## FOREWORD

Welcome to the 6th International Joint Conference on Natural Language Processing (IJCNLP) in Nagoya, Japan. IJCNLP was initiated in 2004 by The Asian Federation of Natural Language Processing (AFNLP) with the major goal to provide a platform for researchers and professionals from around the world to share their experiences related to natural language processing and computational linguistics. In the past years, IJCNLPs were held in 5 different places: Hainan Island (2004), Jeju Island (2005), Hyderabad (2008), Singapore (2009), and Chiang Mai (2011). This year the 6th IJCNLP is held in Nagoya Congress Center on October 14-18, 2013. The conference covers a broad spectrum of technical areas related to natural language and computation. Besides main conference, the program includes 2 keynote speeches, 3 tutorials, 12 demonstrations, and 7 workshops.

We would like to thank many people who contribute their efforts to IJCNLP 2013. Program chairs Ruslan Mitkov and Jong C. Park select a strong set of papers and organize a wonderful program. PC coordinators Jin-Woo Chung and Isabel Duran support authors and PC committee a stable submission and review platform. Workshop chairs Naoaki Okazaki and Scott Wen-tau Yih organize 7 nice pre-conference and post-conference workshops. Tutorial chairs Vincent Ng and Satoshi Sekine choose 3 very good tutorials. Demo chairs Hang Li and Kentaro Torisawa recommend 12 demonstrations. Sponsorship chair Hiromi Nakaiwa designs sponsor packages and finds financial supports. We thank all the sponsors. Publicity chairs Gareth Jones, Gary Geunbae Lee, Diego Mollá-Aliod, Chengqing Zong and Stajner Sanja help circulate the conference information and promote the conference. We would like to express our special thanks to publication chairs Jing Jiang and Lun-Wei Ku. They bore two babies during the organization of the conference. After the hard work, they deliver an excellent proceeding to the participants. Finally, we are very thankful to those people who dedicate their time and energy to IJCNLP 2013, but are not mentioned in the above. Without them, we would not have had a successful conference.

Hsin-Hsi Chen, General Chair, National Taiwan University, Taiwan  
Hitoshi Isahara, Organization Chair, Toyohashi University of Technology, Japan

October 15, 2013

## PREFACE

As the flagship conference of the Asian Federation of Natural Language Processing (AFNLP), IJCNLP continues to establish itself as a highly influential international event. IJCNLP 2013 covers a broad spectrum of technical areas related to Natural Language Processing. The conference includes regular papers, short papers, poster papers, and system demonstrations, as well as pre- and post-conference tutorials and workshops.

This year, we received 363 paper submissions, which is not as many as the record submissions in the previous conference (e.g., 478 in 2011) but still quite admirable, considering the tough competition for good papers this year, with EMNLP 2013 and RANLP 2013, and the fact that many organizations have restricted their spending in the current economic climate. This represents increasing interest in research on NLP and the growing reputation of IJCNLP as an international event. The 363 submissions include 235 regular, 86 short, and 42 poster paper submissions from more than 37 countries. In particular, approximately 63% of the papers are from 14 countries and areas in Asia Pacific, 18% from 14 countries in Europe, 14% from the United States and Canada; in addition, 4% of the papers are from the Middle East and Africa, and 1% come from South America.

We would like to thank all the authors for submitting papers to IJCNLP 2013. The significant increase in the number of submissions, the topics covered and the wide range of demographic areas represent a rapid and steady growth of our field and hold promise for a bright future. We would also like to thank the 23 area chairs and 439 program committee members for writing over 1078 reviews and meta-reviews and for paving the way for the final paper selection. Of all 363 submissions, a total of 88 papers were accepted as regular papers, representing a healthy 24.4% acceptance rate. Additional 56 papers were accepted as short papers, which, together with regular papers, represent a 39.8% acceptance rate. In addition, 74 papers were accepted as poster papers. Due to various reasons, some authors of accepted papers chose to withdraw their submissions afterwards. As a result, we have 85 regular papers (23.4% acceptance rate), 53 short papers (38.0% acceptance rate), and 62 poster papers. All the regular and short papers are presented orally, and all the poster papers are presented in the plenary poster session. We are extremely grateful to the area chairs and program committee members for all their hard work, without which the preparation of this program would not have been possible. The help of PC coordinators is also much appreciated.

We are delighted to have two keynote speakers addressing different aspects of NLP in IJCNLP 2013. Hwee Tou Ng will present a talk about improving students' writing with automated grammatical error correction, including the review of recent research and advances in grammatical error correction. Roberto Navigli will present a talk about BabelNet 2.0, a very large multilingual semantic network that covers 50 languages and provides both lexicographic and encyclopedic knowledge for all the open-class parts of speech. These plenary talks will surely be not only informative but also enlightening to the audience, leading to many innovative research ideas. We would like to thank General Chair Hsin-Hsi Chen, the Local Arrangements Committee headed by Hitoshi Isahara, and the AFNLP Conference Coordination Committee chaired by Yuji Matsumoto, for their help and advice. Thanks to Jing Jiang and Lun-Wei Ku, the Publication Committee Chairs, for putting the proceedings together, and all the other committee chairs for their great work.

We hope that you enjoy the conference!

Ruslan Mitkov, University of Wolverhampton, England, United Kingdom  
Jong C. Park, Korea Advanced Institute of Science and Technology, Republic of Korea  
IJCNLP 2013 Program Committee Chairs

October 15, 2013

**General Chair**

Hsin-Hsi Chen, National Taiwan University, Taiwan

**Program Committee Chairs**

Ruslan Mitkov, University of Wolverhampton, UK  
Jong C. Park, KAIST, Korea

**Local Organization Committee Chair**

Hitoshi Isahara, Toyohashi University of Technology, Japan

**Workshop Committee Chairs**

Naoaki Okazaki, Tohoku University, Japan  
Scott Wen-tau Yih, Microsoft Research, USA

**Tutorial Chairs**

Vincent Ng, The University of Texas at Dallas, USA  
Satoshi Sekine, New York University, USA

**Demo Chairs**

Hang Li, Huawei Technologies Co., China  
Kentaro Torisawa, NICT, Japan

**Sponsorship Committee Chair**

Hiromi Nakaiwa, NTT, Japan

**Publication Committee Chairs**

Jing Jiang, Singapore Management University, Singapore  
Lun-Wei Ku, Academia Sinica, Taiwan

**Finance Committee Chairs**

Masayuki Okabe, Toyohashi University of Technology, Japan  
Masatoshi Tsuchiya, Toyohashi University of Technology, Japan

**Publicity Committee Chairs**

Gareth Jones, Dublin City University, Ireland  
Gary Geunbae Lee, POSTECH, Korea  
Diego Mollá-Aliod, Macquarie University, Australia  
Chengqing Zong, Chinese Academy of Sciences, China

**PC Coodinators**

Jin-Woo Chung, KAIST, Korea  
Isabel Duran, University of Wolverhampton, UK

## **Area Chairs**

### **Phonology and Morphology**

Mans Hulden, University of Arizona, USA

### **Syntax and Semantics**

Mary Dalrymple, University of Oxford, UK

### **Pragmatics and Discourse**

Joey Frazee, University of Texas, USA

### **Dialogue and Dialogue Systems**

Gary Geunbae Lee, POSTECH, South Korea

### **Language Resources**

Key-Sun Choi, KAIST, South Korea

Doaa Samy, Cairo University, Egypt

### **Statistical and ML Language Models**

Fumiyo Fukumoto, University of Yamanashi, Japan

Leonor Becerra Bonache, Universitat Rovira i Virgili, Spain

### **POS Tagging and Parsing**

Sandra Kuebler, Indiana University, USA

Yusuke Miyao, National Institute of Informatics, Japan

### **Semantic Processing**

Alessandro Moschitti, University of Trento, Italy

Idan Szpektor, Yahoo! Research

### **Information Extraction**

Nigel Collier, National Institute of Informatics, Japan

Jin-Dong Kim, Database Center for Life Science, Japan

### **Text Summarisation**

Inderjeet Mani, Yahoo! Labs, Sunnyvale, USA

Helen Meng, Chinese University of Hong Kong, Hong Kong

### **Information Retrieval and QA**

Qiaozhu Mei, University of Michigan, USA

Iustin Dornescu University of Wolverhampton, UK

### **Text Mining**

Wai Lam, Chinese University of Hong Kong, Hong Kong

## **Opinion Mining**

Alfonso Urena, University of Jaen, Spain

## **NLP for Educational Applications**

Jin-Dong Kim, Database Center for Life Science, Japan

Nigel Collier, National Institute of Informatics, Japan

## **Recent NLP Applications**

Constantin Orasan, University of Wolverhampton, UK

## **Machine Translation**

Dekai Wu, The Hong Kong University of Science and Technology, Hong Kong

Young-suk Lee, IBM, USA

## **Reviewers**

Muhammad Abdul-Mageed, Amjad Abu-Jbara, Hani AbuSalem, Karteek Addanki, Khurshid Ahmad, Akiko Aizawa, Ahmet Aker, Iñaki Alegria, Hadi Amiri, Dana Angluin, Kenji Araki, Eiji Aramaki, Ash Asudeh, Sören Auer, Nguyen Bach, Amit Bagga, Alexandra Balahur, Rafael E. ## Table of Contents

<i>Semi-Supervised Answer Extraction from Discussion Forums</i>	
Rose Catherine, Rashmi Gangadharaiyah, Karthik Visweswariah and Dinesh Raghu .....	1
<i>WordTopic-MultiRank: A New Method for Automatic Keyphrase Extraction</i>	
Fan Zhang, Lian'en Huang and Bo Peng .....	10
<i>Towards Contextual Healthiness Classification of Food Items - A Linguistic Approach</i>	
Michael Wiegand and Dietrich Klakow .....	19
<i>Learning a Replacement Model for Query Segmentation with Consistency in Search Logs</i>	
Wei Zhang, Yunbo Cao, Chin-Yew Lin, Jian Su and Chew-Lim Tan .....	28
<i>Precise Information Retrieval Exploiting Predicate-Argument Structures</i>	
Daisuke Kawahara, Keiji Shinzato, Tomohide Shibata and Sadao Kurohashi .....	37
<i>Global Model for Hierarchical Multi-Label Text Classification</i>	
Yugo Murawaki .....	46
<i>(Pre-)Annotation of Topic-Focus Articulation in Prague Czech-English Dependency Treebank</i>	
Jiří Mírovský, Kateřina Rysová, Magdaléna Rysová and Eva Hajičová .....	55
<i>Animacy Acquisition Using Morphological Case</i>	
Riyaz Ahmad Bhat and Dipti Misra Sharma .....	64
<i>The Complexity of Math Problems – Linguistic, or Computational?</i>	
Takuya Matsuzaki, Hidenao Iwane, Hirokazu Anai and Noriko Arai .....	73
<i>Hybrid Models for Lexical Acquisition of Correlated Styles</i>	
Julian Brooke and Graeme Hirst .....	82
<i>Introducing the Prague Discourse Treebank 1.0</i>	
Lucie Poláková, Jiří Mírovský, Anna Nedoluzhko, Pavlína Jínová, Šárka Zikánová and Eva Hajičová .....	91
<i>Multilingual Mention Detection for Coreference Resolution</i>	
Olga Uryupina and Alessandro Moschitti .....	100
<i>A Weakly Supervised Bayesian Model for Violence Detection in Social Media</i>	
Amparo Elizabeth Cano Basave, Yulan He, Kang Liu and Jun Zhao .....	109
<i>Detecting Spammers in Community Question Answering</i>	
Zhuoye Ding, Yeyun Gong, Yaqian Zhou, Qi Zhang and Xuanjing Huang .....	118
<i>Chinese Informal Word Normalization: an Experimental Study</i>	
Aobo Wang, Min-Yen Kan, Daniel Andrade, Takashi Onishi and Kai Ishikawa .....	127
<i>Feature Selection Using a Semantic Hierarchy for Event Recognition and Type Classification</i>	
Yoonjae Jeong and Sung-Hyon Myaeng .....	136
<i>Romanization-based Approach to Morphological Analysis in Korean SMS Text Processing</i>	
Youngsam Kim and Hyopil Shin .....	145

<i>Efficient Word Lattice Generation for Joint Word Segmentation and POS Tagging in Japanese</i> Nobuhiro Kaji and Masaru Kitsuregawa.....	153
<i>A Simple Approach to Unknown Word Processing in Japanese Morphological Analysis</i> Ryohei Sasano, Sadao Kurohashi and Manabu Okumura.....	162
<i>Chinese Word Segmentation by Mining Maximized Substrings</i> Mo Shen, Daisuke Kawahara and Sadao Kurohashi .....	171
<i>Capturing Long-distance Dependencies in Sequence Models: A Case Study of Chinese Part-of-speech Tagging</i> Weiwei Sun, Xiaochang Peng and Xiaojun Wan .....	180
<i>Exploring Semantic Information in Hindi WordNet for Hindi Dependency Parsing</i> Sambhav Jain, Naman Jain, Aniruddha Tammewar, Riyaz Ahmad Bhat and Dipti Sharma.....	189
<i>Towards Robust Cross-Domain Domain Adaptation for Part-of-Speech Tagging</i> Tobias Schnabel and Hinrich Schütze .....	198
<i>Dependency Parsing for Identifying Hungarian Light Verb Constructions</i> Veronika Vincze, János Zsibrita and István Nagy T. ....	207
<i>Written Dialog and Social Power: Manifestations of Different Types of Power in Dialog Behavior</i> Vinodkumar Prabhakaran and Owen Rambow .....	216
<i>Evaluation of the Scusi? Spoken Language Interpretation System – A Case Study</i> Thomas Kleinbauer, Ingrid Zukerman and Su Nam Kim .....	225
<i>A Noisy Channel Approach to Error Correction in Spoken Referring Expressions</i> Su Nam Kim, Ingrid Zukerman, Thomas Kleinbauer and Farshid Zavareh .....	234
<i>Natural Language Query Refinement for Problem Resolution from Crowd-Sourced Semi-Structured Data</i> Rashmi Gangadharaiah and Balakrishnan Narayanaswamy.....	243
<i>Ensemble Triangulation for Statistical Machine Translation</i> Majid Razmara and Anoop Sarkar.....	252
<i>Robust Transliteration Mining from Comparable Corpora with Bilingual Topic Models</i> John Richardson, Toshiaki Nakazawa and Sadao Kurohashi .....	261
<i>SuMT: A Framework of Summarization and MT</i> Houda Bouamor, Behrang Mohit and Kemal Oflazer .....	270
<i>Tuning SMT with a Large Number of Features via Online Feature Grouping</i> Lemao Liu, Tiejun Zhao, Taro Watanabe and Eiichiro Sumita .....	279
<i>Multimodal Comparable Corpora as Resources for Extracting Parallel Data: Parallel Phrases Extraction</i> Haithem Afli, Loïc Barrault and Holger Schwenk .....	286
<i>Bootstrapping Large-scale Named Entities using URL-Text Hybrid Patterns</i> Chao Zhang, Shiqi Zhao and Haifeng Wang .....	293
<i>Feature-Rich Segment-Based News Event Detection on Twitter</i> Yanxia Qin, Yue Zhang, Min Zhang and Dequan Zheng .....	302

<i>Building Chinese Event Type Paradigm Based on Trigger Clustering</i> Xiao Ding, Bing Qin and Ting Liu .....	311
<i>Chinese Named Entity Abbreviation Generation Using First-Order Logic</i> Huan Chen, Qi Zhang, Jin Qian and Xuanjing Huang .....	320
<i>Full-coverage Identification of English Light Verb Constructions</i> István Nagy T., Veronika Vincze and Richárd Farkas .....	329
<i>Detecting Deceptive Opinions with Profile Compatibility</i> Vanessa Wei Feng and Graeme Hirst .....	338
<i>Behind the Times: Detecting Epoch Changes using Large Corpora</i> Octavian Popescu and Carlo Strapparava .....	347
<i>How Noisy Social Media Text, How Different Social Media Sources?</i> Timothy Baldwin, Paul Cook, Marco Lui, Andrew MacKinlay and Li Wang .....	356
<i>Who Had the Upper Hand? Ranking Participants of Interactions Based on Their Relative Power</i> Vinodkumar Prabhakaran, Ajita John and Dorée D. Seligmann .....	365
<i>Readability Indices for Automatic Evaluation of Text Simplification Systems: A Feasibility Study for Spanish</i> Sanja Štajner and Horacio Saggion .....	374
<i>Weasels, Hedges and Peacocks: Discourse-level Uncertainty in Wikipedia Articles</i> Veronika Vincze .....	383
<i>Automatically Developing a Fine-grained Arabic Named Entity Corpus and Gazetteer by utilizing Wikipedia</i> Fahd Alotaibi and Mark Lee .....	392
<i>Ranking Translation Candidates Acquired from Comparable Corpora</i> Rima Harastani, Béatrice Daille and Emmanuel Morin .....	401
<i>Using the Semantic-Syntactic Interface for Reliable Arabic Modality Annotation</i> Rania Al-Sabbagh, Jana Diesner and Roxana Girju .....	410
<i>Mapping Rules for Building a Tunisian Dialect Lexicon and Generating Corpora</i> Rahma Boujelbane, Mariem Ellouze Khemekhem and Lamia Hadrach Belguith .....	419
<i>Hypothesis Refinement Using Agreement Constraints in Machine Translation</i> Ankur Gandhe and Rashmi Gangadharaiah .....	429
<i>Scalable Variational Inference for Extracting Hierarchical Phrase-based Translation Rules</i> Baskaran Sankaran, Gholamreza Haffari and Anoop Sarkar .....	438
<i>A Topic-Triggered Language Model for Statistical Machine Translation</i> Heng Yu, Jinsong Su, Yajuan Lv and Qun Liu .....	447
<i>Reserved Self-training: A Semi-supervised Sentiment Classification Method for Chinese Microblogs</i> Zhiguang Liu, Xishuang Dong, Yi Guan and Jinfeng Yang .....	455
<i>Enhancing Lexicon-Based Review Classification by Merging and Revising Sentiment Dictionaries</i> Heeryon Cho, Jong-Seok Lee and Songkuk Kim .....	463

<i>Exploring the Effects of Word Roots for Arabic Sentiment Analysis</i> Shereen Oraby, Yasser El-Sonbaty and Mohamad Abou El-Nasr .....	471
<i>Topical Key Concept Extraction from Folksonomy</i> Han Xue, Bing Qin, Ting Liu and Chao Xiang .....	480
<i>Uncovering Distributional Differences between Synonyms and Antonyms in a Word Space Model</i> Silke Scheible, Sabine Schulte im Walde and Sylvia Springorum .....	489
<i>Multilingual Word Sense Disambiguation Using Wikipedia</i> Bharath Dandala, Rada Mihalcea and Razvan Bunescu .....	498
<i>Semantic v.s. Positions: Utilizing Balanced Proximity in Language Model Smoothing for Information Retrieval</i> Rui Yan, Han Jiang, Mirella Lapata, Shou-De Lin, Xueqiang Lv and Xiaoming Li .....	507
<i>An Unsupervised Parameter Estimation Algorithm for a Generative Dependency N-gram Language Model</i> Chenchen Ding and Mikio Yamamoto .....	516
<i>Learning a Product of Experts with Elitist Lasso</i> Mengqiu Wang and Christopher D. Manning .....	525
<i>Learning Efficient Information Extraction on Heterogeneous Texts</i> Henning Wachsmuth, Benno Stein and Gregor Engels .....	534
<i>TopicRank: Graph-Based Topic Ranking for Keyphrase Extraction</i> Adrien Bougouin, Florian Boudin and Béatrice Daille .....	543
<i>Understanding the Semantic Intent of Natural Language Query</i> Juan Xu, Qi Zhang and Xuanjing Huang .....	552
<i>Sentiment Classification for Movie Reviews in Chinese Using Parsing-based Methods</i> Wen-Juan Hou and Chuang-Ping Chang .....	561
<i>Sentiment Aggregation using ConceptNet Ontology</i> Subhabrata Mukherjee and Sachindra Joshi .....	570
<i>Detecting Cyberbullying Entries on Informal School Websites Based on Category Relevance Maximization</i> Taisei Nitta, Fumito Masui, Michal Ptaszynski, Yasutomo Kimura, Rafal Rzepka and Kenji Araki	579
<i>A Lexicon-based Investigation of Research Issues in Japanese Factuality Analysis</i> Kazuya Narita, Junta Mizuno and Kentaro Inui .....	587
<i>A Hierarchical Semantics-Aware Distributional Similarity Scheme</i> Shuqi Sun, Ke Sun, Shiqi Zhao, Haifeng Wang, Muyun Yang and Sheng Li .....	596
<i>Labeled Alignment for Recognizing Textual Entailment</i> Xiaolin Wang, Hai Zhao and Bao-Liang Lu .....	605
<i>Context-Based Chinese Word Segmentation using SVM Machine-Learning Algorithm without Dictionary Support</i> Chia-ming Lee and Chien-Kang Huang .....	614

<i>A Common Case of Jekyll and Hyde: The Synergistic Effect of Using Divided Source Training Data for Feature Augmentation</i>	
Yan Song and Fei Xia .....	623
<i>Detecting Polysemy in Hard and Soft Cluster Analyses of German Preposition Vector Spaces</i>	
Sylvia Springorum, Sabine Schulte im Walde and Jason Utt .....	632
<i>Generalized Abbreviation Prediction with Negative Full Forms and Its Application on Improving Chinese Web Search</i>	
Xu Sun, Wenjie Li, Fanqi Meng and Houfeng Wang .....	641
<i>Prosody-Based Unsupervised Speech Summarization with Two-Layer Mutually Reinforced Random Walk</i>	
Sujay Kumar Jauhar, Yun-Nung Chen and Florian Metze .....	648
<i>Mining the Gaps: Towards Polynomial Summarization</i>	
Marina Litvak and Natalia Vanetik .....	655
<i>Detecting Domain Dedicated Polar Words</i>	
Raksha Sharma and Pushpak Bhattacharyya .....	661
<i>Can I Hear You? Sentiment Analysis on Medical Forums</i>	
Tanveer Ali, David Schramm, Marina Sokolova and Diana Inkpen .....	667
<i>Construction of Emotional Lexicon Using Potts Model</i>	
Braja Gopal Patra, Hiroya Takamura, Dipankar Das, Manabu Okumura and Sivaji Bandyopadhyay	674
<i>Suicidal Tendencies: The Automatic Classification of Suicidal and Non-Suicidal Lyricists Using NLP</i>	
Matthew Mulholland and Joanne Quinn .....	680
<i>Unsupervised Word Class Induction for Under-resourced Languages: A Case Study on Indonesian</i>	
Meladel Mistica, Jey Han Lau and Timothy Baldwin .....	685
<i>An Efficient Active Learning Framework for New Relation Types</i>	
Lisheng Fu and Ralph Grishman .....	692
<i>Parsing Dependency Paths to Identify Event-Argument Relations</i>	
Seung-Cheol Baek and Jong Park .....	699
<i>Augmentable Paraphrase Extraction Framework</i>	
MeiHua Chen, YiChun Chen, ShihTing Huang and Jason S. Chang .....	706
<i>Automatic Prediction of Evidence-based Recommendations via Sentence-level Polarity Classification</i>	
Abeed Sarker, Diego Mollá-Aliod and Cécile Paris .....	712
<i>Clustering Microtext Streams for Event Identification</i>	
Jie Yin .....	719
<i>Automatic Corpora Construction for Text Classification</i>

Patrick Ziering, Lonneke van der Plas and Hinrich Schütze .....	844
<i>Mining Japanese Compound Words and Their Pronunciations from Web Pages and Tweets</i>	
Xianchao Wu .....	849

<i>A Factoid Question Answering System Using Answer Pattern Matching</i> Nagehan Pala Er and Ilyas Cicekli .....	854
<i>Chinese Short Text Classification Based on Domain Knowledge</i> Xiao Feng, Yang Shen, Chengyong Liu, Wei Liang and Shuwu Zhang .....	859
<i>Applying Graph-based Keyword Extraction to Document Retrieval</i> Youngsam Kim, Munhyong Kim, Andrew Cattle, Julia Otmakhova, Suzi Park and Hyopil Shin	864
<i>Semi-supervised Classification of Twitter Messages for Organization Name Disambiguation</i> Shu Zhang, Jianwei Wu, Dequan Zheng, Yao Meng and Hao Yu .....	869
<i>Word in a Dictionary is used by Numerous Users</i> Eiji Aramaki, Sachiko Maskawa, Mai Miyabe, Mizuki Morita and Sachi Yasuda .....	874
<i>Extracting Evaluative Conditions from Online Reviews: Toward Enhancing Opinion Mining</i> Yuki Nakayama and Atsushi Fujii .....	878
<i>Cognate Production using Character-based Machine Translation</i> Lisa Beinborn, Torsten Zesch and Iryna Gurevych .....	883
<i>An Empirical Study of Combing Multiple Models in Bengali Question Classification</i> Somnath Banerjee and Sivaji Bandyopadhyay .....	892
<i>A Two-Stage Classifier for Sentiment Analysis</i> Dai Quoc Nguyen, Dat Quoc Nguyen and Son Bao Pham .....	897
<i>Exploiting User Search Sessions for the Semantic Categorization of Question-like Informational Search Queries</i> Alejandro Figueroa and Guenter Neumann .....	902
<i>Influence of Part-of-Speech and Phrasal Category Universal Tag-set in Tree-to-Tree Translation Models</i> Francisco Oliveira, Derek F. Wong, Lidia S. Chao, Liang Tian and Liangye He .....	907
<i>Interest Analysis using PageRank and Social Interaction Content</i> Chung-chi Huang and Lun-Wei Ku .....	912
<i>Time Series Topic Modeling and Bursty Topic Detection of Correlated News and Twitter</i> Daichi Koike, Yusuke Takahashi, Takehito Utsuro, Masaharu Yoshioka and Noriko Kando ....	917
<i>A Distant Supervision Approach for Identifying Perspectives in Unstructured User-Generated Text</i> Attapol Thamrongrattanarit, Colin Pollock, Benjamin Goldenberg and Jason Fennell .....	922
<i>An Approach of Hybrid Hierarchical Structure for Word Similarity Computing by HowNet</i> Jiangming Liu, Jinan Xu and Yujie Zhang .....	927
<i>Extracting Causes of Emotions from Text</i> Alena Neviarouskaya and Masaki Aono .....	932
<i>Automated Grammar Correction Using Hierarchical Phrase-Based Statistical Machine Translation</i> Bibek Behera and Pushpak Bhattacharyya .....	937
<i>Finding Dependency Parsing Limits over a Large Spanish Corpus</i> Muntsa Padró, Miguel Ballesteros, Héctor Martínez and Bernd Bohnet .....	942

<i>High Quality Dependency Selection from Automatic Parses</i> Gongye Jin, Daisuke Kawahara and Sadao Kurohashi .....	947
<i>Building Specialized Bilingual Lexicons Using Word Sense Disambiguation</i> Dhouha Bouamor, Nasredine Semmar and Pierre Zweigenbaum .....	952
<i>Predicate Argument Structure Analysis using Partially Annotated Corpora</i> Koichiro Yoshino, Shinsuke Mori and Tatsuya Kawahara .....	957
<i>Statistical Dialogue Management using Intention Dependency Graph</i> Koichiro Yoshino, Shinji Watanabe, Jonathan Le Roux and John R. Hershey .....	962
<i>Repairing Incorrect Translation with Examples</i> Junguo Zhu, Muyun Yang, Sheng Li and Tiejun Zhao .....	967
<i>Phrase-based Parallel Fragments Extraction from Comparable Corpora</i> Xiaoyin Fu, Wei Wei, Shixiang Lu, Zhenbiao Chen and Bo Xu .....	972
<i>A Hybrid Approach for Anaphora Resolution in Hindi</i> Praveen Dakwale, Vandan Mujadia and Dipti M Sharma .....	977
<i>Structure Cognizant Pseudo Relevance Feedback</i> Arjun Atreya V, Yogesh Kakde, Pushpak Bhattacharyya and Ganesh Ramakrishnan .....	982
<i>Cross-Domain Answer Ranking using Importance Sampling</i> Anders Johannsen and Anders Søgaard .....	987
<i>Morphological Analysis of Tunisian Dialect</i> Inès Zribi, Mariem Ellouze Khemakhem and Lamia Hadrich Belguith .....	992
<i>Disambiguating Explicit Discourse Connectives without Oracles</i> Anders Johannsen and Anders Søgaard .....	997
<i>Updating Rare Term Vector Replacement</i> Tobias Berka and Marian Vajteršic .....	1002
<i>Statistical Morphological Analyzer for Hindi</i> Deepak Kumar Malladi and Prashanth Mannem .....	1007
<i>Induction of Root and Pattern Lexicon for Unsupervised Morphological Analysis of Arabic</i> Bilal Khaliq and John Carrol .....	1012
<i>Using Shallow Semantic Parsing and Relation Extraction for Finding Contradiction in Text</i> Minh Quang Nhat Pham, Minh Le Nguyen and Akira Shimazu .....	1017
<i>Using Transliteration of Proper Names from Arabic to Latin Script to Improve English-Arabic Word Alignment</i> Nasredine Semmar and Houda Saadane .....	1022
<i>A Semi-Supervised Method for Arabic Word Sense Disambiguation Using a Weighted Directed Graph</i> Laroussi Merhbene, Anis Zouaghi and Mounir Zrigui .....	1027
<i>Incremental Segmentation and Decoding Strategies for Simultaneous Translation</i> Mahsa Yarmohammadi, Vivek Kumar Rangarajan Sridhar, Srinivas Bangalore and Baskaran Sankaran	1032

<i>Two Case Studies on Translating Pronouns in a Deep Syntax Framework</i> Michal Novák, Zdenek Zabokrtsky and Anna Nedoluzhko .....	1037
<i>Bootstrapping Phrase-based Statistical Machine Translation via WSD Integration</i> Hien Vu Huy, Phuong-Thai Nguyen, Tung-Lam Nguyen and M.L Nguyen .....	1042
<i>Orthographic and Morphological Processing for Persian-to-English Statistical Machine Translation</i> Mohammad Sadegh Rasooli, Ahmed El Kholy and Nizar Habash .....	1047
<i>Interoperability between Service Composition and Processing Pipeline: Case Study on the Language Grid and UIMA</i> Trang Mai Xuan, Yohei Murakami, Donghui Lin and Toru Ishida .....	1052
<i>Improving Calculation of Contextual Similarity for Constructing a Bilingual Dictionary via a Third Language</i> Takashi Tsunakawa, Yosuke Yamamoto and Hiroyuki Kaji .....	1057
<i>Two-Stage Pre-ordering for Japanese-to-English Statistical Machine Translation</i> Sho Hoshino, Yusuke Miyao, Katsuhito Sudoh and Masaaki Nagata .....	1062
<i>Grammatical Error Correction Using Feature Selection and Confidence Tuning</i> Yang Xiang, Yaoyun Zhang, Xiaolong Wang, Chongqiang Wei, Wen Zheng, Xiaoqiang Zhou, Yuxiu Hu and Yang Qin .....	1067
<i>An Online Algorithm for Learning over Constrained Latent Representations using Multiple Views</i> Ann Clifton, Max Whitney and Anoop Sarkar .....	1072
<i>Synonym Acquisition Using Bilingual Comparable Corpora</i> Daniel Andrade, Masaaki Tsuchida, Takashi Onishi and Kai Ishikawa .....	1077
<i>Exploring Verb Frames for Sentence Simplification in Hindi</i> Ankush Soni, Sambhav Jain and Dipti Misra Sharma .....	1082
<i>Dirichlet Processes for Joint Learning of Morphology and PoS Tags</i> Burcu Can and Suresh Manandhar .....	1087
<i>Parser Accuracy in Quality Estimation of Machine Translation: A Tree Kernel Approach</i> Rasoul Samad Zadeh Kaljahi, Jennifer Foster, Raphael Rubino, Johann Roturier and Fred Hollowood .....	1092
<i>Attribute Relation Extraction from Template-inconsistent Semi-structured Text by Leveraging Site-level Knowledge</i> Yang Liu, Fang Liu, Siwei Lai, Kang Liu, Guangyou Zhou and Jun Zhao .....	1097
<i>Optimum Parameter Selection for K.L.D. Based Authorship Attribution in Gujarati</i> Parth Mehta and Prasenjit Majumder .....	1102
<i>Modeling User Leniency and Product Popularity for Sentiment Classification</i> Wenliang Gao, Naoki Yoshinaga, Nobuhiro Kaji and Masaru Kitsuregawa .....	1107
<i>A Generalized LCS Algorithm and Its Application to Corpus Alignment</i> Jin-Dong Kim .....	1112
<i>Semantic Naïve Bayes Classifier for Document Classification</i> How Jing, Yu Tsao, Kuan-Yu Chen and Hsin-Min Wang .....	1117

<i>Cluster-based Web Summarization</i>	
Yves Petinot, Kathleen McKeown and Kapil Thadani . . . . .	1124
<i>Automated Activity Recognition in Clinical Documents</i>	
Camilo Thorne, Marco Montali, Diego Calvanese, Elena Cardillo and Claudio Eccher . . . . .	1129
<i>Large-Scale Text Collection for Unwritten Languages</i>	
Florian R. Hanke and Steven Bird . . . . .	1134
<i>A Self-learning Template Approach for Recognizing Named Entities from Web Text</i>	
Qian Liu, Bingyang Liu, Dayong Wu, Yue Liu and Xueqi Cheng . . . . .	1139
<i>Accurate Parallel Fragment Extraction from Quasi-Comparable Corpora using Alignment Model and Translation Lexicon</i>	
Chenhui Chu, Toshiaki Nakazawa and Sadao Kurohashi . . . . .	1144
<i>Meta-level Statistical Machine Translation</i>	
Sajad Ebrahimi, Kourosh Meshgi, Shahram Khadivi and Mohammad Ebrahim Shiri Ahmad Abady	
1151	
<i>Bayesian Induction of Bracketing Inversion Transduction Grammars</i>	
Markus Saers and Dekai Wu . . . . .	1158
<i>Estimating the Quality of Translated User-Generated Content</i>	
Raphael Rubino, Jennifer Foster, Rasoul Samad Zadeh Kaljahi, Johann Roturier and Fred Hol-	
lowood . . . . .	1167
<i>Selective Combination of Pivot and Direct Statistical Machine Translation Models</i>	
Ahmed El Kholly, Nizar Habash, Gregor Leusch, Evgeny Matusov and Hassan Sawaf . . . . .	1174
<i>Multiword Expressions in the Context of Statistical Machine Translation</i>	
Mahmoud Ghoneim and Mona Diab . . . . .	1181
<i>Uncertainty Detection for Natural Language Watermarking</i>	
György Szarvas and Iryna Gurevych . . . . .	1188
<i>KySS 1.0: a Framework for Automatic Evaluation of Chinese Input Method Engines</i>	
Zhongye Jia and Hai Zhao . . . . .	1195
<i>Automatic Extraction of Social Networks from Literary Text: A Case Study on Alice in Wonderland</i>	
Apoorv Agarwal, Anup Kotalwar and Owen Rambow . . . . .	1202
<i>Using the Web to Train a Mobile Device Oriented Japanese Input Method Editor</i>	
Xianchao Wu, Rixin Xiao and Xiaoxin Chen . . . . .	1209
<i>A Novel Approach Towards Incorporating Context Processing Capabilities in NLIDB System</i>	
Arjun Akula, Rajeev Sangal and Radhika Mamidi . . . . .	1216
<i>Iterative Development and Evaluation of a Social Conversational Agent</i>	
Annika Silvervarg and Arne Jönsson . . . . .	1223
<i>A Hybrid Morphological Disambiguation System for Turkish</i>	
Mucahid Kutlu and Ilyas Cicekli . . . . .	1230
<i>A Dynamic Confusion Score for Dependency Arc Labels</i>	
Sambhav Jain and Bhasha Agrawal . . . . .	1237

<i>Increasing the Quality and Quantity of Source Language Data for Unsupervised Cross-Lingual POS Tagging</i>	
Long Duong, Paul Cook, Steven Bird and Pavel Pecina . . . . .	1243
<i>Towards the Annotation of Penn TreeBank with Information Structure</i>	
Bernd Bohnet, Alicia Burga and Leo Wanner . . . . .	1250
<i>Constituency and Dependency Relationship from a Tree Adjoining Grammar and Abstract Categorical Grammars Perspective</i>	
Aleksandre Maskharashvili and Sylvain Pogodalla . . . . .	1257
<i>Named Entity Extraction using Information Distance</i>	
Sangameshwar Patil, Sachin Pawar and Girish Palshikar . . . . .	1264
<i>Feature-based Neural Language Model and Chinese Word Segmentation</i>	
Mairgup Mansur, Wenzhe Pei and Baobao Chang . . . . .	1271
<i>Human-Computer Interactive Chinese Word Segmentation: An Adaptive Dirichlet Process Mixture Model Approach</i>	
Tongfei Chen, Xiaojun Zou, Weimeng Zhu and Junfeng Hu . . . . .	1278
<i>Effect of Non-linear Deep Architecture in Sequence Labeling</i>	
Mengqiu Wang and Christopher D. Manning . . . . .	1285
<i>Case Study of Model Adaptation: Transfer Learning and Online Learning</i>	
Kenji Imamura . . . . .	1292
<i>Source and Translation Classification using Most Frequent Words</i>	
Zahurul Islam and Armin Hoenen . . . . .	1299
<i>Comparison of Algorithmic and Human Assessments of Sentence Similarity</i>	
John Mersch and R. Raymond Lang . . . . .	1306
<i>Effective Selectional Restrictions for Unsupervised Relation Extraction</i>	
Alan Akbik, Larysa Visengeriyeva, Johannes Kirschnick and Alexander Löser . . . . .	1312
<i>Bootstrapping Semantic Lexicons for Technical Domains</i>	
Patrick Ziering, Lonneke van der Plas and Hinrich Schütze . . . . .	1321
<i>Long-Distance Time-Event Relation Extraction</i>	
Alessandro Moschitti, Siddharth Patwardhan and Chris Welty . . . . .	1330
<i>Unsupervised Extraction of Attributes and Their Values from Product Description</i>	
Keiji Shinzato and Satoshi Sekine . . . . .	1339
<i>Stance Classification of Ideological Debates: Data, Models, Features, and Constraints</i>	
Kazi Saidul Hasan and Vincent Ng . . . . .	1348
<i>University Entrance Examinations as a Benchmark Resource for NLP-based Problem Solving</i>	
Yusuke Miyao and Ai Kawazoe . . . . .	1357
<i>Linguistically Aware Coreference Evaluation Metrics</i>	
Chen Chen and Vincent Ng . . . . .	1366
<i>An Empirical Assessment of Contemporary Online Media in Ad-Hoc Corpus Creation for Social Events</i>	
Kanika Narang, Seema Nagar, Sameep Mehta, L V Subramaniam and Kuntal Dey . . . . .	1375

<i>Diagnosing Causes of Reading Difficulty using Bayesian Networks</i> Pascual Martínez-Gómez and Akiko Aizawa .....	1383
<i>Word Co-occurrence Counts Prediction for Bilingual Terminology Extraction from Comparable Corpora</i> Amir Hazem and Emmanuel Morin .....	1392
<i>Measuring the Effect of Discourse Relations on Blog Summarization</i> Shamima Mithun and Leila Kosseim .....	1401
<i>Supervised Sentence Fusion with Single-Stage Inference</i> Kapil Thadani and Kathleen McKeown .....	1410
<i>Detecting and Correcting Learner Korean Particle Omission Errors</i> Ross Israel, Markus Dickinson and Sun-Hee Lee .....	1419
<i>Automatic Identification of Learners' Language Background Based on Their Writing in Czech</i> Katsiaryna Aharodnik, Marco Chang, Anna Feldman and Jirka Hana .....	1428

# Conference Program

## October 15, 2013 (Tuesday)

09:00-09:20 Opening (Reception Hall)

09:20-10:20 Keynote Speech - Hwee Tou Ng (National University of Singapore) (Reception Hall)

10:20-10:50 Coffee Break

10:50-12:05 Regular Papers

### Information Extraction I (Reception Hall)

10:50–11:15 *Semi-Supervised Answer Extraction from Discussion Forums*  
Rose Catherine, Rashmi Gangadharaiah, Karthik Visweswariah and Dinesh Raghu

11:15–11:40 *WordTopic-MultiRank: A New Method for Automatic Keyphrase Extraction*  
Fan Zhang, Lian'en Huang and Bo Peng

11:40–12:05 *Towards Contextual Healthiness Classification of Food Items - A Linguistic Approach*  
Michael Wiegand and Dietrich Klakow

### Information Retrieval I (Room 141 + 142)

10:50–11:15 *Learning a Replacement Model for Query Segmentation with Consistency in Search Logs*  
Wei Zhang, Yunbo Cao, Chin-Yew Lin, Jian Su and Chew-Lim Tan

11:15–11:40 *Precise Information Retrieval Exploiting Predicate-Argument Structures*  
Daisuke Kawahara, Keiji Shinzato, Tomohide Shibata and Sadao Kurohashi

11:40–12:05 *Global Model for Hierarchical Multi-Label Text Classification*  
Yugo Murawaki

**October 15, 2013 (Tuesday) (continued)**

**Syntax and Semantics (Room 131 + 132)**

10:50–11:15 *(Pre-)Annotation of Topic-Focus Articulation in Prague Czech-English Dependency Treebank*

Jiří Mírovský, Kateřina Rysová, Magdaléna Rysová and Eva Hajičová

11:15–11:40 *Animacy Acquisition Using Morphological Case*

Riyaz Ahmad Bhat and Dipti Misra Sharma

11:40–12:05 *The Complexity of Math Problems – Linguistic, or Computational?*

Takuya Matsuzaki, Hidenao Iwane, Hirokazu Anai and Noriko Arai

**Pragmatics and Discourse (Room 133 + 134)**

10:50–11:15 *Hybrid Models for Lexical Acquisition of Correlated Styles*

Julian Brooke and Graeme Hirst

11:15–11:40 *Introducing the Prague Discourse Treebank 1.0*

Lucie Poláková, Jiří Mírovský, Anna Nedoluzhko, Pavlína Jínová, Šárka Zikánová and Eva Hajičová

11:40–12:05 *Multilingual Mention Detection for Coreference Resolution*

Olga Uryupina and Alessandro Moschitti

12:05-13:30 Lunch

13:30-15:10 Regular Papers

**October 15, 2013 (Tuesday) (continued)**

**Text Mining (Reception Hall)**

- 13:30–13:55 *A Weakly Supervised Bayesian Model for Violence Detection in Social Media*  
Amparo Elizabeth Cano Basave, Yulan He, Kang Liu and Jun Zhao
- 13:55–14:20 *Detecting Spammers in Community Question Answering*  
Zhuoye Ding, Yeyun Gong, Yaqian Zhou, Qi Zhang and Xuanjing Huang
- 14:20–14:45 *Chinese Informal Word Normalization: an Experimental Study*  
Aobo Wang, Min-Yen Kan, Daniel Andrade, Takashi Onishi and Kai Ishikawa
- 14:45–15:10 *Feature Selection Using a Semantic Hierarchy for Event Recognition and Type Classification*  
Yoonjae Jeong and Sung-Hyon Myaeng

**Phonology and Morphology (Room 141 + 142)**

- 13:30–13:55 *Romanization-based Approach to Morphological Analysis in Korean SMS Text Processing*  
Youngsam Kim and Hyopil Shin
- 13:55–14:20 *Efficient Word Lattice Generation for Joint Word Segmentation and POS Tagging in Japanese*  
Nobuhiro Kaji and Masaru Kitsuregawa
- 14:20–14:45 *A Simple Approach to Unknown Word Processing in Japanese Morphological Analysis*  
Ryohei Sasano, Sadao Kurohashi and Manabu Okumura
- 14:45–15:10 *Chinese Word Segmentation by Mining Maximized Substrings*  
Mo Shen, Daisuke Kawahara and Sadao Kurohashi

**October 15, 2013 (Tuesday) (continued)**

**POS Tagging and Parsing (Room 131 + 132)**

- 13:30–13:55 *Capturing Long-distance Dependencies in Sequence Models: A Case Study of Chinese Part-of-speech Tagging*  
Weiwei Sun, Xiaochang Peng and Xiaojun Wan
- 13:55–14:20 *Exploring Semantic Information in Hindi WordNet for Hindi Dependency Parsing*  
Sambhav Jain, Naman Jain, Aniruddha Tammewar, Riyaz Ahmad Bhat and Dipti Sharma
- 14:20–14:45 *Towards Robust Cross-Domain Domain Adaptation for Part-of-Speech Tagging*  
Tobias Schnabel and Hinrich Schütze
- 14:45–15:10 *Dependency Parsing for Identifying Hungarian Light Verb Constructions*  
Veronika Vincze, János Zsibrita and István Nagy T.

**Dialogue and Dialogue Systems (Room 133 + 134)**

- 13:30–13:55 *Written Dialog and Social Power: Manifestations of Different Types of Power in Dialog Behavior*  
Vinodkumar Prabhakaran and Owen Rambow
- 13:55–14:20 *Evaluation of the Scusi? Spoken Language Interpretation System – A Case Study*  
Thomas Kleinbauer, Ingrid Zukerman and Su Nam Kim
- 14:20–14:45 *A Noisy Channel Approach to Error Correction in Spoken Referring Expressions*  
Su Nam Kim, Ingrid Zukerman, Thomas Kleinbauer and Farshid Zavareh
- 14:45–15:10 *Natural Language Query Refinement for Problem Resolution from Crowd-Sourced Semi-Structured Data*  
Rashmi Gangadharaiah and Balakrishnan Narayanaswamy
- 15:10-15:40 Coffee Break
- 15:40-17:45 Regular Papers

**October 15, 2013 (Tuesday) (continued)**

**Machine Translation I (Reception Hall)**

- 15:40–16:05 *Ensemble Triangulation for Statistical Machine Translation*  
Majid Razmara and Anoop Sarkar
- 16:05–16:30 *Robust Transliteration Mining from Comparable Corpora with Bilingual Topic Models*  
John Richardson, Toshiaki Nakazawa and Sadao Kurohashi
- 16:30–16:55 *SuMT: A Framework of Summarization and MT*  
Houda Bouamor, Behrang Mohit and Kemal Oflazer
- 16:55–17:15 *Tuning SMT with a Large Number of Features via Online Feature Grouping*  
Lemao Liu, Tiejun Zhao, Taro Watanabe and Eiichiro Sumita
- 17:15–17:35 *Multimodal Comparable Corpora as Resources for Extracting Parallel Data: Parallel Phrases Extraction*  
Haithem Afli, Loïc Barrault and Holger Schwenk

**Information Extraction II (Room 141 + 142)**

- 15:40–16:05 *Bootstrapping Large-scale Named Entities using URL-Text Hybrid Patterns*  
Chao Zhang, Shiqi Zhao and Haifeng Wang
- 16:05–16:30 *Feature-Rich Segment-Based News Event Detection on Twitter*  
Yanxia Qin, Yue Zhang, Min Zhang and Dequan Zheng
- 16:30–16:55 *Building Chinese Event Type Paradigm Based on Trigger Clustering*  
Xiao Ding, Bing Qin and Ting Liu
- 16:55–17:20 *Chinese Named Entity Abbreviation Generation Using First-Order Logic*  
Huan Chen, Qi Zhang, Jin Qian and Xuanjing Huang
- 17:20–17:45 *Full-coverage Identification of English Light Verb Constructions*  
István Nagy T., Veronika Vincze and Richárd Farkas

**October 15, 2013 (Tuesday) (continued)**

**Recent NLP Applications I (Room 131 + 132)**

- 15:40–16:05 *Detecting Deceptive Opinions with Profile Compatibility*  
Vanessa Wei Feng and Graeme Hirst
- 16:05–16:30 *Behind the Times: Detecting Epoch Changes using Large Corpora*  
Octavian Popescu and Carlo Strapparava
- 16:30–16:55 *How Noisy Social Media Text, How Different Social Media Sources?*  
Timothy Baldwin, Paul Cook, Marco Lui, Andrew MacKinlay and Li Wang
- 16:55–17:20 *Who Had the Upper Hand? Ranking Participants of Interactions Based on Their Relative Power*  
Vinodkumar Prabhakaran, Ajita John and Dorée D. Seligmann
- 17:20–17:45 *Readability Indices for Automatic Evaluation of Text Simplification Systems: A Feasibility Study for Spanish*  
Sanja Štajner and Horacio Saggion

**Language Resources I (Room 133 + 134)**

- 15:40–16:05 *Weasels, Hedges and Peacocks: Discourse-level Uncertainty in Wikipedia Articles*  
Veronika Vincze
- 16:05–16:30 *Automatically Developing a Fine-grained Arabic Named Entity Corpus and Gazetteer by utilizing Wikipedia*  
Fahd Alotaibi and Mark Lee
- 16:30–16:55 *Ranking Translation Candidates Acquired from Comparable Corpora*  
Rima Harastani, Béatrice Daille and Emmanuel Morin
- 16:55–17:20 *Using the Semantic-Syntactic Interface for Reliable Arabic Modality Annotation*  
Rania Al-Sabbagh, Jana Diesner and Roxana Girju
- 17:20–17:45 *Mapping Rules for Building a Tunisian Dialect Lexicon and Generating Corpora*  
Rahma Boujelbane, Mariem Ellouze Khemekhem and Lamia Hadrich Belguith
- 19:30-21:30 Reception (ANA Crowne Plaza Hotel Grand Court Nagoya)

**October 16, 2013 (Wednesday)**

09:00-10:15 Regular Papers

**Machine Translation II (Reception Hall East)**

09:00–09:25 *Hypothesis Refinement Using Agreement Constraints in Machine Translation*  
Ankur Gandhe and Rashmi Gangadharaiah

09:25–09:50 *Scalable Variational Inference for Extracting Hierarchical Phrase-based Translation Rules*  
Baskaran Sankaran, Gholamreza Haffari and Anoop Sarkar

09:50–10:15 *A Topic-Triggered Language Model for Statistical Machine Translation*  
Heng Yu, Jinsong Su, Yajuan Lv and Qun Liu

**Opinion Mining I (Reception Hall West)**

09:00–09:25 *Reserved Self-training: A Semi-supervised Sentiment Classification Method for Chinese Microblogs*  
Zhiguang Liu, Xishuang Dong, Yi Guan and Jinfeng Yang

09:25–09:50 *Enhancing Lexicon-Based Review Classification by Merging and Revising Sentiment Dictionaries*  
Heeryon Cho, Jong-Seok Lee and Songkuk Kim

09:50–10:15 *Exploring the Effects of Word Roots for Arabic Sentiment Analysis*  
Shereen Oraby, Yasser El-Sonbaty and Mohamad Abou El-Nasr

**October 16, 2013 (Wednesday) (continued)**

**Semantic Processing I (Room 131 + 132)**

- 09:00–09:25 *Topical Key Concept Extraction from Folksonomy*  
Han Xue, Bing Qin, Ting Liu and Chao Xiang
- 09:25–09:50 *Uncovering Distributional Differences between Synonyms and Antonyms in a Word Space Model*  
Silke Scheible, Sabine Schulte im Walde and Sylvia Springorum
- 09:50–10:15 *Multilingual Word Sense Disambiguation Using Wikipedia*  
Bharath Dandala, Rada Mihalcea and Razvan Bunescu

**Statistical and ML Language Modeling I (Room 133 + 134)**

- 09:00–09:25 *Semantic v.s. Positions: Utilizing Balanced Proximity in Language Model Smoothing for Information Retrieval*  
Rui Yan, Han Jiang, Mirella Lapata, Shou-De Lin, Xueqiang Lv and Xiaoming Li
- 09:25–09:50 *An Unsupervised Parameter Estimation Algorithm for a Generative Dependency N-gram Language Model*  
Chenchen Ding and Mikio Yamamoto
- 09:50–10:15 *Learning a Product of Experts with Elitist Lasso*  
Mengqiu Wang and Christopher D. Manning
- 10:15-10:45 Coffee Break
- 10:45-12:00 Regular Papers

**October 16, 2013 (Wednesday) (continued)**

**Information Extraction III / Question Answering (Reception Hall East)**

10:45–11:10 *Learning Efficient Information Extraction on Heterogeneous Texts*  
Henning Wachsmuth, Benno Stein and Gregor Engels

11:10–11:35 *TopicRank: Graph-Based Topic Ranking for Keyphrase Extraction*  
Adrien Bougouin, Florian Boudin and Béatrice Daille

11:35–12:00 *Understanding the Semantic Intent of Natural Language Query*  
Juan Xu, Qi Zhang and Xuanjing Huang

**Opinion Mining II (Reception Hall West)**

10:45–11:10 *Sentiment Classification for Movie Reviews in Chinese Using Parsing-based Methods*  
Wen-Juan Hou and Chuang-Ping Chang

11:10–11:35 *Sentiment Aggregation using ConceptNet Ontology*  
Subhabrata Mukherjee and Sachindra Joshi

11:35–12:00 *Detecting Cyberbullying Entries on Informal School Websites Based on Category Relevance Maximization*  
Taisei Nitta, Fumito Masui, Michal Ptaszynski, Yasutomo Kimura, Rafal Rzepka and Kenji Araki

**Semantic Processing II (Room 131 + 132)**

10:45–11:10 *A Lexicon-based Investigation of Research Issues in Japanese Factuality Analysis*  
Kazuya Narita, Junta Mizuno and Kentaro Inui

11:10–11:35 *A Hierarchical Semantics-Aware Distributional Similarity Scheme*  
Shuqi Sun, Ke Sun, Shiqi Zhao, Haifeng Wang, Muyun Yang and Sheng Li

11:35–12:00 *Labeled Alignment for Recognizing Textual Entailment*  
Xiaolin Wang, Hai Zhao and Bao-Liang Lu

**October 16, 2013 (Wednesday) (continued)**

**Statistical and ML Language Modeling II (Room 133 + 134)**

10:45–11:10 *Context-Based Chinese Word Segmentation using SVM Machine-Learning Algorithm without Dictionary Support*  
Chia-ming Lee and Chien-Kang Huang

11:10–11:35 *A Common Case of Jekyll and Hyde: The Synergistic Effect of Using Divided Source Training Data for Feature Augmentation*  
Yan Song and Fei Xia

11:35–12:00 *Detecting Polysemy in Hard and Soft Cluster Analyses of German Preposition Vector Spaces*  
Sylvia Springorum, Sabine Schulte im Walde and Jason Utt

12:00–13:10 Lunch

13:10–15:30 Short Papers

**Recent NLP Applications / Text Summarization / Opinion Mining (Reception Hall East)**

13:10–13:30 *Generalized Abbreviation Prediction with Negative Full Forms and Its Application on Improving Chinese Web Search*  
Xu Sun, Wenjie Li, Fanqi Meng and Houfeng Wang

13:30–13:50 *Prosody-Based Unsupervised Speech Summarization with Two-Layer Mutually Reinforced Random Walk*  
Sujay Kumar Jauhar, Yun-Nung Chen and Florian Metze

13:50–14:10 *Mining the Gaps: Towards Polynomial Summarization*  
Marina Litvak and Natalia Vanetik

14:10–14:30 *Detecting Domain Dedicated Polar Words*  
Raksha Sharma and Pushpak Bhattacharyya

14:30–14:50 *Can I Hear You? Sentiment Analysis on Medical Forums*  
Tanveer Ali, David Schramm, Marina Sokolova and Diana Inkpen

14:50–15:10 *Construction of Emotional Lexicon Using Potts Model*  
Braja Gopal Patra, Hiroya Takamura, Dipankar Das, Manabu Okumura and Sivaji Bandyopadhyay

15:10–15:30 *Suicidal Tendencies: The Automatic Classification of Suicidal and Non-Suicidal Lyricists Using NLP*  
Matthew Mulholland and Joanne Quinn

**October 16, 2013 (Wednesday) (continued)**

**Language Resources / Information Extraction / Text Mining (Reception Hall West)**

- 13:10–13:30 *Unsupervised Word Class Induction for Under-resourced Languages: A Case Study on Indonesian*  
Meladel Mistica, Jey Han Lau and Timothy Baldwin
- 13:30–13:50 *An Efficient Active Learning Framework for New Relation Types*  
Lisheng Fu and Ralph Grishman

# Semi-Supervised Answer Extraction from Discussion Forums

Rose Catherine, Rashmi Gangadharaiah, Karthik Visweswariah, Dinesh Raghu

IBM Research  
Bangalore, India

{rosecatherinek, rashgang, v-karthik, diraghu1} @in.ibm.com

## Abstract

Mining online discussions to extract answers is an important research problem. Methods proposed in the past used supervised classifiers trained on labeled data. But, collecting training data for each target forum is labor intensive and time consuming, thus limiting their deployment. A recent approach had proposed to extract answers in an unsupervised manner, by taking cues from their repetitions. This assumption however, does not hold true in many cases. In this paper, we propose two semi-supervised methods for extracting answers from discussions, which utilize the large amount of unlabeled data available, alongside a very small training set to obtain improved accuracies. We show that it is possible to boost the performance by introducing a related, but parallel task of identifying acknowledgments to the answers. The accuracy achieved by our approaches surpass the baselines by a wide margin, as shown by our experiments.

## 1 Introduction

Online discussion forums, also known as community question answering (CQA) sites, are internet sites that provide a medium for users to discuss and share information on a wide range of topics. Due to their vast popularity, gradually, they have aggregated a massive collection of discussion data. Mining such forums have numerous applications such as improving question-answer (QA) retrieval (Cong et al., 2008), learning important insights like features of products that are drawing negative reviews (Lakkaraju et al., 2011) or discovering longstanding unresolved severe technical issues (Gangadharaiah and Catherine, 2012) etc. For this reason, substantial research effort has been directed at mining discussions, in recent

times. In this paper, we focus on the specific problem of extracting answers from these discussions.

In forums, typically a user starts a discussion by posting a question to which multiple members of the forum suggest answers. The discussion evolves into a complex multi-party conversation as the question gets refined, with additional details specified, clarifications sought, multiple answers provided, frequent digressions, and occasional follow-up discussions and acknowledgments, altogether spanning several pages. Answers easily get buried deep within this and locating them automatically is far from straightforward.

In this paper, we propose two semi-supervised approaches that require only a very small amount of training data (only 3 manually tagged discussion threads) and achieve high accuracy levels by using the available unlabeled data. With this, we eliminate the need to collect vast amounts of training data, thus aiding faster deployment for new domains. Specifically, our contributions are:

- *A semi-supervised answer extraction method for discussions:* This paper makes the first attempt at extracting answers from discussions in a semi-supervised manner. We show how existing features can be engineered into a co-training framework to accomplish this.
- *A parallel co-training method to leverage acknowledgments for improved answer extraction accuracy:* We motivate and demonstrate that it is possible to improve the performance tremendously by introducing a related task of identifying acknowledgments in the discussions, which we run as a parallel task alongside the main answer extraction task (Section 5).
- We demonstrate that with a very small training data and by using the available unlabeled data, it is possible to extract answers from forums with an accuracy that is substantially better than extracting them in an unsupervised manner or in a fully supervised setting.

The rest of the paper is organized as follows: Section 2 discusses related work. Section 3 sets the terminology and introduces the co-training framework, which is used throughout this paper. Section 4 details how the co-training framework can be applied to the answer extraction task. Section 5 introduces the acknowledgment extraction task in a parallel co-training framework. Experiments and results are discussed in Section 6 followed by conclusions in Section 7.

## 2 Related work

Research in the area of extracting question and answers from online forums, has grown considerably. Almost all approaches proposed so far for this task are supervised learning methods. Ding et al. (2008), Kim et al. (2010), Raghavan et al. (2010) and Kim et al. (2012) employed Conditional Random Fields, Hong and Davison (2009), Huang et al. (2007) and Catherine et al. (2012) used Support Vector Machines (SVM), Shrestha and McKeown (2004) learnt rules using Ripper, and Yang et al. (2009) used Struct SVMs for extracting answers. The obvious downside to these methods is that for any new domain or forum, substantial amounts of manually labeled training examples have to be collected. This is usually time consuming and costly. Gandhe et al. (2012) proposed an approach for adapting an answer extractor trained on one domain to another, by separating out the lexical characteristics of an answer from its domain relevance. However, learning the lexical characteristics still required a training set.

A recent work by Cong et al. (2008) proposed an unsupervised method using PageRank-style random walks on a graph representation of the discussion, with the hypothesis that inter-candidate similarities can improve accuracy of the answer extraction task. The intuition is that posts that bear more resemblance to other posts in the thread have higher chances of being answers. However, in a lot of discussion forums, especially those related to troubleshooting and problem resolution, we found that this assumption usually does not hold. An answer that was suggested earlier in the discussion is not usually suggested again – only new ones or a modification of the same would appear. A general observation here was that posts that had similar content as other posts were found to be others complaining about the same issue. This was also noted by Gandhe et al. (2012) and Catherine et al. (2012). Nevertheless, (Cong et al., 2008) is the

only work so far, that sought to extract answers without supervision.

One of the methods proposed in this paper that uses a parallel acknowledgment classification task, belongs to the family of Multi-Task Learning (MTL) (Caruana, 1997) since what is learned for each task is used to improve the other task. However, to the best of our knowledge, this is the first work that proposes a MTL-type answer classifier for forums in a semi-supervised setting. Cross-Training (Sarawagi et al., 2003) is a related methodology which improves classification performance on one taxonomy by accessing labels from another taxonomy for the *same* document. Our method differs because, the answer and acknowledgment labels are on *different* posts.

Some other closely related works are listed below; however, their focus is different from the task proposed in this paper. Jijkoun and de Rijke (2005) proposed a method to automatically extract question–answer pairs from FAQ pages using formatting cues. Since it is known that the entry following the question is definitely an answer, they did not have to classify the entries. Sarencheh et al. (2010) proposed a semi-automatic wrapper induction method for extracting different structural components of a discussion, like the time of posting, author name, content of the post etc. Answer retrieval is another closely related task where the emphasis is on retrieving the most relevant post (Xue et al., 2008). The scope of our paper, however, is limited to tagging posts in forum discussions as answers or not.

## 3 Preliminaries

### 3.1 Terminology and Scope

A discussion in an online forum is created when a user posts a question. Other members of the forum reply to this post or to other replies, thereby evolving the discussion. A sample discussion with 7 posts including 2 answers and 2 acknowledgments, is shown in Figure 1. In this paper, we use the terms *discussion* and *thread* (as in, a thread of discussion) interchangeably.

An answer is typically spread over multiple sentences within the same post, especially in the case of non-factoid answers. It would have been ideal, if the system extracted answers at the granularity of a sentence. However, the inter-annotator agreement<sup>1</sup> for answer sentences in our dataset (Section 6) was a mere 0.19. Hence, we extract answers at

<sup>1</sup>[http://en.wikipedia.org/wiki/Cohen's\\_kappa](http://en.wikipedia.org/wiki/Cohen's_kappa)

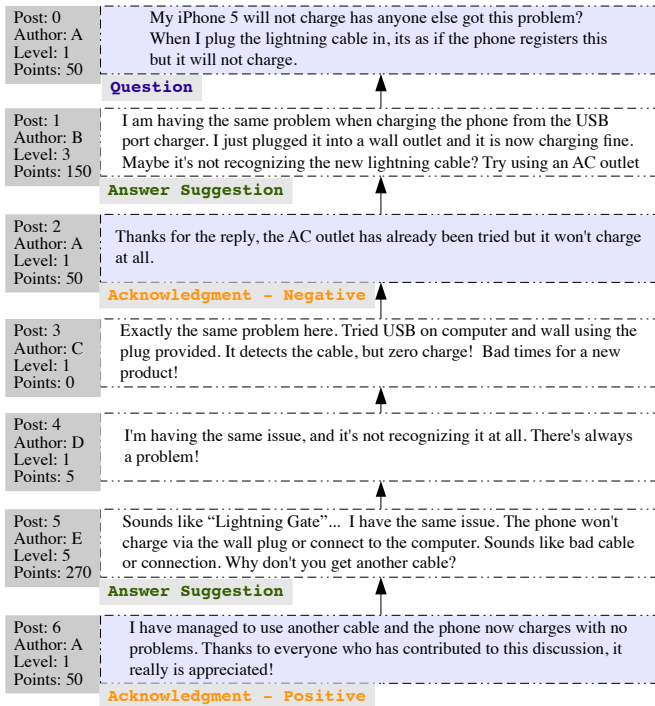

Figure 1: A Sample Discussion

a post level – a post is classified as an answer if any sentence within it suggests a solution.

Digressions are very common in such community question answering systems. We do not attempt to find these questions or separate out the sub-discussions. Question detection as well as disentangling multi-party discussions, is a well researched area (Cong et al., 2008; Elsner and Charniak, 2010), and is outside the scope of this paper. For the purposes of this paper, the first post is the question and we attempt to find answers to only this question. Answers to other questions within the discussion are negative examples.

### 3.2 Co-Training Methodology

Co-Training introduced by Blum and Mitchell (1998), is a general framework for semi-supervised classification, where the features for classifying each data point can be partitioned into two distinct sets or views. The views are such that either of them is sufficient to classify any data-point, had there been enough training examples.

The algorithm proceeds in two half-steps: in iteration  $i$ , the current set of labeled examples  $L^i$  (initially, a very small set) is used to train a classifier  $C_1$  that uses only one view  $v_1$  of each training instance and another classifier  $C_2$  that uses only view  $v_2$ .  $C_1$  and  $C_2$  are then used to classify the unlabeled points, and the most confident  $m$  predictions are moved from the unlabeled pool  $U$  to the set of labeled examples, which are used

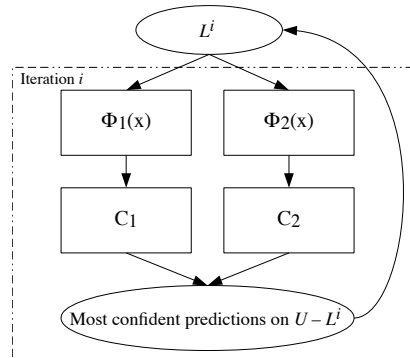

Figure 2: Co-Training Framework

for training in the  $i + 1^{th}$  iteration. Essentially, each classifier teaches the other by providing examples which the other would have misclassified. Figure 2 shows this workflow, where  $\Phi_1$  and  $\Phi_2$  are the feature vectors of the input corresponding to the two views  $v_1$  and  $v_2$ . The paper showed that when the two views are independent given the label of the data point (conditional independence), any initial weak predictor can be boosted to a high accuracy using unlabeled examples by co-training. This was empirically evaluated for a webpage classification task where  $v_1$  was the set of words in the webpage and  $v_2$ , the anchor texts of all links pointing to that page. Co-training framework is widely used in many text mining tasks like parsing (Sarkar, 2001), machine translation (Callison-Burch, 2002) and for creating parallel corpora (Callison-Burch and Osborne, 2003).

### 4 Answer Extraction by Co-Training: ANS CT Model

To apply the co-training framework to the task of answer extraction, we need two independent views of the data. Prior work in supervised answer extraction from forum discussions have reported good accuracies when using features constructed from the structure of the thread (Ding et al., 2008; Hong and Davison, 2009; Kim et al., 2010; Catherine et al., 2012). This provides us with one of the views, which we refer to as the STRUCT view.

Cong et al. (2008) had previously used pattern mining for the related task of question sentence extraction. Similarly, Jindal and Liu (2006) had used pattern mining for identifying comparative sentences in a supervised learning setting. We mine patterns on the sentences of the posts and employ it as the second view, which we refer to as the PATTERN view. The exact set of features are explained in the subsections below.

Note that we have used only a modest set of features in both STRUCT and PATTERN views, to highlight the effect of co-training in improving the answer extraction accuracy.

#### 4.1 STRUCT view

Compared to a general text document, discussion threads have a structure, which can be used to construct features for classification. The features that we use, referred to as STRUCT features henceforth, are listed in Table 1. All the features are eventually converted to binary attributes for the experiments, where numerical attributes are grouped into a suitable number of buckets. Each binary value corresponds to a dimension in the STRUCT view,  $\Phi_{struct}^i$ , which is 1 if that attribute-value was present in the post; else, is set to 0.

STRUCT Feature	Description
Author Rating	A forum specific value measuring the expertise of the author. Could be numerical (e.g. 50 points) or categorical (e.g. Expert).
Relative Post Position	The position of the post with respect to the thread. It is grouped into Beginning, Middle and End.
Post Rating	A measure of how informative the post is. Could be numerical (e.g. 50 votes) or categorical (e.g. Helpful).

Table 1: STRUCT features for a post

#### 4.2 PATTERN view

Consider the below snippets from different discussion threads. Some words have been intentionally masked to illustrate that it is possible to identify to a considerable extent, that these are answer suggestions from the structure of the sentence and without regard to the context or the question.

... You can see if X will solve it ...  
 ... Try resetting your X with the Y turned off and then turn it back on after the X is fully booted back up ...  
 ... Go to A -> B -> C and toggle the D mode ...  
 ... X is no longer supported by Y ...

The PATTERN view uses a pattern mining module, which mines the answer posts in  $L^i$  to discover the most frequent sequential patterns,  $FP^i$  for iteration  $i$ . Each such discovered pattern  $p \in FP^i$  corresponds to a dimension in the PATTERN view,  $\Phi_{pattern}^i$ , which is 1 if  $p$  matches (is sub-sequence of) any sentence of the post.

We implemented the PrefixSpan (Pei et al., 2001) algorithm for mining sequential patterns, but with the following modifications to contain the blow up in the number of patterns:

- Variable Minimum Support: the number of items in which a pattern appears is called its *support*, and minimum support, `min_sup` is an input parameter that determines whether a pattern is frequent enough. We set `min_sup` to  $\max(\text{min\_sup}_0, \text{frac} \times \text{numItems}^i)$ , where `frac` is a preset fraction, set to 0.03 in our experiments,  $\text{numItems}^i$  is the number of items being mined in iteration  $i$ , and `min_sup0` is a default minimum, set to 3 in our experiments.
- Pattern Length: only patterns of length at least `min_len`, set to 3 in our experiments, are acceptable.
- Item Gap: the items of a frequent pattern are sequential, but not consecutive, thus allowing PrefixSpan to pick items that are arbitrary number of items apart (`gap`). We constrain the gap between items of a pattern to a maximum of `max_gap`, set to again 3 in our experiments.

Posts are mined at a sentence level, for which we use OpenNLP<sup>2</sup> sentence detector.

##### 4.2.1 Text Pre-Processing

We found that using the exact words limited the number of frequent patterns that could be found. To minimize this problem, we used Part-Of-Speech (POS) tags of the words to:

- Replace all nouns with their POS tags.
- Replace all verbs with its root/stemmed (using Porter stemmer (Porter, 1980)) form and its POS tag. For example, `restarting` becomes `restart VBG`. We let PrefixSpan pick the verb-stem and/or the POS tag according to their support.

All words are lowercased. A discussion on the set of patterns that were detected is in Section 6.3.

## 5 Leveraging Acknowledgment Signals: ANS-ACK PCT Model

In this section, we motivate and introduce a related task of extracting acknowledgments in forum discussions and inducing signals from them to improve the accuracy of the answer extraction task.

Merriam-Webster<sup>3</sup> defines an acknowledgment as a recognition or favorable notice of an act or achievement. Acknowledgment is an inevitable component of any conversation, especially, when it evolves around seeking assistance. And so they find their place in forum discussions too. Consider the below snippets taken from replies by question

<sup>2</sup><http://opennlp.apache.org>

<sup>3</sup><http://www.merriam-webster.com>

authors. They are grouped according to their polarity – Positive, Negative and Neutral.

**Positive:** author reports that the suggestion solved the issue.

... Great! That solved it! Thanks a bunch ...  
... Thanks for your help. Finally got it working ...  
... Switching on X did the trick. Now I can Y without any problem ...  
... Thanks a lot guys. X solved my woes. I must have Y-ed it by mistake at some point ...

**Negative:** the suggestion did not solve the issue.

... That didn't help. Any other suggestions? ...  
... I tried that. It is still showing X ...  
... Getting the same X. Thanks anyway ...  
... Thanks for your advice. Unfortunately, it didn't help!

**Neutral:** it is not clear if the issue was solved, but the statement is an acknowledgment nevertheless

... Thanks for the reply ...  
... I will try that ...  
... Thanks for the helpful advice. Hope resetting X properly will fix my problem ...  
... I'm reinstalling X. Will keep you posted ...

Similar to the case of answer sentences in Section 4, the above examples can be easily identified as acknowledgments and it is fairly clear that the posts to which the above sentences are replies, are answer suggestions. Note that this can be determined without knowing the contents of the latter, if we can assume that the reply-to relation of the posts is known. This however is not always the case. In a small study conducted, we found that only 75% of forums displayed or had the required information in the html of the webpage for constructing the reply-to relation of the posts, out of 12 technical forums that we inspected. In the absence of this information, (Wang et al., 2011; Seo et al., 2009; Wang and Rosé, 2010) propose techniques to automatically recover the structure. For the purposes of this paper, we assume that the reply-to structure of the discussion thread is given.

ANS-ACK PCT (ANSWER ACKnowledgment Parallel Co-Training) aims to leverage signals from acknowledgment posts, to better identify answer posts. We cast this as another instance of semi-supervised learning task (another co-training instance) which runs in parallel to the main answer extraction instance of co-training. Hence the name, PARALLEL co-training.

It is worth listing down some of the design decisions for this choice of approach:

(i) There is no public dataset available to train an acknowledgment classifier. So, it is important to note here that the task of detecting acknowledgments cannot be fully supervised where a large

amount of training data is collected for the specific domain; this will defeat the entire purpose of semi-supervised answer extraction.

(ii) For the initial small training set required for the semi-supervised approach, we do not label additional threads. Instead, we create a training set from the initial training set of the answer extraction task by marking replies from the question author to posts that are answers, as positive examples. Other replies from the question author become negative examples. To avoid getting influenced by digressions, we do not consider replies from other authors.

(iii) The reader might suggest using acknowledgment as one of the views within the co-training instance of answer detection, instead of two parallel co-training instances. i.e. to mark all posts that have an acknowledgment as an answer in that view. Here, we would like to point out that acknowledgment is a strong indicator only when it is available. In other words, even if we learn to classify acknowledgment posts perfectly, it cannot classify all answer posts perfectly since not all answers are acknowledged. In our test set (Section 6), there were 559 answers, but only 173 of them had any reply from the question author (30.9%), of which only 72% were actually acknowledgments, as found through manual inspection (the rest had to do with refining the question, requesting clarification on the answer, etc.). So, the hope is to learn how to use the signal when it is available, and not rely on it exclusively by using it as one of the two views of answer co-training.

The acknowledgment extraction uses the same two views – STRUCT and PATTERN – for its co-training instance, similar to the ANS CT model of Section 4, to generate the views,  $^{ack}\Psi_{struct}^i$  and  $^{ack}\Psi_{pattern}^i$ , respectively. Except that here, positive examples are the posts that are acknowledgments, as obtained by Point (ii) above.

## 5.1 Parallel Co-Training for Answer Extraction

Parallel Co-Training is a method for semi-supervised learning where there are two (or more) co-training instances corresponding to different, but related learning tasks running side by side, where in iteration  $i$ , each task can induce features based on the current state of the system. i.e. using the outcome of iteration  $i - 1$  of other tasks. Figure 3 depicts Parallel Co-Training for the specific case of answer extraction, where:

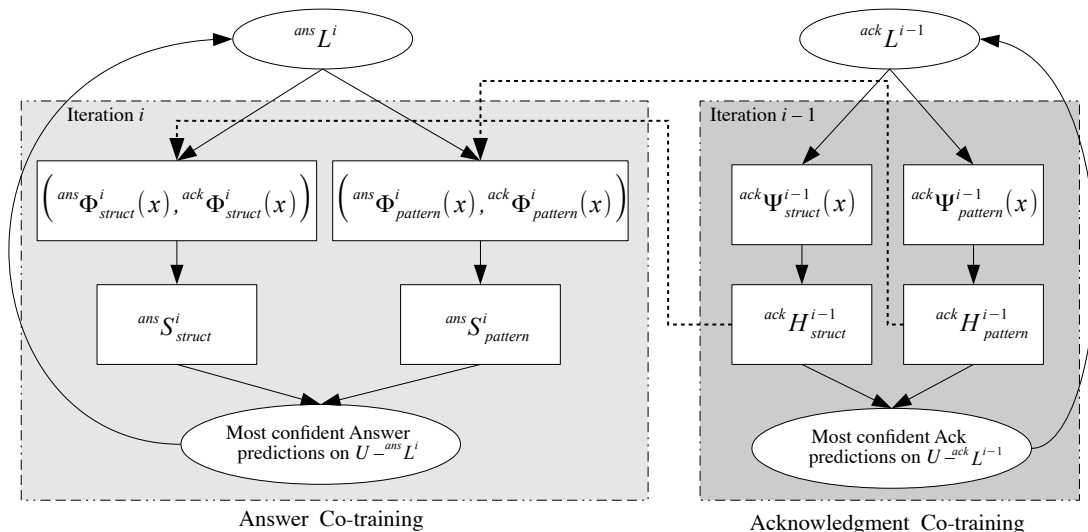

Figure 3: Parallel Co-Training Methodology

- Two tasks run in parallel:
  1. Answer Co-training: the main task which learns to classify each post as  $\text{ans}$  or  $\overline{\text{ans}}$ .
  2. Acknowledgment Co-training: the auxiliary task which learns to classify each post as  $\text{ack}$  or  $\overline{\text{ack}}$ .
- In iteration  $i$ , Answer Co-training uses the Acknowledgment classifiers,  $\text{ack} H_{i-1}^{i-1}$  of the  $i-1^{\text{th}}$  iteration, to induce more features (detailed in Section 5.2),  $\text{ack} \Phi^i$  which is then concatenated to its original feature vector,  $\text{ans} \Phi^i$ , to get the new feature vector  $(\text{ans} \Phi^i, \text{ack} \Phi^i)$  (we use  $(\vec{A}, \vec{B})$  to represent concatenation of two vectors, where the length of the new vector is  $|\vec{A}| + |\vec{B}|$ ). The concatenated feature vector is then used to train the answer classifiers  $\text{ans} S^i$  of the  $i^{\text{th}}$  iteration.
- The STRUCT view of Answer Co-training uses predictions from the acknowledgment classifier that was trained on the STRUCT view of Acknowledgment Co-training, and similarly for the PATTERN view, so that the concatenated features vectors still remain independent.

## 5.2 Inducing Features from Acknowledgments

Given a thread and acknowledgment tags on some of the posts, the most obvious feature that can be induced on an answer post is a `hasAck` feature which is `True` if any child of this post is marked as an acknowledgment; else `False`. All features that we generated are listed in Table 2.

ACK Feature	Description
Has Ack	True if this post has a reply that is tagged as an acknowledgment; else False.
Ack Distance	The number of posts, in the chronological order, between this post and its acknowledgment.
Last Ack Distance	The number of posts, in the chronological order, between this post and the last acknowledgment post in the thread.

Table 2: Features induced from Acknowledgments

## 6 Experiments

We crawled about 140K threads from Apple Discussions<sup>4</sup>. From these, after discarding those with no replies, 303 threads were randomly chosen, and manually tagged. The inter-annotator agreement<sup>5</sup> between 3 annotators for this task was 0.71. For the experiments, the training set had 3 of the tagged threads and the remaining 300 formed the test set, the statistics of which are in Table 3.

Statistics	Training Set	Test Set
No. of Threads	3	300
Avg. Length of Threads	6.3	5.8
Avg. Answers per Thread	1.9	1.8
Fraction of Answers with Question Author’s reply <sup>6</sup>	47.4%	30.9%

Table 3: Statistics of the Training and Test Sets

We used Support Vector Machines (Vapnik, 1995) (implementation from the LibSVM<sup>7</sup> library) for all the individual classifiers,  $\text{ans} S^i$  and

<sup>4</sup><https://discussions.apple.com>

<sup>5</sup>[http://en.wikipedia.org/wiki/Cohen's\\_kappa](http://en.wikipedia.org/wiki/Cohen's_kappa)

<sup>7</sup><http://www.csie.ntu.edu.tw/~cjlin/libsvm/>

$ack H^i$ , used in the different views of the co-training instances of ANS CT and ANS-ACK PCT models.

### 6.1 Study of Improvement in Answer Extraction Accuracy

	STRUCT	PATTERN	COMBINED
SVM	1.1%	2.5%	28.6%
ANS CT	55.6%	55.6%	55.6%
ANS-ACK PCT	63.7%	63.6%	67.8%

Table 4: F Scores for the Answer Extraction task

To demonstrate the benefits of co-training, we first trained a supervised classifier (SVM) on the training set for answer extraction, separately on the two views – STRUCT and PATTERN. With such a little amount of training data, the classifiers gave unimpressive F scores (van Rijsbergen, 1979), shown in the first row of Table 4. The COMBINED classifier is a combination of the individual STRUCT and PATTERN classifiers, computed as:  $(P(\text{ans}|S_{combined}) \propto P(\text{ans}|S_{struct}) \times P(\text{ans}|S_{pattern}))$ ; and similarly for  $\overline{\text{ans}}$ . The post is tagged as  $\text{ans}$  if  $P(\text{ans}|S_{combined}) \geq P(\overline{\text{ans}}|S_{combined})$ . Else, it is  $\overline{\text{ans}}$ .

Next, we performed 40 iterations of co-training and in each step, 5 threads with the most confident predictions were added by each view from the unlabeled pool to the training set. If more than one thread had the same confidence, any one thread was chosen randomly. The accuracies achieved by ANS CT after the final iteration (averaged over 3 runs) is listed in Table 4. Clearly, both STRUCT and PATTERN classifiers drastically improved their F scores and the COMBINED classifier showed a substantial 94% improvement over the SVM baseline. The growth of F score of the two sub-classifiers as the co-training proceeds, is plotted in Figure 4. It can be seen that both the classifiers reached their best within 10 iterations and did not improve any further.

