considered when constructing teaching materials. However, existing lists of cognates are usually limited in size and only available for very few language pairs. In order to improve language learning support, we aim at automatically creating lists of related words between two languages, containing both, true and false cognates.

In order to construct such cognate lists, we need to decide whether a word in a source language has a cognate in a target language. If we already have candidate pairs, string similarity measures can be used to distinguish cognates and unrelated pairs (Montalvo et al., 2012; Sepúlveda Torres and Aluisio, 2011; Inkpen et al., 2005; Kondrak and Dorr, 2004). However, these measures do not take the regular production processes into account that can be found for most cognates, e.g. the English suffix *-tion* becomes *-ción* in Spanish like in *nation-nación* or *addition-adición*. Thus, an alternative approach is to manually extract or learn production rules that reflect the regularities (Gomes and Pereira Lopes, 2011; Schulz et al., 2004).

All these methods are based on string alignment and thus cannot be directly applied to language pairs with different alphabets. A possible workaround would be to first transliterate foreign alphabets into Latin, but unambiguous transliteration is only possible for some languages. Methods that rely on the phonetic similarity of words (Kondrak, 2000) require a phonetic transcription that is not always available. Thus, we propose a novel production approach using statistical character-based machine translation in order to directly produce cognates. We argue that this has the following advantages: (i) it captures complex patterns in the same way machine translation captures complex rephrasing of sentences, (ii) it performs better than similarity measures from previous work on cognates, and (iii) it also works for language pairs with different alphabets.

## 2 Character-Based Machine Translation

Our approach relies on statistical phrase-based machine translation (MT). As we are not interested in the translation of phrases, but in the transformation of character sequences from one language into the other, we use words instead of sentences and characters instead of words, as shown in Figure 1. In the example, the English character sequence *cc* is mapped to a single *c* in Spanish and the final *e* becomes *ar*. It is important to note that these mappings only apply in certain contexts. For example, *accident* becomes *accidente* with a double *c* in Spanish and not every word-final *e* is changed into *ar*. In statistical MT, the training process generates a phrase table with transformation probabilities. This information is combined with language model probabilities and a search algo-

Figure 1: Character-based machine translation

rithm selects the best combination of sequences. The transformation is thus not performed on isolated characters, it also considers the surrounding sequences and can account for context-dependent phenomena. The goal of the approach is to directly produce a cognate in the target language from an input word in another language. Consequently, in the remainder of the paper, we refer to our method as COP (COgnate Production).

Exploiting the orthographic similarity of cognates to improve the alignment of words has already been analyzed as a useful preparation for MT (Tiedemann, 2009; Koehn and Knight, 2002; Ribeiro et al., 2001). As explained above, we approach the phenomenon from the opposite direction and use statistical MT for cognate production.

Previous experiments with character-based MT have been performed for different purposes. Pennell and Liu (2011) expand text message abbreviations into proper English. In Stymne (2011), character-based MT is used for the identification of common spelling errors. Several other approaches also apply MT algorithms for transliteration of named entities to increase the vocabulary coverage (Rama and Gali, 2009; Finch and Sumita, 2008). For transliteration, characters from one alphabet are mapped onto corresponding letters in another alphabet. Cognates follow more complex production patterns. Nakov and Tiedemann (2012) aim at improving MT quality using cognates detected by character-based alignment. They focus on the language pair Macedonian-Bulgarian and use English as a bridge language. As they use cognate identification only as an intermediary step and do not provide evaluation results, we cannot directly compare with their work. To the best of our knowledge, we are the first to use statistical character-based MT for the goal of directly producing cognates.

## 3 Experimental Setup

Figure 2 gives an overview of the COP architecture. We use the existing statistical MT engine Moses (Koehn et al., 2007). The main difference of character-based MT to standard MT is the lim-

Figure 2: Architecture of our Cognate Production (COP) approach

ited lexicon. Our tokens are character n-grams instead of words, therefore we need much less training data. Additionally, distortion effects can be neglected as reordering of ngrams is not a regular morphological process for cognates.<sup>1</sup> Thus, we deal with less variation than standard MT.

**Training** As training data, we use existing lists of cognates or lists of closely related words and perform some preprocessing steps. All duplicates, multiwords, conjugated forms and all word pairs that are identical in source and target are removed. We lowercase the remaining words and introduce # as start symbol and \$ as end symbol of a word. Then all characters are divided by blanks. Moses additionally requires a language model. We build an SRILM language model (Stolcke, 2002) from a list of words in the target language converted into the right format described above. On the basis of the input data, the Moses training process builds up a phrase table consisting of character sequences in our case. As a result of the training process, we receive a cognate model that can be used to produce cognates in the target language from a list of input test words.

**Cognate Production** Using the learned cognate model, Moses returns a ranked  $n$ -best list containing the  $n$  most probable transformations of each input word. In order to eliminate non-words, we check the  $n$ -best list against a lexicon list of the target language. The filtered list then represents our set of produced cognates. Note that, as discussed in Section 1, the list will contain true and false cognates. The distinction can be performed using a bilingual dictionary (if available) or with statistical and semantic measures for the identification of false friends (Mitkov et al., 2008; Nakov et al., 2007). For language learning, we need both

types of cognates as foreign words also trigger wrong associations in learners (see Section 5.4).

**Evaluation Metrics** In order to estimate the cognate production quality without having to rely on repeated human judgment, we evaluate COP against a list of known cognates. Existing cognate lists only contain pairs of true cognates, but a word might have several true cognates. For example, the Spanish word *música* has at least three English cognates: *music*, *musical*, and *musician*. Therefore, not even a perfect cognate production process will be able to always rank the right true cognate on the top position. In order to account for the issue, we evaluate the coverage using a relaxed metric that counts a positive match if the gold standard cognate is found in the  $n$ -best list of cognate productions. We determined  $n = 5$  to provide a reasonable approximation of the overall coverage.

We additionally calculate the mean reciprocal rank (MRR) as

$$MRR = \frac{1}{|C|} \sum_{i=1}^{|C|} \frac{1}{rank_i}$$

where  $C$  is the set of input words and  $rank_i$  the rank of the correct cognate production. For example, if the target cognate is always ranked second-best, then the MRR would be 0.5.<sup>2</sup>

Note that in our language learning scenario, we are also interested in words that might be associated with the foreign word by learners, but are actually not true cognates (e.g. the English word *muse* might also be mistakenly associated with *música* by language learners). Unfortunately, an evaluation of the false cognates produced by COP is not covered by those metrics and thus left to a qualitative analysis as performed in section 5.4.

<sup>1</sup>We use these parameters: -weight-1 1 -weight-d 0 -weight-w -1 -dl 0 -weight-t 0.2 0.2 0.2 0.2 0.2

<sup>2</sup>BLEU (Papineni et al., 2002) is the common evaluation metric for MT, but would be misleading in our setting.

## 4 Experiments & Results

We conducted a set of experiments that cover different aspects of the cognate production process. First, we test whether the approach is able to learn simple production rules. We select optimal parameters and test the influence of the size and quality of the available training data. We then compare our best model to previous work. For these experiments, we use the language pair English-Spanish, as a large manually collected list of cognates is available for training and evaluation.

### 4.1 Ability to Learn Production Rules

We train COP on a list of just ten cognates all following the same production process in order to test whether COP can generally learn cognate production rules. We test two different processes: i) the pattern (*~tion*→*~ción*), as in *tradition-tradición* ii) the pattern (*~ance*→*~ancia*) as in *elegance-elegancia*. The experiment shows that COP correctly produces the respective target cognates for new input words with the same pattern. We can conclude that COP succeeds in learning the necessary patterns for cognate production. In the following, we investigate whether our approach can also be applied to noisy training data containing a mixture of many different production processes.

### 4.2 Parameter Selection

We vary the following COP parameters: the character  $n$ -gram size used for tokenization, the order of the language model, the lexicon used for filtering, and tuning of Moses parameters. We collected a list of 3,403 English-Spanish cognates and split it into training set (2,403), development set (673), and test set (327).<sup>3</sup> Table 1 shows the coverage in the 5 best productions and the MRR for each parameter.

**N-gram Size** We start with the  $n$ -gram size parameter that determines the tokenization of the input, the respective format for unigrams, bigrams, and trigrams for the word *banc* looks as follows:

`# b a n c $ / # b b a a n n c c $ / # b a b a n a n c n c $`

Higher order  $n$ -grams in general increase the vocabulary and thus lead to better alignment. However, they also require a larger amount of training data, otherwise the number of unseen instances is

<sup>3</sup>The cognates have been retrieved from several web resources and merged with the set used by Montalvo et al. (2012). All test cognate list can be found at: <http://www.ukp.tu-darmstadt.de/data>

		Cov. (n=5)	MRR
1)	Unigram	.63	.43
	<b>Bigram</b>	.65	.49
	Trigram	.51	.40
2)	LM-order 5	.68	.48
	<b>LM-order 10</b>	.65	.49
3)	Web1T-Filter	.68	.52
	<b>Wordlist-Filter</b>	.65	.54
4)	Moses Tuning	.66	.54

Table 1: Parameter selection for COP. The settings in bold are used for the subsequent experiments.

too high. We find that bigrams produce slightly better results than unigrams and trigrams, this is in line with findings by Nakov and Tiedemann (2012). Thus, in the following experiments, we use character bigrams.

**Language Model** The next parameter is the language model which determines the probability of a sequence in the target language, e.g. a model of order 5 considers sequences of character  $n$ -grams up to a maximum length of 5. Order 5 seems to be already sufficient for capturing the regular character sequences in a language. However, the ranks for the order-10 model are slightly better and as our “vocabulary” is very limited, we can safely decide for the language model of order 10.

**Lexicon Filter** For filtering the  $n$ -best cognate productions, we tried two different lexicon filter lists. A relatively broad one extracted from the English Web1T (Brants and Franz, 2006) word counts, and a more restrictive corpus-based list. The more restrictive filter decreases the coverage as it also eliminates some correct solutions, but it improves the MRR as non-words are deleted from the  $n$ -best list and the ranking is adjusted accordingly. The choice of the filter adjusts the trade-off between cognate coverage and the quality of the  $n$ -best list. For our language learning scenario, we decide to use the more restrictive filter in order to assure high quality results.

**Moses Parameters** Finally, we tune the Moses parameter weights by applying minimum error rate training (Och and Ney, 2003) using the development set, but it makes almost no difference in this setting. Tuning optimizes the model with respect to the BLEU score. For our data, the BLEU score is quite high for all produced cognate candidates, but it is not indicative of the usefulness of the transformation. A word containing one wrong character is not necessarily better than a word con-

Figure 3: COP learning curve

taining two wrong characters. This explains why tuning has little effect.

Generally, COP reaches a coverage of about 65%. If we consider an n-best list with the 100 best translations (instead of only 5), the coverage increases only by less than 1% on average, i.e. the majority of the correct cognates can be found in the top 5. This is also reflected by the high MRR. In the following experiments, we use the optimal parameter setting (highlighted in Table 1).

### 4.3 Training Data Size & Quality

As we have seen in the experiments in Section 4.1, COP is able to learn a production rule from only few training instances. However, the test dataset contains a variety of cognates following many different production processes. Thus, we evaluate the effect of the size of the training data on COP. The learning curve in Figure 3 shows the results. As expected, both coverage and MRR improve with increasing size of the training data, but we do not see much improvement after about 1,000 training instances. Thus, COP is able to learn stable patterns from relatively few training instances.

However, even a list of 1,000 cognates is a hard constraint for some language pairs. Thus, we test if we can also produce satisfactory results with lower quality sets of training pairs that might be easier to obtain than a list of cognates.

We use word pairs extracted from the freely available multilingual resources UBY (Gurevych et al., 2012) and Universal WordNet (UWN) (de Melo and Weikum, 2009). UBY combines several lexical-semantic resources, we use translations which were extracted from Wiktionary. UWN is based on WordNet and Wikipedia and provides automatically extracted translations for over 200 languages that are a bit noisier compared to UBY translations. Additionally, we queried the Microsoft Bing translation API using all words from

	Training Size	Cov. (n=5)	MRR
Cognates	1,000 / 2,403	.57/.65	.48/.54
Transl.	UBY 1,000 / 6,048	.53/.69	.47/.56
	UWN 1,000 / 10,531	.50/.69	.43/.54
	Bing 1,000 / 5,567	.51/.64	.44/.54
Knowledge-free	1,000 / 34,019	.21/.47	.18/.33

Table 2: Influence of data size and quality

an English word list as query words.<sup>4</sup> We also test a knowledge-free approach by pairing all words from the English and Spanish Web1T corpus.<sup>5</sup> While the translation pairs always share the same meaning, this is not the case for the Web1T pairs, where the majority of pairs will be unrelated.

In order to increase the ratio of possible cognates in the training data, we apply a string similarity filter using the XDICE-measure with a threshold of 0.425<sup>6</sup> on the translation pairs. For the knowledge-free pairs, we use a stricter threshold of 0.6 in order to account for the lower quality.

For a fair quality comparison, we first limit the number of training instances to 1,000, where (as shown above) the performance increases leveled off. The left columns for coverage and MRR in Table 2 show the results. It can be seen, that the results for the translation pairs extracted from UBY, UWN and Bing are only slightly inferior to the use of manually collected cognates for training. The small differences between the resources mirror the different level of linguistic control that has been applied in their creation. The knowledge-free pairs from Web1T yield drastically inferior results. We can conclude that training data consisting of selected cognates is beneficial, but that a high quality list of translations in combination with a string similarity filter can also be sufficient and is usually easier to obtain.

In a follow-up experiment, we use the full size of each training set. As expected, coverage and MRR both increase in all settings. Even with the knowledge-free training set that introduces many noisy pairs, satisfactory results can be obtained. This shows that COP can be used for the production of cognates, even if no language-specific information beyond a lexicon list is available.

### 4.4 Comparison to Previous Work

Previous work (Kondrak and Dorr, 2004; Inkpen et al., 2005; Sepúlveda Torres and Aluisio, 2011;

<sup>4</sup><http://www.bing.com/translator>

<sup>5</sup>We only use every 5th word in order to limit the number of results to a manageable size.

<sup>6</sup>The threshold was selected to cover ~80% of the test set.

	Cov. (n=5)	MRR
DICE	.46	.21
XDICE	.52	.25
LCSR	.51	.24
SpSim	.52	.22
COP	<b>.65</b>	<b>.54</b>

Table 3: Comparison of different approaches for cognate production.

Montalvo et al., 2012) is based on similarity measures that are used to decide whether a candidate word pair is a cognate pair, while COP directly produces a target cognate from the source word. In order to compare those approaches to COP, we pair the English input words from the previous experiments with all words from a list of Spanish words<sup>7</sup> and consider all resulting pairs as candidate pairs. For each pair, we then calculate the similarity score and rank the pairs accordingly. As the similarity measures often assign the same value to several candidate pairs, we get many pairs with tied ranks, which is problematic for computing coverage and MRR. Thus, we randomize pairs within one rank and report averaged results over 10 randomization runs.<sup>8</sup>

We compare COP to three frequently used string similarity measures (LCSR, DICE, and XDICE), which performed well in (Inkpen et al., 2005; Montalvo et al., 2012), and to SpSim which is based on learning production rules. The longest common subsequence ratio (LCSR) calculates the ratio of the length of the longest (not necessarily contiguous) common subsequence and the length of the longer word (Melamed, 1999). DICE (Adamson and Boreham, 1974) measures the shared character bigrams, while the variant XDICE (Brew and McKelvie, 1996) uses extended bigrams, i.e. trigrams without the middle letter. SpSim (Gomes and Pereira Lopes, 2011) is based on string alignment of identical characters for the extraction and generalization of the most frequent cognate patterns. Word pairs that follow these extracted cognate patterns are considered equally similar as pairs with identical spelling.

Table 3 shows the results. The differences between the individual similarity measures are very small, string similarity performs on par with SpSim. The low MRR indicates that the four measures are not strict enough and consider too many candidate pairs as sufficiently similar. COP

<sup>7</sup>In order to ensure a fair comparison, we use the Spanish word list that is also used as lexicon filter in COP.

<sup>8</sup>The average standard deviation is 0.01.

	Language Pair	Cov. (n=5)	MRR
Same alphabet	en-es	.65	.54
	es-en	.68	.48
	en-de	.55	.46
Cross-alphabet	en-ru	.59	.47
	en-el	.61	.37
	en-fa	.71	.54

Table 4: COP results for other languages

performs significantly better than all other measures for both, coverage and MRR. The results for the similarity measures are comparable to the knowledge-free variant of COP (Cov = .47 and MRR = .33, compare Table 2). Obviously, COP better captures the relevant cognate patterns and thus is able to provide a better ranking of the production list. Another advantage of COP is its applicability to language pairs with different alphabets (see Section 5.2), while the similarity measures can only operate within one alphabet.

## 5 Multilinguality

The previous experiments showed that COP works well for the production of Spanish cognates from English source words. However, in language learning, we need to consider all languages previously acquired by a learner, which leads to a large set of language combinations. Imagine, for example, an American physician who wants to learn German. She has studied Spanish in school and the terminology in her professional field has accustomed her to Greek and Latin roots. When facing a foreign text, she might unconsciously activate cues from any of these languages. Thus, if we want to select suitable text for her, we need to consider cognates from many different languages.

In the following experiments, we test how COP performs for other languages with the same alphabet and across alphabets. In addition, we evaluate how well the cognates produced by COP correlate with human judgments.

### 5.1 Same Alphabet

We first analyze whether the cognate production also works in the reverse direction and test the production of English cognates from Spanish source words. The results in Table 4 (upper part) show that COP works bi-directionally, as the scores for Spanish to English are comparable to those for English to Spanish. In addition, we train a model for another Western European language pair, namely English-German. The results show that COP also works well for other language pairs.

English	Spanish	German	Russian	Greek	Farsi
<i>alcohol</i>	alcohol, alcoholar	alkohol, alkoholisch	алкоголь, алкогольный	αλκοολικό, αλκοολικά	الكي, الكل
<i>coffee</i>	café	-	кофей, кофе	-	قهوه
<i>director</i>	director, directora	direktor, direkt	директор	-	غير, دير
<i>machine</i>	machina	maschine, machen	машина, машина	μηχανή, μαχίν	ماشینی, ماشین
<i>music</i>	músico, música	musik, musisch	-	μουσική, μουσικές	موسى, موسيقى
<i>optimal</i>	óptimo	optimal, optimiert	оптимальный	-	مطلوب
<i>popular</i>	popular	populär	популярный	-	محبوب
<i>theory</i>	teoría	theorie	теория	θεωρία, θεωρίας	نظری, تئوری
<i>tradition</i>	tradición	tradition	традиция, традиционный	-	سنتی, سنت

Table 5: Multilingual cognates for English source words produced by COP

## 5.2 Cross-Alphabet

Previous approaches to cognate identification only operate on languages using the same alphabet. As COP is able to learn correspondences between arbitrary symbols, it can easily be applied on cross-alphabet language pairs. In the previous experiments, we had excluded cognate pairs that have exactly the same string representation. For cross-alphabet pairs, this is not possible. Thus, the task is to tackle both, standard transliteration (as in the English-Greek pair *atlas*-άτλας)<sup>9</sup> and cognate production (as in *archangel*-αρχάγγελος)<sup>10</sup>.

We evaluate COP for Russian (ru), Greek (el), and Farsi (fa). For Russian, we use a list of UBY-pairs as training data. Unfortunately, UWN and UBY contain only few examples for Greek and Farsi, so we use Bing translations of English source words. In order to filter the resulting list of words, we transliterate Russian and Greek into the Latin alphabet<sup>11</sup> and apply a string similarity filter. We do not filter the training data for Farsi, as the transliteration is insufficient.

The lower part of Table 4 lists the results. Given that those language pairs are considered to be less related than English-Spanish or English-German, the results are surprisingly good. Especially the production of Farsi cognates works very well, although the training data has not been filtered. The low MRR for Greek indicates that our lexicon filter is not restrictive enough. COP often produces Greek words in several declinations (e.g. nouns in genitive case) which are not eliminated and lead to a worse rank of the correct target. We conclude that COP also works well across alphabets.

## 5.3 Multilingual Cognates

In order to provide the reader with some examples of cognates produced by COP, we compiled a short list of international words that are likely

<sup>9</sup>The transliteration of άτλας is *atlas*.