Figure 4: ANS CT: F-scores of the STRUCT and PATTERN sub-classifiers after each iteration

Figure 5: ANS-ACK PCT: F scores of the STRUCT and PATTERN sub-classifiers of the *Answer Classifier* after each iteration

Figure 6: ANS-ACK PCT: F scores of the STRUCT and PATTERN sub-classifiers of the *Acknowledgment Classifier* after each iteration

For ANS-ACK PCT, we performed 40 co-training iterations similar to ANS CT; the number of threads chosen after each iteration was similarly set to 5, for both answer and acknowledgment instances. The answer classification accuracies achieved by ANS-ACK PCT after the final iteration (averaged over 3 runs) is also listed in Table 4. Similar to ANS CT, both STRUCT and PATTERN classifiers improved their F scores significantly. The COMBINED classifier showed a substantial 137% improvement over the SVM baseline and 22% improvement over ANS CT. The F score growth of the answer and the acknowledgment classifiers as the co-training proceeds, is plotted in Figure 5 and Figure 6 respectively. Unlike Figure 4, the answer classifiers in Figure 5 continue to improve even after 10 iterations, since the acknowledgment instance is supplying it with more signals. In Figure 6, the PATTERN sub-classifier of the acknowledgment classifier constantly improved throughout the 40 iterations even though its STRUCT counterpart stabilized in about 10 iterations. The F scores of the acknowledgment classifiers at the end of the final iteration was 82.8%, 52.9% and 81.9% respectively for STRUCT, PATTERN and COMBINED.

## 6.2 Comparison between approaches

	Precision	Recall	F score
SVM - STRUCT	75.0%	0.5%	1.1%
SVM - PATTERN	25.9%	1.3%	2.5%
ANS CT	40.6%	88.0%	55.6%
ANS-ACK PCT	56.8%	84.1%	67.8%
CONG	29.7%	55.6%	38.7%

Table 5: Comparison of accuracy measures of different methods for the answer classification task

Graph Propagation based Answer Extraction by Cong et al. (Cong et al., 2008) is an unsupervised method for extracting answers from discussion forums. It is based on the premise that a correct answer will be repeated often within the discussion and thus, the similarity of the post to other posts can be used as a measure of their “answer-ness”. We used our own implementation of this algorithm, referred to as CONG in the experiments. The similarity between posts is computed using Kullback-Leibler divergence (Kullback, 1997), which was reported by the authors to have given the best performance. The Precision, Recall and F scores of CONG are compared with those of the proposed methods in Table 5.

Table 5 shows that both proposed methods perform substantially better than CONG: ANS CT exceeds it by 43.6% and ANS-ACK PCT surpasses it by 75.1% (F score). Consequently, we can conclude that with very small training data, it is possible to achieve high accuracies compared to extracting them in an unsupervised manner.

### 6.3 Discussion: Answer and Acknowledgment Patterns

This section studies the patterns that were mined from answers and acknowledgments, which reveal the types of sentence structures that frequently appear in them. Some of the interesting answer patterns are listed in Table 6. They are grouped into Imperative, Factual, Conditional and Questions, based on manual inspection. Similarly, the acknowledgment sentences also showed interesting patterns, manually grouped into Action and Others, listed in Table 7. From inspecting the answer and acknowledgment patterns, we conjecture that it should be possible to build classifiers based on rules defined over the structure of the sentence, without requiring access to a training set.

## 7 Conclusion and Future Work

In this paper, we proposed two semi-supervised methods for extracting answers from discussion

Pattern Type	Examples
Imperative Sentence	1. go - to - NNS - NN - on 2. you - can - VB - NN 3. VBG - your - NN - NN 4. VB - to - NNS - NN 5. VBG - your - NN 6. check - NN - NN
Fact	7. is - VBZ - not - NN
Conditional Statement	8. if - you - VBP - NN
Questions	9. have - VB - you - tri - VBN - VBG - NN 10. have - you - VBN - VBG - NN

Table 6: Mined Answer Patterns

Pattern Type	Examples
Action	1. i - VBP - to - VB 2. i - VBP - NN - it 3. i - not - VB - NN 4. i - have - VBP - NN, 5. i - am - VBP - VBG - NN
Others	6. but - i - VBP 7. i - am - VBP - sure

Table 7: Mined Acknowledgment Patterns

threads. We showed how the structural features and sentence construction patterns could be engineered into a co-training setting such that by using a very small training set, and the large amount of unlabeled data available, answers could be extracted with high accuracy, substantially surpassing that attained by an unsupervised method. To demonstrate the benefits of our method, we also showed that completely supervised methods would fail to train a decent model with the very little training data that we used.

In one of our methods, we motivated and introduced a related task of identifying acknowledgments to the answers, which was cast in a parallel co-training setting. We proposed new features which the answer labeling instance could induce from the acknowledgment instance. Our experiments showed that having access to this view of the discussion thread substantially improved the answer extraction accuracy.

Our work opens up new directions of research. In the parallel co-training setting, other than inducing features, the co-training instances are essentially independent. In future, we plan to extend it such that the two instances would collaboratively label new threads; this should lead to higher gains since the instances would now strive to achieve higher coherence between their labels. Also, extending the method to extract answers at a lower granularity like a snippet or a sentence, instead of at a post level would be advantageous for domains that have more factoid type answers.

## Abstract

Automatic keyphrase extraction aims to pick out a set of terms as a representation of a document without manual assignment efforts. Supervised and unsupervised graph-based ranking methods have been studied for this task. However, previous methods usually computed importance scores of words under the assumption of single relation between words. In this work, we propose WordTopic-MultiRank as a new method for keyphrase extraction, based on the idea that words relate with each other via multiple relations. First we treat various latent topics in documents as heterogeneous relations between words and construct a multi-relational word network. Then, a novel ranking algorithm, named Biased-MultiRank, is applied to score the importance of words and topics simultaneously, as words and topics are considered to have mutual influence on each other. Experimental results on two different data sets show the outstanding performance and robustness of our proposed approach in automatic keyphrase extraction task.

## 1 Introduction

Keyphrases refer to the meaningful words and phrases that can precisely and compactly represent documents. Appropriate keyphrases help users a lot in better grasping and remembering key ideas of articles, as well as fast browsing and reading. Moreover, qualities of some information retrieval and natural language processing tasks have been improved with the help of document keyphrases, such as document indexing, categorizing, cluster-

ing and summarizing (Gutwin et al., 1999; Krulwich and Burkey, 1996; Hammouda et al., 2005).

Usually, keyphrases are manually assigned by authors, which is time consuming. With the fast development of Internet, it becomes impractical to label them by human effort as articles on the Web increase exponentially. Therefore, automatic keyphrase extraction plays an important role in keyphrases assignment task.

In most existing work, words are assumed under a single relation and then scored or judged within it. Considering the famous TextRank (Mihalcea and Tarau, 2004), a term graph under a single relatedness was built first, then a graph-based ranking algorithm, such as PageRank (Page et al., 1999), was used to determine the importance score for each term. Another compelling example is (Liu et al., 2010), where words were scored under each topic separately.

In this study, inspired by some multi-relational data mining techniques, such as (Ng et al., 2011), we assume each topic as a single relation type and construct an intra-topic word network for each relation type. In other words, it is to map word relatedness within multiple topics to heterogeneous relations, meaning that words have interactions with others based on different topics.

A multi-relational words example of our proposed WordTopic-MultiRank model is shown in Figure 1(a). There are four words and three relations in this example, implying that there are three potential topics contained in the document. Further, we represent such multi-relational data in a tensor shape in Figure 1(b), where each two-dimensional plane represents an adjacency matrix for one type of topics. Then the heterogeneous network can be depicted as a tensor of size  $4 \times 4 \times 3$ , where  $(i, j, k)$  entry is nonzero if the  $i$ th word is related to the  $j$ th word under  $k$ th topic.

After that, we raise a novel measurement of word relatedness considering different topics, and

<sup>‡</sup>Corresponding author.

Figure 1: (a) An example of multi-relational words in graph representation and (b) the corresponding tensor representation.

then apply Biased-MultiRank algorithm to deal with multi-relational words for co-ranking purpose, based on the idea that words and topics have mutual influence on each other. More specifically, a word, connected with highly scored words via highly scored topics, should receive a high score itself, and similarly, a topic, connecting highly scored words, should get a high score as well.

Experiments have been performed on two different data sets. One is a collection of scientific publication abstracts, while the other consists of news articles with human-annotated keyphrases. Experimental results demonstrate that our WordTopic-MultiRank method outperforms representative baseline approaches in specified evaluation metrics. And we have investigated how different parameter values influence the performance of our method.

The rest of this paper is organized as follows. Section 2 introduces related work. In Section 3, details of constructing and applying WordTopic-MultiRank model are presented. Section 4 shows experiments and results on two different data sets. Finally, in Section 5, conclusion and future work are discussed.

## 2 Related Work

Existing methods for keyphrase extraction task can be divided into supervised and unsupervised approaches. The supervised methods mainly treat keyphrase extraction as a classification task, so a model needs to be trained before classifying whether a candidate phrase is a keyphrase or not. Turney (1999) firstly utilized a genetic algorithm with parameterized heuristic rules for keyphrase extraction, then Hulth (2003) added more linguistic knowledge as features to achieve better perfor-

mance. Jiang et al. (2009) employed linear Ranking SVM, a learning to rank method, to extract keyphrase lately. However, supervised methods require a training set which would demand time-consuming human-assigned work, making it impractical in the vast Internet space. In this work, we principally concentrate on unsupervised methods.

Among those unsupervised approaches, clustering and graph-based ranking methods showed good performance in this task. Representative studies of clustering approaches are (Liu et al., 2009) and (Grineva et al., 2009). Liu et al. (2009) made use of clustering methods to find exemplar terms and then selected terms from each cluster as keyphrases. Grineva et al. (2009) applied graph community detection techniques to partition the term graph into thematically cohesive groups and selected groups that contained key terms, discarding groups with unimportant terms. But as is widely known, one of the major difficulties in clustering is to predefine the cluster number which influences performance heavily.

As for basic graph-based approaches, such as (Mihalcea and Tarau, 2004) and (Litvak and Last, 2008), a graph based on word linkage or word similarity was first constructed, then a ranking algorithm was used to determine the importance score of each term. Wan et al. (2007) presented an idea of extracting summary and keywords simultaneously under the assumption that summary and keywords of the same document can be mutually boosted. Moreover, Wan and Xiao (2008a) used a small number of nearest neighbor documents for providing more knowledge to improve performance and similarly, Wan and Xiao (2008b) made use of multiple documents with a cluster context. Recently, topical information was under consideration to be combined with graph-based approaches. One of the outstanding studies was Topic-sensitive PageRank (Haveliwala, 2002), which computed scores of web pages by incorporating topics of the context. As another representative, Topical PageRank (Liu et al., 2010) applied a Biased PageRank to assign an importance score to each term under every latent topic separately.

To the best of our knowledge, previous graph-based researches are based on the assumption that all words exist under a unified relation, while in this work, we view latent topics within documents

as word relations and words as multi-relational data, in order to make full use of word-word relatedness, word-topic interaction and inter-topic impacts.

### 3 WordTopic-MultiRank Method

In this section, we will introduce our proposed WordTopic-MultiRank method in details, including topic decomposition, word relatedness measurement, heterogeneous network construction and Biased-MultiRank algorithm.

#### 3.1 Topic Detection via Latent Dirichlet Allocation

There are some existing methods to infer latent topics of words and documents. Latent Dirichlet Allocation (LDA) (Blei et al., 2003) is adopted in our work as it is more feasible for inference and it can reduce the risk of over-fitting.

Firstly, we denote the learning corpus for LDA as  $C$ , and  $|C|$  represents the total number of documents in  $C$ . The  $i$ th document in the corpus is denoted as  $d_i$ , in which  $i = 1, 2, \dots, |C|$ . Then, words are denoted as  $w_{ij}$  where  $i$  indicates that word  $w_{ij}$  appears in document  $d_i$  and  $j$  refers to  $j$ th position in  $d_i$  ( $j = 1, 2, \dots, |d_i|$ ,  $|d_i|$  is the total word number in  $d_i$ ). Further, topics inferred from  $|C|$  is  $z_k$ ,  $k = 1, 2, \dots, |T|$ , while  $T$  stands for the topic set detected from  $C$  and  $|T|$  is the total number of topics.

According to LDA, observed words in each document are supposed to be generated by a document-specific mixture of corpus-wide latent topics. More specifically, each word  $w_{ij}$  in document  $d_i$  is generated by first sampling a topic  $z_k$  from  $d_i$ 's document-topic multinomial distribution  $\theta_{d_i}$ , and then sampling a word from  $z_k$ 's topic-word multinomial distribution  $\phi_{z_k}$ . And each  $\theta_{d_i}$  is generated by a conjugate Dirichlet prior with parameter  $\alpha$ , while each  $\phi_{z_k}$  is generated by a conjugate Dirichlet prior with parameter  $\beta$ . The full generative model for  $w_{ij}$  is given by:

$$p(w_{ij}|d_i, \alpha, \beta) = \sum_{k=1}^{|T|} p(w_{ij}|z_k, \beta)p(z_k|d_i, \alpha) \quad (1)$$

Using LDA, we finally obtain the document-topic distribution, namely  $p(z_k|d_i)$  for all the topics  $z_k$  on each document  $d_i$ , as well as the topic-word distribution, namely  $p(w_{ij}|z_k)$  for all the words  $w_{ij}$  on each topic  $z_k$ .

In this work, we use GibbsLDA++<sup>1</sup>, a C/C++ implementation of LDA using Gibbs Sampling, to detect latent topics.

#### 3.2 Measurement of Word Relatedness under Multi-relations

Next, we apply Bayes' theorem to get word-topic distribution  $p(z_k|w_{ij})$  for every word in a given document  $d_i$ :

$$p(z_k|w_{ij}) = \frac{p(w_{ij}|z_k, \beta)p(z_k|d_i, \alpha)}{\sum_{k=1}^{|T|} p(w_{ij}|z_k, \beta)p(z_k|d_i, \alpha)} \quad (2)$$

Therefore, we can obtain word relatedness as follows:

$$p(w_{im}|w_{in}, z_k) = p(w_{im}|z_k)p(z_k|w_{in}) \quad (3)$$

where  $m, n = 1, 2, \dots, |d_i|$ , and  $p(w_{im}|w_{in}, z_k)$  represents the relatedness of word  $w_{im}$  and word  $w_{in}$  under  $k$ th topic.

From the view of probability,  $p(z_k|w_{in})$  is the probability of word  $w_{in}$  being assigned to topic  $z_k$  and  $p(w_{im}|z_k)$  is the probability of generating word  $w_{im}$  from the same topic  $z_k$ . Therefore,  $p(w_{im}|w_{in}, z_k)$  shows the probability of generating word  $w_{im}$  if we have observed word  $w_{in}$  under topic  $z_k$ . Obviously, this point of view corresponds with LDA and it connects words via topics.

#### 3.3 Constructing a Heterogeneous Network on Words

Like Figure 1(a) shown in Introduction, now we construct a multi-relational network for words. In the same way mentioned by typical graph-based methods, for every document  $d_i$  in corpus  $C$ , we treat every single word as a vertex and make use of word co-occurrences to construct a word graph as it indicates the cohesion relationship between words in the context of document  $d_i$ . In this process, a sliding window with maximum  $W$  words is used upon the word sequences of documents. Those words appearing in the same window will have a link to each other under all the relations in the network.

Further, we obtain the word relatedness under every topic from Formula (3), and use them as weights of edges for constructing the heterogeneous network. For instance,  $p(w_{im}|w_{in}, z_k)$  is regarded as the weight of the edge from  $w_{in}$  to  $w_{im}$  under  $k$ th relation if there is a co-occurrence relation between the two words in document  $d_i$ .

<sup>1</sup>GibbsLDA++: <http://gibbslda.sourceforge.net>

As (Hulth, 2003) pointed out, most manually assigned keyphrases were noun groups whose pattern was zero or more adjectives followed by one or more nouns. We only take adjectives and nouns into consideration while constructing networks in experiments.

### 3.4 Ranking Algorithm

In our proposed method, we employ Biased-MultiRank algorithm for co-ranking the importance of words and topics. It is obtained by adding prior knowledge of words and topics to Basic-MultiRank, a basic co-ranking scheme designed for objects and relations in multi-relational data. Therefore, we will demonstrate Basic-MultiRank first, then derive Biased-MultiRank algorithm from it.

#### 3.4.1 Basic-MultiRank Algorithm

In this subsection, we take document  $d_i$  into discussion for convenience. First, we call  $\mathcal{A} = (a_{w_{im}, w_{in}, z_k})$  a real  $(2, 1)$ th order  $(|d_i| \times |T|)$ -dimensional rectangular tensor, where  $a_{w_{im}, w_{in}, z_k}$  denotes  $p(w_{im}|w_{in}, z_k)$  obtained in last subsection, in which  $m, n = 1, 2, \dots, |d_i|$  and  $k = 1, 2, \dots, |T|$ . For example, Figure 1(b) is a  $(2, 1)$ th order  $(4 \times 3)$ -dimensional tensor representation of a document, in which there are 4 words and 3 topics.

Then two transition probability tensors  $\mathcal{O} = (o_{w_{im}, w_{in}, z_k})$  and  $\mathcal{R} = (r_{w_{im}, w_{in}, z_k})$  are constructed with respect to words and topics by normalizing all the entries of  $\mathcal{A}$ :

$$o_{w_{im}, w_{in}, z_k} = \frac{a_{w_{im}, w_{in}, z_k}}{\sum_{m=1}^{|d_i|} a_{w_{im}, w_{in}, z_k}} \quad (4)$$

$$r_{w_{im}, w_{in}, z_k} = \frac{a_{w_{im}, w_{in}, z_k}}{\sum_{k=1}^{|T|} a_{w_{im}, w_{in}, z_k}} \quad (5)$$

Here we deal with dangling node problem in the same way as PageRank (Page et al., 1999). Namely, if  $a_{w_{im}, w_{in}, z_k}$  is equal to 0 for all words  $w_{im}$ , which means that word  $w_{in}$  had no link out to any other words via topic  $z_k$ , we set  $o_{w_{im}, w_{in}, z_k}$  to be  $1/|d_i|$ . Likewise, if  $a_{w_{im}, w_{in}, z_k}$  is equal to 0 for all  $z_k$ , which means that word  $w_{in}$  had no link out to words  $w_{im}$  via all topics, we set  $r_{w_{im}, w_{in}, z_k}$  to be  $1/|T|$ . In this way, we ensure that

$$0 \leq o_{w_{im}, w_{in}, z_k} \leq 1, \sum_{m=1}^{|d_i|} o_{w_{im}, w_{in}, z_k} = 1$$

$$0 \leq r_{w_{im}, w_{in}, z_k} \leq 1, \sum_{k=1}^{|T|} r_{w_{im}, w_{in}, z_k} = 1$$

Following the rule of Markov chain, we derive the probabilities like:

$$P[X_t = w_{im}] = \sum_{n=1}^{|d_i|} \sum_{k=1}^{|T|} o_{w_{im}, w_{in}, z_k} \times P[X_{t-1} = w_{in}, Y_t = z_k] \quad (6)$$

$$P[Y_t = z_k] = \sum_{m=1}^{|d_i|} \sum_{n=1}^{|d_i|} r_{w_{im}, w_{in}, z_k} \times P[X_t = w_{im}, X_{t-1} = w_{in}] \quad (7)$$

where subscript  $t$  denotes the iteration number.

Notice that Formula (6) and (7) accord with our basic idea that, a word connected with high probability words via high probability relations, should have a high probability so that it will be visited more likely, and a topic connecting words with high probabilities, should also get a high one.

After employing a product form of individual probability distributions, we decouple the two joint probability distributions in Formula (6) and (7) as follows:

$$P[X_{t-1} = w_{in}, Y_t = z_k] = P[X_{t-1} = w_{in}] P[Y_t = z_k] \quad (8)$$

$$P[X_t = w_{im}, X_{t-1} = w_{in}] = P[X_t = w_{im}] P[X_{t-1} = w_{in}] \quad (9)$$

Considering stationary distributions of words and topics, while  $t$  goes infinity, the WordTopic-MultiRank values are given by:

$$\bar{\mathbf{x}} = [\bar{x}_{w_{i1}}, \bar{x}_{w_{i2}}, \dots, \bar{x}_{w_{i|d_i|}}]^T \quad (10)$$

$$\bar{\mathbf{y}} = [\bar{y}_{z_1}, \bar{y}_{z_2}, \dots, \bar{y}_{z_{|T|}}]^T \quad (11)$$

with

$$\bar{x}_{w_{im}} = \lim_{t \rightarrow \infty} P[X_t = w_{im}] \quad (12)$$

$$\bar{y}_{z_k} = \lim_{t \rightarrow \infty} P[Y_t = z_k] \quad (13)$$

Under the assumptions from Formula (8) to (13), we can derive these from Formula (6) and (7):

$$\bar{x}_{w_{im}} = \sum_{n=1}^{|d_i|} \sum_{k=1}^{|T|} o_{w_{im}, w_{in}, z_k} \bar{x}_{w_{in}} \bar{y}_{z_k} \quad (14)$$

$$\bar{y}_{z_k} = \sum_{m=1}^{|d_i|} \sum_{n=1}^{|d_i|} r_{w_{im}, w_{in}, z_k} \bar{x}_{w_{im}} \bar{x}_{w_{in}} \quad (15)$$

which mean that the score of  $w_{im}$  depends on its weighted-links with other words via all topics and the score of  $z_k$  depends on scores of the words which it connects with.

Now we are able to solve two tensor equations shown below to obtain the WordTopic-MultiRank values of words and relations according to tensor operations Formula (14) and (15):

$$\mathcal{O}\bar{\mathbf{x}}\bar{\mathbf{y}}=\bar{\mathbf{x}} \quad (16)$$

$$\mathcal{R}\bar{\mathbf{x}}^2=\bar{\mathbf{y}} \quad (17)$$

Ng et al. (2011) show the existence and uniqueness of stationary probability distributions  $\bar{\mathbf{x}}$  and  $\bar{\mathbf{y}}$ , then propose MultiRank, an iterative algorithm, to solve Formula (16) and (17) utilizing Formula (14) and (15). We refer it as Basic-MultiRank algorithm, shown as **Algorithm 1**, for the reason that it will be modified later in the following subsection.

---

#### Algorithm 1 Basic-MultiRank algorithm

**Require:** Tensor  $\mathcal{A}$ , initial probability distributions  $\bar{\mathbf{x}}_0$  and  $\bar{\mathbf{y}}_0$  ( $\sum_{m=1}^{|d_i|}[\bar{\mathbf{x}}_0]_{w_m}=1$  and  $\sum_{k=1}^{|T|}[\bar{\mathbf{y}}_0]_{z_k}=1$ ), tolerance  $\epsilon$

**Ensure:** Two stationary probability distributions  $\bar{\mathbf{x}}$  and  $\bar{\mathbf{y}}$

- 1: compute tensor  $\mathcal{O}$  and  $\mathcal{R}$ ;
  - 2: set  $t = 1$ ;
  - 3: Compute  $\bar{\mathbf{x}}_t = \mathcal{O}\bar{\mathbf{x}}_{t-1}\bar{\mathbf{y}}_{t-1}$ ;
  - 4: Compute  $\bar{\mathbf{y}}_t = \mathcal{R}\bar{\mathbf{x}}_t^2$ ;
  - 5: if  $\|\bar{\mathbf{x}}_t - \bar{\mathbf{x}}_{t-1}\| + \|\bar{\mathbf{y}}_t - \bar{\mathbf{y}}_{t-1}\| < \epsilon$ , then stop, otherwise set  $t = t + 1$  and goto Step 3;
  - 6: **return**  $\bar{\mathbf{x}}_t$  and  $\bar{\mathbf{y}}_t$ .
- 

### 3.4.2 Biased-MultiRank Algorithm

Inspired by the idea of Biased PageRank (Liu et al., 2010), we treat document-word distribution  $p(w_{ij}|d_i)$ , which can be computed from Formula (1), and document-topic distribution  $p(z_k|d_i)$ , acquired from topic decomposition, as prior knowledge for words and topics in each document  $d_i$ . Therefore, we modify Formula (16) and (17) by adding prior knowledge to it as follows:

$$(1-\lambda)\mathcal{O}\bar{\mathbf{x}}\bar{\mathbf{y}}+\lambda\bar{\mathbf{x}}_p=\bar{\mathbf{x}} \quad (18)$$

$$(1-\gamma)\mathcal{R}\bar{\mathbf{x}}^2+\gamma\bar{\mathbf{y}}_p=\bar{\mathbf{y}} \quad (19)$$

where,  $\bar{\mathbf{x}}_p=[p(w_{i1}|d_i),p(w_{i2}|d_i),\dots,p(w_{i|d_i}|d_i)]^T$  and  $\bar{\mathbf{y}}_p=[p(z_1|d_i),p(z_2|d_i),\dots,p(z_{|T|}|d_i)]^T$ .

Then we propose Biased-MultiRank, shown as **Algorithm 2**, as a new algorithm to solve the prior-tensors and Formula (18) and (19). Finally it is used in our WordTopic-MultiRank model.

---

#### Algorithm 2 Biased-MultiRank algorithm

**Require:** Tensor  $\mathcal{A}$ , initial probability distributions  $\bar{\mathbf{x}}_0$  and  $\bar{\mathbf{y}}_0$  ( $\sum_{m=1}^{|d_i|}[\bar{\mathbf{x}}_0]_{w_m}=1$  and  $\sum_{k=1}^{|T|}[\bar{\mathbf{y}}_0]_{z_k}=1$ ), prior distribution of words  $\bar{\mathbf{x}}_p$  and topics  $\bar{\mathbf{y}}_p$ , parameters  $\lambda$  and  $\gamma$  ( $0 \leq \lambda, \gamma < 1$ ), tolerance  $\epsilon$

**Ensure:** Two stationary probability distributions  $\bar{\mathbf{x}}$  and  $\bar{\mathbf{y}}$

- 1: compute tensors  $\mathcal{O}$  and  $\mathcal{R}$ ;
  - 2: set  $t = 1$ ;
  - 3: Compute  $\bar{\mathbf{x}}_t = (1-\lambda)\mathcal{O}\bar{\mathbf{x}}_{t-1}\bar{\mathbf{y}}_{t-1} + \lambda\bar{\mathbf{x}}_p$ ;
  - 4: Compute  $\bar{\mathbf{y}}_t = (1-\gamma)\mathcal{R}\bar{\mathbf{x}}_t^2 + \gamma\bar{\mathbf{y}}_p$ ;
  - 5: if  $\|\bar{\mathbf{x}}_t - \bar{\mathbf{x}}_{t-1}\| + \|\bar{\mathbf{y}}_t - \bar{\mathbf{y}}_{t-1}\| < \epsilon$ , then stop, otherwise set  $t = t + 1$  and goto Step 3;
  - 6: **return**  $\bar{\mathbf{x}}_t$  and  $\bar{\mathbf{y}}_t$ .
- 

## 4 Experiment

To evaluate the performance of WordTopic-MultiRank in automatic keyphrase extraction task, we utilize it on two different data sets and describe the experiments specifically in this section.

### 4.1 Experiments on Scientific Abstracts

#### 4.1.1 Data Set

We first employ WordTopic-MultiRank model to conduct experiments on a data set of scientific publication abstracts from the INSPEC database with corresponding manually assigned keyphrases<sup>2</sup>. The data set is also used by Hulth (2003), Mihalcea and Tarau (2004), Liu et al. (2009), and Liu et al. (2010), meaning that it is classically used in the task of keyphrase extraction, and is convenient for comparison.

Actually, this data set contains 2,000 abstracts of research articles and 19,254 manually annotated keyphrases, and is split into 1,000 for training, 500 for validation and 500 for testing.

In this study, we use the 1,000 training documents as corpus  $C$  for topic detection and like other unsupervised ranking methods, 500 test documents are used for comparing the performance with baselines. Following previous work, only the manually assigned uncontrolled keyphrases that occur in the corresponding abstracts are viewed as standard answers.

---

<sup>2</sup>It can be obtained from <http://github.com/snkim/AutomaticKeyphraseExtraction>

#### 4.1.2 Baselines and Evaluation Metrics

We choose methods proposed by Hulth (2003), Mihalcea and Tarau (2004), Liu et al. (2009), and Liu et al. (2010) as baselines for the reason that they are either classical or outstanding in keyphrase extraction task.

Evaluation metrics are *precision*, *recall*, *F1-measure* shown as follows:

$$P = \frac{TP}{TP+FP}, R = \frac{TP}{TP+FN}, F1 = \frac{2PR}{P+R} \quad (20)$$

where  $TP$  is the total number of correctly extracted keyphrases,  $FP$  is the number of incorrectly extracted keyphrases, and  $FN$  is the number of those keyphrases which are not extracted.

#### 4.1.3 Data Pre-processing and Configuration

Documents are pre-processed by removing stop words and annotated with POS tags using Stanford Log-Linear Tagger<sup>3</sup>.

Based on the research result of (Hulth, 2003), only adjectives and nouns are used in constructing multi-relational words network for ranking, and keyphrases corresponding with following pattern are considered as candidates:

$$(JJ)*(NN|NNS|NNP)+$$

in which, JJ indicates adjectives while NN, NNS and NNP represent various forms of nouns.

At last, top- $M$  keyphrases, which have highest sum scores of words contained in them, are extracted and compared with standard answers after stemming by Porter stemmer<sup>4</sup>.

In experiments, we set  $\alpha=1$ ,  $\beta=0.01$  for Formula (1) to (3) empirically, and  $\lambda=0.5$ ,  $\gamma=0.9$  for Formula (18), (19) indicated by (Li et al., 2012). Influences of these parameters will not be discussed further in this work as they have been studied intensively in previous researches.

#### 4.1.4 Experimental Results

In this subsection, we investigate how different parameter values influence performance of our proposed model first, then compare the best results obtained by baseline methods and our model.

First of all, we inspect influences of topic number  $|T|$  on our model performance. Table 1 shows experimental results when  $|T|$  ranges from 20 to 100 while setting window size  $W=2$  and max extracted number  $M=10$ .

<sup>3</sup><http://nlp.stanford.edu/software/tagger.shtml>

<sup>4</sup><http://tartarus.org/martin/PorterStemmer/>

Topic Number	Precision	Recall	F1
20	0.463	0.498	0.479
40	0.464	0.500	0.480
60	0.465	0.502	<b>0.482</b>
80	0.462	0.499	0.480
100	0.462	0.499	0.480

Table 1: Influence of Topic Number  $|T|$

From Table 1, we observe that the performance does not change much when the number of topics varies, showing our model’s robustness under the situation that the actual number of topics is unknown, which is commonly seen in Information Retrieval and Natural Language Processing applications. We can see that  $|T|=60$  produces the best result for this corpus, so we choose 60 for  $|T|$  in comparison with baselines.

Then, we fix  $|T|=60$  and  $M=10$  to demonstrate how our model is affected by the windows size  $W$ . Table 2 presents the metrics when  $W$  ranges from 2 to 10.

Window Size	Precision	Recall	F1
2	0.465	0.502	<b>0.482</b>
4	0.461	0.496	0.477
6	0.462	0.500	0.480
8	0.461	0.499	0.479
10	0.461	0.498	0.478

Table 2: Influence of Window Size  $W$

Our results are consistent with the findings reported by Liu et al. (2009) and Liu et al. (2010), indicating that performance usually does not vary much when  $W$  ranges. More details point out that  $W=2$  is the best.

Moreover, we explore the influence of max extracted number  $M$  by setting  $W=2$  and  $|T|=60$ .

$M$	Precision	Recall	F1
5	<b>0.602</b>	0.393	0.475
10	0.465	0.502	<b>0.482</b>
15	0.420	<b>0.550</b>	0.476

Table 3: Influence of Max Extracted Number  $M$

Table 3 indicates that as  $M$  increases, *precision* falls down while *recall* raises up, and  $M=10$  performs best in *F1-measure*.

At last, Table 4 shows the best results of baseline methods and our proposed model. In fac-

Method	Precision	Recall	F1
Hulth’s (Hulth, 2003)	0.252	0.517	0.339
TextRank (Mihalcea and Tarau, 2004)	0.312	0.431	0.362
Topical PageRank (Liu et al., 2010)	0.354	0.183	0.242
Clustering (Liu et al., 2009)	0.350	<b>0.660</b>	0.457
WordTopic-MultiRank	<b>0.465</b>	0.502	<b>0.482</b>

Table 4: Comparison on Scientific Abstracts

Method	Precision	Recall	F1
ExpandRank(Wan and Xiao, 2008a)	0.288	0.354	0.317
CollaRank(Wan and Xiao, 2008b)	0.283	0.348	0.312
Topical PageRank(Liu et al., 2010)	0.282	0.348	0.312
WordTopic-MultiRank	<b>0.296</b>	<b>0.399</b>	<b>0.340</b>

Table 5: Comparison on DUC2001

t, the best result of (Hulth, 2003) was obtained by adding POS tags as features for classification, while running PageRank on an undirected graph, which was built via using window  $W=2$  on word sequence, resulted best of (Mihalcea and Tarau, 2004). According to (Liu et al., 2009), spectral clustering method got best performance in *precision* and *F1-measure*. On the other hand, Topical PageRank (Liu et al., 2010) performed best when setting window size  $W=10$ , topic number  $|T|=1,000$ . Since the influences of parameters have been discussed above, we set  $W=2$ ,  $|T|=60$  and  $M=10$  as they result in best performance of our model on the same data set.

Table 4 demonstrates that our proposed model outperforms all baselines in both *precision* and *F1-measure*. Noting that baseline methods are all under a single relation type assumption for word relatedness, estimations of their word ranking scores are limited, while WordTopic-MultiRank assumes words as multi-relational data and considers interactions between words and topics more comprehensively.

## 4.2 Experiments on DUC2001

In order to show the generalization performance of our model, we also conduct experiments on another data set for automatic keyphrase extraction task and describe it in this subsection briefly.

Following (Wan and Xiao, 2008a), (Wan and Xiao, 2008b) and (Liu et al., 2010), a data set annotated by Wan and Xiao<sup>5</sup> was used in this experiment for evaluation. This data set is the testing part of DUC2001(Over and Yen, 2004), con-

<sup>5</sup><http://wanxiaojun1979.googlepages.com/>

taining 308 news articles with 2,488 keyphrases manually labeled. And at most 10 keyphrases were assigned to each document. Again, we choose *precision*, *recall* and *F1-measure* as evaluation metrics and use the train part of DUC2001 for topic detection. At last, keyphrases extracted by our WordTopic-MultiRank model will be compared with the ones occurring in corresponding articles after stemming.

As indicated in (Wan and Xiao, 2008b), performance on test set does not change much when co-occurrence window size  $W$  ranges from 5 to 20, and (Liu et al., 2010) also reports that it does not change much when topic number ranges from 50 to 1,500. Therefore, we pick co-occurrence window size  $W=10$  and topic number  $|T|=60$  to run WordTopic-MultiRank model. As for Keyphrase number  $M$ , we vary it from 1 to 20 to obtain different performances. Results are shown in Figure 2.

Figure 2: performance vs. Keyphrase number  $M$

From Figure 2, we can observe how performances of our model change with  $M$ . Actually,

as  $M$  increases from 1 to 20, *precision* decreases from 0.528 to 0.201 in our experiment, while *recall* increases from 0.065 to 0.551. As for *F1-measure*, it obtains maximum value 0.340 when  $M=10$  and decreases gradually as  $M$  leaves 10 farther. Therefore,  $W=10$ ,  $|T|=60$  and  $M=10$  are optimal for our proposed method on this test set.

Table 5 lists the best performance comparison between our method and previous ones. All previous methods perform best on DUC2001 test set while setting co-occurrence window size  $W=10$  and Keyphrase number  $M=10$ , which is consistent with our model.

Experimental results on this data set demonstrate the effectiveness of our proposed model again as it outperforms baseline methods over all three metrics.

## 5 Conclusion and Future Work

In this study, we propose a new method named WordTopic-MultiRank for automatic keyphrase extraction task. It treats words in documents as objects and latent topics as relations, assuming words are under multiple relations. Based on the idea that words and topics have mutual influence on each other, our model ranks importance of words and topics simultaneously, then extracts highly scored phrases as keyphrases. In this way, it makes full use of word-word relatedness, word-topic interaction and inter-topic impacts. Experiments demonstrate that WordTopic-MultiRank achieves better performance than baseline methods on two different data sets. It also shows the good effectiveness and strong robustness of our method after we explored the influence of different parameter values.

In future work, for one thing, we would like to investigate how different corpora influence our method and choose a large-scale and general corpus, such as Wikipedia, for experiments. For another, exploring more algorithms to deal with heterogeneous relation network may help to unearth more knowledge between words and topics, and improve our model performance.

{Michael.Wiegand|Dietrich.Klakow}@lsv.uni-saarland.de

## Abstract

We explore the feasibility of contextual healthiness classification of food items. We present a detailed analysis of the linguistic phenomena that need to be taken into consideration for this task based on a specially annotated corpus extracted from web forum entries. For automatic classification, we compare a supervised classifier and rule-based classification. Beyond linguistically motivated features that include sentiment information we also consider the prior healthiness of food items.

## 1 Introduction

Food plays a substantial part in each of our lives. With the growing health awareness in many parts of the population, there is consequently a high demand for the knowledge about healthiness of food. In view of the variety of both different types of food and nutritional aspects it does not come as a surprise that there is no comprehensive repository of that knowledge. Since, however, much of this information is preserved in natural language text, we assume that it is possible to acquire some of this knowledge automatically with the help of natural language processing (NLP).

In this paper, we take a first step towards this endeavour. We try to identify mentions that a food item is healthy (1) or unhealthy (2).

(1) There is not a healthy diet without a lot of fruits, vegetables and salads.

(2) The day already began unhealthy: I had a piece of cake for breakfast.

This task is a pre-requisite of more complex tasks, such as finding food items that are suitable for certain groups of people with a particular health condition (3) or identifying reasons for the healthiness or unhealthiness of particular food items (4).

(3) Vegetables are healthy, in particular, if you suffer from diabetes.

(4) Potatoes are healthy since they are actually low in calories.

The major problem of identifying some *Is-Healthy* or *Is-Unhealthy* relation is that the simple co-occurrence of a food item and the word *healthy* or *unhealthy* is not sufficiently predictive as shown in (5)-(7).

(5) Chocolate is *not* healthy.

(6) *The industry says* chocolate is healthy, but I guess this is just a marketing strategy.

(7) *If* chocolate is healthy, then I will run for the next presidential election.

We describe the contextual phenomena that underlie these cases and provide detailed statistics as to how often they occur in a typical text collection. From this analysis we derive features to be incorporated into a classifier.

Our experiments are carried out on German data. We believe, however, that our findings carry over to other languages since the aspects addressed in this work are (mostly) language universal. For the sake of general accessibility, all examples will be given as English translations.

To the best of our knowledge, this is the first work that addresses the classification of healthiness of food items using NLP.

## 2 Related Work

In the food domain, the most prominent research addresses ontology or thesaurus alignment (van Hage et al., 2010), a task in which concepts from different sources are related to each other. In this context, hyponymy relations (van Hage et al., 2005) and part-whole relations (van Hage et al., 2006) have been explored. More recently, Wiegand et al. (2012a) examined extraction methods for relations involved in customer advice in a supermarket. In Chahuneau et al. (2012), sentiment information has been related to food prices with the help of a large corpus consisting of restaurant menus and reviews.

In the health/medical domain, the majority of research focus on domain-specific relations involving entities, such as genes, proteins and

drugs (Cohen and Hersh, 2005). More recently, the prediction of epidemics (Fisichella et al., 2011; Torii et al., 2011; Diaz-Aviles et al., 2012; Munro et al., 2012) has attracted the attention of the research community. In addition, there has been research on processing health-care claims (Popowich, 2005) and detecting sentiment in health-related texts (Sokolova and Bobicev, 2011).

### 3 The Dataset

In order to generate a dataset for our experiments, we used a crawl of *chefkoch.de*<sup>1</sup> (Wiegand et al., 2012a) consisting of 418,558 webpages of food-related forum entries. *chefkoch.de* is the largest German web portal for food-related issues.

While we are aware of the fact that the healthiness of food items is also discussed in scientific texts we think that the text analysis on social media serves its own purpose. The language in social media is much more accessible to the general population. Moreover, social media can be considered as an exclusive repository of *popular wisdom* containing, for example, home remedies.

#### 3.1 Healthiness Markers & Food Items

As it is impractical for us to manually label the entire web corpus with healthiness information, we extracted for annotation sentences in which there is a healthiness marker and a mention of a food item. By healthiness marker, we understand an expression that conveys the property of being healthy. Apart from the word *healthy* itself, we came up with 17 further common expressions (e.g. *nutritious*, *healthful* or *in good health*). Since the word *healthy* covers more than 95% of the mentions of healthiness markers in our entire corpus, however, we decided to restrict our healthiness marker exclusively to mentions of that expression. Thus, our main focus in this classification task is the contextual disambiguation, i.e. the task to decide whether a specific co-occurrence of the expression *healthy* and some food item denotes a genuine *Is-(Un)Healthy* relation.

The food items for which we extract co-occurrences with the healthiness marker *healthy* (Table 7) will henceforth be referred to as *target food items*. In order to obtain a suitable list of items for our experiments, we manually compiled a list of frequently occurring types of food.

<sup>1</sup>[www.chefkoch.de](http://www.chefkoch.de)

#### 3.2 “Unhealthy” vs. “Not Healthy”

In order to obtain instances that express an *Is-Unhealthy* relation, we exclusively consider negated instances of the *Is-Healthy* relation (8). We also experimented with a dataset with mentions of the word *unhealthy* (paired with our target food items) to extract instances such as (9).

(8) I am convinced that cake is *not healthy*.

(9) I am convinced that cake is *unhealthy*.

Using the same target food items, the *unhealthy*-dataset is, however, less than 14% of the size of the *healthy*-dataset. We also found that instances of the *Is-Unhealthy*-relation are not easier to detect on the *unhealthy*-dataset, since the *unhealthy*-dataset produced much poorer classifiers for detecting *Is-Unhealthy* relations than the *healthy*-dataset using negations as a proxy.

### 4 Annotation

Our final dataset comprises 2,440 instances, where each **instance** consists of a sentence with the co-occurrence of some food item and the word *healthy* accompanied by the two sentences immediately preceding and the two sentences immediately following it.

The dataset was manually annotated by two German native speakers. On 4 target food items (this corresponds to 574 target sentences)<sup>2</sup> we measured an inter-annotation agreement of Cohen’s  $\kappa = 0.7374$  (Landis and Koch, 1977) which should be sufficiently high for our experiments.

The annotators had to choose from a rich set of category labels that particularly divide the negative examples (i.e. those cases in which the co-occurrence of the target food item and *healthy* neither expresses an *Is-Healthy* nor an *Is-Unhealthy* relation) into different categories.

In the following, we describe the different category labels. Their distribution is shown in Table 1.

#### 4.1 Is-Healthy Relation (HLTH)

This class describes instances in which there holds an *Is-Healthy* relation between the mention of *healthy* and the target food item (10).

(10) Potatoes are incredibly healthy, versatile in the kitchen and very tasty.

Table 1 shows that less than 20% of the co-occurrences of the target food item and *healthy* express this relation. This may already indicate that its extraction is difficult.

<sup>2</sup>This is the only part of the dataset which was annotated by both annotators in parallel.

Type	Abbrev.	Frequency	Percentage
Is-Healthy	HLTH	488	20.00
Is-Unhealthy	UNHLTH	171	7.01
OTHER:			
No Relation	NOREL	788	32.30
Restricted Relation	RESTR	312	12.79
Unspecified Intersection	INTERS	198	8.11
Embedding	EMB	157	6.43
Comparison Relation	COMP	121	4.96
Unsupported Claim	CLAIM	87	3.57
Other Sense	SENSE	77	3.16
Irony	IRO	25	1.02
Question	Q	16	0.66

Table 1: Statistics of the different (linguistic) phenomena.

## 4.2 Is-Unhealthy Relation (UNHLTH)

We already stated in §3.2 that we consider negated instances (11) as instances for the *Is-Unhealthy* relation. We have a fairly broad notion of negation, e.g. (12) and (13) will also be assigned to this category. These *partial* negations are at least as frequent as *full* negations (11). However, we assume that the latter are often employed only as a means of being polite even though the speaker’s intention is that of a full negation. The fact that we also observed fewer mentions of *unhealthy* co-occurring with a target food item than negated mentions of *healthy* would be in line with this theory (*unhealthy* is usually perceived to be more intense/blunter than *not healthy*).

- (11) Chocolate is not healthy.  
(12) Chocolate is not very healthy.  
(13) Chocolate is hardly healthy.

## 4.3 Other Relations

Apart from the two target relations, we observe the following other relationships:

### 4.3.1 Restricted Relation (RESTR)

This category describes cases in which the *Is-Healthy* relation holds provided some additional condition is fulfilled. Typical conditions address a special kind of preparing the target food item (14) or make quantitative restrictions as to the amount of the target food item to be consumed (15). As such, one cannot infer from restricted relations to general properties of food items.

- (14) Steamed vegetables are extremely healthy.  
(15) A teaspoon of honey each day has been proven to be quite healthy.

### 4.3.2 Unspecified Intersection (INTERS)

In relation extraction, syntactic relatedness between the candidate entities of a relation is usually

considered an important cue (Zhou et al., 2005; Mintz et al., 2009). In particular, the specific *type* of syntactic relation needs to be considered. If in our task *healthy* is an attributive adjective of the target food item (16), this is not an indication of a genuine *Is-Healthy* relation that we are looking for. With this construction, one usually refers to all those entities that share the two properties (*intersection*) of being the target food item and being healthy. This case is different from both *HLTH* (17) and *RESTR* (18).

- (16) I usually buy the healthy fat.  
(17) Fat is healthy.  
(18) I usually buy the healthy fat, the one that contains a high degree of unsaturated fatty acids.

*HLTH*, typically realized as a predicative adjective (17), requires that this intersection of properties includes the *entire* set of entities representing the target food item. For both *RESTR* and *INTERS*, on the other hand, this intersection only includes a proper subset of the target food item. In addition, *RESTR* provides some (vital) additional information about this subset that allows it to be (easily) identified (e.g. the property of containing a high degree of unsaturated fatty acids in (18)). However, for *INTERS*, no further properties are specified in order to identify it – the information of being healthy is not telling as we actually want to find out how to detect healthy food. As a consequence, instances of type *INTERS* are hardly informative when it comes to answering whether a particular food item is healthy or not. We do not even know how large the proportion of the intersection with regard to the overall amount of the target food item is. It may well be extremely small. That is why in this work, instances of *INTERS* will neither be used as evidence for the healthiness nor the unhealthiness of a particular food item.

### 4.3.3 Comparison Relation (COMP)

If the target food item is compared with another food item with regard to their healthiness status (19) & (20), one cannot conclude anything regarding the *absolute* healthiness of the target food item. This is due to the fact that a comparison assumes healthiness as a (continuous) scale rather than a binary (discrete) property. It determines the positions of the two food items relative to each other on that particular scale.

- (19) Honey is healthier than chocolate. (target food item: *honey*)  
(20) Honey is as healthy as chocolate. (target food item: *honey*)

#### 4.3.4 Unsupported Claim (CLAIM)

In our initial data analysis, we found frequent cases in which the author of a forum entry reports a (controversial) statement regarding the healthiness status of a particular food item. These claims are often used as a means of starting a discussion about that issue (21).

(21) Some people claim that chocolate is healthy. What do you make of it?

If it is not possible to infer from such reported statement that the reported view is shared by the author (and we found that this is true for many reported statements), we tag it as *CLAIM*.

#### 4.3.5 Question (Q)

There may also be cases in which the *Is-(Un)Healthy* relation is embedded in a question (22).

(22) Is chocolate healthy?

#### 4.3.6 Irony (IRO)

Irony (23) is a figure of speech that can frequently be observed in user-generated text (Tsur et al., 2010). With a proportion of less than 1%, this, however, does not apply for the forum entries that comprise our data collection.

(23) Everyone knows that sweets are healthy, in particular, chocolate with its many calories even makes you lose weight.

#### 4.3.7 Embedding (EMB)

In addition to the previous categories *CLAIM* and *IRO*, there exist other ways of embedding the healthiness relation into a context so that the general validity of it is discarded. We introduce a common label for all those other remaining types that include, for instance, *modal embedding* (24) or *irrealis construction* (25).

(24) Honey could be healthy.

(25) If chocolate were healthy, people eating it wouldn't put on so much weight.

#### 4.3.8 Other Sense (SENSE)

Both the target food item and the German healthiness cue *gesund* are (potentially) ambiguous expressions. For instance, *gesund* can be part of several multiword expressions, such as *gesunder Menschenverstand* (engl. *common sense*).

#### 4.3.9 No Relation (NOREL)

While in all previously discussed cases the target food item and *healthy* are somehow related, there are cases in which the co-occurrence is merely coincidental (26).

(26) Tomatoes are very healthy and they can be ideally served on bread. (target food item: *bread*)

On our dataset, this is the most frequent label.

## 5 Feature Design

All features we use are summarized in Table 2 along examples. Apart from bag of words (*word*), we use following features:

### 5.1 Linguistic Features

The linguistic features are mainly derived from our quantitative data analysis in §4. Given the limited space of this paper, we will only point out some special properties.

The first group of (linguistic) features (Table 2) is designed to detect some relationship between target food item and *healthy*. The co-occurrence within the same clause is usually a good predictor. There are three features to establish this property: *clause*, *boundary* and *otherFood*.

We already pointed out in §4.3.2 that not only syntactic relatedness between *healthy* and the target food item as such but also the specific syntactic relation plays a decisive role for this task. The two most common relations are that *healthy* is a predicative adjective (of the target food item), which is usually indicative of *HLTH*, and that *healthy* is an attributive adjective (of the target food item), which is usually indicative of *INTERS* (on our dataset in more than 90% of the instances labeled with *INTERS* this is the case). This is reflected by the two features *predRel* and *attrRel* (and the back-off features *pred* and *attr*). An additional feature *attrFood* captures a special construction in which *healthy* as an attributive adjective actually denotes *HLTH* instead of *INTERS*.

For the conditional healthiness *RESTR* (§ 4.3.1), we found two predominant subcategories of restrictions: restrictions with regard to the quantity with which the target food item should be consumed (*quant*) and references to a specific subtype of the target food item, which we want to capture with a few precise surface patterns (*spec*) and a feature that checks whether the target food item precedes an attributive adjective (*attrNoH*).

Table 2 also contains features to detect various contextual embeddings (*opHolder*, *question*, *irrealis*, *modal* and *irony*). *opHolder* is to detect cases of *CLAIM*. We assume once some opinion holder other than the author of the forum post (i.e. 1st person pronoun) is identified, there is a *CLAIM*.

We also investigate whether *healthiness* correlates with *sentiment*. For instance, if the author promotes the healthiness of some food item, does this also coincide with positive sentiment (e.g.

*tasty, good* etc.)? Our features *positive/negative polar* check for the presence of polar expressions.

## 5.2 Knowledge-based Features using a Healthiness Lexicon

We also incorporate features referring to the prior knowledge of healthiness of food items. We use a lexicon introduced in Wiegand et al. (2012b) which covers approximately 3000 food items, and we refer to it as *healthiness lexicon*. Each food item is specified as being either healthy or unhealthy in that lexicon. The healthiness judgment has been carried out based on the general nutrient content of each food item. A detailed description of the annotation scheme and annotation agreement can be found in Wiegand et al. (2012b).

The specific features derived from that lexical resource are listed in Table 2. They are divided into two groups. *prior* describes the prior healthiness of the target food item. Since our task is to determine the *contextual* healthiness, the usage of such a feature is legitimate. The *contextual* healthiness need not to coincide with the *prior* healthiness. For instance, in (27), *chocolate* is described as a healthy food item even though it is a priori considered unhealthy.

(27) Chocolate is healthy as it’s high in magnesium and provides vitamin E.

We use this knowledge as a baseline. If we cannot exceed the classification performance of *prior* (alone), then acquiring the knowledge of healthiness with the help of NLP is hardly effective.

*priorCont* describes the prior healthiness status of *neighbouring food items* in the given context.

## 6 Rule-based Classification

We also examine rule-based classifiers since they can be built without any training data. Each classifier is defined by a (large) conjunction of linguistic features. Features indicating a class other than the target class are used as negated features in that conjunction. The rule-based classifiers only consider features where a positive or negative correlation towards the target class is (more or less) obvious. Table 3 shows the rule-based classifiers for each of our classes. For *HLTH*, it basically states that *healthy* has to be a predicative adjective of the target food item (*predRel*), and the target food item and *healthy* have to appear within the same clause (or there is no boundary sign between them). After that, a long list of negated features follows: *quant*, *spec* and *attrNoH*, for exam-

HLTH	$\text{predRel} \wedge (\text{clause} \vee \neg\text{boundary}) \wedge \neg\text{quant} \wedge \neg\text{spec} \wedge \neg\text{attrNoH} \wedge \neg\text{negTarget} \wedge \neg\text{negHealth} \wedge \neg\text{comp} \wedge \neg\text{opHolder} \wedge \neg\text{modal} \wedge \neg\text{irrealis} \wedge \neg\text{question} \wedge \neg\text{sense} \wedge \neg\text{weird}$
UNHLTH	$\text{predRel} \wedge (\text{clause} \vee \neg\text{boundary}) \wedge \neg\text{quant} \wedge \neg\text{spec} \wedge \neg\text{attrNoH} \wedge (\text{negTarget} \vee \text{negHealth}) \wedge \neg\text{comp} \wedge \neg\text{opHolder} \wedge \neg\text{modal} \wedge \neg\text{irrealis} \wedge \neg\text{question} \wedge \neg\text{sense} \wedge \neg\text{weird}$

Table 3: Rule-based classifiers based on linguistic features (Table 2).

ple, are negated because they are typical cues for *RESTR*. The remaining features are negated since they are either indicative of *UNHLTH*, *COMP*, *EMB*, *CLAIM*, *SENSE*, *IRO* or *Q*. The classifier for *UNHLTH* only differs from *HLTH* in that either of the negation cues, i.e. *negTarget* or *negHealth*, has to be present.

## 7 Experiments

In this section we present the results on automatic classification.

### 7.1 Classification of Individual Utterances

In this subsection, we evaluate the performance of the different feature sets on sentence-level classification using supervised learning and rule-based classification. We investigate the detection of the two classes *HLTH* (§4.1) and *UNHLTH* (§4.2). Each instance to be classified is a sentence in which there is a co-occurrence of a target food item and a mention of *healthy* along its respective context sentences. The dataset was parsed using the Stanford Parser (Rafferty and Manning, 2008). We carry out a 5-fold cross-validation on our manually labeled dataset. As a supervised classifier, we use Support Vector Machines (*SVM<sup>light</sup>* (Joachims, 1999) with a linear kernel). For each class, we train a binary classifier where positive instances represent the class to be extracted while negative instances are the remaining instances of the entire dataset (§4).

#### 7.1.1 Comparison of Various Feature Sets

Table 4 lists the results for various feature sets that we experimented with. *take-all* is an unsupervised baseline that considers all instances of our dataset as positive instances (of the class which is examined, i.e. *HLTH* or *UNHLTH*). In other words, this baseline indicates how well the mere co-occurrence of *healthy* and the target food item predicts either of our two classes.<sup>3</sup> Our second

<sup>3</sup>Restricting the co-occurrence to a certain window size did not improve the F-Score of *take-all*.

Word-based Features		
Feature	Abbrev.	Illustration/Further Information
bag of words between the mention of <i>healthy</i> and target food item, and the additional words that precede or follow <i>healthy</i> and target food item	word	N/A
Linguistic Features		
Feature	Abbrev.	Illustration/Further Information
Are target food item and <i>healthy</i> within the same clause?	clause	<i>I like chocolate<sub>target</sub>, even though I consider fruits the healthy option for snacks.</i> Feature operates on parse output.
Is there a punctuation mark between target food item and <i>healthy</i> ?	boundary	<i>I know that vegetables are extremely healthy; but I prefer chocolate<sub>target</sub>.</i> Token-level back-off feature to <i>clause</i> .
Is there another food item between target food item and <i>healthy</i> ?	otherFood	<i>We always had healthy meals with lots of vegetables and <u>salad</u>, but this does not mean that we were not allowed to eat chocolate<sub>target</sub>.</i> Token-level back-off feature to <i>clause</i> .
Is target food item in a prominent position?	prom	Prominent positions: e.g. beginning/end of a sentence/subclause.
Is target food item used as a side dish?	side	<i>Broccoli with potatoes<sub>target</sub> is a healthy dish.</i> Patterns from relation type <i>Served-with</i> used in Wiegand et al. (2012a).
Is <i>healthy</i> a predicative adjective relating to target food item?	predRel	<i>Vegetables are healthy.</i>
Is <i>healthy</i> an attributive adjective relating to target food item?	attrRel	<i>I would recommend buying some healthy fat.</i>
Is <i>healthy</i> a predicative adjective?	pred	<i>I really like bananas<sub>target</sub> and they are healthy, too.</i>
Is <i>healthy</i> an attributive adjective?	attr	<i>For that we need to use some kind of fat<sub>target</sub>; I particularly favour the healthy ones.</i>
Does <i>healthy</i> precede target food item?	precede	If <i>healthy</i> precedes the target food item, then this often indicates <i>attributive</i> usage.
Is <i>healthy</i> an attributive adjective of a general food expression (i.e. <i>meal, dish, food</i> , etc.) that is not target food item?	attrFood	<i>Salad is a healthy dish.</i>
Is there some quantification?	quant	<i>100g per day; in moderation; a teaspoon of;</i> a list of 75 quantifying expressions was collected from the web ( <a href="http://rezepte.nit.at/kuechenmasse.html">rezepte.nit.at/kuechenmasse.html</a> ) and <a href="http://de.wikibooks.org/wiki/Kochbuch/_Maßangaben">de.wikibooks.org/wiki/Kochbuch/_Maßangaben</a> ).
Is target food item modified by an attributive adjective other than <i>healthy</i> ?	attrNoH	<i>steamed vegetables; fried potatoes</i>
Is target food item further specified?	spec	<i>bread<sub>target</sub> made of whole grains; cake<sub>target</sub> with low-fat ingredients;</i> Complementary feature to <i>attrNoH</i> (feature detects specifications in the form of contact clauses or prepositional phrases immediately attached to the target food item).
Is there a cue indicating an opinion holder other than the author?	opHolder	<i>Some people claim that chocolate is healthy.</i> This feature relies on a set of predicates indicating the presence of an opinion holder (Wiegand and Klakow, 2011).
Is target sentence a (direct) question?	question	<i>Is chocolate healthy?</i>
Is <i>healthy</i> embedded in some <i>irrealis</i> context?	irrealis	<i>If honey were healthy; I wonder, whether honey is healthy.</i> Translation of the cues used in hedge classification (Morante and Daelemans, 2009).
Is <i>healthy</i> modified by a modal verb?	modal	<i>Honey might be healthy.</i>
Is target food item negated?	negTarget	<i>No cake is healthy.</i> We adapted to German the negation word lists and the scope modeling from Wilson et al. (2005).
Is <i>healthy</i> negated?	negHealth	<i>Chocolate is not healthy.</i> We adapted to German the negation word lists and the scope modeling from Wilson et al. (2005).
Is there any occurrence of a <i>weird</i> word?	weird	<i>Sure, chocolate is veeeeery healthy.</i> Regular expression detecting suspicious reduplications of characters in order to detect irony.
Does the context suggest that <i>healthy</i> is part of a comparison?	comp	We check for typical inflectional word forms (i.e. <i>healthier</i> and <i>healthiest</i> ) and constructions, such as <i>as healthy as</i> .
Does the context of <i>healthy</i> suggest another sense of the word?	sense	Contexts in which <i>healthy</i> has a different meaning (using online dictionaries, such as <a href="http://www.duden.de/rechtschreibung/gesund">www.duden.de/rechtschreibung/gesund</a> and <a href="http://de.wiktionary.org/wiki/gesund">de.wiktionary.org/wiki/gesund</a> ).
Number of positive/negative polar expressions (excluding mentions of <i>healthy</i> )	polar*	Usage of the German <i>PolArt</i> sentiment lexicon (Klenner et al., 2009).
Number of near synonyms of (un)healthy	syno*	Examples for healthy: <i>high in vitamin, tonic</i> , etc.; examples for unhealthy: <i>carcinogenic, harmful</i> , etc. (manually compiled list of 99 synonyms by an annotator <b>not</b> involved in feature engineering).
Number of diseases	disease*	411 entries, created with the help of the web ( <a href="http://bildung.wikia.com/wiki/Alphabetische_Liste_der_Krankheiten">bildung.wikia.com/wiki/Alphabetische_Liste_der_Krankheiten</a> ).
Task-specific Knowledge-based Features using a Healthiness Lexicon

significantly better than *word*\* at  $p < 0.1$ ° at  $p < 0.05$ ; better than *word+linguistic*† at  $p < 0.05$ ; better than *word+prior*‡ at  $p < 0.05$  (paired t-test)

Table 4: Comparison of different feature sets.

baseline is *prior* (see §5.2 for motivation).

*take-all* has optimal recall but a very poor precision. The second baseline *prior* is notably better. *prior* may help to distinguish between *HLTH* and *UNHLTH* but it does not contribute to distinguishing these classes from the rest of the relation types (Table 1).

If we turn to the features that largely exploit contextual information, i.e. *word* and *linguistic* (§5.1), we find that both features are better than the previous features. This is an indication that learning from text is effective. The same can be said about *word+linguistic* and *word+prior*, which also outperform *word*. *word+linguistic+prior* is the best feature set outperforming both *word+linguistic* and *word+prior*. We conclude that all of the three groups of features we presented in §5 are relevant for this task.

In terms of recall and F-score the supervised classifier always outperforms the rule-based classifier. This does not come as a surprise as the supervised classifier learns from labeled training data while the rule-based classifier is unsupervised. On the other hand, we also find that the precision of the rule-based classifier largely outperforms our best supervised classifier on *HLTH*.

The fact that the best overall F-score achieved is not higher may be ascribed to the heavy noise (spelling/grammar mistakes) contained in our web-data. However, we believe that even with those data we can show the relative effectiveness of the different feature types which is the most relevant aspect in our *proof-of-concept* investigation.

Class	Features
HLTH	prom, attrNoH, predRel, comp, negHealth, <i>negative polarEC</i> , sense, opHolder, irrealis
UNHLTH	negHealth, negTarget, attrRel, comp, diseaseTS, <i>negative polarEC</i>

Table 5: List of the best subset of linguistic features (Table 2) for each individual class.

### 7.1.2 Inspection of Linguistic Features

Table 5 shows the best performing feature subset using a best-first forward selection as implemented in *Weka* (Witten and Frank, 2005). The table shows that diverse features are important including features to detect restricted relations (§4.3.1) (i.e. *attrNoH*) or comparisons (i.e. *comp*), features to distinguish predicative from attributive adjectives for the detection of unspecified intersection (§4.3.2) (i.e. *predRel* and *attrRel*), various features to determine contextual embedding (i.e. *opHolder*, *irrealis* and *negHealth*) and sentiment information (i.e. *negative polarEC*).

### 7.1.3 Detecting Anti-Prior Healthiness

We now take a closer look at *anti-prior* instances which are utterances in which the relation expressed is opposite to the relation that one would *a priori* assume, e.g. *chocolate is healthy* instead of *chocolate is unhealthy*. In our gold standard, we identified these instances with the help of the actual (manually assigned) label and our healthiness lexicon (§5.2).<sup>4</sup> Such instances may be very interesting to extract, even though they are rare (15% on *HLTH* and *UNHTLH*). Previously, supervised classifiers with *word+prior* produced similar performance as classifiers with *word+linguistic* (Table 4). Since linguistic features are fairly expensive to produce, the prior knowledge of healthiness seems an attractive alternative. But this is misleading. Table 6 displays the recall (by supervised classification) on only anti-prior instances and shows that the usage of *prior* which, in isolation, would detect none of these instances, gives a much lower recall than *linguistic* when added to *word*. Therefore, *word+linguistic* would be the preferable feature set if one had to choose between *word+prior* and *word+linguistic*.

<sup>4</sup>Whenever HLTH co-occurs with prior unhealthiness (according to the healthiness lexicon) or UNHLTH co-occurs with prior healthiness, there is an anti-prior instance.

Feature Set	word+prior	word+linguistic
Recall	17.2	54.6

Table 6: Recall on *anti-prior* instances.

## 7.2 Aggregate Classification

Finally, we automatically rank food items according to healthiness based on the aggregate of text mentions. Ideally, the ranking should separate healthy from unhealthy food items. We want to know whether with our text corpus and contextual classification, one can actually approximate a correct prior healthiness. Aggregate classification means that we make a healthiness prediction for a specific food item based on *all* text mentions of that food item co-occurring with the word *healthy*. It may be easier to achieve a robust aggregate classification than a robust individual classification. This is because in aggregate-based tasks, there is a certain degree of redundancy contained in the data, as instances of a group of utterances (belonging to the same food item) may often comprise similar information. For such classifiers, one should focus on a higher precision since a reasonable recall is enabled by the redundancy in the data.

Our baseline **RAW** is completely unsupervised and does not include any linguistic processing. We use the *Pointwise Mutual Information (PMI)* which is estimated on our large web corpus (§3).<sup>5</sup>

$$PMI(\text{food item}, \text{healthy}) = \log \frac{P(\text{food item}, \text{healthy})}{P(\text{food item})P(\text{healthy})} \quad (1)$$

For the automatic classification, we consider **LEARN** which uses the output of the supervised classifier comprising the features *word+linguistic* (we *must* exclude the feature *prior* as this would include the knowledge we want to predict automatically in this experiment)<sup>6</sup> while **RB** is the output of the rule-based classifier we presented in §6 (which does not contain *prior* as a feature either).

In order to convert the classifications of individual utterances for a target food item (by **LEARN** and **RB**) to one ranking score (according to which we rank all the target food items), we simply compute the ratio between instances predicted to be healthy and those predicted to be unhealthy:

$$\text{score}_{LEARN/RB}(\text{food item}) = \frac{\#HLTH_{predicted}(\text{food item})}{\#UNHLTH_{predicted}(\text{food item})} \quad (2)$$

<sup>5</sup>For  $P(\text{food item}, \text{healthy})$ , we consider all *sentences* in which the target food item and *healthy* co-occur.

<sup>6</sup>We train for each target food item a classifier using only the instances with the other target food items as training data.

<b>RAW</b>	wholemeal product > fat > colza oil > vegetables > tea > protein > olive oil > honey > meat > sugar > salad > bread > chocolate > potato > rice > banana > cake > water > egg
<b>LEARN</b>	banana > olive oil > wholemeal product > tea > colza oil > salad > vegetables > protein > potato > chocolate > meat > bread > rice > water > sugar > cake > egg > fat > honey
<b>RB</b>	potato > protein > wholemeal product > banana > olive oil > vegetables > bread > salad > water > tea > colza oil > rice > honey > egg > chocolate > fat > meat > sugar > cake

Table 7: Aggregate ranking; **green** denotes (actual) healthy items, **red** (actual) unhealthy items.

where  $\#HLTH_{predicted}(\text{food item})$  are the number of instances the classifier predicts the label *HLTH* for the target food item while  $\#UNHLTH_{predicted}(\text{food item})$  are the number of instances labeled as *UNHLTH*, respectively.

Table 7 shows the results of the three rankings. The actual labels are derived from the healthiness lexicon (§5.2). The table clearly shows that the ranking produced by **RAW** contains most errors. *fat* is the second most highly ranked food item. This can be explained by the high proportion of *INTERS* (§4.3.2) among the co-occurrences of *fat* and *healthy* (almost 50%). **LEARN** and **RB** produce a better ranking, thus proving that a contextual (linguistic) analysis is helpful for this task. **RB** also outperforms **LEARN** presumably because of its much higher precision (as measured for individual classification in Table 4: 53.4% vs. 40.2% for *HLTH* and 45.0% vs. 40.9% for *UNHLTH*).

## 8 Conclusion

We presented a first step towards contextual healthiness classification of food items. For this task, we introduced a new annotation scheme. Our annotation revealed that many different linguistic phenomena are involved. Thus, this problem can be considered an interesting task for NLP. We demonstrated that a linguistic analysis is not only necessary for classifying individual utterances but also for ranking food items based on an aggregate of text mentions.

## Abstract

Query segmentation is to split a query into a sequence of non-overlapping segments that completely cover all tokens in the query. The majority of methods are unsupervised, however, they are usually not as accurate as supervised methods due to the lack of guidance from labeled data. In this paper, we propose a new paradigm of *learning a replacement model with consistency* (LRMC), to enable unsupervised training with guidance from search log data. In LRMC, we first assume the existence of a base segmenter (an implementation of any existing approach). Then, we utilize a key observation that queries with a similar intent tend to have *consistent* segmentations, to automatically collect a set of labeled data from the outputs of the base segmenter by leveraging search log data. Finally, we employ the auto-collected data to train a replacement model for selecting the correct segmentation of a new query from the outputs of the base segmenter. The results show LRMC can improve state-of-the-art methods by an F-Score of around 7%.

## 1 Introduction

Nowadays *keyword queries* have been adopted as the de-facto query interface by most search engines. Query tokens are not independent or unordered symbols but rather ordered and structured words and phrases with syntactic relationships. Understanding the structure of a query is crucial for achieving better search performance. Such an understanding will also ease other search related applications such as query suggestion and rewriting, where one is able to work on semantic concepts instead of individual tokens. *Query segmentation* (QS), a process of splitting a query into a sequence of non-overlapping segments that

completely cover all tokens, aims to address these challenges. It requires that every segment rendered is a phrase or a semantic unit. For example, given a query “download adobe writer”, four different ways of segmentation are possible. The challenge is to determine which one is correct.

The majority of QS methods are unsupervised, however, they are not as accurate as supervised methods due to lack of guidance from labeled data. On the other hand, supervised models suffer from the problems: (1) new phrases/words are introduced on the web daily, which quickly invalidate static supervised models trained on a certain manually labeled set; (2) it is not feasible to develop a set of labeled data covering all domains on the web. In this paper, we propose a paradigm of *learning a replacement model with consistency* (LRMC), to enable unsupervised training and it improves various unsupervised QS systems.

LRMC first assumes the existence of a base segmentation system (hereafter referred to as ‘*base segmenter*’) which can output top- $n$  segmentations for any query. Then it tries to learn a *replacement model* capable of selecting the correct segmentation of a new query (if one exists) from the output of the base segmenter. Our study on three state-of-the-art systems (Section 5.2) shows that for more than 35% of queries the correct segmentations are not ranked as top-1 but included in the top-5 results of the base segmenter, which implies the potential of LRMC. The keys to our proposal include: (a) how to *automatically* acquire labeled data (i.e., for a query in the labeled data, what its correct segmentation is) and then (b) how to use the labeled data to learn the replacement model.

Our method for the automatic acquisition of the labeled data is motivated by the observation: *Queries with a similar intent tend to have consistent segmentation results*. In this paper, we say that a set of queries have similar intents if and only if they lead to the same set of web documents (i.e., clicks). For example, when issuing to a web

\*Wei Zhang did this work when he was an intern at Microsoft Research Asia.

queries	Rank-1 Segmentation Result	Rank-2 Segmentation Result
download adobe writer free adobe writer download free adobe writer	download adobe   writer <b>free   adobe writer   download</b> <b>free   adobe writer</b>	<b>download   adobe writer</b> free   adobe   writer   download free adobe   writer

Table 1: Segmentation results for queries with a similar intent (Results in bold are considered correct.)

search engine any of the three queries in Table 1, we search for the same set of web pages which can provide ‘free download of Adobe writer’. We denote such a set of queries as ‘*query intent set*’. For the queries in the same *query intent set*, naturally we wish to explain them in the same way and thus require that their segmentations be consistent with each other. We say that  $q_1$  and  $q_2$  are inconsistent in segmentation if there exist more than one common subsequence of tokens having different segment boundaries. In Table 1, we also include the top-2 segmentation results that can possibly be generated by any base segmenter. If we check only the ‘rank-1’ results, we observe that the segmentation ‘download adobe | writer’ disagrees with the other two. This means that we interpret the same sequence of tokens differently for different queries with a same intent, which is not what we expect to have. Instead, we expect to have the *bolded* segmentations in which none of the individual segments for one query disagrees with the segments for another query. In this paper, we propose two methods for selecting such correct segmentations from top- $n$  segmentation results that are about the same *query intent sets*. With these methods, we can automatically build up a training data set, which allows us to train a reliable model.

The replacement model concerns about *whether or not a ‘rank-1’ segmentation  $S^a$  generated by a base segmenter should be replaced by a ‘rank- $k$ ’ ( $k > 1$ ) segmentation  $S^b$* . The decision of the replacement can be made by collectively considering one or multiple local transformations in the form of ‘ $w_i w_{i+1} \mapsto w_i | w_{i+1}$ ’ or ‘ $w_i | w_{i+1} \mapsto w_i w_{i+1}$ ’. ‘ $w_i w_{i+1} \mapsto w_i | w_{i+1}$ ’ means that  $S^a$  does not include a segment boundary between tokens  $w_i$  and  $w_{i+1}$  and  $S^b$  does; Similarly, ‘ $w_i | w_{i+1} \mapsto w_i w_{i+1}$ ’ means the reverse. For example, for the first query in Table 1, we can have the local transformations ‘download adobe  $\mapsto$  download | adobe’ and ‘adobe | writer  $\mapsto$  adobe writer’. The proposed model estimates the score of every local transformation using a binary classifier and then aggregates the individual scores to reach its final decision.

We conduct extensive experiments using two public data sets. The results show that (a) our

method for automatically constructing a set of labeled data with a base segmenter and a set of query intent sets as inputs is effective, capable of discovering correct segmentations missed by the evaluated base segmenters for more than 20% of queries (See **M2** in terms of  $Acc^{qry}$  in Table 3); and (b) our replacement model benefits existing QS approaches and boosts their performance significantly (e.g. the improvement of  $> 7\%$  F-Score on the data WQ10-Majority in Table 4).

We summarize our contributions as follows: (1) on the basis of the observation that queries with a similar intent tend to have consistent segmentations, we propose a method for automatically collecting from search log data a set of labeled data for QS. The method first groups queries in search log data into what we call a ‘query intent set’ and then select correct segmentations by examining the consistency among segmentations for the queries in the same ‘query intent sets’. (2) With the automatically-collected data, we develop a ‘replacement model’ for the purpose of checking whether or not a ‘rank-1’ segmentation generated by a base segmenter should be replaced by a ‘rank- $k$ ’ ( $k > 1$ ) segmentation. (3) We conduct extensive experiments with two publicly available data sets and show that our proposal can effectively boost the performance of state-of-the-art systems (Hagen et al., 2010; Hagen et al., 2011).

## 2 Related Work

Bergsma and Wang (2007) considered the decision to segment or not between each pair of adjacent words as a binary classification problem. Guo et al. (2008), Yu and Shi (2009), and Kiseleva et al. (2010) used methods based on CRF. As the cost of obtaining labeled data is high, they are usually not feasible to develop a set of labeled data covering all the domains on the web and then train a scalable QS model for web search.

The work for web-scale QS are usually unsupervised and utilized various statistics such as mutual information (MI) and frequency count collected from various sources such as web data, query logs, and etc (Risvik et al., 2003; Jones et al., 2006; Huang et al., 2010; Zhang et al., 2009). Li et al. (2011) also used the language model estimated

from click-through documents to backoff the generating process of QS. Tan and Peng (2008) used n-gram frequencies from a large web corpus as well as Wikipedia. Hagen et al. (2010) showed that the raw n-gram could be exploited with an appropriate normalization scheme and achieved surprisingly good accuracy. Later, they enriched the work by including the use of Wikipedia (Hagen et al., 2011). In our evaluation, we compare our proposal with the last two work which represent state-of-the-art.

Our proposal is orthogonal to all the above approaches. LRMC assumes the existence of a base segmenter (an implementation of any above approaches) and it focuses on how to leverage search log data to learn a replacement model for improving the output of base segmenters.

### 3 Problem Settings

**QS.** Let  $q = [w_1, w_2, \dots, w_n]$  denote a query consisting of  $n$  keywords. A segment  $s = [w_i, \dots, w_j] (1 \leq i \leq j \leq n)$  is a subsequence of the query. A segmentation  $S = [s_1|s_2|\dots|s_K]$  for query  $q$  is then defined as a sequence of non-overlapping segments. ‘|’ denotes a segmentation boundary. If we assume there is no order dependency of  $s$ , we can then treat  $S$  as a set  $\{s_k\}_{k=1}^K$ .

**Query Intent.** There exist many definitions on query intent. In this paper we introduce an operational definition on query intent.

**Definition 1** *The query intent( $s$ ) of a query  $q$  is defined as the set of URLs ( $Urls(q)$ ) which are clicked for  $q$  by users of a web search engine.*

Because most queries are ambiguous or multi-faceted (Clarke et al., 2009), we manage to restrict the number of intents into one or a few by grouping more queries together, which leads to the definition of ‘query intent set’.

**Definition 2** *A query intent set  $Q^{INT}$  is a set of queries satisfying the following conditions:*

- a)  $\bigcap_{q \in Q^{INT}} Urls(q) \neq \emptyset$ ;
- b)  $|Q^{INT}| > c$ .

where  $|Q^{INT}|$  denotes the number of elements in  $Q^{INT}$ , and  $c$  is a parameter to control how specific a query intent is; a larger value for  $c$  usually means that the query intent is more specific and thus less ambiguous.

Query intent sets used in our experiments will be detailed in Section 5.1.

## 4 Our Proposal

### 4.1 Overview of the Proposed Paradigm

First, the paradigm LRMC assumes the existence of a base segmenter that is able to output top- $n$  segmentations for any query. Then it tries to learn a *replacement model* capable of replacing the rank-1 segmentation generated by this base segmenter with one rank- $k$  ( $k > 1$ ) segmentation.

LRMC can be illustrated by the following flowchart. First, a query  $q$  is fed into a base segmenter. As a result, a set of segmentations  $\{S_i\}_{i=1}^n$  regarding  $q$  are generated. Subscript  $i$  denotes the rank of the corresponding segmentation. Next,  $\{S_i\}_{i=1}^n$  are fed into a replacement model. The replacement model tries every possible replacement  $S_i$  ( $i > 1$ ) for the rank-1 segmentation  $S_1$  (as indicated by the curved arrows). The trial ends with two possible results: (a) None of the replacements is valid ( $S_1$  cannot be replaced); and (b) one segmentation  $S_i^*$  ( $i^* > 1$ ) is the most likely replacement and thus chosen as the final segmentation for  $q$  (e.g., the replacement of the solid curve).

LRMC is motivated by the following observation: for most cases, the correct segmentation for a query is included in its top- $n$  segmentation results already. Usually, there are not that many likely segmentations for a query and thus correct segmentations cannot be ranked too low by a base segmenter. For example, for any base segmenter in our experiment, more than 93% of queries can have a segmentation that is agreed upon by at least one of the annotators in its top-5 results. Given this observation, what we have to do is not to generate or propose a new segmentation, but to tell which segmentation is correct in the top- $n$  results.

Next, we detail how the replacement model is learned. Specifically, we first introduce how we automatically extract from search log data a set of labeled data with ‘consistency’ as a guidance and then explain how a ‘replacement model’ can be learned from this data set.

### 4.2 Consistency as Supervision

Assume that we have a *query intent set*  $Q^{INT} = \{q_i\}_{i=1}^m$ . With a base segmenter, we generate the top- $n$  segmentation results  $\{S_{ij}\} (1 \leq j \leq n)$  for

each query  $q_i$ , which forms the following matrix:

$$S_{Q^{INT}} = \begin{pmatrix} S_{11} & \underline{S_{12}} & S_{13} & \cdots & S_{1n} \\ S_{21} & \underline{S_{22}} & S_{23} & \cdots & S_{2n} \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ \underline{S_{m1}} & S_{m2} & S_{m3} & \cdots & S_{mn} \end{pmatrix} \begin{array}{l} \leftarrow q_1 \\ \leftarrow q_2 \\ \cdots \\ \leftarrow q_m \end{array}$$

What we manage to achieve is to collect a set of ‘labeled’ data from  $\{S_{ij}\}$ . In the ‘labeled’ data, each query  $q_i$  has only one segmentation  $S_{ij^*}$  ( $S_{ij^*} \in \{S_{ij}\}_{j=1}^n$ ), which we consider ‘correct’. We make use of two types of strategies to choose the ‘correct’ segmentations from  $\mathbf{S}_{Q^{INT}}$  (e.g., those underlined ones in  $\mathbf{S}_{Q^{INT}}$ , namely  $S_{12}, S_{22}, \dots, S_{m1}$ ).

Before explaining the two strategies, let us first introduce how we measure the consistency between two segmentations. The *consistency*  $cst(S, S')$  between segmentations  $S$  and  $S'$  is defined as the number of segments they share, i.e.,

$$cst(S, S') = |S \cap S'| \quad (1)$$

The first strategy (**M1**) that we use as ‘supervision’ for the acquisition of the labeled data is as follows: The correct segmentations for the  $m$  queries in the same *query intent set* should be very consistent with or similar to each other although the segmentations cannot be exactly the same. Thus, the correct segmentations can be chosen with the objective function:

$$(j_1^*, \dots, j_m^*) = \arg \max_{1 \leq j_1, \dots, j_m \leq n} \sum_{1 \leq i < i' \leq m} cst(S_{ij_i}, S_{i'j_{i'}}) \quad (2)$$

where  $j_i^*$  denote the index (or rank) of the correct segmentation for query  $q_i$ .

The other strategy (**M2**) is on the basis of the observation: Although at most only one top- $n$  segmentation can be correct for a query, most segmentations are not totally incorrect, i.e., they include some correct segments while having some incorrect segments as well. Thus, those incorrect segmentations also provide some clues about what can be correct. In addition, as the choices for ‘incorrect segment’ are usually more than those for correct segment, it is relatively hard for incorrect segments to converge to a few. As a result, a correct segment should be more popular than any one single incorrect segment. Given this discussion, we can have the second objective function:

$$(J_1^*, \dots, J_m^*) = \arg \max_{1 \leq j_1, \dots, j_m \leq n} \left( \sum_{1 \leq i, i' \leq m} \sum_{1 \leq j' \leq n} cst(S_{ij_i}, S_{i'j'}) \right) - \sum_{1 \leq i \leq m} cst(S_{ij_i}, S_{ij_i}) \quad (3)$$

Note that  $cst(S_{ij_i}, S_{ij_i}) = |S_{ij_i}|$ . Given one selected segmentation  $S_{ij_i}$ , the objective is to sum up the consistencies between itself and any of the rest in matrix  $S_{Q^{INT}}$ . Thus, by this objective, we choose the segmentations whose segments are agreed with by most top- $n$  segmentations.