<sup>10</sup>The transliteration of αρχάγγελος is *ark'aggelos*.

<sup>11</sup>Using ICU: <http://site.icu-project.org/>

to occur in all languages under study. In Table 5, we give the two top-ranked productions. It can be seen that COP produces both, true and false cognates (e.g. *direkt* for *director*), which is useful for language learning scenarios. Of course, some produced forms are questionable, e.g. the second Farsi match for *music* means *Moses*. Note that the gaps in the table are often cases where the absence of a cognate production is an indicator of COP's quality. For example, the Greek words for *director*, *popular*, and *tradition* are not cognates of the English word but have a very different form.

## 5.4 Human Associations

The examples in Table 5 showed that COP produces not only the correct cognate, but all target words that can be created from the input word based on the learned production processes. In order to assess how well these additional productions of COP correlate with human associations, we conducted a user study. We presented Czech words with German origin to 15 native German speakers that did not have any experience with Eastern-European languages. The participants were asked to name up to 3 guesses for the German translation of the Czech source word. Table 6 gives an overview of the Czech source words together with the German associations named by more than one person (number of mentions in brackets). The table shows that some Czech words are strongly associated with their correct German translations (e.g. *nudle*-*Nudel*), while other words trigger false friend associations (e.g. *talíř*-*Taler*).

Another interesting aspect is the influence of languages besides the L1. For example, the German association *himmel* for the Czech word *cíl* is very likely rooted in the Czech-French association

<sup>14</sup>Note that forms like *stak* also pass the lexicon filter, as this is an infrequent, but nevertheless valid German word. Other words like *san* are part of the German lexicon from city names like *San Francisco*.

Czech	Human associations (German)	COP productions (German)
nudle	<b>Nudel</b> (15)	<b>nudel</b> , nadel, ode
švagr	<b>Schwager</b> (13)	sauger, <b>schwager</b> , berg
šlak	<b>Schlag</b> (12), Schlagsahne (3), schlagen (2)	stak
brýle	<b>Brille</b> (12), brüllen (4)	<b>brille</b> , brie
cíl	<b>Ziel</b> (9), Himmel (2)	set, zelle, teller
žold	<b>Sold</b> (9), Zoll (5), Gold (2), verkauft (2), Schuld (2)	<b>sold</b> , gold, geld
sál	Salz (13) , <b>Saal</b> (8)	set, san, all, <b>saal</b>
taška	<b>Tasche</b> (8), Aufgabe (4), Tasse (4), Taste (2)	task, as, tick
skříň	<b>Schrein</b> (5), Bildschirm/Screen (3), schreien (2)	-
flétna	<b>Flöte</b> (4), Flotte (4), Pfannkuchen (2), fliehen (2)	flut, filet
muset	Museum (11), <b>müssen</b> (3), Musik (3), Muse (2), Mus (2)	<b>mus</b> , most, <b>mus</b> , mit
valčík	Walze (4), <b>Walzer</b> (3), falsch (2)	-
talíř	Taler (5), <b>Teller</b> (2), zahlen (3), teilen (2)	<b>teller</b> , <b>taler</b> , ader
šunka	schunkeln (2), Sonne (2), <b>Schinken</b> (1),	sun
knoflík	Knoblauch (11), knifflig (4), <b>Knopf</b> (1)	-

Table 6: Human associations and cognate productions from Czech to German  
Correct translations are in bold, underlined words are COP productions that match human associations.<sup>14</sup>

*cíl-ciel*.<sup>15</sup> A similar process applies for the association *aufgabe*, which is *task* in English and therefore close to *taška*. These cross-linguistic cognitive processes highlight the importance of considering cognates from all languages a learner knows.

In order to examine how well COP reflects the human associations, we train it on manually collected Czech-German cognates and translation pairs from UBY. The number of training instances is rather small, as a language reform in the 19th century eliminated many Czech words with Austrian or German roots. Consequently, the model does not generalize as well as for other language pairs (see the column “COP Productions” in Table 6).<sup>16</sup> However, it correctly identifies cognates like *nudel*, *brille*, and *sold* which are ranked first by the human participants. As we argued above, COP also correctly produces some of the ‘wrong’ associations, e.g. *gold* or *taler*. Thus, COP is to a certain extent able to mimic the association process that humans apply when identifying cognates.

## 6 Conclusions

We introduced COP, a novel method for cognate production using character-based MT. We have shown that COP succeeds in learning the necessary patterns for producing cognates in different languages and alphabets. COP performs significantly better than similarity measures used in previous work on cognates. COP relies on training data, but we have shown that it can be applied even if no language-specific information beyond a word list is available. A user study on German-Czech cognates supports our assumption that COP

productions are comparable to human associations and can be applied for language learning.

In future work, we will focus on the application of cognates in language learning. True cognates are easier to understand for learners and thus can be an important factor for readability assessment and the selection of language learning examples. False cognates, on the other hand, can be confusing and need to be practiced more frequently. They could also be used as good distractors for multiple choice questions. In addition, COP productions that do not pass the lexical filter might serve as pseudo-words in psycholinguistic experiments as they contain very probable character sequences.

## Abstract

This paper demonstrates that combination of multiple models achieves better classification performance than that obtained by existing individual models for question classification task in Bengali. We have exploited state of the art multiple model combination techniques, i.e., ensemble, stacking and voting on lexical, syntactical and semantic features of Bengali question for the question classification task. Bagging and boosting have been experimented as ensemble techniques. Naïve Bayes, kernel Naïve Bayes, Rule Induction and Decision Tree classifiers have been used as base learners. The experimental results show that classifier combination models outperform existing single model approaches. Overall voting approach has achieved maximum classification accuracy of 91.65% and outperformed the existing single model approaches (maximum accuracy of 87.63%).

## 1 Introduction

Although different types of question answering systems (QA) have different architectures, most of them follow a framework in which question classification (QC) plays an important role (Voorhees, 2001) and QC has significant influence on the overall performance of a QA system (Ittycheriah et al., 2001; Hovy et al., 2001; Moldovan et al., 2003). The task of a question classifier is to assign one or more class labels, depending on classification strategy, to a given question written in natural language.

Basically there are two main motivations for question classification: locating the answer and choosing the search strategy. Knowing the question class not only reduces the search space needed

to find the answer, it can also help to find the true answer in a given set of candidate answers.

One of the main issues of classification modeling is the improvement of classification accuracy. For that purpose, many researchers have recently placed considerable attention to the task of classifier combination methods. The idea is not to rely on a single decision making scheme. Instead, many single classifiers are used for decision making by combining their individual opinions to arrive at a consensus decision.

## 2 Related Work and Motivations

A lot of researches on QC, question taxonomies, and question features are being published continuously. There are basically two different approaches used to classify questions- one is rule based (Hull, 1999; Prager et al., 1999) and another is machine learning based (Zhang et al., 2003; Li and Roth, 2004). However, a number of researchers have also used some hybrid approaches which combine rule-based and machine learning based approaches (Huang et al., 2008; Silva et al., 2011).

Many researchers have investigated the technique of combining the predictions of multiple classifiers to produce a single classifier (Breiman, 1996; Clemen, 1989; Perrone, 1993; Wolpert, 1992). The resulting classifier is generally more accurate than any of the individual classifiers making up the ensemble. Both theoretical (Hansen and Salamon, 1990; Krogh and Vedelsby, 1995) and empirical (Hashem, 1997; Opitz and Shavlik, 1996a, 1996b) researches have been carried out successfully. Last decade a group of researchers focused on classifier combination methods in question classification task. LI *et al.* (2005) trained four SVM classifiers based on four different types of features and combined them with various strategies. Later LI *et al.* (2006) performed similar type of experiments and achieved

improved accuracy on TREC dataset. (Jia et al., 2007; Su et al., 2009) proposed ensemble learning for Chinese question classification.

Recently, (Banerjee and Bandyopadhyay, 2012) have worked on Bengali QC task and achieved 87.63% accuracy using single classifier approach. So far, classifier combination methods have not been used by any researcher in Bengali question classification task. So, we employ the use of classifier combination methods to improve question classification accuracy.

### 3 Question Type Taxonomies

The present work follows the QC taxonomies proposed by (Banerjee and Bandyopadhyay, 2012) for two reasons. First, that is the only standard taxonomy that exists in Bengali QC so far. Secondly, the results of the present work can be compared with the work of (Banerjee and Bandyopadhyay, 2012) to establish the improvement in accuracy.

### 4 Features

In the task of question classification, there is always an important problem to decide the optimal set of features to train the classifiers. Different studies have extracted various features with different approaches. The features in question classification task can be categorized into three different types: lexical, syntactical and semantic features (Loni, 2011).

Loni *et al.* (2011) also represented a question in the QC task similar to document representation in vector space model, i.e., a question is a vector which is described by the words inside it. Therefore a question  $Q$  can be represented as:

$$Q = (W_1, W_2, W_3, \dots, W_{N-1}, W_N)$$

Where,  $W_K$  = frequency of term  $K$  in question  $Q$ , and  $N$  = total number of Terms

We have also used three types of features for QC. We use the same features previously used by (Banerjee and Bandyopadhyay, 2012).

*Lexical features ( $f_{Lex}$ ):* wh-word, wh-word positions, wh-type, question length, end marker, word shape.

*Syntactical features ( $f_{Syn}$ ):* POS tags, head word.

*Semantic features ( $f_{Sem}$ ):* related words, named entity.

### 5 Combined Model Learning for QC

There are three approaches of classifier combination: 1) Ensemble, 2) Stacking and 3) Voting.

Two popular methods for creating accurate ensembles are *bagging* (Breiman, 1996) and *boosting* (Freund and Schapire, 1996; Schapire, 1990). We have used *Rapid Miner*<sup>1</sup> tool in the experiments of this work.

## 6 Experiments

This section describes our empirical study of *ensemble*, *stacking* and *voting* approaches. Each of these three approaches has been tested with Naïve Bayes (NB), Kernel Naïve Bayes (k-NB), Rule Induction (RI) and Decision Tree (DT). The previous work (Banerjee and Bandyopadhyay, 2012) on Bengali question classification task used these four classifiers. So in this work, we have used those classifiers to establish the effect of combining models.

### 6.1 Dataset

The present research work adopts the same corpus used by (Banerjee and Bandyopadhyay, 2012). The corpus consists of 1100 Bengali questions of different domains, e.g., education, geography, history, science etc. We have used 770 questions (70%) for training and rest 330 questions (30%) to test the classification models.

### 6.2 Results

In total thirteen different experiments have been performed. Four different experiments have been performed for each *bagging* and *boosting*. So, altogether eight different experiments have been performed for the ensemble approach. Four different experiments have been performed for *stacking*. But for *voting*, a single experiment has been performed. Actually, each experiment can be thought of as three experiments, because a classifier model has been tested on  $f_{Lex}$ ,  $f_{Syn} + f_{Sem}$  and  $f_{Lex} + f_{Syn} + f_{Sem}$  features separately. The outcome of the experiments have been tabulated and described in the next sub-sections.

In our study, *classification accuracy* has been used to evaluate the results of the experiments. *accuracy* is the widely used evaluation metric to determine the class discrimination ability of classifiers, and is calculated using the following equation:

$$accuracy(\%) = \frac{T_P + T_N}{P + N}$$

<sup>1</sup><http://www.rapidminer.com>

where,  $T_P$  = true positive samples;  $T_N$  = true negative samples;  $P$  = positive samples;  $N$  = negative samples.

It is a primary metric in evaluating classifier performances and it is defined as the percentage of test samples that are correctly classified by the algorithm.

### 6.2.1 Results based on Bagging

Bagging approach has been applied separately to four classifiers (i.e., NB, k-NB, RI and DT) and Table-1 tabulates the detailed information of the accuracy obtained.

BL	$f_{Lex}$	$f_{Lex}+f_{Syn}$	$f_{Lex}+f_{Syn}+f_{Sem}$
NB	81.53%	82.77%	83.25%
k-NB	82.09%	83.37%	84.22%
RI	83.96%	85.61%	86.90%
DT	85.23%	86.41%	<b>91.27%</b>

Table 1: Experimental results of Bagging.

Initially the size (number of iteration) of the base learner is set to 2. Then experiments have been performed with gradually increased size (size>2). The classification accuracy has been increased with increase in size. But after a certain size, the accuracy has been almost stable. At size=2 and feature= $f_{Lex} + f_{Syn} + f_{Sem}$ , the NB classifier achieves 82.23% accuracy and at size>= 9, it becomes stable with 83.25% accuracy. At size=2 and feature= $f_{Lex} + f_{Syn} + f_{Sem}$ , the k-NB classifier achieves 83.87% accuracy and at size>=15, it becomes stable with 84.22% accuracy. At size=2 and feature= $f_{Lex} + f_{Syn} + f_{Sem}$ , the RI classifier achieves 85.97% accuracy and at size>=8, it becomes stable with 86.90% accuracy. At size=2 and feature= $f_{Lex} + f_{Syn} + f_{Sem}$ , the DT classifier achieves 88.09% accuracy and at size>=7, it becomes stable with 91.27% accuracy. It has been observed from the experiments that at each case Bagging with DT requires less size, i.e., less iteration than the other used classifiers. For experiment with  $f_{Lex}$  features, the bagging size of NB, k-NB, RI and DT are 12, 19, 11 and 10 respectively after which classification accuracy becomes stable. And For experiment with  $f_{Lex} + f_{Syn}$  features, the bagging size of NB, k-NB, RI and DT are 10, 17, 9 and 8 respectively after which classification accuracy becomes stable.

### 6.2.2 Results based on AdaBoost.M1

Like bagging, AdaBoost.M1 has also been applied separately to the four classifiers (i.e., NB, k-NB, RI and DT). Table-2 tabulates the detailed information of the accuracy obtained.

Here, we empirically fix the iterations of AdaBoost.M1 for four classifiers to 12, 16, 10 and 8 respectively for features= $f_{Lex} + f_{Syn} + f_{Sem}$ , because the weight of  $1/\beta_t$  is less than 1 after those values. If  $1/\beta_t$  is less than 1, then the weight of classifier model in boosting may be less than zero for that iteration.

BL	$f_{Lex}$	$f_{Lex}+f_{Syn}$	$f_{Lex}+f_{Syn}+f_{Sem}$
NB	81.74%	82.71%	83.51%
k-NB	83.97%	85.63%	86.87%
RI	83.55%	85.59%	86.27%
DT	85.21%	86.58%	<b>91.13%</b>

Table 2: Experimental results of AdaBoost.M1.

Similarly, for features= $f_{Lex} + f_{Syn}$  and features= $f_{Lex}$  the iterations are 13, 18, 12, 9 and 14, 19, 14, 11 respectively for four classifiers correspondingly. The experiment results show that the performance of k-NB classifier has been improved over RI. But, overall DT performs better than all.

### 6.2.3 Results based on Stacking

In stacking, out of four classifiers three classifiers have been used as the *base learner* (BL) and the remaining classifier has been used as *model learner* (ML). So, four experiments have been conducted separately where each classifier get a chance to be the *model learner*. Table-3 shows the detailed information of the accuracy obtained.

BL	ML	$f_{Lex}$	$f_{Lex}+f_{Syn}$	$f_{Lex}+f_{Syn}+f_{Sem}$
k-NB,RI,DT	NB	81.76%	82.79%	83.64%
NB, RI, DT	k-NB	83.86%	85.54%	86.75%
NB,k-NB,DT	RI	85.55%	87.69%	<b>91.32%</b>
NB,k-NB,RI	DT	85.07%	86.73%	89.13%

Table 3: Experimental results of Stacking.

In the first experiment, three classifiers k-NB, RI and DT have been selected as the *base learners* and the NB classifier has been selected as the *model learner*. Similarly, four experiments have been done selecting k-NB, RI and DT as *model learner* respectively. Experimental results show

that with RI as the *model learner* and NB, k-NB, DT as the *base learners*, the classifier achieves best classification accuracy.

#### 6.2.4 Results Based on Voting

In voting, four classifiers altogether have been used as the *base learners* and *majority vote* has been used as voting approach. Table 4 tabulates the detailed information of the accuracy obtained.

BL	$f_{Lex}$	$f_{Lex}+f_{Syn}$	$f_{Lex}+f_{Syn}+f_{Sem}$
NB, RI, k-NB,DT	86.59%	88.43%	<b>91.65%</b>

Table 4: Experimental results of Voting.

## 7 Conclusions and Perspectives

The automated Bengali question classification system by (Banerjee and Bandyopadhyay, 2012) is based on four classifiers namely Naïve Bayes, Kernel Naïve Bayes, Rule Induction and Decision Tree. Table-5 tabulates the detailed information of the accuracy obtained.

BL	$f_{Lex}$	$f_{Lex}+f_{Syn}$	$f_{Lex}+f_{Syn}+f_{Sem}$
NB	80.65%	81.34%	81.89%
k-NB	81.09%	82.37%	83.21%
RI	83.31%	84.23%	85.57%
DT	84.19%	85.69%	<b>87.63%</b>

Table 5: Experimental results of (Banerjee and Bandyopadhyay, 2012)

Naïve Bayes has been used as the baseline and they have achieved 87.63% accuracy using Decision Tree. But, they have used each classifier as single model separately. The present work shows that classifier combination technique can improve the performance of question classification. Each classifier combination model performs well than single classifier model in terms of classification accuracy.

If we compare the results of previous experiment (Banerjee and Bandyopadhyay, 2012) with *bagging* approach, then classification accuracy of all the classifiers have been notably increased. The classification accuracy on  $f_{Lex}$ ,  $f_{Lex} + f_{Syn}$  and  $f_{Lex} + f_{Syn} + f_{Sem}$  features have been increased by 1.04%, 0.72% and 3.64%. Similarly in the *boosting* approach, the classification accuracy of

all the classifiers have been notably increased and on  $f_{Lex}$ ,  $f_{Lex} + f_{Syn}$  and  $f_{Lex} + f_{Syn} + f_{Sem}$  features the classification accuracy have increased by 1.02%, 0.89% and 3.50%. *Stacking* approach notably increases the accuracy on  $f_{Lex} + f_{Syn}$  features than *bagging* and *boosting* approaches. The classification accuracy on  $f_{Lex}$ ,  $f_{Lex} + f_{Syn}$  and  $f_{Lex} + f_{Syn} + f_{Sem}$  features have been increased by 1.36%, 2.74% and 0.69% respectively. *Voting* approach not only increases the classification accuracy but also hits the maximum accuracy on all features than other combined approaches. *Voting* approach increases the classification accuracy on  $f_{Lex}$ ,  $f_{Lex} + f_{Syn}$  and  $f_{Lex} + f_{Syn} + f_{Sem}$  features by 2.40%, 2.40% and 4.02% respectively.

So, overall *voting* approach with *majority voting* has performed best among all four classifiers combination approaches namely *bagging*, *boosting*, *stacking* and *voting*. Experimental results show that classifiers combination approaches outperform the previous single classifier classification approach by (Banerjee and Bandyopadhyay, 2012) for Bengali question classification.

The main future direction of our research is to exploit other lexical, semantic and syntactic features for Bengali question classification. In future an investigation can be performed on including new Bengali interrogatives using a large corpus. It is also worth investigating fine-grained classes for Bengali questions. In the current work, we have only investigated the Bengali questions. But, this work can be applied to other languages having low resources.

# A Two-Stage Classifier for Sentiment Analysis

Dai Quoc Nguyen and Dat Quoc Nguyen and Son Bao Pham

Faculty of Information Technology

Vietnam National University, Hanoi  
{dainq, datnq, sonpb}@vnu.edu.vn

## Abstract

In this paper, we present a study applying reject option to build a two-stage sentiment polarity classification system. We construct a Naive Bayes classifier at the first stage and a Support Vector Machine at the second stage, in which documents rejected at the first stage are forwarded to be classified at the second stage. The obtained accuracies are comparable to other state-of-the-art results. Furthermore, experiments show that our classifier requires less training data while still maintaining reasonable classification accuracy.

## 1 Introduction

The rapid growth of the Web supports human users to easily express their reviews about such entities as products, services, events and their properties as well as to find and evaluate the others' opinions. This brings new challenges for building systems to categorize and understand the sentiments in those reviews.