Both strategies assume that correct segments are more popular than incorrect segments in the top- $n$  output of one reasonably-performing base segmenter. Both strategies will fail if the assumption is not true. Our experiments in Section 5.2, in which both strategies are able to find more correct segmentations than the base segmenters, can be seen as a support for the assumption.

### 4.3 Replacement Model

The replacement model is to tell whether or not a segmentation ranked as top-1 by a base segmenter should be replaced by another segmentation with a rank of  $j$  ( $1 < j \leq n$ ). For example, we have a query  $q$  whose top- $n$  segmentations are  $\{S_{qj}\}_{j=1}^n$ . Then, the input of the replacement model will be a possible replacement  $S_{q1} \mapsto S_{qj}$  ( $j > 1$ ) and the output will be a label ‘1’ or ‘0’. Label ‘1’ means  $S_{q1}$  should be replaced by  $S_{qj}$  and ‘0’ means ‘not’.

With that in mind, we can then make use of ‘consistency’ to create a labeled data set. For example, if query  $q$  belongs to a query intent set  $Q^{INT}$  and its correct segmentation chosen by the objective (2) or (3) is  $S_{qj^*}$ , we can generate the labeled instance(s) as follows:

$$D_q = \begin{cases} \{(S_{q1} \mapsto S_{qj}, 0)\}_{j \neq 1} & \text{if } j^* = 1 \\ \{(S_{q1} \mapsto S_{qj^*}, 1)\} & \text{otherwise} \end{cases} \quad (4)$$

By combining all such data sets together, we then have the final labeled data set  $D = \bigcup_q D_q$ . Note that query  $q$  can come from multiple query intent sets (not just one single set).

Next, we explain how to use the above training data to learn a replacement model.

The decision of whether or not to do the replacement of  $S_{q1} \mapsto S_{qj}$  can be made by collectively considering one or multiple local transformations in the form of ‘ $w_i w_{i+1} \mapsto w_i | w_{i+1}$ ’ or ‘ $w_i | w_{i+1} \mapsto w_i w_{i+1}$ ’. ‘ $w_i w_{i+1} \mapsto w_i | w_{i+1}$ ’ means that  $S_{q1}$  does not include a segment boundary between tokens  $w_i$  and  $w_{i+1}$  and  $S_{qj}$  does; ‘ $w_i | w_{i+1} \mapsto w_i w_{i+1}$ ’ means the reverse.

Let  $T(S_{q1} \mapsto S_{qj})$  denote the set of all possible local transformations from  $S_{q1}$  to  $S_{qj}$  and  $\mathbf{x}$  denote

one element from the set (i.e., one local transformation). If we know the likelihood  $f(\mathbf{x})$  of every individual transformation  $\mathbf{x}$  being valid, the score of replacing  $S_{q_1}$  by  $S_{q_j}$  can then be estimated as  $\sum_{\mathbf{x} \in T(S_{q_1} \mapsto S_{q_j})} f(\mathbf{x})$ .

The likelihood of a local transformation  $\mathbf{x}$  being valid can be estimated with a binary classifier. We employ SVM as the classifier. Given an instance  $\mathbf{x}$ , SVM assigns a score to it based on  $f(\mathbf{x}) = \mathbf{w}^T \mathbf{x} + b$ , where  $\mathbf{w}$  denotes a weight vector and  $b$  denotes an intercept. Given a replacement  $(S_{q_1} \mapsto S_{q_j}, y)$  where  $y \in \{0, 1\}$ , a set of labeled data for the binary classifier is prepared as:  $\{\mathbf{x}, y\}_{\mathbf{x} \in T(S_{q_1} \mapsto S_{q_j})}$ . By considering all the replacements in  $D$ , we will have a final training data set  $\{(\mathbf{x}_i, y_i)\}_{i=1}^N$  for SVM.

On the basis of that, we can do the replacement as follows: If for certain  $j$  ( $j > 1$ )  $\sum_{\mathbf{x} \in T(S_{q_1} \mapsto S_{q_j})} f(\mathbf{x}) > 0$ , we will use the segmentation with  $\arg \max_{1 < j \leq n} \sum_{\mathbf{x} \in T(S_{q_1} \mapsto S_{q_j})} f(\mathbf{x})$  as its index to replace the top-1 segmentation; Otherwise, we will keep using the top-1 segmentation.

#### 4.4 Learning Features

In this section, we describe the features for representing a local transformation  $\mathbf{x}$ , which is in the form of either  $'w_{i_0} w_{i_0+1} \mapsto w_{i_0} | w_{i_0+1}'$  or  $'w_{i_0} | w_{i_0+1} \mapsto w_{i_0} w_{i_0+1}'$ . We utilize four categories of features which are possible indicators of a transformation, representing a variety of information such as lexical, syntactic, semantic and etc.

**Contextual Features: Lexical.** The left and right tokens around the decision position,  $w_{i_0}$  and  $w_{i_0+1}$ , are a good signal of the transformation. In the example of “google desktop | download”, the token ‘download’ is separated from its left neighbor. Such common query tokens in the training data with the property of usually being separated from or being connected to its left/right neighbor can help predict new transformations (e.g. “adobe writer download  $\mapsto$  adobe writer | download”). On the basis of this observation, we adopt the left token  $w_{i_0}$  and the right token  $w_{i_0+1}$  as the features for representing a transformation  $\mathbf{x}$ . Furthermore, sometimes one word alone can not perfectly characterize a transformation. For example, to reject the transformation “diet plan  $\mapsto$  diet | plan”, we have to use the token bigram  $\langle \text{diet plan} \rangle$ . Thus, we include all the token bigrams in the form of  $\langle w_{i_0} w_{i_0+1} \rangle$  as features as well. As we all know, lexical features usually suffer from a data sparse-

ness issue when used in various tasks (Bagga and Baldwin, 1998; Sriram et al., 2010). Fortunately, the web-scale training data we collect from *query intent sets* (Section 4.2) enables us to have a good coverage of lexical features.

**Contextual Features: POS Tag.** Bergsma et al. (2007) show that part-of-speech (POS) tags are useful in their segmentation classification. We also exploit the POS tag pair of  $w_{i_0}$  and  $w_{i_0+1}$  as features. For example, intuitively, “NN NN  $\mapsto$  NN | NN” is more likely to occur than “JJ NN  $\mapsto$  JJ | NN”. The POS tags that we consider include all types of POS tags. Note that this is different from Bergsma et al. (2007). As their segmentation model only takes care of noun phrase queries, their POS tags are restricted to determiners, adjectives, and nouns. The POS tagger by (Roth and Zelenko, 1998) is used in this paper.

**Mutual Information (MI).** Following previous work (Section 2), we also adopt MI between  $w_{i_0}$  and  $w_{i_0+1}$  as our feature. The work (Bergsma and Wang, 2007) also considered the case of a noun phrase with multiple modifiers (e.g. “female bus driver”). To make the segmentation decision between ‘female’ and ‘bus’,  $MI(\text{‘female’}, \text{‘driver’})$  is more suitable to represent the information of not separating them than  $MI(\text{‘female’}, \text{‘bus’})$ . Thus, we also incorporate  $MI(w_{i_0-1}, w_{i_0+1})$  and  $MI(w_{i_0}, w_{i_0+2})$  into our feature set.

Most previous work on QS only can use word-based MI as introduced above. However, in some cases, the MI between tokens can not provide sufficient information for a segmentation decision. For instance, assume that we have the following two queries with their correct segmentations: (1) “download | call of duty | free”; (2) “duty free | shops | sfo”. Only using the token-based mutual information  $MI(\text{‘duty’}, \text{‘free’})$  can not discriminate the two queries from each other and thus can not give different segmentations for ‘duty free’ in the two queries. In our work, as the query has been segmented by a base segmenter, we propose to also use the segment-based MI. In the ‘duty free’ example,  $MI(\text{‘call of duty’}, \text{‘free’})$  will be incorporated for the transformation decision related to “download | call of duty free  $\mapsto$  download | call of duty | free”, where the token-based  $MI(\text{‘duty’}, \text{‘free’})$  does not work.

**Semantic Features.** We define the semantic features on the basis of segments. For a transformation  $'w_{i_0} w_{i_0+1} \mapsto w_{i_0} | w_{i_0+1}'$ , let us denote the

segment including  $w_{i_0}w_{i_0+1}$  (in the first segmentation) as  $s_1$  and denote the segments including  $w_{i_0}$  and  $w_{i_0+1}$  separately (in the second segmentation) as  $s_2$  and  $s_3$ , respectively. To obtain semantic labels for the above three segments, we make use of a web-scale knowledge base of entities, namely Freebase (Bollacker et al., 2008). First, we map the three segments to the Freebase entities by string matching, and then use the names or aliases of the associated categories of the mapped entities as their semantic labels. Finally, the semantic labels for  $s_1$ ,  $s_2$  and  $s_3$  are used as features. Due to the ambiguity, a phrase in a query may be mistakenly linked to a certain entity in the knowledge base. Thus, the semantic features include some noises. However, even with noises such features can still contribute to QS. To illustrate how the semantic features work, consider the query with the assigned semantic label as follows,

[history of the]<sub>NULL</sub> [search engine]<sub>computer software genre</sub>

As pointed out by (Tan et al., 2008), QS approaches which are only based on statistical information (e.g. *MI* and frequencies of n-grams) collected from the Web, cannot guarantee that the resulting segments are meaningful ones. For the query ‘history of the search engine’, a possible segmentation is ‘history of the | search engine’, as both ‘history of the’ and ‘search engine’ occur on the web frequently. In contrast, semantic information can distinguish ‘search engine’ from ‘history of the’, as ‘history of the’ is labeled as NULL and ‘search engine’ is labeled as ‘computer software genre’. Moreover, the learning algorithm can also learn some implicit relations between transformations and semantic labels, e.g. some particular combination of labels for  $s_1$ ,  $s_2$  and  $s_3$  may often trigger or prevent a transformation.

**Rank, Direction and Position Features.** Table 2 shows the values of these features. The rank feature is designed to distinguish among the different segmentation rankings of a base segmenter. For example, this feature can capture the intuition that for a good base segmenter, top ranked segmentations should have more of a chance to be selected. The direction feature is used to distinguish the two kinds of transformations: ‘ $w_iw_{i+1} \mapsto w_i|w_{i+1}$ ’ and ‘ $w_i|w_{i+1} \mapsto w_iw_{i+1}$ ’. The position feature considers decision positions, as transformations in different positions may have different chances.

Rank	$j$ , the rank of the segmentation to which we transform the top-1 segmentation.
Direction	1, if “ $w_iw_{i+1} \mapsto w_i w_{i+1}$ ”; 0, reverse.
Position <sup>left</sup>	Number of words from the decision position to the beginning/end of query.
Position <sup>right</sup>	

Table 2: The ‘rank’, ‘direction’ and ‘position’ features

## 5 Experiments

### 5.1 Experimental Setup

Following Hagen et al. (2011), we evaluate a QS system at three levels: **Query Level**:

$$Acc^{qry} = \frac{\#\text{correctly segmented queries}}{\#\text{queries in the evaluation data set}} \quad (5)$$

**Break Level.** The decision of break is whether or not to insert a segment boundary between two tokens in the query. The break-level accuracy ( $Acc^{brk}$ ) is defined as the proportion of the correctly-made decisions out of all such decisions.

**Segment Level.** Let  $Q^{eval}$  denote the set of queries.  $S_q^{sys}$  is the segmentation generated by a system and  $S_q^{eval}$  is given by a human. Then,

$$P^{sg} = \sum_{q \in Q^{eval}} \frac{|S_q^{sys} \cap S_q^{eval}|}{|S_q^{sys}|} \quad (6)$$

$$R^{sg} = \sum_{q \in Q^{eval}} \frac{|S_q^{sys} \cap S_q^{eval}|}{|S_q^{eval}|} \quad F^{sg} = \frac{2 \cdot P^{sg} \cdot R^{sg}}{P^{sg} + R^{sg}}$$

We use two data sets as introduced in (Bergsma and Wang, 2007) and (Hagen et al., 2010), denoted as ‘Bergsma-Wang-07’ (**BW07**) and ‘Webis-QSeC-10’ (**WQ10**). BW07 includes 500 test queries which all were noun phrase queries. Each query was segmented manually by three annotators (denoted as annotator A, B, and C) respectively. For 44% of the queries, all three annotators agree on the segmentations. Such an agreement between annotators cannot be considered as ‘strong’, which to some extent implies that human annotations may not be so reliable when used for training a segmentation model capable of consistently working over different queries. WQ10 includes 4,850 queries. Each query can be any type of query, not necessarily a noun phrase query. Each query was annotated by ten annotators.

We made use of the mining method in (Hu et al., 2011) for collecting the *query intent sets*. With the search log data and clicks (Apr 1, 2009-Mar 31, 2010) as input, we finally obtained 9,412,308 query intent sets, which totally include 30,902,284 unique queries. The similar queries in each set share more than 10 clicks. Each set includes 2~11 queries. We denote this data set as **QSet**. Note

that this data set does not have any annotations. Thus, we also tried to construct another data set (denoted as  $\mathbf{QSet}^{ann}$ ) by intersecting  $\mathbf{QSet}$  with WQ10.  $\mathbf{QSet}^{ann}$  includes 1,554 queries. Every query in  $\mathbf{QSet}^{ann}$  is then associated with the human annotations from WQ10 and linked to at least one query intent set in  $\mathbf{QSet}$ .

As each query has more than one segmentation due to different annotators, we select segmentation as our reference under two schemes: ‘**Majority**’ where the segmentations agreed upon by a majority of the annotators are chosen as the reference, and ‘**Best**’ where the annotated segmentations that maximize the break accuracy  $Acc^{brk}$  of the evaluated segmenter are chosen as the reference.

We mainly utilized three unsupervised systems as base segmenters. They are described in (Hagen et al., 2010), (Hagen et al., 2011) and (Risvik et al., 2003), denoted as  $\mathbf{Base}^{H-1}$ ,  $\mathbf{Base}^{H-2}$  and  $\mathbf{Base}^{CN}$  respectively. They can represent the state-of-the-art QS performance. For example,  $\mathbf{Base}^{H-2}$  on on data BW07(A) achieves 69.2%  $F^{sg}$  which slightly outperforms the recent unsupervised system (Li et al., 2011) (69.0%  $F^{sg}$ ).

As we focus on web QS, we did not compare LRMC with supervised methods which are only designed for one particular domain. For example, Yu et al. (2009)’s method is for queries of relational databases. The work (Bergsma and Wang, 2007) and the supervised stage of (Bendersky et al., 2009) are only for noun-phrases.

## 5.2 Consistency as Weak Supervision

LRMC relies on a training data which is automatically collected with the help of query intent sets. Thus, in this section, we evaluate the training set collected by  $\mathbf{M1}$  and  $\mathbf{M2}$  (Section 4.2).

In the experiments, we first applied a base segmenter to the queries in  $\mathbf{QSet}$  and then managed to choose one segmentation as correct from the output for each query with either  $\mathbf{M1}$  or  $\mathbf{M2}$ . Last, we evaluated the new output by checking only the segmentations for the queries in subset  $\mathbf{QSet}^{ann}$ . Some queries in  $\mathbf{QSet}^{ann}$  may belong to different intent-sets and in each intent-set may have different segmentation labels as ‘correct’. In our evaluation, we randomly selected one of them as the final label. Besides, we also included an ideal method **Oracle** by which the correct segmentation can always be identified and used as the new output if the segmentation exists in the top- $n$  re-

sults of the base segmenter. Note that **Oracle** is an upper-bound result obtained by directly matching with human’s annotation and cannot be applied to query intent sets  $\mathbf{QSet}$  for collecting labeled data. Table 3 provides the results, where top- $k$  ( $1 \leq k \leq 5$ ) means that the input to  $\mathbf{M1}/\mathbf{M2}$  is the top- $k$  results of the corresponding base segmenter. Note that the top-1 results are the performance of the base segmenters.

By checking the results of **Oracle**, we can find that for every base segmenter, more than 35% of the correct segmentations in the top-5 results are not covered by the top-1 results (in terms of  $Acc^{qry}$ ). In addition, around 90% correct segmentation boundaries ( $Acc^{brk}$ ) are included in the top-5 results of the base segmenters. These findings indicate the feasibility of our replacement model, which tries to replace a rank-1 segmentation by a rank- $k$  ( $k > 1$ ) segmentation.

From the table, we also see that both  $\mathbf{M1}$  and  $\mathbf{M2}$  are able to significantly perform better than the base segmenters do ( $p < 0.05$ , t-test). This can be observed through all the measures. For example, using  $Acc^{qry}$  as the evaluation metric, the percentage of the correct segmentations that  $\mathbf{M2}$  discovers more than the base segmenters do ranges from 20.2% to 24.6%. These improvements prove the underlying assumption that queries with a similar intent tend to have consistent segmentation. Besides, we can see that  $\mathbf{M2}$  can reach a satisfied performance to collect the labeled data. For example, break-level accuracy  $Acc^{brk}$  can reach 80%.

Table 3 also shows that  $\mathbf{M1}$  and  $\mathbf{M2}$  perform best by using top 3 or 4 results from base segmenter. This finding indicates that our framework should work with a reasonable base segmenter.

By comparing the results generated by  $\mathbf{M1}$  and  $\mathbf{M2}$  with all three measures, we see that  $\mathbf{M2}$  consistently performs better than  $\mathbf{M1}$ , and the difference is statistical significant ( $p < 0.05$ , t-test). This tells us that consistency should be calculated with all the top- $n$  segmentations rather than with only the selected segmentations.

## 5.3 Query Segmentation

In this section, we investigate the effectiveness of our LRMC which is a combination of data collecting method and replacement model.

In the experiments, we first made use of  $\mathbf{M2}$  to automatically collect the training data from the query intent sets  $\mathbf{QSet}$ . During the process of col-

Segmenter	Rank	Oracle			M1			M2

Table 3: Consistency as weak supervision on QSet<sup>ann</sup> (Majority)

lecting the data, we took only the top-3 segmentations as input. The training data set collected by M2 contains around 45 million instances (pairs of segmentations). Then, all this labeled data is used to train the replacement model as introduced in Section 4.3. We made use of LIBSVM (Chang and Lin, 2011) and a linear kernel in our experiment. Finally, we applied the learned replacement models to the evaluation data sets BW07 and WQ10.

Table 4 reports the QS results<sup>1</sup>. Following previous work (Bergsma and Wang, 2007; Hagen et al., 2011), we report four groups of results with the data BW07. In each of the first three groups, only the reference segmentations from annotator A, B or C are used. The fourth group is ‘Best’ of BW07. We also report two groups of results (‘Majority’ and ‘Best’) with the data WQ10. Comparing each pair of ‘Base’ and ‘LRMC’, we can see that LRMC proposed in this paper can be successfully spliced onto different base segmenters and significantly improves them over different data sets under the three evaluation metrics  $Acc^{qry}$ ,  $Acc^{brk}$  and  $F^{sg}$ . ( $p < 0.05$ , **t-test**). Especially, the state-of-the-art systems Base<sup>H-1</sup> and Base<sup>H-2</sup> have been significantly improved by LRMC. The improvements prove that the automatically-collected labeled data can guide QS and our replacement model can take advantage of the data.

## 6 Conclusions and Future Work

We have proposed a paradigm LRMC for QS. LRMC assumes the existence of a base segmenter

<sup>1</sup>Note that the results for the base segmenters Base<sup>H-1</sup> and Base<sup>H-2</sup> are not exactly same as those reported in (Hagen et al., 2011) although they are very close. For example, Base<sup>H-1</sup> and Base<sup>H-2</sup> on WQ10 achieve 73.4%  $F^{sg}$  and 74.2%  $F^{sg}$  in the original paper. Ours are 71.2% and 72.1%. The reasons are as follows: For BW07, they used a cleaned version of the data set; for WQ10, they released just a subset of the data used in their experiments.

Data Set	Measure	Base <sup>CN</sup>		Base <sup>H-1</sup>		Base <sup>H-2</sup>	
		Base	LRMC	Base	LRMC	Base	LRMC
BW07 (A)	$Acc^{qry}$	53.4	55.3	55.2	56.7	53.8	55.4
	$Acc^{brk}$	79.3	81.4	80.2	81.9	79.5	81.7
	$F^{sg}$	66.5	69.6	67.5	70.2	66.7	69.8
BW07 (B)	$Acc^{qry}$	37.4	40.2	39.8	41.1	37.8	39.8
	$Acc^{brk}$	73.7	74.9	74.7	76.4	73.8	75.4
	$F^{sg}$	54.3	58.3	55.6	58.7	54.5	58.1
BW07 (C)	$Acc^{qry}$	41.6	44.2	43.8	46.7	42.0	46.9
	$Acc^{brk}$	74.1	75.2	75.0	78.6	74.2	78.6
	$F^{sg}$	56.9	60.4	58.0	62.3	57.1	62.4
BW07 (Best)	$Acc^{qry}$	62.2	67.2	64.6	66.2	65.6	66.8
	$Acc^{brk}$	85.1	90.0	86.1	87.3	87.6	88.7
	$F^{sg}$	74.5	79.6	75.8	78.4	78.6	79.5
WQ10 (Majority)	$Acc^{qry}$	30.0	38.5	31.8	40.1	30.3	39.8
	$Acc^{brk}$	65.3	72.1	66.2	74.0	65.5	73.1
	$F^{sg}$	47.5	55.1	48.5	55.8	47.7	55.6
WQ10 (Best)	$Acc^{qry}$	52.8	60.4	57.0	67.9	59.1	67.6
	$Acc^{brk}$	80.5	84.7	83.5	89.6	84.4	89.5
	$F^{sg}$	67.8	72.7	71.2	79.0	72.1	78.8

Table 4: Performance on query segmentation

and then learns how to select correct segmentations from the output of the base segmenter. The replacement model is trained by a labeled data set which can be automatically collected from *query intent sets*, instead of relying on any human annotation. There exist two interesting directions for future work: (1) we observe that there is still a big gap in performance between the proposed methods and Oracle. According to our analysis, most of the gap is caused by that the incorrect segmentations for some similar queries also happen to have a high consistency when measured by either proposed strategy. Thus, it is worth studying other methods that can address such performance gap. (2) we would like to further explore the concept of query intent sets. In this paper, we assume that similar intent queries tend to have similar segmentations. A reasonable next step is to explore the idea that similar intent queries tend to have similar labels, which can be useful for the task of tagging query segments with semantic labels.

## Abstract

A concept can be linguistically expressed in various syntactic constructions. Such syntactic variations spoil the effectiveness of incorporating dependencies between words into information retrieval systems. This paper presents an information retrieval method for normalizing syntactic variations via predicate-argument structures. We conduct experiments on standard test collections and show the effectiveness of our approach. Our proposed method significantly outperforms a baseline method based on word dependencies.

## 1 Introduction

Most conventional approaches to information retrieval (IR) deal with words as independent terms. In query sentences<sup>1</sup> and documents, however, dependencies exist between words.<sup>2</sup> To capture these dependencies, some extended IR models have been proposed in the last decade (Jones, 1999; Lee et al., 2006; Song et al., 2008; Shinzato et al., 2008). These models, however, did not achieve consistent significant improvements over models based on independent words.

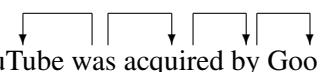

One of the reasons for this is the linguistic variations of syntax, that is, languages are syntactically expressed in various ways. For instance, the same or similar meaning can be expressed using the passive voice or the active voice in a sentence. Previous approaches based on dependencies cannot identify such variations. This is because they use the output of a dependency parser, which generates syntactic (grammatical) dependencies built

<sup>1</sup>In this paper, we handle queries written in natural language.

<sup>2</sup>While dependencies between words are sometimes considered to be the co-occurrence of words in a sentence, in this paper we consider dependencies to be syntactic or semantic dependencies between words.

upon surface word sequences. Consider, for example, the following sentence in a document:

(1) YouTube was acquired by Google.

Dependency parsers based on the Penn Treebank and the head percolation table (Collins, 1999) judge the head of “YouTube” as “was” (“YouTube←was”; hereafter, we denote a dependency by “*modifier←head*”). This dependency, however, cannot be matched with the dependency “YouTube←acquire” in a query like:

(2) I want to know the details of the news that Google acquired YouTube.

Furthermore, even if a dependency link in a query matches that in a document, a mismatch of dependency type can cause another problem. This is because previous models did not distinguish dependency types. For example, the dependency “YouTube←acquire” in query sentence (2) can be found in the following irrelevant document.

(3) Google acquired PushLife for \$25M ...  
YouTube acquired Green Parrot Pictures ...

While this document does indeed contain the dependency “YouTube←acquire,” its type is different; specifically, the query dependency is accusative while the document dependency is nominative. That is to say, ignoring differences in dependency types can lead to inaccurate information retrieval.

In this paper, we propose an IR method that does not use syntactic dependencies, but rather predicate-argument structures, which are normalized forms of sentence meanings. For example, query sentence (2) is interpreted as the following predicate-argument structure (hereafter, we denote a predicate-argument structure by  $\langle \cdot \cdot \cdot \rangle$ ):<sup>3</sup>

<sup>3</sup>In this paper, we use the following abbreviations:

(4) ⟨NOM:Google acquire ACC:YouTube⟩.

Sentence (1) is also represented as the same predicate-argument structure, and documents including this sentence can be regarded as relevant documents. Conversely, the irrelevant document (3) has different predicate-argument structures from (4), as follows:

(5) a. ⟨NOM:Google acquire ACC:PushLife⟩,

b. ⟨NOM:YouTube acquire ACC:Green Parrot Pictures⟩.

In this way, by considering this kind of predicate-argument structure, more precise information retrieval is possible.

We mainly evaluate our proposed method using the NTCIR test collection, which consists of approximately 11 million Japanese web documents. We also have an experiment on the TREC Robust 2004 test collection, which consists of around half a million English documents, to validate the applicability to other languages than Japanese.

This paper is organized as follows. Section 2 introduces related work, and section 3 describes our proposed method. Section 4 presents the experimental results and discussion. Section 5 describes the conclusions.

## 2 Related work

There have been two streams of related work that considers dependencies between words in a query sentence.

One stream is based on linguistically-motivated approaches that exploit natural language analysis to identify dependencies between words. For example, Jones proposed an information retrieval method that exploits linguistically-motivated analysis, especially dependency relations (Jones, 1999). However, Jones noted that dependency relations did not contribute to significantly improving performance due to the low accuracy and robustness of syntactic parsers. Subsequently, both the accuracy and robustness of dependency parsers were dramatically improved (Nivre and Scholz, 2004; McDonald et al., 2005), with such parsers being applied more recently to information retrieval (Lee et al., 2006; Song et al., 2008; Shin-

NOM (nominative), ACC (accusative), DAT (dative), ALL (allative), GEN (genitive), CMI (comitative), LOC (locative), ABL (ablative), CMP (comparative), DEL (delimitative) and TOP (topic marker).

zato et al., 2008). For example, Shinzato et al. investigated the use of syntactic dependency output by a dependency parser and reported a slight improvement over a baseline method that used only words. However, the use of dependency parsers still introduces the problems stated in the previous section because of their handling of only syntactic dependencies.

The second stream of research has attempted to integrate dependencies between words into information retrieval models. These models include a dependence language model (Gao et al., 2004), a Markov Random Field model (Metzler and Croft, 2005), and a quasi-synchronous dependence model (Park et al., 2011). However, they focus on integrating term dependencies into their respective models without explicitly considering any syntactic or semantic structures in language. Therefore, the purpose of these studies can be considered different from ours.

Park and Croft (2010) proposed a method for ranking query terms for the selection of those which were most effective by exploiting typed dependencies in the analysis of query sentences. They did not, however, use typed dependencies for indexing documents.

The work that is closest to our present work is that of Miyao et al. (2006), which proposed a method for the semantic retrieval of relational concepts in the domain of biomedicine. They retrieved sentences that match a given query using predicate-argument structures via a framework of region algebra. Thus, they namely approached the task of sentence matching, which is not the same as document retrieval (or ranking). As for the types of queries they used, although their method could handle natural language queries, they used short queries like “TNF activate IL6.” Because of the heavy computational load of region algebra, if a query matches several thousand sentences, for example, then it requires several thousand seconds to return all sentence matches (though it takes on average 0.01 second to return the first matched sentence).

In the area of question answering, predicate-argument structures have been used to precisely match a query with a passage in a document (e.g., (Narayanan and Harabagiu, 2004; Shen and Lapata, 2007; Bilotti et al., 2010)). However, candidate documents to extract an answer are retrieved using conventional search engines without

predicate-argument structures.

### 3 Information retrieval exploiting predicate-argument structures

#### 3.1 Overview

Our key idea is to exploit the normalization of linguistic expressions based on their predicate-argument structures to improve information retrieval.

The process of information retrieval systems can be decomposed into offline processing and online processing. During offline processing, analysis is first applied to a document collection. For example, typical analyses for English include tokenization and stemming analyses, while those for Japanese include morphological analysis. In addition, previous models using the dependencies between words also used dependency parsing. In this paper, we employ predicate-argument structures analysis, which is detailed in the next subsection.

Following the initial analysis, indexing is performed to produce an inverted index. In most cases, words are indexed as terms, but several previous approaches have also indexed dependencies between words as terms (e.g., (Shinzato et al., 2008)). In our study, however, we do not use syntactic dependencies directly, but rather consider predicate-argument structures. To bring this predicate-argument structure information into the index, we handle predicate-argument structures as a set of typed semantic dependencies. Dependency types are expressed as term features, which are additional information to each term including the list of positions of the term.

As for online processing, we first apply the predicate-argument structure analysis to a query sentence, and then create terms including words and typed semantic dependencies extracted from the predicate-argument structures. Then, we search documents containing these terms from the inverted index, and then finally rank these documents.

In the following subsections, we describe in more detail the procedures of predicate-argument structure analysis, indexing, query processing, and document ranking.

#### 3.2 Analysis of predicate-argument structures

We apply predicate-argument structure analysis to both queries and documents. Predicate-argument

structure analysis normalizes the following linguistic expressions:

- relative clause
- passive voice (the predicate is normalized to active voice)
- causative (the predicate is normalized to normal form)
- intransitive (the predicate is normalized to transitive)
- giving and receiving expressions (the predicate is normalized to a giving expression)

In the case of Japanese, we use the morphological analyzer JUMAN,<sup>4</sup> and the predicate-argument structure analyzer KNP (Kawahara and Kurohashi, 2006).<sup>5</sup> The accuracy of syntactic dependencies output by KNP is around 89% and that of predicate-argument relations is around 81% on web sentences. Examples of this predicate-argument structure analysis are shown in Figures 1 and 2. Figure 1 shows an example of relative clause normalization by predicate-argument structure analysis. The syntactic dependencies of the two sentences are different, but this difference is solved by using predicate-argument structures.

Figure 2 shows an example of intransitive verb normalization by predicate-argument structure analysis. In this example, the syntactic dependencies are the same, but different verbs are used.<sup>6</sup> The analyzer canonicalizes the intransitive verb to its corresponding transitive verb, and also produces the same predicate-argument structure for the two sentences.

If we apply our method to English, deep parsers such as the Stanford Parser<sup>7</sup> and Enju<sup>8</sup> can be employed to achieve predicate-argument structure analysis. The Stanford parser can output typed semantic dependencies that conform to the Stanford dependencies (de Marneffe et al., 2006). Enju is an HPSG parser that outputs predicate-argument structures, and arguments are typed as Arg1, Arg2, and so forth. The representation of the dependency types in Enju is the same as that of PropBank (Palmer et al., 2005).

<sup>4</sup><http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?JUMAN>

<sup>5</sup><http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?KNP>

<sup>6</sup>In many cases, the lemma of a transitive verb is not the same as that of its corresponding intransitive verb in Japanese.

<sup>7</sup><http://www-nlp.stanford.edu/software/lex-parser.shtml>

<sup>8</sup><http://www.nactem.ac.uk/enju/>

Figure 1: An example of relative clause normalization by predicate-argument structure analysis in Japanese. (a) is a normal-order sentence and (b) is a sentence that contains a relative clause, “トムが焼く” (which Tom bakes). Arrows represent syntactic dependencies. Dotted arrows represent semantic dependencies that constitute predicate-argument structures. Both sentences are normalized to the predicate-argument structure (c).

In this way, though our framework itself is language-independent, our method depends on the availability of a predicate-argument structure analyzer for the target language.

### 3.3 Indexing

Our method builds an inverted index from the results of the predicate-argument structure analysis. First, word lemmas are registered as terms. We then need to integrate the predicate-argument structure information into the index. One possibility is to represent each predicate-argument structure as a term, but this method leads to a data sparseness problem. This is because the number of arguments in predicate-argument structures varies greatly not only in documents, but also in queries because of information granularity. For example, to express the same event, a predicate-argument structure can omit time or place information.

Instead, we decompose a predicate-argument structure into a set of typed semantic dependencies. A typed semantic dependency is defined as a typed dependency between a predicate and an argument that the predicate governs. For instance, the predicate-argument structure in Figure 2 can be decomposed into the following two typed semantic dependencies:

- (6) a. トム  $\xleftarrow{\text{NOM}}$  上げる  
(Tom  $\xleftarrow{\text{NOM}}$  raise)
- b. テンション  $\xleftarrow{\text{ACC}}$  上げる  
(tension  $\xleftarrow{\text{ACC}}$  raise)

These typed semantic dependencies are registered as dependency terms in the index. The type information is encoded as a *term feature*, which is an additional field for each dependency term. This term feature consists of both dependency type information and predicate information. We con-

sider major postpositions in Japanese as dependency types (Table 1). If a dependency type is not listed in this table, then this type is regarded as a special type which we classify as “other.” In addition, a dependency that is not the relation between a predicate and its argument is also classified as “other” (e.g., the dependency between verbs).

The predicate information in the term feature refers to the original predicate type for canonicalized predicates. There are four types: passive, causative, intransitive, and giving expression.

### 3.4 Query processing

Hereafter, we describe the steps of online processing. When a query sentence is input, both predicate-argument structure analysis and term extraction are applied to the query sentence in the same way indexing is applied. The extracted terms consist of words and typed semantic dependencies and they are used to retrieve documents.

Note that unnecessary expressions like “教えてください” (please tell me) in a query sentence are not used to extract terms.

### 3.5 Document retrieval and scoring

Using the results of the query processing, documents are then retrieved and ranked. First, documents are retrieved by accessing the inverted index using the terms extracted from the query analysis. Here, we have two options for the logical operator on the terms. If we apply the logical operator AND, we impose a constraint that all the terms must be contained in a retrieved document. Conversely, if we apply the logical operator OR, a retrieved document should have one of the terms. In this study, we use the logical operator OR to retrieve as many documents as possible. This means that we do not apply any methods of selecting or

Figure 2: An example of intransitive verb normalization by predicate-argument structure analysis in Japanese. (a) is an intransitive sentence and (b) is a transitive sentence. Arrows represent syntactic dependencies (they are also semantic dependencies in this case). Both sentences are normalized to the predicate-argument structure (c). In particular, the intransitive verb “上がる” (rise) is a different word from the transitive verb “上げる” (raise) but both are canonicalized to the same transitive verb “上げる” (raise) in the predicate-argument structure.

が	を	に	と	で	から	まで	より	時間	修飾	の	について	として
NOM	ACC	DAT	CNJ	LOC	ABL	DEL	CMP	time	<i>adj</i>	GEN	about	as

Table 1: Dependency type information in Japanese. The first row is the list of dependency types used in our method. The second row means the translations of the first row, where *adj* means adjuncts such as adverbs.

ranking query terms,<sup>9</sup> but rely only on document scoring to examine the effectiveness of the use of predicate-argument structures.

Following document retrieval, a relevancy score is assigned to each document, and the documents are ranked according to these relevancy scores. We use Okapi BM25 (Robertson et al., 1992) for estimating the relevancy score between a query and a document. This measure was originally proposed for models based on terms of independent words, but we slightly extend this measure to include estimating relevancy for typed semantic dependencies that are extracted from predicate-argument structures. Our relevancy score is calculated as a weighted sum of the score of words and the score of dependencies. The score of dependencies is further calculated as a weighted sum of the following two scores: the score of dependencies with consistent (matched) type and that with inconsistent (mismatched) type. In particular, the score of dependencies with inconsistent type is reduced compared to the score of dependencies with consistent type.

We denote a set of words in a query  $q$  as  $T_{qw}$ , and also denote a set of dependencies in  $q$  as  $T_{qd}$ . This set of dependencies is further divided into two types according to the consistency of dependency features:  $T_{qd_C}$  (consistent) and  $T_{qd_I}$  (inconsistent). We define the relevancy score between

query  $q$  and document  $d$  as follows:

$$R(q, d) = \sum_{t \in T_{qw}} BM(t, d) + \beta \left\{ \sum_{t \in T_{qd_C}} BM(t, d) + \gamma \sum_{t \in T_{qd_I}} BM(t, d) \right\}, \quad (1)$$

where  $\beta$  is a parameter for adjusting the ratio of a score calculated from dependency relations to that from words and  $\gamma$  is a parameter for decreasing the weight of inconsistent dependency types. The score  $BM(t, d)$  is defined as:

$$BM(t, d) = IDF(t) \times \frac{(k_1+1)F_{dt}}{K+F_{dt}} \times \frac{(k_3+1)F_{qt}}{k_3+F_{qt}}, \quad (2)$$

$$IDF(t) = \log \frac{N-n+0.5}{n+0.5},$$

$$K = k_1 \left\{ (1-b) + b \frac{l_d}{l_{ave}} \right\},$$

where  $F_{dt}$  is the frequency with which  $t$  appears in document  $d$ ,  $F_{qt}$  is the frequency that  $t$  appears in  $q$ ,  $N$  is the number of documents being searched,  $n$  is the document frequency of  $t$ ,  $l_d$  is the length of document  $d$  (words), and  $l_{ave}$  is the average document length. Finally, we set these Okapi parameters as  $k_1 = 1$ ,  $k_3 = 0$  and  $b = 0.6$ .

We use the following relevancy score for a baseline method that uses only syntactic dependencies, which is explained in section 4:

$$R(q, d) = \sum_{t \in T_{qw}} BM(t, d) + \beta \sum_{t \in T_{qd}} BM(t, d). \quad (3)$$

<sup>9</sup>We only discard unnecessary expressions in a query as described in subsection 3.4.

This equation is the same as the relevancy score used in Shinzato et al. (2008).

## 4 Evaluation

In this section, we evaluate and analyze our proposed method on the standard test collections of Japanese and English.

### 4.1 Evaluation on Japanese Test Collection

#### 4.1.1 Experimental setup

We implemented our proposed method using the open search engine infrastructure TSUBAKI (Shinzato et al., 2008) as a base system. TSUBAKI generates an inverted index from linguistic analyses in an XML format. Note that while TSUBAKI has a facility for using a synonym lexicon, but we did not use it because we performed pure comparisons without referencing synonyms.

We evaluated our proposed method by using the test collection built for the NTCIR-3 (Eguchi et al., 2003) and NTCIR-4 (Eguchi et al., 2004) workshops. These workshops shared a target document set, which consists of 11,038,720 web pages from Japanese domains. We used a high-performance computing environment to perform predicate-argument structure analysis and indexing on these documents. It took three days for analysis and two days for indexing. For the evaluation, we used 127 informational topics (descriptions) defined in the test collections (47 from NTCIR-3 and 80 from NTCIR-4). We also had additional 65 topics that were not used for evaluation in NTCIR-3; we used these 65 topics for parameter tuning. The relevance of each document with respect to a topic was judged as highly relevant, relevant, partially relevant, irrelevant or unjudged. We regarded the highly relevant, relevant, and partially relevant documents as correct answers.

For each topic, we retrieved 1,000 documents, ranked according to the score  $R(q, d)$  in equation (1). We optimized the parameter  $\beta$  as 0.18, and the parameter  $\gamma$  as 0.85 using the additional 65 topics in relation to their mean average precision (MAP) score. We then assessed retrieval performance according to MAP, P@3 (Precision at 3), P@5, P@10 and nDCG@10 (Järvelin and Kekäläinen, 2002). Note that unjudged documents were treated as irrelevant when computing the scores. For the graded relevance of nDCG@10, we mapped highly relevant, relevant, and partially relevant to the values 3, 2, and 1, respectively.

	MAP	P@3	P@5	P@10	nDCG@10
word	0.1665	0.4233	0.4159	0.3706	0.2323
word+dep	0.1704	0.4233	0.4095	0.3730	0.2313
word+pa	<b>0.1727**</b>	<b>0.4418*</b>	<b>0.4175</b>	<b>0.3794*</b>	<b>0.2370**</b>

Table 2: Retrieval performance of two baseline methods (“word” and “word+dep”) and our proposed method (“word+pa”). \*\* and \* mean that the differences between “word+dep” and “word+pa” are statistically significant with  $p < 0.05$  and  $p < 0.10$ , respectively.

	MAP	P@3	P@5	P@10	nDCG@10
word	0.2085	0.4312	0.4302	0.3960	0.2455
word+dep	0.2120	0.4392	0.4286	0.3913	0.2433
word+pa	<b>0.2139**</b>	<b>0.4524</b>	<b>0.4333</b>	<b>0.3976**</b>	<b>0.2484**</b>

Table 3: Retrieval performance without unjudged documents. \*\* means that the differences between “word+dep” and “word+pa” are statistically significant with  $p < 0.05$ .

#### 4.1.2 Retrieval performance evaluation

Table 2 lists retrieval performances. In this table, “word” is a baseline method that uses only words as terms, and “word+dep” is another baseline method that uses words and untyped syntactic dependencies as terms. These untyped syntactic dependencies are also available in the results of the predicate-argument structure analyzer KNP. “word+pa” is our proposed model, which considers predicate-argument structures. We also applied the Wilcoxon signed-rank test to the differences between “word+dep” and “word+pa.”

We can see that our proposed method “word+pa” outperformed the baselines “word” and “word+dep” in all the metrics. In particular, the difference between “word+dep” and “word+pa” in MAP was statistically significant with  $p = 0.01134$ . In addition, P@3 is higher than the baselines by approximately 1.9%. This means that our model can provide more relevant documents on the top of the ranked result. The baseline “word+dep” outperformed the baseline “word” in MAP, which is used as a metric for optimizing the parameters, but did not outperform “word” in P@5 and nDCG@10. That is to say, “word+dep” was not consistently better than “word.”

Generally, relevance judgments on a standard test collection are created using a pooling method, which judges a certain number of documents submitted by every participating system. Systems that are developed after the creation of the test col-

Figure 3: An improved example of relative clause normalization by predicate-argument structure analysis in Japanese. (a) is a part of the query sentence and (b) is a part of a relevant document. Arrows represent syntactic dependencies and dotted arrows represent semantic dependencies. These sentences are normalized to the predicate-argument structures (a') and (b'), respectively.

	MAP	P@3	P@5	P@10	nDCG@10
word+dep	0.1769	0.4444	0.4254	0.3921	0.2373
word+pa	<b>0.1790**</b>	<b>0.4577</b>	<b>0.4317</b>	<b>0.3984*</b>	<b>0.2424**</b>

Table 4: Retrieval performance including additional judgments. The meaning of \*\* and \* is the same as the previous tables.

lection possibly retrieve unjudged documents, but they are usually handled as irrelevant documents, even though they may contain relevant documents. In addition, the number of unjudged documents is likely to increase according to the complexity of systems. To alleviate this bias, we evaluated the three systems without the inclusion of unjudged documents. Table 3 lists the evaluation results. From this table, we can see that “word” was likely to defeat “word+dep,” but “word+pa” consistently outperformed the two baseline methods.

We also evaluated unjudged documents manually. We asked a person who is a certified librarian to judge them. These documents comprise the unjudged documents which appeared in the top 10 results of the two methods (“word+dep” and “word+pa”) for each topic. Table 4 lists the retrieval performances reflecting the inclusion of these additional judgments. From this table, the result of proposed method is consistently better than that of the baseline using syntactic dependencies.

### 4.1.3 Discussions

By introducing the normalization by predicate-argument structures, our proposed method can retrieve relevant documents that cannot be retrieved or ranked below 1,000 documents by the baseline methods. Figures 3 and 4 show improved examples by the proposed method (“word+pa”) compared to the baseline method (“word+dep”). Figure 3 is an example of the effect of normalizing relative clauses. The following sentences are the original query and a part of relevant document:

- (7) a. 天然酵母のパンを作っているパン屋を見つけない  
(I want to find shops that make bread with natural yeast.)  
b. ...塩、酵母のみで作るパンこそが、...  
(... only the bread that (someone) makes using only salt and yeast ...)

Here, (a) is a query and (b) is a sentence in a relevant document. These sentences have different syntactic dependencies as illustrated in Figure 3, but they are normalized to the predicate-argument structures (a') and (b') in Figure 3. The whole predicate-argument structures are different, but they contain the same typed semantic dependency:

- (8) パン  $\xleftarrow{\text{ACC}}$  作る  
(bread  $\xleftarrow{\text{ACC}}$  make).

Figure 4 is an example of the effect of normalizing intransitive verbs. The following sentences are the original sentences in a query and a relevant document:

- (9) a. 各地域でお正月に食べる雑煮に入っている具、またはベースとなる味噌などの違いについて調べたい  
(I wish to find out about differences in the ingredients and miso stock used to make ozoni soup at New Years in each region.)  
b. ... 北海道のお雑煮はシャケやイクラ、じゃがいもを入れるところもある  
(in some places, they put salmon, salmon roe and potato in ozoni soup in Hokkaido)

While different verbs are used to express almost the same meaning in these sentences, they are normalized to the predicate-argument structures (a') and (b') in Figure 4. The whole predicate-argument structures are different, but they contain the same typed semantic dependency:

<p>(a) ... 雑煮に 入っている 具 ...  ozoni-DAT exist ingredients  (ingredients that exist in ozoni soup)</p> <p>(a') &lt;ACC:具 DAT:雑煮 入れる &gt;  (ACC:ingredients DAT:ozoni soup put)</p>	<p>(b) 雑煮は ... 入れる ...  ozoni-TOP put  (put in ozoni soup)</p> <p>(b') &lt;DAT:雑煮 入れる &gt;  (DAT:ozoni soup put)</p>
---	--

Figure 4: An improved example of intransitive verb normalization by predicate-argument structure analysis in Japanese. (a) is a part of the query sentence and (b) is a part of a relevant document. These sentences are normalized to the predicate-argument structures (a') and (b'), respectively. In particular, the intransitive verb “入る” (exist) is a different word from the transitive verb “入れる” (put) but both are canonicalized to the same transitive verb “入れる” (put) in the predicate-argument structures.

(10) 雑煮  $\xleftarrow{\text{DAT}}$  入れる  
(ozoni soup  $\xleftarrow{\text{DAT}}$  put).

Generally speaking, linguistic variations can be roughly divided into two types: syntactic variations and lexical variations. Among syntactic variations, we handled syntactic variations that are related to predicate-argument structures in this study. In our future work, we intend to investigate remaining syntactic variations, such as nominal compounds and paraphrases consisting of larger trees than predicate-argument structures.

The other type is lexical variations, namely synonymous words and phrases. In our approach, they are partially handled in the normalization process to predicate-argument structures. Although handling lexical variations is not the main focus of this paper, we will investigate the effect of incorporating a lexicon of synonymous words and phrases into our model.

## 4.2 Evaluation on English Test Collection

To validate the effectiveness of the proposed method in other languages than Japanese, we also conducted an experiment on English. We used the TREC Robust 2004 test collection (Voorhees, 2004), which consists of 528,155 English documents and 250 topics (TREC topics 301-450 and 601-700). We used the description queries in these topics, which are written in natural language. Stopwords are removed from the parse of a description and dependencies that contain a stopword in either a modifier or a head are also removed. We used the INQUERY stopword list (Allan et al., 2000). Other experimental settings are the same as the Japanese evaluation.

Table 5 lists retrieval performances. In this table, “word” is a baseline method that uses only lemmatized words as terms, and “word+dep” is another baseline method that uses lemmatized words and syntactic dependencies that are analyzed by the state-of-the-art dependency parser

	MAP	P@3	P@5	P@10	nDCG@10
word	0.1344	0.4498	0.4016	0.3297	0.3527
word+dep	0.1350	0.4337	0.4112	0.3317	0.3517
word+pa	<b>0.1396*</b>	<b>0.4618**</b>	<b>0.4257**</b>	<b>0.3482**</b>	<b>0.3659**</b>

Table 5: Retrieval performance of two baseline methods (“word” and “word+dep”) and our proposed method (“word+pa”) on the TREC test collection. The meaning of \*\* and \* is the same as the previous tables.

MaltParser.<sup>10</sup> “word+pa” is our proposed method, which considers predicate-argument structures converted from the typed semantic dependencies output by the Stanford Parser.<sup>11</sup> We can see that our proposed method “word+pa” outperformed the baselines “word” and “word+dep” in all the metrics also on this English test collection.

## 5 Conclusions

This paper described an information retrieval method that exploits predicate-argument structures to precisely capture the dependencies between words. Experiments on the standard test collections of Japanese and English indicated the effectiveness of our approach. In particular, the proposed method outperformed a baseline method that uses syntactic dependencies output by a dependency parser.

For future work, we plan to optimize ranking by using machine learning techniques such as support vector regression, and to capture any remaining syntactic differences that express similar meanings (i.e., paraphrasing). We used the Okapi BM25 system as our baseline in this study. We will also employ a language model-based information retrieval system as a baseline to confirm the robustness of our approach.

<sup>10</sup><http://www.maltparser.org/>

<sup>11</sup>To normalize passive constructions, we applied a rule that converts the dependency type “nsubjpass” to “dobj” and “agent” to “nsubj.”

# Global Model for Hierarchical Multi-Label Text Classification

Yugo Murawaki

Graduate School of Informatics  
Kyoto University  
murawaki@i.kyoto-u.ac.jp

## Abstract

The main challenge in hierarchical multi-label text classification is how to leverage hierarchically organized labels. In this paper, we propose to exploit dependencies among multiple labels to be output, which has been left unused in previous studies. To do this, we first formalize this task as a structured prediction problem and propose (1) a global model that jointly outputs multiple labels and (2) a decoding algorithm for it that finds an exact solution with dynamic programming. We then introduce features that capture inter-label dependencies. Experiments show that these features improve performance while reducing the model size.

## 1 Introduction

Hierarchical organization of a large collection of data has deep roots in human history (Berlin, 1992). The emergence of electronically-available text has enabled us to take computational approaches to real-world hierarchical text classification tasks. Such text collections include patents,<sup>1</sup> medical taxonomies<sup>2</sup> and Web directories such as Yahoo! and the Open Directory Project.<sup>3</sup> In this paper, we focus on *multi-label* classification, in which a document may be given more than one label.

Hierarchical multi-label text classification is a challenging task because it typically involves thousands of labels and an exponential number of output candidates. For efficiency, divide-and-conquer strategies have often been adopted. Typically, the label hierarchy is mapped to a set of local

<sup>1</sup><http://www.wipo.int/classifications/en/>

<sup>2</sup><http://www.nlm.nih.gov/mesh/>

<sup>3</sup><http://www.dmoz.org/>

classifiers, which are invoked in a top-down fashion (Montejo-Ráez and Ureña-López, 2006; Wang et al., 2011; Sasaki and Weissenbacher, 2012). However, local search is difficult to harness because a chain of local decisions often leads to what is usually called error propagation (Bennett and Nguyen, 2009). To alleviate this problem, previous work has resorted to what we collectively call post-training adjustment.

One characteristic of the task that has not been explored in previous studies is that multiple labels to be output have dependencies among them. It is difficult even for human annotators to decide how many labels they choose. We conjecture that they consult the label hierarchy when adjusting the number of output labels. For example, if two label candidates are positioned proximally in the hierarchy, human annotators may drop one of them because they provide overlapping information.

In this paper, we propose to exploit inter-label dependencies. To do this, we first formulate hierarchical multi-label text classification as a structured prediction problem. We propose a global model that jointly predicts a set of labels. Under this framework, we replace local search with dynamic programming to find an exact solution. This allows us to extend the model with features for inter-label dependencies. Instead of locally training a set of classifiers, we also propose global training to find globally optimal parameters. Experiments show that these features improve performance while reducing the model size.

## 2 Task Definition

In hierarchical multi-label text classification, our goal is to assign to a document a set of labels  $\mathbf{m} \subset \mathcal{L}$  that best represents the document. The pre-defined set of labels  $\mathcal{L}$  is organized as a tree as illustrated in Figure 1.<sup>4</sup> In our task, only the

<sup>4</sup>Some studies work on directed acyclic graphs (DAGs), in which each node can have more than one parent (Labrou and

Figure 1: Example of label hierarchy. Leaf nodes, filled in gray, represent labels to be assigned to documents.

leaf nodes (AA, AB, BA and BB in this example) represent valid labels.

Let  $\text{leaves}(c)$  be a set of the descendants of  $c$ , inclusive of  $c$ , that are leaf nodes. For example,  $\text{leaves}(A) = \{AA, AB\}$ .  $p \rightarrow c$  denotes an edge from parent  $p$  to child  $c$ . Let  $\text{path}(c)$  be a set of edges that connect ROOT to  $c$ . For example,  $\text{path}(AB) = \{\text{ROOT} \rightarrow A, A \rightarrow AB\}$ . Let  $\text{tree}(\mathbf{m}) = \bigcup_{l \in \mathbf{m}} \text{path}(l)$ . It corresponds to a subtree that covers  $\mathbf{m}$ . For example,  $\text{tree}(\{AA, AB\}) = \{\text{ROOT} \rightarrow A, A \rightarrow AA, A \rightarrow AB\}$ .

We assume that each document  $x$  is transformed into a feature vector by  $\phi(x)$ . For example, we can use a bag-of-words representation of  $x$ .

We consider a supervised setting. The training data  $\mathcal{T} = \{(x_i, \mathbf{m}_i)\}_{i=1}^T$  is used to train our models. Their performance is measured on test data.

### 3 Base Models

#### 3.1 Flat Model

We begin with the flat model, one of the simplest models in multi-label text classification. It ignores the label hierarchy and relies on a set of binary classifiers, each of which decides whether label  $l$  is to be assigned to document  $x$ .

Various models have been used to implement binary classifiers, including Naïve Bayes, Logistic Regression and Support Vector Machines. We use the Perceptron family of algorithms, and it will be extended later to handle more complex structures.

The binary classifier for label  $l$  is associated with a weight vector  $\mathbf{w}_l$ . If  $\mathbf{w}_l \cdot \phi(x) > 0$ , then  $l$  is assigned to  $x$ . Note that at least one label is assigned to  $x$ . If no labels have positive scores, we choose one label with the highest score.

To optimize  $\mathbf{w}_l$ , we convert the original training

Finin, 1999; LSHTC3, 2012). We leave it for future work.

---

**Algorithm 1** Passive-Aggressive algorithm for training a binary classifier (PA-I).

---

**Input:** training data  $\mathcal{T}_l = \{(x_i, y_i)\}_{i=1}^T$   
**Output:** weight vector  $\mathbf{w}_l$

- 1:  $\mathbf{w}_l \leftarrow \mathbf{0}$
- 2: **for**  $n = 1..N$  **do**
- 3:   shuffle  $\mathcal{T}_l$
- 4:   **for all**  $(x, y) \in \mathcal{T}_l$  **do**
- 5:      $l \leftarrow \max\{0, 1 - y(\mathbf{w}_l \cdot \phi(x))\}$
- 6:     **if**  $l > 0$  **then**
- 7:        $\tau \leftarrow \min\{C, \frac{l}{\|\phi(x)\|^2}\}$
- 8:        $\mathbf{w}_l \leftarrow \mathbf{w}_l + \tau y \phi(x)$
- 9:     **end if**
- 10:   **end for**
- 11: **end for**

---

data  $\mathcal{T}$  into  $\mathcal{T}_l$ .

$$\mathcal{T}_l = \left\{ (x_i, y_i) \mid \begin{array}{l} y_i = +1 \text{ if } l \in \mathbf{m}_i \\ y_i = -1 \text{ otherwise} \end{array} \right\}_{i=1}^T$$

Each document is treated as a positive example if it has label  $l$ ; otherwise it is a negative example. Since local classifiers are independent of each other, we can trivially parallelize training.

We employ the Passive-Aggressive algorithm for training (Crammer et al., 2006). Specifically we use PA-I. The pseudo-code is given in Algorithm 1. We set the aggressiveness parameter  $C$  as 1.0.

#### 3.2 Tree Model

Unlike the flat model, the tree model exploits the label hierarchy. Each local classifier is now associated with an edge  $p \rightarrow c$  of the label hierarchy and has a weight vector  $\mathbf{w}_{p \rightarrow c}$ . If  $\mathbf{w}_{p \rightarrow c} \cdot \phi(x) > 0$ , it means that  $x$  would belong to descendant(s) of  $c$ . Edge classifiers are independent of each other and can be trained in parallel.

We consider two ways of constructing training data  $\mathcal{T}_{p \rightarrow c}$ .

**ALL** — All training data are used as before.

$$\mathcal{T}_{p \rightarrow c} = \left\{ (x_i, y_i) \mid \begin{array}{l} y_i = +1 \text{ if } \exists l \in \mathbf{m}_i, l \in \text{leaves}(c) \\ y_i = -1 \text{ otherwise} \end{array} \right\}_{i=1}^T$$

Each document is treated as a positive example if it belongs to a leaf node of  $c$ , and the rest is negative examples (Punera and Ghosh, 2008).

**SIB** — Negative examples are restricted documents that belong to the leaves of  $c$ 's siblings.

$$\mathcal{T}_{p \rightarrow c} = \left\{ (x, y) \mid \begin{array}{l} y = +1 \text{ if } \exists l \in \mathbf{m}, l \in \text{leaves}(c) \\ y = -1 \text{ if } \exists l \in \mathbf{m}, l \in \text{leaves}(p) \\ \text{and } l \notin \text{leaves}(c) \end{array} \right\}$$

---

**Algorithm 2** Top-down local search.

---

**Input:** document  $x$   
**Output:** label set  $\mathbf{m}$

```
1:  $q \leftarrow [\text{ROOT}], \mathbf{m} \leftarrow \{\}$ 
2: while  $q$  is not empty do
3:    $p \leftarrow$  pop out the first item of  $q, \mathbf{t} \leftarrow \{\}$ 
4:   for all  $c$  such that  $c$  is a child of  $p$  do
5:      $\mathbf{t} \leftarrow \mathbf{t} \cup \{(c, \mathbf{w}_{p \rightarrow c} \cdot \phi(x))\}$ 
6:   end for
7:    $\mathbf{u} \leftarrow \{(c, s) \in \mathbf{t} \mid s > 0\}$ 
8:   if  $\mathbf{u}$  is empty then
9:      $\mathbf{u} \leftarrow \{(c, s)\}$  such that  $c$  has the highest score  $s$ 
       among  $p$ 's children
10:  end if
11:  for all  $(c, s) \in \mathbf{u}$  do
12:    if  $c$  is a leaf node then
13:       $\mathbf{m} \leftarrow \mathbf{m} \cup \{c\}$ 
14:    else
15:      append  $c$  to  $q$ 
16:    end if
17:  end for
18: end while
```

---

This leads to a compact model because low-level edges, which are overwhelming in number, have much smaller training data than high-level edges. This is a preferred choice in previous studies (Liu et al., 2005; Wang et al., 2011; Sasaki and Weissenbacher, 2012).

### 3.3 Top-down Local Search

In previous studies, the tree model is usually accompanied with top-down local search for decoding (Montejo-Ráez and Ureña-López, 2006; Wang et al., 2011; Sasaki and Weissenbacher, 2012).<sup>5</sup> Algorithm 2 is a basic form of top-down local search. At each node, we select children to which edge classifiers return positive scores (Lines 4–7). However, if no children have positive scores, we select one child with the highest score (Lines 8–10). We repeat this until we reach leaves. The decoding of the flat model can be seen as a special case of this search.

Top-down local search is greedy, hierarchical pruning. If a higher-level classifier drops a child node, we no longer consider its descendants as output candidates. This drastically reduces the number of local classifications in comparison with the flat model. At the same time, however, this is a source of errors. In fact, a chain of local decisions accumulates errors, which is known as error propagation (Bennett and Nguyen, 2009). If the decision by a higher-level classifier was wrong, the model has no way of recovering from the error.

---

<sup>5</sup>For other methods, Punera and Ghosh (2008) post-process local classifier outputs by isotonic tree regression.

To alleviate this problem, various modifications have been proposed, which we collectively call post-training adjustment. Sasaki and Weissenbacher (2012) combined broader candidate generation with post-hoc pruning. They first generated a larger number of candidates by setting a negative threshold (e.g.,  $-0.2$ ) instead of 0 in Line 7. Then they filtered out unlikely labels by setting another threshold on the sum of (sigmoid-transformed) local scores of each candidate's path. S-cut (Montejo-Ráez and Ureña-López, 2006; Wang et al., 2011) adjusts the threshold for each classifier. R-cut selects top- $r$  candidates either globally (Liu et al., 2005; Montejo-Ráez and Ureña-López, 2006) or at each parent node (Wang et al., 2011). Wang et al. (2011) developed a meta-classifier which classified a root-to-leaf path using sigmoid-transformed local scores and some additional features. All these methods assume that the models themselves are inherently imperfect and must be supplemented by additional parameters which are tuned manually or by using development data.

## 4 Proposed Method

### 4.1 Global Model

We see hierarchical multi-label text classification as a structured prediction problem. We propose a global model that jointly predicts  $\mathbf{m}$ , or  $\text{tree}(\mathbf{m})$ .

$$\text{score}(x, \mathbf{m}) = \mathbf{w} \cdot \Phi(x, \text{tree}(\mathbf{m}))$$

$\mathbf{w}$  can be constructed simply by combining local edge classifiers.

$$\mathbf{w} = \mathbf{w}_{\text{ROOT} \rightarrow A} \oplus \mathbf{w}_{\text{ROOT} \rightarrow B}, \dots, \oplus \mathbf{w}_{B \rightarrow BB}$$

Its corresponding feature function  $\Phi(x, \text{tree}(\mathbf{m}))$  returns copies of  $\phi(x)$ , each of which corresponds to an edge of the label hierarchy. Thus  $\text{score}(x, \mathbf{m})$  can be reformulated as follows.

$$\text{score}(x, \mathbf{m}) = \sum_{p \rightarrow c \in \text{tree}(\mathbf{m})} \mathbf{w}_{p \rightarrow c} \cdot \phi(x)$$

Now we want to find  $\mathbf{m}$  that maximizes the global score,  $\arg\max_{\mathbf{m}} \text{score}(x, \mathbf{m})$ .

With the global model, we can confirm that local search is a major source of errors. In preliminary experiments, we trained local edge classifiers on **ALL** data and combined the resultant classifiers to create a global model. For 33% of documents in the same dataset, local search found sets of labels whose global scores were lower than the corresponding correct sets of labels.

---

**Algorithm 3** MAXTREE( $x, p$ )

---

**Input:** document  $x$ , tree node  $p$ **Output:** label set  $\mathbf{m}$ , score  $s$ 

```

1:  $\mathbf{u} \leftarrow \{\}$ 
2: for all  $c$  in the children of  $p$  do
3:   if  $c$  is a leaf then
4:      $\mathbf{u} \leftarrow \mathbf{u} \cup \{(\{c\}, \mathbf{w}_{p \rightarrow c} \cdot \phi(x))\}$ 
5:   else
6:      $(\mathbf{m}', s') \leftarrow \text{MAXTREE}(x, c)$ 
7:      $\mathbf{u} \leftarrow \mathbf{u} \cup \{(\mathbf{m}', s' + \mathbf{w}_{p \rightarrow c} \cdot \phi(x))\}$ 
8:   end if
9: end for
10:  $\mathbf{r} \leftarrow \{(\mathbf{m}, s) \in \mathbf{u} \mid s > 0\}$ 
11: if  $\mathbf{r}$  is empty then
12:    $\mathbf{r} \leftarrow \{(\mathbf{m}, s)\}$  such that the item has the highest score
      $s$  among  $\mathbf{u}$ 
13: end if
14:  $\mathbf{m} \leftarrow \bigcup_{(\mathbf{m}, s) \in \mathbf{r}} \mathbf{m}$ 
15:  $s \leftarrow \sum_{(\mathbf{m}, s) \in \mathbf{r}} s$ 
16: return  $(\mathbf{m}, s)$ 

```

---

## 4.2 Dynamic Programming

We show that an exact solution for the global model can be found by dynamic programming.<sup>6</sup> The pseudo-code is given in Algorithm 3. MAXTREE( $x, p$ ) recursively finds a subtree that maximizes the score rooted by  $p$ , and thus we invoke MAXTREE( $x, \text{ROOT}$ ). For  $p$ , each child  $c$  is associated with (1) a set of labels that maximizes the score of the subtree rooted by  $c$  and (2) its score (Lines 3–8). The score of  $c$  is the sum of  $c$ 's tree score and the score of the edge  $p \rightarrow c$ . A leaf's tree score is zero.

To maximize  $p$ 's tree score, we select all children that add positive scores to the parent (Line 10). If no children add positive scores, we select one child that gives the highest score (Lines 11–13). Again, the flat model can be seen as a special case of this algorithm. The selected children correspond to  $p$ 's label set and score (Lines 14–15).

A possible extension to this algorithm is to output  $N$ -best label sets. Since our algorithm is much easier than bottom-up parsing (McDonald et al., 2005), it would not be so difficult (Collins and Koo, 2005).

Dynamic programming resolves the search problem. We no longer require post-training adjustment. It allows us to concentrate on improving the model itself.

<sup>6</sup>Bennett and Nguyen (2009) proposed a similar method, but neither global model nor global training was considered. In their method, the scores of lower-level classifiers were incorporated as meta-features of a higher-level classifier. All these classifiers were trained locally and required burdensome cross-validation techniques.

---

**Algorithm 4** Modification to incorporate branching features. Replace Lines 10–15 of Algorithm 3.

---

```

10:  $r \leftarrow \mathbf{u}$  sorted by  $s$  in descending order
11:  $\mathbf{r}' \leftarrow \{\}$ ,  $s' \leftarrow 0$ ,  $\mathbf{m}' \leftarrow \{\}$ 
12: for  $k = 1..size$  of  $r$  do
13:    $(\mathbf{m}, s) \leftarrow r[k]$ 
14:    $s' \leftarrow s' + s$ ,  $\mathbf{m}' \leftarrow \mathbf{m}' \cup \mathbf{m}$ 
15:    $\mathbf{r}' \leftarrow \mathbf{r}' \cup \{(\mathbf{m}', s' + \mathbf{w}_{\text{BF}} \cdot \phi_{\text{BF}}(p, k))\}$ 
16: end for
17:  $(\mathbf{m}, s) \leftarrow$  item in  $\mathbf{r}'$  that has the highest  $s$ 

```

---

## 4.3 Inter-label Dependencies

Now we are ready to exploit inter-label dependencies. We introduce branching features, a simple but powerful extension to the global model. They influence how many children a node selects. The corresponding function is  $\phi_{\text{BF}}(p, k)$ , where  $p$  is a non-leaf node and  $k$  is the number of children to be selected for  $p$ . To avoid sparsity, we choose one of  $R + 1$  features ( $1, \dots, R$  or  $>R$ ) for some pre-defined  $R$ . To be precise, we fire two features per non-leaf node: one is node-specific and the other is shared among non-leaf nodes. As a result, we append at most  $(I + 1)(R + 1)$  features to the global weight vector, where  $I$  is the number of non-leaf nodes.

All we have to do to incorporate branching features is to replace Lines 10–15 of Algorithm 3 with Algorithm 4. For given  $k$ , we first need to select  $k$  children that maximize the sum of the scores. This can be done by sorting children by score and select the first  $k$  children. We then add a score of branching features  $\mathbf{w}_{\text{BF}} \cdot \phi_{\text{BF}}(p, k)$  (Line 15). Finally we chose a candidate with the highest score (Line 17).

## 4.4 Global Training

Up to this point, the global model is constructed by combining locally trained classifiers. Of course, we can directly train the global model. In fact we cannot incorporate branching features without global training.

Algorithm 5 shows a Passive-Aggressive algorithm for the structured output (Crammer et al., 2006). We can find an exact solution under the current weight vector by dynamic programming (Line 5).<sup>7</sup> The cost  $\rho$  reflects the degree to which the model's prediction was wrong. It is based on the

<sup>7</sup>If we want for some reason to stick to local search, we need to address the problem of "non-violation." With inexact search, the model prediction  $\hat{\mathbf{m}}$  may have a lower score than correct  $\mathbf{m}$ , making the update invalid. Several methods have been proposed to solve this problem (Collins and Roark, 2004; Huang et al., 2012).

---

**Algorithm 5** Passive-Aggressive algorithm for global training (PA-I, prediction-based updates).

---

**Input:** training data  $\mathcal{T} = \{(x_i, \mathbf{m}_i)\}_{i=1}^T$   
**Output:** weight vector  $\mathbf{w}$

- 1:  $\mathbf{w} \leftarrow \mathbf{0}$
- 2: **for**  $n = 1..N$  **do**
- 3:   shuffle  $\mathcal{T}$
- 4:   **for all**  $(x, \mathbf{m}) \in \mathcal{T}$  **do**
- 5:     predict  $\hat{\mathbf{m}} \leftarrow \operatorname{argmax}_{\mathbf{m}} \operatorname{score}(x, \mathbf{m})$
- 6:      $\rho \leftarrow 1 - 2|\mathbf{m} \cap \hat{\mathbf{m}}|/(|\mathbf{m}| + |\hat{\mathbf{m}}|)$
- 7:     **if**  $\rho > 0$  **then**
- 8:        $l \leftarrow \operatorname{score}(x, \hat{\mathbf{m}}) - \operatorname{score}(x, \mathbf{m}) + \sqrt{\rho}$
- 9:        $\tau \leftarrow \min\{C, \frac{l}{\|\Phi(x, \operatorname{tree}(\mathbf{m})) - \Phi(x, \operatorname{tree}(\hat{\mathbf{m}))\|^2}\}$
- 10:        $\mathbf{w} \leftarrow \mathbf{w} + \tau(\Phi(x, \operatorname{tree}(\mathbf{m})) - \Phi(x, \operatorname{tree}(\hat{\mathbf{m}})))$
- 11:     **end if**
- 12:   **end for**
- 13: **end for**

example-based F measure, which will be reviewed in Section 5.3.

Note that what are called “global” in some previous studies are in fact *path*-based methods (Qiu et al., 2009; Qiu et al., 2011; Wang et al., 2011; Sasaki and Weissenbacher, 2012). In contrast, we present *tree-wide* optimization.

#### 4.5 Parallelization of Global Training

One problem with global training is speed. We can no longer train local classifiers in parallel because global training makes the model monolithic. Even worse, label set prediction is orders of magnitude slower than a binary classification. For these reasons, global training is extremely slow.

We resort to iterative parameter mixing (McDonald et al., 2010). The basic idea is to split training data into small “shards” instead of subdividing the model. Algorithm 6 gives a pseudocode, where  $S$  is the number of shards. We perform training on each shard in parallel. At the end of each iteration, we average the models and use the resultant model as the initial value for the next iteration.

Iterative parameter mixing was originally proposed for Perceptron training. However, as McDonald et al. (2010) noted, it is possible to provide theoretical guarantees for distributed online Passive-Aggressive learning.

## 5 Experiments

---

**Input:** training data  $\mathcal{T} = \{(x_i, \mathbf{m}_i)\}_{i=1}^T$   
**Output:** weight vector  $\mathbf{w}$

- 1: split  $\mathcal{T}$  into  $\mathcal{S}_1, \dots, \mathcal{S}_S$
- 2:  $\mathbf{w} \leftarrow \mathbf{0}$
- 3: **for**  $n = 1..N$  **do**
- 4:   **for**  $s = 1..S$  **do**
- 5:      $\mathbf{w}_s \leftarrow$  asynchronously call Algorithm 5 with some modifications:  $\mathcal{T}$  is replaced with  $\mathcal{S}_s$ ,  $\mathbf{w}$  is initialized with  $\mathbf{w}$  instead of  $\mathbf{0}$ , and  $N$  is set as 1.
- 6:   **end for**
- 7:   join
- 8:    $\mathbf{w} \leftarrow \frac{1}{S} \sum_{s=1}^S \mathbf{w}_s$
- 9: **end for**

---

ment consisted of a title, an abstract, a list of authors, a journal name, a set of categories and many other fields. For experiments, we selected a set of documents that (1) were dated 2010 and (2) contained both Japanese title and abstract. As a result, we obtained 455,311 documents, which were split into 409,892 documents for training and 45,419 documents for evaluation.

The number of labels was 3,209, which amounts to 4,030 edges. All the leave nodes are located at the fifth level (the root not counted). Some edges skip intermediate levels (e.g., children of a second-level node are located at the fourth level). On average 1.85 categories were assigned to a document, with a variance of 0.85. The maximum number of categories per document was 9.

For the feature representation of a document  $\phi(x)$ , we employed two types of features.

1. Journal name (binary). One feature was fired per document.
2. Content words in the title and abstract (frequency-valued). Frequencies of the words in the title were multiplied by two.

To extract content words, we first applied the morphological analyzer JUMAN<sup>9</sup> to each sentence to segment it into a word sequence. From each word sequence, we selected content words using the dependency parser KNP,<sup>10</sup> which tagged content words at a pre-processing step. Each document contained 380 characters on average, which corresponded to 120 content words according to JUMAN and KNP.

<sup>9</sup><http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?JUMAN>

<sup>10</sup><http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?KNP>

## 5.2 Models

In addition to the flat model (**FLAT**), the tree model with various configurations was compared. We performed local training of edge classifiers on **ALL** data and **SIB** data as explained in Section 3.2. We applied top-down local search (**LS**) and dynamic programming (**DP**) for decoding. We also performed global training (**GT**) with and without branching features (**BF**).

We performed 10 iterations for training local classifiers. For iterative parameter mixing described in Section 4.5, we evenly split the training data into 10 shards and ran 10 iterations. For branching features introduced in Section 4.3, we set  $R = 3$ .

## 5.3 Evaluation Measures

Various evaluation measures have been proposed to handle multiple labels. The first group of evaluation measures we adopted is document-oriented measures often referred to as *example-based* measures (Godbole and Sarawagi, 2004; Tsoumakas et al., 2010). The example-based precision (**EBP**), recall (**EBR**) and F measure (**EBF**) are defined as follows.

$$\begin{aligned} \text{EBP} &= \frac{1}{T} \sum_{i=1}^T \frac{|\mathbf{m}_i \cap \hat{\mathbf{m}}_i|}{|\hat{\mathbf{m}}_i|} \\ \text{EBR} &= \frac{1}{T} \sum_{i=1}^T \frac{|\mathbf{m}_i \cap \hat{\mathbf{m}}_i|}{|\mathbf{m}_i|} \\ \text{EBF} &= \frac{1}{T} \sum_{i=1}^T \frac{2|\mathbf{m}_i \cap \hat{\mathbf{m}}_i|}{|\hat{\mathbf{m}}_i| + |\mathbf{m}_i|} \end{aligned}$$

where  $T$  is the number of documents in the test data,  $\mathbf{m}_i$  is a set of correct labels of the  $i$ -th document and  $\hat{\mathbf{m}}_i$  is a set of labels predicted by the model.

Another group of measures are called label-based (**LB**) and are based on the precision, recall and F measure of each label (Tsoumakas et al., 2010). Multiple label scores are combined by performing macro-averaging (**Ma**) or micro-averaging (**Mi**), resulting in six measures.

Lastly we used hierarchical evaluation measures to give some scores to “partially correct” labels (Kiritchenko, 2005). If we assume a tree instead of a more general directed acyclic graph, we can formulate the (micro-average) hierarchical

precision (**hP**) and hierarchical recall (**hR**) as follows.

$$\begin{aligned} \text{hP} &= \frac{\sum_{i=1}^T |\text{tree}(\mathbf{m}_i) \cap \text{tree}(\hat{\mathbf{m}}_i)|}{\sum_{i=1}^T |\text{tree}(\hat{\mathbf{m}}_i)|} \\ \text{hR} &= \frac{\sum_{i=1}^T |\text{tree}(\mathbf{m}_i) \cap \text{tree}(\hat{\mathbf{m}}_i)|}{\sum_{i=1}^T |\text{tree}(\mathbf{m}_i)|} \end{aligned}$$

The hierarchical F measure (hF) is the harmonic mean of hP and hR.

## 5.4 Results

Table 1 shows the performance comparison of various models. DP-GT-BF performed best in 5 measures. Compared with FLAT, DP-GT-BF drastically improved LBMiP and hP. Branching features consistently improved F measures. The tree model with local search was generally outperformed by the flat model. Compared with FLAT, DP-ALL and DP-GT, DP-GT-BF yielded statistically significant improvements with  $p < 0.01$ .

DP-ALL outperformed LS-ALL for all but one measures. DP-SIB performed extremely poorly while DP-ALL was competitive with DP-GT-BF. This is in sharp contrast to the pair of LS-ALL and LS-SIB, which performed similarly. Dynamic programming forced DP-SIB’s local classifiers to classify what were completely new to them because they had been trained only on small portions of data. The result was highly unpredictable.

As expected, dynamic programming was much slower than local search. In fact DP-GT-BF was more than 60 times slower than local search. Somewhat surprisingly, it took only 18% more time than FLAT. This may be explained by the fact that DP-GT-BF was 16% smaller in size than FLAT.

Although DP-ALL was competitive with DP-GT and DP-GT-BF, it is notable that global training yielded much smaller models. Branching features brought further model size reduction along with almost consistent performance improvement. This result seems to support our hypothesis concerning the decision-making process of the human annotators. They do not select each label independently but consider the relative importance among competing labels.

## 5.5 Discussion

Table 2 shows the performance of several models on the training data. It is interesting that FLAT and DP-ALL scored much higher on the training data

model	iterations	time (min)	size	EBP	EBR	EBF
FLAT	10	266	73M	.4520	.4111	.3956
LS-ALL	10	<b>5</b>	115M	.3927	.4064	.3713

Table 2: Performance on the training data.

than DP-GT-BF although they were outperformed on the test data. It seems safe to conclude that local training caused overfitting.

We further investigated the models by decomposing them into edges. Figure 2 compares three models. The first three figures (a–c) report the number of non-trivial elements in each weight vector. Edges are grouped by the level of child nodes. Although DP-GT-BR was much smaller in total size than DP-ALL, the per-edge size distributions looked alike. The higher the level was, the larger number of non-trivial features each model required. Compared with DP-SIB, DP-GT-BR had compact local classifiers for the highest-level edges but the rest was generally larger. Intuitively, knowing its siblings is not enough for each local classifier, but it does not need to know all possible rivals.

The last three figures (d–f) report the averaged absolute scores of each edge that were calculated from the model output for the test data. By doing

Figure 3: Heat map of the weight vector for branching features. R is the root level.

this, we would like to measure how edges of various levels affect the model output. Higher-level edges tended to have larger impact. However, we can see that in DP-GT-BR, their impact was relatively small. In other words, lower-level edges played more important roles in DP-GT-BR than in other models.

Figure 3 shows a heat map representation of the weight vector for DP-GT-BR’s branching features. The value of each item is the weight value averaged over parent nodes. All averaged weight values were negative. The penalty monotonically increased with the number of children. It is not easy to compare different levels of nodes because weight values depended on other parts of the weight vector. However, the fact that lower-level nodes marked sharper contrasts between small and large number of children appears to support our

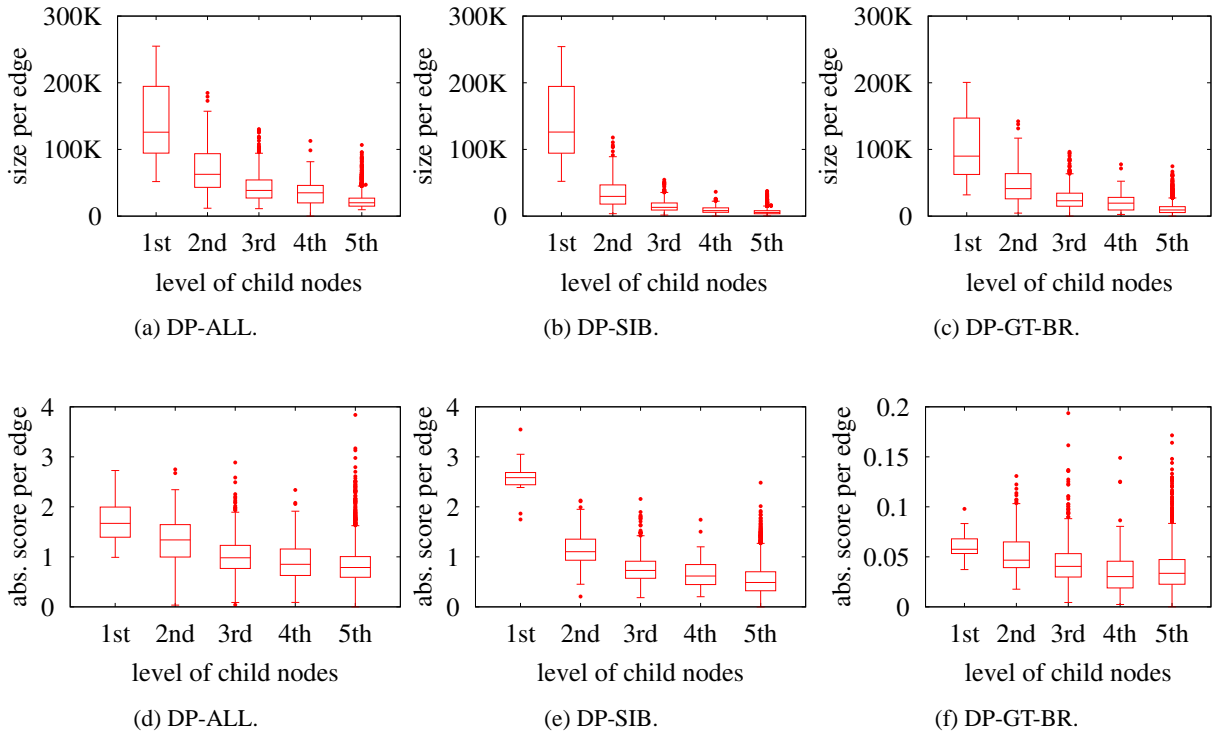

Figure 2: Comparison of model sizes and scores per edge. The definition of size is the same as that in Table 1.

hypothesis about the competitive nature of label candidates positioned proximally in the label hierarchy.

## 6 Conclusion

In this paper, we treated hierarchical multi-label text classification as a structured prediction problem. Under this framework, we proposed (1) dynamic programming that finds an exact solution, (2) global training and (3) branching features that capture inter-label dependencies. Branching features improve performance while reducing the model size. This result suggests that the selection of multiple labels by human annotators greatly depends on the relative importance among competing labels.

Exploring features that capture other types of inter-label dependencies is a good research direction. For example, “Others” labels probably behave atypically in relation to their siblings. While we focus on the setting where only the leaf nodes represent valid labels, internal nodes are sometimes used as valid labels. Such internal nodes often block the selection of their descendants. Also, we would like to work on directed acyclic graphs and to improve scalability in the future.

## Acknowledgments

We thank the Department of Databases for Information and Knowledge Infrastructure, Japan Science and Technology Agency for providing JST-Plus and helping us understand the database. This work was partly supported by JST CREST.

## Abstract

The objective of the present contribution is to give a survey of the annotation of information structure in the Czech part of the Prague Czech-English Dependency Treebank. We report on this first step in the process of building a parallel annotation of information structure in this corpus, and elaborate on the automatic pre-annotation procedure for the Czech part. The results of the pre-annotation are evaluated, based on the comparison of the automatic and manual annotation.

## 1 Introduction

In the past three or four decades, topic-focus articulation (known also as sentence information structure) is a language phenomenon that has attracted an enormous interest in linguistics and has become a “hot” topic of linguistic studies. No wonder then, that these days several linguistic teams (e.g. at the University of Potsdam, University of Berlin, University of Stuttgart, Charles University in Prague) have attempted to include the annotation of information structure in the annotating schemes they propose. Among corpora that contain also annotation of information structure or such type of annotation is planned in them there are e.g. ANNIS database (Annotation of Information Structure, see Dipper et al., 2004), The English Switchboard Corpus (see Calhoun et al., 2005), the corpus DannPASS (Danish Phonetically Annotated Spontaneous Speech, see Paggio, 2006) and the Prague Dependency Treebank (for the information on PDT, see Hajič et al., 2006).

There are also several types of annotation guidelines and schemes for the different corpora, based on various linguistic theories dealing with information structure (e.g. Hajičová et al., 2000;

Nissim et al., 2004; Dipper et al., 2007; Donhauser, 2007; Cook and Bildhauer, 2011).

In our paper, we present the annotation of topic-focus articulation in the Czech part of the Prague Czech-English Dependency Treebank, based on the theory of topic-focus articulation as developed withing the Praguian Functional Generative Description. It is the first step in the process of building a parallel Czech-English corpus annotated with this type of linguistic information.<sup>1</sup>

### 1.1 Topic-Focus Articulation in Prague Treebanks

The first complex and consistent theoretically-based annotation of topic-focus articulation was already fully applied in the first Czech corpus from the Prague corpora family, the Prague Dependency Treebank (PDT; Hajič et al., 2006, updated in Bejček et al., 2012), and is available for the linguistic community. PDT is a large collection of Czech journalistic texts, (basically) manually annotated on several layers of language description (more than 3 thousand documents consisting of almost 50 thousand sentences are annotated on all the levels).

Detailed annotation guidelines that constitute the basis of the handling with the language material were developed (Mikulová et al., 2005) based on the theoretical assumptions of the Functional Generative Grammar (for the first formulations of this formal framework, see Sgall, 1967; Sgall et al., 1986). The annotation of the information structure in PDT is also based on this theory. The same linguistic approach was used in some other annotation schemes connected with the annotation of topic-focus articulation (e.g. Postolache, 2005).

<sup>1</sup> Given the available funds, our present goal is to annotate 5 thousand parallel sentences.

## 1.2 Aim of the Paper

Our effort is concentrated on annotating the topic-focus articulation (TFA) in a parallel corpus – the Prague Czech-English Dependency Treebank (PCEDT), to make possible contrastive studies of this phenomenon. As the first step, we annotate topic-focus articulation in the Czech part of the treebank. The annotation guidelines have been taken over from the PDT approach, i.e. they also follow the theory of Functional Generative Description.

In Section 2, we give an overview of the theoretical background of TFA, Section 3 introduces the Prague Czech-English Dependency Treebank (the data to be annotated). Section 4 describes in detail an automatic pre-annotation procedure that was applied on the data before they were annotated manually by a human annotator. The final step of this part of our research was the evaluation of effectiveness of the automatic pre-annotation, given in Section 5.

## 2 Theoretical Background for Corpus Annotation of Topic-Focus Articulation in PCEDT

The theoretical linguistic background for the creating of the whole corpus PCEDT is the Functional Generative Description (Sgall, 1967; Sgall et al., 1986). Topic-focus articulation in this theoretical framework was described especially by Sgall and Hajičová (summarized in Sgall et al., 1986, Hajičová et al., 1998). On the basis of this, the annotation guidelines for manual annotation of topic-focus articulation in the Prague Dependency Treebank (PDT) were established and are available in the annotation manual for the underlying structure of sentences in Mikulová et al. (2005). These guidelines are used also for the Czech part of the Prague Czech-English Dependency Treebank.

### 2.1 Topic-Focus Articulation in Functional Generative Description

The theory of topic-focus articulation within the framework of Functional Generative Description is based on the aboutness-principle: the topic is the part of a sentence that is spoken about, and, complementarily, the focus is the sentence part that declares something about the topic. From the cognitive point of view, topic may be characterized as the “given” part of the sentence and focus as the “new” one. However, this does not mean that the focus elements cannot be mentioned in

the previous language context at all but they have to bring some non-identifiable information or information in new relations.

Most sentences contain both parts – topic and focus. However, some sentences can be contextually independent (e.g. the first sentence of the text or its title) and they do not have to contain the topic part (these are topic-less sentences). On the contrary, the focus is an obligatory component of every sentence – it is the informatively more important part of the message than the topic.

The basic opposition established by the TFA theory and included in the annotation scheme is the opposition of contextual boundness: each element of the underlying structure of the sentence carries the feature “contextually bound” or “contextually non-bound”. In addition, the contextually bound elements in the topic can be either contrastive, or non-contrastive. Contrastive contextually bound sentence members differ from the non-contrastive ones in the presence of a contrastive stress and in their semantic content – they express contrast to some previous context (e.g. *at home – abroad*).

Non-contrastive contextually bound expressions are marked as 't', contrastive contextually bound expressions are marked as 'c' and contextually non-bound expressions are marked as 't'<sup>2</sup>.

The opposition between contextually bound and contextually non-bound elements serves then as a basis for the bi-partition of the sentence into its topic and focus; according to this hypothesis, an algorithm for topic-focus bi-partition was formulated, implemented and tested on the PDT data, with some rather encouraging results (see Hajičová et al., 2005).

In Czech (Czech is the language of Prague Dependency Treebank and also of one half of the Prague Czech-English Dependency Treebank), the word order position of predicative verb is often the natural boundary between the topic and focus part in the sentence – cf. Example (1).

(1) [Context: *Moje matka má ráda růže a tulipány.*] *Tulipány*<sub>contrastive\_topic</sub> *matka*<sub>topic</sub> *včera*<sub>topic</sub> *koupila*<sub>focus</sub> *na trhu*<sub>focus</sub>

Literally: [Context: *My mother likes roses and tulips.*] *The tulips*<sub>contrastive\_topic</sub> *the mother*<sub>topic</sub> *yesterday*<sub>topic</sub> *bought*<sub>focus</sub> *on the market*<sub>focus</sub>.

<sup>2</sup> The contextually non-bound elements do not have a contrastive and non-contrastive variant in the theory of FGP.

(= *The mother bought the tulips ON THE MARKET*<sup>3</sup> yesterday.)

Several operational tests have been proposed in literature that help to distinguish between topic and focus, the most relevant of them being the question test and the test of negation (for details see Sgall et al., 1986; Hajičová et al., 1998).

In short, the basis of the question test is to ask a question that fully represents the context for the tested sentence. The tested sentence has to be a relevant answer to the question. The sentence members present in both the question and answer are topic members. The elements present only in the answer are members of the focus.

The principle of the negation test is to find out the possible scope of negation in the negative counterpart to the given sentence. In principle, the sentence members that are in the scope of negation in the given context belong to the focus part of the sentence. Other members form the topic part. However, there is a possibility of negative topic, i.e. the topic of the sentence is negated and the focus stands out of the scope (for details see e.g. Sgall et al., 1973).

For detailed information on annotation guidelines of topic-focus articulation in the framework of Functional Generative Description, the online annotation manual is available (see <http://ufal.mff.cuni.cz/pdt2.0/doc/manuals/en/t-layer/html/index.html>).

### 3 Language Material – Prague Czech-English Dependency Treebank

The annotation effort described in this paper is performed on data from the Prague Czech-English Dependency Treebank (PCEDT, Hajič et al., 2012), a manually parsed parallel Czech-English corpus that contains over 1.2 million running words (50 thousand sentences in each of the two languages). The English part consists of texts from the Penn Treebank (Marcus et al., 1993) – articles from the Wall Street Journal. The Czech part contains human translations of the English sentences to Czech.

The annotation (on both language sides) is performed on four language layers: the “word” layer, the morphological layer, the analytical layer (i.e. the layer of surface syntax) and the tectogrammatical layer (i.e. the semantic layer of the deep syntax).

On the topmost (tectogrammatical) layer, individual sentences are organized in dependency

<sup>3</sup> The members that carry the centre of the intonation in the sentence are capitalized (in the translation).

tree structures, according to the style of the Prague Dependency Treebank (PDT). Autosemantic words and coordinating structures are captured in the trees, as well as the valency of verbs (each language has its own valency lexicon in PCEDT). Additionally, the surface sentence ellipsis is reconstructed in the deep sentence structure and also pronominal anaphoric relations are labeled in the texts. The topic-focus articulation is also to be annotated on this layer.

The parallel Czech-English data are aligned manually on the level of sentences and automatically on the level of tectogrammatical nodes.

More detailed information on PCEDT is available on the project website (<http://ufal.mff.cuni.cz/pcedt2.0/en/index.html>).

### 4 Automatic Pre-Annotation

For the annotation of topic-focus articulation in the Czech part of PCEDT, an automatic pre-annotation procedure was developed. The particular steps (rules) of the pre-annotation were mainly established on the basis of the completed annotation of contextual boundness in the Prague Dependency Treebank (i.e. on the basis of annotated Czech texts). The cross-language alignment of tectogrammatical nodes in PCEDT was also exploited (see the pre-annotation step 10 below), allowing for taking advantage of the existence of indefinite articles in English (not present in the Czech language).

Using information from the English side for the pre-annotation of topic-focus articulation in the Czech part is possible, as the topic-focus articulation of the given sentence in the given context should be identical regardless on the language<sup>4</sup>. The surface word order may vary in Czech in comparison with English (cf. the different word order in Example (1) in the two languages) but the topic-focus articulation of the sentence should be the same in both the languages. This theoretical assumption, as well as the quality of the English->Czech translation (from the point of view of topic-focus articulation), can be tested on real corpus data once the annotation on both language sides of PCEDT is finished.

<sup>4</sup> In fact, the topic-focus articulation of the given sentence is the same regardless on the language. However, we operate with a parallel corpus – the English part contains original texts and the Czech one their translations. It is possible that the Czech translations could be inaccurate in some cases – especially regarding the topic-focus articulation. Therefore, the value of contextual boundness could differ in both parts of parallel corpus in a few cases.

So far, the automatic procedure was used for pre-annotation of a sample of the PCEDT Czech part and this pre-annotated sample was subsequently manually annotated by a human annotator. The annotator checked the correctness of the pre-annotation and annotated the rest of the nodes (nodes that had not been pre-annotated). Afterwards, it was evaluated how many changes of the automatic pre-annotation of topic-focus articulation the human annotator had to carry out, i.e. how many mistakes the automatic pre-annotation had made in the data.

It should be noted that the goal of the automatic pre-annotation was to help the human annotators with simple decisions, not to classify every sentence member as contextually bound ('t') or non-bound ('f') element. Our intention was to apply only reliable rules and leave too complex decisions (often depending on the meaning of the text) on the human annotator. We wanted to avoid introducing too many errors in the pre-annotation, as human annotators might be prone to overlooking errors in already annotated nodes and concentrate only (or at least better) on the so far unannotated nodes. For the selection of the pre-annotation steps, we estimated their expected error rates (where possible) based on measurements on the topic-focus annotation in PDT (see the expected error rates of the individual pre-annotation steps below in 4.1). For using a rule, we set the maximum number of expected errors to 10 %.

#### 4.1 Steps of the Pre-Annotation

The following steps have been performed during the automatic pre-annotation. For each step (where possible), we give an estimate of the pre-annotation error (expected error rate, EER), based on the measurement of the phenomenon in the data of Prague Dependency Treebank. The steps have been applied in the presented order. Step 10 takes advantage of the cross-language alignment of words in PCEDT.

1. **Nodes generated** on the tectogrammatical layer **without a counterpart on the analytical layer** (i.e. newly added, but not copied nodes in the tectogrammatical representation) and that do not have functor=RHEM (rhematizer), nor t\_lemma=#Forn (part of a phrase in a foreign language), get automatically assigned tfa='t', i.e. contextually bound, (EER: 0). For an example, see Figure 1.<sup>5</sup>

<sup>5</sup> Sentence members (nodes) that are really expressed in the surface sentence structure (that appear on both the analytical

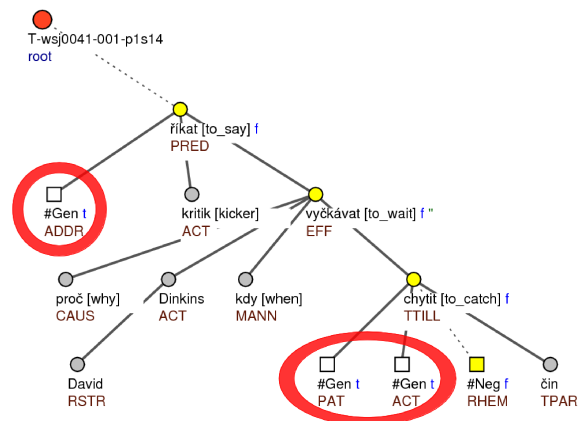

Figure 1: Example of a sentence tree structure in the Czech part of PCEDT: circled nodes represent the automatically pre-annotated sentence members marked as 't' (contextually bound)

Figure 1 represents the following Czech sentence – Example (2) from PCEDT:

(2) „Proč David Dinkins,“ říká kritik, „vždycky vyčkává, dokud není chyten při činu?“  
 “David Dinkins,” says the kicker,  
 “Why does he always wait until he's caught?”

In the surface (analytical) structure of the given sentence with the Czech verb *řikat* (to say), the Addressee is not present explicitly although this verb has the Addressee (apart from the Effect, the Actor and the non-obligatory Patient) in its valency frame (*someone*.obligatory\_Actor says *something*.obligatory\_Effect to *someone*.obligatory\_Addressee about *something/somebody*.non-obligatory\_Patient). So the Addressee is present only in the deep (tectogrammatical) sentence structure (in Figure 1, it is captured as a small square with the symbol of Addressee ADDR). The sentence members that appear only implicitly in the sentence (as the Addressee in this case) are not supposed to carry some new, important information (because their presence in the /surface part of the/ sentence is not necessary) and therefore they are automatically pre-annotated as contextually bound (fur-

and the tectogrammatical layer) are displayed as small circles in the figure. Members that are present only in the deep sentence structure (on the tectogrammatical layer) and do not appear in the surface sentence structure (i.e. not on the analytical layer) are displayed as small squares.

White colour represents contextually bound sentence members (they are also depicted with 't' next to the lemma); yellow colour (light grey in b/w) represents contextually non-bound sentence members (they are depicted with 'f'). The grey members do not have any value of contextual boundness yet (they were not automatically pre-annotated and they will be manually annotated by a human annotator).

ther examples are the sentence members Patient PAT and Actor ACT by the Czech verb *chytiť* – *to catch*: *somebody*<sub>obligatory\_Actor</sub> *catches some-one*<sub>obligatory\_Patient</sub>, see Figure 1).

2. **Nodes generated at the tectogrammatical layer that are members of coordination/apposition** and have an analytical counterpart (they are copied nodes; it also means that it is not e.g. #Forn), get assigned  $tfa='t'$ , i.e. contextually bound, (EER: 0), see Example (3) from PCEDT.

(3) „Nyní,“ říká Joseph Napolitan, průkopník politické televize, „je cílem jít do útoku jako první, poslední a [jít]<sub>t</sub> vždycky.“

“Now,“ says Joseph Napolitan, a pioneer in political television, “the idea is to attack first and [to attack]<sub>t</sub> always.”

This pre-annotation step concerns also other cases of sentence members that are not present in the surface (analytical) structure but appear in the deep (tectogrammatical) layer. These nodes are not newly added to the structure, e.g. because of the valency verb frame, but they appeared in some previous structures and they are omitted in the surface structure (and copied to the deep structure) because the reader can understand them easily from the previous context as in the phrases from Example (3): *to attack first* and *(to attack) always*. Since these members (present only implicitly in the sentence) are obviously deducible from the context, they are considered as contextually bound and therefore they are pre-annotated as such.

3. **Nodes where a grammatical, textual or segment coreference starts**, get  $tfa='t'$ , i.e. contextually bound, (EER: 1:100), see Example (4) from PCEDT.

(4) A *Dinkins* podle *svých<sub>t</sub>* slov nevěděl, že *muž, kterého<sub>t</sub>* platili v rámci kampaně za přesvědčování voličů k účasti, byl odsouzen za únos.

And, says Mr. *Dinkins*, *he<sub>t</sub>* didn't know the *man his<sub>t</sub>* campaign paid for a get-out-the-vote effort had been convicted of kidnapping.

This step of the automatic pre-annotation takes advantage of the finished annotation of coreference in the PCEDT texts. Sentence elements that are anaphors<sup>6</sup> of a coreference relation are sup-

<sup>6</sup> A reference to an entity or event that has already been mentioned in the preceding text; the two mentions –

posed to be contextually bound and therefore they are automatically assigned the value 't'.

There are two coreference relations in Example (4): 1. *Dinkins* – *svých (he)*; 2. *muž (man) – kterého (his)*. The members that refer to some previous sentence members (*svých* and *kterého* in this case) are automatically pre-annotated as contextually bound.

In another example from PCEDT, depicted in Figure 2, starting nodes (anaphors) of grammatical coreference (three intra-sentential more or less vertical arrows) and textual coreference (two horizontal arrows going from the second tree to the first one) are pre-annotated as contextually bound.

4. Nodes with **functor=PRED** that are **not newly generated** and whose  $t\_lemma$  does not appear in the previous sentence, get  $tfa='f'$ , i.e. contextually non-bound, (EER: 1:40), see Example (5) from PCEDT.

(5) „Pamatujete si na Pinocchia?“ říká<sub>f</sub> ženský hlas.

“Remember Pinocchio?“ says<sub>f</sub> a female voice.

The data of previously annotated Prague Dependency Treebank demonstrated that most Predicates (in corpus marked as PRED) are contextually non-bound – therefore, they are pre-annotated as 'f'.

5. **Newly generated nodes with functor=PRED** get  $tfa='t'$ , i.e. contextually bound, (EER: 1:100), see Example (6) from PCEDT.

In contrast to the step 4), Predicates that are not present in the surface sentence structure are pre-annotated as contextually bound, cf. step 3).

(6) Na obrazovce vidíme dvě zkreslené rozmazané fotografie, **pravděpodobně<sub>MOD.f</sub>** [vidíme]<sub>t</sub> fotografie dvou politiků.

The screen shows two distorted, unrecognizable photos, **presumably<sub>MOD.f</sub>** [shows]<sub>t</sub> [photos] of two politicians.

6. **Other verbal nodes** (gram/sempos=v) with **functor** from the set {ADDR, AIM, CAUS, ACMP, MANN, PAT, EFF, AUTH, BEN, COMPL, EXT, ORIG, RESL, TFHL, TSIN} get  $tfa='f'$ , i.e. contextually non-bound, (EER: 1:10), see Example (7) from PCEDT.

anaphor (the latter in the text) and antecedent (the former) are connected by a coreference relation.

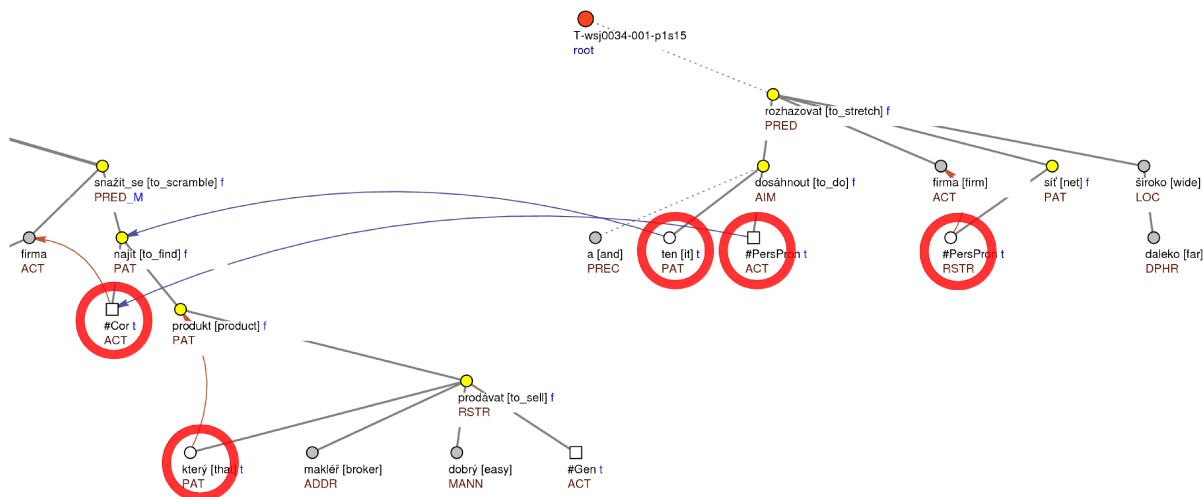

Figure 2: Two trees representing two sentences; the indexes in the sentences and the arrows in the trees denote coreference chains; starting nodes of the coreference links are marked by large circles: *Soukromí investoři se s léty od burzy odvracejí a investiční firmy[2] se snaží [firmy][2] najít[1] produkty[4], které[4] by se makléřům dobře prodávaly. A aby toho[1] [firmy][2] dosáhly, rozhazují firmy[3] své[3] síť široko daleko. (In original: As individual investors have turned away from the stock market over the years, securities firms[2] have scrambled to [firms][2] find[1] new products[4] that[4] brokers find easy to sell. And the firms[3] are stretching their[3] nets far and wide to [firms][2] do it[1].)*

Note that there is no link between *firm* in the first tree and *firm* in the second tree, as only pronominal coreference is annotated in the data. Otherwise, chains [2] and [3] would be one coreference chain.

The example has been cropped to fit the page (the left part of the first tree).

The data of the Prague Dependency Treebank also demonstrated that most sentence members expressed as dependent clauses (i.e. containing a finite verb) and having the semantic role of Addressee, Aim, Cause, Accompaniment, Patient, Effect, Author, Benefactor, Complement, Extent, Origo, Result or Temporal modifications (expressing *for how long* or *since when*) are contextually non-bound – therefore, they are pre-annotated as non-bound also in data of the Prague Czech-English Dependency Treebank.

(7) „Porovnejte tyto dva kandidáty na starostu.“.Effect<sub>f</sub> říká hlasatel.  
 “Compare two candidates for mayor.“.Effect<sub>f</sub> says the announcer.

7. Nodes with **functor** from the set {PARTL, DENOM, MOD, EXT} get tfa='f', i.e. contextually non-bound, (EER: 1:10), see again Example (6) above from PCEDT.

The data of the Prague Dependency Treebank further demonstrated that most sentence members assigned the semantic role of independent interjectional clause (marked as PARTL), independent non-parenthetical nominal clause (DENOM), atomic expression with a modal meaning (MOD) or adjunct expressing extent (EXT) are contextually non-bound and therefore they are pre-annotated as such.

In the Example (6), the sentence member *pravděpodobně (presumably)* is in the role of an atomic expression with a modal meaning (MOD) and therefore it will be automatically assigned the value 'f'.

8. Nodes with **functor=RHEM** (i.e. they have a function of a rhematizer) that are not in the first position in the sentence, get tfa='f', i.e. contextually non-bound, (EER: 1:10), see Example (8) from PCEDT.

(8) Letošek je rokem, kdy se negativní reklama, po léta přítomná ve většině politických kampaní jen<sub>f</sub> druhotně, stala hlavní událostí.  
 This is the year the negative ad, for years [only]<sub>f</sub> a secondary presence in most political campaigns, became the main event.

The rhematizers (as e.g. English particles *only, for example, also, especially, principally*) mostly precede a focus element and in the theory of TFA, they are also considered contextually non-bound. However, also contrastive contextually bound expressions can follow the rhematizers – typically at the beginning of the sentence (and in this case, also the rhematizers are contextually bound). Therefore, only such rhematizers are pre-annotated as contextually non-bound that are not placed in the initial position in the sentence.

9. Nodes with **t\_lemma=tady (here)** get  $tfa='t'$ , i.e. contextually bound, (EER: 1:10), see Example (9) from PCEDT.

Some lemmas (especially with a deictic function like *here*) appear as contextually bound in most cases (but not in all – see e.g. *What happens here<sub>t</sub> and now?*), which observation is also made use of in the automatic pre-annotation.

(9) *Ředitelka Wardová se rozhodla zbavit se „balastu“ v učitelském sboru a obnovit bezpečnost a také tu<sub>t</sub> byly další nové faktory, které pracovaly v její prospěch.*

*Mrs. Ward resolved to clean out “deadwood” in the school’s faculty and restore safety, and she also had some new factors [here]<sub>t</sub> working in her behalf.*

10. Nodes that are **Czech counterparts of English nodes** that in the English sentence are placed after their governing verb on the surface and that are **preceded by an indefinite article**, get  $tfa='f'$ , i.e. contextually non-bound, (EER: unknown), see Example (10) from PCEDT.

(10) *The war over federal judicial salaries takes a victim.* ↓  
*Válka o platy federálních soudců si žádá svou první oběť<sub>f</sub>.*

In Example (10), the sentence member *victim* is modified by the indefinite article *a* in the English variant of the sentence, which leads to the assumption that this member is contextually non-bound. Since the value of the same sentence member should be identical both in English and in Czech variant of the sentence, also the Czech member *oběť* (that is the counterpart of the *victim*) is supposed to be contextually non-bound.

The following steps of the automatic pre-annotation are performed after the previous steps have been applied on all nodes of the given tree:

11. **Daughters of a verb that has  $tfa='f'$**  and that is not on the first or second position (in its clause), if they appear after the governing verb on the surface, get  $tfa='f'$ , i.e. contextually non-bound, (EER: unknown), see Example (11) from PCEDT.

(11) *Na konci druhé světové války se Německo vzdalo<sub>f</sub> dříve než Japonsko<sub>f</sub>...*

*At the end of World War II, Germany surrendered<sub>f</sub> before Japan<sub>f</sub>...*

This step of the pre-annotation makes use of the fact that in Czech, the surface word order often is used to express the topic-focus articulation. Under the condition that the contextually non-bound predicative verb is placed further to the right than on the second position in the sentence and that the sentence has a non-marked word order<sup>7</sup> (i.e. emotionally neutral), it is possible to assume that the sentence members following the predicative verb are contextually non-bound.

12. Nodes with **functor=RSTR** that are **daughters of a node with  $tfa='f'$** , get  $tfa='f'$ , i.e. contextually non-bound, (EER: 1:30).

(12) *Zasedání společného výboru sněmovny a senátu se koná v případě, že sněmovna a senát schválí zákon v odlišné<sub>f</sub> podobě.*

*The Senate-House conference committee is used when a bill is passed by the House and Senate in different<sub>f</sub> forms.*

The final step of the automatic pre-annotation is based on the fact that the adnominal adjuncts modifying its governing noun (in the annotated corpus marked as RSTR) often have a very high degree of communicative dynamism because their primary function is to specify something. Therefore, they are pre-annotated as contextually bound (if they modify a non-bound element at the same time).

## 5 Evaluation of the Automatic Pre-Annotation

At the time of submitting the final version of the paper, more than one thousand automatically pre-annotated sentences have also been manually annotated by a human annotator<sup>8</sup> and could be used for evaluation of the pre-annotation.

In 59 documents (1,145 sentences, 22,436 nodes on the tectogrammatical layer), 7,864 nodes out of 19,105  $tfa$ -relevant nodes have been automatically pre-annotated (i.e. 41.1 %).

Table 1 gives an overview of how many times the individual pre-annotation steps have been applied. Based on the estimates presented in Sec-

<sup>7</sup> The human annotator decides whether the word order is marked or non-marked (it is not possible to check it automatically in our procedure of pre-annotation).

<sup>8</sup> There were actually two annotators, working on different parts of the data. For simplicity, we refer to them as 'a human annotator'. Only during a training phase (performed on a few documents), the two annotators worked on the same data and their discrepancies were subsequently checked by an arbiter and discussed.

tion 4.1 (for the two unknown estimates in steps 10 and 11 we used EER: 1:10), we can calculate the expected number of errors in the pre-annotation as (about) 340 errors.

step	short description	count
1	generated, no a-counterpart	1,988
2	generated, member of coord/app	127
3	anaphor of a coreference	742
4	PRED, not generated	1,189
5	PRED, generated	0
6	other verbal nodes (set of func.)	825
7	set of functors	435
8	RHEM (not first in sentence)	366
9	t_lemma=tady (here)	8
10	indefinite article in English	779
11	subseq. daughter of a verb in focus	237
12	RSTR daughters of a node in focus	1,168

Table 1: Usage of the individual pre-annotation steps

In the manual annotation, the annotator changed the pre-annotated value in 294 cases (i.e. 3.7 % of pre-annotated nodes). Table 2 shows details on the manually performed changes.

	pre-annotated value	
	't'	'f'
changed to 'c'	11	26
changed to 't'	-	244
changed to 'f'	13	-
no change	2,841	4,729

Table 2: The distribution of changes of automatically pre-annotated TFA-values manually made by human annotators

The numbers show that the automatic pre-annotation is more successful in marking contextually bound sentence members, as only 0.8 % of nodes pre-annotated as 't' and 5.4 % of nodes pre-annotated as 'f' were manually changed to another value.

	PDT 2.0	sample of PCEDT
contr. contextually bound ('c')	5.4 %	5.7 %
non-contr. contextually bound ('t')	31.3 %	33.6 %
contextually non-bound ('f')	63.3 %	60.7 %

Table 3: The percentage distribution of manually annotated TFA-values in PDT (training data) and so far annotated sample of the Czech part of PCEDT

The inability of the pre-annotation procedure to set the 'c' value (contrastive contextually bound) does not harm the results much, as only 37 (0.5 %) pre-annotated nodes were manually changed to this value, and the overall ratio of contrastive contextually bound nodes among all (manually) annotated nodes both in PDT and PCEDT is less than 6 % (see Table 3).

The main limitations of the pre-annotation are in its coverage (more than half of the nodes are not pre-annotated) and in its natural inability to take the meaning of the text into account (and thus being unable to better distinguish between 't' and 'f' values).

From another point of view, the results suggest that the expected error rates (estimated on PDT) are accurate and that the automatic pre-annotation is sufficiently reliable and serves as a substantial help to the annotators.<sup>9</sup>

## 6 Conclusion

The paper presented the first part of the project of parallel annotation of topic-focus articulation in the Prague Czech-English Dependency Treebank (PCEDT). We described the annotation principles and schemes, and elaborated on 12 automatic steps of the pre-annotation procedure for the Czech part of the treebank. The pre-annotation is able to mark over 40 % of the whole text (the rest is supposed to be annotated by human annotators). It can distinguish between contextually bound and non-bound sentence elements with the average success rate over 96 %, as shown by the evaluation on manually annotated texts.

## Acknowledgment

We gratefully acknowledge support from the Grant Agency of the Czech Republic (grants P406/12/0658 and P406/2010/0875). This work has been using language resources developed and/or stored and/or distributed by the LINDAT-Clarín project of the Ministry of Education of the Czech Republic (project LM2010013).

## Abstract

Animacy is an inherent property of entities that nominals refer to in the physical world. This semantic property of a nominal has received much attention in both linguistics and computational linguistics. In this paper, we present a robust unsupervised technique to infer the animacy of nominals in languages with rich morphological case. The intuition behind our method is that the control/agency of a noun depicted by case marking can approximate its animacy. A higher control over an action implies higher animacy. Our experiments on Hindi show promising results with  $F_\beta$  and *Purity* scores of 89 and 86 respectively.

## 1 Introduction

Animacy can either be defined as a biological property or a grammatical category of nouns. In a strictly biological sense, living entities are animate, while all non living entities are inanimate. However, in its linguistic sense, the term is synonymous with a referent's ability to act or instigate events volitionally (Kittilä et al., 2011). Although seemingly different, linguistic animacy can be implied from biological animacy. In linguistics, the manifestation of animacy and its relevance to linguistic phenomena have been studied quite extensively. Animacy has been shown, cross linguistically, to control a number of linguistic phenomena. Case marking, argument realization, topicality or discourse salience are some phenomena highly correlated with the property of animacy (Aissen, 2003; Bresnan et al., 2007; De Swart et al., 2008; Branigan et al., 2008). In linguistic theory, how-

ever, animacy is not seen as a dichotomous variable, rather a range capturing finer distinctions of linguistic relevance. Animacy hierarchy proposed in Silverstein's influential article on "animacy hierarchy" (Silverstein, 1986) ranks nominals on a scale of the following gradience: *1st pers* > *2nd pers* > *3rd anim* > *3rd inanim*. Several such hierarchies of animacy have been proposed following (Silverstein, 1986). One basic scale taken from (Aissen, 2003) makes a three-way distinction as *humans* > *animates* > *inanimates*. These hierarchies can be said to be based on the likelihood of a referent of a nominal to act as an agent in an event (Kittilä et al., 2011). Thus higher a nominal on these hierarchies higher the degree of agency/control it has over an action. In morphologically rich languages, the degree of agency/control is expressed by case marking. Case markers capture the degree of control a nominal has in a given context (Hopper and Thompson, 1980; Butt, 2006). They rank nominals on the continuum of control as shown in (1)<sup>1</sup>. Nominals marked with Ergative case have highest control and the ones marked with Locative have lowest.

$$\text{Erg} > \text{Gen} > \text{Inst} > \text{Dat} > \text{Acc} > \text{Loc} \quad (1)$$

In this work, we demonstrate that the correlation between the aforementioned linguistic phenomena is highly systematic, therefore can be exploited to predict the animacy of nominals. In order to utilize the correlation between these phenomena for animacy prediction, we choose to use an unsupervised learning method. Since, using a supervised learning technique is not always feasible. The resources required to train supervised algorithms are expensive to create and unlikely to

<sup>1</sup>Ergative, Genitive, Instrumental, Dative, Accusative and Locative in the given order.

exist for the majority of languages. We show that an unsupervised learning method can achieve results comparable to supervised learning in our setting (see Section 5). Further, based on our case study of Hindi, we propose that given the morphological case corresponding to Scale (1), animacy can be predicted with high precision. Thus, given the morphological case our approach should be portable to any language. In the context of Indian languages, in particular, our approach should be easily extendable. In many Indo-Aryan languages<sup>2</sup>, the grammatical cases listed on Scale (1) are, in fact, morphologically realized (Masica, 1993, p. 230) (Butt and Ahmed, 2011).

In what follows, we first present the related work on animacy acquisition in Section 2. In Section 3, we will describe our approach for acquiring animacy in Hindi using case markers listed in (2). Section 3.1 describes the data used in our experiments, followed by discussion on feature extraction and normalization. In Section 4, we discuss the extraction of data sets from Hindi Wordnet for the evaluation of results of our experiments. In Section 5, we describe the results with thorough error analysis and conclude the paper with some future directions in Section 6.

## 2 Related Work

In NLP, the role of animacy has been recently realized. It provides important information, to mention a few, for anaphora resolution (Evans and Orasan, 2000), argument disambiguation (Dell’Orletta et al., 2005), syntactic parsing (Øvrelid and Nivre, 2007), (Bharati et al., 2008) and verb classification (Merlo and Stevenson, 2001). Lexical resources like wordnet usually feature animacy of nominals of a given language (Fellbaum, 2010; Narayan et al., 2002). However, using wordnet, as a source for animacy, is not straightforward. It has its own challenges (Orsan and Evans, 2001; Orsan and Evans, 2007). Also, it’s only a few privileged languages that have such lexical resources available. Due to the unavailability of such resources that could provide animacy information, there have been some notable efforts in the last few years to automatically acquire animacy. The important and worth mentioning works in this direction are (Øvrelid, 2006) and (Øvrelid, 2009). The works focus on Swedish and Norwegian common nouns using dis-

---

<sup>2</sup>Indo-Aryan is a major language family in India.

tributional patterns regarding their general syntactic and morphological properties. Other works in the direction are (Bowman and Chopra, 2012) for English and (Baker and Brew, 2010) for English and Japanese. All these works use supervised learning methods on a manually labeled data set. These works use highly rich linguistic features (e.g., grammatical relations) extracted using syntactic parsers and anaphora resolution systems. The major drawback of these approaches is that they can not be extended to resource poor languages because these languages can not satisfy the prerequisites of these approaches. Not only the availability of manually annotated training data, but also the features used restrict their portability to resource poor languages. Our approach, on the other hand, is based on unsupervised learning from raw corpus using a small set of case markers. Therefore, it can be extended to any language with morphologically realized grammatical case listed on Scale (1).

## 3 Our Approach

As noted by Comrie (1989, p. 62), a nominal can have varying degrees of control in varying contexts irrespective of its animacy. The noun phrase *the man*, for example, is always high in animacy, but it may vary in degree of control. It has high control in *the man deliberately hit me* and minimal control in *I hit the man*. In morphologically rich languages, case markers capture the varying control a nominal has in different contexts. In Hindi, for example, a nominal, in contexts of high control, occurs with a case marker listed high on hierarchy (1) (e.g., ergative), while in contexts of low control is marked with a case marker low on (1) (e.g., locative). Because of the varying degrees of control a nominal can have across contexts, approximating animacy from control would be misleading. Therefore, we generalize the animacy of a nominal from its overall distributions in the corpora. Now the question is, how to generalize the animacy from the mixed behavior that a nominal displays in a corpora? The linguistic notion of markedness addresses this problem. An unmarked observation, in linguistics, means that it is more frequent, natural, and predictable than a marked observation (Croft, 2002). Although, a given nominal can have varying degrees of control in different contexts irrespective of its animacy, its unmarked behavior should correlate well with

its literal animacy, i.e., animates should more frequently be used in contexts of high control while in-animates should be used in contexts of low control. A high degree of animacy necessarily implies high degree of control. So the prototypical use of animates is in the contexts of high control and of inanimates in the contexts of low control. As the discussion suggests, animates should occur more frequently with the case markers towards the left of the Scale (1), while inanimates should occur more frequently with the ones towards the right of the Scale. Thus, animates should have a left-skewed distribution on Scale (1), while inanimates should have a right-skewed distribution.

In this work, we have exploited the systematic correlations between the linguistic phenomena, as discussed, to approximate animacy of Hindi nominals. Our methodology relies on the distributional patterns of a nominal with case markers capturing its degree of control. Distributions of each nominal are extracted from a large corpus of Hindi and then they are clustered using fuzzy *cmeans* algorithm. Next, we discuss our choice of clustering, feature extraction and normalization.

### 3.1 Feature Extraction and Normalization

In order to infer animacy of a nominal, we extracted its distributions with the case markers corresponding to (1) except genitives<sup>3</sup>. Case markers of Hindi corresponding to (1) are listed in (2) (Mohan, 1990, p. 72).

$$\text{ne} > \text{kaa} > \text{se} > \text{ko} > \text{ko} > \{\text{mem, par, tak, se, ko}\} \quad (2)$$

Since *ko* and *se* are ambiguous, as shown in (2), we approximated them to the prototypical cases they are usually used for. *ko* is approximated to dative while *se* is approximated to instrumental case. The ambiguity in these case makers, however, has a profound impact on our results as discussed in Section 5. A mixed-domain corpora of 87 million words is used to ensure enough case marked instances of a nominal. The extraction of distributional counts is simple and straightforward in Hindi. Words immediately preceding case markers are considered as nouns since case markers almost always lie adjacent to the nominals they mark, however, occasionally they are separated by emphatic particles like *hi* ‘only’. In such cases particles are removed to extract the distribution by

<sup>3</sup>Genitives are highly ambiguous in Hindi and hardly discriminate animates from in-animates.

using a list of stop words. Since, Hindi nouns decline for number, gender and case, we use Hindi morph-analyzer, built in-house, to generate lemmas of inflected word forms so that their distributions can be accumulated under their corresponding lemmas. Further, the distributional counts of each nominal are scaled to unity so as to guard against the bias of word frequencies in our clustering experiments. Consider a distribution of two nominals *A* and *B* with case markers *X* and *Y*. Say *A* occurs 900 times with *X* and 100 times with *Y* and *B* occurs 18 times with *X* and 2 times with *Y*. Although, these nominals seem to have different distributions, apart from being similarly skewed, both of them have similar relative frequency of occurrence with *X* and *Y*. We aim, therefore, to normalize the distributional counts of a nominal with the case markers it occurs with. The distributional counts are normalized to unity by the frequency of a given nominal in the corpora, as shown in (3). This ensures that only the nominals of similar relative frequency distributions are clustered together. Beside, normalizing the distributions, we set a frequency threshold, for a nominal to be included for clustering to  $> 10$ , which ensures its enough instances to unravel its unmarked or prototypical behavior.

$$x' = \frac{x_i}{\sum_{i=1}^k x_i} \quad (3)$$

$x'$  is the normalized dimensions in a feature vector of a nominal  $x$ .  $k$  is the number of coordinates and  $x_i$  is the  $i^{\text{th}}$  coordinate of  $x$ .

### 3.2 Soft Clustering

Animacy is an inherent and a non varying property of entities that nominals refer to. However, due to lexical ambiguity animacy of a nominal can vary as the context varies. In Hindi, the ambiguity can be attributed to the following:

- **Personal Names:** In Hindi, common nouns are frequently used as person names or as a component of them. For example, noun ‘baadal’ meaning ‘cloud(s)’ can also be used as a ‘person name’; similarly ‘vijay’ can either mean ‘victory’ or can be a ‘person name’.
- **Metonymies:** Metonymies or complex types (logical polysemy) like institute names, country names etc, can refer to a building,

a geographical place or a group of individuals depending on the context of use. These words are not ambiguous per se but show different aspects of their semantics in different contexts (logically polysemous). For example, *India* can either refer to a geographical place or its inhabitants.

These ambiguities imply that some nominals can belong to both animate and inanimate classes. In order to address this problem of mixed membership, we used soft clustering approach in this work. In comparison with hard clustering methods, in which a pattern belongs to a single cluster, soft clustering algorithms allow patterns to belong to all clusters with varying degrees of membership. One of the most widely used soft clustering algorithms is the fuzzy  $c$ -means algorithm (henceforth FCM) (Bezdek et al., 1984). The FCM algorithm attempts to partition a finite set of  $n$  objects  $K = \{k_1, \dots, k_n\}$  into a collection of  $c$  fuzzy clusters with respect to some given criterion. Given a finite set of data, the algorithm returns a list of  $c$  cluster centers  $C = \{c_1, \dots, c_c\}$  and a partition matrix  $W = w_{i,j} \in [0, 1]$ ,  $i = 1, \dots, n$ ,  $j = 1, \dots, c$ , where each element  $w_{i,j}$  tells the degree to which element  $k_i$  belongs to cluster  $c_j$ . Like the k-means algorithm, the FCM aims to minimize an objective function, given as:

$$J_m(U, \beta) = \sum_{i=1}^c \sum_{k=1}^n u_{ik}^m D_{ik}(x_k, \beta_i) \quad (4)$$

where

$u_{ik}$  is the membership of the  $k$ th object in the  $i$ th cluster;

$\beta_i$  represents the  $i$ th cluster prototype;

$m \geq 1$  is the degree of fuzziness;

$c \geq 2$  is the number of cluster;

$n$  represents the number of data points;

$D_{ik}(x_k, \beta_i)$  is the Euclidean distance between  $k^{th}$  object and  $i^{th}$  cluster center.

## 4 Evaluation

In this section, we discuss the extraction of evaluation sets for the validation of the clustering results. When a clustering solution has been obtained for a data set, it must also be presented in a manner which provides an overview of the content of each cluster. For that matter, we need an evaluation set that can provide class labels for each nominal *a priori*. The clustering task is then to

assign these nominals to a given number of clusters such that each cluster contains all and only those nominals that are members of the same class. Given the ground truth class labels, it is trivial to determine how accurate the clustering results are. This evaluation set is built using the Hindi wordnet<sup>4</sup> (Narayan et al., 2002), a lexical resource composed of synsets and semantic relations. Animacy of a nominal is taken from concept ontologies listed in the wordnet. We created two data sets using Hindi Wordnet:

- SET-1: This set contains nominals that are either animate or inanimate across senses listed in the wordnet. For example, nominals like *baalak* ‘boy’ with all senses animate and *patthar* ‘stone’ with all senses inanimate would fall under this set, whereas *kuttaa* ‘dog’ or ‘pawl’ with varying animacy across senses would not qualify to be included in this set. The sense hierarchies corresponding to animate (dog) and inanimate (pawl) senses of noun *kuttaa* are represented in Figure 1. There are 6039 nominals in this set. It is used to evaluate the results and determine the accuracy of clustering.
- SET-2: In this set all the nominals listed in wordnet are extracted irrespective of their animacy. There are around 7030 (SET-1+991) nominals in this set. It is used to evaluate the borderline cases with equal likelihood to fall in any cluster.

Figure 1: Animate and Inanimate Senses of noun *kuttaa*

It must be noted that only those nominals that satisfy the marked threshold of  $>10$  are considered, as discussed in Subsection 3.1.

## 5 Experiments and Results

In this section, we will discuss our clustering experiments followed by a thorough error analysis of

<sup>4</sup><http://www.cfilt.iitb.ac.in/wordnet/webhwn/wn.php>

	Animate			In-animate		
	Precision	Recall	F-score	Precision	Recall	F-score
Baseline	66.99	44.45	53.44	97.82	39.78	56.56
SVM	78.90	77.70	78.24	95.15	95.43	95.29
<b>Cmeans</b>	<b>57.8</b>	<b>89.18</b>	<b>70.0</b>	<b>97.3</b>	<b>85.65</b>	<b>91.15</b>
<b>Swedish</b>	81.9	64.0	71.8	96.4	98.6	97.5

Table 1: Comparison of Results.

the results achieved. In order to put our approach into perspective, we will first setup a baseline and establish a supervised benchmark for the task. For both the classification and clustering experiments (discussed shortly), we use SET-1. All the experiments are performed with the feature vectors representing the behavior of the corresponding nominals towards the case system of Hindi. The results are listed in Table 1.

### 5.1 Baseline

As discussed in Section 3, animates should occur more frequently with the case markers to the left of the Scale (2), while inanimates should occur more frequently with the ones to the right of the Scale. Thus, we used the frequency of a nominal with the case markers on the edges of the Scale (2), i.e., *ne* and *mem*, to set up the baseline. If a nominal occurs more frequently with *ne*, it is considered as animate, whereas if it occurs more frequently with *mem*, it is considered as inanimate. As the Table 1 shows, we could only achieve an average recall of 42 by this approach. This implies that the interaction of a nominal with the overall case system of a language, rather than an individual case marker, provides a better picture about its animacy.

### 5.2 Supervised Classification

For supervised classification, we used Support Vector Machines (SVMs). To train and test the SVM classifier, we used the LIBSVM package (Chang and Lin, 2011). We performed a 5-fold cross validation with a random 80-20 split of SET-1 for training and testing the classifier. The average accuracies are reported in Table 1. Although, the overall accuracy of supervised classification is higher, it comes with a cost of manual annotation of training data.

### 5.3 Clustering

A clustering experiment is performed with FCM clustering algorithm on SET-1 and SET-2, with

parameters  $c$  ‘number of clusters’ and  $m$  ‘degree of fuzziness’ set to 2. We used the  $F_\beta^5$  and *purity* to evaluate the accuracy of our clustering results, which are two widely used external clustering evaluation metrics (Manning et al., 2008). In order to evaluate the results, each nominal in SET-1 is assigned to the cluster  $j$  for which its cluster membership  $w_k^c$  (the degree of membership of a nominal  $k$  to cluster  $j$ ) is highest; i.e.,  $\text{argmax}_{c \in C} \{w_k^c\}$ . As shown in Table 2, the clustering solution by FCM has achieved  $F_\beta$  and purity scores of 89 and 86. Further, cluster 1 roughly corresponds to the Hindi wordnet inanimate class of nominals (86 recall) and cluster 2 corresponds to the Hindi wordnet animate class (89 recall). In (Øvrelid, 2009) and (Bowman and Chopra, 2012) animate nouns are reported as a difficult class to learn. The problem is attributed to the skewness in the training data. Animate nouns occur less frequently than inanimate nouns. In our clustering experiments, however, animates have shown higher predictability than inanimates. We have achieved a high recall on both animate as well as inanimate nominals. Further, we infer animacy of all types of nominals while (Øvrelid, 2009) and (Bowman and Chopra, 2012) have restricted the learning only for common noun lemmas. Furthermore, our method also identifies ambiguous nominals, as shown in Table 4. Although less feasible, we also present the results produced by Øvrelid (2009) ( $>10$ ) in Table 1 for a rough comparison.

Cluster	Animate	In-animate	$F_\beta$	Purity
1	117	4246	91	97
2	965	711	70	58
Total	1082	4957	89	86

Table 2: Clustering Results on SET-1.

As presented in Table 3, there are 828 instances

<sup>5</sup> $\beta$  is a coefficient of the relative strengths of precision and recall. We have set its value to 1, for all the results we have reported in this paper.

of wrong clustering. However, upon close inspection the clustering of these instances seems theoretically grounded, thus adding more weight to our results. We discuss these instances below:

1. **Personal Names:** As discussed in Section 3.1, personal names are ambiguous and can be used as common nouns with generic reference. Hindi Wordnet doesn't enlist personal names (except for very popular names), though their common usages are listed. For example the noun *baadal* 'cloud' is present in wordnet while its use as personal name is not listed. In the corpora used for the extraction of distributions, around 325 such nouns are actually used as personal names. Although, these nouns are correctly clustered as animates, they are evaluated as instances of wrong clustering, because of the inanimate sense they have in the Hindi Wordnet. This addresses the problem of **low precision** and **low purity** for animate nominals in our experiments. Similarly, the names used for gods, goddesses and spirits are also treated as inanimates in Hindi Wordnet. However, corpus distributions project them as animates due to their high ability to instigate an action. An example case that was wrongly clustered is *rab* 'God'.
2. **Lower Animates:** Although wordnet lists these nominals as animates which in fact they are, they are linguistically seen as inanimates and thus are clustered as such. In our experiments, *titli* 'butterfly' is clustered with inanimates.
3. **Natural Forces:** These nominals have a high control over an action and their distributions are more like higher animates. *bhuchaal* 'earthquake' is an instance of this over generalization.
4. **Psychological Nouns:** Nouns like *pare-shaanii* 'stress' are conceptualized as a force affecting us psychologically. These nominals are thus distributed like nominals of high control, which leads to an over generalization of these nouns as animates.
5. **Metonymies:** Nouns like country names, as discussed in Section 3.1, apart from referring to geographical places can also refer to

their inhabitants, teams, governments. Wordnet only treats these terms as inanimates (place). *Australia*, though treated as inanimate in Hindi Wordnet, is clustered with animates in our experiments.

6. **Machines:** A few cases of machines are also seen to be over generalized as animates. Machines show an animate like control (directly or indirectly) over an action.
7. **Nouns of Disability:** As these expressions refer to animates with some disability, they lack any control over an action and are distributed like inanimates. An example of this over generalization is noun *ghaayal* 'wounded'.
8. **Others:** These are actual instances of wrong clustering and as we noticed, these instances could probably be addressed by choosing an optimal frequency threshold to capture the unmarked (prototypical) behavior of a nominal. We have not addressed the tuning of this parameter in this work. However, we plan to take it up in future.

Nominal Type	Nominal Count
<i>Personal Name</i>	325
<i>Lower Animate</i>	104
<i>Natural Force</i>	67
<i>Psychological Nouns</i>	74
<i>Metonymies</i>	86
<i>Machine</i>	30
<i>Nouns of Disability</i>	44
<i>Others</i>	98
<b>Total</b>	<b>828</b>

Table 3: Error Classification on SET-1

In order to evaluate the ambiguous nominals that can have both animate and inanimate references in different contexts, we use SET-2. The borderline cases i.e, the nominals whose cluster membership score  $w_k^c$  is  $\sim 0.5$  are evaluated against the ambiguous nominals listed in SET-2. As shown in Table 4, from 991 ambiguous nominals 535 are clustered with inanimates in Cluster 1, while 439 cases are clustered with animates in Cluster 2. The fact that these nominals possess both the animate and inanimate senses, clustering them in either of the class should not be considered wrong. Although they have differing animacy as listed in Hindi Wordnet, probably they have

been used only in animate or inanimate sense in the corpora used in our experiments. Table 4 also shows that 187 nominals have a uniform distribution over the factors that discriminate animacy. Among these 150 nouns are listed as inanimate in Hindi Wordnet. Upon close inspection, these cases were found to be metonymies. As discussed earlier, Hindi Wordnet treats metonymies as inanimate, but in fact they are ambiguous. Thus our clustering of these nominals is justified.

Cluster	Animate	In-animate	Ambiguous
1	107	4149	535
2	955	658	439
$w_k^c \approx 0.5$	20	150	17
Total	1082	4957	991

Table 4: Clustering Results on SET-2

In Section 3, we stated that the distributions of nominals will be skewed on the control hierarchy. The results have clearly indicated that such skewness does in fact exist in the data, as shown in Figure 2. The cluster prototypes, returned by the fuzzy clustering, show animates are left skewed while inanimates are right skewed on the hierarchy of control. However, in our clustering experiments the order of dative/accusative and instrumental case markers on the control hierarchy (Scale 1) has been swapped. The dative/accusative case is more biased towards animates while instrumental case shows the reverse tendency. The reason for this is the ambiguity in these case markers. The instrumental case *se* mark roles such as cause, instrument, source and material. Among which cause and instrument imply high control while source and material imply a low control over an action. Almost 82% of instances of instrumental case depict a non-causal role while only 18% show a causal relation as annotated in the Hindi dependency treebank (Bhatt et al., 2009). Similarly, the dative/accusative case *ko* is used for experiencer subject, direct and indirect objects (Mohan, 1990, p. 72). Among these, only direct objects realized by definite inanimates are *ko* marked (Differential Object Marking), thus making it a more probable case marker for animates.

Before concluding the paper, we will discuss some of the issues related to the portability of our approach to other languages with rich morphological case. We will briefly discuss these issues below:

Figure 2: Skewed Marked Distribution of Cluster Prototypes.

- Case Ambiguity or Case Syncretism:** For an ideal performance, we expect a separate case marker for each individual case listed on Scale 1. Unfortunately, case markers are usually ambiguous. A case marker can have more than one case function in a language. In our work on Hindi, we saw that case ambiguity does have an impact on the results. We could afford to exclude highly ambiguous genitive case marker from our experiments (Mohan, 1990). However, how case ambiguity will impact the animacy prediction in other languages remains to be seen.
- Nominal Ambiguity:** As a matter of fact, animacy is an inherent and a non-varying property of nominal referents. However, due to lexical ambiguity (particularly metonymy), animacy of a word form may vary across contexts. We have addressed this problem by capturing the mixed membership of such ambiguous nominals. However, since animacy of a nominal is judged on the basis of its distribution, the animacy of an ambiguous nominal will be biased towards the sense with which it occurs in a corpora.
- Type of Morphology:** Case marking may be realized in different ways depending on the morphological type of a language. In case of inflectional and agglutinative languages, case markers, if present, are bound to a noun stem, while in analytical languages they are free morphemes usually lying adjacent to a nominal they mark. Although, the way case markers are realized may not affect the animacy prediction directly, it may impact the extraction of case marked distribution of nominals. Particularly, in case of agglutinative and inflectional languages extracting the multiple case marked word forms of a particular noun stem could be a challenging task.

## 6 Conclusion

In this work we report a technique to exploit the systematic correspondences between different linguistic phenomena to infer the important semantic category of animacy. The case marked distributions of nominals are clustered with fuzzy *cmeans* clustering into two clusters that approximate the binary dimensions of animacy. We achieved satisfactory results on the binary distinction of nominals on animacy. A  $F_\beta$  score of 89 and purity of 86 confirm efficiency of our approach. However, the performance of our system can be further improved by incorporating features from a dependency parser and an anaphora resolution system, as discussed in (Øvrelid, 2009).

In view of the Indo-Wordnet project (Bhattacharyya, 2010) that aims to build wordnet for major Indian languages, our approach can be used to predict animacy of nouns to leverage the cost and time associated with manual creation of such resources. Given the availability of large data on web for many Indian languages, our method can predict this information with satisfactory results. In the future, we also plan to explore the interaction between control and verb semantics, so as to classify verbs based on the amount of control required. This information can also be incorporated into the process of building Indo-wordnets.

## Acknowledgments

We would like to thank the anonymous reviewers for their useful comments which helped to improve this paper. We furthermore thank Sambhav Jain for his help and useful feedback.

## Abstract

We present a simple, logic-based architecture for solving math problems written in natural language. A problem is firstly translated to a logical form. It is then rewritten into the input language of a solver algorithm and finally the solver finds an answer. Such a clean decomposition of the task however does not come for free. First, despite its formality, math text still exploits the flexibility of natural language to convey its complex logical content succinctly. We propose a mechanism to fill the gap between the simple form and the complex meaning while adhering to the principle of compositionality. Second, since the input to the solver is derived by strictly following the text, it may require far more computation than those derived by a human, and may go beyond the capability of the current solvers.

Empirical study on Japanese university entrance examination problems showed positive results indicating the viability of the approach, which opens up a way towards a true end-to-end problem solving system through the synthesis of the advances in linguistics, NLP, and computer math.

## 1 Introduction

Development of an NLP system usually starts by decomposing the task into several sub-tasks. Such a modular design is mandatory not only for the reusability of the component technologies and the extensibility of the system, but also for the sound and steady advancement of the research field. Each module, however, has to attack its sub-task in isolation from the entirety of the task, usually with a quite limited form and amount of knowledge. The separated sub-task is hence not

necessarily easy even for human. This problem has been investigated in various directions, including the solutions to the error-cascading in pipeline models (Finkel et al., 2006; Roth and Yih, 2007, e.g.), the injection of knowledge into the processing modules (Koo et al., 2008; Pitler, 2012, e.g.), and the invention of a novel way of modularization (Bangalore and Joshi, 2010, e.g.).

In this paper, we present a simple pipeline architecture for natural language math problem solving, and investigate the issues regarding the separation of the semantic composition mechanism and the mathematical inference. Although the separation between these two may appear to be of different nature than the above-mentioned issues regarding the system modularization, as we will see later, the technical challenges there are also in the tension between the generality of an implemented theory as a reusable component, and its coverage over domain-specific phenomena.

In the system, a problem is analyzed with a Combinatory Categorical Grammar (Steedman, 2001) coupled with a semantic representation based on the Discourse Representation Theory (Kamp and Reyle, 1993) to derive a logical form. The logical form is then rewritten to the input language of a solver algorithm, such as specialized math algorithms and theorem provers. The solver finally finds an answer through inference.

Natural language problem solving in math and related domain is a classic AI task, which has served as a good test-bed for the integration of various AI technologies (Bobrow, 1964; Charniak, 1968; Gelb, 1971, e.g.). Besides its attraction as a pure intellectual challenge, it has direct applications to the natural language interface for the formal systems such as databases, theorem provers, and formal proof checkers. The necessity of the interaction between language understanding and backend solvers has been pointed out in some of the classic works and also in closely related works

**terms**  $t ::= v \mid f(t_1, \dots, t_k) \mid \Lambda v.t \mid \Lambda v.D$   
**conditions**  $C ::= P(t_1, \dots, t_k) \mid \neg D \mid D_1 \rightarrow D_2$   
**DRSs**  $D ::= (\{v_1, \dots, v_k\}, \{C_1, \dots, C_m\})$

Figure 1: Syntax of DRS

such as Winograd’s SHRDLU (1971). A clear separation of the two layers is, however, an essential property for a wide-coverage problem solving system since we can extend it in a modular fashion, by the enhancement of the solver or the addition of different types of solvers.

The research question in the current paper is thus summarized as follows:

1. Can we derive the logical form of the problems compositionally, with no intervention of mathematical inference, and how?
2. Can we solve such a direct translation of the text to a logical form with the current state-of-the-art automatic reasoning technology?

After a brief overview of the system pipeline (§3), we present a technique for capturing the dynamic properties of the syntax-semantics mapping in the math problem text, which, at first sight, seem to call for mathematical inference during the derivation of a logical form (§4). We then describe remaining issues we found so far in the semantic analysis of math problem text (§5). Finally, the viability of the approach is empirically evaluated on real math problems taken from university entrance examinations. In the evaluation, we apply a solver to the logical forms derived through manually annotated CCG derivations and DRSs on the problem text (§6). In the current paper, we thus exclusively focus on the formal aspect of the semantic analysis, setting aside the problem of its automation and disambiguation. The final section concludes the paper and gives future prospects including the automatic processing of the math text.

## 2 Preliminaries

### 2.1 Discourse Representation Structure

We use a variant of Discourse Representation Structure (DRS) (Kamp and Reyle, 1993) for the semantic representation. DRS has been developed for the formal analysis of various discourse phenomena, such as anaphora and quantifier scopes beyond a single sentence.

Fig. 1 shows the syntax of DRS used in this paper.<sup>1</sup> In the definitions,  $f$  and  $P$  respectively denote a function and a predicate symbol and  $v$  denotes a variable. The definition is slightly extended from that by van Eijck and Kamp (2011) for incorporating higher-order terms. A term of the form  $\Lambda v.M$  denotes lambda abstraction in the object language, which is used to represent (mathematical) functions and sets<sup>2</sup>; we reserve  $\lambda$  for denoting the abstraction over DRSs (and terms) for the composition of DRSs. We define the interpretation of a DRS  $D$  indirectly through its translation  $D^\circ$  to a (higher-order) predicate logic as in Fig. 2.

As defined in Fig. 2, a DRS  $D = (\mathbf{V}, \mathbf{C})$  is basically interpreted as a conjunction of the conditions in  $\mathbf{C}$  that is quantified existentially by all the variables in  $\mathbf{V}$ . However, as in the second clause in Fig. 2, the variables in the antecedent of an implication are universally quantified and their scopes also cover the succedent; this definition is utilized in the analysis of sentences including indefinite NPs, such as donkey sentences.

The mechanism of the DRS composition in this paper is based on the formulation by van Eijck and Kamp (2011). They use an operation called merge (denoted by  $\bullet$ ) to combine two DRSs. Assuming no conflicts of variable names, it can be defined as:  $(\mathbf{V}_1, \mathbf{C}_1) \bullet (\mathbf{V}_2, \mathbf{C}_2) := (\mathbf{V}_1 \cup \mathbf{V}_2, \mathbf{C}_1 \cup \mathbf{C}_2)$ . Roughly speaking, this operation amounts to form the conjunction of the conditions in  $\mathbf{C}_1$  and  $\mathbf{C}_2$  allowing the conditions in  $\mathbf{C}_2$  to refer to the variables in  $\mathbf{V}_1$ . Consider the following discourse:

- $s_1$ : A monkey <sup>$x$</sup>  is sleeping.  
 $s_2$ : It <sub>$x$</sub>  holds a banana.

Assuming the anaphoric relation indicated by the super/sub-scripts, we have their DRSs as follows:

$$D_1 = (\{x\}, \{\text{monkey}(x), \text{sleep}(x)\})$$

$$D_2 = (\{y\}, \{\text{banana}(y), \text{hold}(x, y)\})$$

By merging them, we have

$$D_1 \bullet D_2 = \left( \{x, y\}, \left\{ \begin{array}{l} \text{monkey}(x), \text{sleep}(x), \\ \text{banana}(y), \text{hold}(x, y) \end{array} \right\} \right),$$

which is translated to  $\exists x. \exists y. (\text{monkey}(x) \wedge \dots \wedge \text{hold}(x, y))$  as expected.

<sup>1</sup>Disjunction can be defined by using implication and negation:  $D_1 \vee D_2 := (\{\}, \{\neg D_1\}) \rightarrow D_2$ .

<sup>2</sup>We represent the application of a  $\Lambda$ -term to another term, such as  $(\Lambda x.D)t$  and  $(\Lambda x.t_1)t_2$ , either by a special predicate  $\text{App}(f, x) \equiv fx$  or a function  $\text{app}(f, x) := fx$  according to the type of  $f$ . Compound terms of the form  $t_1 t_2$  are hence not in the definitions.

$$\begin{array}{lll}
\text{Assuming } D_1 = (\{v_1, \dots, v_k\}, \{C_1, \dots, C_m\}), & (\neg D)^\circ := \neg D^\circ & (\Lambda v.D)^\circ := \Lambda v.(D^\circ) \\
D_1^\circ := \exists v_1 \dots \exists v_k. (C_1^\circ \wedge \dots \wedge C_k^\circ) & (P(t_1, t_2, \dots))^\circ := P(t_1^\circ, t_2^\circ, \dots) & (\Lambda v.t)^\circ := \Lambda v.(t^\circ) \\
(D_1 \rightarrow D_2)^\circ := \forall v_1 \dots \forall v_k. ((C_1^\circ \wedge \dots \wedge C_m^\circ) \rightarrow D_2^\circ) & (f(t_1, t_2, \dots))^\circ := f(t_1^\circ, t_2^\circ, \dots) & v^\circ := v
\end{array}$$

Figure 4: Example of combinatory rules

## 2.2 Combinatory Categorical Grammar

Combinatory Categorical Grammar (CCG) (Steedman, 2001) is a lexicalized grammar formalism. In CCG, the association between a word  $w$  and its syntactic/semantic property is specified by a lexical entry of the form  $w := C : S$ , where  $C$  is the category of  $w$  and  $S$  is the semantic interpretation of  $w$ . A category is either a basic category (e.g., S, N, NP) or a complex category of the form  $X/Y$  or  $X \setminus Y$ . For instance, we can assign the following categories and semantic interpretations to the region notation “[0, +∞)” and a bare noun phrase “positive number”:

$$\begin{array}{l}
[0, +\infty) := \text{NP} : \Lambda x.(\{\}, \{x \geq 0\}) \\
\text{positive number} := \text{N} : \lambda x.(\{\}, \{x > 0\})
\end{array}$$

since the region notation behaves as a proper noun and it can be represented by its characteristic function, while “positive number” functions like a common noun (recall that  $\Lambda$  is for the abstraction in the object language and  $\lambda$  stands for the abstraction for the DRS composition). A handful of combinatory rules define how the categories and the semantic interpretations of constituents are combined to derive a larger phrase. Fig. 4 shows two of the rules. A part of a derivation tree for “When the centers of  $C_1$  and  $C_2$  coincide” is shown in Fig. 3. As shown in the figure, the semantic representation in DRS is composed by the beta reduction and the DRS merge operation. As we will see in §4, there are certain types of discourse for which the basic DRS composition machinery described so far does not suffice. We will return to this after a brief description of the whole system.

## 3 A Simple Pipeline for Natural Language Math Problem Solving

The main result in the current paper is a mechanism of semantic composition and an empirical support for our overall design choice. Although the NLP modules for the automatic processing and disambiguation are still under development, we show a brief overview of the whole system to give a clear image on the different representations of a problem at different stages of the pipeline.

**From text to logical form** The system receives a problem text with L<sup>A</sup>T<sub>E</sub>X-style markup on the symbolic mathematical expressions: e.g.,

Let  $a > 0$ ,  $b \leq 0$ , and  $0 < p < 1$ .  
 $\$P(p, p^2)\$$  is on the graph of the  
function  $y = ax - bx^2$ . Write  $b$  in  
terms of  $a$  and  $p$ .

We process the mathematical expressions with a symbolic expression analyzer and produce their possible interpretations as lexical entries. For instance,  $y = ax - bx^2$  in the above example will receive at least two interpretations:

$$\begin{array}{l}
\$y = ax - bx^2\$ := S : (\{\}, \{y = ax - bx^2\}) \\
\$y = ax - bx^2\$ := \text{NP} : \Lambda x.ax - bx^2.
\end{array}$$

The first lexical entry is for the usages such as “Hence  $y = ax - bx^2$ ,” where the expression denotes a proposition and behaves as a sentence. The second entry is for the usage as a noun phrase as in the example, which stands for a function.

We add such dynamically generated lexical entries to the lexicon and then analyze the sentences with a CCG parser. From the resulting CCG derivation trees, we will obtain a DRS for each sentence. For the above example, we will have the following DRSs (the third one is in the extended

language we'll introduce in the next section):

$$\begin{aligned} D_1 &= (\{\}, \{a > 0, b \leq 0, 0 < p, p < 1\}) \\ D_2 &= (\{\}, \{P = (p, p^2), \text{on}(P, \Lambda x.ax - bx^2)\}) \\ D_3 &= \text{Find}(b') [cc; \exists^{-1}a; \exists^{-1}p; b = b'] \end{aligned}$$

A discourse structure analyzer receives the DRSs and determines the logical relations among them while selecting an antecedent for each anaphoric expression. The net result of this stage is a large DRS that represents the whole problem. For the above example, we have their sequencing as the result:  $D_1; D_2; D_3$ . The sequencing operator (;) basically means conjunction (merge) of the DRSs, but it is also used to connect the meanings of a declarative sentence and an imperative sentence. The large DRS is then translated by a process defined in the next section, giving a HOPL formula enclosed by a directive to the solver:

$$\text{Find}(b') \left[ \begin{array}{l} a > 0 \wedge b \leq 0 \wedge 0 < p \wedge p < 1 \wedge \\ \exists P. \left( \begin{array}{l} P = (p, p^2) \wedge \\ \text{on}(P, \Lambda x.ax - bx^2) \wedge b = b' \end{array} \right) \end{array} \right],$$

where  $\text{Find}(v)[\phi]$  is a directive to find the value of variable  $v$  that satisfies the condition  $\phi$ .

**From logical form to solver input** Many of the current automatic reasoners operate on first-order formulas. To utilize them, we hence have to transform the HOPL formula in a directive to an equivalent first-order formula. Such transformation is of course not possible in general. However, we found that a greedy rewriting procedure suffices for that purpose on all of the high-school level math problems used in the experiment.

In the rewriting procedure, we iteratively apply several equivalence-preserving transformations including the beta-reduction of  $\Lambda$ -terms and rewriting of the predicates and functions using their definitions. For the above example, by using some trivial simplifications and the definition of  $\text{on}(\cdot, \cdot)$ :

$$\forall x. \forall y. \forall f. (\text{on}((x, y), f) \leftrightarrow (y = fx)),$$

we have the following directive holding a first-order formula:

$$\text{Find}(b') \left[ \begin{array}{l} a > 0 \wedge b \leq 0 \wedge 0 < p \wedge p < 1 \wedge \\ p^2 = ap - bp^2 \wedge b = b' \end{array} \right].$$

**Solver Algorithms** In addition to the generic first-order theorem provers, we can use specific algorithms as the solver when the formula is expressible in certain theories. Among them, many

mathematical and engineering problems can be naturally translated to formulas consisting of polynomial equations, inequalities, quantifiers ( $\forall, \exists$ ) and boolean operators ( $\wedge, \vee, \neg, \rightarrow$ , etc). Such formulas construct sentences in the first-order theory of real closed fields (RCF).

In his celebrated work, Tarski (1951) showed that RCF allows quantifier-elimination (QE): for any RCF formula  $\phi(x_1, \dots, x_n)$ , there exists an equivalent quantifier-free formula  $\psi(x_1, \dots, x_n)$  in the same vocabulary. For example, the formula  $\exists x.(x^2 + ax + b \leq c)$  can be reduced to a quantifier-free formula  $a^2 - 4b + 4c \geq 0$  by QE.

Automated theorem proving is usually very costly. For example, QE for RCF is doubly exponential on the number of quantifier alternations in the input formula. The problems containing only six variables may be hard for today's computer with the best algorithm known. However, several positive results have been attained as the result of extensive search for practical algorithms during the last decades (see (Caviness and Johnson, 1998)). Efficient software systems of QE have been developed on several computer algebra systems, such as SyNRAC (Iwane et al., 2013).

## 4 Formal Analysis of Math Problem Text

In this section, we first summarize the most prominent issues we found so far in the linguistic analysis of high-school/college level math problems and then present a solution.

### 4.1 Problems

**Context-dependent meanings of superlatives and their alike** The meaning of a superlatives and semantically similar expressions such as "maximum" generally depends highly on the context. For example, the interpretation of "John was the tallest" depends on the group (of people) that is prominent in the discourse:

There were ten boys. John was the tallest.

This context-dependency can be made more explicit by paraphrasing it to a comparative (Heim, 2000): "John was taller than *anyone else*," where "anyone else" refers, depending on the context, to the group against which John was compared.

In math text, however, we can usually determine the range of the "anyone else" without ambiguity:

Assume  $a + b = 3$ . Find the maximum value of  $ab$ .

Here, the set of values that should be compared against the maximum value is, with no ambiguity, all the possible values of  $ab$  that is determined by the preceding context. Once we have a representation of such a set, it is easy to write the semantic interpretation of the phrase “maximum value of  $\alpha$ .” But, how can we obtain a representation of such a set without inference?

**Discrimination between free/bound variable**  
We can explicitly specify that a variable should be interpreted as being free, as in:

Let  $R$  be a square with perimeter  $l$ .  
Write the area of  $R$  in terms of  $l$ .

This discourse may be translated to

$$\text{Find}(a) \left[ \exists R. \left( \begin{array}{l} \text{is\_square}(R) \wedge \\ \text{perimeter\_of}(R) = l \wedge \\ \text{area\_of}(R) = a \end{array} \right) \right]$$

but not to

$$\text{Find}(a) \left[ \exists R. \exists l. \left( \begin{array}{l} \text{is\_square}(R) \wedge \\ \text{perimeter\_of}(R) = l \wedge \\ \text{area\_of}(R) = a \end{array} \right) \right]$$

since, assuming the proper definitions of the functions and predicates, the first one is equivalent to  $\text{Find}(a)[a = l^2/16]$  but the second one is equivalent to  $\text{Find}(a)[a > 0]$ . How can we specify a variable be *not* bound?

**Imperatives** Math problems usually include imperatives such as “Find/Write...,” and “Prove/Show...”. How can we derive correct interpretations of those imperatives, which depend on the semantic content of preceding declarative sentences, but are not a part of the declarative meaning of a discourse?

## 4.2 Solution by iDRS

Although the above-mentioned phenomena are quite common in math problem text, we found it is difficult to derive the meanings of such expressions within the basic compositional DRS framework introduced in §2. All of the examples above involve the manipulation and modification of the context in a discourse.

We present an extension of the DRS composition mechanism that covers expressions like the above examples. The basic idea is to introduce another layer of semantic representation called iDRS hereafter, which provides a device to manipulate

**terms**  $t ::= v \mid f(t_1, \dots, t_k) \mid \Lambda v.t \mid \Lambda v.I$

**iDRS**  $I ::= P(t_1, \dots, t_k) \mid \neg I \mid I_1 \rightarrow I_2 \mid \exists v \mid I_1; I_2 \mid \exists^{-1}v \mid \text{Find}(v)[I] \mid \text{Show}[I] \mid cc$

Figure 5: Syntax of iDRS

the representation of the preceding context during the semantic composition.<sup>3</sup>

First we define the syntax of iDRS as in Fig. 5. In the definition, the variables  $P, f, t$ , and  $v$  follows the same convention as in the DRS definition. In words, an iDRS represents either a DRS condition (the first row of the definition of  $I$ ), a quantification  $\exists v$ , which corresponds to a DRS having only one variable,  $(\{v\}, \{\})$ , a sequencing  $I_1; I_2$  of two iDRSs, or the new ingredients in the rest of the definition that will be explained shortly.

The “anti-quantifier”  $\exists^{-1}v$  means an operation that cancels the quantification on  $v$  that precedes  $\exists^{-1}v$ .  $\text{Find}(v)[I]$  is a directive that requires to find the set of the values of variable  $v$  which satisfy the condition represented by  $I$ . Similarly,  $\text{Show}[I]$  is a directive that requires to prove the statement represented by  $I$ . Note that these two directives are not specific to any solvers; The choice of the solver depends on the theory (e.g., RCF) under which the formula in a directive is understood. The last element,  $cc$ , can be considered as a special ‘variable’, through which we can always retrieve an iDRS representation of the context that precedes the position marked by the  $cc$ .

Using these new ingredients, we can now write, for instance, the semantic representation of the phrase “maximum value” as follows:

$$\text{N/NP}_{\text{of}} : \lambda x. \lambda m. \max(\Lambda y. (cc; y = x), m),$$

assuming that the two-place predicate  $\max(s, m)$  is defined to be true iff  $m$  is the maximum element in the set  $s$  (represented by a  $\Lambda$ -term). A sentence “the maximum value of  $x$  is  $m$ ” will thus have  $\max(\Lambda y. (cc; y = x), m)$  as its semantic representation, which means that  $m$  is the maximum value of  $x$  that satisfies the condition specified by the preceding context.

<sup>3</sup>This approach shares much with a kind of dynamic semantics such as those by Bekki (2000) and Brasoveanu (2012), in which a representation of the context can also be accessed in the semantic language. An important difference is that in their approaches the context is represented as a set of assignment functions, while we represent them directly as an iDRS. This difference is crucial for our purpose since we eventually need to obtain a (first-order) formula on which an automatic reasoner operates.

$\{\{I_1; I_2\}\}_c := \{\{I_1\}\}_c; \{\{I_2\}\}_{c; [I_1]_c}$	$\llbracket cc; I \rrbracket_c := c; \llbracket I \rrbracket_c$	$\llbracket P(t_1, \dots) \rrbracket_c := P(\llbracket t_1 \rrbracket_c, \dots)$
$\{\{\text{Find}(v)[I]\}\}_c := \text{Find}(v) \llbracket [I]_c \rrbracket$	$\llbracket cc \rrbracket_c := c$	$\llbracket \exists v \rrbracket_c := \exists v$
$\{\{\text{Show}[I]\}\}_c := \text{Show} \llbracket [I]_c \rrbracket$	$\llbracket I_1; I_2 \rrbracket_c := \llbracket I_1 \rrbracket_c; \llbracket I_2 \rrbracket_{c; [I_1]_c}$	$\llbracket \exists^{-1} v \rrbracket_c := \exists^{-1} v$
$\{\{I_1 \rightarrow I_2\}\}_c := \{\{I_2\}\}_{c; [I_1]_c}$	$\llbracket I_1 \rightarrow I_2 \rrbracket_c := \llbracket I_1 \rrbracket_c \rightarrow \llbracket I_2 \rrbracket_{c; [I_1]_c}$	$\llbracket v \rrbracket_c := v$
$\{\{I\}\}_c := \epsilon$	$\llbracket \neg I \rrbracket_c := \neg \llbracket I \rrbracket_c$	$\llbracket f(t_1, \dots) \rrbracket_c := f(\llbracket t_1 \rrbracket_c, \dots)$
	$\llbracket \text{Find}(v)[I] \rrbracket_c := \exists v; \llbracket I \rrbracket_c$	$\llbracket \Lambda v. t \rrbracket_c := \Lambda v. \llbracket t \rrbracket_c$
	$\llbracket \text{Show}[I] \rrbracket_c := \llbracket I \rrbracket_c$	$\llbracket \Lambda v. I \rrbracket_c := \Lambda v. \llbracket I \rrbracket_c$

Figure 6: Transformation from iDRS to directive sequence

Let's take the following problem as an example:

Let  $p > 0$ .  $R$  is a rectangle whose perimeter is  $p$ . Find the maximum value of the area of  $R$  as a function of  $p$ .

We have its iDRS representation shown below, by parsing the sentences and composing the resulting iDRSs into one (in this case, just by sequencing the three sentences' iDRSs):

$$\left[ \begin{array}{l} 0 < p; \\ \text{is\_rectangle}(R); \text{perimeter\_of}(R) = p; \\ \exists m; \max(\Lambda x. [cc; x = \text{area\_of}(R)], m); \\ \text{Find}(a)[cc; \exists^{-1} p; a = m] \end{array} \right]$$

We then bind all free variables in the iDRS at their narrowest scopes:

$$\left[ \begin{array}{l} \exists p; 0 < p; \\ \exists R; \text{is\_rectangle}(R); \text{perimeter\_of}(R) = p; \\ \exists m; \max(\Lambda x. [cc; x = \text{area\_of}(R)], m); \\ \text{Find}(a)[cc; \exists^{-1} p; a = m] \end{array} \right]$$

This amounts to assume each variable appearing in a problem text is, unless it is explicitly quantified, interpreted to be existentially quantified as default, and to be universally quantified if it appears in the antecedent of an implication.

The iDRS is then processed by the functions  $\{\{\cdot\}\}_c$  and  $\llbracket \cdot \rrbracket_c$  defined in Fig. 6. In the definition,  $\epsilon$  stands for an empty sequence. The function  $\{\{\cdot\}\}_c$  extracts the imperative meaning from an iDRS, using  $\llbracket \cdot \rrbracket_c$  as a 'sub-routine' that extracts the declarative meaning from an iDRS. The suffix  $(c)$  of the two functions stands for the preceding context represented as an iDRS. When  $\llbracket \cdot \rrbracket_c$  processes a sequence  $I_1; I_2$  or an implication  $I_1 \rightarrow I_2$ , the declarative content of  $I_1$  (i.e.,  $\llbracket I_1 \rrbracket_c$ ) is appended to the preceding context  $c$ , and  $c; \llbracket I_1 \rrbracket_c$  is passed as the preceding context when processing  $I_2$ . When  $\llbracket \cdot \rrbracket_c$  finds a  $cc$  variable, it substitutes the  $cc$  with the current context stored in the suffix.