In particular, document-level sentiment classification systems aim to determine either a positive or negative opinion in a given opinionated document (Turney, 2002; Liu, 2010). In order to construct these systems, classification-based approaches (Pang et al., 2002; Pang and Lee, 2004; Mullen and Collier, 2004; Whitelaw et al., 2005; Kennedy and Inkpen, 2006; Martineau and Finin, 2009; Maas et al., 2011; Tu et al., 2012; Wang and Manning, 2012) utilizing machine learning to automatically identify document-level sentiment polarity are still mainstream methods obtaining state-of-the-art performances. It is because of possibly combining various features such as: bag of words, syntactic and semantic representations as well as exploiting lexicon resources (Wilson et al., 2005; Ng et al., 2006; Taboada et al., 2011) like SentiWordNet (Baccianella et al., 2010). In these systems, Naive Bayes (NB) and Support Vector Machine (SVM) are often applied for training learning models as they are frequently used as baseline methods in task of text classification (Wang and Manning, 2012). Although NBs are very fast classifiers requiring a small amount training data, there is a loss of accuracy due to the NBs' conditional independence assumption. On the other hand, SVMs

achieve state-of-the-art results in various classification tasks; however, they may be slow in the training and testing phases.

In pattern recognition systems, reject option (Chow, 1970; Pudil et al., 1992; Fumera et al., 2000; Fumera et al., 2004) is introduced to improve classification reliability. Although it is very useful to apply reject option in many pattern recognition/classification systems, it has not been considered in a sentiment classification application so far.

In this paper, we introduce a study combining the advantages of both NB and SVM classifiers into a two-stage system by applying reject option for document-level sentiment classification. In the first stage of our system, a NB classifier, which is trained based on a feature representing the difference between numbers of positive and negative sentiment orientation phrases in a document review, deals with easy-to-classify documents. Remaining documents, that are detected as "hard to be correctly classified" by the NB classifier in the use of rejection decision, are forwarded to process in a SVM classifier at the second stage, where the *hard* documents are represented by additional bag-of-words and topic-based features.

## 2 Our approach

This section is to describe our two-stage system for sentiment classification. Figure 1 details an overview of our system's architecture.

Figure 1: The architecture of our two-stage classifier.

In this positive (pos) and negative (neg) classification problem of sentiment polarity, we reject every sentiment document  $D$  satisfying the following rejection decision based on conditional probabilities:

$$(\tau_1 > P(pos|D) \text{ and } P(pos|D) \geq P(neg|D))$$

**OR**

$$(\tau_2 > P(neg|D) \text{ and } P(neg|D) > P(pos|D))$$

where thresholds  $\tau_1, \tau_2 \in [0, 1]$ . Otherwise, if document  $D$  does not satisfy the rejection decision, it is accepted to be classified by the NB.

A NB classifier at the first stage is to categorize accepted documents. Rejected sentiment documents, that are determined as *hard* to be correctly classified (most likely to be miss-classified) by the NB classifier in applying reject option, are processed at the second stage in a SVM classifier. In our system, the NB classifier categorizes document reviews based on a feature namely DiffPosNeg while the SVM one classifies document reviews with additional bag-of-words (BoW) and topic features.

### DiffPosNeg feature

We exploit the opinion lexicons<sup>1</sup> of positive words and negative words (Hu and Liu, 2004) to detect the sentiment orientation of words in each document. We then employ basic rules presented in (Liu, 2010) to identify the sentiment orientation of phrases. The numerical distance between the numbers of positive and negative opinion phrases in a document  $D$  is referred to as its DiffPosNeg feature value.

### BoW features

The BoW model is the most basic representation model used in sentiment classification, in which each document is represented as a collection of unique unigram words where each word is considered as an independent feature. We calculate the value of feature  $i$  in using *term frequency - inverse document frequency* weighting scheme for the document  $D$  as following:

$$BoW_{iD} = \log(1 + tf_{iD}) * \log \frac{|\{D\}|}{df_i}$$

where  $tf_{iD}$  is the occurrence frequency of word feature  $i$  in document  $D$ ,  $|\{D\}|$  is the total number of documents in the data corpus  $\{D\}$ , and  $df_i$  is the number of documents containing the feature  $i$ . We then normalize BoW feature vector of the document  $D$  as below:

$$\overrightarrow{\eta BoW_D} = \frac{\sum_{\delta \in \{D\}} \|\overrightarrow{BoW_\delta}\|}{|\{D\}| * \|\overrightarrow{BoW_D}\|} * \overrightarrow{BoW_D}$$

### Topic features

Our system also treats each document review as a “bag-of-topics”, and considers each topic as a feature. The topics are determined by using Latent Dirichlet Allocation (LDA) (Blei et al., 2003). LDA is a generative probabilistic model to discover topics for a corpus of documents. LDA represents each document as a probability distribution over latent topics, where each topic is modeled by a probability distribution over words. Using Bayesian inference methods, LDA computes posterior distribution for unseen documents. In our system, we refer to topic probabilities as topic feature values.

## 3 Experimental results

### 3.1 Experimental setup

We conducted experiments on the publicly available standard polarity dataset V2.0<sup>2</sup> of 2000 movie reviews constructed by Pang and Lee (2004).

We did not apply stop-word removal, stemming and lemmatization because such stop-words as negation words (e.g: no, not, isn’t) were used in the basic rules to reverse the sentiment orientation of phrases, and as pointed out by Leopold and Kindermann (2002) stemming and lemmatization processes could be detrimental to accuracy. We kept 4000 most frequent words for each polarity class, after removing duplication, we had total 5043 BoW features.

For extracting LDA topic features, we used the JGibbLDA implementation<sup>3</sup> developed by Phan and Nguyen (2007), in which  $\alpha$  is set to 0.5,  $\beta$  is set to 0.1 and the number of Gibbs sampling iterations is set to 3000. We exploited a corpus<sup>4</sup> of 50000 unlabeled movie reviews published by Maas et al. (2011) to build LDA topic models. We then applied these models to compute the posterior probability distribution over latent topics for each movie review in the experimented dataset of 2000 reviews.

In order to compare with other published results, we evaluate our classifier based on 10-fold cross-validation. We randomly separate the dataset into 10 folds; giving one fold size of 100 positive and 100 negative reviews. This evaluation procedure is repeated 10 times that each fold is used as the testing dataset, and 9 remaining folds are merged as the training dataset. All our performance results are reported as the average accuracy over the testing folds.

We utilized WEKA’s implementations (Hall et al., 2009) of NB and SVM’s fast training Sequential Minimal Optimization algorithm (Platt, 1999) for learning classification with the WEKA’s default parameters (e.g: the linear kernel for SVM).

### 3.2 Results without reject option

Table 1 provides accuracies achieved by the single NB and SVM classifiers without the reject option: our NB and SVM classifiers were trained on the whole training dataset of 9 folds according to the above 10-fold cross-validation scheme. We consider BoW model as a baseline, similar to other approaches (Pang and Lee, 2004; Whitelaw et al., 2005; Tu et al., 2012).

In table 1, the accuracy results based on only *Diff-PosNeg* feature are 70.00% for NB and 69.55% for SVM. The highest accuracies in utilizing LDA topics are 78.05% for NB classifier and 85.30% for SVM classifier due to 50 topic features. Besides, the accuracy accounted for SVM at 86.30% over the combination of

Table 2: Results in applying reject option (8 folds for training), and in other SVM-based methods

$\tau_1$	$\tau_2$	$r_{Pos}$	$r_{Neg}$	NB	SVM	Accuracy
0.79	0.81	0.764	0.987	236 13	1519 232 (tuned thresholds)	<b>87.75</b>
0.82	0.80	0.796	0.990	205 9	1554 232	<b>87.95</b>
1.0	1.0	1.0	1.0	0 0	1752 248	87.60
Pang and Lee (2004)				BoW		87.15
				BoW with minimum cuts		87.20
Whitelaw et al. (2005)				BoW (48314 features)		87.00
				BoW and appraisal groups (49911 features)		90.20
Kennedy and Inkpen (2006)				Contextual valence shifters with 34718 features		86.20
Martineau and Finin (2009)				BoW with smoothed delta IDF		88.10
Maas et al. (2011)				Full model and BoW		87.85
				Full model + additional unlabeled data + BoW		88.90
Tu et al. (2012)				BoW		87.05
				BoW & dependency trees with simple words		88.50
Wang and Manning (2012)				NBSVM-Unigram		87.80
				NBSVM-Bigram		89.45

Table 1: Results without reject option

Features	NB	SVM
BoW (baseline)	73.55	<b>86.05</b>
20 LDA topics	77.55	82.05
30 LDA topics	74.95	79.65
40 LDA topics	76.60	82.15
50 LDA topics	78.05	85.30
60 LDA topics	75.80	83.40
DiffPosNeg	70.00	69.55
DiffPosNeg & BoW	73.50	86.30
DiffPosNeg & 50-LDA	79.35	85.45
BoW & 50-LDA	73.60	87.70
DiffPosNeg & BoW & 50-LDA	73.85	87.70

DiffPosNeg and BoW features is greater than the baseline result of 86.05% with only BoW features. By exploiting a full combination of DiffPosNeg, BOW and 50 LDA topic features, the SVM classifier gains the exceeding accuracy to 87.70%.

### 3.3 Results in applying reject option

In terms of evaluating our two-stage approach, if the fold<sub>*i*th</sub> is selected as the testing dataset, the fold <sub>$(i^{th}+1)\%10$</sub>  will be selected as the development dataset to estimate reject thresholds while both NB and SVM classifiers will be learned from 8 remaining folds. By varying the thresholds' values, we have found the most suitable values  $\tau_1$  of 0.79 and  $\tau_2$  of 0.81 to gain the highest accuracy on the development dataset.

Table 2 presents performances of our sentiment classification system in employing reject option, where the NB classifier was learned based on the DiffPosNeg feature, and the SVM classifier was trained on the full combination of DiffPosNeg, BoW and 50 LDA topic features (total 5094 features). In the table 2,  $r_{Pos}$  and  $r_{Neg}$  are reject rates corresponding with positive label and negative label in the *testing* phase:

$$r_{Pos} = \frac{\text{number of rejected positive reviews}}{1000}$$

$$r_{Neg} = \frac{\text{number of rejected negative reviews}}{1000}$$

$$\text{Overall\_reject\_rate} = \frac{r_{Pos} + r_{Neg}}{2}$$

With the values  $\tau_1$  of 0.79 and  $\tau_2$  of 0.81, our two-stage classifier achieves the result of 87.75% on the testing dataset that as illustrated in table 2, it is comparable with other state-of-the-art SVM-based classification systems, many of which used deeper linguistic features. In total 10 times of cross fold-validation experiments for this accuracy, the NB accepted 249 documents to perform classification and rejected 1751 documents to forward to the SVM. Specifically, the NB correctly classified 236 documents whilst the SVM correctly categorized 1519 documents.

Additionally, in the setup of taking 8 folds for training NB and SVM, and not taking 1 fold of development into account, by directly varying values  $\tau_1$  and  $\tau_2$  on the testing dataset, our system can reach the highest result of 87.95% which is 1.9% and 0.35% higher than the SVM-based baseline result (86.05%) and the accuracy (87.60%) of the single SVM classifier without reject option, respectively.

### 3.4 Results in using less training data

To assess the combination of advantages of NB (requiring small amount of training data) and SVM (high performance in classification tasks), we also carried out experiments of using less training data. In this evaluation, if the fold<sub>*i*</sub> is selected as testing data, the fold <sub>$(i+1)\%10$</sub>  will be selected as training dataset to build the NB classifier. Applying the rejection decision on 8 remaining folds with given reject thresholds, the dataset of rejected documents are used to learn the SVM classifier.

In experiments, the single NB classifier without reject option attains an averaged accuracy of 69.9% that

is approximately equal to the accuracy on 9-fold training dataset at 70% as provided in the table 1. This comes from that our proposed *DiffPosNeg* feature is simple enough to obtain a good NB classifier from small training set. In these experiments, the given thresholds applied in the training phase to learn the SVMs are reused in the testing phase (i.e. the same thresholds for both training and testing phases).

Table 3: Reject option results using less training data

$\tau_1$	$\tau_2$	$r_{Pos}^*$	$r_{Neg}^*$	$r_{Pos}$	$r_{Neg}$	$Acc_S$	Accuracy
0.95	0.63	0.722	0.478	0.722	0.475	84.80	80.55
0.64	0.75	0.483	0.723	0.486	0.729	84.80	82.35
0.72	0.65	0.495	0.496	0.491	0.494	83.75	80.50
0.78	0.69	0.606	0.605	0.609	0.600	84.65	82.30
0.88	0.74	0.764	0.770	0.765	0.770	85.80	84.35
0.97	0.78	0.906	0.905	0.908	0.910	86.65	85.75

Table 3 summaries some reject option-based results taking less training data to learn the SVMs based on the full combination of 5094 features, where  $r_{Pos}^*$  and  $r_{Neg}^*$  are reject rates in the *training* phase, and  $Acc_S$  denotes the accuracy of the single SVM classifier without reject option. With the modest overall reject rate of 0.493 in testing phase, our classifier reached an accuracy of 80.50%, which it outperformed the single NB.

Table 4: Results with SVM trained on *DiffPosNeg* and BoW

$\tau_1$	$\tau_2$	$r_{Pos}^*$	$r_{Neg}^*$	$r_{Pos}$	$r_{Neg}$	$Acc_S$	Accuracy
0.95	0.63	0.722	0.478	0.722	0.475	84.50	80.55
0.64	0.75	0.483	0.723	0.486	0.729	84.00	81.60
0.80	0.68	0.618	0.591	0.622	0.585	83.90	81.05
0.85	0.73	0.726	0.745	0.732	0.753	84.65	83.65
0.97	0.78	0.906	0.905	0.908	0.910	85.70	84.85
0.92	0.80	0.854	0.941	0.861	0.945	85.70	85.35

In other experiments using less training data as presented in table 4, we trained the SVM classifier based on the combination of *DiffPosNeg* and BoW features. For the overall reject rate of 0.903 in testing phase, our system gained a result of 85.35% that is a bit of difference against the accuracy of the single SVM at 85.70%.

Table 3 and table 4 show that our classifier produced reasonable results in comparison with single NB and SVM classifiers without reject option.

### 3.5 Discussion

It is clearly that a different set of features could be used for learning the NB classifier at the first classification stage in our system. However, as mentioned in section 3.4, it is sufficient to have a good NB classifier learned from an unique *DiffPosNeg* feature. Furthermore, an obvious benefit of having the NB based on only one *easy-to-extract* feature is to enhance the efficiency in terms of time used in the document classification process. That is the reason why we applied only the *DiffPosNeg* feature at the first stage.

With regards to the processing time efficiency, it is because there are no recognition time evaluations associated to the other compared systems as well as it is not straightforward to re-implement those systems, hence, the comparison over processing time with the other systems is not crucial to our evaluation. Nevertheless, we believe that our classifier enables to get a fast complete recognition in which time spent to extract features is also taken into accounts, where the majority amount of the classification time is allocated to the feature extraction process.

Considering to feature extraction time, let  $\Gamma_1$  be the time taken to extract *DiffPosNeg* feature and  $\Gamma_2$  be the time spent for extracting other features (i.e. BoW and LDA topic features): our two-stage system then costs ( $\Gamma_1 + overall\_reject\_rate * \Gamma_2$ ) as opposed to ( $\Gamma_1 + \Gamma_2$ ) by the single SVM without reject option. Depending on the overall reject rate, our system could get a significant increase in the complete recognition time while the returned accuracy of our system is promising compared to that of the single SVM classifier.

## 4 Conclusion

In this paper, we described a study combining NB and SVM classifiers to construct a two-stage sentiment polarity system by applying reject option. At the first stage, a NB classifier processes easy-to-classify documents. Hard-to-classify documents, which are identified as most likely to be miss-classified by the first NB classifier in using rejection decision, are forwarded to be categorized in a SVM classifier at the second stage.

The obtained accuracies of our two-stage classifier are comparable with other state-of-the-art SVM-based results. In addition, our classifier outperformed a bag-of-words baseline classifier with a 1.9% absolute improvement in accuracy. Moreover, experiments also point out that our approach is suitable for under-resourced tasks as it takes less training data while still maintaining reasonable classification performance.

## Abstract

This work proposes to semantically classify question-like search queries (e.g., “oil based heel creams”) based on the context yielded by preceding search queries in the same user session. Our novel approach is promising as our initial results show that the classification accuracy improved in congruence with the number of previous queries used to model the question context.

## 1 Introduction

Open question answering (QA), i.e., fully automatic systems that find best answers to natural language questions of any type and domain, is still a challenging research problem. On the other hand side, search engines are getting smarter and smarter in order to fulfill users’ information requests. This motivates users to enter more sophisticated search queries (e.g., more complete questions) rather than few keywords, when they are looking for precise information needs (e.g., answers related to precise problems). This is also experienced by the fact that through search engines, it is likely to exploit answer databases of community based question answering (cQA) systems including Yahoo! Answers, if the search query is close to a QA-system like question. Then matching such a question with those in the cQA database is more likely to recognize plausible cQA paraphrases because of close textual relatedness. Furthermore, as the analysis of our data sources suggests, users often express semantically related series of questions in order to guide the search for better answers, and as such, are already performing interactions with search engines. In a general sense, searching is a sequence of queries in the same user session aimed at satisfying an underlying goal that the user is trying to achieve (Rose and Levinson, 2004).

Thus, we believe that it will be inevitable to further automatize a semantic analysis of search queries within user sessions, i.e., to analyze the semantic relatedness of a series of questions whether they constitute actually a session of semantically related questions entered by the same user.

Our contribution into these directions is the exploration of automatic methods to semantically classify question-like search queries, based on the context provided by preceding search queries in the same user session. An important aspect, tackled in this paper, is whether and how much contextual information extracted from user-specific search query sessions helps to effectively train and apply a model to predict the semantic category of a question-like informational search query (cf. (Broder, 2002; Rose and Levinson, 2004)).

Our method recognizes question-like queries by inspecting their associations with Yahoo! Answers pages via user clicks, providing the additional benefit of linking each query with an entry in the Yahoo! Answers category system. Thus our target semantic labeling set comprises 27 categories including business, environment, health, pets, sports and travel. As a consequence, we are able to completely automatize our approach without the need of manually annotated training material, and to automatically create a huge annotated corpus of semantically labeled question-like search queries. We then consider all search queries of a current session entered before the current labeled one as candidate sources for contextual information, and perform different experiments in order to explore the effect of different contextual window sizes. In a nutshell, our approach finished with 50.96% accuracy by exploiting nine previous search queries as window size.

## 2 Related Work

To the best of our knowledge, our work pioneers the idea of profiting from search sessions

for semantically categorizing question-like informational search queries. Broadly speaking, our study is related to community question answering (cQA) (Zhao et al., 2011), user session analysis (Cao et al., 2009), and closer to web query understanding (Reisinger and Pasca, 2011).

In a broad sense, (Rose and Levinson, 2004) proposed a framework for understanding the underlying goals of user searches. They outlined a taxonomy which its first level models three ends: informational (learn something by reading or viewing), navigational (going to a specific web-site) and resource (obtain videos, maps, etc.).

Later, in a more specific manner, the work of (Yin and Shah, 2010) seeks to understand search queries bearing a particular type of entity (e.g., musician) by classifying their generic user intents (e.g., songs, tickets, lyrics and mp3). They built a taxonomy of search intents by exploiting clustering algorithms, capturing words and phrases that frequently co-occur with entities in user queries, and by examining the click relationships between different intent phrases. Posteriorly, (Xue and Yin, 2011) extended this work by organizing query terms within named entity queries into topics, helping to better the understanding of major search intents about entities. The study of (Cheung and Li, 2012) presented an unsupervised approach to cluster queries with similar intents which, in their work, are patterns consisting of a sequence of semantic concepts or lexical items.

In effect, named entities cooperate on understanding user intents better, however detecting named entities in search queries is a difficult task, because named entities are not in standard form and search queries are typically very short (Guo et al., 2009). Thus, (Du et al., 2010) exploited query sequences in search sessions for dealing the lack of context in short queries, when distinguishing named entities on queries.