By applying  $\{\{\cdot\}\}_\epsilon$  to the iDRS of a problem, we can extract the logical form of the problem as a

sequence of directives. For the example problem, we have a single directive as follows:

$$\text{Find}(a) \left[ \begin{array}{l} \exists p; 0 < p; \\ \exists R; \text{is\_rectangle}(R); \text{perimeter\_of}(R) = p; \\ \exists m; \max(\Lambda x. \left[ \begin{array}{l} \exists p; 0 < p; \\ \exists R; \text{is\_rectangle}(R); \\ \text{perimeter\_of}(R) = p; \\ \exists m; x = \text{area\_of}(R) \end{array} \right], m); \\ \exists^{-1} p; a = m \end{array} \right]$$

Now, by the definition of  $\{\{\cdot\}\}_c$  and  $\llbracket \cdot \rrbracket_c$ , the iDRS  $I$  inside a directive  $\text{Find}(v)[I]$  or  $\text{Show}[I]$  includes only those elements that have a counterpart in the basic DRS except for the "anti-quantifiers." We can hence convert it to a HOPL formula, by first canceling the quantifications  $\exists v$  that precede  $\exists^{-1} v$  (i.e., deleting all occurrences of  $\exists v$  that appear before an occurrence of  $\exists^{-1} v$  in the iDRS, and deleting  $\exists^{-1} v$  itself), then converting it to a DRS by replacing the sequencing operator ';' to the merge operator, and finally translating it to a HOPL formula according to Fig. 2.

## 5 Remaining Issues in the Semantic Analysis of Math Problem Text

The mechanism presented in §4 significantly enhanced the coverage of the analysis over real problems. We however found several phenomena that can not be handled now.

**Free/bound variable distinction without a cue phrase** We have presented a mechanism to 'un-bind' the variables specified by a cue phrase, such as "(find  $x$ ) in terms of ( $y$ )." Some types of variables however have to be left free even without any explicit indication, e.g.:

Let  $p > 0$ . Find the area of a circle with radius  $p$ , centered at the origin.

Assuming  $\text{circle}(x, y, r)$  denotes a circle with radius  $r$  and centered at  $(x, y)$ , we want to derive

$$\text{Find}(a) [p > 0; a = \text{area\_of}(\text{circle}(0, 0, p))],$$

but our default variable binding rule gives

$\text{Find}(a) [\exists p; p > 0; a = \text{area\_of}(\text{circle}(0, 0, p))]$ .

This directive means to find the range of the areas of the circles with arbitrary radii, which is apparently not a possible reading of the problem. We found such cases in 3 out of the 32 test problems used in the experiment shown later.

**Scope inversion by a cue phrase** The hierarchy of the quantifier scopes in math text mostly follows the linear order of the appearance of the variables (either overtly quantified or not). This general rule can however be superseded by the effect of a cue phrase, as shown in the example problem and its possible translation in Fig. 7. In the figure, the formula inside the Show-directive mostly follows the discourse structure, in that the predicates from the first and the second sentence respectively form the antecedent and the succedent of the implication. The quantification on  $F$  is however dislocated from its default scope, i.e., the succedent, and moved to the outset of the formula by the effect of the underlined cue phrases. To handle such cases correctly, we would need a more involved mechanism for the manipulation of the context representation through the *cc* variable.

**Idiomatic expressions** As in other text genres, idiomatic multiword expressions are also problematic as can be seen in the following example:

By choosing  $x$  sufficiently large,  $y = 1/x$  can be made as close to 0 as desired.

As the example shows, a set phrase involving complex syntactic relations, e.g., “can do X as Y as desired by choosing Z sufficiently W” and “X approaches Y as Z approaches W,” can convey idiomatic meanings in math.

## 6 Empirical Results

We tested the feasibility of our approach on a set of problems selected from Japanese university entrance exams. Specifically, we wanted 1) to test the coverage of the semantic composition mechanism presented in §4 on real problems, and 2) to verify that there is no significant loss in the capability of the system due to the additional computational cost incurred by the separation of the semantic analysis from the mathematical reasoning.

The second point was confirmed by providing the ideal (100% correct) output from the

(forthcoming) NLP components to a state-of-the-art automatic reasoner and comparing the result against the performance of the reasoner on the input formulated by a human expert. Specifically, we manually gave the semantic representations of the problems as iDRSs or CCG derivation trees, and then automatically rewrote them into the language of RCF. The resulting formulas were fed to a solver to see whether the answers be returned in a realistic amount of time (30 seconds). The solver was implemented on SyNRAC (Iwane et al., 2013), which is an RCF-QE solver implemented as an add-on to Maple, and the (in)equation solving commands of Maple.

The problems were taken from the entrance exams of five first-tier universities in Japan (Tokyo U., Kyoto U., Osaka U., Kyushu U., and Hokkaido U.) for fiscal year 2001, 2003, 2005, 2007, 2009 and 2011. There were 249 problems in total. From them, we first eliminated those that included almost no natural language text, such like calculation problems. We then chose, from the remaining non-straightforward word problems, all the problems which could be solved with SyNRAC and Maple when the input was formulated by an expert of computer algebra. The formulation by an expert was done, of course, with no manual calculation, but otherwise it was freely done including the division of the solving process into several steps of QE and (in)equation solving.

As the result of that, we got 32 test problems, each of which contained 3.9 sentences on average. They include problems on algebra (of real and complex numbers), 3D and 2D geometry, calculus, and their combinations. For analyzing the result in more detail, we divided the problems into 78 sub-problems for which the correctness of the answers can be judged independently.

### 6.1 From discourse analysis to the solution

For the first experiment, we manually encoded the problems in the form of iDRSs. Each sentence in a problem was first encoded as a single iDRS, and the sentence-level iDRSs were combined (again manually) into a problem-level iDRS using the connectives defined in the iDRS syntax. In the manual encoding, the granularity of the representation, i.e., the smallest units of the semantic representation, was kept at the level of the actual words in the text whenever possible, intending that the resulting iDRSs closely match the representation

Problem: Point  $P$  is on the circle  $x^2 + y^2 = 4$  and  $l_P$  is the normal line to the circle at  $P$ . Show that  $l_P$  passes through a fixed point  $F$  irrespective of  $P$ .

$$\text{Show } \left[ \exists F. \left( \forall P. \forall l_P. \left( \left( \begin{array}{l} P \text{ is on } x^2 + y^2 = 4 \text{ and} \\ l_P \text{ is the normal line to the circle at } P \end{array} \right) \rightarrow l_P \text{ passes through } F \right) \right) \right]$$

Figure 7: Scope inversion by cue phrases

Let  $O(0, 0)$ ,  $A(2, 6)$ ,  $B(3, 4)$  be 3 points on the coordinate plane. Draw the perpendicular to line  $AB$  through  $O$ , which meets  $AB$  at  $C$ . Let  $s, t$  be real numbers, and let  $P$  be such that  $\overrightarrow{OP} = s\overrightarrow{OA} + t\overrightarrow{OB}$ . Answer the following questions.

(1) Calculate the coordinates of point  $C$ , and write  $|\overrightarrow{CP}|^2$  in terms of  $s$  and  $t$ .

(2) Let  $s$  be constant, and let  $t$  vary in the range  $t \geq 0$ . Calculate the minimum of  $|\overrightarrow{CP}|^2$ .

Figure 8: Kyushu University 2009 (Science Course) Problem 1

composed from word-level semantic representations. In the iDRS encoding of the 32 problems, the context-fetching mechanism through ‘*cc*’ variable was needed in 15 problems and the canceling of quantification was needed in 6 problems. These mechanisms thus significantly enhanced the coverage of the semantic composition machinery.

After rewriting the iDRSs to RCF formulas<sup>4</sup>, we fed them to the solver and got perfect answers for 19 out of the 32 problems. Out of the 78 sub-problems, 56 sub-problems (72%) were successfully solved. 12% of the sub-problems (9 sub-problems) failed due to the timeout in the QE solver. Besides the timeout, a major cause of the failures (7 sub-problems) was the fractional power (mainly square root) in the formula. Although we can mechanically erase the fractional powers to get an RCF formula, it was not implemented in the solver.<sup>5</sup> The remaining 6 sub-problems needed the free/bound variable distinction without any cue phrase (§5). Although half of them could be solved by manually specifying the free variables, we did not count them as solved here.

## 6.2 From syntactic analysis to the answer

We chose 14 problems from the 19 problems which were fully solved with the iDRS encod-

<sup>4</sup>The knowledge-base used to rewrite the HOPL formulas to first-order RCF formulas included 230 axioms for 86 predicates and 98 functions.

<sup>5</sup>In the formulation by the human expert, the use of square roots were avoided by encoding the conditions differently (e.g.,  $x \geq 0 \wedge x^2 = 2$  instead of  $\sqrt{x} = 2$ ).

ings. We manually analyzed the text following the CCG-based analyses of basic Japanese constructions given by Bekki (2010). We annotated the 44 sentences in the 14 problems with full CCG derivation trees and anaphoric links. We selected the 14 problems so that they cover different types of grammatical phenomena as much as possible. The final CCG lexicon contained 240 lexical entries (109 for function words and the rest for content words). The iDRS representations were then derived by (automatically) composing the semantic representations of the words according to the derivation trees and combining the sentence-level iDRSs to a problem-level iDRS as in the first experiment. Out of the 14 problems, we got fully correct answers for 13 problems. In the 14 problems, there were 33 sub-problems and we got correct answers for 32 of them; On only one sub-problem, the solver could not return an answer within the time limit. Fig. 8 shows an English translation of one of the 13 problems successfully solved with the CCG derivation trees as the input.

Overall, the results on the real exam problems were very promising: 72% of the sub-problems were successfully solved with the formula derived from a sentence-by-sentence, direct encoding of the problem. The experiment with manually annotated CCG derivation trees further showed that there was almost no additional cost introduced by the mechanical derivation of the logical forms from the word-level semantic representations.

## 7 Conclusion and Prospects

We have presented a logic-based architecture for automatic problem solving. The experiments on the university entrance exams showed positive results indicating the viability of the modular design.

Future work includes the development of the processing modules, i.e., the symbolic expression analyzer, the parser, and the discourse structure analyzer. Another future work is to incorporate different types of solvers to the system for covering a wider range of problems, with the ability to choose a solver based on the content of a problem.

## Abstract

Automated lexicon acquisition from corpora represents one way that large datasets can be leveraged to provide resources for a variety of NLP tasks. Our work applies techniques popularized in sentiment lexicon acquisition and topic modeling to the broader task of creating a stylistic lexicon. A novel aspect of our approach is a focus on multiple related styles, first extracting initial independent estimates of style based on co-occurrence with seeds in a large corpus, and then refining those estimates based on the relationship between styles. We compare various promising implementation options, including vector space, Bayesian, and graph-based representations, and conclude that a hybrid approach is indeed warranted.

## 1 Introduction

Though lexical resources are useful for many NLP tasks, manual lexicon creation is often onerous, particularly for aspects of language for where full coverage requires hundred of thousands of annotations. This work deals with one such aspect which we refer to as stylistic variation. This should not be understood in a purely aesthetic sense, but as reflecting various high-level aspects of the text, including genre and social identity. Some tasks relevant to style so defined include genre classification (Kessler et al., 1997), author profiling (Rosenthal and McKeown, 2011), social relationship classification (Peterson et al., 2011), sentiment analysis (Wilson et al., 2005), readability classification (Collins-Thompson and Callan, 2005), and text generation (Hovy, 1990). Following the classic work of Biber (1988), computational modeling of style has often focused on textual statistics and the frequency of function words and syntac-

tic categories. There are, of course, manually-constructed lists which capture some aspects of style, for instance resources related to psycholinguistics (Coltheart, 1980), but these are necessarily limited in scope. Our interest is in providing broad lexical coverage, potentially in any language. Here, we will show that style is particularly amenable to corpus-based automated lexical acquisition.

Our approach to this problem is grounded in methods popularized for polarity lexicon creation (Turney and Littman, 2003), but we take a more holistic view than is typical, simultaneously tackling the acquisition of several styles in a single model. Not only is this theoretically warranted, due to the correlation effects resulting from the oral/literate spectrum of register, but we also show it can offer practical gains: our hybrid models first derive initial estimates of each style from a large social media corpus, and then refine these estimates based partially on the results from other styles. We demonstrate that various popular methods are applicable to this problem, and indeed a single method might not provide the best results for all styles. For evaluation, we use a consensus annotation, the results of which also raise interesting questions about annotation for more continuous kinds of variation.

## 2 Related Work

In English manuals of style and other prescriptivist texts (Strunk and White, 1979; Kane, 1983), writers are urged to pay attention to various aspects of lexical style, including elements such as familiarity, readability, formality, fanciness, colloquialness, specificity, concreteness, and objectivity; these stylistic categories reflect common aesthetic judgments about language, but are also inextricably linked to the conventions of register and genre. See Biber and Conrad (2009) for a discussion of the relationship between register, genre,

and style as traditionally defined in descriptive linguistics. Some researchers have posited a few fixed styles (Joos, 1961) or a small, discrete set of situational constraints which determine style and register (Halliday and Hasan, 1976); by contrast, the applied approach of Biber (1988) and theoretical framework of Leckie-Tarry (1995) offer a more continuous interpretation of register variation. In Biber’s approach, functional dimensions such as *Involved vs. Informational*, *Argumentative vs. Non-argumentative*, and *Abstract vs. Non-abstract* are derived in an unsupervised manner from a mixed-genre corpus, with the labels assigned depending on where features (a small set of known indicators of register) and genres fall on each spectrum. The theory of Leckie-Tarry posits a single main cline of register with one pole (the oral pole) reflecting a reliance on the context of the linguistic situation, and the other (the literate pole) reflecting a reliance on cultural knowledge. The more specific elements of register are represented as subclines which are strongly influenced by this main cline, creating probabilistic relationships between related dimensions.

Computational linguistics research most similar to ours has focused on classifying the lexicon in terms of individual aspects relevant to style (e.g. formality, specificity, readability, and concreteness) (Brooke et al., 2010; Pan and Hsieh, 2010; Kidwell et al., 2009; Turney et al., 2011). Of particular methodological relevance is work on the induction of polarity lexicons based on co-occurrence in large corpora (Turney and Littman, 2003; Velikovich et al., 2010), or connections in WordNet (Rao and Ravichandra, 2009; Baccianella et al., 2010); semi-supervised vector space and graph methods are common, and several of the methods we apply here are taken directly from or inspired by work in this area.

### 3 Word annotation

In this study, we consider six styles—colloquial, literary, concrete, abstract, subjective, and objective—which are clearly represented in the lexicon, which are mentioned often in the relevant English linguistics literature, and which have strong positive and negative correlations with other styles in the group. Many (but not all) of these correlations are related to the oral/literate distinction. Our definition of each style (adapted from our annotation guidelines) is given below.

**Colloquial** Words which are used primarily in very informal contexts, for instance slang words and internet abbreviations.

**Literary** Words which you would expect to see primarily in literature; these words often feel old-fashioned or flowery.

**Concrete** Words which refer to events, objects, or properties of objects in the physical world that you would be able to see, hear, smell, or touch.

**Abstract** Words which refer to something that requires major psychological or cultural knowledge to grasp; complex ideas which can’t purely be defined in physical terms.

**Subjective** Words which are strongly emotional or reflect a personal opinion.

**Objective** Words which are emotionally distant, explicitly avoiding any personal opinion, instead projecting a sense of disinterested authority.

Our method and evaluation relies on having a set of seed words for each style. The words used in this study were originally collected from various sources by the authors; we included words that we considered clear members of a particular stylistic category—though they might also belong to other categories—with little or no ambiguity with respect to that style. Colloquial seeds consist of English slang terms and acronyms, e.g. *cuz*, *gig*, *asshole*, *lol*. The literary seeds were primarily drawn from web sites which explain difficult language in texts such as the Bible and *Lord of the Rings*; examples include *behold*, *resplendent*, *amiss*, and *thine*. The concrete seeds all denote physical objects and actions, e.g. *shove* and *lamppost*, while the abstract seeds all involve nontrivial concepts *patriotism* and *nonchalant*. For our subjective seeds, we used an edited list of strongly positive and negative terms from a manually-constructed sentiment lexicon (Taboada et al., 2011), e.g. *gorgeous* and *depraved*, and for our objective set we selected words from sets of near-synonyms where one was clearly an emotionally-distant, formal alternative, e.g. *residence* (for *home*) or *occupied* (for *busy*). We filtered initial lists to 150 of each type (900 in total), removing words which did not appear in the corpus or which occurred in multiple lists.

Relying on a single annotator, however, is problematic, and a more serious issue with our original

Table 1: Fleiss’s kappa for 5-way annotation, by style.

Style	Kappa
Literary	0.61
Abstract	0.37
Objective	0.55
Colloquial	0.85
Concrete	0.67
Subjective	0.63
Average	0.61

seed sets is that many of the seeds belong on multiple lists, reflecting the fact that stylistic correlations occur at the lexical level. This interferes with evaluation, since we need to be fairly certain not only which seeds are in a category, but which are not. Therefore, we carried out a full annotation study with 5 annotators, asking each annotator to tag all 900 words for each of the 6 styles according to guidelines we prepared. One of the authors was included as an annotator (this annotation was carried out prior to all the others), but the other four were unfamiliar with the project; all were native English speakers with at least an undergraduate degree, and all reported reading a variety of text genres for work and/or pleasure. We provided written guidelines explaining each style in detail, and asked annotators to make judgments based on what they felt to be the most common sense. Communication among annotators was restricted during the process, but we allowed access to other resources (e.g. the internet) and answered general questions about the guidelines that came up during the process. A few annotators had obviously skewed numbers for certain styles relative to other annotators due to misinterpretation of the guidelines, and we provided non-specific feedback for revision in these cases. The Fleiss’s kappa (Fleiss, 1971) values for our 5-way annotation study are presented in Table 1.<sup>1</sup>

The kappa values in Table 1 indicate agreement well above chance, but several of the dimensions (and the average) are below the 0.67 standard for reliable annotation (Artstein and Poesio, 2008), and only one (colloquial) reaches the higher 0.8 standard. This suggests that there is a sizable subjective aspect to these judgments and we should be somewhat skeptical of the judgment

<sup>1</sup>The annotations and our guidelines are available at [http://cs.toronto.edu/~jbrooke/style\\_annotations.zip](http://cs.toronto.edu/~jbrooke/style_annotations.zip).

of any particular annotator. However, we had forced our annotators to make a boolean choice for each style, which may be somewhat inappropriate for somewhat non-discrete phenomenon like style. Taboada et al. (2011), when validating their fine-grained manual polarity lexicon (which included annotation of both polarity and strength), demonstrated that Mechanical Turk worker disagreement on a boolean task seemed to correspond fairly well to ranges on a scale: there was agreement at the extremes of polarity, but increasing disagreement towards the middle.

With this in mind, we used our initial annotations to create a new annotation task for two of our external annotators: the goal was to investigate whether annotators can identify relative differences in degree suggested by either agreement or disagreement with their choices by other annotators. First, we extracted minority opinions, defined here as word/style combinations where the annotator agreed with exactly one other annotator and disagreed with the three others, and consensus opinions, defined as those where all the annotators agreed. We randomly paired each minority opinion word/style with a consensus opinion; for both opinions, the annotator in question had made the same judgment (both yes, or both no), but some of the other annotators had made different choices. We then asked our annotators (who were unaware of the exact nature of the experiment) to pick, among two words they had tagged the same in the first round, the word which had ‘more’ of the relevant stylistic quality.

In the negative case (where the annotator had originally marked both as not having the style), the results are stark: in 97% of the cases, the annotator picked the minority opinion (i.e. the word which some other annotators had marked yes), suggesting that the annotator could identify the stylistic tendencies of the (mixed-agreement) word, but had nonetheless excluded it, probably because there were much clearer examples of this style and other styles which could be more clearly applied to the word. In the positive case, the annotators preferred the word with group consensus 82.7% of the time, which is indeed the pattern we would predict if the minority opinion is less extreme; the positive case is more subtle than the negative case, where many of the words used for comparison very clearly do not belong to the relevant style. These results are consistent with the

Table 2: Number of seeds, by style.

Style	Positive	Negative
Literary	132	660
Abstract	107	599
Objective	245	495
Colloquial	163	684
Concrete	190	572
Subjective	258	487

idea that disagreement is a rough indicator of degree, and that not all disagreement should be dismissed as noise or some other failure of annotation. Of course, this also indicates that relative or continuous (e.g. Likert scale) judgments might be preferable to boolean ones, but in this case boolean annotation is far more practical, and indeed desirable for both model creation and evaluation.

For our final seed set, our positive annotations include all word/style combinations where a majority of annotators marked yes, whereas our negative annotations include only terms where there was complete consensus; words where only 1 or 2 annotators marked yes were removed from consideration as seeds (for that particular style). The summary of the counts for main seed set are presented in Table 2.

## 4 Methods

Our method for stylistic lexicon acquisition breaks down into three steps. The first is to apply one of several methods which leverages co-occurrence in a large corpus to derive, for each word, a raw score for each style. We then take that raw score and normalize it; the resulting number can be used directly to compare words relevant to a style. Finally, we consider the vector formed by these normalized style scores, and apply other methods which further refine this vector, implicitly taking into account the correlations among styles. The elements of the refined vector correspond to the degree of each style, so if we apply this method for all words in our vocabulary we create a full-coverage lexicon.

### 4.1 Corpus analysis

For all the methods in this section, we use the same corpus, the ICWSM Spinn3r 2009 dataset (Burton et al., 2009), which has been used successfully in earlier work (Brooke et al., 2010). Social media corpora are particularly appropriate for research

on style, since they contain a variety of registers. Here, we include all 2.46 million texts in the Tier 1 portion which contained at least 100 word types. Hapax legomena were excluded, since they could not possibly offer any co-occurrence information, but otherwise we did not filter or lemmatize words: our full vocabulary is 1.95 million words.

Our simplest method uses pointwise mutual information (PMI) (Church and Hanks, 1990), a popular metric for measuring the association between words. Since standard PMI has a lower bound of  $-\infty$  when the joint probability is 0 (a common occurrence since many of our words are relatively rare), we actually use a normalized version, NPMI, which has an upper bound of 1 and a lower bound of  $-1$ .

$$NPMI(x,y) = \left( \log \frac{p(x,y)}{p(x)p(y)} \right) \left( \frac{1}{\log p(x,y)} \right)$$

Following earlier work (Brooke et al., 2010), here and elsewhere we do not use the term frequency within a document (which is less relevant to style). Instead the probabilities are calculated using the number of documents where the word or words appear divided by the total number of documents. The raw score  $r_{ij}$  for style  $i$  of word  $w_j$  is simply the sum of its NPMI with the associated set of seeds  $S_i$ :

$$r_{ij} = \sum_{s \in S_i} NPMI(w_j, s)$$

Our second method, LSA, was applied to formality by Brooke et al. (2010) and concreteness by Turney et al. (2011). We begin by converting our corpus into a binary word-document matrix, and carry out latent semantic analysis (Landauer and Dumais, 1997), which includes a singular value decomposition of the matrix and dimensionality reduction to  $k$  dimensions. Assuming  $\mathbf{v}_w$  denotes the resulting  $k$ -dimensional vector for word  $w$ , we calculate  $r_{ij}$  as:

$$r_{ij} = \sum_{s \in S_i} \cos(\theta(\mathbf{v}_{w_j}, \mathbf{v}_s))$$

Our third method, using latent Dirichlet allocation (Blei et al., 2003), is more novel for lexical acquisition, and we address the specifics of this method in more detail in other work (Brooke and Hirst, 2013). Briefly, LDA is a Bayesian topic model which assumes that texts are generated via a

distribution of topics for each text ( $\theta$ ), and a distribution of words for each topic ( $\beta$ ); given a corpus, appropriate values for  $\theta$  and  $\beta$  are derived using inference, in this case variational Bayes inference using the original implementation provided by Blei et al. (2003). Our method works by seeding each of six topics in an LDA model (corresponding to our six styles) by dividing the entire initial probability mass among the seeds and running two iterations of the model, which distributes some of the probability mass to co-occurring words. In our previous work, we found further iterations had no benefit and even slightly degraded the model. For the LDA method,  $r_{ij}$  corresponds directly to  $\beta_{ij}$  of the resulting model which is just the probability of topic (style)  $i$  generating  $w_j$ .

## 4.2 Normalization

The raw numbers derived from corpus analysis methods discussed above cannot be used directly as indicators of style: the frequencies of both the seeds and the words being predicted have significant effect on the relative and absolute magnitudes of each style for all our methods, and performance using just these numbers is near chance. However, in two steps we can normalize these numbers to a form where the magnitude does directly reflect degree of a style. Again,  $r_{ij}$  refers to the raw score for style  $i$  and word  $j$  from some corpus analysis method. First, we take steps to ensure that  $r_{ij}$  is nonnegative. For LDA this is unnecessary (since  $r_{ij}$  is based on a probability distribution), but for NPMI and LSA it is needed, since both involve summing over items which vary between  $-1$  and  $1$ . We can ensure that these are positive by adding a constant equal to the number of seeds. Next, we convert the result to a style ‘distribution’ for each word:

$$r'_{ij} = \frac{r_{ij} + |S_i|}{\sum_{k=1}^6 r_{kj} + |S_k|}$$

The result is still not useful, since frequency (and count) of seeds clearly still has an effect. To focus on the differences between words, we subtract the means for each style and divide by the standard deviation

$$b_{ij} = \frac{r'_{ij} - \bar{r}'_i}{\sigma_{r'_i}}$$

to reach  $b_{ij}$ , the base for the ‘style space’ methods in the next subsection.

## 4.3 Style Vector Optimization

Given a vector that represents the styles for a given word, we wish to refine the vector to improve performance on relative judgments for individual styles. Here, we test two options: the first transforms the stylistic vectors into  $k$ -Nearest Neighbor (kNN) graphs, where we can apply label propagation. The second option treats the vector as a set of features for supervised linear regression, one for each style, using a specialized loss function. Both methods rely on having a style vector representation of not only our target words, but also our seed (training) words. For LSA and NPMI, we used leave-one-out crossvalidation to create these vectors; for LDA, however, it was impractical to do a full run of the model for each word, and so we used 10-fold crossvalidation instead.

A vector-space representation offers a number of obvious similarity functions for building a  $k$ NN graph: we test two here, inverse Euclidean distance (L2) and cosine similarity (cos). A more difficult problem is the choice of  $k$  (for  $k$ NN  $k$ ): here, we estimate a good  $k$  from the training set. Since the training set and dimensionality of the data is (now) fairly small, we simply test on all possible intervals of 5, and choose the best (often near 50, though we saw values as low as 10 and as high as 90) using our pairwise evaluation (see Section 5.1). Since our label propagation method works independently for each style, we can choose a different  $k$  for each.

For label propagation, we use the simple one-step propagation function from Kang et al. (2006). Here,  $K$  is our similarity function (which returns zero if seed  $s$  is not one of the  $k$  nearest neighbors), and  $z_{ij}$  is the resulting confidence score, which we use as our new estimate for the style:

$$z_{ij} = \sum_{w_s \in S_i} K(w_j, w_s)$$

Obviously, the main work here is done by the similarity function, which implicitly includes information from other stylistic dimensions by preferring words which are close not just on the relevant dimension, but in the stylistic space as a whole. There are of course more sophisticated, multi-step approaches to label propagation, e.g. the one used by Rao and Ravichandran (2009), but a single-step approach has clear advantages in light of our large vocabulary and dense graph; we leave exploration of whether unlabeled words can help further to fu-

ture work. We did test the one-step correlated label propagation method proposed by Kang et al. but found it was ineffective, probably because it increases the effects of correlation, which is actually counter to our needs.

The information provided by label propagation is distinct enough that it can be successfully combined with the original (base) vector. As with  $k$  for  $k$ NN, we estimated a good weighting for this combination using the training data, testing at 0.01 intervals. Since we noted some interdependence, we combined this step with the selection of ( $k$ NN)  $k$ . Again, this ratio can be different for each style.

Our second vector optimization technique is an adaption of supervised linear regression. Linear regression usually involves minimizing squared distance of the output of the model from the training set, assuming there are known values of expected output. In this case, however, we don't have reliable values for specific degrees of a style. We proceed by replacing the least-squared loss function with a loss function based on our evaluation metric (see Section 5.1):

$$L(\theta) = \sum_{w_j \in S_{i,p}} \sum_{w_m \in S_{i,n}} I(h_\theta(b_{ij}) < h_\theta(b_{im}))$$

Here,  $S_{i,p}$  and  $S_{i,n}$  refer to the positive and negative examples of style  $i$ , respectively,  $h_\theta$  is the linear regression function, and  $I$  is an indicator function equal to 1 if the statement is true, and 0 otherwise.

Using such a loss function discourages standard approaches to linear regression, but in this context (a small feature space and training set), it is reasonably practical to search the space exhaustively for weights which provide a (near-)optimal result (on the training data).<sup>2</sup> Starting with full weight (1) on the feature corresponding to the dimension being derived and 0 on all others, we search the range  $-1$  to  $1$  at 0.001 intervals for the other dimensions, proceeding in order based on the greatest difference across positive and negative examples of each style. We found that one such iteration across each element of the vector was sufficient, resulting in a stable model. This method can be applied on the initial vector, or on a vector that has already been refined by some other method, i.e. the output of label propagation.

<sup>2</sup>At the suggestion of a reviewer, we also tried applying SVMrank to this regression; it was much faster but performance was worse.

## 5 Evaluation

### 5.1 Setup

Our evaluation is based on the pairwise comparison of words which are known (from our annotation) to differ relevant to a certain style. Accuracy for a test set  $S_i$  (of a style  $i$ ) is defined as the number of instances where the expected inequality exists between a pair of opposing words, divided by the total number of such pairings:

$$Accuracy(S_i) = \frac{\sum_{w_j \in S_{i,p}} \sum_{w_m \in S_{i,n}} I(z_{ij} > z_{im})}{|S_{i,p}| \cdot |S_{i,n}|}$$

Here  $z$  can refer to any of the metrics for style discussed in the previous section. The major advantage of this definition of accuracy is that it does not require an arbitrary cutoff point, but 100% accuracy nonetheless indicates that the two sets are perfectly separable. Also, it does not assume anything about the degree of difference between two words, e.g. that more is better, since for any given pair of words we cannot be certain what an ideal difference would be.

We evaluate using 3-fold crossvalidation, using the original 150-per-style annotation of our 900 words for the purposes of stratifying the data, which allows for balanced sets of 600 for training and 300 for testing. All seeding, training, and evaluation use the majority annotation of the 5 annotators, discussed in Section 3. Since the initial splits add a significant random factor, all results here are averaged over 5 runs, with the same 5 runs (i.e. same splits) used for all evaluated conditions.

### 5.2 Comparison of models

Table 3 shows a comparison of the performance of various models, organized by the method of corpus analysis. First, we note that most of these numbers are quite high, almost all are above 80% and most are above 90%. It is worth mentioning that if only direct opposites are considered (e.g. colloquial versus literary, concrete versus abstract), most dimensions reach results above 99%; our multi-style evaluation here offers a more realistic view. Among individual styles, colloquial words seem the most distinct, which is consistent with the results of human annotation. Acquisition of subjectivity, on the other hand, is strikingly more difficult than the other styles.

Based only on average accuracy, we could conclude that  $LSA > LDA > NPMI$  with respect

Model	By Style						Average
	Lit.	Abs.	Obj.	Coll.	Conc.	Subj.

to extracting relevant stylistic information from the corpus. That NPMI is the worst performing method is not surprising, since it relies only on direct co-occurrence between seeds and test words, and is not able to take advantage of larger patterns in the data; we would expect similar results for other simple relatedness measures. Though LSA is better overall, the distinction between LSA and LDA is more subtle, since in fact LDA is the higher performing model for two of the six styles, and its poorer overall performance can be attributed to a rather dismal showing for literary words, worse than NPMI. This is interesting because subjective and concrete words, where LDA does well, are the most common in the corpus, whereas literary words are consistently the least common. We posit, based on this and our earlier research focused on the LDA method, that successful low-dimensional seeded LDA requires styles (topics) that are reasonably well-represented in the corpus; when that condition is met, LDA will likely do better than LSA because it will

distinguish rather than collapse correlated styles. LSA, on the other hand, is robust against the scarcity problem because it requires only that a set of words have a reasonably distinct  $k$ -dimensional profile to form a coherent style.

Based on the results in Table 3, we can conclude decisively that both of our optimization techniques are effective. The effects are particularly marked for NPMI, but is reasonably consistent across all three corpus analysis techniques and the various individual styles. With regards to the similarity function in label propagation, we found that cosine similarity, a less common choice for building graphs, was generally as good as, and often better than, Euclidean distance. The vector resulting from label propagation also consistently benefited from being combined with the base vector, the result being better than either alone. It is not entirely clear which of the two optimization methods is to be preferred (their effects seem roughly similar), though linear regression seems to have edge when using LSA. Combining the two methods seems a

good strategy, particularly for LDA.

The LSA results presented here mostly use  $k = 500$ , a fairly standard choice. However, we tested other values, in particular extremely low values ( $k = 20$ ) to see if we could confirm our supposition (Brooke et al., 2010) that much stylistic information is contained with the first few dimensions of LSA. Our results suggest that the basic supposition is valid, since the difference between the two conditions for most dimensions is not large, but the identification of subjectivity (not considered by Brooke et al. 2010) does seem to benefit greatly from a higher-dimensional vector.

## 6 Qualitative analysis

To investigate further the successes and failures of our method, we carried out two qualitative examinations of the output of our model. First, we looked at those words within our annotated set of words which consistently caused the most errors across the various splits and runs. Second, we ran a high-performing LSA model built from the entire seed set on a subset of our vocabulary (we excluded words of document frequency less than 100), creating lexicons for each style; we manually inspected non-seed words that were ranked highest on each dimension.

The clearest result from the inspection of the seed output was that many of the false negatives involve words that are strong on some other dimension, typically on the other side of the oral/literate divide. For example, the most difficult-to-identify literary and abstract terms are strongly subjective (e.g. *loathe* and *obscene*), while the most difficult objective word, *translucent*, is very concrete. The most difficult concrete words are literary (*yoke*, *raiment*) or objective (*conflagration*), and the most difficult subjective words are also somewhat objective (*eminent*) or abstract (*autocratic*). Interestingly, a manual inspection of the weights for linear regression suggests that our optimization is correcting for just this kind of situation: we generally see negative weights on (what we would predict to be) positively correlated styles, and vice versa. However, in certain cases where one style has a much larger role in determining the co-occurrence pattern in the corpus, this correction may be insufficient.

Most of the false positives, by contrast, involve overextension of each category in predictable ways. For example, our highest ranking literary

words from the general vocabulary were mostly very good, but contained a few words that are obvious over-generalizations into biblical and fantasy texts, e.g. *locust* and *sorcerers*, while among the objective words there were a number of academia-relevant words that are really more abstract than objective, e.g. *coauthors* and *peer-review*. Our derived colloquial words contained many (sometimes purposeful) misspellings (*wayy*, *annnd*) which we could argue are genuinely colloquial; less clear are the many lower-case celebrity names (e.g. *miley*), but the fact that the bloggers used lower case does make them non-standard. Consistent with our qualitative results, subjective was the most problematic in the general vocabulary: though there were many good subjective words, there were a lot of other words which suggest topics that people tend to express opinions about, e.g. *sitcoms*, *entertainer*, or *flick*; movie-related words are particularly common, which might be a reflection the lexicon we took our subjective seeds from.

## 7 Conclusion

We have presented a methodology for deriving high-quality stylistic lexicons from corpora. A key aspect of our approach its hybrid nature: information is first extracted (using efficient, well-established methods) in a semi-supervised fashion from large corpora, and then refined using fully-supervised techniques. We argue that there are clear benefits in looking at multiple styles simultaneously, not only in terms of improving performance but also in taking our evaluation beyond ‘toy’ situations where we ignore the complexities and interactions among styles, drawing connections with broader insights from linguistics.

One possible criticism of our method is that we use only co-occurrence information, and not other information (e.g. word morphology) which could be relevant to particular styles in English; this option should be explored further, particularly in the optimization phase where we can easily add other features, though we stress that our ultimate goal is to derive methods that are easily extensible to more styles and more languages. We have also not considered word senses or multiword expressions, but both can and should be added to the model.

## Abstract

We present the Prague Discourse Treebank 1.0, a collection of Czech texts annotated for various discourse-related phenomena "beyond the sentence boundary". The treebank contains manual annotations of (1), discourse connectives, their arguments and senses, (2), textual coreference, and (3), bridging anaphora, all carried out on 50k sentences of the treebank. Contrary to most similar projects, the annotation was performed directly on top of syntactic trees (from the previous project of the Prague Dependency Treebank 2.5), benefiting thus from the linguistic information already existing on the same data. In this article, we present our theoretical background, describe the annotations in detail, and offer evaluation numbers and corpus statistics.

## 1 Introduction and Motivation

Large collections of gold standard language data are known to build an indispensable base for many NLP algorithms. Reliable morphological tagging and syntactic analysis (phrasal or dependency) are nowadays quite a standard information in language corpora released all over the world. With the gradually increasing interest in modeling discourse structure or using various discourse features<sup>1</sup> in different NLP tasks (anaphora resolution, summarization, MT), also the development of resources aimed at representing various discourse-related aspects has gained on importance. Moreover, both theoretical discourse research and NLP algorithms can benefit from a reliable **multi-dimensional** analysis of the data (Webber et al., 2003, Stede, 2004). There are already several elaborate theoretical concepts on

<sup>1</sup> The term of *discourse* in this paper is used in two meanings. The broader interpretation is roughly equal to *text* (as in *discourse structure*, *discourse features* or *discourse coherence*) whereas the narrower sense denotes semantic relations between propositions (as in *discourse relations*).

discourse coherence brought to life in real-data annotation (see Sections 1.1 and 1.2). Still, it is only in recent years that large-scale corpora with manual annotations of sentential **and** discourse level phenomena have become available. Even fewer such corpora exist that combine more types of manual discourse-level annotations.

In this paper, we present a large-scale manual annotation project for Czech in which, apart from the "standard" analysis of a sentence (morphology, syntactic trees), several discourse phenomena are marked, all over the same data: pronominal, nominal and zero<sup>2</sup> coreference, discourse connectives (henceforth DCs) and the semantic relations they express, and the associative relations of the so-called bridging anaphora.

The paper is structured as follows: In Sections 1.1 and 1.2, brief overviews of recent projects concerning discourse relations and coreference + bridging anaphora are described, respectively. In Section 2, data and tools used in Prague Discourse Treebank (PDiT) are introduced. Section 3 describes the annotation scenario and is followed by evaluation of the project in comparison with similar projects (Section 4) and basic distribution numbers (Section 5). We conclude with discussion (Section 6).

### 1.1 Corpora of Discourse Relations

The first attempts in representing discourse structure date over a decade back. One of very first and most influential projects was the RST-Treebank (Carlson et al., 2001), an annotation project over the English texts of Wall Street Journal. In accordance with the Rhetorical Structure Theory of Mann and Thompson (1988), the whole document is represented as a single tree-like structure. Wolf and Gibson (2005) propose a less con-

<sup>2</sup> Czech is a pro-drop language. The restored ellipses in the underlying sentence analysis allow us to annotate zero forms as co-referential.

Figure 1. Annotation of two sentences. Discourse relations are represented by thick orange arrows, textual coreference by dark blue slim arrows, bridging anaphora by light blue slim arrows. Grammatical coreference (the only one in the figure is between nodes *co [what]* and *upouštět [to abandon]*) is represented by a brown slim arrow.

strained model in Discourse Graphbank by giving up the requirement of a tree-structure. These approaches are referred to as "deep discourse parsing" or modeling of global coherence (whole document = one connected structure) in contrast to the so-called "shallow discourse parsing" or local coherence modeling of the lexically grounded approaches, which are based on identification of discourse markers and relations they express. The most influential of the latter is the Penn Discourse Treebank (for English, PDTB, Prasad et al., 2008) with several subsequent similarly aimed corpora for different languages, the project presented here being one of them.

Resources manually annotated for (some type of) discourse phenomena are already available or work-in-progress for various languages, including Chinese (Zhou and Xue, 2012), Arabic (Al-Saif and Markert, 2010), Turkish (Zeyrek et al., 2010), Hindi (Oza et al., 2009), French (Afantenos et al., 2012, Danlos et al., 2012), German (Stede, 2004, Gastel et al., 2011) and others. Additionally, the relevance of the PDTB annotation concept was further tested on specific domains, e.g. on spoken dialogs (Italian, Tonelli et al., 2010) and on biomedical texts (English, Prasad et al., 2011).

## 1.2 Corpora of Coreference and Bridging Relations

There is a number of different large-scale annotated corpora for coreference and anaphoric relations. The largest annotated corpora for English include MUC (Hirschman and Chinchor, 1997), ACE (Doddington et al., 2004), OntoNotes (Pradhan et al., 2007), GNOME (Poesio, 2004), ARRAU (Poesio and Artstein, 2008). The coreference annotations for other languages than English are more limited. The most well-known corpora including anaphoric information are

AnCorra (Recasens and Martí, 2009) for Spanish and Catalan, VENEX (Poesio et al., 2004a) for spoken and written Italian, the Italian Live Memories Corpus (Rodríguez et al., 2010), TüBA-D/Z (Hinrichs et al., 2004) and Postdam Commentary Corpus (Stede, 2004, Krasavina and Chiarcos, 2007) for German, and some others.

Early work on bridging relations dates back to the mid-70s. Clark (1975) documents several ways in which an inference is needed to understand the meaning intended by the speaker. Clark names several types of bridging relations such as set-membership, part-whole, roles, reasons and consequences. Bridging relations have been later investigated by Poesio et al. (1997, 2004b). The annotation of bridging relations in different projects includes different types of relations. In the GNOME corpus (Poesio, 2004), such bridging relations as set-membership, subset, and part-whole are annotated. The Copenhagen Dependency Treebank (Korzen and Buch-Kromann, 2011) has a very detailed annotation scheme based on general semantic roles. Another way to capture bridging relations is to define them vaguely, e.g. as a reference which is made to a subpart of an object that has already been mentioned in the discourse (Hendrickx et al., 2011) or to mark as bridging all non-coreferent anaphoric references. The last approach was used in Hou et al. (2013), providing a reasonably sized and reliably annotated corpus for English.

To our knowledge, there are only few corpus projects portraying phenomena "beyond the sentence boundary" that gather different types of textual information, or, in other words, offer some kind of multi-dimensional discourse annotation. The texts of Wall Street Journal have undergone various annotations but they arose within different projects and frameworks – rhet-

TEMPORAL	CONTINGENCY	CONTRAST	EXPANSION
synchronous	reason – result	confrontation	conjunction
asynchronous	<i>pragmatic reason – result</i>	opposition	exemplification
	condition	<i>pragmatic contrast</i>	specification
	<i>pragmatic condition</i>	restrictive opposition	equivalence
	explication	concession	generalization
	purpose	correction	conjunctive alternative
		gradation	disjunctive alternative

Table 1: Distribution of discourse types in the data

orical structure analysis in RST-Treebank (385 WSJ articles), Discourse Graphbank (135 texts from AP Newswire and WSJ), Penn Discourse Treebank 2.0 (2,159 WSJ articles), OntoNotes (a substantial portion of the WSJ-Penn Treebank annotated for coreference) etc. A multi-dimensional analysis within a single project was conducted for French in AnnoDis (Afantenos et al. 2012, an intersection of all annotations on 13 articles), for German in the Potsdam Commentary Corpus (Stede, 2004, 170 texts), and lately in TüBa-D/Z (Gastel et al., 2011, 919 sentences in 31 articles). These projects include inter alia some particular version of a "global" discourse analysis, annotation of connectives and their senses, and coreference annotation.

## 2 Data and Tools

As the base data for the annotation, we used the Prague Dependency Treebank 2.5 (PDT, Bejček et al., 2012), which is an update of the Prague Dependency Treebank 2.0 (Hajič et al., 2006). It is a treebank of almost 50 thousand sentences of Czech newspaper texts, annotated manually on three levels of annotation: morphological, analytical and tectogrammatical. The annotation of a sentence at the highest, tectogrammatical layer captures the deep syntax and the information structure of a sentence and is represented by a dependency tree.

For the annotation of discourse relations, textual coreference and bridging anaphora, we used several extensions to a highly customizable tree editor TrEd (Pajas and Štěpánek, 2008). Technically, each of the annotated relations is represented as an arrow connecting two tectogrammatical nodes. The two nodes represent the two arguments of the relation, i.e. typically the subtrees of the nodes. All information about the relation is kept in a set of dedicated attributes at the initial node of the relation, containing a unique identifier of the target node of the relation, type of the relation, and other pieces of information (depending on the relation, e.g. a connective for the

discourse relation). The relation is depicted as a curved arrow between the nodes, see Figure 1. For details on the annotation tool for discourse, see Mírovský et al. (2010a), for details on the annotation tool for textual coreference and bridging anaphora, see Mírovský et al. (2010b).

## 3 Annotation

The following subsections 3.1 and 3.2 describe the annotation principles for the two subprojects in PDiT, the annotation of discourse relations and the annotation of textual coreference and bridging anaphora. Detailed descriptions of the annotation guidelines can be found in annotation manuals (Poláková et al., 2012a, Nedoluzhko et al., 2011). Figure 1 shows the annotation of two sentences in Example 1 in all these aspects.

(1) *Zato londýnská Chelsea je velkou neznámou nejen pro Viktorii Žižkov. Podle zpráv však anglický klub upouští od typického ostrovního fotbalu, což by mohlo být výhodou.*

*But then London Chelsea is a big unknown not only for Victoria Žižkov. According to reports, however, the English club abandons the typical island football, which could be an advantage.*

### 3.1 Discourse

Annotating discourse relations in PDiT is inspired by the PDTB lexical approach of connective identification (Prasad et al., 2008) but it also takes advantage of the Prague tradition of dependency treebanking. This means in practice that some discourse information (intra-sentential) could have been extracted from the previous rich annotation of syntax, with only minor enhancements (Jínová et al., 2012b). In the first release of PDiT, we only focused on discourse relations indicated by overly present (explicit) discourse connectives, i.e. expressions like *but*, *however*, *as a result*, *even though* etc.<sup>3</sup> Every DC is thought of as a discourse-level predicate that

<sup>3</sup> Some remarks on annotation of the implicit DCs and of the so-called alternative lexicalizations of connectives (AltLex) are added in the discussion in Section 6.

takes two discourse units as its arguments. Only discourse relations connecting clausal arguments (with a predicate verb), i.e. not those between nominalizations or deictic expressions were annotated in version 1.0. Additionally, the Prague discourse annotation includes marking of list structures (as a separate type of discourse structure) and marking of some smaller text phenomena: article headings, figure captions, non-coherent texts like collections of news etc.

The annotation of discourse relations consisted of two phases, first being manual and the subsequent including automatic extraction of relevant syntactic features. For the manual part, the annotators had at their disposal both plain text and the tree structures, the annotation itself was carried out on syntactic (tectogrammatical) dependency trees, as we did not want to lose connection with and information from the analyses of previous levels. Intra-sentential discourse relations, i.e. those that had already been captured within the syntactic (tectogrammatical) analysis, were only to be newly annotated if their discourse semantics differed from the tectogrammatical interpretation (Jinová et al., 2012b), otherwise they were automatically extracted and mapped onto the discourse annotation.

#### Automatic Extraction of Syntactic Features

An automatic procedure was designed to extract discourse-relevant features from the syntactic level of description, i.e. the intra-sentential discourse relations. As mentioned earlier, the tectogrammatical tree structures offer some types of information that can be transferred to the discourse-level annotation. In general, this concerns subordinate syntactic relations between clauses with labels like causality, conditionality, temporality, concession etc.; and coordinate syntactic relations between clauses of one sentence with selected coordinative labels like conjunction, disjunction, opposition or contrast, confrontation etc. These relations were semi-automatically mapped onto the discourse annotation. (Jinová et al., 2012b).

#### Semantic labels

The Prague discourse label set was inspired by the tectogrammatical functors (Mikulová et al., 2005) and also by Penn sense tag hierarchy (Miltsakaki et al., 2008). Table 1 shows the discourse-semantic label set used for PDiT 1.0. The four main semantic classes, Temporal, Contingency, Contrast (Comparison) and Expansion are identical to those in PDTB but the hierarchy it-

self is only two-level. The third level is captured by the direction of the discourse arrow. The annotators, unlike in the Penn approach, were not allowed to only assign the major class, they always had to decide for a single relation within one of the classes.<sup>4</sup> Within these four classes, the types of the relations partly differ from the Penn types and go closer to Prague tectogrammatical functors and/or are a matter of language-specific distinctions. Compared to the PDTB label set, we added the categories of *purpose* and *explication* in the Contingency group and *restrictive opposition* and *gradation* to the Contrast group. In the PDTB, four pragmatic meanings are distinguished and annotated: *pragmatic cause*, *condition*, *contrast* and *concession*. In the Prague scenario, three pragmatic senses were annotated, pragmatic concession and pragmatic contrast joined to one group, for the lack of reliable distinctive features.<sup>5</sup>

#### Post-annotation checks and fixes

After the manual annotation of discourse relations was finished, some checks turned up to be necessary, especially for relations whose nature revealed to be more complicated in real data than we had expected on the basis of linguistic handbooks. After having collected all examples of these relations (namely *specification*, *explication*, *generalization*, *exemplification* and *equivalence*) in our data and established more complex definitions of their nature, annotation of these relations was manually unified in the whole data. Also some DCs required unification via post-annotation. Additionally, the part of the data which was annotated first was fully re-annotated at the end since we expected it might have suffered from initial inexperience of the annotators.

Results of the automatic extraction were checked randomly on several hundreds of examples. All discrepancies found were integrated in an automatic script (treatment of multiple DCs, multiple coordinations etc.). Only two situations required manual checks and fixes: i) Due to a complicated situation in a tree, the automatic extraction failed in 23 cases of DC identification (opposed to 10,482 cases with correct identification). ii) Solely manual treatment was necessary for constructions with a discourse-relevant clause dependent on a complex predicate structure with

<sup>4</sup> In special cases, they had the option to assign an additional secondary relation.

<sup>5</sup> It may be that different text types require slightly different sets of semantic labels. For instance, some discourse projects use a more fine-grained set of pragmatic senses (e.g. for spoken dialogs).

an infinitive or a noun phrase. In such cases only semantics allowed to distinguish if the clause is related to the whole structure or only to the infinitive or noun phrase.<sup>6</sup>

### 3.2 Coreference and Bridging Relations

In PDiT 1.0, two types of coreference (grammatical and textual) and six types of bridging relations are marked. The **grammatical coreference** typically occurs within a single sentence, the antecedent being able to be derived on the basis of grammatical rules of a given language (Czech). It includes relative pronouns, verbs of control, reflexive pronouns, reciprocity and verbal complements (Mikulová et al., 2005). **Textual coreference** marks coreferential relations between language expressions referring to the same discourse entity when the reference is not expressed by grammatical means alone, but also via context. Anaphoric (occasionally cataphoric) relations are expressed by various linguistic means (pronouns, synonyms, generalizing nouns etc.). Textual coreference has been annotated in two time periods. First, the so-called pronominal textual coreference was manually annotated. It was restricted to cases in which a demonstrative *this* or an anaphoric pronoun of the 3rd person, also in its zero form, are used (Kučová and Hajičová, 2004). Afterwards, the annotation of textual coreference was extended to cases where the anaphoric expression is represented by other means such as full noun phrases, adverbs (*there, then* etc.) and some types of numerals and pronouns left out during the first stage (Nedoluzhko et al., 2013).

The textual coreference is further classified into two types – coreference of noun phrases with specific (type SPEC) or generic (type GEN) reference. Compare examples (2) and (3):

(2) *Mary* and John went together to Israel, but *Mary* [type SPEC] had to return because of the illness.

(3) *Dogs* bark. This is the way how *they* [type GEN] express their emotions.

Discourse deixis (reference to a non-nominal antecedent) is annotated as a textual coreference link when referring to a clause or a sentence. If a noun phrase endophorically refers to a discourse segment that is larger than one sentence or it is understood by inferencing from a broader context, the antecedent is not specified.<sup>7</sup>

A specifically marked link for **exophora** denotes that the referent is "out" of the co-text, it is known only from the actual situation. In the same way as for segments, the new nominal and adverbial links were added.

For the **bridging relations**, the following types are distinguished: part-of relation (*room - ceiling*), set – subset (*students – some students*) and FUNCT (*trainer – football team*) traditional relations, CONTRAST for coherence relevant discourse opposites (e.g. *this year – next year*), ANAF for explicitly anaphoric relations without coreference (*second world war – at that time*) and the further underspecified group REST, which is mainly used to capture such types of bridging relations as location – inhabitants or event – argument. A more detailed description of the types can be found in Nedoluzhko and Mirovský (2011).

#### Automatic Preannotation

For the textual coreference, only a limited preannotation was carried out: We used a list of pairs of words that with a high probability form a coreferential pair in texts. Most of the pairs in the list consist of a noun and a derived adjective, which are different in Czech, e.g. Praha – pražský (in English: Prague – Prague, like in the sentence: *He arrived in Prague and found the Prague atmosphere quite casual*). The rest of the list is formed by pairs consisting of an abbreviation and its one-word expansion, e.g. ČR – Česko (similarly in English: USA – States). The whole list consists of more than 6 thousand pairs obtained automatically from the morphological synthesizer for Czech, manually checked and slightly extended.

### 4 Inter-Annotator Agreement

Several annotators annotated the data but (for obvious reasons of limited resources) each part of the data has only been annotated by one of them. Only 4% of the data (44 documents, 2,084 sentences) have been annotated in parallel by two annotators of discourse relations, and 3% (39 documents, 1,606 sentences) have been annotated in parallel by two annotators of textual coreference and bridging anaphora. We used the parallel (double) annotations for measuring the inter-annotator agreement, and for analyzing the most common errors, i.e. difficult parts of the annotation.

<sup>7</sup> This decision is considered to be provisional. The antecedents are supposed to be specified in further phases of the annotation.

<sup>6</sup> For more details, see Jínová et al. (2012b).

To evaluate the inter-annotator agreement on texts annotated in parallel by two annotators, we used several measures. The connective-based F1-measure (Mírovský et al., 2010c) was used for measuring the agreement on the recognition of a discourse relation, the chain-based F1-measure was used for measuring the agreement on the recognition of a coreference or bridging relation. A simple ratio and Cohen's  $\kappa$  were used for measuring the agreement on the type of the relations in cases where the annotators recognized the same relation.<sup>8</sup>

In the connective-based measure, we consider the annotators to be in agreement on recognizing a discourse relation if the two connectives they mark (each of the connectives marked by one of the annotators) have a non-empty intersection (technically, a connective is a set of tree nodes). For details, see Jínová et al. (2012a).

In the chain-based measure, we consider the annotators to be in agreement on recognizing a coreference or a bridging relation if two nodes connected by an arrow by one of the annotators have also been connected by the other annotator; coreference chains are taken into account, i.e. it is sufficient for the agreement if the arrow starts in or goes to a node that is coreferentially connected (possibly transitively) with the node used for the relation by the other annotator.

Table 2 shows the results of the inter-annotator agreement measurements.

relation	F1	agreement on types	Cohen's $\kappa$
discourse	0.83	0.77	0.71
text. coref.	0.72	0.90	0.73
bridging	0.46	0.92	0.89

Table 2: Inter-annotator agreement

Comparison of the inter-annotator agreement with other similar projects is difficult, as the projects usually use different annotation schemes and different scores. Nevertheless, some comparisons can be done:

The simple ratio agreement on types in discourse relations (0.77 on all parallel data, the third column of Table 2) is the closest measure to the way of measuring the inter-annotator agreement used on subsenses in the Penn Discourse Treebank 2.0, reported in Prasad et al. (2008). Their agreement was 0.8.

<sup>8</sup> In all our measurements, only inter-sentential discourse relations have been counted, as the intra-sentential relations were mostly annotated automatically.

In the annotation of coreference relations in OntoNotes, the inter-annotator agreement on English was 80.9 for newspaper texts and 78.4 for magazine texts. On Chinese, the agreement was 73.6 for newspaper texts and 74.9 for magazine texts (reported in Pradhan et al. 2012). These numbers can be compared with our chain-based F1 measure (0.72 in the second column of Table 2), as it is similar to the MUC-6 score they used.

As to the bridging anaphora, we can compare our chain-based F1 score (0.46 in the second column of Table 2) to F1 score on recognition of bridging relations reported for the annotation of the COREA corpus (Dutch texts); their agreement on newspaper texts was 0.39 (reported in Hendrickx et al., 2011).

## 5 The Corpus in Numbers<sup>9</sup>

Table 3 shows total numbers of annotated relations in the whole data of PDiT.

relation	count
discourse relations	20,542
- discourse inter-sentential	6,195
- discourse intra-sentential	14,347
textual coreference	87,299
grammatical coreference <sup>10</sup>	23,272
bridging anaphora	33,154

Table 3: Total numbers of annotated relations in PDiT

bridging type	count
ANAF	847
CONTRAST	2,305
FUNCT_P	516
PART_WHOLE	2,017
P_FUNCT	1,743
REST	2,226
SET_SUB	13,106
SUB_SET	5,885
WHOLE PART	4,509
<b>total</b>	<b>33,154</b>

Table 4: Distribution of bridging types in PDiT

In addition to the numbers in Table 3, there have been annotated 445 members of lists, 4,188 headings, 1,505 coreference relations to segment and 689 references out of the text (exophora).

<sup>9</sup> Please note that 1/10 of the PDT/PDiT data has been designated to evaluation tests. Numbers presented in this section include also this part of the data. Therefore, these numbers should not be used in any experiments tested on the evaluation test data of PDT/PDiT!

<sup>10</sup> mostly annotated already in PDT

Table 4 shows a distribution of bridging types annotated in PDiT. Table 5 shows the total number of individual discourse types annotated in PDiT.

discourse type	full name	count
conc	concession	878
cond	condition	1,369
confr	confrontation	654

## 6 Discussion

In the first release of PDiT, the annotation of discourse relations is limited to relations expressed by explicit DCs (coordinating conjunctions, particles, adverbs etc.), other tags between adjacent sentences were not inserted, unlike in some similar projects. Alternative lexicalizations (AltLex) are not annotated in PDiT, their thorough analysis is a recent work in progress. Entity-based relations (EntRel) are, in our view, a matter of coreference and bridging annotation.

### Implicit connectives

Annotation of implicit connectives has been in all known attempts a problematic task, as the IAA numbers are rather low. For implicit connectives (not present on the surface, a DC must be "inferred" from the context), we conducted an experimental annotation of 100 sentences, trying to remove factors known as repeatedly disturbing.<sup>11</sup> The annotators agreed in 49% on type of

<sup>11</sup> The annotation was carried out by two most experienced annotators, the chosen text types were from an accessible domain (cultural event description), the texts were short, up

to 35 sentences each. Another option would be to underspecify the sense hierarchy but we did not do that. Instead, we allowed for labels coref, bridging (=EntRel) and NoRel.

the relation. If only the distinction between *any* discourse relation on one side and coref + bridging relation on the other side was taken into consideration, the agreement was slightly higher – 58%. The most problematic issue revealed to be distinguishing between elaborative relations and relations based only on coreference. The restriction of the annotation only to slots between adjacent sentences was found useful for simplifying the annotation but it did not always match the annotators' intuition where the argument borders should be (e.g. if only the sentence-last dependent clause relates to the following sentence). Although the annotators were able to agree in most cases after discussion, the results convinced us to reconsider the annotation setting for implicit DCs before any future annotation.

Another phenomenon not present in PDiT in comparison with PDTB is attribution. We believe that this information can be at least partially obtained from syntactic features of the syntactic layers of PDT (e.g. attributes for direct speech, parentheses, verbal valency etc.).

## 7 Conclusion

We described the Prague Discourse Treebank 1.0, PDiT 1.0, a large collection of Czech texts that offers a rare combination of manual annotations of discourse relations, textual coreference and bridging anaphora. PDiT 1.0 is an extension of PDT 2.5 and all the annotation presented in this paper was carried out on the dependency trees of the tectogrammatical (deep syntax) layer. It was released in November 2012 under the Creative Commons Attribution-NonCommercial-ShareAlike 3.0 Unported License and it is available at the LINDAT-Clarin repository<sup>12</sup> (Poláková et al., 2012b).

Recently, we focus on extensions of the annotation for the upcoming release of PDT 3.0. A genre classification of the corpus texts for the purposes of data clustering in automatic experiments has been finished. Annotation of alternative lexicalizations (AltLex) and anaphoric expressions of 1st and 2nd person are in progress.

### Acknowledgment

We gratefully acknowledge support from the Grant Agency of the Czech Republic (projects n.

## Abstract

This paper proposes a novel algorithm for multilingual mention detection: we extract mentions from parse trees via kernel-based SVM learning. Our approach allows for straightforward mention detection for any language where (not necessary perfect) parsing resources are available, without any complex language-specific rule engineering. We also investigate possibilities for incorporating automatically acquired mentions into an end-to-end coreference resolution system. We evaluate our approach on the Arabic and Chinese portions of the CoNLL-2012 dataset, showing a significant improvement over the system with the baseline mention detection.

## 1 Introduction

Accurate mention detection (MD) is a vital prerequisite for a variety of Natural Language Processing tasks, in particular, for Relation Extraction (RE) and Coreference Resolution (CR). If a toolkit cannot extract mentions reliably, it will obviously be unable to assign them to relations or entities.

Many studies on RE and CR report evaluation figures on *gold* mentions: in such a setting, a system is supplied with correct mention boundaries and/or semantic classes or other relevant properties. It can, in theory, be argued that such a methodology provides better insights on performance of RE and CR algorithms per se. It has been demonstrated, however, that evaluation results on gold mentions are misleading: for example, Ng (2008) shows that unsupervised CR algorithms exhibit promising results on gold mentions, that are not mirrored in a more realistic evaluation on automatically detected mentions.

The exact scope of the mention detection task varies considerably depending on the annotation

guidelines. Thus, some corpora consider all the (non-embedding) NPs to be mentions, some corpora do not allow for non-referential mentions and some do not mark singleton referential mentions, that do not participate in coreference relations. In addition, some guidelines may restrict the annotation to specific semantic types.

A number of linguistic studies focus on various syntactic, semantic and discourse clues that might help identify nominal constructions that cannot participate in coreference relations. Possible features include, among others, specific syntactic constructions for expletive pronouns, negation, modality and quantification (Karttunen, 1976). Several algorithms have been proposed recently, trying to tackle some of the addressed phenomena within a computational approach. Thus, a number of algorithms have been developed recently to identify expletive usages of “it” (Evans, 2001; Boyd et al., 2005; Bergsma and Yarowsky, 2011). While these approaches are potentially beneficial for mention detection in English, for other languages, neither theoretical nor computational studies are available at the moment. In this paper, we use tree kernels to extract relevant syntactic patterns automatically, without assuming any prior knowledge of the input language.

In this paper, we propose a learning-based solution to the mention detection task. We use SVMs (Joachims, 1999) with syntactic tree kernels (Collins and Duffy, 2001; Moschitti, 2008; Moschitti, 2006) to classify parse tree nodes as  $\pm$ mentions. Our approach does not require any language- or corpus-specific engineering and thus can be easily adapted to cover new languages or mention annotation schemes.

The rest of paper is organized as follows. In the next section, we define the task and discuss our tree and vector representations. Section 4 presents MD evaluation figures. Finally, in Section 5 we incorporate our MD module into an end-to-end

coreference resolution system.

## 2 Related Work

Until recently, most RE and CR toolkits have been evaluated on the ACE datasets (Dodgington et al., 2004). The ACE guidelines restrict possible mentions to be considered to specific semantic types (PERSON, LOCATION and so on). Moreover, mentions are annotated with their minimal and maximal span, allowing for relaxed matching between gold and automatically extracted boundaries. In such a setting, the mention detection task can be cast as a tagging problem, similar to the named entity recognition and classification task. A number of systems have followed this scenario, demonstrating reliable performance (Florian et al., 2004; Ittycheriah et al., 2003; Zitouni and Florian, 2008).

In the past years, however, several corpora have been created from a more linguistic perspective: for example, the OntoNotes dataset (Hovy et al., 2006; Pradhan et al., 2012) provides annotation for unrestricted coreference. The guidelines differ significantly from the ACE scheme: mentions correspond to parse nodes and can be of any semantic type, the systems are expected to recover mention boundaries exactly. The OntoNotes mentions—unlike ACE ones—correspond to large NP structures (embedding NP nodes in gold parse trees), so a traditional approach (e.g., one of those mentioned above), which aims at identifying basic NP chunks, would not be applicable here. Therefore, any MD method for OntoNotes would rely on parsing.

The OntoNotes corpus has been used for evaluating end-to-end CR systems at two CoNLL shared tasks (2011 and 2012). At the 2011 shared task, the participants relied on rule-based modules for extracting mention boundaries from parse trees. This was relatively straightforward, as the task was devoted to CR in English and most participants could use their in-house MD modules developed and refined in the past decade. At the 2012 shared task, however, the systems were expected to provide end-to-end coreference resolution for Arabic and Chinese. As it turned out, most groups could not adapt their MD rules to cover these two languages and fell back to very simple baselines (e.g., “use all NP nodes as mentions”). Kummerfeld et al. (2011) investigated various post- and pre-filtering heuristics for

adapting their mention detection algorithm to the OntoNotes English data in a semi-automatic way, reporting mixed results.

## 3 Mention extraction from parse trees

We recast MD as a *node filtering* task: each candidate node is classified as either mention or not. In this study, we consider all “NP” nodes to be candidates for MD. As Table 1 shows, this is a reasonable assumption for the OntoNotes dataset, as almost 90% of all the mentions for both Arabic and Chinese correspond to NP nodes. The remaining 11-14% of mentions can mostly be attributed to parsing errors: as we aim at end-to-end processing with no gold information available, we run our system on automatically extracted parse trees, it is therefore possible that a mention corresponds to a gold NP node that has not been labeled correctly in an automatic parse tree.

	train		development	
	NP-nodes	%	NP-nodes	%
ARB	24068	87.23	2916	87.91
CHN	88523	85.96	12572	88.52

Table 1: NP-nodes in OntoNotes for Arabic (ARB) and Chinese (CHN): total numbers and percentage of mentions that are NP-nodes.

Not all the NP nodes, however, correspond to a mention. Such non-mention NPs fall into several categories:

- **Embedded NPs.** When an NP is embedded into another one, only the outer NP is used to represent a mention:

$$(1) \quad [MENTION-NP[NP \text{This type}] \text{ of earthquake}] \text{ has no precursors. }^1$$

A number of heuristics have been proposed for English to identify and discard embedded NPs, based on available head-finding algorithms, e.g., (Collins, 1999). For other languages, however, the task of finding a head of a given NP in a constituency tree is not trivial.

- **Non-referential NPs.** Depending on the annotation guidelines, non-referential NPs can

<sup>1</sup>We use English OntoNotes examples throughout this paper to illustrate discussed phenomena, as our approach is language-independent. The evaluation, however, is done on Arabic and Chinese.

either be marked as mentions or not. In OntoNotes, non-referential NPs should not be annotated:

(2) This type of earthquake has [ $NP$ no precursors].

- **Singleton NPs.** In some CR corpora (for example, ACE), mentions are annotated even if they do not participate in any coreference relations. In other corpora (MUC and OntoNotes), such *singletons* are not marked. When singletons are not marked, the MD tasks becomes considerably more difficult: the performance of an MD component cannot be measured and optimized directly, but only in conjunction with a coreference resolver.
- **Erroneous NPs.** When we evaluate an end-to-end system, we expect it to process raw input and thus rely on automatically extracted parse trees. Some NP-nodes might be incorrect, not corresponding to any NP in the gold tree. Such nodes cannot be mentions:

(3) At the meeting, Huang Xiangning read [ $NP$ the earthquake prediction] that they had previously issued.

“The earthquake prediction” is considered to be an NP node by the parser. In the gold data, however, this node does not exist at all. And even if it existed, the mention should correspond to its embedding NP node, “the earthquake prediction that the had previously issued” (cf. example 1 above). While this problem is less crucial for English, parsing resources for other languages are still scarce and less reliable.

### 3.1 Tree Representation

We use kernel-based SVMs to classify nodes as  $\pm$ mentions. This requires representing a relevant fragment of a tree with a specific node marked as “C-NP” (candidate). We start from a straightforward representation: using automatically generated parse trees provided within the CoNLL data distribution, we generate one example for each NP node: the example corresponds to the entire parse tree with just a single node re-labeled as “C-NP”. The assigned class label reflects the fact that this particular node corresponds to some gold mention or not. For example, the full parse tree for our sentence (1-2) will generate one positive (for “This

type of earthquake”, shown on Figure 1) and three negative examples (for “This type”, “earthquake” and “no precursors”).

While this representation might work for our toy example, for a longer sentence it would provide irrelevant information. Consider again the tree on Figure 1. To generate a training example we append “C-” to one NP node, keeping all the remaining nodes as-is. The tree kernel operates on subtrees of the given structure, so, effectively, it will consider a lot of tree fragments that do not contain the marked node. These fragments will affect the treatment of different examples, possibly with conflicting class labels. It will not only make learning slow but also introduce spurious evidence, decreasing the system’s performance. We have therefore investigated two possibilities for pruning our trees.

Our first pruning algorithm (“up-down”) starts from the node of interest (C-NP) and goes up for  $u$  nodes. From each node on the path, it considers all its children up to the depth  $d$ . The first part of Figure 2 shows a pruned tree for  $u = 2, d = 1$  for the node “This type of earthquake.”

Our second pruning algorithm (“radial”) starts from the node of interest and considers all the nodes in the tree that are reachable from it via at most  $n$  edges. The second part of Figure 2 shows a pruned tree for  $n = 2$  for the same node.

### 3.2 Vector Representation

In addition to (pruned) trees, we also provide vector representations of our NPs. For each NP, we extract its basic properties: number, gender, person, mention type (name, nominal or pronoun) and the number of other NPs in the document that have the same surface form. To extract mention properties, we have to compute the head. However, the goal of our study is to provide an MD algorithm that is adaptable to different languages without extensive engineering. We have therefore deliberately relied on an over-simplistic heuristic for finding an NP head: either the last or the first noun in an NP is considered a head, depending on some very basic information on a word order in a specific language. Given the head, we extract its properties from the CoNLL data in a straightforward way (for example, we have compiled a list of pronouns with their gender, number and person values from the training data and so on). This is done fully automatically and doesn’t require any

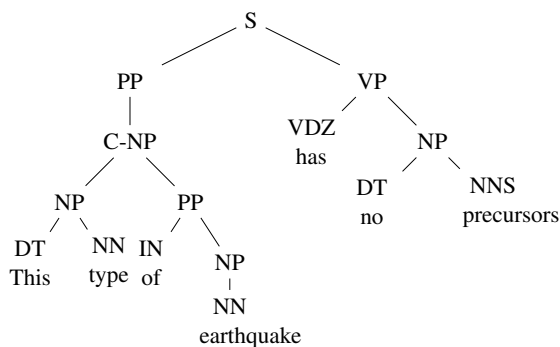

Figure 1: Parse tree for “This type of earthquake”, examples (1-2): before pruning.

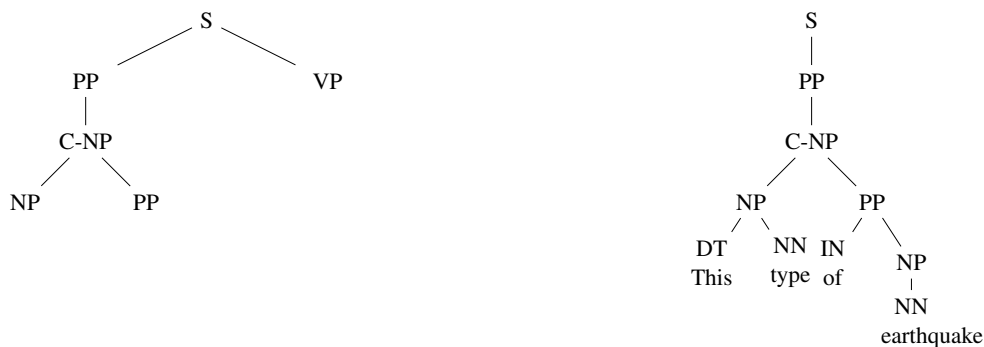

Figure 2: Up-down (left) vs. radial (right) pruning for “This type of earthquake,” examples (1-2)

language-specific manual engineering.

Table 2 lists the features for our vector representation. Nominal values are binarized, leading to 10 binary or continuous features.

feature	possible values
Gender	F,M,Unknown
Definiteness	Yes, No
Number	Sg,Pl,Du,Unknown
MentionType	Name,Nominal,Pronoun
#same-surface NPs in the doc	continuous (normalized)

Table 2: Features used for Mention Detection: each feature describes an individual NP

## 4 Evaluating MD

In this section we provide evaluation results on both Arabic and Chinese. We reserve a small portion of the CoNLL training data (around 20k instances for each language) for training an MD system. Another small subset (around 5k instances) is reserved for fitting the system parameters. The evaluation results are reported on the CoNLL development data. Note that we evaluate the NP-

node classifier, so the system receives no penalty for missing mentions that are not NPs. In Section 5 below, however, we will assess the impact of MD on the end-to-end CR system and thus penalize for missing non-NP mentions.

As a baseline (“all-NP”), we consider all the NP nodes to be mentions. Table 3 below compares this baseline against mentions extracted automatically from different representations. We use Syntactic Tree Kernels (TK) implemented within the SVM-TK toolkit<sup>2</sup> to induce the classification.

As our results suggest, vector representation does not provide enough information for robust mention detection.<sup>3</sup> Indeed, without tree kernels, the system is only able to learn a major class labeling. This highlights the importance of a model that is able to handle structured input, learning relevant patterns directly from parse trees.

As discussed in Section 3 above, full trees contain too much misleading evidence. A single parse tree might contain several dozens of NP nodes, so,

<sup>2</sup><http://disi.unitn.it/moschitti/Tree-Kernel.htm>

<sup>3</sup>As a pilot experiment, we also added bag-of-words features to our vector representations, but this didn’t yield any improvement.

representation	pruning	R	P	F
Arabic				
all-NP	N/A	100	18.0	30.5
vectors	N/A	0	N/A	N/A
trees	-	53.9	45.5	49.4
trees	d=3, u=1	59.5	50.4	54.6
trees	n=2	59.6	64.7	62.0
trees+vectors	d=3, u=1	65.1	52.9	58.4
trees+vectors	n=2	66.0	66.1	66.1
Chinese				
all-NP	N/A	100	27.9	43.6
vectors	N/A	0	N/A	N/A
trees	-	65.0	55.8	60.0
trees	d=1, u=1	73.0	56.9	63.9
trees	n=2	69.7	63.7	66.6
trees+vectors	d=1, u=1	75.6	60.7	67.4
trees+vectors	n=3	71.3	68.9	70.1

Table 3: Performance of the MD classifier on the development set

using a full sentence tree to represent a particular candidate node provides confusing input for the classifier. This is reflected with a low classifier performance on full representations.

Both pruning strategies have resulted in a substantial improvement in the performance level. The radial pruning has significantly outperformed the up-down strategy. Moreover, the radial pruning depends on just one parameter and can therefore be optimized faster.

Finally, joint vector and tree representation further outperforms a plain tree-based model. It must be noted, however, that our MD features (Table 2) require at least some minimal amount of language-specific engineering.

## 5 Incorporating TK-based Mention Detection into an end-to-end coreference resolution system

For our experiments, we use BART – a modular toolkit for coreference resolution that supports state-of-the-art statistical approaches to the task and enables efficient feature engineering (Versley et al., 2008). BART has originally been created and tested for English, but its flexible modular architecture ensures its portability to other languages and domains.

In our evaluation experiments, we follow a very simple model of coreference, namely, the mention-pair approach advocated by Soon et al.

(2001) and adopted in many studies ever since. We believe, however, that more complex models of coreference will also benefit from our MD algorithm: most state-of-the-art CR systems treat mention detection as a preprocessing step that is not affected by further processing and therefore we expect them to yield better performance when such a preprocessing is achieved in a more robust way.

Creating a robust coreference resolver for a new language requires linguistic expertise and language-specific engineering. This cannot and, moreover, should not be avoided by fully language-agnostic methods. Our approach to end-to-end coreference resolution relies on a universal MD component that requires no linguistic engineering – it facilitates the development of coreference resolvers in the narrow sense, by providing them with input mentions. We must stress that the resolvers themselves are not supposed to be universal: in fact, a number of linguistic studies on coreference address various language-specific challenging problems (e.g., zero pronouns, different marking of information status etc).

Below we describe the adjustments we made to BART to cover Arabic and Chinese and then report on our experiments for integrating kernel-based MD into BART to provide an end-to-end coreference resolution for these languages.

### 5.1 Adapting BART to Arabic and Chinese

The modularity of the BART toolkit enables its straightforward adaptation to different languages. This includes creating meaningful linguistic representations of mentions (“mention properties”) and, optionally, some experiments on feature selection and engineering.

We extracted some properties (sentence boundaries, lemmata, speaker id) for Arabic and Chinese directly from the CoNLL/OntoNotes layers<sup>4</sup>. Mention types are inferred from PoS tags.

We compiled lists of pronouns for both Arabic and Chinese from the training and development data. For Arabic, we used gold PoS tags to classify pronouns into subtypes, person, number and gender. For Chinese, no such information is available, so we consulted several grammar sketches and lists of pronouns on the web. Finally, we extracted a list of gender affixes for Arabic along

<sup>4</sup>Recall that all the layers, apart from the Arabic lemma, were computed using state-of-the-art preprocessing tools by the CoNLL organizers and do not contain gold information

with a list of gender-classified lemmata from the training data.

We assessed the list of features, supported by BART, discarding those that require unavailable information (for example, the `aliasing` feature relies on semantic types for named entities that are not available within the CoNLL/OntoNotes distribution for languages other than English). We also created two additional features: `LemmataMatch` (similar to string match, but uses lemmata instead of tokens) and `NumberAgreementDual` (similar to commonly used number agreement features, but supports dual number). Both features are expected to provide important information for coreference in Arabic, a morphologically rich language.

We ran a feature selection experiment to further remove irrelevant features (BART were only tested on European languages, thus several features reflected patterns more common for Germanic and Romance languages). This resulted in two feature sets, one for each language, listed in Table 4. For comparison, we also show the baseline features (cf. below).

## 5.2 Incorporating Kernel-based MD into a Coreference Resolver

Coreference resolution systems have different tolerance for precision and recall MD errors. If a spurious mention is introduced, the CR system might still assign it to no coreference chain and thus discard from the output partition. If a correct mention is missed, however, the system has no chance of recovering it as it does not even start processing such a mention. This suggests that an MD module should be tuned to yield better recall.

To assess the impact of MD precision and recall errors on the performance of our coreference resolver, we run a simulation experiment. We start from the upper bound baseline: the MD module considers all the true (gold) NP mentions to be positive and all the spurious ones – to be negative. We then randomly distort this baseline, adding spurious mentions and removing correct ones, to arrive at a predefined performance level. The resulting MD output is then sent to our coreference resolution system and its performance is measured. As a measure of the CR system performance, we use the MELA F-score – an average of MUC,  $B^3$  and  $CEAF_e$  metrics, the official performance measure at the CoNLL shared task (Pradhan et al., 2012).

Figure 3 shows the results of our simulation experiment on the development data. Each line on the figure corresponds to a single MD recall level (varying from 100% to 70%). On the horizontal axis, we plot the MD precision (from 10% to 100%) and on the vertical axis – the end-to-end system MELA F-score. The curves support our intuition that reliable MD recall is crucial for coreference: when the MD recall drops to around 70%, the MELA score remains at the baseline level even for very high MD precision. It must be noted that our simulation experiment relies on an unrealistic assumption: we assume all the errors to be independent. In a more practical setting, the MELA F-score for a given combination of MD precision and recall can be higher, because the coreference system might fail to resolve the same NPs that are problematic for the MD module. Nevertheless, the curves illustrate the fact that any MD module should be strongly biased towards recall in order to be useful for coreference resolution.

We therefore reran our optimization experiments to fit more parameters of the MD module. Recall from Section 4 that we already used a small amount of CoNLL training data to fit our  $d$ ,  $u$  and  $n$  values. We expanded the set of parameters, using the end-to-end performance (MELA F-score) to select optimal values on the same subset. Table 5 lists all the parameters of our MD module.

d, u	up-down pruning thresholds
n	radial pruning threshold
j	precision-recall trade-off (SVM-TK)
c	cost factor (SVM-TK)
s	size of MD vs. CR data splits
r	tree vs. tree+vector representation

Table 5: Parameters optimized on a held-out data

Our experiments reveal that, indeed, a recall-oriented version of our MD classifier yields the most reliable end-to-end resolution. Table 6 shows the MD performance of the best classifier selected according to the MELA score. While the F-scores of these biased classifiers are, obviously, much lower than their unbiased counterparts, they still manage to filter out a substantial amount of noun phrases, at the same time maintaining a very high recall level.

Finally, Tables 7 and 8 show the MELA score of BART on the CoNLL-2012 development and test sets respectively. To evaluate the impact of our

feature		Baseline	Arabic	Chinese
StringMatch	$M_i$ and $M_j$ have the same surface form	+	+	+
MentionType	relevant types of $M_i$ and $M_j$ , (cf. Soon et al.)	+	+	+
GenderAgree	$M_i$ and $M_j$ agree in gender	+	+	+
NumberAgree	$M_i$ and $M_j$ agree in number	+		+
NumberAgreeDual	-*- , supports dual number		+

Table 4: Features used for Coreference Resolution in Arabic and Chinese: each feature describes a pair of mentions  $\{M_i, M_j\}$ ,  $i < j$ , where  $M_i$  is a candidate antecedent and  $M_j$  is a candidate anaphor

kernel-based MD (TKMD), we compare its performance against two baselines. The lower bound, "all-NP", considers all the NP-nodes in a parse tree to be candidate mentions. The upper bound, "gold-NP" only considers gold NP-nodes to be candidate mentions. Note that the upper bound does not include mentions that do not correspond to NP-nodes at all (around 12% of all the mentions in the development data, cf. Table 1 above).