Our study focuses on the semantic categorization of question-like search queries, which cover a wide variety of informational queries that do not necessarily bear named entities. In particular, this paper studies the impact of preceding queries in user sessions for tackling the lack of context in this semantic categorization. Our approach is supervised trained with a large set of automatically tagged samples via inspecting click patterns between search queries and Yahoo! answers questions.

### 3 Our Approach

This section presents our automatic corpus acquisition and annotation technique, and later the features utilized by our supervised models.

#### 3.1 Corpus Acquisition

Our corpus is distilled from a commercial search engine query log, more specifically, it considers queries in English submitted in the US from May 2011 to January 2013. We extracted ca. 65 millions full user sessions containing questions by keeping only those sessions connected to Yahoo! Answers via at least one user click. We assume that these clicks signal that, at some point during these sessions, users prompted questions and discovered pertinent information on the clicked Yahoo! Answer pages. Since sessions can cover a large period of time, and thus a wide variety of search needs, we split them into transactions by means of two criteria.

First, we benefited from the time difference that two consecutive queries were sent to the search engine. We used a gap of 300 seconds as session splitter, assuming that longer periods of time indicate that users are likely to have changed their search needs. This size for this temporal cut-off has been popularly used for segmenting query logs (Gayo-avello, 2009). Secondly, conventionally, navigational queries (e.g., “*twitter*”) are prompted by users when they want to reach a particular web-site they bear in mind. As a rule of thumb, most frequent queries in search logs are navigational (Broder, 2002; Rose and Levinson, 2004). Thus we used all search queries having a frequency higher than 1,000 across our session corpus as additional transaction splitters.

Next, in order to study the impact of preceding queries in the session on the tagging of a new submitted question-like search query, we kept only transactions containing at least ten queries, where a user click links the tenth or a later query with Yahoo! Answers, and hence with one of its categories. In other words, we studied the impact of until nine historical queries. In total, this pre-processing gave us 1,098,778 transactions, where 15.87% and 3.41% of them are composed exactly of ten and 20 queries, respectively.

Table 1 shows a transaction consisting of 13 queries. Several ten-element transactions can be derived from one transaction. In this table, two query sequences: 1-10 and 3-12 are acquired,

Number	Search query	Clicked hosts
1	you tube how do i make a heel strap	<b>Beauty &amp; Style</b>
2	cracked heel repair	
3	wraps for cracked heel repair	www.pantryspa.com
4	oil based moisturizer brands	
5	oil based moisturizer cream brands	ezinearticles.com

10	is vaseline considered a oil based moisturizer	<b>Beauty &amp; Style</b>
11	vaseline uses	www.ehow.com
12	is vaseline an oil moisturizer	<b>Beauty &amp; Style</b>
13	goodle	www.google.com

Table 1: A transaction (categories are shown for clicked Yahoo! Answers pages).

since queries ten and twelve are connected to Yahoo! Answers. Overall, we obtained 1,772,696 smaller transactions containing only ten elements, in which the 10th query is related to Yahoo! Answers by means of a user click.

### 3.2 Features

Basically, we took into account several features, which were a) derived from all search queries in the transaction; and b) targeted at inferring categories of preceding queries in the transaction, that is to say expect from the one being classified. In the first group, we have:

- **Bag-of-Words (BoW)** models a search query by their words and their respective frequencies.
- WordNet<sup>1</sup> semantic relations for extending search queries with a) words that include query terms in their the semantic range; and b) words that are included in the semantic range of any query term. The former (SR-A) comprises relations such as hypernyms (e.g., pressure → distress) and holonyms (e.g., professor → staff), while the latter (SR-B) relations like hyponyms (e.g., pressure → oil/gas pressure) and meronyms (e.g., service → supplication).

We only considered elements with an absolute frequency higher than three in the corpus. In the second group, that is attributes extracted exclusively from the window size of until nine search queries, we benefited from:

- **Clicked hosts (CH)** are pairs host/click count corresponding to previously clicked URLs

<sup>1</sup>wordnet.princeton.edu

(see table 1). Note that a search query can be connected not necessarily with only one clicked host, but with many.

- **Category terms in URLs (CTU)** checks as to whether or not any of the terms in any previously clicked URL is a term in any of the categories in the Yahoo! Answers taxonomy. We use simple sign matchings to detect word boundaries within full URLs (e.g., slash, hyphen and underscore). We used lower-case for these matchings.
- **Yahoo! Answers Categories (YAC)** of previously clicked Yahoo! answers pages in the session. In our working example (see table 1), the category “*Beauty & Style*”.
- Similarly to YAC, we add words belonging to categories of previously **clicked Wikipedia pages (WC)**. We used words instead of full category names as many are not standardized.

## 4 Experiments and Results

In our empirical setting, we profited from SVM Multiclass as a multi-class classifier<sup>2</sup> (Crammer and Singer, 2001; Tsochantaridis et al., 2004). In all experiments, we use three-fold cross validation operating on our automatically annotated ten queries transaction corpus, since this collection is relatively large.

As for a **baseline**, we built a centroid vector (CV) for each class, and assign to each testing sample the label pertaining to the best scoring centroid vector afterwards. Here, we also conducted a three-fold cross-validation. Results achieved by this baseline and most SVM configurations indicate that the performance improves in tandem with

<sup>2</sup>svmlight.joachims.org/svm\_multiclass.html

h	CV	SVM BoW	SVM BoW +						
			CH	CTU	YAC	WC	SR-A	SR-B	Combined
0	24.31	30.52	-	-	-	-	35.65	41.09	40.23
1	28.19	34.73	28.62	34.78	36.53	33.48	40.72	43.44	44.06
2	30.45	37.99	27.38	36.61	41.27	36.11	41.43	46.56	45.54
3	31.81	41.13	27.64	41.13	45.04	41.16	43.43	46.79	45.45
4	32.60	42.52	30.92	42.37	47.24	42.42	43.52	47.30	46.49
5	33.21	43.75	33.85	43.75	48.95	43.75	44.84	47.60	47.60
6	33.62	<b>44.60</b>	35.60	<b>44.60</b>	49.14	<b>45.12</b>	44.93	47.90	48.76
7	33.87	43.28	37.90	43.20	49.35	43.22	45.79	47.91	49.62
8	34.07	43.59	38.00	43.70	48.02	44.23	46.18	48.94	50.38
9	<b>34.27</b>	43.69	<b>38.39</b>	43.93	<b>50.02</b>	44.83	<b>46.38</b>	<b>49.39</b>	<b>50.96</b>

Table 2: Classification accuracy (%).  $h$  denotes the window (context) size.

the window size, that is the amount of session context. This comparison also shows that SVM exploits the context more efficiently: it requires a smaller number (6) of previous queries to accomplish a growth from 34.27% to 44.60% accuracy (see table 2). This is a key observation as it is also key to maximize the performance using as few as possible context, since this is not always available, especially when the user session is beginning.

Results reaped by models, that ignore context information ( $h=0$ /"Combined" in table 2), show that features, attempting at discovering semantic hints about the new question-like search query, play a vital role. A combination of SR-A and SR-B improve the accuracy by about 10% (from 30.52% to 40.23%). This sheds light on the reason why the clicked host (CH) property was detrimental as several hosts (e.g., Wikipedia) are ambiguous, in other words, they aim at many potential categories. In fact, using this clicked host attribute the performance drops closer to the baseline.

Conversely, evidence from categories related to previously clicked Wikipedia (WC) links aids in enhancing the accuracy with respect to SVM+BoW (45.12% and  $h=6$ ). This improvement is slight as the amount of clicked Wikipedia links is small with respect to the whole collection. On the other hand, categories of previously clicked Yahoo! Answers pages bettered the performance substantially (50.02% and  $h=9$ ). A reason to this is the fact that we are dealing with question-oriented transactions, and hence clicks to Yahoo! Answers can be more frequent and relevant than clicks to Wikipedia. This finding indicates that specialized click patterns manifest across question-oriented search query transactions.

In light of our outcomes, we can conclude that semantic relations provided by WordNet at the word level are extremely useful. In particu-

lar, our figures show that adding SR-B type relations brought about an increase in accuracy from 30.52% to 41.09% and 49.39% without and with session context information, respectively.

Overall, our session context-aware approach combined (column "Combined" in table 2) with our features aimed at inferring semantic content (i.e., SR-A and SR-B) and query categories (i.e., CTU, WC and YAC) finished best (50.96%). This doubled the centroid vector baseline lacking of contextual information and it substantially improved a naive SVM built on BoW.

On a final note, inspecting the confusion matrix corresponding to the best configuration, we discovered that most recurrent misclassifications are due to categories "*Education & Reference*" and "*Health*", which were perceived as "*Science & Mathematics*". These error rates were (59.89%) and (36.25%), respectively.

## 5 Conclusions and Future Work

This study shows that the context provided by preceding queries in user search sessions improves the semantic labeling of QA-like informational search queries. Our results also point out to the positive contribution of semantically-based features.

As future work, we envision the use of linked data for drawing additional semantic inferences, thus assisting in improving the semantic tagging. Additionally, we envisage the use of sharper session segmentation techniques for identifying question-oriented transactions more accurately.

In principle, it would also be possible to build classifiers for checking as to whether or not a user input is a question-like search query, and for determining their semantic classes by some semantic database (e.g., an ontology). Actually, we also leave this open for future research.

## Abstract

Tree-to-tree Statistical Machine Translation models require the use of syntactic tree structures of both the source and target side in learning rules to guide the translation process. In order to accomplish the task, available treebanks for different languages are used as the main resources to collect necessary information to handle the translation task. However, since each treebank has its own defined tags, a barrier is inherently created in highlighting alignment relationships at different syntactic levels for different tag-sets. Moreover, these models are typically over constrained. This paper presents a unified tag-set for all languages at Part-of-Speech and Phrasal Category level in tree-to-tree models. Different experiments are conducted to study for its feasibility, efficiency, and translation quality.

## 1 Introduction

The study of Statistical Machine Translation (SMT) (Lopez, 2008) relying on syntactic information has received wide attention in recent years. In particular, syntactic information is being integrated either on the source or target or both side(s) in training translation models for handling the translation task. In *hierarchical* models (Chiang, 2007) that consider syntactic information (Zollmann and Venugopal, 2006), the input sentence is analyzed and translated by synchronous context free grammars (SCFG) hierarchically with extra linguistic information. In *string-to-tree* SMT models (Galley et al., 2004; Zhang et al., 2011), the output of the translation always follows a grammatical syntax of the target language. In *tree-to-string* SMT models (Liu et al., 2006; Wu et al., 2010), source side syntax is used to generate the

translation output. Finally, by considering the syntax of both the source and target languages, *tree-to-tree* SMT models (Zhang et al., 2008; Liu et al., 2009) tend to be the best among the previous models. Basically, all of these models require two extra components: (1) *syntax parsers* (He et al., 2012; Petrov et al., 2006) in obtaining annotated syntax trees for training the models, and (2) *monolingual treebanks* (a detailed list can be found in Petrov et al. (2012)) for training the parsers. Currently, many of them are publicly available through Internet, institutions and data consortiums.

Independently from the method used, although there are many treebanks available, they typically have their own tag-set defined for different languages, ranging from tens to hundreds of tags, which is hard to conduct the research in a multilingual environment. As a consequence, Petrov et al. (2012) developed a universal Part-of-Speech (POS) tag-set for twenty five different languages. However, at phrasal level, disagreements between the languages remain undefined.

This paper presents a study of the application of universal tag-set from POS to phrasal category level in tree-to-tree translation models. In the POS tag level, we basically used the universal tag-set proposed by Petrov et al. (2012) in mapping original tags into universal ones. In order to fulfill the missing relationships at phrasal category level, a mapping work of phrasal tags for Chinese (Zh), English (En), French (Fr), German (De), and Portuguese (Pt) is presented. The main objective is to partially relax syntactic constraints imposed to the original models by having more generalizations in the unified tag-set proposed. With fewer tags defined between languages, fewer syntax rules will be extracted during the training phase, which reduces the computation load, possible rule ambiguities, and increases the translation efficiency. Although we only focus on five languages, extensions to other languages are possible.

Tag	Chinese	English	French	German	Portuguese

Table 1: Mappings from original Phrasal Category to Universal tags

This paper is organized as follows. Section 2 gives the mapping details from POS and phrasal category level tags into universal ones. Section 3 presents the application of universal tags in tree-to-tree models. Section 4 details the experiment results conducted. Section 5 introduces related work followed by a conclusion.

## 2 Universal Tag-set

A two level universal tag-set is defined in the annotation of syntactic trees for different languages. In the first level, a universal POS tag-set (Petrov et al., 2012) is converted for all leave nodes. It consists of twelve different tags, including: *NOUN* (noun), *VERB* (verb), *ADJ* (adjective), *ADV* (adverb), *PRON* (pronoun), *DET* (determiner and article), *ADP* (preposition and postposition), *NUM* (numeral), *CONJ* (conjunction), *PRT* (particle), “.” (punctuation marks) and *X* (others). However, some tags proposed in their original work are not considered at this stage. For example, the original tag *NP* in English, which is supposed to be converted into *NOUN* at POS level, is only changed to *CNP* at the phrasal category stage for better differentiating its actual meaning at tree level.

In phrasal category level, nine universal tags are defined for higher level nodes: *CNP* (noun phrase), *CVP* (verb phrase), *CAJP* (adjective phrase), *CAVP* (adverb phrase), *CPP* (preposition phrase), *CS* (sentence/sub-sentence), *CCONJP* (conjunction phrase), *CCOP* (coordinated phrase), and *CX* (others). Corresponding mappings at a

phrasal category level for Zh, En, Fr, De, and Pt language are listed in Table 1.

The proposed conversion is carefully designed by studying the actual meaning of the original tags based on previously published work. Although it is common to find out disagreements between tag-sets across different languages due to their inherent characteristics, the objective of this paper is to unify different tags which are used in most of the treebanks at clause level.

## 3 Rule Extraction Process

The rule extraction process for tree-to-tree models based on universal tag-set is similar to hierarchical phrase-based model (Chiang, 2007), which considers SCFG rules for handling the translation task. The main difference is that rules where there are syntactic labels for non-terminals are extracted. Given a word aligned sentence tree pair  $T(f_1^J)$  and  $T(e_1^I)$ , each rule in the model is a three tuple consisting of variables  $ST(f_{j_1}^{j_2})$ ,  $ST(e_{i_1}^{i_2})$ , and  $\tilde{A}$  respectively.  $ST(f_{j_1}^{j_2})$  is a sub-tree covering the interval span  $[j_1, j_2]$  of  $T(f_1^J)$ ; similarly,  $ST(e_{i_1}^{i_2})$  denotes the target sub-tree covering the interval span  $[i_1, i_2]$  of  $T(e_1^I)$ ; and  $\tilde{A}$  is the alignment between terminals and leaf non-terminals of the two trees, such that  $\forall (j, i) \in \tilde{A} : j_1 \leq j \leq j_2 \leftrightarrow i_1 \leq i \leq i_2$  holds.

The extraction process starts with standard phrase extraction, and for all the phrases found, a rule is created for each instance. Based on this initial rule set, the rest of all possible rules are iden-

tified based on a simple criterion: these phrases should be subsumed by larger pairs in this set. As an example, if there is another rule  $\langle ST(\gamma) \parallel ST(\alpha) \parallel A^t \rangle$  such that the pair  $(\gamma, \alpha)$  includes another sub-phrase  $(f_{j_1}^{j_2'}, e_{i_1}^{i_2'})$ , i.e.  $\gamma = \gamma_1 f_{j_1}^{j_2'} \gamma_2$  and  $\alpha = \alpha_1 e_{i_1}^{i_2'} \alpha_2$ , then a new rule  $\langle ST(\gamma_1 X \gamma_2) \parallel ST(\alpha_1 X \alpha_2) \parallel \hat{A} \rangle$  will be created, where  $\hat{A}$  contains alignment information for all the terminals and non-terminals. As syntax information is provided for both sides, for each pair, it must have a node in both trees which subsumes the corresponding string. In other words, non-terminal label checks to their related syntax nodes are necessary in assigning correct tags to all non-terminals in the rules.

$$\begin{aligned}
 & [NP][NP] \text{ 在 巴黎 } [VRD][VBD] \circ [IP] \parallel \\
 & [NP][NP] [VRD][VBD] \text{ in Paris } . [S] \parallel \quad (1) \\
 & 0-0 \ 1-2 \ 2-3 \ 3-1 \ 4-4
 \end{aligned}$$

As an example, in rule (1), the top node of the source tree is  $[IP]$ , the top node of the target tree is  $[S]$ , and both trees have five children. Alignment information between terminals and non-terminals is associated by their numerical positions. It might appear cases in which the source and target node have different tags assigned due to language divergences. As an example, in order to have a valid substitution of  $[VRD][VBD]$ , it requires to have a rule in which the source has a  $VRD$  tag and the target has a  $VBD$  tag. Thus, for all non-terminals except the top node, it consists of the source and target tag.

Once all the rules are learned from the entire corpus, probability scores are calculated, which are used in the decoding stage. In addition, glue rules are added in allowing combinations of partial translation fragments monotonically.

The proposed mapping from the original into universal tag-set is advantageous in two aspects. Firstly, in some sense, after the conversion is performed, some rules become more generalized and relaxed compared to the original model. As an example, in Chinese tag-set, as verb phrase related tags ( $VP$ ,  $VCD$ ,  $VCP$ ,  $VNV$ ,  $VPT$ ,  $VRD$ ,  $VSB$ ) are all grouped into  $CVP$ , more coverage in the selection of rules is expected. In particular, suppose that in the original tag-set, “想一想” (think) is tagged as  $VCD$  (verb compounds), while in universal tag-set, it is tagged as  $CVP$ . In this case, it

is obvious that the phrase “想一想” (think) can only be associated to rules with  $VCD$  but not to verb phrases ( $VP$ ), which limits its usage. As a consequence, a wider coverage of rules is available during the decoding process.

Secondly, since many similar tags in the original tag-set are grouped as only one universal tag, many rules will be merged together, resulting in a smaller size compared to the original model.

## 4 Experiments

The training environment is executed in a server equipped with a Xeon processor at 2.9GHz, with 192G physical memory. All the experiments are carried out in Moses toolkit (Koehn et al., 2007). Different language pairs are considered in the experiments, including Fr-En, De-En, Zh-En, and Zh-Pt. The bilingual data we used for Fr-En and De-En are extracted from Europarl Parliament (version 7), while Zh-En and Zh-Pt parallel information are extracted from online web-sites. All sentences are parsed by Berkeley parser (Petrov et al., 2006) and word-aligned by using GIZA++ based on five iterations of IBM model 1, three for IBM models 3 and 4, and five for HMM alignment (Och and Ney, 2003). We used a 5-gram language model for all the languages based on the SRILM toolkit (Stolcke, 2002).

Different test sets are considered, including: news-test (NT) data (2009, 2010, 2011) for Fr-En and De-En, which are extracted from the international workshop of SMT (WMT) held annually by the ACL’s special interest group for MT; test data for Zh-En and Zh-Pt are extracted from online web pages.

We limited the length of the sentences to be less than fifty, and all of them should be valid aligned parse trees for all the training and testing data. For Chinese, a segmentation model (Zhang et al., 2003) is used for detecting word boundaries.

Table 2 shows the translation quality measured in terms of BLEU metric (Papineni et al., 2002) with the original (Ori.) and universal (Uni.) tag-set. When Chinese is considered as the source, results are lower than the ones targeted for European languages, probably affected by the corpus selection, size of the corpus, parsing success rate, non-standard linguistic phenomena (Wong et al., 2012), etc. In particular, we observed that the parsing accuracy (either on the original or universal tag-set) for Chinese language is lower compared

	Fr-En		De-En	
	Ori.	Uni.	Ori.	Uni.
NT 2009	11.57	11.59*	9.64	9.66
NT 2010	10.81	10.84*	10.48	10.55*
NT 2011	12.12	12.15	9.43	9.44
	Zh-En		Zh-Pt	
	Ori.	Uni.	Ori.	Uni.
Test Data	4.79	4.85	3.87	3.88

Table 2: Translation quality comparison

Language Pair	System	VmPeak (KB)	Rule Size
Fr-En	Ori.	1,002,040	1,223,261
	Uni.	982,208	1,190,177
De-En	Ori.	761,108	926,907
	Uni.	745,724	887,317
Zh-En	Ori.	826,032	853,315
	Uni.	812,144	832,099
Zh-Pt	Ori.	686,932	813,405
	Uni.	682,308	804,356

Table 3: Memory usage and rule size

with other languages, which possibly led to poorer alignment relationships at tree level. However, there is an improvement for all the language pairs with different test sets considered by comparing with the baseline approach. Moreover, we measured the improvements over the baseline based on the significant test method proposed by Koehn (2004). The results that are significantly better than the baseline at  $p = 0.05$  are shown by \*. For NT 2010, the results are totally significant, while others' significance rate is better at a range between 97% and 99.4%.