Tables 7 and 8 also show the performance level of BART's rule-based MD module that was developed for English. Although this heuristic has proved reliable on the English data, for example, at the CoNLL 2011 and 2012 shared tasks, it is not robust enough to be ported as-is to other languages: indeed, the performance of the heuristic MD on Arabic and Chinese is lower than the all-NP baseline. This highlights the importance of a learning-based approach: while rule-based MD shows good results for English, we cannot expect spending ten more years on designing similar systems for other languages.

	R	P	F
Arabic	90.67	31.07	46.28
Chinese	98.37	38.27	55.1

drastically when one shifts from a realistic evaluation (the "all-NP" baseline) to gold NP mentions. Kernel-based MD is able to recover part of this difference, providing significant improvements over the baseline (t-test on individual documents,  $p < 0.05$ ).

Another important point is the difference between our basic feature set and more specific features (cf. Table 4). The contribution of extra features is relatively small and not significant, which is not surprising given the fact that all of them are very naive and do not address any coreference-

Figure 3: Performance of an end-to-end coreference resolution system for different values of MD Recall and Precision in a simulation experiment: MELA F-score on the Arabic and Chinese development data.

related phenomena specific for Arabic and Chinese. However, the extra features help more when the MD improves. This suggests that a robust MD module is an essential prerequisite for further work on coreference in new languages: a more accurate set of mentions provides a better testbed for manually engineered language-specific features or constraints.

## 6 Conclusion and Future Work

In this paper we have investigated possibilities for language-independent mention detection based on syntactic tree kernels. We have shown that a kernel-based approach can provide a robust pre-processing system that is a vital prerequisite for fast and efficient development of end-to-end multilingual coreference resolvers.

We have evaluated different tree and vector representations, showing that the best performance is

achieved by applying radial pruning to parse trees and augmenting the resulting representation with feature vectors, encoding very basic and shallow properties of candidate NPs.

We have investigated possibilities of incorporating our MD module to an end-to-end coreference resolution system. Our evaluation results show significant improvement over the system relying on the “all-NP” baseline for both Arabic and Chinese. It should be stressed that no other baseline is available without using deep linguistic expertise.

In the future, we plan to follow two directions to further improve our algorithm. First, we want to consider more global models of MD, providing joint inference over sets of NP nodes, and, possibly, incorporating CR predictions as well. Several studies (Daume III and Marcu, 2005; Denis and Baldridge, 2009) followed this direction recently, showing promising results for joint MD and CR modeling.

Second, we want to combine our learning-based MD with more traditional heuristic systems. While our approach provides a fast reliable testbed and allows CR researchers to specifically focus on coreference, rule-based MD modules have been created for a variety of languages, especially for European ones, in the past decade. We believe that by combining such systems with our kernel-based algorithm, we can build MD modules that show a high performance level and, at the same time, are more robust and portable to different domains and corpora.

## Abstract

Social streams have proven to be the most up-to-date and inclusive information on current events. In this paper we propose a novel probabilistic modelling framework, called violence detection model (VDM), which enables the identification of text containing violent content and extraction of violence-related topics over social media data. The proposed VDM model does not require any labeled corpora for training, instead, it only needs the incorporation of word prior knowledge which captures whether a word indicates violence or not. We propose a novel approach of deriving word prior knowledge using the relative entropy measurement of words based on the intuition that low entropy words are indicative of semantically coherent topics and therefore more informative, while high entropy words indicates words whose usage is more topical diverse and therefore less informative. Our proposed VDM model has been evaluated on the TREC Microblog 2011 dataset to identify topics related to violence. Experimental results show that deriving word priors using our proposed relative entropy method is more effective than the widely-used information gain method. Moreover, VDM gives higher violence classification results and produces more coherent violence-related topics compared to a few competitive baselines.

## 1 Introduction

Social media and in particular Twitter has proven to be a faster channel of communication when compared to traditional news media, as we have witnessed during events such as the Middle East revolutions and the 2011 Japan earthquake; acting as social sensors of real-time events (Sakaki et al., 2010). Therefore the identification of topics discussed in these channels

could aid in different scenarios including violence detection and emergency response. In particular the task of classifying tweets as violence-related poses different challenges including: high topical diversity; irregular and ill-formed words; event-dependent vocabulary characterising violence-related content; and an evolving jargon emerging from violent events.

Indeed, machine learning methods for classification present difficulty on short texts (Phan et al., 2008). A large body of work has been proposed for the task of topic classification of Tweets (Milne and Witten., 2008; Gabrilovich and Markovitch, 2006; Genc et al., 2011; Muñoz García et al., 2011; Kasiviswanathan et al., 2011; Meij et al., 2012). Recent approaches have also been proposed (Michelson and Macskassy, 2010; Cano et al., 2013), to alleviate microposts sparsity by leveraging existing social knowledge sources (e.g Wikipedia). However, while the majority of these approaches rely on supervised classification techniques, others do not cater for the violence detection challenges. To the best of our knowledge very few have been devoted to violent content analysis of Twitter, and none has carried out deep violence-related topic analysis. Since violence-related events tend to occur during short to medium life spans, traditional classification methods which rely on labelled data can rapidly become outdated. Therefore in order to maintain tuned models it is necessary the continuous learning from social media in order to capture those features representing violent events. Indeed, the task of violence classification demands more efficient and flexible algorithms that can cope with rapidly evolving features. These observations have thus motivated us to apply unsupervised or weakly supervised approaches for domain-independent violence classification.

Another shortcoming of previous classification approaches is that they only focus on detecting the overall topical category of a document. However they do not perform an in-depth analysis to discover the latent topics and the associated document category.

When examining violence-related data, analysts are not only interested in the overall violence of one particular tweet but on the understanding of the type of emerging violence-related events. For example the word “killing” may have a violent-related orientation as in “mass killing” while it has a non-violent one in “killing time”. Therefore, detecting topic and violence-relatedness simultaneously should serve as a critical function in helping analysts by providing more informative violence-related topic mining results.

In this paper, we introduce the Violence Detection Model (VDM), which focuses on document-level violence classification for general domains in conjunction with topic detection and violence-related topic analysis. The model extends the Latent Dirichlet Allocation (LDA) (Blei et al., 2003) by adding a document category (violent or non-violent) layer between the document and the topic layer. It is related to the joint sentiment-topic (JST) model for simultaneous sentiment and topic detection (Lin and He, 2009; Lin et al., 2012). However, while JST assumes the per-document sentiment-topic distributions, VDM only has a single document category-topic distribution shared across all the documents. This is because tweets are short compared to typical review documents and hence modelling per-tweet category-topic distribution could potentially generate less coherent topics. In VDM, we also assume that words are generated either from a category-specific topic distribution or from a general background model. This helps reducing the effects of background words and learn a model which better captures words concentrating around category-specific topics. As will be discussed later, VDM outperforms JST in both violence detection from tweets and topic coherence measurement. Furthermore, while JST incorporates word prior sentiment knowledge from existing sentiment lexicons, we propose a novel approach to derive word prior knowledge based on the relative entropy measurement of words.

We proceed with related work on topic classification on Twitter. Since the Bayesian model studied here is closely related to the LDA model, we also review existing approaches of incorporating supervised information into LDA training. We then present our proposed VDM model and describe a novel approach of deriving word priors using relative entropy from DBpedia<sup>1</sup> articles and tweets annotated using OpenCalais<sup>2</sup>. Following that, we present the dataset used in the paper and discuss experimental results obtained in comparison to a few baselines. Finally, we conclude the paper.

## 2 Related Work

The task of detecting violent-related tweets can be viewed as a topical classification (TC) problem in which a tweet is labelled either as violent or non-violent related. Since the annotation of Twitter content is costly, some approaches have started to explore the incorporation of features extracted from external knowledge sources (KS) and the use of unsupervised or semi-supervised approaches to solve the TC problem. Since the model proposed in this paper makes use of both external KSs and topic models, we have divided the review of related work into approaches which rely on external KSs and approaches based on LDA model learning.

In the first case, Genc et al. (2011) proposed a latent semantic topic modelling approach, which mapped a tweet to the most similar Wikipedia<sup>3</sup> articles based on the tweets’ lexical features. Song et al. (2011) mapped a tweet’s terms to the most likely resources in the Probbase KS. These resources were used as additional features in a clustering algorithm which outperformed the simple bag of words approach. Munoz et al. (2011) proposed an unsupervised vector space model for assigning DBpedia URIs to tweets in Spanish. They used syntactical features derived from PoS (part-of-speech) tagging, extracting entities using the Sem4Tags tagger (Garcia-Silva et al., 2010) and assigning DBpedia URIs to those entities by considering the words appearing in the context of an entity inside the tweets. In contrast to these approaches, rather than labelling a tweet with KS URIs, we make use of DBpedia violence-related articles as one possible source of information from which prior lexicons can be derived.

Recently, Cano et al. (2013) proposed a supervised approach which makes use of the linked structure of multiple knowledge sources for the classification of Tweets, by incorporating semantic metagraphs into the feature space. However, in this study rather than extending the feature space with DBpedia derived features, we propose a strategy for characterising Violence related topics through the use of relative entropy, which filters out irrelevant word features. Moreover the proposed VDM model not only classifies documents as violent-related but also derives coherent category-topics (collection of words labelled as violent-related and non-violent related).

Our VDM model incorporates word prior knowledge into model learning. Here, we also review existing approaches for the incorporation of supervised information into LDA model learning. The supervised LDA (sLDA) (Blei and McAuliffe, 2008) uses empirical topic frequencies as a covariant for

<sup>3</sup><http://wikipedia.org>

a regression on document labels such as movie ratings. The Dirichlet-multinomial regression (DMR) model (Mimno and McCallum, 2008) uses a log-linear prior on document-topic distributions that is a function of observed meta data of the document. Labeled LDA (Ramage et al., 2009) defines a one-to-one correspondence between LDA’s latent topics and observed document labels and utilize a transformation matrix to modify Dirichlet priors. Partially Labeled LDA (PLDA) extends Labeled LDA to incorporate per-label latent topics (Ramage et al., 2011). The DF-LDA model (Andrzejewski et al., 2009) employs must-link and cannot-link constraints as Dirichlet Forest priors for LDA learning, but it suffers the scalability issue. Most recently, the aspect extraction model for sentiment analysis (Mukherjee and Liu, 2012) assumes that a seed set is given which consists of words together with their respective aspect category. Then depending on whether a word is a seed or non-seed word, a different route of multinomial distribution will be taken to emit the word. Our work was partially inspired by the previously proposed joint sentiment-topic model (JST) (Lin and He, 2009; Lin et al., 2012), which extracts topics grouped under different sentiments, relying only on domain-independent polarity word prior information.

While the afore-mentioned approaches assume the existence of either document label information or word prior knowledge, we propose to learn word prior knowledge using relative entropy from DBpedia and tweets annotated using OpenCalais. Moreover the proposed VDM model relies on the assumptions that the document category-topic distribution is shared across all documents in a corpus and words are generated either from a category-specific topic distribution or from a general background distribution. As we will discuss in section 5 these assumptions along with the proposed strategies for prior lexicon derivation show promising results outperforming various other topic models.

### 3 Violence Detection Model (VDM)

We propose a weakly-supervised violence detection model (VDM) here. In this model violence labels are associated with documents, under which topics are associated with violence labels and words are associated with both violence labels and topics. The graphical model of VDM is shown in Figure 1.

Assume a corpus of  $D$  documents denoted as  $\mathcal{D} = \{d_1, d_2, \dots, d_D\}$ ; where each document consists of a sequence of  $N_d$  words denoted by  $d = (w_1, w_2, \dots, w_{N_d})$ ; and each word in a document is an item from a vocabulary index of  $V$  different terms denoted by  $1, 2, \dots, V$ . We also assume that when an author writes a tweet message, she first decides whether

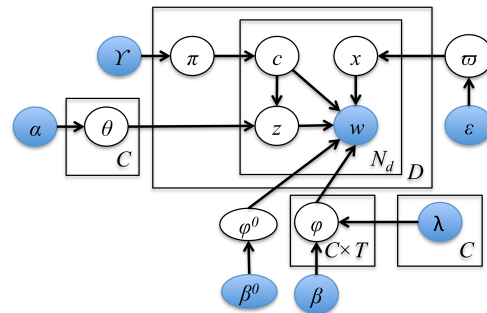

Figure 1: Violence detection model (VDM).

the tweet is violent-related or not. We use a category variable  $c$  to indicate violent-related topics or non-violent topics. If  $c = 0$ , the tweet is non-violent and the tweet topic is drawn from a general topic distribution  $\theta_0$ . If  $c = 1$ , the tweet is violent-related and the tweet topic is drawn from a violent category specific topic distribution  $\theta_1$ . Finally, each word of the tweet message is generated from either the background word distribution  $\phi^0$ , or the multinomial word distribution for the violent-related topics  $\phi_{c,z}$ . The generative process of VDM is shown below.

- Draw  $\omega \sim \text{Beta}(\epsilon), \varphi^0 \sim \text{Dirichlet}(\beta^0), \varphi \sim \text{Dirichlet}(\beta)$ .
- For each tweet category  $c = 1, \dots, C$ ,
  - for each topic  $z$  under the tweet category  $c$ , draw  $\theta_{cz} \sim \text{Dirichlet}(\alpha)$ .
- For each document  $m \in \{1..D\}$ ,
  - draw  $\pi_m \sim \text{Dirichlet}(\gamma)$ ,
  - For each word  $n \in \{1..N_d\}$  in document  $m$ ,
    - \* draw  $x_{m,n} \sim \text{Multinomial}(\omega)$ ;
    - \* if  $x_{m,n} = 0$ ,
      - draw a word  $w_{m,n} \sim \text{Multinomial}(\varphi^0)$ ;
    - \* if  $x_{m,n} = 1$ ,
      - draw a tweet category label  $c_{m,n} \sim \text{Multinomial}(\pi_m)$ ,
      - draw a topic  $z_{m,n} \sim \text{Multinomial}(\theta_{c_{m,n},n})$ ,
      - draw a word  $w_{m,n} \sim \text{Multinomial}(\varphi_{c_{m,n},z_{m,n}})$ .

We have a latent random variable  $x$  associated with each word token and acts as a switch. If  $x = 0$ , words are generated from a background distribution. If  $x = 1$ , words are sampled from the corpus-specific multinomial  $\varphi_{c,z}$  decided by the tweet category label (non-violent or violent)  $c$  and the tweet topic  $z$ .

#### 3.1 Model Inference

We use Collapsed Gibbs Sampling (Griffiths and Steyvers, 2004) to infer the parameters of the model and the latent violent categories and topics assignments for tweets, given observed data  $\mathcal{D}$ . Gibbs sampling is a Markov chain Monte Carlo method which

allows us to repeatedly sample from a Markov chain whose stationary distribution is the posterior of interest, switch variable  $x$ , category label  $c$ , and topic  $z$  here, from the distribution over that variable given the current values of all other variables and the data. Such samples can be used to empirically estimate the target distribution. Letting the index  $t = (m, n)$  denote  $n^{\text{th}}$  word in document  $m$  and the subscript  $-t$  denote a quantity that excludes data from  $n^{\text{th}}$  word position in document  $m$ , the conditional posterior for  $x_t$  is:

$$P(x_t = 0 | \mathbf{x}_{-t}, \mathbf{c}, \mathbf{z}, \mathbf{w}, \Lambda) \propto \frac{\{N_m^0\}_{-t} + \epsilon}{\{N_m\}_{-t} + 2\epsilon} \times \frac{\{N_{w_t}^0\}_{-t} + \beta^0}{\sum_{w'} \{N_{w'}\}_{-t} + V\beta^0}, \quad (1)$$

where  $N_m^0$  denotes the number of words in document  $m$  assigned to the background component,  $N_m$  is the total number of words in document  $m$ ,  $N_{w_t}^0$  is the number of times word  $w_t$  is sampled from the background distribution.

$$P(x_t = 1 | \mathbf{x}_{-t}, \mathbf{c}, \mathbf{z}, \mathbf{w}, \Lambda) \propto \frac{\{N_m^s\}_{-t} + \epsilon}{\{N_m\}_{-t} + 2\epsilon} \times \frac{\{N_{w_t}^s\}_{-t} + \beta}{\sum_{w'} \{N_{w'}\}_{-t} + V\beta}, \quad (2)$$

where  $N_m^s$  denotes the number of words in document  $m$  sampled from the category-topic distributions,  $N_{w_t}^s$  is the number of times word  $w_t$  is sampled from the category-topic specific distributions.

The conditional posterior for  $c_t$  and  $z_t$  is:

$$P(c_t = k, z_t = j | \mathbf{c}_{-t}, \mathbf{z}_{-t}, \mathbf{w}, \Lambda) \propto \frac{N_{d,k}^{-t} + \gamma}{N_d^{-t} + C\gamma} \cdot \frac{N_{d,k,j}^{-t} + \alpha_{k,j}}{N_{d,k}^{-t} + \sum_j \alpha_{k,j}} \cdot \frac{N_{k,j,w_t}^{-t} + \beta}{N_{k,j}^{-t} + V\beta}, \quad (3)$$

where  $N_{d,k}$  is the number of times category label  $k$  has been assigned to some word tokens in document  $d$ ,  $N_d$  is the total number of words in document  $d$ ,  $N_{d,k,j}$  is the number of times a word from document  $d$  has been associated with category label  $k$  and topic  $j$ ,  $N_{k,j,w_t}$  is the number of times word  $w_t$  appeared in topic  $j$  and with category label  $k$ , and  $N_{k,j}$  is the number of words assigned to topic  $j$  and category label  $k$ .

Once the assignments for all the latent variables are known, we can easily estimate the model parameters  $\{\pi, \theta, \varphi, \varphi^0, \omega\}$ . We set the symmetric prior  $\epsilon = 0.5$ ,  $\beta_0 = \beta = 0.01$ ,  $\gamma = (0.05 \times L)/C$ , where  $L$  is the average document length,  $C$  is the total number of category labels, and the value of 0.05 on average allocates 5% of probability mass for mixing. The asymmetric prior  $\alpha$  is learned directly from data using maximum-likelihood estimation (Minka, 2003)

and updated every 40 iterations during the Gibbs sampling procedure. We run Gibbs sampler for 1000 iterations and stop the iteration once the log-likelihood of the training data converges under the learned model.

### 3.2 Deriving Model Priors through Relative Entropy

Detecting violence and extremism from text closely relates to sentiment and affect analysis. While sentiment analysis primarily deals with positive, negative, or neutral polarities, affect analysis aims to map text to much richer emotion dimensions such as joy, sadness, anger, hate, disgust, fear, etc. In the same way violence analysis maps violence polarity into violence words such as looting, revolution, war, drugs and non-violent polarity to background words such as today, happy, afternoon. However, as opposed to sentiment and affect prior lexicon derivation, the generation of violence prior lexicons pose different challenges. While sentiment and affect lexicon, rarely changes in time, words relevant to violence tend to be event dependent.

In this section we introduce a novel approach for deriving word priors from social media, which is based on the measurement of the relative entropy of a word in a corpus. Assume a source corpus consisting of  $N$  documents denoted as  $\mathcal{SD} = \{\mathbf{sd}_1, \mathbf{sd}_2, \dots, \mathbf{sd}_N\}$ , where each document is labelled as not violent or violent. We define the following metrics:

1. **Corpus Word Entropy:** The entropy of word  $w$  in corpus  $\mathcal{SD}$  is measured as follows:

$$E_{SD}(w) = - \sum_{i=1}^N p(w | \mathbf{sd}_i) \log p(w | \mathbf{sd}_i), \quad (4)$$

where  $p(w | \mathbf{sd}_i)$  denotes the probability of word  $w$  given the document  $\mathbf{sd}_i$  and  $N$  the total number of documents.  $E_{SD}(w)$  captures the dispersion of the usage of word  $w$  in the corpus. Our intuition is that low entropy words are indicative of semantically coherent topics and therefore more informative, while high entropy words indicates words whose usage is more topical diverse and therefore less informative.

2. **Class Word Entropy:** The entropy of word  $w$  given the class label  $c$  is defined as follows:

$$E_{CWE}(w, c) = - \sum_{i=1}^N p(w | \mathbf{sd}_i^c) \log p(w | \mathbf{sd}_i^c), \quad (5)$$

where  $C$  denotes the number of classes (in our case violent and non-violent) and  $p(w | \mathbf{sd}_i^c)$  denotes the probability of word  $w$  given the document  $\mathbf{sd}_i$  in class  $c$ . In contrast to the general  $E_{SD}$ , the class word entropy characterises the usage of a word in a particular document class.

3. **Relative Word Entropy (RWE)**: In order to compare the word entropy used on documents in different categories, we measure the word relative entropy as follows:

$$RWE(w, c) = \frac{E_{CWE}(w, c)}{E_{SD}(w)} \quad (6)$$

The RWE provides information on the relative importance of that word to a given document class.

After deriving the RWE of each word given a class (i.e. violent or non-violent), we sorted words based on their RWE values in ascending order. Since our intuition is that lower entropy levels are more indicative of semantically coherent topics we choose the top  $K$  words of each class. We then built a matrix  $f$  of size  $K \times C$ , where  $C$  is the total number of document classes or category labels. The  $k$ th entry stores the probability that feature  $k$  is assigned with category label  $c$ . The matrix  $f$  essentially captures word prior knowledge and can be used to modify the Dirichlet prior  $\beta$  of category-topic-word distributions. We initialize each element of the matrix  $\beta$  of size  $C \times T \times V$  to 0.01 and then perform element-wise multiplication between  $\beta$  and  $f$  with the topic dimension ignored.

## 4 Experimental Setup

### 4.1 Dataset Description

The experimental setup consists of three stages: 1) derivation of word prior lexicon; 2) training of VDM and baselines; and 3) testing. For the first stage, we explored three different ways to construct a labelled document corpora for deriving prior lexicons. The first one is based on a Twitter corpus labelled using OpenCalais. This corpus comprises over 1 million tweets collected over a period of two months starting from November 2010. In order to build the Twitter-based violent dataset for deriving priors, we extracted tweets labelled as “War & Conflict” and considered them as violent annotations, while for the non-violent annotations we considered tweets annotated with labels other than this one (e.g. Education, Sports). We denote this dataset as **TW**. It is worth noting that the annotated results generated by OpenCalais are very noisy. We have evaluated OpenCalais on our manually annotated test set and only obtained an F-measure of 38%. Nevertheless, as will be seen later, word prior knowledge extracted from such noisy annotated tweets data is still very helpful in learning the VDM model for violence detection from tweets.

The second dataset for deriving priors is based on DBpedia which is a knowledge source derived from Wikipedia. The latest version of DBpedia consists of over 1.8 million resources, which have been classified

into 740 thousand Wikipedia categories, and over 18 million YAGO<sup>4</sup> categories. For constructing the violence related corpus we queried DBpedia for all articles belonging to categories and subcategories under the “violence” category, from which we kept their abstract as the document content. After removing those categories with less than 1000 articles, we obtained a set of 28 categories all related to violence. The resulting set of articles represented the violent set while for the non-violent rather than using non-violent related articles from DBpedia we opted for using the collection of Tweets from **TW** annotated as non-violent by OpenCalais. This decision was made in order to balance differences across the DBpedia and Twitter lexicons. This resulting dataset is referred to as **DB**.

Since the average word per article abstract in DBpedia exceeds the one of tweets, we decided to build a third dataset where the violent DBpedia documents resemble tweets in their size. In order to do so, we took into account that the average number of words per tweet in **TW** before preprocessing is 9.6. Then from each violent document in the **DB** dataset, we generated tweet size documents by chunking the abstracts into 9 or less words. We then combine the chunked documents from **DB** with **TW** and refer to the final dataset as **DCH**.

These datasets were used for deriving priors for the first stage. For the second stage, we built a training set of tweets derived from the TREC Microblog 2011 corpus<sup>5</sup>, which comprises over 16 million tweets sampled over a two week period (January 23rd to February 8th, 2011). This time period includes 49 different events including violence-related ones such as Egyptian revolution, and Moscow airport bombing, and non-violence related such as the Super Bowl seating fiasco. We sampled a subset of 10,581 tweets as our training set and manually annotated another 1,759 tweets as our test set. Details about the statistics of the training and testing datasets are presented in Table 1 under the label “Main Dataset”.

We preprocessed the described datasets by first removing: punctuation, numbers, non-alphabet characters, stop words, user mentions, links and hashtags. We then performed Lovins stemming in order to reduce the vocabulary size. Finally to address the issue of data sparseness, we removed words with a frequency lower than 5.

### 4.2 Deriving Model Priors

We derive word prior knowledge from the three datasets mentioned above, namely **TW**, **DB** and **DCH**; applying the relative word entropy (RWE)

<sup>4</sup><http://www.mpi-inf.mpg.de/yago-naga/yago/>

<sup>5</sup><http://trec.nist.gov/data/tweets/>

	Datasets for Priors		
	TW	DB	DCH
Vio	10,432	4,082	32,174
Non-Vio	11,411	11,411	11,411
	Main Dataset		
	Training Set	Testing Set	
Vio	10,581	759	
Non-Vio		1000	

Table 1: Document statistics of the datasets used for deriving prior lexicons and for training and testing the proposed model and baselines.

approach introduced in section 3.2 for word prior lexicon generation. For comparison purposes, we also employ the widely-used information gain (IG) method to select highly discriminative words under each class from the datasets. Table 2 presents the word statistics of the prior lexicons generated using these two different methods<sup>6</sup>. It worth noting that **DB** consists of 4,082 violent-related documents (DBpedia abstracts) and 11,411 non-violent documents (non-violent tweets). Since the average word per abstract is much larger in size than the one of a tweet, having a very low number of non-violent features selected using IG is expected as the violence class is over represented per violent document. This is the reason why we built another dataset by chunking the DBpedia abstracts to produce tweet-size documents (**DCH**). Having a balanced number of words per document in both violent and non-violent categories leads to more balanced priors, as shown in Table 2, where the number of non-violent features increased from 99 (in **DB**) to 1,345 (in **DCH**) using IG.

	IG			RWE		
	TW	DB	DCH	TW	DB	DCH
Vio	1,249	2,899	1,612	875	3,388	3,786
Non-Vio	1,749	99	1,345	2,595	879	2,438

Table 2: Statistics of the word prior lexicons.

### 4.3 Baselines

For comparison purposes, we have tested the following baselines:

**Learned from labelled features.** The word prior knowledge can be used as labelled feature constraints which can be incorporated into a MaxEnt classifier training with Generalized Expectation (GE) con-

<sup>6</sup>While the number of words selected for IG was set to 3000, the criteria for selecting the top  $K$  words in the RWE approach was based on taking the highest coherent level of entropy containing more than 5 words. Then from the sorted list of words we selected those whose entropy was smaller than this level.

straints (Druck et al., 2008) or Posterior Regularization (PR) (Ganchev et al., 2010). We use the implementation provided in MALLETT with default parameter configurations for our experiments and refer these two methods as *ME-GE* and *ME-PR* respectively.

**JST.** If we set the number of sentiment classes to 2 (violent or non-violent), then we can learn the Joint Sentiment-Topic (JST) model from data with the word prior knowledge incorporated in a similar way as the VDM model.

**PLDA.** The Partially-Labeled LDA (PLDA) (Ramage et al., 2011) model assumes that some document labels are observed and models per-label latent topics. It is somewhat similar to JST and VDM except that supervised information is incorporated at the document level rather than at the word level. The training set is labelled as violent or non-violent using OpenCalais. Such pseudo document labels are then incorporated into PLDA for training.

The hyperparameters of PLDA and JST are set to be the same as those for VDM.

## 5 Experimental Results

In this section we compare the overall classification performance of VDM and a set of proposed baselines. We performed a series of experiments to investigate the impact of the prior derivation strategies (RWE and IG) on classification performance, using the six prior lexicons introduced in Section 4.2. Some of the research questions addressed in this section are as follows: Do lexicons built from DBpedia contain useful features which can be applied for the violence classification of Tweets?; If so, to what extent these lexicons help the classification task?. We also present the overall evaluation of the proposed VDM against the proposed baselines based on the semantic coherence of the generated topics. All the experiments reported here were conducted using a 5 fold 3 trial setting.

### 5.1 Violence Classification Results vs. Different Word Priors

Table 3 compares the results obtained for violence classification for the proposed VDM model against the baselines, using prior lexicons derived with the proposed RWE strategy and the IG baseline approach. We can observe that although both *ME-GE* and *ME-PR* present a very high precision for word priors obtained from **TW** regardless using either IG or RWE, they also present a very low recall. This indicates that although the documents labelled as “violent” with these models were correctly identified, much of the rest of the violent documents in the testing set remained unidentified. We can also observe that the best results in terms of F-measure were obtained for the VDM model using the word priors derived from **TW** using RWE, which significantly outper-

	Prior	ME-GE			ME-PR			JST			VDM		
		<i>P</i>	<i>R</i>	<i>F1</i>	<i>P</i>	<i>R</i>	<i>F1</i>	<i>P</i>	<i>R</i>	<i>F1</i>	<i>P</i>	<i>R</i>	<i>F1</i>
IG	TW	0.7737	0.0337	0.0646	0.6300	0.1034	0.1777	0.6939	0.9362	0.7969	0.75	0.9288	0.8297
	DB	0.4604	0.9704	0.6245	0.5634	0.6955	0.4773	0.6493	0.9228	0.7622●	0.6455	0.9141	0.7566
	DCH	0.4862	0.2447	0.3255	0.5680	0.2949	0.3274	0.7113	0.9291	0.8057	0.7575	0.92	0.8309
RWE	TW	0.7100	0.1342	0.2249	0.9125	0.0373	0.0717	0.7235	0.9296	0.8136	0.8258	0.8919	0.8575
	DB	0.4958	0.1844	0.2686	0.5303	0.0540	0.0981	0.6882	0.9421	0.7952	0.7024	0.9212	0.7969
	DCH	0.5161	0.1731	0.2588	0.8485	0.0091	0.0179	0.73	0.9351	0.8199	0.8189	0.8804	0.8484

Table 3: The performance of the classifiers using prior features derived from TW, DB and DCH ( $dbp + tw$ ). The number of topics is set to 5 for JST and VDM. The values highlighted in bold corresponds to the best results obtained in F-measure, while the shaded cells indicate the best results in F-measure for each scenario. Blank notes denotes that the F-measure of VDM significantly outperforms the baselines while ● denotes JST outperforms VDM. Significance levels:  $p$ -value  $< 0.01$

forms the baseline models ( $t$ -test with  $\alpha < 0.01$ ). To compare VDM against JST, we varied the topics  $T \in \{1, 5, 10, 15, 20, 25, 30\}$  and our significance test results revealed that VDM outperforms JST significantly ( $t$ -test with  $\alpha < 0.01$ ) over all the topic settings except for the JST using **DB** lexicon priors.

When comparing the effectiveness of the use of DBpedia as a source of prior lexicon, we can observe that the use of the full articles’ abstracts in the derivation of the prior lexicons **DB** did not present an improvement over the models based on Twitter derived lexicons (**TW**). However, the strategy of chunking DBpedia articles’ abstracts into tweet size documents (**DCH**), did help in boosting the overall F-measure in JST ( $t$ -test with  $\alpha < 0.05$ ). In the case of VDM, the use of **DCH** achieved an F-measure very close to the one obtained using Twitter prior lexicons (**TW**).

When comparing the effectiveness of the proposed RWE strategy against the IG baseline for deriving prior lexicons, we can observe that RWE consistently outperformed in F-measure for the JST and VDM models on all the three prior lexicon scenarios with the improvement ranging between 1-4% although it fails to boost F-measure on both ME-GE and ME-PR.

In the subsequent experiments, we incorporated word prior knowledge extracted from **TW** using our proposed RWE method.

## 5.2 Varying Number of Topics

We compare the violence classification accuracy of our proposed VDM model against PLDA and JST with different topic number settings. It can be observed from Figure 2 that with single topic setting, all the three models give a similar violence classification results. However, when increasing the number of topics, PLDA performs much worse than both JST and VDM with the violence classification accuracy stabilising around 60%. In PLDA, document labels of the training set were obtained using OpenCalais. As mentioned in Section 4.1, OpenCalais gave an F-measure of 38% for violence classification on the test

set. Hence document labels of the training set are not reliable. This explains the low classification accuracy of PLDA.

VDM gives fairly stable violence classification results across different topic numbers. The violence classification accuracy using JST attains the best with single topic and drops slightly with the increasing number of topics. This is because JST assumes the per-tweet category-topic distribution and potentially generates less coherent topics which affects the violence classification accuracy.

Figure 2: Violence classification Accuracy versus different topic numbers.

## 5.3 Topic Extraction

Table 4 presents two topic examples of violent and non-violent topics generated by VDM, JST and PLDA. We can observe that the topics revealed by VDM are representative of some of the events appearing during January/February 2011. For example, T1 gives an insight on the spreading of the Middle East Arab revolution, while T2 provides information regarding the Moscow airport bombing. For the case of non-violent topics, VDM revealed topics which appeared to be less semantically coherent than those of violent topics. However when reading the non-violent VDM T1, it gives an insight of the super bowl game related to the Jets. When checking the topics revealed

VDM				JST				PLDA			
Violent		Non-Violent		Violent		Non-Violent		Violent		Non-Violent	
T1	T2	T1	T2	T1	T2	T1	T2	T1	T2	T1	T2
middle	crash	bowl	people	middle	crash	game	day	kill	game	crash	wow
east	kill	game	hate	government	nat	win	good	moscow	win	polic	cut
give	moscow	win	give	police	museum	jets	free	bomb	jets	drug	block
power	bomb	jets	damn	revolution	moscow	bowl	people	airport	watch	protester	arm
idea	airport	fan	shit	world	loot	fan	thing	leave	today	arrest	till
government	tweets	watch	miss	arm	report	reason	work	islam	play	car	officer
live	thought	today	fuck	streets	bomb	go	hope	injure	car	people	nat
time	injure	gone	hah	day	airport	damn	life	crash	fan	kill	fire
fall	arrest	damn	close	watch	kill	injure	today	report	damn	top	support
spread	dead	car	guy	live	morn	play	hah	victim	hate	part	london
upris	world	friends	sense	support	secure	run	back	terror	best	show	american

Table 4: Topic examples extracted under Violent and Non-Violent Labels for topic setting of 30 topics.

by JST, we can observe that although words seem to be semantically coherent for both violent and non-violent topics, there are words which belong to different violent events. For example the JST violent T2 mixes the Moscow bombing event with the Egyptian protesters Museum attack event. When checking the topics produced by PLDA we can see that it fails to correctly characterise violent and non-violent topics, since PLDA T2 should have been clearly classified as non-violent and the non-violent PLDA T1 as violent. Moreover in the violent PLDA T1 topic which presents violent related words, we can empirically identify more than one event involved.

In order to measure the semantic topical coherence of VDM and the proposed baselines, we made use of the Pointwise Mutual Information (PMI) metric proposed in (Newman et al., 2010). PMI is an automatic topic coherence evaluation which has been found to correspond well with human judgements on topic coherence. In particular, a coherent topic should only contain semantically related words and hence any pair of the top words from the same topic should have a large PMI value. For each topic, we compute its PMI by averaging over the PMI of all the word pairs extracted from the top 10 topic words. Figure 3 shows the PMI values of topics extracted under the violence and non-violence classes with the topic numbers varying between 5 and 30. It can be observed that JST and PLDA give similar PMI results. However, VDM outperforms both by a large margin.

## 6 Conclusions and Future Work

In this paper, we have proposed a novel violence detection model (VDM), which enables the identification of text containing violent content and extraction of violence-related topics over social media data. VDM learning requires the incorporation of word prior knowledge which captures whether a word indicates violence or not. We propose a novel approach of deriving word prior knowledge using the measurement of relative entropy of words (RWE). Extensive experiments on the tweets data sampled from the TREC Microblog 2011 dataset show that our proposed RWE is more effective in deriving word prior knowledge compared to information gain. Moreover, the VDM model gives significantly better violence classification results compared to a few competitive baselines. It also extracts more coherent topics.

In future work, we intend to explore online learning strategies for VDM to adaptively update its parameters so that it can be used for violence detection from social streaming data in real-time.

# Detecting Spammers in Community Question Answering

Zhuoye Ding, Yeyun Gong, Yaqian Zhou, Qi Zhang, Xuanjing Huang

Fudan University

School of Computer Science

{09110240024,12110240006,zhouyaqian,qz,xjhuang}@fudan.edu.cn

## Abstract

As the popularity of Community Question Answering(CQA) increases, spamming activities also picked up in numbers and variety. On CQA sites, spammers often pretend to ask questions, and select answers which were published by their partners or themselves as the best answers. These fake best answers cannot be easily detected by neither existing methods nor common users. In this paper, we address the issue of detecting spammers on CQA sites. We formulate the task as an optimization problem. Social information is incorporated by adding graph regularization constraints to the text-based predictor. To evaluate the proposed approach, we crawled a data set from a CQA portal. Experimental results demonstrate that the proposed method can achieve better performance than some state-of-the-art methods.

## 1 Introduction

Due to the massive growth of Web 2.0 technologies, user-generated content has become a primary source of various types of content. Community Question Answering (CQA) services have also attracted continuously growing interest. They allow users to submit questions and answer questions asked by other users. A huge number of users contributed enormous questions and answers on popular CQA sites such as Yahoo! Answers<sup>1</sup>, Baidu Zhidao<sup>2</sup>, Facebook Questions<sup>3</sup>, and so on. According to a statistic from Yahoo, Yahoo! Answers receives more than 0.82 million questions

and answers per day<sup>4</sup>.

On CQA sites, users are primary contributors of content. The volunteer-driven mechanism brings many positive effects, including the rapid growth in size, great user experience, immediate response, and so on. However, the open access and reliance on users have also made these systems becoming targets of spammers. They post advertisements or other irrelevant answers aiming at spreading advertise or achieving other goals. Some spammers directly publish content to answer questions asked by common users. Additionally, another kind of spammers (we refer them as “*best answer spammers*”) create multiple user accounts, and use some accounts to ask a question, the others to provide answers which are selected as the best answers by themselves. They deliberately organize themselves in order to deceive readers. This kind of spammers are even more hazardous, since they are neither easily ignored nor identifiable by a human reader. Google Confucius CQA system also reported that best answer spammers may generate amounts of fake best answers, which could have a non-trivial impact on the quality of machine learning model (Si et al., 2010).

With the increasing requirements, spammer detection has received considerable attentions, including e-mails(L.Gomes et al., 2007; C.Wu et al., 2005), web spammer (Cheng et al., 2011), review spammer (Lim et al., 2010; N.Jindal and B.Liu, 2008; ott et al., 2011), social media spammer (Zhu et al., 2012; Bosma et al., 2012; Wang, 2010). However, little work has been done about spammers on CQA sites. Filling this need is a challenging task. The existing approaches of spam detection can be roughly into two directions. The first direction usually relied on costly human-labeled training data for building spam classifiers based on textual features (Y.Liu et al., 2008; Y.Xie et al.,

<sup>1</sup><http://answers.yahoo.com>

<sup>2</sup><http://zhidao.baidu.com>

<sup>3</sup><http://www.facebook.com>

<sup>4</sup><http://yanswersblog.com/index.php/archives/2010/05/03/1-billion-answers-served>

2008; Ntoulas et al., 2006; Gyongyi and Molina, 2004). However, since fake best answers are well designed and lack of easily identifiable textual patterns, text-based methods cannot achieve satisfactory performance. Another direction relied solely on hyperlink graph in the web (Z.Gyongyi et al., 2004; Krishnan and Raj, 2006; Benczur et al., 2005). Although making good use of link information, link-based methods neglect the content-based information. Moreover, unlike the web, there is no explicit link structure on CQA sites. So two intuitive research questions are: (1) Is there any useful link-based structure for spammer detection in CQA? (2) If so, can the two techniques, i.e., content-based model and link-based model, be integrated together to complement each other for CQA spammer detection?

To address the problems, in this paper, we first investigate the link-based structure in CQA. Then we formulate the task as an optimization problem in the graph with an efficient solution. We learn a content-based predictor as an objective function. The link-based information is incorporated into textual predictor by the way of graph regularization. Finally, to evaluate the proposed approach, we crawled a large data set from a commercial CQA site. Experimental results demonstrate that our proposed method can improve the accuracy of spammer detection.

The major contributions of this work can be summarized as follows: (1) To the best of our knowledge, our work is the first study on spammer detection on CQA sites; (2) Our proposed optimization model can integrate the advantages of both content-based model and link-based model for CQA spammer detection. (3) Experimental results demonstrate that our method can improve accuracy of spammer detection.

The remaining of the paper is organized as follows: In section 2, we review a number of the state-of-the-art approaches in related areas. Section 3 analyzes the social network of CQA sites. Section 4 presents the proposed method. Experimental results in test collections and analysis are shown in section 5. Section 6 concludes this paper.

## 2 Related Work

Most of current studies on spam detection can be roughly divided into two categories: content-based model and link-based model.

Content-based method targets at extracting ev-

idences from textual descriptions of the content, treating the text corpus as a set of objects with associated attributes, and applying some classification methods to detect spam (P.Heymann et al., 2007; C.Castillo et al., 2007; Y.Liu et al., 2008; Y.Xie et al., 2008). Fetterly proposed quite a few statistical properties of web pages that could be used to detect content spam (D.Fetterly et al., 2004). Benevenuto went a step further by addressing the issue of detecting video spammers and promoters and applied the state-of-the-arts supervised classification algorithm to detect spammers and promoters (Benevenuto et al., 2009). Lee proposed and evaluated a honeypot-based approach for uncovering social spammers in online social systems (Lee et al., 2010). Wang proposed to improve spam classification on a microblogging platform (Wang, 2010).

An alternative web spam detection technique relies on link analysis algorithms, since a hyperlink often reflects some degree of similarity among pages (Gyongyi and Garcia-Molina, 2005; Gyongyi et al., 2006; Zhou et al., 2008). Corresponding algorithms include TrustRank (Z.Gyongyi et al., 2004) and AntiTrustRank (Krishnan and Raj, 2006), which used a seed set of Web pages with labels of trustiness or badness and propagate these labels through the link graph. Moreover, Benczur developed an algorithm called SpamRank which penalized suspicious pages when computing PageRank (Benczur et al., 2005).

## 3 Analysis on Social Network

Before analyzing the social network in CQA, we introduce some definitions. We refer users on CQA sites are someone who ask at least one question or answer at least one question. Moreover, users are divided into two categories: spammers and legitimate users. We define spammers as users who post at least one question or one answer intent to create spam.

A CQA site is particularly rich in user interactions. These interactions can be represented by Figure 1(a), where a particular question has a number of answers associated with it, represented by an edge from the question to each of the answer. We also include vertices representing authors of question or answers. An edge from a user to a question means that the user asked the question, and an edge from an answer to a user means that the answer was posted by this user. In the example,

a user  $U_1$  asks a question  $Q_1$ , while users  $U_4$ ,  $U_5$  and  $U_6$  answers this question. In order to observe the relation between users more clearly and directly, we summarize the relations between users as a graph shown in Figure 1(b). This graph contains vertices representing the users and omits the actual questions and answers that connect the users.

Figure 1: (a) Graph with users, questions, and answers in CQA; (b) Summary graph of users in CQA

Figure 2: User graph with different relations in CQA (a) Question-answer relation; (b) Best-answer relation; (c) Non-best-answer relation

Three kinds of major relations among users on CQA sites are defined as follows:

**Question-answer relation:** As shown in Figure 2(a),  $U_4$  answers  $U_1$ 's question. We define that  $U_4$  and  $U_1$  have Question-answer relation. Furthermore, Question-answer relation can be divided into two disjoint sets: best-answer relation and non-best-answer relation.

**Best-answer relation:**  $U_1$  selects  $U_5$ 's answer as the best answer. We define that  $U_1$  and  $U_5$  have best-answer relation. The solid lines in Figure 2(b) express the best-answer relation.

**Non-best-answer relation:**  $U_1$  does not select  $U_4$ 's answer as the best answer. We define that  $U_1$  and  $U_4$  have non-best-answer relation. The dashed lines in Figure 2(c) express the non-best-answer relation.

### 3.1 Best-answer Consistency Property

From analyzing data crawled from CQA site, we present the following property about best-answer

relation:

**Best-answer consistency property:** If  $U_i$  selects  $U_j$ 's answer as the best answer, the classes of users  $U_i$  and  $U_j$  should be similar.

We explain this property as follows: consider that a legitimate user is unlikely to select a spammer's answer as the best answer due to its low quality, while a legitimate user is unlikely to answer a spammer's question, so the possibility of a spammer selecting a legitimate user's answer will also be small. This means that two users linked via best-answer relation are more likely to share similar property than two random users.

### 3.2 Characteristics of Best Answer Spammer

Different from the general spammers, some spammers generate many fake best answers to obtain higher status in the community. We refer them as *best answer spammers*. In order to generate fake best answers, a spammer creates multiple user accounts first. Then, it uses some of the accounts to ask questions, and others to provide answers. Such spammers may post low quality answers to their own questions, and select those as the best by themselves. They may generate lots of fake best answers, which may highly impact the user experience.

Furthermore, when the spammer's intention is just advertising, we can easily identify signs of its activity: repeated phone numbers or URLs and then ignore them. However, when the spammer's intention is to obtain higher reputation within the community, the spam content may lack obvious patterns. Fortunately, there are still some clues that may help identify best answer spammers. Two characteristics are described as follows:

**High best answer rate:** Best answer rate is the ratio of answers selected as the best answer among the total answers. This kind of spammers have an incredible high best answer rate, compared to normal users. Specifically, in a possible best answer spammer pair, sometimes only one user has an incredible high best answer rate. Because normally one responses for asking and another for answering. So we calculate the best answer rate  $BR(i, j)$  for a user pair  $(u_i, u_j)$  based on the maximum of their best answer rates:

$$BR(i, j) = \text{Max}(BR(i), BR(j)) \quad (1)$$

Where  $BR(i)$  is the best answer rate of  $u_i$ .

**Time margin score:** To be efficient, best answer spammers tend to answer their own ques-

tion quickly. We consider the time margin score  $Time(i, j)$  between a question posted and answered for  $u_i$  and  $u_j$  as an evidence.

$$Time(i, j) = \begin{cases} 1, & \text{if } TimeMargin(i, j) < \varepsilon \\ 0, & \text{otherwise} \end{cases} \quad (2)$$

where  $TimeMargin(i, j)$  is the real time margin between  $u_i$  asks a question and  $u_j$  answers this question and  $\varepsilon = 30$  minutes.

The best answer spammer score  $s(i, j)$  for a user pair  $(u_i, u_j)$  can be calculated as the combination of these two scores:

$$s(i, j) = \mu BR(i, j) + (1 - \mu)Time(i, j) \quad (3)$$

$\mu$  is trade-off of two scores, here we simply set  $\mu = 0.5$ . The value of  $s(i, j)$  is between 0 to 1. The higher  $s(i, j)$  is, the more likely  $u_i$  and  $u_j$  is a pair of the best answer spammers.

## 4 Spammer Detection on CQA Sites

In this section, the framework of our proposed approach is presented. First, the problem is formally defined. Next, we build a baseline supervised predictor that makes use of a variety of textual features, and then the consistency property and best answer spammer characteristics are incorporated by adding regularization to the textual predictor, last we discuss how to effectively optimize it.

### 4.1 Problem Statement

On CQA sites, there are three distinct types of entities: users  $U = \{u_1, \dots, u_{l+u}\}$ , answers  $A = \{a_1, \dots, a_M\}$ , and questions  $Q = \{q_1, \dots, q_N\}$ . The set of users  $U$  contains both  $U_L = \{u_1, \dots, u_l\}$  of  $l$  labeled users and  $U_U = \{u_{l+1}, \dots, u_{l+u}\}$  of  $u$  unlabeled users. We model the social network for  $U$  as a directed graph  $G = (U, E)$  with adjacency matrix  $A$ , where  $A_{ij} = 1$  if there is a link or edge from  $u_i$  to  $u_j$  and zero otherwise.

Given the input data  $\{U_L, U_U, G, Q, A\}$ , we want to learn a predictor  $c$  for a user  $u_i$ .

$$c(u_i) \rightarrow \{\text{spammer, legitimate user}\} \quad (4)$$

Legitimacy score  $y_i$  ( $0 \leq y_i \leq 1, i = 1, 2, \dots, n$ ) is computed for all the users. The lower  $y_i$  is, the more likely  $u_i$  is a spammer.

### 4.2 Text-based Spammer Prediction

In this subsection, we build a baseline predictor based on textual features in a supervised fashion.

We regard the legitimacy scores as generated by combining textual features.

We consider the following textual features.

- *The Length of answers*: The length may to some extent indicate the quality of the answer. The average length of answers is calculated as a feature.
- *The ratio of Ads words in answers*: Advertising of products is the main goal of a kind of spammers and they repeat some advertisement words in their answers.
- *The ratio of Ads words in questions*: Some spammers will refer some Ads in questions in order to get attention from more users.
- *The number of received answers*: The number of received answers can indicate the quality of the question.
- *Best answer rate*: Best answer rate can show the quality of their answers.
- *The number of answers*: It can indicate the authority of a user.
- *Relevance of question and answer*: We measure the average content similarity over a pair of question and answer which is computed using the standard cosine similarity over the bag-of-words vector representation.
- *Duplication of answers*: The Jaccard similarity of answers are applied to indicate the duplication of answers.

With these features, suppose there are in total  $k$  features for each user  $u_i$ , denoted as  $x_i$ . Then  $X = (x_1, x_2, \dots, x_n)$  is the  $k$ -by- $n$  feature matrix of all users. Based on these features, we define the legitimacy score of each user as follows,

$$y_i = w^T x_i \quad (5)$$

where  $w$  is a  $k$ -dimensional weight vector.

Suppose we have legitimate/spammer labels  $t_i$  in the training set.

$$t_i = \begin{cases} 1, & u_i \text{ is labeled as legitimate user} \\ 0, & u_i \text{ is labeled as spammer} \end{cases} \quad (6)$$

We will then define the loss term as follows,

$$\Omega(w) = \frac{1}{l} \sum_{i=1}^l (w^T x_i - t_i)^2 + \alpha w^T w \quad (7)$$

Once we have learned the weight vector  $w$ , we can apply it to any user feature vector and predict the class of unlabeled users.

### 4.3 Regularization for Consistency Property

In Section 4.2, each user is considered as a stand-alone item. In this subsection, we exploit social information to improve CQA spammer detection.

In Section 3.1, the consistency property has been analyzed that users connected via best-answer relation are more similar in property. So the property is enforced by adding a regularization term into the optimization model. The regularization is acted in a collection data set, including a small amount of labeled data ( $l$  users) and a large amount of unlabeled data ( $u$  users). Then the regularization term is formulated as:

$$REG_1(U) = \sum_{i,j}^{l+u} A_{ij} (y_i - y_j)^2 \quad (8)$$

Minimizing the regularization constraint will force users who have best-answer relation belong to the same class. We formulate this as graph regularization. The graph adjacency matrix  $A$  is defined as  $A_{ij} = 1$  if  $u_j$  selects  $u_i$ 's answer as the best answer, and zero otherwise. Then, Equation 8 becomes:

$$REG_1(w) = \sum_{i,j}^{l+u} A_{ij} (w^T x_i - w^T x_j)^2 \quad (9)$$

With this regularization, then the objective function Equation 7 becomes:

$$\begin{aligned} \Omega_1(w) = & \frac{1}{l} \sum_{i=1}^l (w^T x_i - t_i)^2 + \alpha w^T w \\ & + \beta \sum_{i,j}^{l+u} A_{ij} (w^T x_i - w^T x_j)^2 \end{aligned} \quad (10)$$

### 4.4 Regularization for Best Answer Spammer

In this subsection, we focus on best answer spammers. Since they cannot be easily detected by only textual features (Equation 7), we introduce an additional penalty score  $b_i$  to each user  $u_i$  which indicates the possibility of becoming a best answer

spammer. With the penalty score  $b_i$ , Equation 5 can be redefined as follows:

$$y_i = w^T x_i - b_i \quad (11)$$

where  $b_i$  is a non-negative score.

In order to obtain  $b_i$ , characteristics of best answer spammers are incorporated by adding graph regularization to the optimization problem. The regularization is also acted in a collection data set. Two kinds of regularization are presented as follows:

#### Penalty for Best Answer Spammers in Pairs

As described in Section 3.2, the score  $s(i, j)$  indicates the possibility of  $u_i$  and  $u_j$  becoming a pair of best answer spammers (Equation 3). We expect  $u_i$  and  $u_j$ , who create the spam together, should share this possibility together, as follows:  $b_i + b_j = e \times s(i, j)$ , where  $e$  is a penalty factor, we empirically set it to 0.5.

Then we can also formulate this as graph regularization as:

$$REG_2(b) = \sum_{i<j}^{l+u} A_{ij} (b_i + b_j - e \times s(i, j))^2 \quad (12)$$

#### Penalty Assignment for Individual User

After introducing a penalty score to the user pair  $(u_i, u_j)$ , we have to decide how they share this penalty.

Penalty is assigned to  $u_i$  and  $u_j$  similarly. This can be also formulated as graph regularization as follows:

$$REG_3(b) = \sum_{i<j}^{l+u} A_{ij} (b_i - b_j)^2 \quad (13)$$

With the regularization for best answer spammer, the objective function becomes:

$$\begin{aligned} \Omega_3(w, b) = & \frac{1}{l} \sum_{i=1}^l (w^T x_i - b_i - t_i)^2 + \alpha w^T w \\ & + \beta \sum_{i,j}^{l+u} A_{ij} ((w^T x_i - b_i) - (w^T x_j - b_j))^2 \\ & + \gamma \sum_{i<j}^{l+u} A_{ij} (b_i + b_j - e \times s(i, j))^2 \\ & + \delta \sum_{i<j}^{l+u} A_{ij} (b_i - b_j)^2 \end{aligned} \quad (14)$$

## 4.5 Optimization Problem

By considering all the components of the objective function introduced in the previous subsection, we can obtain the optimization problem. Our goal is to minimize the objective function to get optimal parameters vector  $w^*$  and penalty vector  $b$ . For solving the optimization problem, we apply a kind of limited-memory Quasi-Newton(LBFGS)(Liu and Nocedal, 1989). After obtaining the optimal parameter vector  $w^*$  and  $b$ , we can use the following scoring function  $y_i = w^{*T}x_i - b_i$  to calculate scores for unlabeled users. Users with low scores will be regarded as spammers.

## 5 Experiments

In this section, the experimental evaluation of our approach is presented. Firstly, we introduce the details of our data sets. Then the prediction performance of our proposed approach is compared with other methods. Finally, we test the contribution of the loss term and each regularization term on these real data sets and conduct some further analysis.

### 5.1 Data Collections

In order to evaluate our proposed approach to detect CQA spammers from the CQA site, we need a training/test collection of users, classified into the target categories. However, to the best of our knowledge, no such collection is currently available, thus requiring us to build one.

We consider a CQA user is a user if he has posted at least one question or one answer. Moreover, we define spammer as a user who intends to create one spam. Examples of spams are: (1) an advertisement of a product or web site. (2) Completely unrelated to the subject of question. A user that is not a spammer is considered legitimate. Then we will explain the strategy of crawling data from a CQA site, Baidu Zhidao, one of the most popular CQA site in China. We randomly select 50 seed users covering different topics, including sports, entertainment, medicine and technology. The crawler follows links of question asked and question answered, gathering information on different attributes of users, including content of all responded questions and answers. The crawler ran for one week, gathering 29,257 users and 299,815 Q&A pairs. From the collection data, we randomly select a training set of 1000 users for learning

process and a test set of 698 users for evaluation.

Three annotators were asked to label the users as spammers or legitimate users in both training and test set. All of the judges are Chinese and have used Baidu Zhidao frequently. The annotators judge the property of a user comprehensively based on the content information (quality of their answers, i.e. advertising and duplication of answers) and social information (interaction with other possible-spammers). The Cohen’s Kappa coefficient is around 0.85, showing fair to good agreement. And our test collection contains 698 users, including 525 legitimate users and 173 spammers.

### 5.2 Metrics and Settings

To measure the effectiveness of our proposed method, we use the standard metrics such as precision, recall, the F1 measure. Precision is the ratio of correctly predicted users among the total predicted users by system. Recall(R) is the ratio of correctly predicted users among the actual users manually assigned. F1 is a measure that trades off precision versus recall. F1 measure of the spammer class is  $2PR/(P + R)$ .

We fix the parameter  $\alpha$  in optimization method to 0.0005 which gives the best performance for the textual predictor and simply set the coefficients  $\beta = 0.5$   $\gamma = \delta = 1$  in the objective function. The problem of parameter sensitivity will be tested in Section 5.6. In the optimization process, initial value of  $w_i$  is set to a random value range from 0 to 1 and initial value of  $b_i$  is set to 0.

### 5.3 Comparison with Other Methods

Since there has been little work on QA spam detection, we implement four state-of-the-art methods for comparison, where TrustRank and AntiTrustRank are selected to represent link-based model, while Decision Tree and SVM are two content-based classifiers.

- **Our approach:** Optimization with regularization terms that Similarity with best-answer relation, penalty for Best answer spammer. (Equation 14)
- **TrustRank:** TrustRank is a well-known link-based method in Web spam detection, which is totally based on the Web link graph(Z.Gyongyi et al., 2004).

- **AntiTrustRank**: AntiTrustRank is another well-known link-based method, which assumes that a web page pointing to spam pages is likely to be spam (Krishnan and Raj, 2006).
- **Decision Tree**: Castillo et al. applied a base classifier, decision tree, for spam detection, the features include content-based and link-based features (C. Castillo et al., 2007).
- **SVM**: We applied another state-of-the-art classifier SVM (Cortes and Vapnik, 1995). The features are the same as that used in Decision Tree method.

Methods	Precision	Recall	F1
TrustRank	0.581	0.485	0.529
AntiTrustRank	0.632	0.545	0.585
Decision Tree	0.891	0.740	0.808
SVM	0.898	0.748	0.816
<b>Our approach</b>	<b>0.925</b>	<b>0.861</b>	<b>0.892</b>

Table 1: Performance comparison with other methods

In Table 1, the performance of each method is listed for comparison. From the table, we have the following observations.

First, taking the advantages of both content-based model and link-based model, our optimization approach outperforms baselines under all metrics. This indicates the robustness and effectiveness of our approach.

The second observation is link-based models (**TrustRank** and **AntiTrustRank**) cannot perform well. The explanations are as follows. (1) Link-based models rely solely on hyperlinks, without considering content-based features. However, as described in section 4.2, the content can provide a strong hint for detecting spammers. (2) A technical requirement of link-based model is that the link graph must be strongly connected, which may be the case in Web, but it is not the case in QA user question-answer graph. We measured on our collection dataset and found that the graph density (defined as  $D = \frac{2|E|}{|V|(|V|-1)}$  for a graph with vertices  $V$  and edges  $E$ ) of user question-answer graph is only  $10^{-4}$ . The small connectivity limits the performance of link-based model. This indicates that link-based models cannot be directly applied to CQA spammer detection. Considering

that our proposed approach can integrate content-based features and link-based features effectively, we regard our approach as very complementary to the state-of-the-art link-based methods.

Another observation is that the content-based classifiers underperform our approach. And **SVM** performs slightly better than **Decision Tree**. This shows the advantages of our proposed regularization in section 4. Regularization for consistency can propagate the labeled information among users, and regularization for best answer spammers help to identify the best answer spammers.

#### 5.4 Contribution of Loss and Regularization

In this subsection, we validate the contribution of our proposed loss term and regularization terms by the performance of real spammer detection task. And Table 2 lists the results of each method for comparison. We consider the following methods.

**BL**: Optimization using only content-based features. (Equation 7)

**REG:Sim**: Optimization with one regularization term that Similarity with best-answer relation. (Equation 10)

**REG:Sim+BAS**: Optimization with all regularization terms that Similarity with best-answer relation, penalty for Best Answer Spammer. (Equation 14)

Methods	Precision	Recall	F1
BL	0.911	0.711	0.798
REG:Sim	<b>0.945</b>	0.699	0.804
REG:Sim+BAS	0.925	0.861	<b>0.892</b>

Table 2: Performance of our optimization methods with different regularization for comparison

From the results we have the following observations: (1) Our content-based classifier **BL** performs well, due to the well-formed supervised learning model and reasonable features. (2) The performance of **REG:Sim** improves over **BL**, especially in the Precision measure because the social information is useful. (3) **REG:Sim+BAS** can significantly improve over **BL** especially in Recall measure. Because after adding penalty to best answer spammer, some best answer spammers can be detected successfully.

#### 5.5 Contribution of Content-based Features

In this subsection, we test the robustness of the features described in Section 4.2.

Figure 4: Parameter Sensitivity

Figure 3: Content features comparison

To measure the discrimination power between spammers and legitimate users of each proposed attribute, we generate a Receiver Operating Characteristics (ROC) curve. ROC curves plot false positive rate on the X axis and true positive rate on the Y axis. The closer the ROC curve is to the upper left corner, the higher the overall accuracy is. Samples with the lowest scores (10%, 20%...100%) for each attribute are labeled as spammers respectively. The (ROC) curve are shown in Figure 3. Figure 3 shows the discrimination power of each content feature we described in Section 4.2. The first observation is that all of the content features are discriminative. The feature of Ads words in questions is the most powerful. Because few legitimate users will repeat Ads words in questions, so this feature can help to identify spammers more easily. Note that the feature of the best answer rate do not perform well. Because some best answer spammers also have high best answer rate.

## 5.6 Parameter Sensitivity

Our optimization approach have four parameters  $\alpha, \beta, \gamma, \delta$  to set: the tradeoff weight for each regularization term. The value of the regulariza-

tion weight controls our importance in the regularizer: a higher value results in a higher penalty when violating the corresponding regularization. So we mainly evaluate the sensitivity of our model with parameters by fixing all the other parameters and let one of  $\{\alpha, \beta, \gamma, \delta\}$  varies. Figure 4 shows the prediction performance in F1 measure varying each parameter. As we observed over a large range of parameters, our approach (**REG:Sim+BAS**) achieves significantly better performance than **BL** method. It indicates that the parameters selection will not critically affect the performance of our optimization approach.

## 6 Conclusion

In this paper, we first studied social networks on CQA sites. We found that spammers are usually connected to other spammers via the best-answer relation. We also studied the “best answer spammers” on CQA sites, which cannot be easily detected for lack of identifiable textual patterns. Our proposed model incorporated the link-based information by adding regularization constraints to the textual predictor. Experimental results demonstrated that our method is more effective for spammer detection compared to other state-of-the-art methods. Besides obtaining better performance, we have also analyzed the CQA social networks, which gives us insight on the model design.

## Abstract

We study the linguistic phenomenon of informal words in the domain of Chinese microtext and present a novel method for normalizing Chinese informal words to their formal equivalents. We formalize the task as a classification problem and propose rule-based and statistical features to model three plausible channels that explain the connection between formal and informal pairs. Our two-stage selection-classification model is evaluated on a crowdsourced corpus and achieves a normalization precision of 89.5% across the different channels, significantly improving the state-of-the-art.

## 1 Introduction

Microtext – including microblogs, comments, SMS, chat and instant messaging (collectively referred to as *microtext* by Gouwset *et al.* (2011) or *network informal language* by Xia *et al.* (2005)) – is receiving a larger research focus from the computational linguistic community. A key challenge is the presence of *informal words* – terms that manifest as *ad hoc* abbreviations, neologisms, unconventional spellings and phonetic substitutions. This phenomenon is so prevalent a challenge in Chinese microtext that the dual problems of informal word recognition and normalization deserve research. Given the close connection between an informal word and its formal equivalent, the restoration (normalization) of an informal word to its formal one is an important pre-processing step for NLP tasks that rely on string matching or word frequency statistics (Han *et al.*, 2012).

It is important to note that simply re-training models trained on formal text or annotated mi-

crotext is insufficient: user-generated microtexts exhibit markedly different orthographic and syntactic constraints compared to their formal equivalents. For example, consider the informal microtext “河蟹社会” (formally, “和谐社会”; “harmonious society”). A machine translation system may mistranslate it literally as “crab community” based on the meaning of its component words, if it lacks knowledge of the informal word “河蟹” (“和谐”; “harmonious”). It is thus desirable to normalize informal words to their standard formal equivalents before proceeding with standard text processing workflows.

In this work, we present a novel method for normalizing informal word to their formal equivalents. Specifically, given an informal word with its context as input, we generate hypotheses for its formal equivalents by searching the Google Web 1T corpus (Brants and Franz, 2006). Prospective informal-formal pairs are further classified by a supervised binary classifier to identify correct pairs. In the classification model, we incorporate both rule-based and statistical feature functions that are learned from both gold-standard annotation and formal domain synonym dictionaries. Also importantly, our method does not directly use words or lexica as features, keeping the learned model small yet robust to inevitable vocabulary change.

We evaluate our system on a crowdsourced corpus, achieving good performance with a normalization precision of 89.5%. We also show that the method can be effectively adapted to tackle the synonym acquisition task in the formal domain. To our best knowledge, this is the first work to systematically explore the informal word phenomenon in Chinese microtext. By using a formal domain corpus, we introduce a method that effectively normalizes Chinese informal words through different, independent channels.

\*This research is done in part during Aobo Wang’s internship in NEC Corporation.

## 2 Related Work

Previous works that address a similar task includes the study on abbreviations with their definitions (e.g., (Park and Byrd, 2001; Chang and Teng, 2006; Li and Yarowsky, 2008b)), abbreviations and acronyms in medical domain (Pakhomov, 2002), and transliteration (e.g., (Wu and Chang, 2007; Zhang et al., 2010; Bhargava and Kondrak, 2011)). These works dealt with such relations in formal text, but as we earlier argued, similar processing in the informal domain is quite different.

Probably the most related work to our method is Li and Yarowsky (2008a)’s work. They tackle the problem of identifying informal–formal Chinese word pairs in the Web domain. They employ the Baidu<sup>1</sup> search engine to obtain definition sentences – sentences that define or explain Chinese informal words with formal ones – from which the pairs are extracted and further ranked using a conditional log-linear model. Their method only works for definition sentences, where the assumption that the formal and informal equivalents co-occur nearby holds. However, this assumption does not hold in general social network microtext, as people often directly use informal words without any explanations or definitions.

While seminal, Li and Yarowsky’s method has other shortcomings. Relying on a search engine, the system recovers only highly frequent and conventional informal words that have been defined on the web, relying heavily on the quality of Baidu’s index. In addition, the features they proposed are limited to rule-based features and  $n$ -gram frequency, which does not permit their system to explain how the informal–formal word pair is related (*i.e.*, derived by which channel).

Normalizing informal words is another focus area in related work. An important channel for informal–formal mapping (as we review in detail later) is phonetic substitution. In work on Chinese, this is often done by measuring the Pinyin similarity<sup>2</sup> between an informal–formal pair. Li and Yarowsky (2008a) computed the Levenshtein distance ( $LD$ ) on the Pinyin of the two words in the pair to reflect the phonetic similarity. However, as a general string metric,  $LD$  does not

<sup>1</sup>[www.baidu.com](http://www.baidu.com)

<sup>2</sup>Pinyin is the official phonetic system for transcribing the sound of Chinese characters into Latin script.  $PYSim(x, y)$  is used to denote the similarity between two Pinyin string “ $x$ ” and “ $y$ ” hereafter.

capture the (dis-)similarity between two Pinyin pronunciations well as it is too coarse-grained. To overcome this shortcoming, Xia et al. (2008) propose a source channel model that is extended with phonetic mapping rules. They evaluated the model on manually-annotated phonetically similar informal–formal pairs. The disadvantage is that these rules need to be manually created and tuned. For example,  $Sim(chi, qi)$  is calculated as  $Sim(ch, q) * Sim(i, i)$  (here, “ $ch$ ” and “ $q$ ” are *Pinyin initials* and “ $i$ ” is a *Pinyin final*, as per convention), in which  $Sim(ch, q) = 0.8$  and  $Sim(i, i) = 1.0$  are defined manually by the annotators. As informal words and their usage in microtext continually evolve, they noted that it is difficult for annotators to accurately weigh the similarities for all pronunciation pairs. We concur that the labor of manually tuning weights is unnecessary, given annotated informal–formal pairs. Finally, we make the key observation that the similarity of initial and final pairs are not independent, but may vary contextually. As such, a decomposition of  $Sim(chi, qi)$  as  $Sim(ch, q) * Sim(i, i)$  may not be wholly accurate.

To tackle these problems as a whole, we propose a two-step solution to the normalization task, which involves formal candidate generation followed by candidate classification. Our pipeline relaxes the strong assumptions described by prior work and achieves significant improvement over the previous state-of-the-art.

## 3 Data Analysis

To bootstrap our work, we analyzed sample Chinese microtext, hoping to gain insight on how informal words relate to their formal counterparts. To do this, we first needed to compile a corpus of microtext and annotate them.

We utilized the Chinese social media archive, PrEV (Cui et al., 2012), to obtain Chinese microblog posts from the public timeline of Sina Weibo<sup>3</sup>, the most popular Chinese microtext site with over half a billion users. To assemble a corpus for annotation, we first followed the convention from (Wang et al., 2012) to preprocess and label *URLs*, *emoticons*, “*@usernames*” and *Hash-tags* as pre-defined words. We then employed *Zhubajie*<sup>4</sup>, one of China’s largest crowdsourcing platforms to obtain third-party (*i.e.*, not by the

<sup>3</sup><http://open.weibo.com>

<sup>4</sup><http://www.zhubajie.com>

original author of the microtext) annotations for any informal words, as well as their normalization, sentiment and motivation for its use (Wang et al., 2010). Our coarse-grained sentiment annotations use the three categories of “positive”, “neutral” and “negative”. Motivation is likewise annotated with the seven categories listed in Table 1:

to avoid (politically) <b>sensitive</b> words	17.8%
to be <b>humorous</b>	29.2%
to hedge criticism using <b>euphemisms</b>	12.1%
to be <b>terse</b>	25.4%
to <b>exaggerate</b> the post’s mood or emotion	10.5%
<b>others</b>	5.0%

Table 1: Categories used for motivation annotation, shown with their observed distribution.

In total, we spent US\$110 to annotate a subset of 5,500 posts (12,446 sentences), in which 1,658 unique informal words were annotated. Each post was annotated by three annotators where conflicts were resolved by simple majority. Annotations were completed after a five-week span and are publicly available<sup>5</sup> for comparative study.

### 3.1 Data Feature Analysis

From our observation of the annotated informal-formal word pairs, we identified three key channels through which the majority of informal words originate, summarized in Table 2. Here, the first column describes these channels, giving each channel’s observed frequency distribution as a percentage. Together, they account for about 94% of the channels by which informal words originate. The final “Motivation (%)” column also gives the distributional breakdown of motivations behind each of the channels as annotated by our crowdsourced annotators. We now discuss each channel.

**Phonetic Substitutions** form the most well-known channel where the resultant informal words are pronounced similar to their formal counterparts. It is also the channel responsible for most informal word derivation. It has been reported to account for 49.1% (Li and Yarowsky, 2008a) in the Web domain and for 99% in Chinese chats (Xia et al., 2006). In our study of the microtext domain, we found it to be responsible for 63% (Table 2). As highlighted in bold in the table, normalization in this channel is realized by a **character-**

<sup>5</sup><http://wing.comp.nus.edu.sg/portal/downloads.html>

**character** Pinyin mapping. An interesting special case occurs when the Chinese characters are substituted for Latin alphabets, where the alphabets form a Pinyin acronym. In these cases, each letter maps to a Pinyin initial (e.g., “bs” → ‘b’+ ‘s’ → “bi” + “shi” (鄙视(**bi shi**); “to despise”)), each of which maps to a single Chinese character. As such, we view this special case as also following the character-character mapping.

We found that phonetic substitutions are motivated by different intents. Slightly over half of the words are used to be humorous. This resonates well with the informal context of many microtexts, such that authors take advantage of expressing their humor through lexical choice. Another large group (28.9%) of informal words are variations of *politically sensitive words* (e.g., the names of politicians, religious movements and events), whose formal counterparts are often forbidden and censored by search engines or Chinese government officials. Netizens often create such phonetically equivalent or close variations to express themselves and communicate with others on such issues. An additional 18.7% of such word pairs are used euphemistically to avoid the usage of their harsher, formal equivalents. The remaining substitutions are explainable as typographical errors, transliterations, among other sources.

The **Abbreviation** channel contains informal words that are shortenings of formal words. Normalizing these informal words is equivalent to expanding short forms to corresponding full forms. As suggested by Chang and Teng (2006), we also agree that Chinese abbreviation expansion can be modeled as **character-word** mapping. The statistics in Table 2 suggest 19% of informal words come from this channel, and are used to save space and to make communication efficient, especially given the format and length limitations in microtext.

**Paraphrases** mark informal words that are created by a mixture of paraphrasing, abbreviating and combining existing formal words. We observe that the informal manifestation usually do not retain any of the original characters in their formal equivalents, but still retain the same meaning as a single formal word, or two meanings combined from two formal words. These words are created to enhance emotional response in an exaggerated (66.3%) and/or terse (27.3%) manner. For example in Table 2, “给力” as a whole comes from the

Channel (%)	Informal Word	Formal Word	Translation	Sentiment	Motivation (%)
<b>Phonetic Substitutions</b> (63)	河蟹(he2 xie4)	和谐(he2 xie2)	harmonious	positive	<b>sensitive</b> (28.9)
	鸭梨(ya1 li2)	压力(ya1 li4)	pressure	neutral	<b>humorous</b> (45.2)
	<b>bs</b>	鄙视(bi shi)	despise	negative	<b>euphemism</b> (18.7)
<b>Abbreviation</b> (19)	乘早(cheng2 zao3)	趁早(chen4 zao3)	as soon as possible	neutral	<b>others</b> (7.2)
	桌游 剧透	桌面_游戏 剧情_透露	board game tell the spoilers	neutral neutral	<b>terse</b> (100)
<b>Paraphrase</b> (12)	给力	很棒	awesome	positive	<b>exaggerate</b> (66.3)
	暴汗	非常_尴尬	very embarrassed	negative	<b>terse</b> (27.3)
	卖萌	可爱	cute	positive	<b>others</b> (6.4)

Table 2: Classification of Chinese informal words as originating from three primary channels. Pronunciation is indicated with Pinyin for phonetic substitutions, while characters in bold are linked to the motivation for the informal form.

paraphrase of the single formal word “很棒”, sharing the meaning of “awesome”. As another example, “暴汗” (“very embarrassed”) originates from two sources: “暴” meaning “十分” (“very”) and “汗” meaning “尴尬” (“embarrassed”). From this observation, we feel that both **character-word** and **word-word** mappings may adequately model the normalization process for this channel.

## 4 Methodology

Drawing on our observations, we propose a two step generation-classification model for informal word normalization. We first *generate* potential formal candidates for an input informal word by combing through the Google 1T corpus. This step is fast and generates a large, prospective set of candidates which are input to a second, subsequent classification. The subsequent classification is a binary yes/no classifier that takes both rule-based and statistical features derived from our identified three major channels to identify valid formal candidates.

Note that an informal word  $O$  (here,  $O$  for observation), even when used in a specific, windowed context  $C(O)$ , may have several different equivalent normalizations  $T$  (here,  $T$  for target). This occurs in the abbreviation (桌游 as (桌面 or 桌上) 游戏) and paraphrase (给力 很棒 or 很好 or 厉害) channels, where synonymous formal words are equivalent. In the case where an informal word is explainable as a phonetic substitution, only one formal form is viable. Our classification model caters for these multiple explanations.

Figure 1 illustrates the framework of the proposed approach. Given an input Chinese microblog post, we first segment the sentences into words and recognize informal words leveraging the approach proposed in (Wang and Kan, 2013).

For each recognized informal word  $O$ , we search the Chinese portion of the Google Web1T corpus using lexical patterns, obtaining  $n$  potential formal (normalized) candidates. Taking the informal word  $O$ , its occurrence context  $C(O)$ , and the formal candidate  $T$  together, we generate feature vectors for each three-tuple, i.e.,  $\langle O, C(O), T \rangle$ <sup>6</sup>, consisting of both rule-based and statistical features. These features are used in a supervised binary classifier to render the final yes (informal-informal pair) or no (not an appropriate formal word explanation for the given informal word) decision.

### 4.1 Pre-Processing

As an initial step, we can recognize informal words and segment the Chinese words in the sentence by applying joint inference based on a Factorial Conditional Random Field (FCRF) methodology (Wang and Kan, 2013). However, as our focus in this work is on the normalization task, we use the manually-annotated gold standard informal words ( $O$ ) and their formal equivalents ( $T$ ) provided in our annotated dataset. To derive the informal words’ context  $C(O)$ , we use the automatically-acquired output of the preprocessing FCRF, although noisy and a source of error.

### 4.2 Formal Candidate Generation

Given the two-tuple  $\langle O, C(O) \rangle$  generated from pre-processing, we produce a set of hypotheses  $|T|$  which are formal candidates corresponding to  $O$ . We use two assumptions to guide us in the selection of prospective formal equivalents of  $O$ . We first discuss Assumption 1 (as [A1]):

<sup>6</sup>For notational convenience, the informal word context  $C(O)$  is defined as  $W_{-i} \dots O \dots W_i$ ; here,  $i$  refers to the index of the word with respect to  $O$ , which we set in this work to 3.

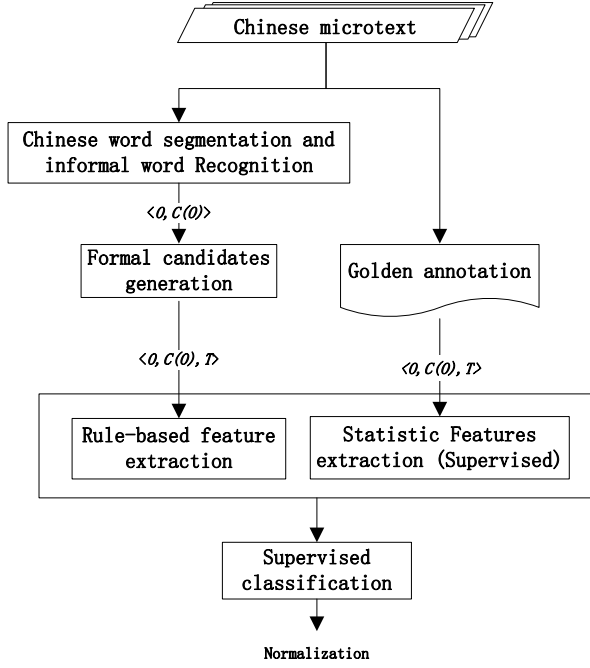

Figure 1: Our framework consists of the two steps of informal word recognition and normalization. Normalization breaks down to its component steps of candidate generation and classification.

[A1] The informal word and its formal equivalents share similar contextual collocations.

To implement [A1], we define several regular expression patterns to search the Chinese Web 1T corpus, as listed in Table 3. All entries that match at least one of the five rules are collected as formal candidates. Specifically,  $W_*$  refers to the word in context  $C(O)$ .  $T$  denotes any Chinese candidate word, and  $\hat{T}$  a word sharing at least one character in common with the informal word  $O$ .

$W_{-1} T W_1$	$W_{-2} W_{-1} T$	$T W_1 W_2$
$W_{-1} \hat{T}$		$\hat{T} W_1$

Table 3: Lexical patterns for candidate generation.

Our assumption is similar to the notion used for paraphrasing: that the informal version can be substituted for its formal equivalent(s), such that the original sentence’s semantics is preserved in the new sentence. For example, in the phrase “建设\_河蟹\_社会”, the informal word “河蟹” is exactly equivalent to its formal equivalent “和谐”, as the resulting phrase “建设\_和谐\_社会” (“build the harmonious society”) carries exactly the same semantics. This is inferrable when both the informal word  $O$  and the candidate share the same con-

textual collocations of “建设” and “社会”.

As the Web1T corpus consists of  $n$ -grams taken from approximately one trillion words indexed from Chinese web pages, queries for each informal word  $O$  can return long result lists of up to 20,000 candidates. To filter noise from the resulting candidates, we adopt Assumption 2 [A2]:

[A2] Both the original informal word in its context – as well as the substituted formal word within the same context – are frequent in the general domain.

We operationalize this by constraining the prospective normalization candidates to be within the top 1,000 candidates ranked by the trigram probability ( $P(W_{-1} T W_1)$ ). This probability is calculated by the BerkeleyLM (Pauls and Klein, 2011) trained over Google Web 1T corpus. Note that this constraint makes our method more efficient over a brute-force approach, in exchange for loss in recall. However, we feel that this trade-off is fair: by retaining the top 1000 candidates, we observed the loss rate of gold standard answers in each of the channels is 14%, 15%, and 17% for phonetic substitution, abbreviation and paraphrase, respectively. This is in comparison with the final loss rate of over 70% reported by Li and Yarowsky (2008a).

Given the annotations, the three-tuples ( $\langle O, C(O), T \rangle$ ) generated from the resulting list of candidates are labeled as  $Y$  ( $N$ ) as positive (negative) instances. As there are a much larger number of negative than positive instances for each  $O$ , this results in data skew.

### 4.3 Feature Extraction for Classification

For the classification step, we calculate both rule-based and statistical features for supervised machine learning. We leverage our previous observations to engineer features specific to a particular channel. We describe both classes of features, listing its type (*binary* or *continuous*) and which channel it models (*phonetic substitution*, *abbreviation*, *paraphrase*, or *all*), as a two tuple. We accompany each rule with an example, showing Pinyin and tones, when appropriate.

#### 4.3.1 Rule-based Features (5 features).

- $O$  contains valid Pinyin script  $\langle b, ph \rangle$   
e.g., “冻shi了” (“冻死si3了”; “too cold”)
- $O$  contains digits  $\langle b, ph \rangle$   
e.g., “v5” (“威wei1武wu3”; “mighty”)

- $O$  is a potential Pinyin acronym  $\langle b, ph \rangle$   
e.g., “bs” (“鄙bi3视shi4”; “despise”)
- $T$  contains characters in  $O$ ?  $\langle b, ph \rangle$   
e.g., “桌游” (“桌面游戏”; “board games”)
- The percentage of characters common between  $O$  and  $T$   $\langle c, all \rangle$

### 4.3.2 Statistical Features (7 features).

We describe these features in more detail, as they form a key contribution in this work. Note that the statistical features that leverage information from both informal and formal domains are derived via maximum likelihood estimation on the appropriate training data.