Table 3 measures the average peak virtual memory (VmPeak) usage, and the actual number of rules generated. It is concluded that there is a decrease of 2% in terms of the peak virtual memory compared to the baseline, and a decrease of 1% to 4% in terms of distinct rules.

In short, although the improvement in terms of the translation quality is not high, it significantly reduces not only the rule table size but also memory requirements, which is very beneficial when larger data are considered.

## 5 Related Work

Some of earlier work focused in describing alignment relationships in dependency tree-to-tree

structures based on synchronous tree mapping grammars (Eisner, 2003), and synchronous dependency insertion grammars (Ding and Palmer, 2005). However, their work is targeted on dependency grammars, which is simpler than CFG equivalent formalisms (Fox, 2002). Other studies reported the use of syntactic information from conventional bilingual parsed trees. Zhang et al. (2008) proposed a tree sequence alignment model for bilingual trees. Liu et al. (2009) considered packed forests instead of 1-best trees for the whole translation process. Although both methods tend to increase rule coverage and to relax the over-constrained problem, they require tailored and sophisticated decoders. Zhai et al. (2011) considered the addition of bilingual phrases and binarization of parse trees to deal with the problems.

In this work, we proposed the substitution of original tags into universal ones, which has a higher level of abstraction in partially increasing the rule coverage while reducing the size of the rule table. Moreover, our approach does not require big changes in tree-to-tree models for accomplishing the translation task.

## 6 Conclusion

This paper presents the application of universal tag-set defined at the POS and the phrasal category level to tree-to-tree models. A phrasal category tag-set is defined for Chinese, English, French, German, and Portuguese. With the universal tag-set, learned rules become more generalized and compact. Moreover, this could partially relax the over-constrained disadvantage of traditional tree-to-tree models. Based on the experiment results, better accuracy is obtained compared with the baseline (without tag conversion) and better efficiency due to the reduced number of rules in the proposed method. In the future, we intend to further evaluate the proposed strategy for more languages, with proper universal tags defined, and to study their actual relationships in the learned rules in deducing new strategies to further reduce the rule table size.

## Abstract

We introduce a method for learning to predict reader interest. In our approach, social interaction content and both syntactic and semantic features of words are utilized. The proposed method involves estimating topical interest preferences and determining the informativity between articles and their social content. In interest prediction, we integrate articles' *quality* social feedback representing readers' opinions into articles to get information which may identify readers' interests. In addition, semantic aware PageRank is used to find reader interest with the help of word interestingness scores. Evaluations show that PageRank benefits from proposed features and interest preferences inferred across articles. Moreover, results conclude that social interaction content and the proposed selection process help to accurately cover more span of reader interest.

## 1 Introduction

Web keyword extraction tools such as KEA ([www.nzdl.org/Kea/](http://www.nzdl.org/Kea/)) typically look at articles from authors' perspective to calculate the importance of a word in articles. However, keywords are not necessarily words that interest readers. We found that articles could be analyzed more towards reader interest if a system exploited social interaction content (e.g., reader feedback) in social media.

Consider the content of an example article. The Web post describes a newly-renovated old house and the history, life style, and surrounding sightseeing sites of a historical city where it is located. Most keyword tools can easily identify keywords *the old house* (謝宅) and *the historical city* (台南). However, article readers might also be interested in less frequent words like *life style* (生活) and *traditional market* (市場), and single-occurrence like *rental fees* (費用), which are also mentioned in most reader feedback.

In the proposed method, an article was transformed into a word graph where vertices were words in the article and edges between vertices indicated words' co-occurrences. To distinguish associate/key words from words of reader interest, readers' *quality* interaction feedback was considered when building the word graph. Subsequently, word interest preferences and PageRank were utilized to find interest terms. Weightings concerning syntactic and semantic features are utilized in PageRank. Moreover, content-source and content-word weighted PageRank were exploited to return words for interest evaluation. The predicted interests can further be used as candidates for social tagging or article recommendation.

## 2 Related Work

The state-of-the-art keyword extraction methods have been applied to a myriad of natural language processing tasks including document categorization and summarization (Manning and Schütze, 2000; Litvak and Last, 2008), indexing (Li et al., 2004), information retrieval (Turney, 2000), and text mining on social networking or micro-blogging services (Li et al., 2010; Zhao et al., 2011; Wu et al., 2010). Here we extract keywords related to readers' interests.

Recently, collaborative tagging or social tagging has grown in popularity among Web services and received much attention (Golder and Huberman 2006; Halpin et al., 2007). Instead of analyzing user (tagging) activity or tag frequencies, we analyze articles and their social interaction content to predict reader interests.

Researches have been done on reader profiling for content recommendation. White et al. (2009) examined five types of contextual information in website recommendation while Ye *et al.* (2012) further explored social influence on item recommendation. Moreover, Tsagkias and Blanco (2012) concentrated on analyzing users' browsing behavior on news articles, and Jin (2012) recommended contents through a unified, per-

sonalized messaging system. In our work, the accumulated social interaction content is utilized to help determine the interest of future reader.

In studies more related to our work, Liu (2010) and Zhao (2011) present PageRank for keyword analyses using article topic information. The main difference from our current work is that we integrate social content and (global) topical interest preferences for words into (local) content-word weighted PageRank algorithm.

### 3 Finding Interests

To introduce the finding process of interests, we start from the problem statement. Given an article collection of various topics from social media (e.g., blogs), an article *ART*, and its reader feedback *FB*, our goal is to determine a set of interest words that are likely to represent the interest of future readers after reading *ART*.

#### 3.1 Estimating Topical Interest Preferences

Basically, the estimation of topical interest preferences is to calculate the significance or degree of references of a word in a domain topic. The learning process contains four stages: (1) Generate article-word pairs in training data, (2) Generate topic-word pairs in training data, (3) Estimate interest preferences for words w.r.t. article topics based on different strategies, and (4) Output word-and-interest-preference-score pairs for various estimation strategies. In the first two stages of the learning process, we generate two sets of article and word information. The input to these stages is a set of articles with author-chosen topics and, if any, their reader feedback responses. The output is a set of pairs of article ID and word in the article, e.g., (*art*=1, *w*="old house"), and a set of pairs of article topic and word in the article, e.g., (*tp*="travel", *w*="old house"). Note that the article referred here may or may not contain the social reader feedback (See Section 4). In the third stage, we utilize aforementioned sets to estimate reader interest preferences for words across articles and across domain topics. Six different estimation strategies are as follows.

**tfidf.** The first estimation is a traditional yet powerful one, tfidf (term frequency multiplied by inversed document frequency):

$$\text{tfidf}(art, w) = \text{freq}(art, w) / \text{artFreq}(w).$$

**Pr(*w*|*tp*).** The second leverages a word's Maximum Likelihood Estimation under a given topic:

$$\Pr(w | tp) = \text{freq}(tp, w) / \sum_{w'} \text{freq}(tp, w').$$

**Pr(*tp*|*w*).** The third computes the topic-wise senses of a word:

$$\Pr(tp | w) = \text{freq}(tp, w) / \sum_{tp'} \text{freq}(tp', w).$$

**entropy.** The fourth is entropy which utilizes the uncertainty in topics to estimate its topic spectrum or its topic focus:

$$\text{entropy}(w) = -\sum_{tp} \Pr(tp | w) \times \lg(\Pr(tp | w)).$$

**Pr-Entropy(*w*|*tp*).** The fifth further considers topic uncertainty in MLE:  $\Pr(w | tp) / 2^{\text{entropy}(w)}$ .

**Pr-Entropy(*tp*|*w*).** The last is a combination of the third and the fourth:  $\Pr(tp | w) / 2^{\text{entropy}(w)}$ .

These six estimations all take global information (i.e., article collection) into account.

#### 3.2 Predicting Interest for Future Reader

Reader interests were predicted using the procedure in Figure 1. In this procedure we exploit semantic aware PageRank and reader feedback in social media to evaluate readers' interest in an article word. According to our observations, the collection of the reader feedback may reveal the common interest and browse habits of potential readers of the same article.

However, not all reader feedback responds to the article. Therefore, we screen reader feedbacks in Step (1) based on the article *ART*, its feedbacks *FB* and interest preference scores *IntPrefs*. The algorithm for identifying reader responses of a good quality, called *quality* reader responses hereafter, is as follows.

(1) *ngramsart* = generateNgram(*ART*)

(2) *Focused* = findFocused(*IntPrefs*)

(3) *selectedSt* = NULL

for each sentence *st* in *FB*

(4a) *ngramsst* = generateNgram(*st*)

(4b) *informativityco* = Coverage-evaluate(*ngramsst*, *ngramsart*)

(4c) *informativityfo* = Focus-evaluate(*ngramsst*, *Focused*)

(4d) append *st* into *selectedSt* if conditions hold

return *selectedSt*

Each response is evaluated at sentence level concerning informativity checked in two aspects. The first concerns the topic cohesion between reader response sentence *st* and article *ART*. Similar to BLEU's (Papineni et al., 2002) weighted ngram precision in machine translation, we compute the weighted ngram coverage of *st* (Step (4b)) on *ART* and favor the coverage of longer ngrams. Larger ngram coverage indicates higher topic correlation between the two. The second considers the topic distributions of words in *st*. We first rank and identify the words expected to have low topic uncertainty. Entropy estimation in

Section 3.2 is used for this purpose to find *Focused* (Step (2)). Then the informativity on topic focus of *st* is computed as the percentage of its words in set *Focused*. In the end, we prune reader sentences in *FB* according to the thresholds set for *informativity<sub>co</sub>* and *informativity<sub>fo</sub>* (Step (4d)).

After incorporating quality feedback *qualityFB* into *ART* (Step (2) in Figure 1), we construct a word graph for both the article and social content. The word graph is represented by a *v*-by-*v* matrix **EW** where *v* is the vocabulary size. **EW** stores normalized edge weights for word  $w_i$  and  $w_j$  (Step (4) and (5)). Note that the graph is directional from  $w_i$  to  $w_j$  and that edge weights are the words' co-occurrence counts within window size *WS*.

```

procedure PredictInterest(ART,FB,IntPrefs,λ,α,N)
(1) qualityFB=selectInformativeFB(ART,FB,IntPrefs)
(2) Concatenate ART with qualityFB into Content
//Construct word graph for PageRank
(3) EWv×v=0v×v
    for each sentence st in Content
        for each word  $w_i$  in st
            for each word  $w_j$  in st where  $i < j$  and  $j - i \leq WS$ 
                if not IsContWord( $w_i$ ) and IsContWord( $w_j$ )
(4a)    EW[i,j]+= $1 \times m \times srcWeight$ 
                elif not IsContWord( $w_i$ ) and not IsContWord( $w_j$ )
(4b)    EW[i,j]+= $1 \times (1/m) \times srcWeight$ 
                elif IsContWord( $w_i$ ) and not IsContWord( $w_j$ )
(4c)    EW[i,j]+= $1 \times (1/m) \times srcWeight$ 
                elif IsContWord( $w_i$ ) and IsContWord( $w_j$ )
(4d)    EW[i,j]+= $1 \times m \times srcWeight$ 
(5) normalize each row of EW to sum to 1
//Iterate for PageRank
(6) set IP $1 \times v$  to
        [IntPrefs( $w_1$ ), IntPrefs( $w_2$ ), ..., IntPrefs( $w_v$ )]
(7) initialize IN $1 \times v$  to [ $1/v, 1/v, \dots, 1/v$ ]
    repeat
(8a) IN' =  $\lambda \times \mathbf{IN} \times \mathbf{EW} + (1 - \lambda) \times \mathbf{IP}$ 
(8b) normalize IN' to sum to 1
(8c) update IN with IN' after the check of IN and IN'
        until maxIter or avgDifference(IN, IN')  $\leq smallDiff$ 
(9) rankedInterests=Sort words in decreasing order of IN
    return the N rankedInterests with highest scores

```

Figure 1. Determining readers' words of interest.

Two semantic features are used in PageRank. Firstly, we weigh edges according to connecting words' syntactic parts-of-speech via edge multiplier *m*. We distinguish content words (e.g., nouns, verbs, adjectives and adverbs) from are not and implement three different levels of content-word score aggregation. Particularly, we have *slightly* content word centered score propagation when  $m > 1$  in Step (4a) and  $m = 1$  in Step (4b) to (4d), while we have *moderate* content word aggregation when  $m > 1$  in Step (4a) and (4d) and  $m = 1$  in Step (4b) and (4c). The third is to

*aggressively* make a non-content word's score flow to its content word partners by setting *m* in Step (4a) and  $1/m$  in Step (4b) where  $m > 1$ , and, circulate more  $w_i$ 's score to content words if  $w_i$  is a content word (i.e.,  $m > 1$  in Step (4c) and (4d)). The second semantic feature concerns source of words. Words may come from authors or readers, and *srcWeight* is set to  $\alpha$  if *st* is from *ART* and  $1 - \alpha$  otherwise. Smaller  $\alpha$ 's favor readers' perspectives more while functioning as a PageRank key-word extraction system if  $\alpha$  is one.

We set the one-by-*v* matrix **IP** of interest preference model using interest preferences for words in Step (6) and initialize the matrix **IN** of PageRank scores. Here we use word interestingness scores in Step (7). Then we re-distribute words' interestingness scores until the number of iterations or the average score differences of two consecutive iterations reach their respective limits. In each iteration, a word's interestingness score is the linear combination of its interest preference score and the sum of the propagation of its inbound words' previous PageRank scores. For the word  $w_j$  and any edge ( $w_i, w_j$ ) in *ART* and any edge ( $w_k, w_j$ ) in *qualityFB*, its new PageRank score is computed as

$$\mathbf{IN}'[1,j] = \lambda \times \left( \alpha \times \sum_{i \in v} \mathbf{IN}[1,i] \times \mathbf{EW}[i,j] + (1 - \alpha) \times \sum_{k \in v} \mathbf{IN}[1,k] \times \mathbf{EW}[k,j] \right) + (1 - \lambda) \times \mathbf{IP}[1,j]$$

Once the iterative process stops, we rank words according to their final interestingness scores and return *N* top-ranked words.

## 4 Experiments

In this section, we first present the data sets for training and evaluating *InterestFinder* (Section 4.1). Then, Section 4.2 reports the experimental results under different window sizes, content-word aggregation levels, estimation strategies of interest preferences.

### 4.1 Data Sets

We collected 6,600 articles from the blog website Wretch (www.wretch.cc) in November, 2012. In total, there were twelve first-level topics and 45 categories at the second tier. The example pre-defined two- to three-tier topic ontology ranged from Travel:Domestic to Life:Pets or from Fashion:Makeup to Technology:Games. Author-specified topic information was exploited to derive the estimation scores of interest preferences in Section 3.2. We also collected readers' feedback to the articles. We randomly chose 30 articles from training set for testing. Two human

judges annotated interested words after reading the articles in the test set.

	nDCG	P	MRR
<i>w/o</i>	.778	.397	.728
<i>agr@m=2</i>	.765	.390	.719
<i>mod@m=2</i>	.782	.390	.747
<i>slg@m=2</i>	<b>.792</b>	<b>.397</b>	.741

Table 1. System performance of different content-word aggregation levels at  $N=5$ .

## 4.2 Experimental Results

Our evaluation metrics are normalized discounted cumulative gain nDCG (Jarvelin and Kekalainen, 2002), precision (i.e., P), and mean reciprocal rank (i.e., MRR). We first examine the effectiveness of our semantic feature regarding content words in interest predictions. Table 1 suggests that while *slight* (*slg*) content word propagation is helpful, *moderate* (*mod*) and *aggressive* (*agr*) are not. Inflating content words’ statistics is simply sufficient. In addition, we found that smaller window size ( $WS=3$ ) fit more to our context of mixed-code blogs, while suitable window sizes were much larger in news articles and research abstracts (Liu et al., 2010).

Table 2 summarizes the interest prediction quality of two baselines, *entropy* and *tfidf*, and PageRank (PR) with different interest preference estimations on test set. In Table 2, *entropy* and *tfidf*, taking local (the article) and global (whole article collection) information into account, outperform PageRank using solely local information ( $PR+tf$ ). Among all,  $PR+tfidf$  achieves the best performance. Compared to  $PR+Pr$ ’s, *entropy* in  $PR+PrEntropy$ ’s does help to discern topical interest words. Moreover, the benefit of *entropy* is more evident when better estimation strategy  $Pr(tp|w)$  is applied: common words receive too much attention in  $Pr(w|tp)$  making readers’ interest words harder to come by.

(a) @ $N=5$	nDCG	P	MRR
<i>Entropy</i>	.677	.287	.659
<i>Tfidf</i>	.719	.313	.676
$PR+tf$	.657	.310	.632
$PR+Pr(w tp)$	.631	.290	.583
$PR+Pr(tp w)$	.673	.317	.639
$PR+PrEntropy(w tp)$	.636	.283	.584
$PR+PrEntropy(tp w)$	<b>.773</b>	<b>.337</b>	<b>.725</b>
$PR+tfidf$	<b>.792</b>	<b>.397</b>	<b>.741</b>

Table 2. System performance using article information alone at  $N=5$ .

We further exploit the collected reader feedback to train the baseline *tfidf* and our best sys-

tem  $PR+tfidf$ . Table 3 compares their interest predictions against judges’ interest and annotated words, within reader feedback, of interest in the articles. Note that the *tfidf* on reader feedback alone does not perform better.

(a) @ $N=5$	judges’ interest	general readers’ interest		
	nDCG	hit	nDCG	MRR
$(tfidf)_{none}$	.719	.10	.087	.075
$(tfidf)_{all}$	.699	.10	.079	.072
$(PR+tfidf)_{none}$	.792	.19	.137	.122
$(PR+tfidf)_{Coverage}$	.805	<b>.30</b>	<b>.186</b>	<b>.166</b>
$(PR+tfidf)_{Focus}$	.779	.27	.156	.137
$(PR+tfidf)_{Coverage+Focus}$	.794	<b>.30</b>	<b>.182</b>	<b>.164</b>

Table 3. System performance using *slg* at  $m=4$ ,  $WS=3$ ,  $\alpha=0.4$  and  $N=5$

In Table 3 we observe that (1) using all reader feedback is no better than using none (rows of *tfidf*) because not all feedback respond to the articles; (2) semantic feature of content source works well with *Coverage-* and *Focus-evaluate*. And *Coverage-* and *Focus-evaluate* are effective in checking informativity of social interaction data.  $(PR+tfidf)_{Coverage}$  or  $(PR+tfidf)_{Focus}$  achieves better performance on general readers’ interest while maintaining the prediction power on judges’ interest. (3) the chain of *Coverage-* and *Focus-evaluate*  $(PR+tfidf)_{Coverage+Focus}$  further prunes 6 and 12 percent of the reader sentences compared to the individual, and, encouragingly, using one-fourth of reader interactions still helps.

Based on the findings in Table 2 and 3, we believe that proposed interest preference models, semantic features (i.e, content source and content word), and the informativity check on social interaction content are simple yet helpful in suggesting good and representative reader interests.

## 5 Conclusion

We have introduced a method for predicting reader interest in an article. In interest prediction, we turn to social interaction content instead of reader profile and browse history. The method involves estimating topical interest preferences, screening public reader responses, and leveraging semantic features such as words’ sources (i.e., from article authors or readers) and words’ parts-of-speech in PageRank. We have implemented and evaluated the method as applied to interest analysis. In two separate evaluations, we have shown that *quality* social interaction content and semantic aware PageRank help to accurately cover broader spectrum of reader interest.

## Abstract

News and twitter are sometimes closely correlated, while sometimes each of them has quite independent flow of information, due to the difference of the concerns of their information sources. In order to effectively capture the nature of those two text streams, it is very important to model both their correlation and their difference. This paper first models their correlation by applying a time series topic model to the document stream of the mixture of time series news and twitter. Next, we divide news streams and twitter into distinct two series of document streams, and then we apply our model of bursty topic detection based on the Kleinberg's burst detection model. This approach successfully models the difference of the two time series topic models of news and twitter as each having independent information source and its own concern.

## 1 Introduction

The background of this this paper is in two types of modeling of information flow in news stream, namely, burst analysis and topic modeling. Both types of modeling, to some extent, aim at aggregating information and reducing redundancy within the information flow in news stream.

First, when one wants to detect a kind of topics that are paid much more attention than usual, it is usually necessary for him/her to carefully watch every article in news stream at every moment. In such a situation, it is well known in the field of time series analysis that Kleinberg's modeling of bursts (Kleinberg, 2002) is quite effective in detecting burst of keywords. Second, topic models such as LDA (latent Dirichlet allocation) (Blei et

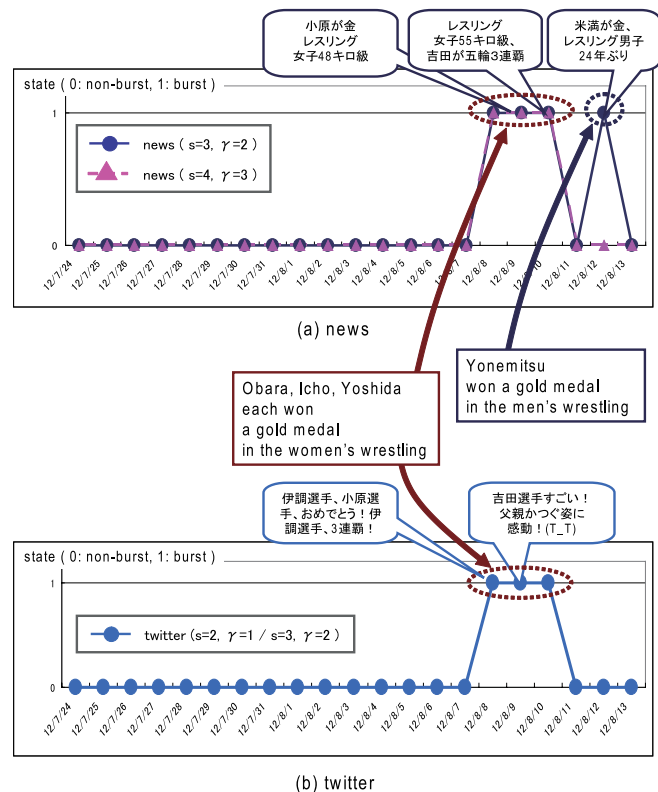

Figure 1: Optimal State Sequence for the Topic “wrestling”

al., 2003) and DTM (dynamic topic model) (Blei and Lafferty, 2006) are also quite effective in estimating distribution of topics over a document collection such as articles in news stream. Unlike LDA, in DTM, we suppose that the data is divided by time slice, for example by date. DTM models the documents (such as articles of news stream) of each slice with a  $K$ -component topic model, where the  $k$ -th topic at slice  $t$  smoothly evolves from the  $k$ -th topic at slice  $t - 1$ .

Based on those arguments above, Takahashi et al. (2012) proposed how to integrate the two types of modeling of information flow in news stream. Here, it is important to note that Kleinberg's modeling of bursts is usually applied only to bursts of keywords but not to those of topics. Thus, Taka-

hashi et al. (2012) proposed how to apply Kleinberg’s modeling of bursts to topics estimated by a topic model such as DTM. Typical results of applying the technique to time series news stream can be illustrated as in Figure 1 (a). In this example, we first estimate time series topics through DTM, among which is the one “wrestling” as shown in this figure. Then, we can detect the burst of the topic on the dates when those two Japanese wrestlers won the gold medals.

Unlike Takahashi et al. (2012), this paper studies the issue of time series topic modeling and bursty topic detection of possibly correlated news and twitter. News and twitter are sometimes closely correlated, while sometimes each of them has quite independent flow of information, due to the difference of the concerns of their information sources. In order to effectively capture the nature of those two text streams, it is very important to model both their correlation and their difference. This paper first models their correlation by applying a time series topic model to the document stream of the mixture of time series news and twitter. This approach successfully models the time series topic models of news and twitter as closely correlated to each other. Next, we divide news streams and twitter into distinct two series of document streams, and then we apply our model of bursty topic detection based on the Kleinberg’s burst detection model. With this procedure, we show that, even though we estimate the time series topic model with the document stream of the mixture of news and twitter, we can detect bursty topics individually both in the news stream and in twitter. This approach again successfully models the difference of the two time series topic models of news and twitter as each having independent information source and its own concern.

## 2 Time Series Documents Set for Evaluation

In this paper, we collect time series news articles of a certain period as well as tweets texts of the same period that are closely related to the news articles. Then, we construct a time series document set consisting of the mixture of the news articles and tweets texts (Table 1) and use it for evaluation.

### 2.1 News

As the news stream documents set for evaluation, during the period from July 24th to August 13th,

Table 1: Time Series Documents Set

news articles	tweets	total # of document
2,308	57,414	59,722

2012, we collected 3,157 Yomiuri newspaper articles, 4,587 Nikkei newspaper articles, and 3,458 Asahi newspaper articles which amount to 11,202 newspaper articles in total<sup>1</sup>. Then, we select a subset of the whole 11,202 newspaper articles which are related to “the London Olympic game”, where we collect 2,308 articles that contain at least one of 8 keywords<sup>2</sup> into the subset. The subset consists of 659 Yomiuri newspaper articles, 679 Nikkei newspaper articles, and 970 Asahi newspaper articles.

### 2.2 Twitter

As the tweet text data set for evaluation, during the period from July 24th to August 13th, 2012, we collected 9,509,774 tweets from the Twitter<sup>3</sup> with the Streaming API. Then, we removed tweets with official retweets and those including URLs, and 7,752,129 tweets remained. Finally, we select a subset which are related to “the London Olympic game”. Here, we collect 57,414 tweets that contain at least one of the 8 keywords listed above, which are closely related to “the London Olympic game”, into the subset.

## 3 Kleinberg’s Bursts Modeling

Kleinberg (2002) proposed two types of frameworks for modeling bursts. The first type of modeling is based on considering a sequence of message arrival times, where a sequence of messages is regarded as bursty if their inter-arrival gaps are too small than usual. The second type of modeling is, on the other hand, based on the case where documents arrive in discrete *batches* and in each batch of documents, some are *relevant* (e.g., news text contains a particular word) and some are *irrelevant*. In this second type of bursts modeling, a sequence of batched arrivals could be considered bursty if the fraction of relevant documents alternates between reasonably long periods in which the fraction is small and other periods in which it is large. Out of the two modelings, this paper em-

<sup>1</sup><http://www.yomiuri.co.jp/>, <http://www.nikkei.com/>, and <http://www.asahi.com/>.

<sup>2</sup>五輪 (*Gorin* (“Olympic” in Chinese characters)), ロンドン (London), オリンピック (Olympic (in katakana characters)), 金メダル (gold medal), 銀メダル (silver medal), 銅メダル (bronze medal), 選手 (athlete), 日本代表 (Japanese national team)

<sup>3</sup><https://twitter.com/>

employs the latter, which is named as *enumerating bursts* in Kleinberg (Kleinberg, 2002).

#### 4 Applying Time Series Topic Model

As a time series topic model, this paper employs DTM (dynamic topic model) (Blei and Lafferty, 2006). In this paper, in order to model time series news stream in terms of a time series topic model, we consider date as the time slice  $t$ . Given the number of topics  $K$  as well as time series sequence of batches each of which consists of documents represented by a sequence of words  $w$ , on each date  $t$  (i.e., time slice  $t$ ), DTM estimated the distribution  $p(w|z_n)$  ( $w \in V$ , the vocabulary set) of a word  $w$  given a topic  $z_n$  ( $n = 1, \dots, K$ ) as well as that  $p(z_n|b)$  ( $n = 1, \dots, K$ ) of a topic  $z_n$  given a document  $b$ , where  $V$  is the set of words appearing in the whole document set. In this paper, we estimate the distributions  $p(w|z_n)$  ( $w \in V$ ) and  $p(z_n|b)$  ( $n = 1, \dots, K$ ) by a Blei’s toolkit<sup>4</sup>, where the parameters are tuned through a preliminary evaluation as the number of topics  $K = 50$  as well as  $\alpha = 0.01$ . The DTM topic modeling toolkit is applied to the time series document set shown in Table 1, which consists of the mixture of the news articles and tweets texts. Here, as a word  $w$  ( $w \in V$ ) constituting each document, we extract Japanese Wikipedia<sup>5</sup> entry titles as well as their redirects.

#### 5 Modeling Bursty Topics Independently from News and Twitter

In this section, we are given a time series document set which consists of the mixture of two types of documents originating from two distinct sources, e.g., news and tweets. In this situation, we assume that a time series topic model is estimated with the mixture of two types of time series documents, where the distinction of the two sources is ignored at the step of time series topic model estimation. Then, the following procedure presents how to model bursty topics for each of the two types of time series documents independently. This means, in the case of news and twitter, that, although the time series topic model is estimated with the mixture of time series news articles and tweets texts, bursty topics are detected independently from news and twitter.

<sup>4</sup><http://www.cs.princeton.edu/~blei/topicmodeling.html>

<sup>5</sup><http://ja.wikipedia.org/>

In this bursty topic modeling, first, we suppose that, on the date  $t$  (i.e., time slice  $t$ ), we have two types of documents  $b_x$  and  $b_y$  each of which originates from the source  $x$  and  $y$ , respectively. Then, for the source  $x$ , we regard a document  $b_x$  as *relevant* to a certain topic  $z_n$  that are estimated through the DTM topic modeling procedure, to the degree of the amount of the probability  $p(z_n|b_x)$ . Similarly for the source  $y$ , we regard a document  $b_y$  as *relevant* to a certain topic  $z_n$ , to the degree of the amount of the probability  $p(z_n|b_y)$ . Next, for the source  $x$ , we estimate the number  $r_{t,x}$  of relevant documents out of a total of  $d_{t,x}$  simply by summing up the probability  $p(z_n|b_x)$  over the whole document set (similarly for the source  $y$ ):

$$r_{t,x} = \sum_{b_x} p(z_n|b_x) \quad r_{t,y} = \sum_{b_y} p(z_n|b_y)$$

Once we have the number  $r_{t,x}$  and  $r_{t,y}$  for the sources  $x$  and  $y$ , then we can estimate the total number of relevant documents throughout the whole batch sequence  $\mathbf{B} = (B_1, \dots, B_m)$  as  $R_x = \sum_{t=1}^m r_{t,x}$  and  $R_y = \sum_{t=1}^m r_{t,y}$ . Denoting the

total numbers of documents on the date  $t$  for the sources  $x$  and  $y$  as  $d_{t,x}$  and  $d_{t,y}$ , respectively, we have the total numbers of documents throughout the whole batch sequence as  $D_x = \sum_{t=1}^m d_{t,x}$  and

$D_y = \sum_{t=1}^m d_{t,y}$ , respectively. Finally, we can estimate

the expected fraction of relevant documents as  $p_{0,x} = R_x/D_x$  and  $p_{0,y} = R_y/D_y$ , respectively. Then, by simply following the formalization of bursty topics we proposed in Takahashi et al. (2012), it is quite straightforward to model bursty topics independently for each of the two sources  $x$  and  $y$ . In the following evaluation, we consider the sources  $x$  and  $y$  as time series news articles and tweet texts shown in Table 1. As the two parameters  $s$  and  $\gamma$  for bursty topic detection<sup>6</sup>, we compare two pairs  $s = 4, \gamma = 3$  and  $s = 3, \gamma = 2$  for time series news articles, and  $s = 3, \gamma = 2$  and  $s = 2, \gamma = 1$  for tweets text.

## 6 Evaluation

### 6.1 The Procedure

As the evaluation of the proposed technique, we examine the correctness of the detected bursty top-

<sup>6</sup> $s$  is a parameter for scaling expected fractions of relevant documents between burst / non-burst states.  $\gamma$  is a parameter for the cost of moving from the non-burst state to the burst state. The details of the two parameters are described in Kleinberg (2002) and Takahashi et al. (2012).

Table 2: Evaluation Results: Precision of Detecting Bursty Topics (for 34 Topics relevant to “the London Olympic Games” out of the whole 50)

	bursts detected in both news and twitter	bursts detected only in one of news and twitter
news	per day: 87.5 % (14/16)	per day: 100 % (2/2), per topic: 100 % (1/1)
twitter	per topic 87.5 % (7/8)	per day: 100 % (32/32), per topic: 100 % (13/13)

ics. For each topic  $z_n$ , collect the documents  $b$  which satisfies  $z_n = \operatorname{argmax}_{z'} p(z'|b)$  into the set  $B_{1st}(z_n)$ . Then, we first judge whether most of the collected documents (both news articles and tweets texts)  $b \in B_{1st}(z_n)$  have relatively similar contents. If so, next we examine the correctness of the detected burst of that topic.

We evaluate the detected bursty topics per day or per topic. As for “per day evaluation”, we examine whether, on each day of the burst, the detected burst is appropriate or not. As for “per topic evaluation”, we examine whether, for each topic, all of the detected bursts are appropriate or not.

Out of the whole 50 topics, we manually select 34 that are relevant to “the London Olympic games”, and show the evaluation results of detecting bursty topics in Table 2. Here, as the two parameters  $s$  and  $\gamma$  for bursty topic detection, we show those with  $s = 4$  and  $\gamma = 3$  for news and  $s = 3$  and  $\gamma = 2$  for tweets, for which we have the highest precision in bursty topic detection. We also classify the detected bursts per day and detected bursty topics (i.e., *per topic*) into the following two types: (a) *the bursty topic is shared between news and twitter*, and (b) *the bursty topic is detected only in one of news and twitter*.

## 6.2 Evaluation Results

As shown in Table 2, for the bursty topic of type (b), precisions for both “per day” and “per topic” evaluation are 100% (both for news and twitter). The proposed technique is quite effective in detecting many bursty topics that are observed only in twitter. For the bursty topic of type (a), over detection of bursty topics is only for one topic, which is about “*politics*”. The reason why this over detection occurred is mainly because we observed fewer numbers of news articles and tweets on politics during the period of “the London Olympic games”, and then, the periods other than “the London Olympic games” are detected as bursty. Also

Figure 2: Optimal State Sequence for the Topic “good looking athletes” (observed only in twitter)

for the bursty topic of type (a), reasons of bursts in news articles and tweets texts are almost the same as each other. This result clearly supports our claim that the proposed technique is quite effective in detecting closely related bursty topics in news and twitter.

Figure 1 plots the optimal state sequence for the topic “wrestling” for both news and twitter. For this topic, some of the bursts are shared between news and twitter, so we also show the results of aligning bursts between news and twitter. Figure 2 also plots the optimal state sequence for the topic “good looking athletes”, where for this topic, all the documents are from the source twitter and bursts are detected only for twitter<sup>7</sup>.

## 7 Conclusion

This paper showed that, even though we estimate the time series topic model with the document stream of the mixture of news and twitter, we can detect bursty topics independently both in the news stream and in twitter. Among several related works, Diao et al. (2012) proposed a topic model for detecting bursty topics from microblogs. Compared with Diao et al. (2012), one of our major contributions is that we mainly focus on the modeling of correlation and difference between news and twitter.

<sup>7</sup>It is surprising that tweets that mentioned good looking athletes are collected altogether in this topic. Many tweets collected in this topic on the non-bursty days said that he/she likes a certain athlete. And, those tweets share the terms 選手 (athlete) and 好き (like). But, especially on the days when the bursts were observed, much more people posted that the Japanese judoka Matsumoto and the German gymnast Nguyen were so impressive because of their looking. This is why we observed bursts on those days.

## Abstract

With the overabundance of online user-generated content, the ability to filter based on relevant perspectives is becoming increasingly important. Identifying the perspective of the authors with the review text would enhance the retrieval of pertinent information. This problem can be traditionally formulated as a text classification task and solved by annotating the data and building a supervised learning system. However, rare classes might render annotation even more difficult and expensive. Here, we used a distant supervision approach to identify restaurant reviews that were written from the perspective of a vegetarian, and we achieved a macro-average F1 score of 79.40% with minimal annotation effort.

## 1 Introduction

The center of the information world has shifted from select few authorities to the global wisdom of the crowd and user-generated content. While useful and large, the volume of the information requires efficient organization, information retrieval, and data mining techniques to select the most relevant contents. For example, restaurant goers looking for vegetarian-friendly restaurants might want to read restaurant reviews that are written by a vegetarian. Authors' perspectives potentially provide a meaningful axis along which the documents can be organized.

Past studies have formulated this problem as a document-level supervised text classification

---

\*The author conducted the work during his internship at Yelp.

problem (Manning et al., 2008), but the supervised learning paradigm might not be suitable in certain scenarios. Supervised learning algorithms can achieve superior performance compared to unsupervised learning algorithms at the expense of costly annotation efforts in creating labeled datasets for the algorithms to learn from. The perspectives that we would like to identify, however, might be very specific and somewhat rare in the document collection. To continue with the restaurant review example, only an estimated of 3.2% of the U.S. population identify themselves as vegetarian (Haddad and Tanzman, 2003), so the restaurant reviews written from the perspective of a vegetarian might be very rare in the corpus.

This rare class problem necessitates a larger number of annotated documents to collect sufficient positive examples. For instance, approximately 10,000 data instances must be labeled in order to obtain a mere 320 data points for vegetarian reviews. Additionally, the resulting classifier trained on a specific annotated corpus will tend to be biased toward that text domain, and the performance might degenerate when the classifier is applied to text in another domain. Although the rare class problem is well studied in supervised settings (He and Ghodsi, 2010; Joshi et al., 2001), to our knowledge we have not encountered a distantly supervised algorithm applied to a dataset where a rare class is of interest.

Distant supervision approaches address these problems by exploiting prior knowledge or external resources to gather large number of training data or features to train a classifier without manual annotation. A distant supervision algorithm might start by using a set of simple rules or a knowledge base to form distant supervision criteria (Mintz et al., 2009), then create an ini-

tial training set from such criteria. The labels of these initial training samples are sometimes said to be *weakly labeled* because they are not individually supervised or manually labeled by a human annotator. Instead, the labels are distantly supervised by heuristics or informed by an extensive knowledge base. For instance, a distant supervision approach has been applied to Twitter data, which is massive and hard to annotate (Marchetti-Bowick and Chambers, 2012). Emoticons were used to identify tweets with positive or negative sentiments, which then served as training samples for supervised classifiers (Go et al., 2009). Notably, distant supervision approaches were successfully used in relation extraction. Mintz et al. (2009) employed a knowledge base to extract patterns and features for a relation extraction system, where the supervised training data were relatively small and domain specific.

The supervised learning paradigm might not suit ever-growing user-generated datasets that contain rare classes and suffer from prohibitive annotation cost. Here, we present a distant supervision approach for identifying rare author’s perspectives in unstructured user-generated content. This method alleviates the problem of rare classes and reduces the time and cost of annotating data.

## 2 Corpus and Task Description

We randomly selected ten million user-generated restaurant reviews in English from yelp.com, a consumer review website.<sup>1</sup> The review authors’ personal information was removed from the data. Most of the text consists of well formed sentences, due to the greater character limit than, say, Twitter. Although, like most unstructured user-generated corpora, these reviews contain typos and non-standard structure, e.g. ASCII art and use of dashes as bullet points. Each review contains 151.04 tokens on average, so we have a total of approximately 1.5 billion tokens in this dataset.

For this corpus, we focus on identifying the restaurant reviews that are written from the perspective of a vegetarian. We annotated a small number of reviews to use as a test set for final evaluation. Each review was annotated independently by two annotators. The inter-annotator agreement is moderate (Cohen’s  $\kappa = 0.58$ ). Only 34 reviews out of 1,021 labeled reviews are labeled as written

---

<sup>1</sup>The corpus is available upon request on the website [www.yelp.com/academic\\_dataset](http://www.yelp.com/academic_dataset)

from the perspective of a vegetarian, which suggests that this perspective occurs rarely in the corpus.