**Pinyin Similarity**  $\langle c, ph \rangle$ . Although Levenshtein distance ( $LD$ ; employed in (Li and Yarowsky, 2008a)) is a low cost metric to measure string similarity, it has its drawbacks when applied to Pinyin similarity. As an example, the informal word “淫yin2 才cai2” is normalized to “人ren2 才cai2”, meaning “talent”. This suggests that  $PYSim(yin, ren)$  should be high, as they compose an informal-formal pair. However this is in contrast to evidence given by  $LD$  as  $LD(yin, ren)$  is large (especially compared with the  $LD(yin, yi)$ , in which “yi” is a representative Pinyin string that has an edit distance with “yin” of just 1). For the manual annotation method, it is difficult for annotators to accurately weigh the similarities for all pronunciation pairs, since it is weighted arbitrarily. And the labor of manually tuning weights may be unnecessary, given annotated informal-formal pairs.

To tackle these drawbacks, we propose to fully utilize the gold standard annotation (i.e., informal-formal pairs applicable to the Phonetic Substitution channel) and to empirically estimate the Pinyin similarity from the corpus in a supervised manner. In our method, Pinyin similarity is formulated as:

$$PYSim(T|O) = \prod PYSim(t_i|o_i) \quad (1)$$

$$\begin{aligned} PYSim(t_i|o_i) &= PYSim(py(t_i)|py(o_i)) \\ &= \mu P(py(t_i)|py(o_i)) + \lambda P(ini(t_i)|py(o_i)) \\ &\quad + \eta P(fin(t_i)|py(o_i)) \end{aligned} \quad (2)$$

Here, the  $t_i$  ( $o_i$ ) stands for the  $i$ th character in word  $T$  ( $O$ ). Let the function  $py(x)$  return the

Pinyin string of a character and functions  $ini(x)$  ( $fin(x)$ ) return *initial* (*final*) of a Pinyin string  $x$ . We use linear interpolation algorithm for smoothing, with  $\mu$ ,  $\lambda$  and  $\eta$  as weights summing to unity. Then,  $P(py(t_i)|py(o_i))$ ,  $P(ini(t_i)|py(o_i))$  and  $P(fin(t_i)|py(o_i))$  are estimated using maximum likelihood estimation over the training set.

**Lexicon and Semantic Similarity**  $\langle c, ab + pa \rangle$ . For the remaining two channels, we extend the source channel model (SCM) (Brown et al., 1990) to estimate the character mapping probability. In our case, SCM aims to find the formal string  $T$  that the given input  $O$  is most likely normalized to.

$$\hat{T} = \arg \max_T P(T|O) = \arg \max_T P(O|T)P(T) \quad (3)$$

As discussed in Section 3, for both the two channels we use interpolation to model character-word mappings. Assuming the character-word mapping events are independent, we obtain:

$$P(O|T) = \prod P(o_i|t_i) \quad (4)$$

where  $o_i$  ( $t_i$ ) refers to  $i$ th character of  $O$  ( $T$ ). However, this SCM model suffers serious data sparsity problems, when the annotated microtext corpus is small (as in our case). To further address the sparsity, we extend the source channel model by inserting part-of-speech mapping models into Equation 4.

$$P(O|T) = \prod P'(o_i|t_i) \quad (5)$$

$$P'(o_i|t_i) = \alpha P(o_i|t_i) + \beta P(o_i|pos(t_i), pos(o_i)) \quad (6)$$

Here, let the function  $pos(x)$  return the part-of-speech (POS) tag of  $x$ <sup>7</sup>. Both  $P(o_i|t_i)$  and  $P(o_i|pos(t_i), pos(o_i))$  are then estimated using maximum likelihood estimation over the annotated corpus. In parallel with the Pinyin similarity estimation,  $\alpha$  and  $\beta$  are weights for the interpolation, summing to unity.

We give the intuition for our formulation.  $P(o_i|t_i)$  measures the probability of using character  $o_i$  to substitute for the given word  $t_i$ .  $P(o_i|pos(t_i), pos(o_i))$  measures the probability of using character  $o_i$  as the substitution of any word  $t_i$ , given the POS tag is mapped from  $pos(t_i)$  to  $pos(o_i)$ . Finally, given the limited availability of gold standard annotations, we can optionally use

<sup>7</sup>Implemented in our system by the FudanNLP toolkit <https://code.google.com/p/fudannlp/>.

formal domain synonym dictionaries to improve our model’s estimation lexical and semantic similarity.

**N-gram Probabilities**  $5 \times \langle c, all \rangle$ . We generate new sentences by substituting informal words with candidate formal words. The probabilities of the generated trigrams and bigrams (within a window size of 3) are computed with BerkeleyLM, trained on the Web1T corpus. The features capture how likely the candidate word is used in the informal domain. The five features are:

- Trigram probabilities:  $P(W_{-2}W_{-1}T)$ ;  $P(W_{-1}T W_1)$ ;  $P(T W_1 W_2)$
- Bigram probabilities:  $P(W_{-1} T)$ ;  $P(T W_1)$

## 5 Experiments

In our architecture, the candidate generation procedure is unsupervised. The part that does need tuning is the final, supervised classifier that renders the binary decision on each 3-tuple, as to whether the  $O-T$  pair is a match, so for this task we select the best classifier among three learners. The statistics reported by Li and Yarowsky (2008a) is then used as a baseline\* performance. We mark this with an asterisk to indicate that the comparison is just for reference, where the performance figures are taken directly from their published work, as we did not reimplement their method nor execute it on our contemporary data.

As a second analysis point, we compare our system – with and without features derived from synonym dictionaries – to assess how well our method adapts from formal corpora. Finally we show that our method is also effective to acquire synonyms for the formal domain (formal–formal pairs, in contrast to our task’s informal–formal pairs).

### 5.1 Data Preparation

We collected 1036 unique informal–formal word pairs with their informal contexts were collected from our annotated corpus for cross-fold validation. As any supervised classifier would do, we testing logistic regression (LR), support vector machine (SVM) and decision tree (DT) learning models, provided by WEKA3 (Hall et al., 2009). To acquire formal domain synonyms, we option-

ally employed the Cilin<sup>8</sup> and TYCDict<sup>9</sup> dictionaries.

## 5.2 Results

We adopt the standard metrics of precision, recall and  $F_1$  for the evaluation, focusing on the the positive (correctly matched as informal–formal pair)  $Y$  class.

### 5.2.1 Classifier choice

Table 4 presents the evaluation results over different classifiers. In this first experiment, data from all the channels are merged together and the result reported is the outcome of 5-fold cross validation. Lexicon similarity features are derived only from the training corpus. As the DT classifier performs best, we only report DT results for subsequent experiments.

Classifier	Pre	Rec	$F_1$
SVM	.646	.273	.383
LR	.567	.340	.430
DT (C4.5)	.886	.443	.590

Table 4: Performance comparison using different classifiers.

### 5.2.2 Comparison with Baseline\*

To make a direct comparison with the baseline\*, we perform cross-fold validation using data each of three channels separately. Since Li and Yarowsky (2008a) formalized the task as a ranking problem, we show the reported Top1 and Top10 precision in Table 5<sup>10</sup>.

Our model achieves high precision for each channel, compared with the baseline\* performance. From Table 5 we observe that normalizing words due to Phonetic Substitution is relatively easy as compared to the other two channels. That is because given the fixed vocabulary of standard Chinese Pinyin, the Pinyin similarity measured from the corpus is much more stable than the estimated lexicon or semantic similarity. The low recall for the Paraphrase channel suggests the difficulty of inferring the semantic similarity between word pairs.

<sup>8</sup>[http://ir.hit.edu.cn/phpwebsite/index.php?module=pagemaster&PAGE\\_user\\_op=view\\_page&PAGE\\_id=162](http://ir.hit.edu.cn/phpwebsite/index.php?module=pagemaster&PAGE_user_op=view_page&PAGE_id=162)

<sup>9</sup><http://www.datatang.com/data/29207/>

<sup>10</sup>Due to the difference in classification scheme, we re-computed the reported value, given our classification.

Channel	System	Pre	Rec	$F_1$
Phonetic Substitution	OurDT	.956	.822	.883
	LY Top1	.754	—	—
	LY Top10	.906	—	—
Abbreviation	OurDT	.807	.665	.729
	LY Top1	.118	—	—
	LY Top10	.412	—	—
Paraphrase	OurDT	.754	.331	.460
	LY Top1	—	—	—
	LY Top10	—	—	—

Table 5: Performance, analyzed per channel. “—” indicate no comparable prior reported results.

### 5.2.3 Final Loss Rate

We note that there is a tradeoff between the data scale and performance. By keeping the Top 1000 candidates, we observed an 18.8% overall loss of correct formal candidates (breaking down as 14.9% for Phonetic Substitutions, 22.8% for Abbreviations and 31.8% for Paraphrases). Based on this statistics, the final loss rate is 64.1%. By comparison, Li and Yarowsky (2008a)’s seed bootstrapped method’s self-stated loss rate is around 70%.

### 5.2.4 Channel Knowledge and Use of Formal Synonym Dictionaries

In the real-world, we have to infer the channel an informal word originates from. To assess how well our system does without channel knowledge, we merged the separate channel datasets together and train a single classifier.

To investigate the impact of the formal synonym dictionaries, two configurations – with and without features derived from synonym dictionaries – were also tested. To upper bound achievable performance, we trained an oracular model with the correct channel as an input feature. In the results presented in Table 6, we see that the introduction of the features from the formal synonym dictionaries enhances performance (especially recall) of the basic feature set. As upper-bound performance is still significantly higher, future work may aim to improve performance by first predicting the originating channel.

### 5.2.5 Formal Domain Synonym Acquisition

To evaluate our method in the formal text domain, we take the synonym pairs from TYCDict as the test corpus and use the microtext data together with Cilin dictionaries as training. The experiment

Feature set	Pre	Rec	$F_1$
w/o	.886	.443	.590
w	<b>.895</b>	<b>.583</b>	<b>.706</b>
w + channel	.915	.638	.752

Table 6: Performance over different feature sets. “w” (“w/o”) refers to the model trained with (without) features from formal synonym dictionaries. “channel” refers to the model trained with the correct channel given as an input feature.

follows the same workflow as is done for the earlier microtext experiments, except that the context is extracted from the Chinese Wikipedia<sup>11</sup>. As we obtained solid performance, ( $Pre = .949$ ,  $Rec = .554$  and  $F_1 = .699$ ), we feel that our method can be applied to synonym acquisition task in the formal domain.

## 6 Conclusion

Based on our observations from a crowdsourced annotated corpus of informal Chinese words, we perform a systematic analysis about how informal words originate. We show that there are three main channels – phonetic substitution, abbreviation and paraphrase – that are responsible for informal creation, and that the motivation for their creation varies by channel.

To operationalize informal word normalization we suggest a two-stage candidate generation-classification method. The results obtained are promising, bettering the current state of the art with respect to both  $F_1$  and loss rate. In our detailed analysis, we find that channel knowledge can still improve performance and is a possible field for future work.

## Abstract

Event recognition and event type classification are among the important areas in text mining. A state-of-the-art approach utilizing deep-level lexical semantics and syntactic dependencies suffers from a limitation of requiring too large feature space. In this paper, we propose a novel feature selection method using a semantic hierarchy of features based on WordNet relations and syntactic dependencies. Compared to the well-known feature selection methods, our proposed method reduces the feature space significantly while keeping the same level of effectiveness. For noun events, it improves effectiveness as well as efficiency. Moreover, we expect the proposed feature selection can be applied to the other types of text classification using hierarchically organized semantic resources such as WordNet.

## 1 Introduction

Feature selection is an important issue in text-based classification because features can be generated in a number of different ways from text. Selecting features affects not only efficiency when the space is big but also classification effectiveness by eliminating noise features (Manning, Raghavan, & Schütze, 2008). In this paper, we propose a new feature selection method that utilizes semantic aspects of word features and discuss its relative merits compared to other well-known feature selection methods.

Among many text-based classification problems, this research focuses on event recognition

(a kind of binary classification) and type classification that have been studied extensively to improve performance of applications such as automatic summarization (Daniel, Radev, & Allison, 2003) and question answering (Pustejovsky, 2002). For event recognition and type classification, TimeML has served as a representative annotation scheme of events (Pustejovsky, Castaño, et al., 2003), which are defined as situations that happen or occur and expressed by verbs, nominalizations, adjectives, predicative clauses or prepositional phrases. TimeML defines seven types of events, REPORTING, PERCEPTION, ASPECTUAL, I\_ACTION, I\_STATE, STATE, and OCCURRENCE (Pustejovsky, Knippen, Littman, & Saurí, 2007), to which a recognized event text is classified for event type classification.

Different approaches to recognize and classify TimeML events have been proposed, ranging from rule-based approaches (Saurí, Knippen, Verhagen, & Pustejovsky, 2005) to supervised machine learning techniques based on lexical semantic classes and morpho-syntactic information around events (Bethard & Martin, 2006; Boguraev & Ando, 2007; Jeong & Myaeng, 2013; Llorens, Saquete, & Navarro-Colorado, 2010). Jeong & Myaeng (2013) recently showed that using the deeper-level of semantics increased the performance. They obtained the best performance in their classification experiments when lexical semantic features using hypernyms at the maximum depth of eight in WordNet were used for the event candidates and the words having syntactic dependency. While the approach showed a meaningful improvement, it has a problem of generating too many features.

Semantic features that can be mapped to a structure like WordNet have hierarchical relationships. In this situation, when two features

have a hypernym-hyponym relationship, the higher-level feature encompasses the lower-level one (see Figure 1-(a)). If a conventional feature selection method were used, therefore, the selected features would include both overly specific, low-level features and more general ancestors that cover the characteristics of the children (see Figure 1-(b)). When the general features are accurate and specific enough to represent the class, their descendants are unnecessary and redundant. When redundant features of similar kind are used, they cause not only efficiency problems but also potential overfitting of the model because the resulting model may become biased towards the semantics covered by the sub-tree containing the features.

Figure 1. Feature Selection in Hierarchical Feature Space

It is important to select the features that are sufficiently general to encompass more specific features found in the training data but specific enough to utilize deep-level semantics available in the hierarchy (see Figure 1-(c)). The leftmost feature in (c) covers the semantics of the two features under it without having to keep them. Choosing the feature in the center and the rightmost feature has a similar effect and at the same time avoids using the overly general feature that encompasses both as well as the sibling of the rightmost one, which is not an appropriate one. In other words, we should select as general a feature as possible as long as none of them are considered irrelevant for the class, thereby it can cover the semantics of the features underneath it, without which we can achieve better efficiency.

In short, we propose a method for solving the problem of using features that are semantically redundant. Assuming that all the features can be organized in the form of a hierarchy, the method attempts to select the features that are as specific as possible as long as there are no semantically redundant features.

## 2 Event Recognition and Type Classification Task

We first describe the task for recognition and type classification of TimeML events. For word-

based event recognition and type classification, we converted the phrase-based annotations into a form with BIO-tags. For each word in a document, we assign a label indicating whether it is inside or out-side of an event (i.e., BIO2<sup>1</sup> label) as well as its type. For type classification, in addition, each word must be classified into one of the known event classes. Figure 2 illustrates an example of chunking and labeling components of an event in a sentence.

Word	Event Label	Event Type Label
All	O	O
75	O	O
people	O	O
on	B-EVENT	B-STATE
board	I-EVENT	I-STATE
the	O	O
Aeroflot	O	O
Airbus	O	O
died	B-EVENT	B-OCCURRENCE
.	O	O

Figure 2. Event chunking for a sentence, “All 75 people on board the Aeroflot Airbus died.” B-EVENT, I-EVENT and O refer to the beginning, inside and outside of an event.

Our method consists of three parts: preprocessing, feature extraction and selection, and classification. The preprocessing part analyzes raw text for tokenization, PoS tagging, and syntactic parsing (dependency parsing). It is done by the Stanford CoreNLP package<sup>2</sup>, which is a suite of natural language processing tools. Then, the feature extraction part converts the preprocessed data into the feature space, followed by feature selection. Finally, the classification part determines whether the given word is an event or not and its type using a maximum entropy (ME) classifier.

## 3 Feature Candidate Generation

Because the goal of the proposed method is to automatically select the most valuable features, we generate feature sets based on the same criteria of Jeong & Myaeng’s work (2013), which showed better performance for TimeML event than the state-of-the-art approach. The details are below:

<sup>1</sup> IOB2 format: (B)egin, (I)inside, and (O)utside

<sup>2</sup> Stanford CoreNLP, <http://nlp.stanford.edu/software/corenlp.shtml>

**Lexical Semantic Features (LSF).** The set of target words’ lemmas and their all-depth WordNet semantic classes (i.e., hypernyms). For example, a noun “*drop*” that is mapped to such a WordNet class is always an event regardless of its context in a sentence in the TimeBank corpus (Pustejovsky, Hanks, et al., 2003).

**Windows Features (WF).** The lemma, hypernyms, and PoS of the context defined by a five-word window [-2, +2] around a target word.

**Dependency-based Features (DF).** They are similar with WF, but the context is defined by syntactic dependencies. This feature type differs from WF because the context may go beyond the fixed size window and the features are not just words. Increasing the window size for WF instead of using this feature type is not an option because it would end up including some noise by including too big a context. Four dependencies we consider are: subject (SUBJ), object (OBJ), complement (COMP), and modifier (MOD).

- **SUBJ type.** A feature is formed with the governor or dependent word and its hypernyms that has the SUBJECT relation (*nsubj* and *nsubjpass*) with the target word.
- **OBJ type.** It is the governor or dependent word and its hypernyms, which has the OBJECT relation (*dobj*, *iobj*, and *pobj*) with the target word. In “... *delayed the game* ...”, for instance, the verb “*delay*” can describe the temporal state of its object noun, “*game*”.
- **COMP type.** It indicates the governor or dependent word and its hypernyms, which has the COMPLEMENT relation (*acomp* and *xcomp*) with the target word. In “... *called President Bush a liar* ...”, for example, the verb “*called*” makes the state of its object (“*Bush*”) into the complement noun, “*liar*”. In this case, the word “*liar*” becomes a STATE event.
- **MOD type.** It refers to the dependent words and their hypernyms in MODIFIER relation (*amod*, *advmod*, *partmod*, *tmod* and so on). This feature type is based on the intuition that some modifiers such as temporal expression reveal the word it modifies has a temporal state and therefore is likely to be an event.

**Combined Features (CF).** They are a combination of LSF and DF (or WF). A certain DF may not be an absolute clue for an event by itself but only when it co-occurs with a certain lexical or semantic aspect of the target word.

#### 4 Feature Selection Based on Semantic Hierarchy

Since a large number of features are generated with the aforementioned feature generation method, it is necessary to filter out those whose roles in classification are minimal. We first remove the feature candidates whose frequency in the training data is less than two. If a target word containing the feature candidate is determined not to be an event more than 50% in the training data, it is also eliminated. The remaining feature candidates are then organized into a meaning hierarchy so that we can apply the tree-based feature selection method.

An entailment relationship between two features,  $f_i \gg f_j$ , is established by a hypernym/hyponym relationship, syntactic dependency, or occurrence sequence as in Table 1. A and D represent an ancestor and a descendent in a feature hierarchy tree with  $A \gg D$ . We call the LSF and DF (or WF) features in CF as target and context elements, respectively. LSF can be an ancestor of CF because LSF does not consider the surrounding context of a target word whereas CF includes the context.  $CF_{LD}$  and  $CF_{LW}$  mean CF of LSF and DF and CF of LSF and WF, respectively.

A	D	Condition
LSF	LSF	A is hypernym of D.
LSF	$CF_{LD}$ or $CF_{LW}$	A is synset/hyponym of target in D. e.g.) $process_{LSF} \gg (report_{DF}, process_{LSF})$
DF	DF	Same dependency type. A is the hypernym of D.
DF	$CF_{LD}$	Same dependency with the target. A is synset/hyponym of surrounding in D. e.g.) $report_{DF} \gg (report_{DF}, process_{LSF})$
WF	WF	Same position from target. A is the hypernym of D.
WF	$CF_{LW}$	Same position from target. A is the synset/hyponym of the context in D. e.g.) $before_{WF} \gg (before_{WF}, launch_{LSF})$
$CF_{LD}$	$CF_{LD}$	Same dependency with target. The target and the context of A

A	D	Condition
		are the synset/hypernym of those of D, respectively.
CF <sub>LOW</sub>	CF <sub>LOW</sub>	Same position from target. The target and the context of A are the synset or hypernym of those of D, respectively.

A: Ancestor, D: Descendant (A >> D)

Table 1. Entailment Relation of Features

#### 4.1 Feature Tree Generation

Given that the entailment relationship >> can be established between two features, we can construct a feature tree that becomes a basis for tree-based feature selection. We begin with a tree that only has a root node R, a meta-feature that is the ancestor of all features. R entails and keeps adding new features to the tree until all the features are added to the tree. We define  $a$ ,  $d$ , and  $c$  for ancestor, descendent, and child features with the relationships  $a \gg d$  and  $a > c$  where  $>$  means  $c$  is a child of  $a$ , restricting that there is no node between  $a$  and  $c$  with  $a \gg c$ . Figure 3 illustrates the detail algorithm of feature tree generation.

When a new feature  $f$  is added to the (sub-)tree whose root is  $a$  and  $a \gg f$ ,  $f$  either becomes a child of  $a$  or is added to one of the sub-trees of  $a$  (line 9~28). If there is  $c$  such that  $c \gg f$ ,  $f$  is added to a subtree whose root is  $c$  (line 14~17). On the other hand, if  $f \gg c$ ,  $f$  replaces  $c$ , and  $c$  is entered to the sub-tree whose root is  $f$  (line 19~25). Finally if  $f$  has no entailment relation with any of the children nodes of  $a$ ,  $f$  is added as a child of  $a$  (line 26~27).

```

1 program GenerateTree;
2 F := feature candidates set;
3 r := root of feature tree;
4 begin
5   for f in F do
6     add_feature(r, f);
7   end;
8
9   procedure add_feature (a, f)
10  a : ascendant feature;
11  f : new feature;
12  begin
13    for c of a's children
14      if f is descendant of c then
15        begin
16          add_feature (c, f);
17          break;
18        end
19      else
20        if c is descendant of f then
21          begin
22            remove c from a's children;
23            add f to a's children;
24            add_feature (f, c);

```

```

24         break;
25       end;
26     if no child of a is ancestor or
27     descendant of f then
28       a's children <- f;
29     end.

```

Figure 3. Feature Tree Generation Algorithm

#### 4.2 Tree-Based Feature Selection

The key idea of the selection algorithm we devised is to evaluate each of the paths in the tree and select the appropriate node (i.e. feature). A path is defined to be the list of nodes between the root and a leaf node. In essence, the problem of selecting nodes or features from a tree is converted into smaller problems of selecting a node from individual paths. The process is illustrated with Figure 4 where each node of the tree except the root represents a feature. The tree has  $n$  paths corresponding to the number of leaf nodes. The algorithm selects the most representative node on a path, which is marked with a black node in Figure 4.

Figure 4. Paths between the root and the leaf nodes in a feature tree

To select the most representative feature on a path, we employed the notion of *lift*, which has been used widely in the area of association rule mining to compute the degree to which two items are associated (Tufféry, 2011). More specifically, it is defined as Equation (1) where  $P(f)$  indicate the probability of a feature  $f$  in training data set.  $P(E|f)$  is the conditional probability of events occurring given that  $f$  occurs.

$$lift(f) = \frac{P(E|f)}{P(f)} \quad (1)$$

While general feature selection methods such as  $\chi^2$  are based on the degree of belief, our selection method considers the reliability and applicability (or generality) of a feature. In other words, a feature we choose should have a high *lift* value (i.e., high reliability) and lie closest to the root on a path so that we can broaden its applicability.

These criteria would be particularly true when the amount of training data is not sufficient.

However, selecting the feature at the highest level in the tree may not be the best choice. In Figure 4, for example, even if the node  $F_i$  in grey is determined to be the most representative one for the path 1, it may not be the best one. In this case,  $F_j$  may be a better one because it happens to be the representative node for the path between  $F_i$  and  $L_1$ . However, there is a chance that the sub-tree of  $F_i$  may have important features (i.e.,  $L_3, L_5$ ) that end up elevating  $F_i$ 's weight unfairly. Instead of  $F_i$ , using  $F_j$  would be a better choice.

In order to handle this problem, we developed an algorithm where the key idea works as in Figure 5. We first collect all the representative features from the paths based on the reliability and generality criteria mentioned above (line 29~45). For each representative node, we check if any of the descendant nodes have been selected as a representative node of other paths (line 21). If the condition is met, the node is no longer considered as a representative node (line 23). The same process is applied to the sub-tree whose root is the node just deleted from the set of representative nodes (line 25). Up to now, this process does not require manually checking the performance for the selected features.

```

1  program SelectFeatures;
2  T := feature tree
3  F := selected feature set
4  begin
5    F ← ∅;
6    select_features(T);
7  end;
8
9  procedure select_from_tree
10 t := subtree of T
11 begin
12   r ← root of t
13   L ← leaf features of t
14   for l of L
15     p ← path from r to l;
16     f ← select_from_path (p);
17     add f to F;
18   end;
19   for f of F
20     D ← descendants of f;
21     if {d | d ∈ D and d ∈ F} ≠ ∅
22   then
23     begin
24       remove f from F;
25       t_f ← subtree of t whose root
26       is f
27       select_from_tree (t_f);
28     end;
29   end.
30 procedure select_from_path
31 p := feature path
32 begin

```

```

32   cur ← front of p
33   while
34     next ← next of cur
35     if next is null then
36   begin
37     add cur to F;
38     return;
39   end;
40   if lift(cur) ≥ lift(next) then
41   begin
42     add cur to F;
43     return;
44   end;
45 end.

```

Figure 5. Tree-Based Feature Selection Algorithm

We select the final features among those obtained through the above process by employing a widely used feature selection method (in our case,  $\chi^2$ ). It is because the most representative feature in a path might not be effective one in the entire feature space.

## 5 Experiment

### 5.1 Experimental Setup

The main goal of the experiment is to examine the efficacy of the proposed tree-based feature selection method in the context of event recognition and event type classification. For test collection, we use the TimeBank 1.2 corpus (Pustejovsky, Hanks, et al., 2003), which is the most recent version of TimeBank, annotated with the TimeML 1.2.1 specification. It contains 183 news articles and more than 61,000 non-punctuation tokens, among which 7,935 represent events.

We analyzed the corpus to investigate on the distribution of PoS (Part of Speech) for the tokens annotated as events. Most events are expressed in verbs and nouns. Sum of the two PoS types covers about 93% of all the event tokens, which is split into about 65% and 28% for verb and nouns, respectively.

The experiment is designed to see the effect of the selection method by using the feature candidates generated by the work of Jeong & Myaeng (2013), which showed the best performance in TimeML event recognition and classification in the literature. It generates feature sets based on the same criteria of the proposed method using syntactic dependencies and WordNet hypernyms. To find the concept (i.e., synset) of a target word, we applied the word sense disambiguation module of BabelNet (Ponzetto & Navigli, 2010). We also used Stanford Parser (Klein & Manning,

2003) to get the syntactic dependency based features.

A maximum entropy (ME) classifier was used because it showed the best performance for the tasks at hand, according to the literature. We also considered SVM, another popular machine learning algorithm in natural language processing. The evaluation was done by 5-fold cross validation, and the data of each fold was randomly selected. For the classifier, we used the Mallet machine learning package (McCallum, 2002) and Weka (Witten, Frank, & Hall, 2011).

## 5.2 Evaluation

We first evaluated the proposed tree-based feature selection in comparison with two widely accepted feature selection methods: information gain (IG) and  $\chi^2$ . For each feature selection method, we chose the number of features that gave the best performance in F1. In Table 2, TSEL means the pure tree-based feature selection without the reselection process using  $\chi^2$  whereas TSEL+ $\chi^2$  means the proposed method followed by  $\chi^2$ .

Compared to  $\chi^2$ , TSEL dramatically reduced the feature space significantly by 73.93% and 54.42% for event recognition and type classification, respectively, but the decrease of effectiveness was insignificant for the both tasks. The decrease was compensated by the reselection process (hence the TSEL+ $\chi^2$  case) to the point of 1.26% improvement over the  $\chi^2$  case. For type classification, only 40.68% of the features required by  $\chi^2$  were enough to achieve the same level of effectiveness achieved  $\chi^2$ . Due to the decrease of feature space, the running times of classification tasks (except preprocessing) were also quite reduced. The time-savings by TSEL were about 40% and 45% of  $\chi^2$  in the recognition and the type classification.

Event Recognition (ME)				
	IG	$\chi^2$	TSEL	TSEL + $\chi^2$
# features	202,495	255,371	66,578 (-73.93%)	64,041 (-74.92%)
P	0.8878	0.8720	0.8664	0.8779
R	0.8413	0.8531	0.8571	0.8687
F1	0.8639	0.8624	0.8617 (-0.08%)	0.8733 (+1.26%)
T	4.12 s	4.14 s	2.52 s (-39.13%)	2.51 s (-39.37%)

<sup>3</sup> We use  $\chi^2$  for discussion instead of IG because it showed the better performance than IG for the verb and noun event classification, which is the main focus of the research.

Type Classification (ME)				
	IG	$\chi^2$	TSEL	TSEL + $\chi^2$
# features	291,408	267,226	121,793 (-54.42%)	108,705 (-59.32%)
P	0.8050	0.8117	0.7847	0.8411
R	0.6340	0.6199	0.6334	0.6026
F1	0.7094	0.7029	0.7010 (-0.28%)	0.7021 (-0.11%)
T	9.73 s	9.69 s	5.31 s (-45.20%)	5.28 s (-45.51%)

P: Precision, R: Recall  
T: Running Time of Classification  
(at PC with 3.0 GHz Core 2 Duo CPU and 8 GB memory)

Table 2. Comparisons in time and effectiveness for event recognition and type classification

Event Recognition (SVM)				
	IG	$\chi^2$	TSEL	TSEL + $\chi^2$
# features	202,495	255,371	66,578 (-73.93%)	64,041 (-74.92%)
P	0.8277	0.8048	0.7338	0.8128
R	0.8406	0.8592	0.8806	0.8576
F1	0.8341	0.8311	0.8005	0.8346

Type Classification (SVM)				
	IG	$\chi^2$	TSEL	TSEL + $\chi^2$

P	0.6189	0.6179	0.6633	0.6833
R	0.6931	0.6531	0.6790	0.6700
F1	0.6539	0.6350	0.6711	0.6766

Table 3. Comparisons in effectiveness for event recognition and type classification using SVM classifier

Looking at the performance of different PoS types, we found that the performance of noun events was more meaningfully improved with a significantly reduced feature set. With the feature set reduction ratios of 81.66% and 81.50% for recognition and type classification, respectively, we achieved 6.85% and 3.94% of increase in F1<sup>4</sup>. For verbs, the numbers of features used for class recognition were also reduced significantly, but the F1 scores were slightly decreased. Our analysis shows that the increase in effectiveness for nouns is mainly attributed to the fact that the synsets of most nouns are located at a deep level of WordNet hierarchy. On the contrary, the hierarchy for verbs is not as deep as that of nouns. Note that the tree-based selection method is most helpful when heavy redundancy of features with a deep hierarchy causes a problem.

<sup>4</sup> The results are statistically significant with  $p < 0.05$ .

Recognition (ME)				
	Verb		Noun	
	# features	F1	# features	F1
$\chi^2$	90,792	0.9393	123,480	0.7138
TSEL	40,189 (-55.74%)	0.9385 (-0.09%)	25,169 (-79.62%)	0.7273 (+1.89%)
TSEL + $\chi^2$	40,180 (-55.74%)	0.9386 (-0.07%)	22,644 (-81.66%)	0.7627 (+6.85%)

Classification (ME)				
	Verb		Noun	
	# features	F1	# features	F1
$\chi^2$	217,287	0.7406	47,080	0.6288
TSEL	99,100 (-54.39%)	0.7220 (-2.51%)	21,722 (-53.86%)	0.6149 (-2.21%)
TSEL + $\chi^2$	49,550 (-77.20%)	0.7223 (-2.47%)	8,708 (-81.50%)	0.6536 (+3.94%)

Table 4. Feature space sizes and effectiveness values for noun and verb events in event recognition and type classification

Figure 6 and 7 show the performance changes incurred by reducing the feature sets for different feature selection methods. The lines start from the point where all the selected features were used in each method and continue with a decrement of 10% of the feature set all the way to the minimum of 10% of the originally selected feature set. The starting points of TSEL+ $\chi^2$  indicate the results of pure TSEL. Despite the elimination of many features, the pure TSEL does not much harm the F1 compared to the best cases of IG and X2. It clearly shows that reducing the size of feature sets is less detrimental with the proposed method in almost all the cases than the other selection methods. TSEL also shows the possibility to select valuable features without manual check of performance for the feature space size. For event type classification, the manual selection process (TSEL+ $\chi^2$ ) is still needed in order to find the best features but it guarantees the more effectiveness.

(a) Verb Event Recognition

(b) Noun Event Recognition

Figure 6. Performance change with feature set reduction in event recognition in each of the feature selection methods

(a) Verb Event Type Classification

(b) Noun Event Type Classification

Figure 7. Performance change with feature set reduction in event type classification in each of the feature selection methods

For the type classification task, Table 5 shows detailed scores for all the event types separately. An improvement is observed for most of the event types except for OCCURRENCE. Our analysis shows that this is related to the size of the training data. Since the ratio of OCCURRENCE events is about 53% of all the events in the TimeBank corpus, the training data for the OCCURRENCE type is much bigger than the others. It indicates that the feature redundancy is problematic when the training data is relatively small and that careful selection of features is particularly important to avoid overfitting.

	$\chi^2$	TSEL+ $\chi^2$
REPORTING	0.9111	0.9201 (+0.99%)

## 6 Related Work

EVITA (Saurí et al., 2005) is the first event recognition tool for TimeML specification. It recognizes events by using both linguistic and statistical techniques. It uses manually encoded rules based on linguistic information as main features to recognize events. It also uses WordNet classes to those rules for nominal event recognition, and checks whether the head word of noun phrase is included in the WordNet event classes. For sense disambiguation of nouns, it utilizes a Bayesian classifier trained on the SemCor corpus.

Boguraev & Ando (2007) analyzed the TimeBank corpus and presented a machine-learning based approach for automatic TimeML events annotation. They set out the task as a classification problem, and used a robust risk minimization (RRM) classifier to solve it. They used lexical and morphological attributes and syntactic chunk types in bi- and tri-gram windows as features.

Bethard & Martin (2006) developed a system, STEP, for TimeML event recognition and type classification. They adopted syntactic and semantic features, and formulated the event recognition task as classification in the word-chunking paradigm. They used a rich set of features: textual, morphological, syntactic dependency and some selected WordNet classes. They implemented a Support Vector Machine (SVM) model based on those features.

Llorens et al. (2010) presented an evaluation on event recognition and type classification. They added semantic roles to features, and built the Conditional Random Field (CRF) model to

recognize events. They conducted experiments about the contribution of semantic roles and CRF and reported that the CRF model improved the performance but the effects of semantic role features were not significant.

Jeong & Myaeng (2013) argued and demonstrated that unit feature dependency information and deep-level WordNet hypernyms are useful for event recognition and type classification. Their proposed method utilizes various features including lexical semantic and dependency-based combined features. In the TimeBank 1.2 corpus, the approach achieved 0.8601 and 0.7058 in F1 in event recognition and type classification, respectively.

## 7 Conclusion

In this paper, we proposed a novel feature selection method for event recognition and event type classification, which utilizes a semantic hierarchy of features. While our current work is based on the WordNet hierarchy and syntactic dependencies, the proposed method can be applied as long as it is possible to utilize a feature hierarchy, and shows the possibility to select valuable features without manual check of performance for the feature space size.

Our experimental results show that the proposed method is significantly effective in reducing the feature space compared to the well-known feature selection methods, and yet the overall effectiveness is similar to or sometimes better than a state-of-the-art approach depending on the PoS of the events. In particular, the effectiveness for noun events was improved quite meaningfully when the feature space was reduced significantly.

Although the proposed method showed the encouraging results, it still has some limitations. One issue is on the depth of the features in hierarchy. For verb, most features are located at shallow levels so the feature space reduction ratio is lower than those of noun. It implies that we need other approaches for verbs. Another one is on the recall. The proposed method showed high precision but relative lower recall. We conjecture that one reason is the lack of lexical information due to small size of TimeBank corpus.

Not only to improve recall but also for extensibility of the proposed method, we need to utilize other larger-scale resources for this tasks and even apply the proposed method for other types of text classification.

## Abstract

In this research, we suggest an approach to retrieval-related tasks for Korean SMS text. Most of the previous approaches to such text used morphological analysis as the routine stage of the preprocessing workflow, functionally equivalent to POS tagging. However, such approaches suffer difficulties since Short Message Service language usually contains irregular orthography, atypically spelled words, unspaced segments, etc. Two experiments were conducted to measure how well these problems can be avoided with the transliteration of Korean to Roman letters. In summary, we will argue that such a Romanization-based retrieval method has several advantages since it provides an easier way to preprocess the data with a variety of linguistic rules.

## 1 Introduction

In this internet era, everyday people express opinions, comments, or sentiments; all of which can be accessed via the web. Particularly with the popularization of mobile computing devices, it has become easier than ever for people to share messages using social media services like Twitter or Facebook. However, such an environment brings new challenges for researchers who aim to analyze or interpret this linguistic data. One of the problems they encounter is that these written texts have a different form than those in published books or articles. They were often called as short message service language, txt-speak,

chat-speak, etc. This new data source has received attentions from various fields and researchers working in the field of sentiment analysis and opinion-mining often find that dealing with such texts using traditional approaches is problematic.

For agglutinative languages like Korean, since words are formed by combining lemmas and various affixes, morphological analysis is required to find the functional meaning of each component. Most previous studies used morphological analysis only to preprocess the text, but this approach exhibits several weaknesses when used on the data that is written in SMS-like languages. First of all, texts are often unspaced to save on typing time and sentence length (e.g., Twitter only allows 140 characters per tweet). Secondly, many words are not typed in the same way as their dictionary entries; the letters are changed or reduced to smaller units due to morpho-phonetic variation and abbreviation processes.

This paper will propose a new approach to overcome these shortcomings for morphologically rich languages while making use of Korean case studies. This approach adopts Yale Romanization to transliterate Korean alphabets into Roman letters, which, due to the way it handles Korean characters, allows for a more intuitive and easier way of implementing the relevant rewriting rules and handling morpho-phonetic changes.

In Section 2, the problems of morphological analysis will be described and the properties of Korean SMS language will be reviewed. This will be followed up in Section 3 by an introduction to the Romanization-based framework and the method of employing linguistic rules. Section 4 will detail two retrieval experiments which were prepared to show the effectiveness of this approach. The first experiment was designed to observe whether the Romanization method could

handle unspaced texts. The second experiment explored the possibility of covering phonetic variations of the target words using a small set of linguistic rules.

## 2 Related Research

Transliteration methods have often been used for the task of keyword matching across different languages (Chen and Ku, 2002; Fujii and Ishikawa, 2001). In contrast, Han (2006) applied the transliteration method to perform part-of-speech tagging for Korean texts using Xerox Finite State Tool. Similarly, this paper proposes using the method not for Korean-English word equivalents but for Korean-to-varied Korean word detection.

### 2.1 Problems of morphological analysis: lack of lexicon

As the number of the users using social networking services increases rapidly, sentiment analysis or opinion mining capable of automatically extracting the sentiment orientation from online posts has been gaining attention from NLP researchers (Hu and Liu, 2004; Kim and Hovy, 2004; Wiebe, 2000; Pak and Paroubek, 2010). As stated above, Korean is an agglutinative language and the chunks distinguished by space must be further separated into roots and affixes before they can be assigned a part-of-speech tag. This whole procedure is performed by morphological analysis and is critical to determining the meaning of a component. However, it is also known that such analysis can cause errors when not equipped with complete word entries to analyze the text. Such 'lack of lexicon' problems arise because after the morphological analysis categorizes all listed words in the sentence it classifies the remaining words as general nouns (Jang and Shin, 2010). Consider the following.

- (1) 너무 진부한 내용  
 nemu cinpuha-n nayyong  
 too stale-AD<sup>1</sup> content  
 'too stale contents'
- (2) 너무/a 진부/ncs 하/xpa ㄴ/exm 내용/nc  
 nemu/a<sup>2</sup>cinpu/ncs ha/xpa n/exm nayyong/nc

<sup>1</sup> Abbreviates: AD(adnominal suffix), NM(nominative particle), IN(instrumental particle), SC(subordinative conjunctive suffix), CP(conjunctive particle), PST(past tense suffix), DC(declarative final suffix), RE(retrospective suffix), CN(conjectural suffix), PR(pronoun), PP(propositive suffix), AC(auxiliary conjunctive suffix), GE (genitive particle), LC(Locative particle)

- (3) 너/npp 무진/nc 부/nc 한/nc 내용/nc  
 ne/npp mucin/nc pu/nc han/nc nayyong/nc  
 'you Mujin(place name) wealth resentment contents'

Sentence (3) is a misanalyzed version of sentence (1). The morphological analyzer's dictionary did not include the word entry ('cinbu') so the analyzer had to ignore the previous spacing and take the proper noun ('mucin') as a possible morpheme instead (Jang and Shin, 2010; p. 500).

As can be inferred from examples (1) ~ (3), typical morphological analysis consists of two stages: first, a sentence or clause is decomposed into relevant morphemes and then, second, the distinguished morphemes are assigned part-of-speech tags which denote grammatical function. The reason why the morpheme separation stage precedes POS tagging is to avoid the sparse data problem caused by the multiplicity of morphological variants of the same stem (Han and Palmer, 2005). However, the morpheme-based POS tagger in this process is vulnerable to irregular variations of word stems and, unfortunately, such variants are often found on the web. By the same reason it also produces erroneous results given unspaced texts since the complexity of the decomposing morphemes is very high.

This paper assumes that the morpheme analysis procedure is not feasible to process the SMS texts. In order to alleviate the pain, this research will focus on how one can extract the expected items from the linguistic data with which morpheme analysis does not work.

### 2.2 Properties of Korean SMS language

Socio-linguistic studies of the Korean SMS language have revealed that the irregular variations within the language are not arbitrarily irregular. The five distinguished properties have been summarized in Table 1 (Park, 2006; Lee, 2010; Kim, 2011).

Some of the properties in Table 1 can be found in English SMS texts as well, hinting that this set of the features may be due to common factors. 'Addition of sounds' is known as epenthesis phenomenon, existing in many languages including English; Crystal (2008) contended that many features of the texting language (logograms, initialisms, pictograms, abbreviations, nonstandard spellings) are not entirely new and have already been in writing systems for centuries.

<sup>2</sup> POS tags: a(adverb), ncs(stative common noun), xpa(adjective-derived suffix), exm(adnominal suffix), nc(common noun), npp(personal pronoun)

Properties	Examples
Ignoring spacing	그녀가 학교에 갔다. (spaced: ‘그녀가 학교에 갔다’) Ku nyeca-ka hakkyo-ey ka-ss-ta The woman(nyeca)-NM school(hakyo)-LC go-PST-DC ‘The woman went to school’
Linking sound or phonetic writing	멋있어 -> 머시써 mes-iss-e ‘gorgeous’ -> me-si-sse
Reductions or shortenings	메일 -> 멜 meyil ‘mail’ -> meyl 서울 -> 셀 sewul ‘Seoul’ -> sel
Acronyms or abbreviation	애니메이션 -> 애니 ay-ni-mey-i-syen ‘animation’ -> ay-ni 비밀번호 -> 비번 pi-mil-pen-ho ‘password’ -> pi-pen
Addition of sounds	아빠 -> 압빠 a-ppa ‘daddy’ -> ap-ppa 여보 -> 여봉 ye-po ‘honey’ -> ye-pong

Table 1. Summarization of properties in Korean SMS text

Ling and Baron (2007) reported that lexical shortening is the one of the most significant characteristics one can see in text messages. However, ‘ignoring spacing’ is the exception, since Korean suffixes can play as good predictors for the roles or the functions of the preceding stem. As such, removing spaces between phrases does not severely deteriorate the readers’ understanding given the content.

This study will focus on only three of the features presented in Table 1: Unspacing, Linking, and lexical reduction. According to linguistic analysis (Park, 2006; Lee, 2010), liaison and vowel reduction were very common among the phonetic variation of the words. Following that observation, this paper will incorporate a set of rules (presented in Park, 2006) in its experiment. Also, it will make use of the Romanization transliteration with the given phonological rules to cope with the lexical variations of the linguistic data.

### 3 Romanization-based morpheme retrieval process

This section will provide the detailed contents of the lexical variation generation process. Basically, the generation process consists of the three main sub-modules: word-ending addition, vowel-change rules, and vowel omission. Each of these modules contains a set of linguistic rules. As a result, each target word in the list obtains its variants. These variants can then be used to check the input sentence for derived forms of the target word.

#### 3.1 Yale Romanization

Yale Romanization is the transliteration systems developed at Yale University for Romanizing Mandarin, Cantonese, Korean, and Japanese. The Yale system of Korean<sup>3</sup> is generally used in linguistics and is adopted as the application of the transliteration process in this work. There are two other Romanization systems, Revised Romanization of Korean and McCune-Reischauer system, but since the emphasis of the systems is on how to transliterate entire Korean words to a string of elements of a pronounceable alphabet, only Yale Romanization has a one-to-one correspondence between Korean letters and English letters. Therefore, the other two systems are not considered in this study.

#### 3.2 Korean syllable

The Korean alphabet, called Hangeul, consists of blocks of multiple letters with each block representing a single syllable. For example, the first word of the Korean word, 한글 (hangeul), can be decomposed into three letters (‘ㅎ’/‘h’, ‘ㅏ’/‘a’, and ‘ㄴ’/‘n’) though it is represented as a single character (or block) in Korean orthography. One advantage of using Yale Romanization is the ability to linearize the Korean syllables into a sequence of the phonemes and thus allowing the linking of alphabets with their sound properties. The examples in Table 1 show this phenomenon

<sup>3</sup> <http://search.cpan.org/dist/Encode-Korean/lib/Encode/Korean/Yale.pm>

clearly. Although it seems ‘멧있어’(mes-iss-e) and ‘머시씨’(me-si-sse) have quite different word forms, their romanized forms are identical; implicating that the latter is the phonetic writing version of the former.<sup>4</sup> Morphological analysis has difficulty when analyzing such phonetically written words since it makes distinctions based on Hangul syllables instead of the string of the letters. That is, ‘mes-iss-e’ and ‘me-si-sse’ are discriminated because the hyphens are taken as the boundary of the syllables even though this is not the case during pronunciation.

### 3.3 Implementation of linguistic rules

#### 3.3.1 Conjugation of verbs and adjectives

In Korean grammar, verbs or adjectives do not come as independent morphemes, but always present along with an appropriate conjugation. This paper considers 17 word endings for the romanized target words, following the standard grammar of Korean (~다 ‘~ta’, ~은 ‘~un’, ~는 ‘~nun’, ~고 ‘~ko’, ~기 ‘~ki’, ~냐 ‘~nya’, ~었다 ‘~essta’, ~았다 ‘~assta’, ~든지 ‘~tunci’, ~던지 ‘~tenci’, ~지 ‘~ci’, ~게 ‘~key’, ~음 ‘~um’, ~ㅁ ‘~m’, ~습니 ‘~supni’, ~읍니 ‘~upni’, ~구 ‘~kwu’). When the target lexical entry is given with its part-of-speech information, and if it belongs to the categories of noun or adjective, the 17 endings are added to the base word, generating 17 different word forms to be included in the lexicon paradigm set.

#### 3.3.2 Vowel contraction or change

This paper accepted the five vowel variation rules from Park (2006) as follows:

- (4) ‘o’ + ‘a’ -> ‘wa’. e.g., pho-hang (‘Pho-hang’) -> phwang<sup>5</sup>
- (5) ‘wu’ + ‘e’ -> ‘ye’. e.g., swu-ep (‘a class’) -> syep
- (6) ‘wu’ + ‘i’ -> ‘wi’. e.g., pwi-in (‘wife’) -> pwin
- (7) ‘i’ + ‘a’ -> ‘ya’. e.g., ki-an (‘draft’) -> kyan

<sup>4</sup> It is worth to noting that it becomes easier to apply re-writing rules to the romanized Hangul text because of its’ linearity.

<sup>5</sup> Note that the rule of ‘H-weak’ is manipulated here and the rule functionally works by omitting any ‘h’ between of sonorants. This rule helps to capture the typical linking sound phenomenon in Korean.

- (8) ‘i’ + ‘e’ -> ‘ye’. e.g., ki-ek (‘memory’) -> kyek

The rules in (4) ~ (8) are supplied to the ‘vowel-change’ function that takes the Romanized target word as input and returns its changed form as the output.

#### 3.3.3 Vowel reduction

The vowel reduction rules used in this paper aim to catch two types of shortening; the first type is concerned with the middle syllable of the whole word while the second works on the last syllable. As described in section 3.2, one Hangul syllable consists of several letters and, if the syllable is the target area of the reduction process, the contained vowel may be removed. Therefore, considering the first word of the Korean word, 한글 (hangul), Romanized as ‘han’, if one omits the vowel (‘a’) then the result would be ‘hngul’.

Previous studies showed that Korean SMS language has frequent vowel reductions (Park, 2006; Lee, 2010; Kim, 2011) with the middle and final syllables being the most common targets for reduction. The example sentence (9) presents the omission of the vowel in the middle syllable and (10) provides an example of reduction in the final syllable.

- (9) sa-mwu-sil (‘office’) -> sam-sil
- (10) key-im (‘game’) -> keym

## 4 Experiment

Sentiment analysis or opinion mining techniques that utilize retrieval tasks to obtain the training sets or corpus data have to extract subjective chunks or morphemes from the real-world data. In fact, if one chooses to use an annotated subjective word list for the study, one must still go through the process of confirming whether the items in the given list are in the raw input data. For that reason, an effective retrieval operation is required for research which needs to manage unorganized message texts. This section documents two experiments. The first is on the effectiveness of the proposed approach for unspaced tweet texts, while the second focuses on lexical variation.

### 4.1 Data

A large tweet dataset was obtained from another study (Lee et al., 2011). This dataset contained 5,913,888 tweets from 11,379 users up

Method \ Condition	Spaced			Unspaced		
	Precision	Recall	F-Measure	Precision	Recall	F-Measure
Romanization-based method	0.67	<b>0.79</b>	0.73	0.67	<b>0.79</b>	<b>0.73</b>
Morpheme analysis method	<b>0.94</b>	0.72	<b>0.82</b>	<b>0.95</b>	0.29	0.44

Table 2. Results of retrieval test for spacing factor

until the date of 14th Mar 2011. All the Twitter-specific components were filtered beforehand such as Twitter ID, Retweet marker, URL, and hash-tags. To form the list of the target sentiment words, 2823 sentiment word-morphemes, all annotated with their POS tags, were exploited from the previous study of the sentiment analysis on Korean movie reviews (Ko and Shin, 2010).

Since it is needed to construct the test dataset for the first experiment, 100 tweets were randomly selected from the tweet corpus and were manually annotated using the target sets found in the sentiment word list (as a result, 128 items were found in the 100 tweets).

For the second experiment, because no annotated corpus of Korean SMS texts was available, 80 tweets from the corpus were manually collected, each containing at least one irregular word (92 types in total). The varied word in the tweet was marked as the target and its corresponding original entry was restored and recorded in the target lexicon list.

#### 4.2 Experiment 1: Spaced vs. Unspaced

This experiment involved conducting a simple retrieval test for the selected 100 tweets using the sentiment word list as described above. To make a comparison with the proposed approach, the performance of the morphological analysis method also needed to be evaluated. As such, the data was tested using a Korean morphology analyzer.<sup>6</sup>

For the experimental conditions, one factor (spacing) was manipulated, providing two types of test dataset for the different approaches. Since removing all the spaces from the sentences would have left the morphological analyzer inoperable, only the spaces around the target were deleted to create the unspaced condition.

Table 2 shows the results of the retrieval experiment: how well each method found the target items and how many they picked incorrectly. The morpheme analysis-based approach barely chose any wrong targets, but it missed too many right

answers (the precision was 27% higher than the precision of Romanization-based method, while marking 7% lower recall rate). Although the morpheme analysis-based approach showed higher performance on the spaced text (0.82 versus 0.73 on F-Measure), the method proved ineffective against unspaced texts (the recall, compared to the Romanization method, was severely decreased from 0.72 to 0.29).

Following expectations, the Romanization-based method was very robust against unspaced texts. This phenomenon is easily explained by considering that the method searched for the target strings without any regard for morpheme boundaries. In contrast, the morpheme analysis-based method took the incoming chunks and separated them into morphemes, but when text is unspaced the morpheme analyzer has to perform word-segmentation as well as morpheme-analysis. Thus one would anticipate an increase in errors when the input text is not properly spaced, because it would increase the complexity of the analysis process.

However, unlike the predictions, the Romanization-based method recorded a lower precision than the morphological analysis-based approach. This result might be due to the set of short-length words in the target list. For example, words consisting of one or two letters such as ‘ak’ (both ‘evil’ or ‘music’ in English) may be erroneously identified in other words such as in ‘ak-ki’ (‘musical instrument’) since such short strings are likely to occur if only by chance. Thus, the Romanization-based method has a higher risk of errors if the system is supplied with such short terms. In the experiment above, the employed sentiment words were morphemes (not phrases or clauses), which is unfavorable for the Romanization approach. However, it is worthwhile to acknowledge that this is mitigated by employing the conjugation module, implying that well-defined rules can enhance performance.

<sup>6</sup> We used the Korean morpheme analyzer distributed from the 21st century Sejong Project ([http://www.sejong.or.kr/dist\\_frame.php](http://www.sejong.or.kr/dist_frame.php)).

Model	Precision	Recall	F-Measure
Vowel-reduction+, H weak+, Vowel-change+	0.80	<b>0.55</b>	<b>0.65</b>
Vowel-reduction+, H weak+, Vowel-change-	0.79	0.52	0.63
Vowel-reduction+, H weak-, Vowel-change+	0.79	0.53	0.63
Vowel-reduction-, H weak+, Vowel-change+	0.96	0.25	0.40
Vowel-reduction-, H weak-, Vowel-change+	0.96	0.23	0.37
Vowel-reduction-, H weak+, Vowel-change-	0.89	0.22	0.36
Vowel-reduction+, H weak-, Vowel-change-	0.78	0.5	0.61

Morphological analysis-based method	<b>1.0</b>	0.067	0.13

Table 3. Results of retrieval tests for phonetically changed words

### 4.3 Experiment 2: Covering phonetic changes in the lexicon

Experiment 1 dealt with the cases where morpheme’s grammatical category information was given, allowing the use of conjugation rule functions. Experiment 2 considers the situation in which specific words or expressions are given without POS tags and with phonetic variations of the targets which must be resolved before its original can be retrieved from the tweet data.

A retrieval experiment was conducted given the test data as described in section 4.1. Unlike Experiment 1, this experiment utilized the sub-modules of the lexical shortening (as stated in section 3.3). The result is displayed in Table 3.

The numbers in bold of Table 3 refer to the highest values for the column (tied values are treated as the same). The conjugation function is not carried out here because of a lack of grammatical category information, thus only three kinds of functions were manipulated as above. While vowel-change rules only care about the replacement of vowels, vowel-reduction rules cope with the circumstances in which the vowels in the word are omitted, resulting in a shortened form. H-weak rule is the only component that relates to any consonant change phenomena in this system; removing the phoneme ‘h’ between word syllables under specific conditions (e.g., The Korean word, ‘coh-a’ meaning ‘good’ is reduced to ‘co-a’). The notation [+/-] indicates whether the mentioned function was employed in the construction of the target paradigm set.

As can be seen in Table 3, the full model (including all the three sub-modules) outperforms the other models, proving the research assumption that implementation of linguistic rules would cover a subset of the lexical variations in the SMS language. With capturing the case alone, even the weakest model (with neither vowel-reduction/change nor H-weak functions) showed better results than those of morphological analy-

sis. This is because it could find type-equivalence between tokens such as ‘cwuk-um’ (죽음, ‘death’) and ‘cwu-kum’ (죽음, ‘death’), obtaining the higher F-score (0.38 vs. 0.13).

Obviously, the strongest module affecting the results is the vowel-reduction function. Remember that this function has two omission rules for the middle and the last syllables of the target items.

The model (with vowel-reduction off and the other two functions on) clearly reveals the effect of this sub-module by exhibiting a rapid drop in F-score from 0.65 for the full-model to 0.40 for the current model.

This effect is due to the high frequency of the vowel-reduction variations. Table 4 summarizes the types of variation in the test data, providing an explanation for the results in Table 3. The proportion of phoneme reduction instances can be seen to be about a third of the total occurrences (36 out of 104, or approximately 35 percent), and it accounts for the steep decrease in F-score when the vowel-reduction function is not adopted. It is also worth noting that vowel-reduction in the first-syllable is quite rare; consistent with the linguistic analysis of empirical research (Park, 2006; p. 466). The creation of vowel-reduced forms clearly had a large effect, lowering the accuracy from 0.96 to 0.80. This is because the shortened targets can also be found as sub-string of bigger words. However, this shortcoming does not weaken the efficiency of the whole approach. The morphological analysis-based retrieval method found only a few items in the data, which was expected considering that this analysis is dependent on a syllable-based word lexicon.

In short, though a small set of the linguistic rules were employed, and even using them is still far from achieving complete coverage, the results of the experiment implicate that such a rule-based system can capture at least part of the vast, complicated range of linguistic variations.

Type	Specified type		Count
Linking Sound			8

## 5 Discussion and Conclusion

This paper confirmed that employing language-specific rules to handle SMS language text can enhance the results of the retrieval process. Although it is known that morphological analysis hardly produces erroneous results in formally written texts such as newspaper articles, the analysis results were made much worse for the SMS data in our experiments, which presented the motivation to pursue an additional approach. The procedure of sentiment analysis or opinion mining generally involves searching for items which are defined as subjectively meaningful, but typical morphological analysis cannot deal with the irregular changes of the web texts.

The reason why the morphological analysis does not work on such data is clear. The built-in stemmer or normalization process of the analyzer is not designed to cope with that kind of the text. However, in this paper, we tried to point out that judging the text as not well-formed enough to be processed is too quick. Instead, a set of generative rules to handle such texts were proposed and implemented in our experiments. Although those rules could be imported to a future morphological analyzer giving it broader coverage, suffice it to state that the text on the internet is not as simple as newspaper articles to the analyzers currently available.

For such a case, this proposed method could be an alternative way to preprocess Korean SMS texts and it should be noted that there could be similar approaches for other morphologically rich languages like Japanese or Turkish. Normalizing text is a very complicated task for the type of the languages and well-organized module would be needed if it has to manipulate SMS

texts for any morpheme-level retrieval process.

A Romanization transliteration scheme is used in this study because it naturally represents the phonetic properties of Korean syllables while providing a more intuitive way to apply a set of defined rules to the sequence. Since phonemic variation is quite common in SMS texts, as mentioned, this approach seems useful and practical regarding the results of the experiments. Although the size of the dataset which was used for the test is small, the sample set contained cases which were well known in previous literature and their linguistic patterns were consistent with reports (Park, 2006; Lee, 2010; Kim, 2011). However, to make the approach practical enough to be used by field engineers, a large scale corpus would be required to find the optimal set of the transformation rules, which is left for future study due to the lack of such annotated data at the time of writing.

### Acknowledgments

We would like to thank Lee, W., Cha, M. and Yang, H. for their kind approval to use the Tweet corpus and the three anonymous reviewers for their helpful comments.

## Abstract

This paper investigates the importance of a word lattice generation algorithm in joint word segmentation and POS tagging. We conducted experiments on three Japanese data sets to demonstrate that the previously proposed pruning-based algorithm is in fact not efficient enough, and that the pipeline algorithm, which is introduced in this paper, achieves considerable speed-up without loss of accuracy. Moreover, the compactness of the lattice generated by the pipeline algorithm was investigated from both theoretical and empirical perspectives.

## 1 Introduction

Many approaches to joint word segmentation and POS tagging can be interpreted as reranking with a word lattice (Jiang et al., 2008), wherein a small lattice is generated for an input sentence, and then the lattice paths are reranked to obtain the optimal one. Examples of such a method include (Asahara and Matsumoto, 2000; Kudo et al., 2004; Kruengkrai et al., 2006; Jiang et al., 2008).

In such a framework, it is crucial to develop an efficient lattice generation algorithm. Since there are  $n_{+1}C_2 = O(n^2)$  word candidates, where  $n$  is the number of characters in the sentence, to be included in the lattice, it is prohibitively expensive to check all of them exhaustively. Such a naive method constitutes a severe bottleneck in a reranking system. Accordingly, in practice, it is necessary to resort to some technique to speed-up lattice generation.

It is, however, not straightforward to speed-up lattice generation for reranking, because there are

requirements that the lattice has to satisfy and it is necessary to achieve a speed-up while satisfying those requirements. Most importantly, the lattice should contain a sufficient amount of correct words; otherwise, the accuracy of the reranking system will be seriously degraded. Moreover, the lattice should be small: an excessively large lattice spoils the efficiency of the reranking system because it is expensive to find the optimal path of such a lattice.

For the reasons stated above, it is not readily obvious what sort of technique is effective for lattice generation. Despite its practical importance, this question, however, has not been well studied. For example, (Kudo et al., 2004) used a dictionary to filter word candidates. While indeed efficient, such a method is obviously prone to removing out-of-vocabulary (OOV) words from a lattice and degrade accuracy (Uchimoto et al., 2001). Jiang et al. (2008) employed a pruning-based algorithm to reduce the  $O(n^2)$  cost, but they did not investigate computational time required.

Given the above issues, the present study revisits lattice reranking by exploring the effectiveness of the lattice generation algorithm. Specifically, large-scale experiments were conducted on three Japanese data sets. The results of the experiments show that the pruning-based algorithm (Jiang et al., 2008) in fact incurs a non-negligible computational cost, which constitutes a bottleneck in the reranking system. Moreover, a pipelined lattice generation algorithm (see Section 3) was investigated as an alternative to the pruning-based one, and it was demonstrated that the reranking system using the pipeline algorithm speeds up the reranking more than 10 times without loss of accuracy. After that, the compactness of the lattice generated by the pipeline algorithm was examined from not

Input sentence: 東京都に住む (To live in Tokyo metropolis)

Word lattice:

Figure 1: Example lattice (Kudo et al., 2004). The circle and arrow represent the node and edge, respectively. The bold edges represent the correct analysis.

only theoretical but also empirical perspectives.

The first contribution of this study is to shed light on the importance of the lattice generation algorithm in lattice reranking. As mentioned earlier, past studies paid little attention to elaborating the lattice generation algorithm. On the contrary, the results of our experiments reveal that the design of the lattice generation algorithm crucially affects the performance of the reranking system (including speed, accuracy, and lattice size).

The second contribution is to provide clear empirical evidence concerning the effectiveness of the pipeline algorithm. Although the pipeline algorithm itself is a simple application of well-known techniques (Xue, 2003; Peng et al., 2004; Neubig et al., 2011) and does not have much novelty, its effectiveness has been left unexplored in the context of lattice reranking. Consequently, its merits (or demerits) in relation to the pruning-based algorithm have also been unknown.

The third contribution is to develop an accurate reranking system based on the pipeline algorithm. The developed system achieved considerably higher F<sub>1</sub>-score than three software tools that are widely used in Japanese NLP (JUMAN<sup>1</sup>, MeCab<sup>2</sup>, and Kytea<sup>3</sup>), while achieving high speed close to two of the three.

## 2 Preliminaries

As a preliminary, a word lattice and lattice reranking for joint word segmentation and POS tagging are explained in Sections 2.1 and 2.2, respectively. After that, the pruning-based lattice generation algorithm proposed by Jiang et al. (2008) is introduced in Section 2.3.

### 2.1 Word lattice

A word lattice, or lattice for short, is a data representation that compactly encodes an exponentially large number of word segmentations and POS tagging results (Kudo et al., 2004; Jiang et al., 2008).

An example lattice is illustrated in Figure 1. A lattice is formally a directed acyclic graph. A node (a circle in Figure 1) corresponds to the position between two characters, representing a possible word boundary. Moreover, two special nodes,  $b$  and  $e$ , represent the beginning and ending of the sentence. An edge (an arrow) represents a word-POS pair  $(w, t)$ , where  $w$  is a word defined by two nodes, and  $t$  is a member of the predefined POS tag set.

Since every path from node  $b$  to  $e$  represents one candidate analysis of the sentence, the task of joint word segmentation and POS tagging can be seen as locating the most probable path amongst those in the lattice. Dynamic programming is usually used to locate the optimal path.

For later convenience, notations that will be used throughout this paper are introduced as follows.  $x$  and  $y$  are used to denote an input sentence and a lattice path. It is presumed that sentence  $x$  has  $n$  characters, and  $c_i$  is used to denote the  $i$ -th character ( $1 \leq i \leq n$ ).  $w$  and  $t$  are used to denote a word and a POS tag, respectively.

### 2.2 Lattice reranking

Lattice reranking is an approximate inference technique for joint word segmentation and POS tagging (Jiang et al., 2008). In this approach, a small lattice is generated for an input sentence, and the paths of the lattice are then reranked to obtain the optimal one. The advantage of this approach is that the search space is greatly reduced in the same manner as conventional list-based reranking (Collins, 2000), while an exponentially large num-

ber of candidates is maintained in the lattice (Jiang et al., 2008).

In this framework, the task of joint word segmentation and POS tagging can be formalized as

$$\hat{y} = \arg \max_{y \in L(x)} \text{SCORE}(x, y) \quad (1)$$

where  $\hat{y}$  is the optimal path,  $L(x)$  is the lattice created for sentence  $x$ , and  $\text{SCORE}(x, y)$  is a function for scoring path  $y$  of lattice  $L(x)$ . For notational convenience, lattice  $L(x)$  is treated as a set of paths.

In this paper we explore the algorithm for generating the lattice  $L(x)$ . A naive approach requires  $O(n^2)$  time to determine which word candidate to include in  $L(x)$ , as mentioned in Section 1, and constitutes a bottleneck. Although additional time is required to perform the  $\arg \max$  operation, it is practically negligible because the lattice generated in this framework is generally small.

### 2.3 Pruning-based algorithm

Jiang et al. (2008) proposed a pruning-based lattice generation algorithm for reranking. Here, we briefly describe their algorithm. Interested readers may refer to (Jiang et al., 2008) for its details.

The pruning-based algorithm generates a lattice, specifically the edge set  $E$  constituting a lattice, by considering each character in a left-to-right fashion (Algorithm 1). The algorithm enumerates word-POS pairs  $(w, t)$ , or edges, that end with the current character,  $c_i$ , and stores them in the candidate list,  $C$  (line 5-10). Top-scored  $k$  edges in  $C$  are then moved to  $E$  (line 11). Note that the word length  $l$  is limited to, at most,  $K$  characters (line 5).

This algorithm can be understood as pruning  $O(n^2)$  candidate space by setting threshold  $K$  on the maximum word length. Although this method is much more efficient than exhaustively searching over the entire candidates, it still incurs non-negligible computational overhead, as we will demonstrate in the experiments.

An additional issue involving the pruning-based algorithm is how to determine the value of  $K$ . Although a smaller value of  $K$  reduces computational cost more, it is prone to remove more correct word-POS pairs from the search space. While this trade-off was not investigated by Jiang et al. (2008), it is examined in our experiment (see Section 5).

## 3 Pipeline Algorithm

As an alternative to the pruning-based algorithm, a pipelined lattice generation algorithm, which generates words and POS tags independently, is proposed here. In a nutshell, this method first generates the word set  $W$  constituting the lattice (Algorithm 2 line 2), and it then generates POS tags for each of the words (line 4).

The advantage of this approach is that it can naturally avoid searching the  $O(n^2)$  candidate space by exploiting a character-based word segmentation model (Xue, 2003; Peng et al., 2004; Neubig et al., 2011) to obtain the word set  $W$ . This algorithm has linear-time complexity in the sentence length and hence is efficient.

This section proceeds as follows. Sections 3.1 and 3.2 describe how to generate words and POS tags, respectively. The computational complexity is then examined in Section 3.3.

### 3.1 Word generation

The character-based word segmentation model (Xue, 2003; Peng et al., 2004; Neubig et al., 2011) is used to generate word set  $W$  (Figure 2 line 2). This model performs segmentation by assigning tag sequence  $\mathbf{b}$  to the input sentence:

$$\mathbf{b} = \arg \max_{\mathbf{b}} \Lambda_w \cdot \mathbf{F}_w(x, \mathbf{b})$$

Name	Template
Char. $n$ -gram	$\langle c_{i-1}, b_i \rangle, \langle c_i, b_i \rangle, \langle c_{i+1}, b_i \rangle, \langle c_{i-2}, c_{i-1}, b_i \rangle, \langle c_{i-1}, c_i, b_i \rangle, \langle c_i, c_{i+1}, b_i \rangle, \langle c_{i+1}, c_{i+2}, b_i \rangle,$ $\langle c_{i-3}, c_{i-2}, c_{i-1}, b_i \rangle, \langle c_{i-2}, c_{i-1}, c_i, b_i \rangle, \langle c_{i-1}, c_i, c_{i+1}, b_i \rangle, \langle c_i, c_{i+1}, c_{i+2}, b_i \rangle, \langle c_{i+1}, c_{i+2}, c_{i+3}, b_i \rangle$
Char. type $n$ -gram	$\langle c'_{i-1}, b_i \rangle, \langle c'_i, b_i \rangle, \langle c'_{i+1}, b_i \rangle, \langle c'_{i-2}, c'_{i-1}, b_i \rangle, \langle c'_{i-1}, c'_i, b_i \rangle, \langle c'_i, c'_{i+1}, b_i \rangle, \langle c'_{i+1}, c'_{i+2}, b_i \rangle,$ $\langle c'_{i-3}, c'_{i-2}, c'_{i-1}, b_i \rangle, \langle c'_{i-2}, c'_{i-1}, c'_i, b_i \rangle, \langle c'_{i-1}, c'_i, c'_{i+1}, b_i \rangle, \langle c'_i, c'_{i+1}, c'_{i+2}, b_i \rangle, \langle c'_{i+1}, c'_{i+2}, c'_{i+3}, b_i \rangle$
Dictionary	$\langle \text{BEGIN}, b_i \rangle, \langle \text{END}, b_i \rangle, \langle \text{INSIDE}, b_i \rangle, \langle \text{BEGIN}, s, b_i \rangle, \langle \text{END}, s, b_i \rangle, \langle \text{INSIDE}, s, b_i \rangle$

Table 1: Feature templates of word generation.  $c_i$  and  $c'_i$  represent the target character and its type, respectively.  $c'_i$  specifically takes one of the following values: (1) Roman alphabet, (2) Chinese *kanji* characters, (3) Japanese *hiragana* characters, (4) Japanese *katakana* characters, (5) numerical symbols, or (6) others. The neighboring characters and their types are similarly referred to as  $c_{i-1}$ ,  $c_{i+1}$ ,  $c'_{i+1}$ , and so on.  $b_i$  is the tag ( $B$  or  $I$ ) given to the target character. BEGIN and END represent whether a word in a dictionary begins with or ends before the target character, respectively. INSIDE means that the target character is inside the word.  $s$  denotes the length (1, 2, 3, 4, or  $5 \leq$ ) of the word registered in the dictionary.

Name	Template
Word	$\langle w, t \rangle$
Word length	$\langle \text{LENGTH}(w), t \rangle$
Affix	$\langle c_i, t \rangle, \langle c_i, c_{i+1}, t \rangle, \langle c_{j-1}, t \rangle, \langle c_{j-2}, c_{j-1}, t \rangle$
Neighboring string	$\langle c_{i-1}, t \rangle, \langle c_{i-2}, c_{i-1}, t \rangle, \langle c_{i-3}, c_{i-2}, c_{i-1}, t \rangle, \langle c_j, t \rangle, \langle c_j, c_{j+1}, t \rangle, \langle c_j, c_{j+1}, c_{j+2}, t \rangle$
Dictionary	$\langle \text{DICT}(w, t) \rangle, \langle \text{DICT}(w, t), t \rangle$

Table 2: Feature templates of POS tag generation.  $w = c_i c_{i+1} \dots c_{j-1}$  represents the word string, and  $t$  represents the target POS tag.  $\text{LENGTH}(w)$  returns the length of the word  $w$  in the number of characters: 1, 2, 3, 4, or  $5 \leq$ .  $\text{DICT}(w, t)$  is an indicator representing that word  $w$  with POS tag  $t$  is registered in a dictionary. The features in the last row are fired only when the target word is found in a dictionary.

where  $\mathbf{b} = b_1 \dots b_n$  is the character-based tag sequence that encodes the segmentation results;  $b_i = B$  and  $b_i = I$  represent whether the  $i$ -th character is the beginning or inside of a word, respectively.  $\mathbf{\Lambda}_w$  and  $\mathbf{F}_w(x, \mathbf{b})$  are weight and feature vectors, respectively.

The model is trained with the averaged structured perceptron (Collins, 2002) due to its simplicity and efficiency. The features illustrated in Table 1, as well as tag bigrams, were used for the training. The features in Table 1 is basically taken from (Neubig et al., 2011). The first two rows represent character strings surrounding the target character; the last row represents dictionary-based features similar to those described in (Neubig et al., 2011). The dictionary-based features are fired if a string in a sentence is registered as a word in a dictionary, and they encode whether the string begins with or ends before the target character, or includes the target character.

$\alpha$ -best outputs of this segmentation model are used to obtain word set  $W$ :

$$W = \cup_{i=1 \dots \alpha} W_i$$

where  $W_i$  is a word set included in the  $i$ -th best output. Hyperparameter  $\alpha$  controls the size of

word set  $|W|$  and is tuned by using development data.

### 3.2 POS tag generation

To generate POS tags for each word (Figure 2 line 4), a linear model was used. Given sentence  $x$  and word  $w$ , it assigns the following score to each POS tag  $t$  (Neubig et al., 2011):

$$\mathbf{\Lambda}_t \cdot \mathbf{F}_t(x, w, t)$$

where  $\mathbf{\Lambda}_t$  and  $\mathbf{F}_t(x, w, t)$  are weight and feature vectors, respectively. Averaged perceptron was used for training (Freund and Schapire, 1999).

Table 2 shows the feature templates. Word string, word length, prefixes and suffixes up to length two were used, and the adjacent strings of the word up to length three were used. We also check the presence of the word in a dictionary.

For each word, top- $\beta$  tags were used as the POS tag set  $T$  (line 4). Hyperparameter  $\beta$  is also tuned by using development data.

### 3.3 Computational complexity

Unlike the pruning-based algorithm, the pipeline algorithm can generate words of arbitrary lengths. Nevertheless, it still only needs  $O(n)$  time. This

can be proved as follows. First, the word segmentation model takes  $O(n)$  time to output word set  $W$ , since this step can be efficiently performed by dynamic programming. In addition, since  $O(|W|) = O(n)$ , the outer loop of the algorithm requires  $O(n)$  time. This can be verified as

$$|W| = |\cup_{i=1 \dots \alpha} W_i| \leq \sum_{i=1 \dots \alpha} |W_i| \leq \alpha n$$

where  $|W_i| \leq n$ . Since the process in lines 4-7 is independent of  $n$ , the pipeline algorithm requires  $O(n)$  time.

It also follows from the above discussion that the lattice size, that is, the number of edges, is also linear in the sentence length, i.e.,  $O(|E|) = O(n)$ . Consequently, since the node degree is at most  $\alpha$  (i.e., not dependent on  $n$ ), the lattice path can be efficiently reranked in  $O(n)$  time by using dynamic programming.

## 4 Perceptron-based Reranker

This section presents our reranker. Since the main focus of this study is in not reranking but lattice generation, a perceptron-based reranker was developed by simply following the procedure proposed by (Huang, 2008).

The scoring function  $\text{SCORE}(x, y)$  in equation (1) is defined as follows:

$$\begin{aligned} \hat{y} &= \arg \max_{y \in L(x)} \text{SCORE}(x, y) \\ &= \arg \max_{y \in L(x)} \Lambda \cdot \mathbf{F}(x, y) \end{aligned}$$

where  $\Lambda$  is the weight vector and  $\mathbf{F}(x, y)$  is the feature vector.

### 4.1 Training

The averaged perceptron algorithm was used to train weight vector  $\Lambda$  (Huang, 2008). Note here two minor technical issues that have to be addressed before the perceptron algorithm can be used for training the reranker.

First, the generated lattice  $L(x)$  might not include the oracle path. This possibility is avoided by simply adding all the nodes and edges in the oracle lattice to  $L(x)$ . This approach worked reasonably well in our experiments, while having the advantage of being simpler than the alternative (Huang, 2008; Jiang et al., 2008).

Second, the same data should not be used for training the lattice generator (i.e., the two models

described in Sections 3.1 and 3.2) and reranker. If the same data were used, we will end up using injuriously better lattices when training the reranker than testing. To meet this requirement, the training data were split into ten subsets. During training of the reranker, the lattices of each subset were provided by the lattice generator trained by using the remaining nine subsets. During testing, on the other hand, the lattice generator trained by using the entire training data was used.

## 4.2 Features

The features used for training the reranker include those listed in Table 1 and Table 2, as well as POS tag bigrams. For the features in Table 1, BIES encoding (Nakagawa, 2004) is used. Since all those features can be factorized, the optimal path is located by using dynamic programming.

## 5 Experiment

The effectiveness of the lattice generation algorithm was investigated in the experiment described in the following. Sections 5.1, 5.2, and 5.3 explain our experimental setting: data sets, lattice generation algorithms to be compared, and hyperparameter tuning. The experimental results are reported in Section 5.4. The experiments were performed on a computer with 3.2 GHz Intel® Xeon™ CPU and 32 GB memory.

### 5.1 Data sets

Three evaluation data sets were developed from three corpora: Kyoto Corpus (KC) version 4.0 (Kurohashi and Nagao, 1998), Kyoto university NTT Blog Corpus (KNBC) version 1.0 (Hashimoto et al., 2011), and Balanced Corpus of Contemporary Written Japanese (BCCWJ) (Maekawa, 2008). Each corpus was randomly split into three parts: training, development, and test set. The size of each data set is listed in Table 3.

JUMAN dictionary version 7.0<sup>4</sup> was used to extract the dictionary-based features in the experiments using KC and KNBC. Because BCCWJ adopts word segmentation criteria and a POS tag set different from those of the other two corpora, a different dictionary, UniDic version 1.3.12<sup>5</sup>, was used in the experiment using BCCWJ.

KNBC	3453	385	348
BCCWJ	47,547	6144	5741

Table 3: The number of sentences included in the three data sets.

## 5.2 Lattice generation algorithms

Two types of rerankers were implemented: one uses the pruning-based lattice generation algorithm, and the other uses the pipeline algorithm. All the rerankers were trained in the same manner as described in Section 4.

Although Jiang et al. (2008) fixed pruning threshold  $K$  as 20,  $K \in \{5, 10, 20\}$  was tested to examine the effect of this parameter. As a result, three rerankers that use the pruning-based algorithm were thus created.

The pruning-based algorithm uses a character-based model<sup>6</sup> to obtain top- $k$  edges (Figure 1 line 11). Although Jiang et al. (2008) proposed several features to train this model, they are simplistic compared with those used in the pipeline algorithm (i.e., Table 1 and 2). To make the comparison as fair as possible, the feature listed in Table 1 and BIES encoding were used (c.f., Section 4.2) were used. The features listed in Table 2 were not used, because they are not usable in a character-based model. It is considered that this feature set is comparable with that used by the pipeline algorithm, because the reranker using the pruning-based algorithm achieved comparable F<sub>1</sub>-score with the one using the pipeline algorithm when  $K$  is large (see Section 5.4).

## 5.3 Hyperparameter tuning

Hyperparameter  $k$  of the pruning-based algorithm was tuned with the development data. The tuning was done by searching over  $\{1, 2, 4, 8, 16, \dots, 256\}$  and selecting  $k$  that gen-

<sup>6</sup>Not detailed this model in this paper; refer to (Jiang et al., 2008) for details.

erated the lattice with the fewest edges amongst those covering at least  $\theta\%$  of the correct edges.

Since the pipeline algorithm also has hyperparameters  $(\alpha, \beta)$ , the hyperparameters were tuned in a similar manner by performing a grid search over  $\{1, 2, 4, 8, 16, \dots, 256\} \times \{1, 2, 4, 8, 16, \dots, 256\}$ .

The value of  $\theta$  was set as 99, 97, and 99 for the three data sets, respectively. A smaller value of  $\theta$  was used for KNBC because over 99% coverage could not be achieved in this data set.

## 5.4 Results

Table 4 summarizes the time in seconds spent on lattice generation, overall processing time spent on reranking, average number of candidates per sentence (see below), word-level F<sub>1</sub>-score in the joint task, and average lattice size per sentence, where lattice size refers to the number of edges in a lattice.

As for the pruning-based algorithm, the number of candidates refers to the number of words to be considered (Figure 1 line 6). As for the pipeline algorithm, it refers to the size of word set  $W$  (Figure 2). This number serves as an estimation of the computational cost. Notice that it corresponds to the time consumed by the two outer loops in Figure 1 or by the outer loop in Figure 2.

The symbol † is used to represent that the difference in F<sub>1</sub>-score from the best-performing system is statistically significant ( $p < 0.01$ ). Bootstrap resampling with 1,000 samples was used to test the statistical significance.

### 5.4.1 Runtime

Table 4 reveals that the reranking system using the pruning-based algorithm consumes the vast majority of the time for lattice generation. In other words, the pruning-based algorithm is not efficient enough. This inefficiency was not pointed out in previous studies, e.g., (Zhang and Clark, 2010; Sun, 2011).

The results in Table 4 also demonstrate that the reranker using the pipeline algorithm is an order of magnitude faster than the pruning-based algorithms. It is significantly faster than even the case that  $K = 5$ . This result indicates the importance of using an efficient lattice generation algorithm in the reranking system.