## 3 Methodology

We employed simple phrase matching to collect weakly labeled data. If a review contains the phrase “I’m a vegetarian,” “I’m vegetarian,” or “As a vegetarian, I,” we regard those reviews as written from the perspective of a vegetarian. On the other hand, if a review mentions beef, pork, or chicken without the word “fake” preceding it, then such review is tagged as not written from a perspective of a vegetarian. These simple phrase matching rules are applied to every review in the corpus. The reviews that are not selected by the rules are discarded from the weakly labeled training data.

This weakly labeled training set is used to train a two-way classification Multinomial Naive Bayes model. The classifier uses all of the words in the documents as features. Weakly labeled data are noisier than manually labeled data, which might cause the classifier to be less generalizable due to overwhelming noisy features. Thus, we perform feature selection by using the Bayesian Information Criterion (BIC) to reduce noise and improve the performance (Schwarz, 1978; Forman, 2003). We noted that the proportion of each perspective in the weakly labeled data does not necessarily match the true proportion. We therefore manually set the prior probabilities of the labels to 0.9 and 0.1 for non-vegetarian and vegetarian respectively.

In general, one can use any arbitrary criteria to cull weakly labeled data from the corpus, as long as the criteria are high in precision. If the corpus is massive, which is usually the case in user-generated content on the web, then we afford to sacrifice recall for less noisy training instances. With regard to training classifiers, one can choose any supervised learning algorithm.

## 4 Experiment Setup and Results

Our distant supervision criteria identified 12,514 reviews written from the perspective of a vegetarian, and 3,076,256 reviews not written from such perspective. 7,193,878 reviews were left unannotated and discarded because they don’t contain any of the phrases in our criteria. These reviews constitute weakly labeled training data and account for roughly 30% of the original unlabeled data of ten million reviews.

	Precision	Recall	$F_1$
Vegetarian	80.85	80.07	80.46
Non-vegetarian	97.50	97.62	97.56
Macro-average	89.17	88.84	89.01

Table 1: 7-fold cross-validation results based on the weakly labeled data. The classifier achieved the macro-averaged  $F_1$  measure of 89.01.

#### 4.1 Experiment 1

To evaluate the distant supervision method as it is applied to this task, we ran a 7-fold cross-validation on the weakly labeled training data and computed precision, recall, and  $F_1$  measure for each class. The words used to collect weakly labeled data build the nearly perfect classifier features, therefore we excluded those words from the feature set before training the classifier. The results are shown in Table 1. We achieve the macro-average  $F_1$  score of 89.01% and the accuracy rate of 95.67%.

#### 4.2 Experiment 2

The evaluation based on the 7-fold cross-validation over the weakly labeled data might not accurately reflect how well the resulting classification will perform when applied to the unlabeled dataset. We evaluated the classifier on the manually annotated test set detailed in the earlier section. Like the first experiment, all of the words and phrases involved in gathering weakly labeled data were excluded from the feature set for training a classifier. The test set has a total of 1,021 labeled reviews, none of which overlaps with the original unlabeled dataset.

The classifier was evaluated on four different subsets of the test set to see the performance of the system in different scenarios:

1. All reviews in the test set. The reviews are for restaurants which also include bars and coffee shops, where the perspectives of vegetarians are even more rare or not applicable.
2. All reviews in the test set that are longer than 250 characters. Some reviews are too short to contain useful information for the vegetarian perspectives. This subset contains 623 reviews.
3. Food reviews only. In this scenario, we exclude reviews for bars and coffee shops. We

were left with 316 reviews.

4. Food reviews that are longer than 250 characters. This subset contains 270 reviews.

The classifier attained the best performance when tested on food reviews longer than 250 characters. In this scenario, it achieved the macro-averaged  $F_1$  score of 79.40% and an accuracy rate of 92.22%. The baseline accuracy by guessing non-vegetarian for all reviews is 88.88%. The performance report for all scenarios is summarized in Table 2.

The  $F_1$  scores for vegetarian perspectives are lower across all experimental conditions possibly because of the highly imbalanced label distribution or insufficient positive training samples. Since any supervised algorithms can be integrated with our distant supervision approach, these problems can be remedied by downsampling or models that are robust to imbalanced data (Japkowicz, 2000).

It is important to note that the set of rules alone do not make any prediction on the label of our test set, because the phrases that constitute the rules do not match any of the reviews in the test set. Therefore, the distantly supervised training is necessary to build a classifier.

## 5 Discussion

In our proposed method for identifying vegetarian-written reviews, we exploited the fact that some of the reviews are already weakly labeled, motivating the words and phrases used for the distant supervision criteria. The key step for this approach is writing rules or criteria for collecting the weakly labeled data. As we focus on massive unstructured user-generated text, the criteria we use must be highly precise to prevent mislabeled data from being introduced into the training process. Although high-precision rules by definition will only recognize a small percentage of the positive samples, the problem is remedied by the fact that user-generated data are massive and constantly grow larger. In this study, our restrictive rules yield 12,514 reviews written from the perspective of a vegetarian, which is approximately 0.001% of the original dataset but suffices to build a classifier, as shown by the evaluation result.

Our approach can be thought of as similar to the bootstrapping technique, which has been explored extensively in the context of relation extraction (Gabbard et al., 2011) and text classifica-

	size	Vegetarian			Non-vegetarian			Overall	
		P	R	F1	P	R	F1	Acc.	F1
Long food reviews	270	66.67	60.00	63.15	95.06	96.25	95.65	92.22	79.40
Long reviews only	623	71.42	50.00	58.82	93.97	97.50	95.70	92.22	77.26
Food reviews only	316	64.51	58.82	61.53	95.08	96.09	95.59	92.08	78.56
All reviews	1,021	32.22	58.52	41.66	98.54	95.74	97.12	94.51	69.39

Table 2: Evaluation result based on the manually annotated test set. The reviews that contain more than 250 characters are considered long. The system performs the best when tested with long food reviews only.

tion (Mccallum, 1999). A bootstrapping algorithm starts with a small set of annotated seed training instances. Classifier training or pattern extraction is done based on the seed instances and then used to reap more training instances from the unlabeled data. This cycle continues for multiple iterations, and the performance is monitored at each iteration to ensure the improvement. A downside of this approach is that one bad iteration might introduce many mislabeled instances, degenerating the algorithm. In practice, extra human supervision must then check if the new training instances in each iteration are acceptable (Freedman et al., 2011). Our distant supervision approach requires human supervision only when writing criteria for initial training instances.

Unlike bootstrapping, our approach trains the classifier only once. Therefore, classifiers that take long to train such as Support Vector Machine can be trained within reasonable amount of time. When paired with automatic feature selection like the one used in this study, building a distantly supervised classifier is a matter of coming up with high-precision criteria to initiate the algorithm. If the criteria for distant supervision are precise enough, very little noise will be introduced into the training instances. These characteristics of our approach are attractive for massive data from user-generated content that might render computational cost of bootstrapping too costly.

## 6 Conclusion and Future Directions

We presented a distant supervision approach to identify authors’ perspectives in an unstructured, user-generated, and possibly massive corpus. Our experiment shows that high-precision restrictive rules can potentially gather weakly labeled data to train a classifier robust enough to perform well on the rest of the corpus. This method demonstrates the potential to enhance user experi-

ence on a user-generated business review website like www.yelp.com, by allowing an information-retrieval system that can fetch documents based on authors’ perspectives.

As a future direction, this similar method can be applied to massive user-generated microblogs like Twitter data to identify authors’ perspectives. For example, if one could identify each tweet as written by a Republican or a Democrat, one might be able to mine opinions from each political party separately. One could also endeavor to identify documents written by the same authors. For instance, a vegetarian is more likely to write from the perspective of a vegetarian, so we can restrict distant supervision rules to require consistent labels for the same authors in order for the reviews to enter the training set.

## Abstract

Word similarity computing is an important and fundamental task in the field of natural language processing. Most of word similarity methods perform well in synonyms, but not well between words whose similarity is vague. To overcome this problem, this paper proposes an approach of hybrid hierarchical structure computing Chinese word similarity to achieve fine-grained similarity results with HowNet 2008. The experimental results prove that the method has a better effect on computing similarity of synonyms and antonyms including nouns, verbs and adjectives. Besides, it performs stably on standard data provided by SemEval 2012.

## 1 Introduction

Word similarity computing plays an important role in various fields, such as Natural Language Understanding and Cognitive Science (Bunescu and Huang, 2010b; Mohler et al., 2011; Wang and Wan, 2011;). Moreover, it is a pivotal method in Word Sense Disambiguation (WSD).

Two main types of word similarity computing methods have been proposed. One is usually based on the thesaurus. The methods of this type utilize the structure of thesaurus (Liu and Li, 2002; Ge et al., 2010) with the advantages of preciseness and deep usage of word semantics, but a relatively complete semantic dictionary is required in order to ensure the presence of words in thesaurus. The other methods are based on large-scale corpora with some inevitable disadvantages, such as the frequent need of large-scale corpora, noise, low search efficiency etc. (Nakov and Hearst, 2008). Therefore, it is fine to create a refined thesaurus with Internet resource or large-scale corpora (Morita et al., 2011; Navigli and Ponzetto, 2010; Davidov and Rappoport, 2010) as an interim for computing word similarity.

WordNet is deemed to be very valuable thesaurus. Since Chinese that belongs to isolated

language is different from English that belongs to inflected language and the complex Chinese grammar is highly ambiguous, computing Chinese words similarity is more difficult than English under the same lack of systematic resource. HowNet is also a valuable bilingual knowledge thesaurus organized by Zhongdong Dong.

HowNet uses a markup language called KDML to describe word's concept which facilitates computer processing (Li et al., 2012). A different semantic of one word has a different DEF description. DEF is defined by a number of sememes and the descriptions of semantic relations between words. It is worth to mention that sememes are the most basic and the smallest units which cannot be easily divided (Liu and Li, 2002), and they are extracted from about six thousands of Chinese characters (Dong and Dong, 2006). An example of one DEF of *saleslady* can be described as a tree-like structure (Figure 1). The details of description in HowNet can be accessed in the paper (Dong, 2002).

In closely related works, Liu (2002) proposed an up-down algorithm on HowNet 2000 and achieved a good result. Li (2012) proposed an algorithm based on the hierarchic DEF description of words on HowNet 2002. In HowNet 2008, hierarchic DEF (Dong and Dong, 2002) definition is involved not only in words, but also in sememes. The algorithm proposed by Liu is useful, especially in example-based machine translation. The algorithm proposed by Li is detailedly experimented only in synonyms. The algorithm proposed in this paper fuses hierarchic DEF definition of sememe and hierarchic structure of sememe. It performs better and more stably both between the high similarity words namely synonyms and between the vague similarity words.

The remainder of the paper is organized as follows: Section 2 describes our algorithm in detail. Section 3 presents the experimental results and comparison. In the last section, conclusions are put forward and future work is discussed.

## 2 Similarity Computing

### 2.1 DEF similarity computing

The hierarchy of DEF is introduced as a tree-like structure. Due to different relation on the edge of trees, computing DEF similarity, unlike conventional tree similarity is one of our core works.

The similarity between one pair of nodes in the same layer of tree comes from two types of similarity, namely the relation similarity from that of its children nodes and sememe similarity itself which is described later in detail in section 2.2.

Figure 1. DEF hierarchy of *saleslady*

Figure 2. DEF hierarchy of *conductor*

For relation similarity, we take *saleslady* (Figure 1) and *conductor* (Figure 2) for example (Li, 2012) which are similar on morphology. When computing a pair of nodes similarity, such as root nodes, they are regarded as current calculating nodes (CN). Then both of CN themselves and the children nodes of CN are taken into consideration. CN (*human*) of *saleslady* has relations of *hostof*, *domain*, *modify* and *none* (no relation). With the same relations in CN (*human*) of *conductor*, we get the similarity of children nodes as one relation similarity of a pair of CN. In other words, the similarity of children nodes which have the same relation with their respective father nodes will be computed. If there is no match, the relation similarity is defaulted as small constant  $\delta$ . Every pair of nodes should be calculated in DEF tree in the same layer as formula (1).

$$Sim_{node}(S_1, S_2) = \beta_{rela} \frac{1}{N} \sum_{i=1}^N Sim_{rela\_i}(S_1, S_2) + \beta_s Sim_s(S_1, S_2) \quad (1)$$

Where,  $N$  denotes  $N$  different kinds of relations,  $Sim_{rela\_i}(S_1, S_2)$  denotes the  $i$ -th relation similarity which in fact expresses the children node similarity of the pair  $(S_1, S_2)$ ,  $Sim_s(S_1, S_2)$  denotes sememe similarity, and  $\beta_{rela} \geq 0$ ,  $\beta_s \geq 0$ ,  $\beta_{rela} + \beta_s = 1$ . Bottom-to-up algorithm will be used to recursively compute DEF similarity in order to achieve the root node similarity as the DEF similarity.

$$Sim_{DEF}(S_1, S_2) = Sim_{node}(S_1, S_2) \text{ if } S_1 = root1, S_2 = root2$$

The key point of DEF similarity computing method is not only taking the migration process of the nodes in the DEF tree into consideration (Li, 2012), but also using the relation between children nodes and their respective father node. In this way, the structure information from the DEF tree can be fully exploited.

However, there are special sememe (Attribute Sememe and Secondary Feature Sememe) whose weights are so high that the similarity unreasonably increases. Therefore, the formula (2) derived from the formula (1) is used to compute node similarity with a penalty factor  $\varepsilon$ .

$$Sim_{node}(S_1, S_2) = \beta_{rela} \frac{1}{N} \sum_{i=1}^N Sim_{rela\_i}(S_1, S_2) + \varepsilon \cdot \beta_s Sim_s(S_1, S_2) \quad (2)$$

### 2.2 Sememe similarity computing

The sememes are also described by DEF in HowNet2008. Therefore, sememe similarity ( $Sim_s(S_1, S_2)$ ) can be divided into two parts, namely structure similarity and DEF similarity.

#### 2.2.1 Structure similarity between sememes

In related works, many features of tree, such as the distance, depth and the least common nodes (LCN) in tree, have been used. This paper uses formula (3) below to compute structure similarity of sememe similarity

$$StructSim(S_1, S_2) = \frac{\alpha \cdot (\text{depth}(S_1) + \text{depth}(S_2))}{\alpha \cdot (\text{depth}(S_1) + \text{depth}(S_2)) + \text{dist}(S_1, S_2) + |\text{depth}(S_1) - \text{depth}(S_2)|} \quad (3)$$

Where,  $\text{depth}(S_1)$  represents depth of  $S_1$  in sememe tree, and  $\text{dist}(S_1, S_2)$  is the distance between  $S_1$  and  $S_2$  in sememe tree. It is clear that structure similarity of sememes increases with shorter distance between the sememes and a smaller difference in depth.

In the process of computing structure similarity, if there exists an antonym relation or converse relation between  $S_1$  and  $S_2$ , or so does the same relation in the path between  $S_1$  and  $S_2$  in sememe tree, mark a flag with “-”. However, antonym

relation and converse relation listed in HowNet document are too strict. Synonym Dictionary is used to extend antonym and converse relation.

### 2.2.2 DEF similarity between sememes

A special phenomenon exists in two aspects. On the one hand, in the process of computing DEF similarity, sememe similarity computing is needed. On the other hand, in the process of computing sememe similarity, DEF similarity computing is needed. This phenomenon brings about a cyclical calculation. In order to terminate infinite cyclical calculation, cyclical calculation will be processed only twice using formula (4)

$$Sim_s(S_1, S_2) = \begin{cases} StructSim(S_1, S_2) & \text{if last circle} \\ \beta_{struct} StructSim(S_1, S_2) + \beta_{DEF} Sim_{DEF}(S_1, S_2) & \text{if not last circle} \end{cases} \quad (4)$$

Where,  $StructSim(S_1, S_2)$  denotes structure similarity, and  $\beta_{struct} \geq 0$ ,  $\beta_{DEF} \geq 0$ ,  $\beta_{struct} + \beta_{DEF} = 1$ .  $Sim_{DEF}(S_1, S_2)$  equals 1 if there is no DEF description of sememe in both  $S_1$  and  $S_2$ . Convergence with cyclical calculation instead of twice will be researched in our future work.

### 2.3 Word similarity computing

Formula (5) below will be used to compute similarity between words containing one or more DEF description by

$$Sim_w(W_1, W_2) = \pm \max_{i=1..n, j=1..m} |Sim_{DEF}(S_{1i}, S_{2j})| \quad (5)$$

Where,  $S_{1i}$  is the  $i$ -th DEF of word  $W_1$ ,  $S_{2j}$  is the  $j$ -th DEF of word  $W_2$ , “+” and “-” depend on the flag (section 2.2.1) of max DEF similarity. In formula (5), we choose maximum DEF similarity as word similarity by default.

## 3 Experiment and Comparison

General parameters in experiments derive from Liu’s and Li’s. The special parameters are optimized with greedy algorithm. Table 1 gives all the parameters of experiment.

### 3.1 Nouns and Verbs experiment

The result of our approach contrasted with Liu’s and Li’s is shown in Table 2. In Liu’s approach,

general parameter	$\alpha$	$\delta$	$\beta_{rela}$	$\beta_s$
value	1.6	0.1	0.3	0.7
special parameter	$\beta_{struct}$	$\beta_{DEF}$	$\varepsilon$	
value	0.4	0.6	0.1	

Table 1. Parameters of experiment

the similarity between words, such as pair of “man” and “father” and pair of “pink” and “crimson”, is unreasonable. Our algorithm performs as well as Li’s in solving this problem. What’s more, through adding flag to mark antonym relation, our algorithm performs better than Li on some pairs of words, such as “man” and “woman” with a flag “-” marking antonym.

### 3.2 Adjectives experiment

Li’s algorithm and Liu’s algorithm never take antonym relation into consideration. Jiang (2008) extends Liu’s algorithm by using antonym relation. Table 3 shows that our result is much better than Jiang’s result in many words. As we know, “beautiful” and “shifty-eyed” is strictly a pair of antonyms, and “shifty-eyed” is “ugly” but not vice versa.

Word 1	Word 2	Liu’s result	Li’s result	Our result
男人 (man)	女人 (woman)	0.8611	0.8955	-0.9957
男人 (man)	父亲 (father)	1.0000	0.8902	0.8904
男人 (man)	母亲 (mother)	0.8611	0.7857	-0.8875
粉红色 (pink)	深红色 (crimson)	1.0000	0.8500	-0.9829
名声 (reputation)	硬度 (hardness)	0.6176	/	0.2585
三伏 (hot)	冬眠 (hibernate)	0.0429	/	-0.6555

Table 2. Comparison of nouns and verbs

Word 1	Word 2	Jiang’s result	Our result
美丽 (beautiful)	丑陋 (ugly)	-1.0000	-1.0000
美丽 (beautiful)	贼眉鼠眼 (shifty-eyed)	-1.0000	-0.9662
美丽 (beautiful)	优雅 (elegant)	0.7884	0.9264
舒服 (comfortably)	残疾 (handicap)	-0.0664	-0.7989
勇敢 (brave)	坚强 (strong)	0.7884	0.9500

Table 3. Comparison of adjectives

### 3.3 Synonyms experiment

In synonyms experiment, nearly 8000 pairs of words are randomly chosen as experimental data. The result (Figure 3) illustrates the effectiveness of our approach, since most of synonyms similarity is very high. Table 4 shows that our approach performs better than Li’s in computing similarity of synonyms.

Figure 3. Result of synonyms experiment

	sim>0.9	sim>0.8	sim>0.7
Li's approach	60.89%	68.75%	72.85%
Our approach	66.05%	70.21%	74.76%

Table 4. Percentage of synonyms in different ranges

### 3.4 Antonyms experiment

Nearly 3000 pairs of antonyms are crawled from web resource for experiment. And the experimental results of antonyms come from two parts. One is the absolute value of antonyms experimental result denoting antonymous degree that is shown in Figure 4, and the other one is the flag “-” (section 2.2.1) marking antonym. Table 5 shows the percent of antonym in different ranges of similarity. Table 6 shows the number of pairs of antonyms with flag “-” by our approach.

The experimental results prove the high effectiveness of our approach of computing word similarity for most of antonyms similarity. However, it performs not very well in finding the flag “-” which marks antonym. With the development of HowNet, our approach will perform better.

Absolute similarity	>0.9	>0.8	>0.7
	50.02%	61.89%	68.70%

Table 5. Percentage of antonyms in different ranges

method	number in 3000 pairs
Original	863
Extend-Antoymys	966

Table 6. Number of antonyms with flag “-”

### 3.5 SemEval experiment

The datasets of Evaluating Chinese Word Similarity task In SemEval 2012 is used as the experimental data, of which the values are normalized as [0, 1]. The experimental data (130 pair words) covers similarity ranging from 0 to 1. Experimental data are sequenced by their similarity

from high to low. The result of experiments is shown in Figure 5.

Figure 4. Result of antonyms experiment

Compared with Liu's method, the result shows that in the pairs of high similarity words, the difference of similarity is nearly 0.095. Besides, the largest difference is lower than 0.1. In Figure 5, the low difference value (0.01) between the highest difference and lowest difference is verified that the approach proposed by this paper is effective and stable in different range of similarity.

Figure 5. Comparison of experimental results

## 4 Conclusions and Future work

This paper proposes a new approach for computing word similarity between Chinese words using HowNet. The contribution can be concluded below. (1) Improve the accuracy of similarity by using EF description in sememe hierarchy; (2) substantiate that different kinds of sememe describe DEF in different weight; (3) use the Synonym Dictionary to alleviate strict limitations in antonym and converse relation.

Due to the importance of word context, in future, for documents, a method to choose suitable DEF for the word is necessary depending on context instead of maximum DEF similarity. Moreover, the alignment between sub-description of DEF is meaningful in computing semantic similarity. We will pay extra attention to sub-tree alignment. Based on these, we will optimize parameters for various applications.

## Abstract

This paper focuses on the novel task of automatic extraction of phrases related to causes of emotions. The analysis of emotional causes in sentences, where emotions are explicitly indicated through emotion keywords can provide the foundation for research on challenging task of recognition of implicit affect from text. We developed a corpus of emotion causes specific for 22 emotions. Based on the analysis of this corpus we introduce a method for the detection of the linguistic relations between an emotion and its cause and the extraction of the phrases describing the emotion causes. The method employs syntactic and dependency parser and rules for the analysis of eight types of the emotion-cause linguistic relations. The results of evaluation showed that our method performed with high level of accuracy (82%).

## 1 Introduction and Background

Emotional reactions to three salient aspects of the world, namely (1) events and their consequences, (2) agents and their actions, and (3) objects, are based on the nature of cognitive origins and can be triggered under specific conditions (Ortony et al., 1988). The cognitive model of emotions (OCC model of emotions) arranges 22 emotions in three substantially independent classes according to the aspects of the world that are in focus of evaluation.

Recently, the task of automatic recognition of distinct emotions conveyed in text has been gaining increased attention of researchers in the areas of natural language processing and computational linguistics (Alm, 2008; Aman and Szpakowicz, 2008; Boucouvalas, 2003; Chaumartin, 2007; Katz et al., 2007; Kozareva et al., 2007; Liu et al., 2003; Neviarouskaya et al., 2011; Purver and

Battersby, 2012; Strapparava and Mihalcea, 2008; Suttles and Ide, 2013). To understand emotions expressed in written language, it is important to analyse the causes of emotions ("*what caused a particular emotion*") and eliciting conditions ("*under what conditions*"). The challenge of emotion cause detection in text has been recently tackled by Chen et al. (2010), who developed two sets of linguistic pattern-based features (manually generalized patterns and automatically generalized patterns) for extraction of causes for emotions in Chinese. The linguistic-pattern-based methodology described in (Chen et al., 2010) inspired the development of a method for the identification of Italian sentences that contain emotion cause phrases and the retrieval of emotion – emotion cause phrase couples (Russo et al., 2011). In their subsequent work, Caselli et al. (2012) semi-automatically assigned polarity values to Italian nouns that potentially represent nominal cause events associated with emotions.

In this work, we introduce a novel method for automatic extraction of emotion causes. The main contributions of our work are as follows: (1) development of a corpus of emotion causes and (2) deep analysis of cause events specific for 22 emotions from the OCC model. The analyses of emotional causes in sentences, where emotions are explicitly indicated through emotion keywords, and conditions that lead to emotional experience can provide the foundation for research on challenging task of recognition of implicit affect from text.

## 2 Development and Analysis of the Corpus of Emotion Causes

### 2.1 Creation of the Dataset of Sentences with Explicitly Indicated Emotions

In the text of (Ortony et al., 1988), about 130 tokens (emotion words) have been distributed between 22 emotion types. For example, '*glad*' and

'happy' correspond to *Joy* emotion class; 'scared' and 'terrified' are associated with *Fear* emotion; and 'awe' and 'esteem' describe *Admiration* emotion. We consider these tokens as seed terms for extraction of sentences that contain information on what caused the particular emotion.

In addition to 22 sentences provided in (Ortony et al., 1988) as examples for each emotion type, we manually collected 510 sentences with emotion tokens and explicitly mentioned emotion causes from online ABBYY Lingvo dictionary (<http://www.lingvo-online.ru/en>). 118 emotion tokens were found productive, resulting in at least one cause-containing sentence per emotion token.

The corpus consisting of 532 sentences was manually annotated. The annotation task included the following subtasks: (1) to define an agent or an experiencer of emotion specified by emotion token; (2) to delimit the phrase describing the cause of emotion; (3) to define the linguistic relation between emotion and its cause; (4) to classify the cause event as positive, negative, or neutral; and (5) to extract tokens that influence the polarity of the phrase.

## 2.2 Corpus Analysis

We performed the detailed analysis of the created corpus. The agent or experiencer of emotion specified by emotion token was defined in 495 sentences (93% from the whole corpus). In the corpus, about 46% of sentences are related to positive emotions, and about 54% of sentences express negative emotions.

The analysis of polarity of cause events from the annotated corpus showed the following distribution of the causes according to the sentiment categories: (1) positive – about 27%; (2) negative – about 29%; and (3) neutral – about 44% of the cause events. These figures emphasize the fact that the cause of emotion expressed in text is not necessarily described by sentiment words. Interesting observation is that cause events are negative in 2.9% of sentences with positive emotions, and positive cause events occur in 4.5% of sentences with negative emotions (for example, '*And people changed from diet to diet and felt guilty [negative emotion] because they continued to like the things they weren't supposed to*').

The important feature that was identified in each sentence was the linguistic relation between emotion and its cause. Based on the analysis of the annotated data, we distinguish eight types of such linguistic relations:

1. One-word preposition (OWP). For example, 'at' in the sentence '*And while she gaped*

*with disappointment at his lukewarmness, he got himself away, at ten*'.

2. Complex preposition (CP). For example, 'because of' in the sentence '*He was himself a Greek, and there were many who felt offended because of his height*'.

3. Coordinating conjunction (CC). For example, 'for' in the sentence '*La Cote was much depressed, for he had scored here the worst failure of his campaign*'.

4. Subordinating conjunction (SC). For example, 'because' in the sentence '*And people changed from diet to diet and felt guilty because they continued to like the things they weren't supposed to*'.

5. Subject (SUBJ). For example, in the sentence '*His tone scared her more than anything she could remember*', the subject 'his tone' represents the cause of *Fear* emotion expressed by the verb 'scared'.

6. Verb or predicate (V). For example, the predicate 'filled with' connects the *Joy* emotion with its cause in the sentence '*As for the captain, the presence in his room of the children, who came to cheer up Ilusha, filled his heart from the first with ecstatic joy*'.

7. Object (OBJ). For example, in the sentence '*I adore poetry*', the object 'poetry' triggers *Love* emotion that is reflected through the verb 'adore'.

8. Attributive nominal (ATT). For example, in the sentence '*It is a sad tale, a very sad tale*', emotional adjective 'sad' describes the noun 'tale' through attributive nominal relation (in this sentence, 'tale' causes *Distress* emotion).

In Table 1, the specific emotion-cause linguistic relations that were found in our corpus of sentences are listed according to their frequency. One-word prepositions (including 'to', 'for', 'of', 'at', 'with', 'by', 'about', 'over' etc.) acting as linkages between emotion tokens and phrases describing the cause of emotion occur in about 68.2% of sentences. Subordinating conjunctions (examples include 'that', 'when', 'because', 'as' etc.) constitute about 21.4% of sentences. The object and subject are the next frequent relation types (about 6% and 2.3% of sentences, respectively).

## 3 Method for Extraction of Emotion Causes

Our method for automatic extraction of emotion causes is based on the analysis of syntactic and dependency information from the parser. In our

work we employ Connexor Machine Syntax (<http://www.connexor.eu/technology/machinese/>) that is applied to each sentence in order to get lemmas, dependencies, syntactic and morphological information (see example in Table 2). Using parser output, the method extracts phrases that characterize the emotion causes.

The algorithm detects and extracts cause phrases introduced by prepositions (OWP and CP) through three rules:

1. POSTMODIFIER rule: if morphological tag of the cause marker is *PREP* and this preposition is linked with the emotion token through *mod* syntactic relation, then extract all tokens related to this preposition.

2. NEXT TOKEN rule: if morphological tag of the cause marker is *PREP* and syntactic relation of this preposition is unavailable (*null* relation), then if this cause marker directly follows the emotion token, extract all tokens related to this preposition.

3. VERB-MEDIATED RELATION rule: if morphological tag of the cause marker is *PREP* and this preposition is directly connected with

Table 2. Example of parser output

verb, to which emotion token is related within the clause, and the id of preposition is higher than that of emotion token, then extract all tokens related to this preposition.

The rules for extraction of phrases connected to emotion tokens through conjunctions (SC and CC) are as follows:

1. THAT rule: if morphological tag of the '*that*' cause marker is *CS* and the id of conjunction is higher than that of emotion token, then if verb of subordinate clause, to which the conjunction '*that*' is connected, is related to emotion token through chain of relations, extract all tokens related to the verb of subordinate clause.

2. DEPENDENT CLAUSE rule: if morphological tag of the cause marker is *CS* or *CC*, and the dependent verb, to which conjunction is related, is connected to the main verb, to which emotion token is related (here, the emotion token might be the verb itself), then extract all tokens related to the verb of dependent clause.

To detect verbs for the above rules, the algorithm looks for the following functional tags: @+FMAINV (finite main verb), @-FMAINV (nonfinite main verb), and @<P-FMAINV (nonfinite clause as preposition complement).

The extraction of emotion causes represented by either subject (SUBJ), or predicate (V), or object (OBJ), or attributive nominal (ATT) linguistic relations is based on the analysis of *subj*, *obj*, and *att* syntactic relations and the corresponding tokens.

## 4 Evaluation

Based on the emotion cause phrases extracted by human annotator from our corpus consisting of 532 sentences, we evaluated the appropriateness of the phrases extracted by our algorithm. In each pair of phrases, the number of words was calculated (namely, number of gold standard tokens and number of automatically extracted tokens). Then, the number of words correctly extracted by our algorithm was found, and we calculated precision, recall, and F-score for each automatically extracted phrase. The results averaged over all the phrases are given in Table 3 (including the results on different groups and all emotion cause linguistic relations).

Emotion cause linguistic relations	Accuracy of phrase extraction		
	Precision	Recall	F-score
Prepositions (OWP, CP)	0.715	0.723	0.700
Conjunctions (SC, CC)	0.470	0.549	0.473
Subject, predicate, object, and attributive nominal (SUBJ, V, OBJ, ATT)	0.787	0.793	0.772
All relations	<b>0.670</b>	<b>0.692</b>	<b>0.658</b>
All relations (after improving the method based on error analysis)	<b>0.821</b>	<b>0.852</b>	<b>0.810</b>

Table 3. Evaluation of the appropriateness of automatically extracted emotion causes

As seen from the obtained results, our algorithm achieved the highest level of precision (0.787) in extracting emotion cause phrases represented by subject, predicate, object, and attributive nominal linguistic relations, while it was least precise (0.470) in case of emotion causes introduced by conjunctions. We obtained good results considering all emotion cause linguistic relations: precision in 0.670, recall in 0.692, and F-score in 0.658.

We performed an error analysis on the sentences, where our method failed to extract correct phrases. The classification and distribution of errors is given in Table 4. In most cases (about 44.8%), the method failures were due to missing rule for infinitive marker 'to' (morphological tag *INFMARK*>, in contrast to preposition tag *PREP*). For example, 'to' in the sentence *In that regard, New Zealand is proud to work towards nuclear disarmament with the other members of the New Agenda Coalition*. About 22.4% of errors were caused by inability of the parser to output correct tags for syntactic relations. Analysis of 'when' as a relative adverb (*ADV* and *WH* morphological tags), in addition to it as a subor-

Error type	Frequency (number)	Frequency (%)
Infinitive marker 'to'	60	44.78
Null or incorrect tag from parser	30	22.39
'When' as a relative adverb	18	13.43
Missing subordinating conjunction 'that'	11	8.21
THAT rule	4	2.99
POSTMODIFIER rule	3	2.24
Emotion phrase 'look forward'	3	2.24
Reference resolution	3	2.24
Coordinating conjunction in SUBJ and OBJ rules	2	1.5
<b>Total</b>	<b>134</b>	<b>100</b>

Table 4. Classification and distribution of errors

ordinating conjunction, would deal with about 13.4% of errors. We found that the emotion causes represented by subordinate clauses without such a marker of subordination as 'that' pose the main challenge, as the parser outputs *null* relations for such dependent clauses (for example, clause *I never had to lie then* in the sentence *I reckon I was so glad I never had to lie then*). The analysis of errors showed the necessity to improve several rules (such as THAT, POSTMODIFIER, SUBJ, and OBJ rules). The method would also benefit from adding reference resolution. For example, using reference resolution, the method could extract *these difficulties* instead of *they* as emotion cause from the sentence *I could not dwell upon these difficulties fully, for they made me far too uneasy*.

After improving the emotion cause extraction method by adding and modifying the rules, we obtained the following evaluation results: precision in 0.821, recall in 0.852, and F-score in 0.810 (last row in Table 3). In that way, our method performed with about 15% gain in accuracy.

## 5 Conclusions

The main contributions of our work are the creation of a corpus of emotion causes specific for 22 emotions from the OCC model and the development of a novel method for extraction of emotion causes from sentences based on the analysis of syntactic and dependency information provided by the parser. In future research we plan to improve our emotion cause extraction method and incorporate the automatic detection of an experiencer of emotion specified by emotion token and the classification of causes as positive, negative, or neutral.

## Abstract

We introduce a novel technique that uses hierarchical phrase-based statistical machine translation (SMT) for grammar correction. SMT systems provide a uniform platform for any sequence transformation task. Thus grammar correction can be considered a translation problem from incorrect text to correct text. Over the years, grammar correction data in the electronic form (i.e., parallel corpora of incorrect and correct sentences) has increased manifolds in quality and quantity, making SMT systems feasible for grammar correction. Firstly, sophisticated translation models like hierarchical phrase-based SMT can handle errors as complicated as reordering or insertion, which were difficult to deal with previously through the mediation of rule based systems. Secondly, this SMT based correction technique is similar in spirit to human correction, because the system extracts grammar rules from the corpus and later uses these rules to translate incorrect sentences to correct sentences. We describe how to use Joshua, a hierarchical phrase-based SMT system for grammar correction. An accuracy of 0.77 (BLEU score) establishes the efficacy of our approach.

## 1 Introduction

We consider grammar correction as a translation problem - translation from an incorrect sentence to a correct sentence. The correcting system is trained using a parallel corpus of incorrect and their corresponding correct sentences. The system learns SCFG (synchronous context free grammar) rules (Chiang, 2005) during translation. SCFG rules look like this:-

- $X \rightarrow X_1 \text{ of } X_2, X_1 \text{ for } X_2$

The above rule implies that phrases  $X_1$  and  $X_2$  in source language are translated to phrases in target language, while *of* is replaced with *for*. The position of both phrases w.r.t. *of* remains same in the target language, which means there is no reordering of phrases.

After generating such grammar rules, it converts the erroneous sentence to a tree using the rules of grammar, i.e., the left hand side of the SCFG rules. It then applies correction rules, i.e., the right hand side of the SCFG rules, to convert the tree as explained later in section 3. The yield of the tree generates the corrected sentence.

Here are various types of errors that one encounters in grammar correction:

Article choice errors:- *a Himalayas is the longest mountain range in the world.* The correct translation is '*the Himalayas is the longest mountain range in the world*'.

Preposition errors:- *Helicopter crashed at central London.* The correct translation is '*Helicopter crashed in central London*'.

Word form errors:- *The rain mays fall in July* should be changed to '*The rain may fall in July*'.

Word insertion errors:- *The court deemed necessary that she respond to the summons* should be changed to '*The court deemed it necessary that she respond to the summons*'.

Reordering errors:- *never we miss deadlines* should be corrected to '*we never miss deadlines*'.

Article choice errors and preposition errors have been tackled by rule based techniques. But rules are customized, so to say, for each error, which is a time consuming and fragile process. SMT, on the other hand, treats all errors uniformly, considering error correction as a translation problem. Secondly, problems such as reordering or word insertion are well known in machine translation.

The roadmap of the paper is as follows. In section 2, we discuss previous work. In section 3, we elaborate on how hierarchical machine translation system can do automatic grammar correction. Section 4 states the grammar rules that are extracted by the system automatically. In section 5, we present our experiments followed by the results in section 6. We conclude in section 7 with pointers to future work.

## 2 Background

Initially the work that has been done in grammar correction is based on identifying grammar errors. Chodorow and Leacock (2000) used an ngram model for error detection by comparing correct ngrams with ngrams to be tested. Later, classification techniques like Maximum entropy models have been proposed (Izumi et al., 2003; Tetreault and Chodorow, 2008; Tetreault and Chodorow, 2008). These classifiers not only identify errors, but also correct them. These methods do not make use of erroneous words thus making error correction similar to the task of filling empty blanks. While in editing sentences, humans often require the information in the erroneous words for grammar correction.

In other works, machine translation has been previously used for grammar correction. Brockett (2006) used phrasal based MT for noun correction of ESL students. Désilets and Hermet (2009) translate from native language L1 to L2 and back to L1 to correct grammar in their native languages. Mizumoto (2012) also used phrase-based SMT for error correction. He used large-scale learner corpus to train his system. These translation techniques suffered from lack of good quality parallel corpora and also good translation systems.

If high quality parallel corpus can be obtained, the task of grammar correction becomes easy using a powerful translation model like hierarchical phrase based machine translation.

## 3 Automatic grammar correction using hierarchical phrase-based SMT

In this section we discuss the working and the implementation of the grammar correction system.

### 3.1 Working

Grammar correction can be seen as a process of translation of incorrect sentences to correct ones. Basically the translation system needs a parallel

corpus of incorrect and correct sentences. The system starts with an alignment to obtain word to word translation probabilities. The second stage is grammar extraction using the hiero style of grammar (Chiang, 2005). Non-terminals are generalized form of phrases, *i.e.*, all possible phrases allowed in the framework of Chiang (2005) are represented by the symbol  $X$ . There is another symbol  $S$  to start the parse tree. These rules are in the form of SCFG rules. If the incorrect sentence is, ‘*few has arrived*’ and the correct sentence is, ‘*few have arrived*’, the grammar rules extracted are :-

- $X \rightarrow \text{few has } X_1, \text{ few have } X_1$
- $X \rightarrow \text{arrived}, \text{ arrived}$

The first rule means that *few has* followed by a phrase may be translated to *few have* followed by translation of that phrase. Second rule suggests that any phrase that yields *arrived* can be translated to *arrived*.

After the grammar extraction is done, the left sides of the grammar rules are stripped and used to generate the parse tree of the sentence *few has arrived*.

Here are the left side rules:-

- $X \rightarrow \text{few has } X_1$
- $X \rightarrow \text{arrived}$

Also, there is a “glue rule” to combine two trees or just derive a non terminal from the start symbol  $S$ .

- $S \rightarrow S^1 X \mid X$

The glue rule is used to start the parsing process. It generates a sub-tree for the string *few has* and a non-terminal for *arrived*. Then the right side rules are used to convert *few has* to *few have* as shown in Figure 1, while *arrived* is translated as *arrived*.