Table 4 also indicates that the number of the candidates roughly correlates with the actual computation time spent on lattice generation. This correlation confirms that the speed-up is achieved mainly by reducing the number of word candidates to be considered.

#### 5.4.2 F<sub>1</sub>-score

F<sub>1</sub>-score of the reranking systems was investigated next. The pipeline algorithm achieved comparable or higher F<sub>1</sub>-score than the pruning-based algorithm. This result shows that the speed-up does not come at the cost of accuracy.

It is crucial for the pruning-based algorithm to select an appropriate threshold value,  $K$ . If the value is too small, F<sub>1</sub>-score will significantly drop. In case that  $K = 5$ , F<sub>1</sub>-score was statistically significantly worse than that attained by the best-performing system for all three data sets ( $p < 0.01$ ). On the other hand, an excessively large value ( $K = 20$ ) does not contribute to the increase of F<sub>1</sub>-score so much, while it considerably degrades the speed.

#### 5.4.3 Lattice size

Table 4 shows that the pipeline algorithm usually generates smaller lattices than the pruning-based algorithm. This is because the pruning-based algorithm has no mechanisms to prune nodes (Jiang et al., 2008). To be more specific, the pruning-based algorithm always produces  $n + 1$  nodes for a sentence with  $n$  characters; hence, the lattice size is prone to grow large. The pipeline algorithm is, on the other hand, free from such a problem.

The coverage of the correct edges as the function of the average lattice size was investigated as follows (Figure 2). For the pruning-based algorithm, which has only one hyperparameter,  $k$ , the graph was drawn by changing  $k$  over  $\{1, 2, 4, 8, 16\}$ . Note that the graph for  $K = 10$  is omitted, because almost the same lattices are generated for  $K = 10$  and  $K = 20$ . For the pipeline algorithm,  $\alpha = 32$  is fixed and  $\beta$  is changed over  $\{1, 2, 4, 8, 16\}$  to draw the two-dimensional graphs. It is clear that the lattice generated by

	KC	KNBC	BCCWJ

Kytea	†96.95	†90.91	†97.10
Our reranker	<b>97.94</b>	<b>93.92</b>	<b>98.10</b>

Table 5: Comparison of F<sub>1</sub>-score with that achieved by the existing software.

the pipeline algorithm generally achieves higher coverage, while having a smaller number of edges than the pruning-based algorithm.

As discussed in Section 3.3, the size of word set  $|W|$  is linear in the sentence length. This analysis empirically justified as follows. The number of words is illustrated in Figure 3 as a function of sentence length. The three graphs in the figure clearly illustrate that the number of words grows linearly with increasing sentence length.

## 6 Comparison with Existing Software

As an additional experiment, the proposed pipeline-algorithm-based reranking system was compared with three software tools popular in Japanese NLP: JUMAN, MeCab (Kudo et al., 2004), and Kytea (Neubig et al., 2011).

Table 5 compares the F<sub>1</sub>-score of the proposed system with that attained by the three tools. Bootstrap resampling with 1,000 samples was used for the statistical significance test. The symbol † indicates that the F<sub>1</sub>-score is significantly lower than that achieved by the proposed system ( $p < 0.01$ ). It is clear that the proposed system outperforms the existing tools in the case of two of the three data sets, while performing comparably with JUMAN in the case of KNBC. Note that JUMAN is a rule-based system and is not applicable to BCCWJ because of the discrepancy in the definition of the segmentation criteria and POS tag set.

The speeds of the algorithms were also investigated. The proposed system processed 1400 sentences in a second, while JUMAN, MeCab, and Kytea processed 2100, 29000, and 3200 sentences, respectively. This result demonstrates that the proposed reranking system using the pipeline algorithm successfully achieved speed close to the two of the three tools, while keeping considerably higher F<sub>1</sub>-score.

## 7 Related Work

Several methods, other than the pruning-based algorithm (Jiang et al., 2008), have been developed

Figure 2: Coverage as the function of average lattice size (left: KC; middle: KNBC; right: BCCWJ).

Figure 3: Number of words as a function of sentence length (left: KC; middle: KNBC; right: BCCWJ).

for lattice generation. However, they are dependent on an external dictionary and have limitations in handling OOV words. For example, Kudo et al. (2004) built a lattice based on dictionary-lookup. While efficient, such a method is prone to remove OOV words from a lattice and degrade accuracy (Uchimoto et al., 2001). Other researchers (Nakagawa and Uchimoto, 2007; Kruengkrai et al., 2009) used a word-character hybrid model, which combines dictionary-lookup and character-based modeling of OOV words. This method still has difficulty in using word-level information of OOV words.

The techniques utilized by the pipelined lattice generation algorithm have also been used elsewhere (Sassano, 2002; Peng et al., 2004; Shi and Wang, 2007; Neubig et al., 2011; Wang et al., 2011). However, the present study is the first to investigate the effectiveness of such a technique in the context of lattice reranking. Empirical studies similar to the ones made in this study are not found in the other work.

Zhang and Clark (2008) and Zhang and Clark (2010) proposed a fast decoding algorithm for joint word segmentation and POS tagging. The present study is largely complementary with theirs, since it did not investigate to improve decoding algorithm. Their algorithm should be useful for the decoding of our reranker especially when dynamic programming is not effective; for example, nonlocal features are used.

## 8 Conclusion

The effectiveness of the lattice generation algorithms used in joint word segmentation and POS tagging was investigated. While lattice generation has not been paid much attention to in previous studies, the present study demonstrated that the design of a lattice generation algorithm has a significant impact on the performance of a reranking system. It was showed that the simple pipeline algorithm outperforms the pruning-based algorithm. We hope that the pipeline algorithm serves as a simple but effective building block of future researches.

## Abstract

This paper presents a simple but effective approach to unknown word processing in Japanese morphological analysis, which handles 1) unknown words that are derived from words in a pre-defined lexicon and 2) unknown onomatopoeias. Our approach leverages derivation rules and onomatopoeia patterns, and correctly recognizes certain types of unknown words. Experiments revealed that our approach recognized about 4,500 unknown words in 100,000 Web sentences with only 80 harmful side effects and a 6% loss in speed.

## 1 Introduction

Morphological analysis is the first step in many natural language applications. Since words are not segmented by explicit delimiters in Japanese, Japanese morphological analysis consists of two subtasks: word segmentation and part-of-speech (POS) tagging. Japanese morphological analysis has successfully adopted lexicon-based approaches for newspaper articles (Kurohashi et al., 1994; Asahara and Matsumoto, 2000; Kudo et al., 2004), in which an input sentence is transformed into a lattice of candidate words using a pre-defined lexicon, and an optimal path in the lattice is then selected. Figure 1 shows an example of a word lattice for morphological analysis and an optimal path. Since the transformation from a sentence into a word lattice basically depends on the pre-defined lexicon, the existence of unknown words, i.e., words that are not included in the pre-defined lexicon, is a major problem in Japanese morphological analysis.

There are two major approaches to this problem: one is to augment the lexicon by acquiring unknown words from a corpus in advance (Mori and Nagao, 1996; Murawaki and Kurohashi, 2008) and the other is to introduce better unknown word processing to the morphological ana-

Figure 1: Example of word lattice. The bold lines indicate the optimal path.

lyzer (Nagata, 1999; Uchimoto et al., 2001; Asahara and Matsumoto, 2004; Azuma et al., 2006; Nakagawa and Uchimoto, 2007). Although both approaches have their own advantages and should be exploited cooperatively, this paper focuses only on the latter approach.

Most previous work on this approach has aimed at developing a single general-purpose unknown word model. However, there are several types of unknown words, some of which can be easily dealt with by introducing simple derivation rules and unknown word patterns. In addition, as we will discuss in Section 2.3, the importance of unknown word processing varies across unknown word types. In this paper, we aim to deal with unknown words that are considered important and can be dealt with using simple rules and patterns.

Table 1 lists several types of Japanese unknown words, some of which often appear in Web text. First, we broadly divide the unknown words into two classes: words derived from the words in the lexicon and the others. There are a lot of informal spelling variations in Web text that are derived from the words in the lexicon, such as “あなた” (y0u) instead of “あなた” (you) and “冷たーーい” (cooooool) instead of “冷たい” (cool). The types of derivation are limited, and thus most of them can be resolved by introducing derivation rules. Unknown words other than those derived from known words are generally difficult to resolve using only simple rules, and the lexicon augmentation approach would be better for them. However, this is not true for onomatopoeias. Although Japanese is rich in onomatopoeias and some of them do not

Unknown words derived from known words		
Type	Unknown word	Original word
<i>Rendaku</i> * (sequential voicing)	(たまご) ざけ ((tamago-)zake, sake-nog)	ざけ ( <i>sake</i> , Japanese alcoholic drink)
Substitution with long sound symbols*	ほんとう (troo)	ほんとう (true)
Substitution with lowercases*	あなた (y0u)	あなた (you)
Substitution with normal symbols	うれい (h@ppy)	うれしい (happy)
Insertion of long sound symbols*	冷た——い (cooooool)	冷たい (cool)
Insertion of lowercases*	冷たああい (cooooool)	冷たい (cool)
Insertion of vowel characters	冷たああい (cooooool)	冷たい (cool)

Unknown words other than those derived from known words		
Type	Unknown word	Corresponding English expression
Onomatopoeia with repetition*	かあかあ	caw-caw
Onomatopoeia w/o repetition*	シュツと	hiss
Rare word / New word	除染 / ツイッター	decontamination / Twitter

Table 1: Various types of Japanese unknown words. The “\*” denotes that this type is the target of this research. See Section 2.2 for more details.

appear in the lexicon, most of them follow several patterns such as ‘*ABAB*,’ ‘*AつBり*,’ and ‘*ABつと*,’<sup>1</sup> and they thus can be resolved by considering typical patterns.

Therefore, in this paper, we introduce derivation rules and onomatopoeia patterns to the unknown word processing in Japanese morphological analysis, and aim to resolve 1) unknown words derived from words in a pre-defined lexicon and 2) unknown onomatopoeias.

## 2 Background

### 2.1 Japanese morphological analysis

As mentioned earlier, lexicon-based approaches have been widely adopted for Japanese morphological analysis. In these approaches, we assume that a lexicon, which lists a pair consisting of a word and its corresponding part-of-speech, is available. The process of traditional Japanese morphological analysis is as follows:

1. Build a lattice of words that represents all the candidate sequences of words from an input sentence.
2. Find an optimal path through the lattice.

Figure 1 in Section 1 shows an example of a word lattice for the input sentence “父は日本人” (My father is Japanese), where a total of six candidate paths are encoded and the optimal path is marked with bold lines. The lattice is mainly built with the words in the lexicon. Some heuristics are also used for dealing with unknown words, but in most cases, only a few simple heuristics are used. In fact, the three major Japanese morphological analyzers, JUMAN (Kurohashi and Kawahara, 2005), ChaSen (Matsumoto et al., 2007),

<sup>1</sup>‘*A*’ and ‘*B*’ denote Japanese characters, respectively.

and MeCab (Kudo, 2006), use only a few simple heuristics based on the character types, such as hiragana, katakana, and alphabets<sup>2</sup>, that regard a character sequence consisting of the same character type as a word candidate.

The optimal path is searched for based on the sum of the costs for the path. There are two types of costs: the cost for a candidate word and the cost for a pair of adjacent parts-of-speech. The cost for a word reflects the probability of the occurrence of the word, and the connectivity cost of a pair of parts-of-speech reflects the probability of an adjacent occurrence of the pair. A greater cost means less probability. The costs are manually assigned in JUMAN, and assigned by adopting supervised machine learning techniques in ChaSen and MeCab, while the algorithm to find the optimal path is the same, which is based on the Viterbi algorithm.

### 2.2 Types of unknown words

In this section, we detail the target unknown word types of this research.

*Rendaku* (sequential voicing) is a phenomenon in Japanese morpho-phonology that voices the initial consonant of the non-initial portion of a compound word. In the following example, the initial consonant of the Japanese noun “ざけ” (*sake*, alcoholic drink) is voiced into “ざけ” (*zake*):

- (1) たまご ざけ (eggnog)  
*ta ma go - za ke.*

Since the expression “ざけ” (*zake*) is not included in a standard lexicon, it is regarded as an unknown word even if the original word “ざけ” (*sake*) is included in the lexicon. There are a lot

<sup>2</sup>Four different character types are used in Japanese: *hiragana*, *katakana*, Chinese characters, and Roman alphabet.

of studies on *rendaku* in the field of phonetics and linguistics, and several conditions that prevent *rendaku* are known, such as Lyman’s Law (Lyman, 1894), which stated that *rendaku* does not occur when the second element of the compound contains a voiced obstruent. However, few studies dealt with *rendaku* in morphological analysis. Since we have to check the adjacent word to recognize *rendaku*, it is difficult to deal with *rendaku* using only the lexicon augmentation approach.

Some characters are substituted by peculiar characters or symbols such as long sound symbols, lowercase *kana* characters<sup>3</sup>, in informal text. First, if there is little difference in pronunciation, Japanese vowel characters ‘あ’(a), ‘い’(i), ‘う’(u), ‘え’(e), and ‘お’(o) are sometimes substituted by long sound symbols ‘ー’ or ‘〜.’ For example, a vowel character ‘う’ in the Japanese adjective “ほんとう” (*hontou*, true) is sometimes substituted by ‘ー’ and this adjective is written as “ほんとー” (*hontô*, troo). We call this phenomenon **substitution with long sound symbols**. As well as long sound symbol substitution, some *hiragana* characters such as ‘あ’(a), ‘い’(i), ‘う’(u), ‘え’(e), ‘お’(o), ‘わ’(wa), and ‘か’(ka) are substituted by their lowercases: ‘あ,’ ‘い,’ ‘う,’ ‘え,’ ‘お,’ ‘わ,’ and ‘か.’ We call this phenomenon **substitution with lowercases**.

There are also other types of derivation, that is, some characters are inserted into a word that is included in the lexicon. In the following examples, long sound symbols and lowercase are inserted into the Japanese adjective “冷たい” (cool).

- (2) 冷たーーーい (Insertion of  
(coooooo) long sound symbols)
- (3) 冷たあああい (Insertion of lowercases)  
(coooooo)

In addition to the unknown words derived from words in the lexicon, there are several types of unknown words that contain rare words such as “除染” (decontamination), new words such as “ツイッター” (Twitter), and onomatopoeias such as “かああ” (caw-caw). We can easily generate Japanese onomatopoeias that are not included in the lexicon. Most of them follow several patterns, such as ‘ABAB,’ ‘AㄗBり,’ and ‘ABつと,’ and we classified them into two types, **onomatopoeias with repetition** such as ‘ABAB,’ and **onomatopoeias without repetition** such as ‘AㄗBり.’

<sup>3</sup>In this paper, we call the following characters lowercase: ‘あ,’ ‘い,’ ‘う,’ ‘え,’ ‘お,’ ‘わ,’ and ‘か.’

### 2.3 Importance of unknown word processing of each type

The importance of unknown word processing varies across unknown word types.

We give three example sentences (4), (5), and (6), which include the unknown words “もこもこ” (fluffy), “除染” (decontamination), and “ツイッター” (Twitter), respectively. In these examples, (a) denotes the desirable morphological analysis and (b) is the output of our baseline morphological analyzer, JUMAN version 5.1 (Kurohashi and Kawahara, 2005).

- (4) Input: ふわふわでもこもこの肌触り。  
(A soft and fluffy feeling to the touch.)  
(a) ふわふわ / で / もこもこ / の / 肌触り。  
soft and fluffy of touch  
(b) ふわふわ / でも / こもこ / この肌触り。  
soft but straw matting this touch
- (5) Input: 除染が必要。  
(Decontamination is required.)  
(a) 除染 / が / 必要。  
decontamination is required  
(b) 除 / 染 / が / 必要。  
UNKNOWN WORD UNKNOWN WORD is required
- (6) Input: 昨日、ツイッターを始めた。  
(I started Twitter yesterday.)  
(a) 昨日、 / ツイッター / を / 始めた。  
yesterday Twitter ACC started  
(b) 昨日、 / ツイッター / を / 始めた。  
yesterday UNKNOWN WORD ACC started

In the case of (4), the unknown word “もこもこ” (fluffy) is divided into three parts by JUMAN, and influences the analyses of the adjacent function words, that is, “で” (and) is changed to “でも” (but) and “の” (of) is changed to “この” (this), which will strongly affect the other NLP applications. The wide scope of influence is due to the fact that “もこもこ” consists of *hiragana* characters like most Japanese function words. On the other hand, in the case of (5), although the unknown word “除染” (decontamination) is divided into two parts by JUMAN, there is no influence on the adjacent analyses. Moreover, in case of (6), although there is no lexical entry of “ツイッター” (Twitter), the segmentation is correct thanks to simple character-based heuristics for out-of-vocabulary (OOV) words.

These two unknown words do not contain *hiragana* characters, and thus, we think it is important to resolve unknown words that contain *hiragana*. Since unknown words derived from words in the lexicon and onomatopoeias often contain *hi-*

*ragana* characters, we came to the conclusion that it is more important to resolve them than to resolve rare words and new words that often consist of *katakana* and Chinese characters.

## 2.4 Related work

Much work has been done on Japanese unknown word processing. Several approaches aimed to acquire unknown words from a corpus in advance (Mori and Nagao, 1996; Murawaki and Kurohashi, 2008) and others aimed to introduce better unknown word model to morphological analyzer (Nagata, 1999; Uchimoto et al., 2001; Asahara and Matsumoto, 2004; Nakagawa and Uchimoto, 2007). However, there are few works that focus on certain types of unknown words.

Kazama et al. (1999)’s work is one of them. Kazama et al. improved the morphological analyzer JUMAN to deal with the informal expressions in online chat conversations. They focused on substitution and insertion, which are also the target of this paper. However, while our approach aims to develop heuristics to flexibly search the lexicon, they expanded the lexicon, and thus their approach cannot deal with an infinite number of derivations, such as “冷たい—い,” and “冷—たい—” for the original word “冷たい.” In addition, Ikeda et al. (2009) conducted experiments using Kazama et al.’s approach on 2,000,000 blogs, and reported that their approach made 37.2% of the sentences affected by their method worse. Therefore, we conjecture that their approach only benefits a text that is very similar to the text in online chat conversations.

Kacmarcik et al. (2000) exploited the normalization rules in advance of morphological analysis, and Ikeda et al. (2009) replaced peculiar expressions with formal expressions after morphological analysis. In this research, we exploit the derivation rules and onomatopoeia patterns in morphological analysis. Owing to such a design, our system can successfully deal with *rendaku*, which has not been dealt with in the previous works.

UniDic dictionary (Den et al., 2008) handles orthographic and phonological variations including *rendaku* and informal ones. However, the number of possible variations is not restricted to a fixed number because we can insert any number of long sound symbols or lowercases into a word, and thus, all the variations cannot be covered by a dictionary. In addition, as mentioned above, since we

Input: “おいしかったで—す” (おいしかったです, It was delicious)

Figure 2: Example of a word lattice with new nodes “おい,” “おいしかった,” and “で—す.” The broken lines indicate the added nodes and paths, and the bold lines indicate the optimal path.

have to take into account the adjacent word to accurately recognize *rendaku*, the lexical knowledge alone is not sufficient for *rendaku* recognition.

For languages other than Japanese, there is much work on text normalization that aims to handle informal expressions in social media (Beaufort et al., 2010; Liu et al., 2012; Han et al., 2012). However, their target languages are segmented languages such as English and French, and thus they can focus only on normalization. On the other hand, since Japanese is an unsegmented language, we have to also consider the word segmentation task.

## 3 Proposed Method

### 3.1 Overview

We use the rule-based Japanese morphological analyzer JUMAN version 5.1 as our baseline system. Basically we only improve the method for building a word lattice and do not change the process for finding an optimal path from the lattice. That is, our proposed system only adds new nodes to the word lattice built by the baseline system by exploiting the derivation rules and onomatopoeia patterns. If the new nodes and their costs are plausible, the conventional process for finding the optimal path will select the path with added nodes.

For example, if a sentence “おいしかったで—す.” is input into the baseline system, it builds the word lattice that is described with solid lines in Figure 2. However, this lattice does not include such expressions as “おいしかった” and “で—す” since they are not included in the lexicon. Our proposed system transforms the informal expressions into their standard expressions such as “おいしかった” (delicious) and “です” (was) by exploiting the derivation rules, adds their nodes into the word lattice, and selects the path with these added nodes.

### 3.2 Resolution of unknown words derived from words in the lexicon

We deal with five types of unknown words that are derived from words in the lexicon: *rendaku*, substitution with long sound symbols, substitution with lowercases, insertion of long sound symbols, and insertion of lowercases. Here, we describe how to add new nodes into the word lattice.

**Rendaku** The procedure to add unvoiced nodes to deal with *rendaku* differs from the others. Since only the initial consonant of a word is voiced by *rendaku*, there is at most one possible voiced entry for each word in the lexicon. Hence, we add the voiced entries into the trie-based lexicon in advance if the original word does not satisfy any conditions that prevent *rendaku* such as Lyman’s Law.

For example, our system creates the entry “ざけ” (zake) from the original word “さけ” (sake), and adds it into the lexicon. When the system retrieves words that start from the fourth character in the example (1) in Section 2.2, “たまござけ,” the added entry “ざけ” (zake) is retrieved. Since *rendaku* occurs for the initial consonant of the non-initial portion of a compound word, our system adds the retrieved word only when it is the non-initial portion of a compound word.

#### Substitution with long sound symbols and lowercases

In order to cope with substitution with long sound symbols and lowercases, our system transforms the input text into normalized strings by using simple rules. These rules substitute a long sound symbol with one of the vowel characters: ‘あ,’ ‘い,’ ‘う,’ ‘え,’ and ‘お,’ that minimizes the difference in pronunciation. These rules also substitute lowercase characters with the corresponding uppercase characters. For example, if the sentence “ほんとうにおいしい。” (It is trooly DELicious.) is input, the nodes generated from the normalized string “ほんとうにおいしい。” are added to the word lattice along with the nodes generated from the original string.

#### Insertion of long sound symbols and lowercases

In order to cope with the insertion of long sound symbols and lowercases, our system transforms the input text into a normalized string using simple rules. These rules delete long sound symbols and lowercase characters that are considered to be inserted to prolong the original word pronunciation. For example, if the sentence “冷たあぁーいであーす。” (It iiiiss coooool.) is input, the nodes generated from the normalized string “冷

Pattern	Example	Transliteration
<i>ABAB</i>	たゆたゆ	tayu-tayu
<i>ABCABC</i>	ぽっかぽっか	pokka-pokka
<i>ABCDABCD</i>	ちよろりちよろり	chorori-chorori

Table 2: Onomatopoeia patterns with repetition and their examples. ‘A,’ ‘B,’ ‘C,’ and ‘D’ denote either *hiragana* or *katakana*. We consider only repetitions of two to four characters.

Pattern	Example	Transliteration
$H_1\text{っ}H_2$ り	ぽっこり	pokkori
$K_1\text{ッ}K_2$ リ	マッターリ	mattari
$H_1\text{っ}H_2Y$ り	ぺっちやり	pecchari
$K_1\text{ッ}K_2Y$ リ	ポッチャリ	pocchari
$K_1K_2\text{っ}と$	チラっと	chiratto
$K_1K_2\text{ッ}と$	パキッと	pakitto

Table 3: Onomatopoeia patterns without repetition and their examples. ‘H,’ denotes the *hiragana*, ‘K’ denotes the *katakana*, and ‘Y’ denotes the palatalized consonants such as ‘ゃ.’

たいです。” are added into the word lattice. We do not consider partly deleted strings such as “冷たあいでーす。” and the combination of substitution and insertion to avoid combinatorial explosion. Therefore, our system cannot deal with unknown words generated by both insertion and substitution, but such words are rare in practice.

**Costs for additional nodes** Our system imposes small additional costs to the node generated from the normalized string to give priority to the nodes generated from the original string. We set these costs by using a small development data set.

### 3.3 Resolution of unknown onomatopoeias

There are many onomatopoeias in Japanese. In particular, there are a lot of unfamiliar onomatopoeias in Web text. Most onomatopoeias follow limited patterns, and we thus can easily produce new onomatopoeias that follow these patterns. Hence, it seems more reasonable to recognize unknown onomatopoeias by exploiting the onomatopoeia patterns than by manually adding lexical entries for them.

Therefore, our system lists onomatopoeia candidates by using onomatopoeia patterns, as shown in Tables 2 and 3, and adds them into the word lattice. Figure 3 shows examples. The number of potential entries of onomatopoeias with repetition is large, but the candidates of onomatopoeias with repetition can be quickly searched for by using a simple string matching strategy. On the other hand, to search the candidates of onomatopoeias without repetition is a bit time consuming com-

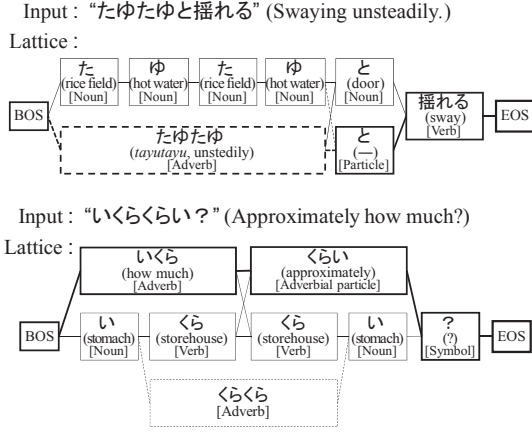

Figure 3: Examples of a word lattice with new nodes of onomatopoeia. The broken lines indicate the added nodes and paths, and the bold lines indicate the optimal path. While the optimal path includes the added node in the upper example, it does not in the lower example.

pared with trie search. However, the number of potential entries of onomatopoeias without repetition is not so large, and thus our system adds all possible entries of onomatopoeias without repetition into the trie-based lexicon in advance.

## 4 Experiments

### 4.1 Setting

We used 100,000 Japanese sentences to evaluate our approach. These sentences were obtained from an open search engine infrastructure TSUBAKI (Shinzato et al., 2008), which included at least one *hiragana* character and consisted of more than twenty characters

We first estimated the recall. Since it is too costly to create a set of data with all unknown words annotated, we made a set of data with only our target unknown words annotated. We could apply a set of regular expressions to reduce the unknown word candidates by limiting the type of unknown words. We manually annotated 100 expressions for each type, and estimated the recall.

A high recall, however, does not always imply that the proposed system performs well. It might be possible that our proposed method gives bad effects on non-target words. Therefore, we also compared the whole analysis with and without the rules/patterns from the following seven aspects:<sup>4</sup>

<sup>4</sup>There are two major reasons why we did not use the precision, recall and F-measure metrics to evaluate the overall performance. The first reason is that to create a large set of annotated data is too costly. The second reason, which is more essential, is that there is no clear definition of Japanese

1. The number of positive changes for 100 different outputs:  $P_{100D}$ .
2. The number of negative changes for 100 different outputs:  $N_{100D}$ .
3. The number of different outputs for 100,000 sentences:  $D_{100kS}$ .
4. The estimated number of positive changes for 100,000 sentences:  $P_{100kS}^*$ .
5. The estimated number of negative changes for 100,000 sentences:  $N_{100kS}^*$ .
6. The relative increase of the nodes:  $Node_{inc}$ .
7. The relative loss in speed:  $SP_{loss}$ .

Different outputs indicate cases in which the systems with and without rules/patterns output a different result. First, for each type of rule/pattern, we extracted 100 different outputs and manually classified them into three categories: the system with the rules/patterns was better (positive), the system without the rules/patterns was better (negative), and both outputs were undesirable (others). When these outputs differed in word segmentation, we only compared the segmentation but did not take into account the POS tags. On the other side, when these outputs did not differ in word segmentation, we compared the POS tags. Tables 6-10 list several examples. For example, “面白がれる” (can feel amused) in Table 6 should be analyzed as one word, but both systems with and without rules for *rendaku* divided it into several parts, and such a case is labeled as others.

We counted the number of different outputs for 100,000 sentences. We then calculated the estimated numbers of positive/negative changes for the sentences by using the equations:

$$X_{100kS}^* = D_{100kS} \times X_{100D}/100.$$

We also counted the number of created nodes in lattice and calculated the relative increase, which would affect the time for finding the optimal path from the word lattice, and measured the analysis time and calculated the relative loss in speed.

### 4.2 Results and Discussion

Table 4 lists the recall of our system for each unknown word type with the number of words that are covered by the UniDic dictionary. Note that while our system’s recall denotes the ratio of actually recognized words, the coverage of UniDic word segmentation, especially for unknown words. That is, we can accept various word boundaries. We thought it is more straight-forward and efficient to compare the differences between a baseline system and the proposed system.

Unknown word type	Recall of our system	# of words in UniDic
<i>Rendaku</i> (sequential voicing)	83/100	95
Substitution with long sound symbols	99/100	67
Substitution with lowercases	100/100	84
Insertion of long sound symbols	96/100	50
Insertion of lowercases	96/100	73
Onomatopoeia with repetition	89/100	78
Onomatopoeia w/o repetition	94/100	47

Table 4: Recall of our system and the coverage of UniDic.

only denotes the number of words included in the dictionary, which can be interpreted as the upper bound of the system based on UniDic. We can confirm our system achieved high recall for each type of unknown word. Since UniDic covered 95% of unknown words of *rendaku* type, we would be able to improve the *rendaku* recognition by incorporating UniDic and our approach that takes into account the adjacent word. Except for *rendaku*, our system’s recall was higher than the coverage of UniDic, which confirms the effectiveness of our method.

Table 5 summarizes the comparison between the analyses with and without the rules/patterns. In short, our method successfully recognized all types of unknown words with few bad effects. By introducing all the derivation rules and onomatopoeia patterns, there are 4,560 improvements for 100,000 sentences with only 80 deteriorations and a 6.2% loss in speed. In particular, the derivation rules of insertion and substitution of long sound symbols and lowercases produced 3,327 improvements for 100,000 sentences at high recall values (see Table 4) with only 27 deteriorations and a 3.8% loss in speed. We confirmed from these results that our approaches are very effective for unknown words in informal text. Since the number of newly added nodes was small, the speed loss is considered to be derived not from the optimal path searching phase but from the lattice building phase.

Table 6 lists some examples of the changed outputs by introducing the derivation rules for *rendaku*. As listed in Table 4 and 5, the *rendaku* processing produced more negative changes and the lower recall value compared with the other types. This indicates that *rendaku* processing is more difficult than resolving informal expressions with long sound symbols or lowercases. Since long sound symbols and lowercases rarely appear in the lexicon, there are few likely candidates other than the correct analysis. On the other hand, voiced characters often appear in the lexicon and formal

Our system	Baseline	Gold standard
Positive		
Input: 洗濯ばさみ (clothespin)		
洗濯 <b>ば</b> さみ	洗濯/ば/さみ	洗濯 <b>ば</b> さみ
Negative		
Input: 借入れがない方 (the man without)		
借入れ <b>が</b> ない	借 <b>入</b> れ <b>が</b> ない	借 <b>入</b> れ <b>が</b> ない
Others		
Input: 面白 <b>か</b> れる (can feel amused)		
面白 <b>か</b> れる	面白/か/れる	面白 <b>か</b> れる

Table 6: Examples of different outputs by introducing the derivation rule for *rendaku*. The ‘/’ denotes the boundary between words in the corresponding analysis, and the bold font indicates the correct output, that is, the output is the same as the gold standard.

Our approach	Baseline	Gold standard

Others (insertion)		
Input: す <b>げ</b> 豪華 (very luxury)		
す <b>げ</b> 豪華	すげ/豪華	す <b>げ</b> 豪華

Table 7: Examples of different outputs by introducing derivation rules for long sound symbol substitution and insertion.

text, and thus, there are many likely candidates.

Table 7 lists some examples of the changed output by introducing the derivation rules for informal spelling with long sound symbols. We labeled the change of the analysis “OK だよ” (It’s OK) as negative because the baseline system correctly tagged the POS of “だ” unlike our proposed system, but the baseline system could not also correctly resolve the entire phrase. There was no different output that our proposed system could not resolve but the baseline system could fully resolve.

Table 8 lists some examples of the changed outputs by introducing the derivation rules for informal spelling with lowercase. We labeled the change of the analysis “ゆみ**い**の布団” (Yumi’s bedclothes) as negative because the baseline system correctly segmented the postpositional particle “の” unlike our proposed system. Again for this example, the baseline system could not correctly resolve the entire phrase. Along with the informal spelling with long sound symbols, there was no different output that our proposed system could not resolve but the baseline system could fully resolve.

Rules/patterns	$P_{100D}$	$N_{100D}$	$D_{100kS}$	$P_{100kS}^*$	$N_{100kS}^*$	$Node_{inc.}$	$SP_{loss}$
<i>Rendaku</i> (sequential voicing)	37	8	379	140	30	0.553%	2.0%
Substitution with long sound symbols	55	1	920	506	9	0.048%	0.8%
Substitution with lowercases	78	1	1,762	1,374	18	0.039%	0.7%
Insertion of long sound symbols	84	0	1,301	1,093	0	0.038%	1.9%

たゆたゆと	たゆたゆと	たゆたゆと
Negative		
Input: あらあら (wow wow)		
あらあら	あら/あら	あら/あら

Table 9: Examples of different outputs by introducing onomatopoeia patterns with repetition.

Our system	Baseline	Gold standard
Positive		
Input: ぺっ/ちゃり (flat)		
ぺっ/ちゃり	ぺっ/ちゃり	ぺっ/ちゃり
Input: チラっと (at a glance)		
チラっと	チラ/っと	チラ/っと

Table 10: Examples of different outputs by introducing onomatopoeia patterns without repetition.

Table 9 lists some examples of the changed outputs by introducing onomatopoeia patterns with repetition. Our system recognized unknown onomatopoeias with repetition at a recall of 89%, which is not very high. However, since there were several repetition expressions other than onomatopoeias, such as “あら/あら” (wow wow) as shown in Table 9, we cannot lessen the cost for onomatopoeias with repetition.

Table 10 lists some examples of the changed outputs by introducing onomatopoeia patterns without repetition. Our system recognized the unknown onomatopoeias without repetition at a recall of 94% and did not output anything worse than

Type	# of types	# of tokens
Covered by Murawaki's Lexicon	13	51
Covered by Wikipedia	68	407
Covered by our method	15	105
Others	22	82
Total	118	645

Table 11: Classification results of unknown words that occur more than two times in KNB corpus.

the baseline output with no loss in speed.

In order to approximate the practical coverage of our method, we classified unknown words that occur more than two times in the Kyoto University and NTT Blog (KNB) corpus<sup>5</sup> into four types: words that are covered by the lexicon created by Murawaki and Kurohashi (2008) (Murawaki's Lexicon), words that are not covered by Murawaki's Lexicon but have entries in Wikipedia, words that are covered only by our method, and the others. Table 11 shows the results. There are total 645 tokens of unknown words that occur more than two times in KNB corpus, 105 of which are newly covered by our method. Since the number of tokens that are covered by neither Murawaki's Lexicon nor Wikipedia is only 187, we can say that the coverage of our method is not trivial.

## 5 Conclusion

We presented a simple approach to unknown word processing in Japanese morphological analysis. Our approach introduced derivation rules and onomatopoeia patterns, and correctly recognized certain types of unknown words. Our experimental results on Web text revealed that our approach could recognize about 4,500 unknown words for 100,000 Web sentences with only 80 harmful side effects and a 6% loss in speed. We plan to apply our approach to machine learning-based morphological analyzers, such as MeCab, with UniDic dictionary, which handles orthographic and phonological variations, in future work.

<sup>5</sup>The KNB corpus consists 4,186 sentences from Japanese blogs, and is available at <http://nlp.kuee.kyoto-u.ac.jp/kunt/>.

## Abstract

A major problem in the field of Chinese word segmentation is the identification of out-of-vocabulary words. We propose a simple yet effective approach for extracting maximized substrings, which provide good estimations of unknown word boundaries. We also develop a new semi-supervised segmentation technique that incorporates retrieved substrings using discriminative learning. The effectiveness of this novel approach is demonstrated through experiments using both in-domain and out-of-domain data.

## 1. Introduction

Chinese sentences are written without explicit word boundaries, which makes Chinese word segmentation (CWS) an initial and important step in Chinese language processing. Recent advances in machine learning techniques have boosted the performance of CWS systems. On the other hand, a major difficulty in CWS is the problem of identifying out-of-vocabulary (OOV) words, as the Chinese language is continually and rapidly evolving, particularly with the rapid growth of the internet.

A recent line of research to overcome this difficulty is through exploiting characteristics of frequent substrings in unlabeled data. Statistical criteria for measuring the likelihood of a substring being a word have been proposed in previous studies of unsupervised segmentation, such as *accessor variety* (Feng et al., 2004) and *branching entropy* (Jin and Tanaka-Ishii, 2006). This kind of criteria has been applied to enhance the performance of supervised segmentation systems (Zhao and Kit, 2007; Zhao and Kit, 2008;

Substring	Freq
一致	3
界限数的期望值	2
一致认定界限	2
的期望值	3
认定界限数的	2
值	4

Table 1. A particular type of substrings with multiple occurrences in the Chinese sentence: “使一致认定界限数的期望值近似于一致正确界限数的期望值，求得一致认定界限的期望值/认定界限数的值。”

Sun and Xu, 2011) by identifying unknown word boundaries.

In this paper, instead of investigating statistical characteristics of batched substrings, we propose a novel method that extracts substrings as reliable word boundary estimations. The technique uses large-scale unlabeled data, and processes it on the fly.

To illustrate the idea, we first consider the following example taken from a scientific text:

“使一致认定界限数的期望值近似于一致正确界限数的期望值，求得一致认定界限的期望值/认定界限数的值。”

Without any knowledge of the Chinese language one may still notice that some substrings like “一致” and “的期望值”, occur multiple times in the sentence and are likely to be valid words or chains of words. Consider a particular type of frequent substring that cannot be simultaneously extended by its surrounding characters while still being equal (Table 1). We can observe that the boundaries of such substrings can be used as perfect word delimiters. We can segment the sentence by simply treating the boundaries of each occurrence of a substring in Table 1 as word

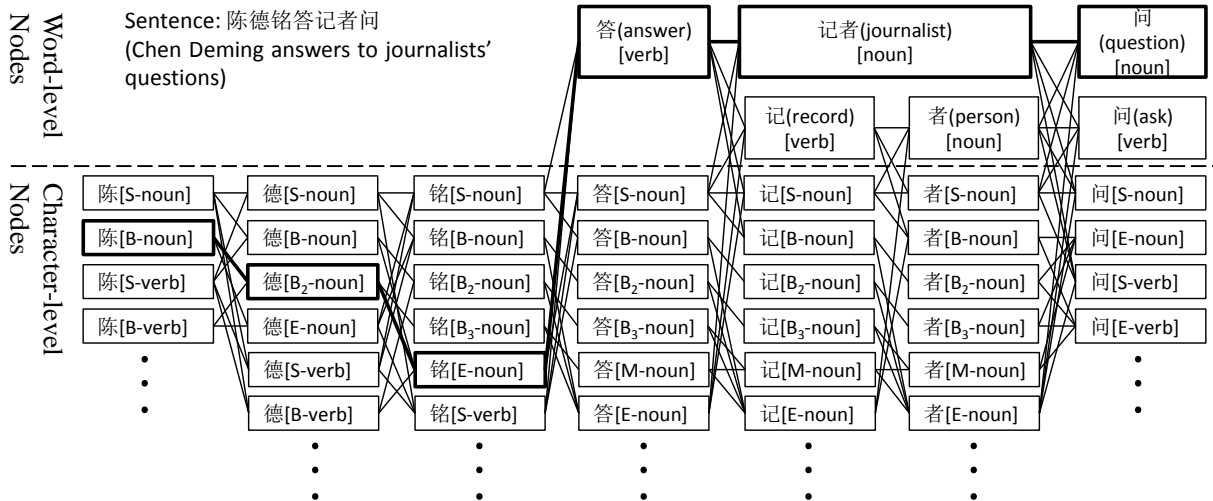

Figure 1. A Word-character hybrid lattice of a Chinese sentence. Correct path is represented by bold lines.

Word Length	1	2	3	4	5	6	7 or more
Tags	<i>S</i>	<i>BE</i>	<i>BB<sub>2</sub>E</i>	<i>BB<sub>2</sub>B<sub>3</sub>E</i>	<i>BB<sub>2</sub>B<sub>3</sub>ME</i>	<i>BB<sub>2</sub>B<sub>3</sub>MME</i>	<i>BB<sub>2</sub>B<sub>3</sub>M...ME</i>

Table 2. Word representation with a 6-tag tagset: *S, B, B<sub>2</sub>, B<sub>3</sub>, M, E*

delimiters:

“使|一致|认定|界限|数|的|期望|值|近似于|一致|正确|界限|数|的|期望|值|，求得|一致|认定|界限|的|期望|值|/|认定|界限|数|的|值|。”

Compared with the gold-standard segmentation, this partial segmentation has a precision of 100% and a recall of 73.3% with regard to boundary estimation. This is high when we consider that the method does not use a trained segmenter or annotated data. While we have obtained this result on a selected instance, it still suggests that unlabeled data has the potential to enhance the performance of supervised segmentation systems by tracking consistency among substrings.

Substrings, such as those listed in Table 1, are retrievable from unlabeled data and can be incorporated with a supervised CWS system to compensate for out-of-vocabulary (OOV) words. In this case the unlabeled data can be either test data only (leading to a purely supervised system), or a large-scale external corpus (leading to a semi-supervised system). We will formally define this particular type of substring, referred to as a “maximized substring”, in a later section.

The remainder of this paper is organized as follows. Section 2 describes our baseline segmentation system, defines maximized substrings, and proposes an efficient algorithm for retrieving these substrings from unlabeled data. Section 3

introduces the maximized substring features. Section 4 presents the experimental results. Section 5 discusses related work. The final section summarizes our conclusions.

## 2. Approach

### 2.1 Baseline Segmentation System

We have used a word-character hybrid model as our baseline Chinese word segmentation system (Nakagawa and Uchimoto, 2007; Kruengkrai et al., 2009). As shown in Figure 1, this hybrid model constructs a lattice that consists of word-level and character-level nodes from a given input sentence. Word-level nodes correspond to words found in the system’s lexicon, which has been compiled from training data. Character-level nodes have special tags called position-of-character (POC) that indicate the word-internal position (Asahara, 2003; Nakagawa, 2004). We have adopted the 6-tag tagset, which (Zhao et al., 2006) reported to be optimal. This tagset is illustrated in Table 2.

Previous studies have shown that jointly processing word segmentation and part-of-speech tagging is preferable to separate processing, which can propagate errors (Nakagawa and Uchimoto, 2007; Kruengkrai et al., 2009). If the training data was annotated by part-of-speech tags, we have combined them with both word-level and character-level nodes.

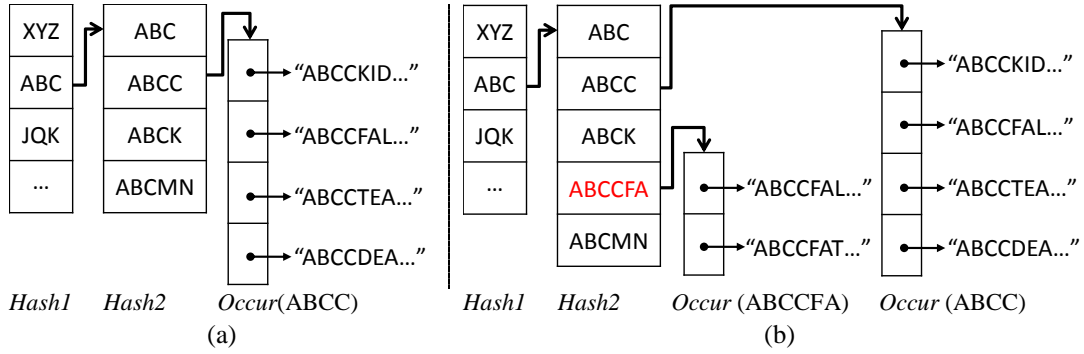

Figure 2. Data structure for maximized substring mining. *Hash1* is the first-level hash with fixed-length prefix keys. *Hash2* is a hash associating to a corresponding key in *Hash1* that stores the list of *maximized substrings* sharing the same fixed-length prefix. *Occur*( $\cdot$ ) is the occurrence list associating to a particular *maximized substrings* with references to all its occurrences in the original positions in the document. (a) shows a certain state of the data structure, and (b) the state after a *maximized substring* “ABCCFA” is inserted with the context being “ABCCFAT...” in the document.

## 2.2 Maximized Substring: the Definition

Frequent substrings in unlabeled data can be used as clues for identifying word boundaries, as we have illustrated in Section 1. Nevertheless, some substrings, although frequent, are not useful to the system. In the example in Section 1, the substring “致认定界” occurs the same amount of times as the substring “一致认定界限”. However, only the latter is a valid identifier for word delimiters: they are non-overlapping, meaning that it is impossible to simultaneously extend all occurrences by surrounding characters. We use the term *maximized substring* to describe these substrings.

Formally, we define *maximized substring* as follows:

*Definition 1 (Maximised substring)*. Given a document  $D$  that is a collection of sentences, denote a length  $n$  substring which starts with character  $c_t$  by  $s_t = [c_t c_{t+1} \dots c_{t+n-1}]$ .  $s_t$  is called a *maximized substring* if:

1. It has a set of distinct occurrences,  $M$ , with at least two elements<sup>1</sup>:  

$$M = \{s_{t_1}, s_{t_2}, \dots, s_{t_m}\}, \quad m > 1, \quad t_1 \neq t_2 \neq \dots \neq t_m \text{ s.t. } s_{t_1} = s_{t_2} = \dots = s_{t_m};$$
 and
2.  $c_{t_i-1} \neq c_{t_j-1}$  and  $c_{t_i+n} \neq c_{t_j+n} \quad \forall i, j = 1, 2, \dots, m, i \neq j$ .

<sup>1</sup> It should be noted that, in order to retrieve a substring, the size of  $M$  is not necessarily identical to its total count in the document.

The substrings listed in Table 1 are therefore maximized substrings, given that  $D$  is the example sentence. Note that these are *not all* maximized substrings extractable from the example sentence, but are the result of the retrieval algorithm that we will describe in the next section.

## 2.3 Maximized Substring Retrieval: Algorithm and Data Structure

The problem of mining frequent substrings in a document has been extensively researched. Existing algorithms generally either use a suffix tree structure (Nelson, 1996) or suffix arrays (Fischer et al., 2005), and make use of the apriori property (Agrawal and Srikant, 1994). The apriori property states that a string of length  $k+1$  is frequent only if its substring of length  $k$  is frequent. The apriori property can significantly reduce the size of enumerable substring candidates. However, as we are only interested in maximized substrings, suffix tree-based algorithms are inefficient in both time and space. We therefore propose a novel algorithm and a compact data structure for fast maximized substring mining.

The data structure is illustrated in Figure 2. It supports fast prefix searching for storing and retrieving maximized substrings, with each entry associated to a list of occurrences that refer to the original positions in the document. Fast prefix matching is a particular advantage of a trie, which is a type of prefix tree. Our structure is different as we use a two-level hash structure for space efficiency and ease of manipulation. This is important, especially during experiments on large-scale unlabeled data.

The first-level hash stores prefixes of a fixed-length,  $m$ , of retrieved substrings. This part of the data structure functions as a filter to screen

out substrings that are shorter than  $m$  characters, as they should not be considered as candidates. This is motivated by our observation that single characters, and sometimes even double-character substrings, are not reliable enough to predict word delimiters. Note that  $m$  is data dependent, for example, the optimal value of  $m$  is 3 characters on the dataset Chinese Treebank (CTB).

Each key of the first-level hash is associated with a second-level hash that stores the retrieved maximized substrings that share a common prefix.

The third-level structure is a linked list of occurrences of a particular maximized substring. This list stores references to the original position of each occurrence of the substring, with the surrounding context being visible so that new (longer) maximized substrings can be found by extension.

We sketch the process of maximized substring retrieval in Pseudocode 1. From the beginning of the document  $D$ , we scan each position and register maximized substrings into the data structure  $H$ . If an incoming substring already exists in  $H$ , we look up its occurrence list to check if its succeeding characters can extend the substring. As the current occurrence list is a set of maximized substrings, there will be only two possible outcomes. Either exactly one element in the occurrence list is found to have a longer common prefix with the incoming substring, in which case we create a new occurrence list consisting of the two lengthened substrings. Alternatively, the prefix remains the same and we add the incoming substring to the occurrence list.

We can easily demonstrate that all substrings retrieved by this algorithm are maximized substrings. However, the algorithm does not generally guarantee to retrieve all maximized substrings from unlabeled data. This is a necessary compromise if we wish to keep the efficiency of one-time scanning. In addition, we have observed in preliminary experiments that retrieving all maximized substrings is not only unnecessary, but can introduce harmful noise. In the next section, we will discuss our solution to this problem.

## 2.4 Short-Term Store

Maximized substrings can provide good estimations of word boundaries, but random noise can be introduced during the retrieval process in Pseudocode 1.

To address this problem, we take advantage of a linguistic phenomenon. It has been observed that a word occurring in the recent past has a

---

### Pseudocode 1: Maximized substring retrieval

```

1  procedure RetrieveMaxSub( $m, D$ )
2     $i \leftarrow 0, H \leftarrow \emptyset$ 
3     $p \leftarrow [c_0 c_1 \dots c_{m-1}]$ 
4     $\triangleleft$  the reference of a length  $m$  substring at
5    the beginning of document  $D$ 
6    until  $i$  reaches the end of document  $D$ 
7       $s \leftarrow$  longest element in  $H$  extendable
8      from  $p$ 
9      if  $|s| = 0$   $\triangleleft$  empty string
10        $occurList \leftarrow \{p\}$ 
11        $\triangleleft$  make the occurrence list of  $p$ 
12        $H.Add(\langle p, occurList \rangle)$ 
13        $\triangleleft$  associate  $p$  with its occurrence list
14       and add to data structure
15        $i \leftarrow i + 1$ 
16        $p \leftarrow [c_i \dots c_{i+m-1}]$ 
17     else
18        $p^* \leftarrow [c_i \dots c_{i+|s|-1}]$ 
19        $(i, p) \leftarrow \text{Maximize}(H, m, i, s, p^*)$ 
20     return  $H$ 
21
22  procedure Maximize( $H, m, i, s, p^*$ )
23    for each  $e$  in  $s.occurList$ 
24       $\langle s_{new}, e_{new}, p_{new}^* \rangle \leftarrow \text{Extend}(e, p^*)$ 
25       $\triangleleft$  find the longest common substring
26       $s_{new}$  between  $e$  and  $p^*$  by simultane-
27      ously extending them with succeeding
28      characters
29      if  $|s_{new}| > |s|$ 
30         $occurList_{new} \leftarrow \{e_{new}, p_{new}^*\}$ 
31         $H.Add(\langle s_{new}, occurList_{new} \rangle)$ 
32         $i \leftarrow i + |s_{new}|$ 
33         $p \leftarrow [c_i \dots c_{i+m-1}]$ 
34      return  $(i, p)$ 
35  end
36   $s.occurList.Add(p^*)$ 
37   $i \leftarrow i + |s|$ 
38   $p \leftarrow [c_i \dots c_{i+m-1}]$ 
39  return  $(i, p)$ 

```

---

much higher probability to occur again soon, when compared with its overall frequency (Kuhn and Mori, 1990). It follows that, for speech recognition, we can then use a window of recent history to adjust the static overall language mode.

This observation is applicable to the task of maximized substring retrieval in the following way. Suppose a substring is registered into the data structure. If the substring is in fact a word, it is much more likely to reoccur in the next 50 to 100 sentences than in the remainder of the corpus (especially when it is a technical term or a named entity). Otherwise the substring should have a more unified probability of reoccurrence across the entire corpus.

This motivated us to introduce a functionality into the process of maximized substring retrieval, called “short-term store” (STS). The STS is an analogy to the cache component in speech recognition as well as the human phonological working memory in language acquisition. It restricts the length of the visible context when retrieving the next candidate of a registered substring, making it proportional to the current number of occurrences of the substring. For a registered substring, the retrieval algorithm scans a certain number of sentences after the latest occurrence of the substring, where the number of sentences  $D(s)$  is determined as follows:

$$D(s) = \begin{cases} \lambda \cdot \text{count}(s), & \text{if } \text{count}(s) < \theta, \\ \infty, & \text{otherwise,} \end{cases}$$

where  $\text{count}(s)$  is the current number of occurrences of  $s$  in the data structure. The parameter  $\lambda$  contributes a fixed-length distance to the visible context. The parameter  $\theta$  works as a threshold of reliability. If we have observed  $s$  at least  $\theta$  times in a short period, we can regard  $s$  as a word, or a sequence of words, with a high level of confidence. Thus,  $D(s) = \infty$  implies that  $s$  is no longer subject to periodical decaying and will stay in the data structure statically.

During the scanning of the  $D(s)$  sentences, if a new occurrence of  $s$  is found, it is added into the data structure and  $D(s)$  is recalculated immediately, starting a new scanning period. If no new occurrences are found, we remove the earliest occurrence of  $s$  from the data structure and then re-calculate  $D(s)$ . Note that we have described the short-term store functionality as if each substring in the data structure is scanned separately. In practice, however, only a small change to Pseudocode 1 is required so that STS is used, making one-time scanning of the unlabeled data sufficient.

Introducing STS into the retrieval process results in a substantial improvement to the quality of retrieved substrings. It is also important that STS greatly improves the processing efficiency for large scale unlabeled data by keeping the size of the data structure relatively small. This is because a substring entry will decay from the data structure if it has not been refreshed in a short period.

### 3. Features

#### 3.1 Baseline Features

For baseline features, we apply the feature tem-

plates described in (Kruengkrai et al., 2009). For further details, please see the original paper. Note that if the part-of-speech tags are not available, we omit those templates involving POS tags.

#### 3.2 Maximized Substring Features

We have incorporated the list of retrieved maximized substrings into the baseline system by using a technique which discriminatively learns their features. For every word-level and character-level node in the lattice, the method checks the maximized substring list for entries that satisfy the following two conditions:

1. The node matches the maximized substring at the beginning, the end, or both boundaries.
2. The length of the node is shorter than or equal to that of the entry.

For example, consider the lattice in Figure 1 with a maximized substring “陈德铭”. All of the character-level nodes of “陈” and “铭” are encoded with maximized substring features. A segmenter will only obtain information on those possible word boundaries that are identified by maximized substrings. The maximized substrings are not directly treated as single words, because a maximized substring can sometimes be a compound word or phrase.

For each match with a maximized substring entry, the technique encodes the following features.

**Basic:** A binary feature that indicates whether the match is at the beginning or end of the maximized substring. It is encoded both individually and as a combination with each other feature types.

**Lexicon:** There is a particular kind of noise in the retrieved list of maximized substrings, namely, those like the substring “中美经”, which has resulted from the two phrases “中美经济” (China and U.S. economy) and “中美经贸” (China and U.S. economic and trade). This happens when the boundary of a maximized substring is a shared boundary character of multiple other words. In this example, the last character “经” of the maximized substring is the character at the beginning of “经济” (economy) and “经贸” (economic and trade). This kind of noise can be identified by checking the context of maximized substrings in system’s lexicon.

Our technique checks the context of the maximized substring in the input sentence and compares it with the system’s lexicon. If any item in the lexicon is found that forms a positional relation with the maximized substring entry (as listed

Sentence: $s = \dots c_{-1}c_0c_1 \dots c_{n-1}c_nc_{n+1} \dots$		Representa- tion
Maximized substring $m = c_0c_1c_2 \dots c_n$		
Lexicon entry $l = c_ic_{i+1}c_{i+2} \dots c_j$		
ID	Positional Relation	
L1	$0 = i < j < n$	
L2	$0 < i < j = n$	
L3	$0 = i < n < j$	
L4	$i < 0 < j = n$	
L5	$0 < i < n < j$	
L6	$i < 0 < j < n$	
L7	$i = n + 1$	
L8	$j = -1$	

Table 3. Lexicon features. Each one represents a positional relation between a maximized substring and a contextual substring which exists in system’s lexicon.

ID	At Beginning	ID	At Ending
B1	<L1,L6>	E1	<L2,L5>
B2	<L6,L8>	E2	<L5,L7>
B3	<L1,L8>	E3	<L2,L7>

Table 4. Lexicon Composition features. Each one represents a combination of two Lexicon features that fire simultaneously.

in Table 3) then the corresponding features are encoded.

**Lexicon Composition:** When a maximized substring is a match to more than one item in the lexicon, a combination of multiple lexicon features is more informative than individual features. We encode the combinations of lexicon features listed as in Table 4.

**Frequency:** We sort the list of maximized substrings by their frequencies. If a maximized substring is among the 10% most frequent it is classed as “highly frequent”, if it is among the top 30% it is “normal”, and all other cases are “infrequent”.

## 4. Evaluation

### 4.1 Setting

To evaluate our approach, we have conducted word segmentation experiments on two datasets. The first is Chinese Treebank 7 (CTB7), which is a widely used version of the Penn Chinese Treebank dataset for the evaluations of word segmentation techniques. We have adopted the same setting of data division as (Wang et al., 2011): the training set, dev set and test set. For CTB7, these sets have 31,131, 10,136 and 10,180 sentences respectively. The second dataset is the second international Chinese word segmentation bakeoff (SIGHAN Bakeoff-2005) (Emerson, 2005), which has four independent subsets: the Academia Sinica Corpus (AS), the Microsoft Research Corpus (MSR), the Hong Kong City University Corpus (CityU) and the Peking University Corpus (PKU). Since POS tags are not available in this dataset, we have omitted all templates that include them. The models and parameters applied on all test sets are those that result in the best performance on the CTB7 dev set.

We have used two different types of unlabeled data. One is the test set itself, which means the system is purely supervised. Another is a large-scale dataset, which is the Chinese Gigaword Second Edition (LDC2007T03). This dataset is a collection of news articles from 1991 to 2004 published by Central News Agency (Taiwan), Xinhua News Agency and Lianhe Zaobao Newspaper. It includes a total amount of over 1.2 billion characters in both simplified Chinese and traditional Chinese.

We have trained all models using the averaged perceptron algorithm (Collins, 2002), which we selected because of its efficiency and stability. To learn the characteristics of unknown words, we built the system’s lexicon using only the words in the training data with a frequency higher than a threshold,  $h$ . This threshold was tuned using the development data. In order to use the maximized substring features, we have used training data as unlabeled data for supervised models, and used both the training data and Chinese Gigaword for semi-supervised models.

We have applied the same parameters for all models, which are tuned on the CTB7 dev set:  $m = 3$ ,  $h = 2$ ,  $\lambda = 100$ , and  $\theta = 3$ .

We have used precision, recall and the F-score to measure the performance of segmentation systems. Precision,  $p$ , is defined as the percentage of

System	P	R	F
Baseline	95.17	95.35	95.26
MaxSub-Test	95.33	95.47	95.40
MaxSub-U	95.65	95.81	95.73

Table 5. Evaluation on CTB7 for the baseline approach and our approach with small and large-scale in-domain unlabeled data respectively.

words that are segmented correctly, and recall,  $r$ , is the percentage of words in the gold standard data that are recognized in the output. The balanced F-score is defined as  $F = 2pr/(p + r)$ .

## 4.2 Experimental Results on In-domain Data

We have compared the performance between the baseline system and our approach. The results are shown in Table 5. Each row in this table shows the performance of the corresponding system. “Baseline” refers to our baseline hybrid word segmentation and POS-tagging system. “MaxSub-Test” refers to the method that just uses the test set as unlabeled data. “MaxSub-U” refers to the method that uses the large-scale unlabeled data. We have focused on the segmentation performance of our systems.

The results show that, using the test data as an additional source of information, “MaxSub-Test” outperforms the baseline method by 0.14 points in F-score. This indicates that our method of using maximized substrings can enhance the segmentation performance even with a purely supervised approach. The improvement increases to 0.47 points in F-score for “MaxSub-U”, which demonstrates the effectiveness of using large-scale unlabeled data.

We have compared our approach with previous work in Table 6. Two methods from (Kruengkrai et al., 2009a; 2009b) are referred to as “Kruengkrai 09a” and “Kruengkrai 09b”, and are taken directly from the report of (Wang et al., 2011). “Wang 11” refers to the semi-supervised system in (Wang et al., 2011). We have observed that our system “MaxSub-U” achieves the best segmentation among these systems. Also, although the performance of our baseline is lower than the systems “Kruengkrai 09a” and “Kruengkrai 09b” because of differences in implementation, the system “MaxSub-Test” (which has used no external resource) has achieved a comparable result.

The results for the SIGHAN Bakeoff-2005 dataset are shown in Table 7. The first three rows (“Tseng 05”, “Asahara 05” and “Chen 05”) show the results of systems that have reached the highest score on at least one corpus (Tseng et al.,

System	F
Baseline	95.26

Zhao 07	95.5	95.6	97.5	95.4
Baseline	95.07	94.53	96.25	95.13
MaxSub-S	95.17	94.61	96.42	95.31
MaxSub-L <sup>+</sup>	95.34	94.79	96.64	<b>95.55</b>

Table 7. F-measure on SIGHAN Bakeoff-2005 test set compared with previous work. “<sup>+</sup>”: semi-supervised systems.

2005; Asahara et al., 2005; Chen et al., 2005). “Best closed” summarizes the best official results on all four corpora. “Zhao 07” and “Zhang 06” represent the supervised segmentation systems in (Zhao and Kit, 2007; Zhang et al., 2006). “Baseline”, “Maxsub-Test” and “MaxSub-U” refer to the same systems as in Table 5. For the unlabeled data, we have used the test sets of corresponding corpora for “MaxSub-Test”, and the Chinese Gigaword for “MaxSub-U”. Other parameters were left unchanged. The results do not indicate that our approach performs better than other systems. However, this is largely because of our baseline not being optimized for these corpora. Nevertheless, when compared with the baseline, our approach has yielded consistent improvements across the four corpora, and on the PKU corpus we have performed better than previous work.

## 4.3 Impacts of Semi-supervised Features and Short-term Store

In Table 8, we have shown the effects of the different maximized substring feature types proposed in this paper. We activated different combinations of feature types in turn and trained separate models. We also investigated the impact of the short-term store by training models without this feature. The rows of this table represent models and corresponding F-measure, trained

System	F
Baseline	95.26
+Basic&Freq	95.50
+All	95.60
+All+STS	<b>95.73</b>

Table 8. Influence of activated feature types and short-term store on CTB7 test data.

System	P	R	F
Baseline	91.88	92.02	91.95
MaxSub-Test	92.43	92.53	92.48

Table 9. Results on out-of-domain data.

and tested on CTB7 with different configurations. The row “Baseline” is baseline system as in Table 5. “+Basic&Freq” represents the system “MaxSub-U” with only basic and frequency features activated, and STS turned off. The row “+All” represents a system activating all maximized substring features but still without STS. The last row “+All+STS” is identical to the system “Maxsub-U”. It is clear that lexicon-based features are effective in discriminating unreliable maximized substring from reliable ones, and the short-term store improves the segmentation performance by filtering out noises during the retrieval of maximized substrings. The combination of these two techniques yields an improvement of 0.23 point in F-measure, and thus are essential when using maximized substrings.

#### 4.4 Experimental Results on Out-of-domain Data

To demonstrate the effectiveness of our method on out-of-domain text, we have conducted an experiment on a test set that was drawn from a corpus of scientific articles. This test set contains 510 sentences that have been manually segmented by a native Chinese speaker. We used the test set as the unlabeled data.

As the results show (Table 9), the system “MaxSub-Test” exceeded the baseline method by 0.53 in F-score, which is a significant improvement. Considering that the amount of unlabeled data is relatively small, it is likely that acquiring large-scale unlabeled data in the same domain will further benefit the accuracy.

## 5. Related Work

The authors of (Feng et al., 2004) proposed accessor variety (AV), a criterion measuring the likelihood of a substring being a word by count-

ing distinct surrounding characters. In (Jin and Tanaka-Ishii, 2006) the researchers proposed branching entropy, a similar criterion based on the assumption that the uncertainty of surrounding characters of a substring peaks at the word boundaries. The authors of (Zhao and Kit, 2007) incorporated accessor variety and another type of criteria, called co-occurrence sub-sequence, with a supervised segmentation system and conducted comprehensive experiments to investigate their impacts. Although the idea behind co-occurrence sub-sequence is similar with maximized substrings, there are several restrictions: it requires post-processing to remove overlapping instances; sub-sequences are retrievable only from different sentences; and the retrieval is performed only on training and testing data. In (Sun and Xu, 2011), the authors proposed a semi-supervised segmentation system enhanced with multiple statistical criteria. Large-scale unlabeled data were used in their experiments.

Li and Sun presented a model to learn features of word delimiters from punctuation marks in (Li and Sun, 2009). Wang et al. proposed a semi-supervised word segmentation method that took advantages from auto-analyzed data (Wang et al., 2011).

Nakagawa showed the advantage of the hybrid model combining both character-level information and word-level information in Chinese and Japanese word segmentation (Nakagawa, 2004). In (Nakagawa and Uchimoto, 2007) and (Kruengkrai et al., 2009a; 2009b) the researchers presented word-character hybrid models for joint word segmentation and POS tagging, and achieved the state-of-the-art accuracy on Chinese and Japanese datasets.

## 6. Conclusion

We propose a simple yet effective approach for extracting maximized substrings from unlabeled data. These are a particular type of substrings that provide good estimations of unknown word boundaries. The retrieved maximized substrings are incorporated with a supervised segmentation system through discriminative learning. We have demonstrated the effectiveness of our approach through experiments in both in-domain and out-of-domain data and have achieved significant improvements over the baseline systems across all datasets<sup>2</sup>.

## Abstract

This paper is concerned with capturing long-distance dependencies in sequence models. We propose a two-step strategy. First, the stacked learning technique is applied to integrate sequence models that are good at exploring local information and other high complexity models that are good at capturing long-distance dependencies. Second, the structure compilation technique is employed to transfer the predictive power of hybrid models to sequence models via large-scale unlabeled data. To investigate the feasibility of our idea, we study Chinese POS tagging. Experiments on the Chinese Treebank data demonstrate the effectiveness of our methods. The re-compiled models not only achieve high accuracy with respect to per token classification, but also serve as a front-end to a parser well.

## 1 Introduction

Sequential classification models provide very important solutions to pattern recognition tasks that involve the automatic assignment of a categorical label to each token of a sequence of observed values. A common example is part-of-speech (POS) tagging, which seeks to assign a grammatical category to each word in an input sentence. *Standard* machine learning algorithms to sequential tagging, e.g. linear-chain conditional random fields and max-margin Markov network, directly exploit local dependencies and perform quite well for a large number of sequence labeling tasks. In these models, usually, the relationships between two (or three) successive labels are parameterized and encoded as a single feature, and Viterbi style dynamic programming algorithms are applied to inference over a lattice. Although sequence models

perform well for many applications, they are inadequate for tasks where many long-distance dependencies are involved.

Sequential classification models play an important role in natural language processing (NLP). Several fundamental NLP tasks, including named entity recognition, POS tagging, text chunking, supertagging, etc., employ sequential classifiers for lexical and syntactic disambiguation. In addition to learning linear chain structures, sequence models can even be applied to acquire hierarchical syntactic structures (Tsuruoka et al., 2009). However, long-distance dependencies widely exist in linguistic structures, and many NLP systems suffer from the incapability of capturing these dependencies. For example, previous work has shown that sequence models alone cannot deal with syntactic ambiguities well (Clark and Curran, 2004; Tsuruoka et al., 2009). On the contrary, state-of-the-art systems usually utilize high complexity models, such as lexicalized PCFG models for syntactic parsing, to achieve high accuracy. Unfortunately, they are not suitable for many real world applications due to the sacrifice of efficiency.

In this paper, we are concerned with capturing long-distance dependencies in sequence models. Our goal is to develop efficient models with linear time complexity that are also capable to capture non-local dependencies. Two techniques are studied to achieve this goal. First, stacked learning (Breiman, 1996) is employed to integrate sequence models that are good at exploring local information and other high complexity models that are good at capturing non-local dependencies. By combining complementary strengths of heterogeneous models, hybrid systems can obtain more accurate results. Second, structure compilation (Liang et al., 2008) is employed to transfer the predictive power of hybrid models to sequence models via large-scale unlabeled data. In particular, hybrid systems are utilized to create large-scale

pseudo training data for cheap sequence models. A discriminative model can be improved by incorporating more features, while a generative latent variable model can be improved by increasing the number of latent variables. By using stacking and structure compilation techniques, a sequence model can be enhanced to better capture long-distance dependencies and to achieve more accurate results.

To demonstrate the feasibility to capture long-distance dependencies in a sequence model, we present our work on Chinese POS tagging. The Chinese language has a number of characteristics that make Chinese POS tagging particularly challenging. While simple sequential classifiers can easily achieve tagging accuracies of above 97% on English, Chinese POS tagging has proven to be more challenging and has obtained accuracies of about 93-94% (Huang et al., 2009; Sun and Uszkoreit, 2012) when applying sequence models. Recent work shows that higher accuracy (c.a. 95%) can be achieved by applying advanced learning techniques to capture deep lexical relations (Sun and Uszkoreit, 2012). Especially, syntagmatic lexical relations have been shown playing an essential role in Chinese POS tagging. To capture such relations, an accurate POS tagging model should know more information about long range dependencies. Previous work has used syntactic parsers in either constituency or dependency formalisms to exploit such useful information (Sun and Uszkoreit, 2012; Hatori et al., 2011). However, it is inappropriate to employ computationally expensive parsers to improve POS tagging for many realistic NLP applications, mainly due to efficiency considerations.

In this paper, we study several hybrid systems that are built upon various complementary tagging systems. We investigate stacked learning to build more accurate solutions by integrating heterogeneous models. Experiments on the Chinese Treebank (CTB) data show that stacking is very effective to build high-accuracy tagging systems. Although predictive powers of hybrid systems are significantly better than individual systems, they are not suitable for large-scale real word applications that have stringent time requirements. To improve POS tagging efficiency without loss of accuracy, we explore unlabeled data to transfer the predictive power of complex, inefficient models to simple, efficient models. Experiments show that

unlabeled data is effective to re-compile simple models, including latent variable hidden Markov models, local and global linear classifiers. On one hand, the precision in terms of word classification is improved to 95.33%, which reaches the state-of-the-art. On the other hand, re-compiled models are adapted based on parsing results, and as a result the ability to capture syntagmatic lexical relations is improved as well. Different from the purely supervised sequence models, re-compiled models also serve as a front-end to a parser well.

## 2 Background

The Chinese language has a number of characteristics that make Chinese POS tagging particularly challenging. For example, Chinese is characterized by the lack of formal devices such as morphological tense and number that often provide important clues for syntactic processing. Chinese POS tagging has proven to be very difficult and has obtained accuracies of about 93-94% (Huang et al., 2009; Li et al., 2011; Hatori et al., 2011; Sun and Uszkoreit, 2012). On the other hand, Chinese POS information is very important for advanced NLP tasks, e.g. supertagging, full parsing and semantic role labeling. Previous work has repeatedly demonstrated the significant performance gap of NLP systems while using gold standard and automatically predicted POS tags (Zhang and Clark, 2009; Li et al., 2011; Tse and Curran, 2012). In this section, we give a brief introduction and a comparative analysis to several models that are recently designed to resolve the Chinese POS tagging problem.

### 2.1 Various Chinese POS Tagging Models

**Local linear model (LLM)** A very simple approach to POS tagging is to formulate it as a local word classification problem. Various features can be drawn upon information sources such as word forms and characters that constitute words. Previous studies on many languages have shown that local classification is inadequate to capture structural information of output labels, and thus does not perform as well as structured models.

**Linear-chain global linear model (LGLM)** Sequence labeling models can capture output structures by exploiting local dependencies among words. A global linear model is flexible to in-

clude linguistic knowledge from multiple information sources, and thus suitable to recognize more new words. A majority of state-of-the-art English POS taggers are based on LGLMs, e.g. structured perceptron (Collins, 2002) and conditional random fields (Lafferty et al., 2001). Such models are also very popular for building Chinese POS taggers (Sun and Uszkoreit, 2012).

**Hidden Markov model with latent variables (HMMLA)** Generative models with latent annotations (LA) obtain state-of-the-art performance for a number of NLP tasks. For example, both PCFG and TSG with refined latent variables achieve excellent results for syntactic parsing (Matsuzaki et al., 2005; Shindo et al., 2012). For Chinese POS tagging, Huang, Eidelman and Harper (2009) described and evaluated a bi-gram HMM tagger that utilizes latent annotations. The use of latent annotations substantially improves the performance of a simple generative bigram tagger, outperforming a trigram HMM tagger with sophisticated smoothing.

**PCFG Parsing with latent variables (PCFGLA)** POS tags can be taken as preterminals of a constituency parse tree, so a constituency parser can also provide POS information. The majority of the state-of-the-art constituent parsers are based on generative PCFG learning, with lexicalized (Collins, 2003; Charniak, 2000) or latent annotation (Matsuzaki et al., 2005; Petrov et al., 2006) refinements. Compared to complex lexicalized parsers, the PCFGLA parsers leverage on an automatic procedure to learn refined grammars and are more robust to parse many non-English languages that are not well studied. For Chinese, a PCFGLA parser achieves the state-of-the-art performance and outperforms many other types of parsers (Zhang and Clark, 2009).

### 2.1.1 Joint POS Tagging and Dependency Parsing (DEP)

(Hatori et al., 2011) proposes an incremental processing model for the task of joint POS tagging and dependency parsing, which is built upon a shift-reduce parsing framework with dynamic programming. Given a segmented sentence, a joint model simultaneously considers possible POS tags and dependency relations. In this way, the learner can better predict POS tags by using bi-lexical dependency information. Their experiments show that the joint approach achieved substantial im-

provements over the pipeline systems in both POS tagging and dependency parsing tasks.

## 2.2 Comparison

We can distinguish the five representative tagging models from two views (see Table 2). From a linguistic view, we can distinguish syntax-free and syntax-based models. In a syntax-based model, POS tagging is integrated into parsing, and thus (to some extent) is capable of capturing long range syntactic information. From a machine learning view, we can distinguish generative and discriminative models. Compared to generative models, discriminative models define expressive features to classify words. Note that the two generative models employ latent variables to refine the output spaces, which significantly boost the accuracy and increase the robustness of simple generative models.

	Generative	Discriminative
Syntax-free	HMMLA	LLM, LGLM
Syntax-based	PCFGLA	DEP

Table 2: Two views of different tagging models.

## 2.3 Evaluation

### 2.3.1 Experimental Setting

Penn Chinese Treebank (CTB) (Xue et al., 2005) is a popular data set to evaluate a number of Chinese NLP tasks, including word segmentation, POS tagging, syntactic parsing in both constituency and dependency formalisms. In this paper, we use CTB 6.0 as the labeled training data for the study. In order to obtain a representative split of data sets, we conduct experiments following the setting of the CoNLL 2009 shared task (Hajič et al., 2009), which is also used by (Sun and Uszkoreit, 2012). The setting is provided by the principal organizer of the CTB project, and has considered many annotation details. This setting is very robust for evaluating Chinese language processing algorithms.

We present an empirical study of the five typical approaches introduced above. In our experiments, to build local and global word classifiers (i.e. LLMs and LGLMs), we implement the feature set used in (Sun and Uszkoreit, 2012). Denote a word  $w$  in focus with a fixed window  $w_{-2}w_{-1}ww_{+1}w_{+2}$ . The features include:

- Word unigrams:  $w_{-2}, w_{-1}, w, w_{+1}, w_{+2}$ ;

Devel.	LLM	LGLM(SP)	LGLM(PA)	HMMLA	PCFGLA	DEP
Overall	93.96%	94.30%/94.49%	94.24%/94.33%	94.16%	93.69%	94.58%
NR	95.07	94.47/94.85	94.41/94.56	94.22	89.84	93.55
NT	97.61	97.22/97.75	97.66/97.59	97.18	96.70	96.84
NN	94.89	94.67/94.79	94.72/94.71	94.30	93.56	94.55
DEC	78.61	81.98/82.36	80.68/81.76	80.60	85.78	86.73
DEG	82.44	85.58/86.72	85.37/85.00	85.19	88.94	89.45
UNK	--	80.0%/81.1%	--	78.2%	--	--

Table 1: Tagging accuracies of different supervised models on the development data.

- Word bigrams:  $w_{-2}w_{-1}$ ,  $w_{-1}w$ ,  $w_w w_{+1}$ ,  $w_{+1}w_{+2}$ ;
- Character  $n$ -gram prefixes and suffixes for  $n$  up to 3.

To train LLMs, we use the open source linear classifier – LIBLINEAR<sup>1</sup>. To train LGLMs, we choose structured perceptron (SP) (Collins, 2002) and passive aggressive (PA) (Crammer et al., 2006) learning algorithms. For the LAHMM and DEP models, we use the systems described in (Huang et al., 2009; Hatori et al., 2011); for the PCFGLA models, we use the Berkeley parser<sup>2</sup>.

### 2.3.2 Results

Table 1 summarizes the performance in terms of per word classification of different supervised models on the development data. We present the results of both first order (on the left) and second order (on the right) LGLMs. We can see that the perceptron algorithm performs a little better than the PA algorithm for Chinese POS tagging. There is only a slight gap between the local classification model and various structured models. This is very different from English POS tagging. Although the local classifier achieves comparable results when respectively applied to English and Chinese, there is much more significant gap between the corresponding structured models. Similarly, the gap between the first and second order LGLMs is very modest too.

From the linguistic view, we mainly consider the disambiguation ability of local and non-local dependencies. Table 1 presents accuracy results of several POS types, including nouns and functional words. The POS types *NR*, *NT* and *NN* respectively represent proper nouns, temporal nouns and other common nouns. We can clearly see that models which only explore local dependencies are

good enough to deal with nouns. Surprisingly, the local classifier that does not directly define features of possible POS tags of other surrounding words performs even better than structured models for proper nouns and other common nouns.

The tag *DEC* denotes a complementizer or a nominalizer, while the tag *DEG* denotes a genitive marker and an associative marker. These two types only include two words: “的” and “之.” The latter one is mainly used in ancient Chinese. 5.19% of words appearing in the training data set is *DEC/DEG*. The pattern of the *DEC* recognition is *clause/verb phrase+DEC+noun phrase*, and The pattern of the *DEG* recognition is *nominal modifier+DEC+noun phrase*. To distinguish the sentential/verbal and nominal modification phrases, the *DEC* and *DEG* words usually need long range syntactic information for accurate disambiguation. We claim that the prediction performance of the two specific types is a good clue of how well a tagging model resolves long distance dependencies. We can see that the two syntactic parsers significantly outperform local models on the prediction of these types of words.

The weak ability for non-local disambiguation also imposes restrictions on using a sequence POS tagging model as front module for parsing. To evaluate the impact, we employ the PCFGLA parser to parse a sentence based on the POS tags provided by sequence models. Table 4 shows the parsing performance. Note that the overall tagging performance of the Berkeley parser is significantly worse than sequence models. However, better POS tagging does not lead to better parsing. The experiments suggest that sequence models propagate too many errors to the parser. Our linguistic analysis can also well explain the poor performance of Chinese CCG parsing when applying the C&C parser (Tse and Curran, 2012). We think the failure is mainly due to overplaying sequence models in both POS tagging and supertag-

Table 4: Parsing accuracies on the development data. *1or* and *2or* respectively denote first order and second order. *LGLM(X)* denotes a stacking model with *X* as the level-0 processing. All stacking models incorporate word clusters to improve the tagging accuracy.

To distinguish the predictive abilities of generative and discriminative models, we report the precision of the prediction of unknown words (UNK). Discriminative learning can define arbitrary (even overlapping) features which play a central role in tagging English unknown words. The difference between generative and discriminative learning in Chinese POS tagging is not that much, mainly because most Chinese words are compactly composed by a very few Chinese characters that are usually morphemes. This language-specific property makes it relatively easy to smooth parameters of a generative model.

### 3 Improving Tagging Accuracy via Stacking

In this section, we study a simple way of integrating multiple heterogeneous models in order to exploit their complementary strength and thereby improve tagging accuracy beyond what is possible by either model in isolation. The method integrates the heterogeneous models by allowing the outputs of the HMMLA, PCFGLA and DEP to de-

fine features for the LLM/LGLM.

#### 3.1 Stacked Learning

*Stacked generalization* is a meta-learning algorithm that has been first proposed in (Wolpert, 1992) and (Breiman, 1996). Stacked learning has been applied as a system ensemble method in several NLP tasks, such as joint word segmentation and POS tagging (Sun, 2011), and dependency parsing (Nivre and McDonald, 2008). The idea is to include two “levels” of predictors. The first level includes one or more predictors  $g_1, \dots, g_K : \mathbb{R}^d \rightarrow \mathbb{R}$ ; each receives input  $\mathbf{x} \in \mathbb{R}^d$  and outputs a prediction  $g_k(\mathbf{x})$ . The second level consists of a single function  $h : \mathbb{R}^{d+K} \rightarrow \mathbb{R}$  that takes as input  $\langle \mathbf{x}, g_1(\mathbf{x}), \dots, g_K(\mathbf{x}) \rangle$  and outputs a final prediction  $\hat{y} = h(\mathbf{x}, g_1(\mathbf{x}), \dots, g_K(\mathbf{x}))$ . The predictor, then, combines an ensemble (the  $g_k$ ’s) with a meta-predictor ( $h$ ).

#### 3.2 Applying Stacking to POS Tagging

We use the LLMs or LGLMs (as  $h$ ) for the level-1 processing, and other models (as  $g_k$ ) for the level-0 processing. The characteristic of discriminative learning makes LLMs/LGLMs very easy to integrate the outputs of other models as new features. We are relying on the ability of discriminative learning to explore informative features, which play a central role in boosting the tagging accuracy. For output labels produced by each auxiliary model, five new *label uni/bi-gram* features are added:  $w_{-1}, w, w_{+1}, w_{-1-w}, w_{-w+1}$ . This choice is tuned on the development data.

Word clusters that are automatically acquired from large-scale unlabeled data have been shown to be very effective to bridge the gap between high and low frequency words, and therefore significantly improve PA tagging, as well as other syntactic processing tasks. Our stacking models are all built on word clustering enhanced discriminative linear models. Five *word cluster uni/bi-gram* features are

added:  $w_{-1}$ ,  $w$ ,  $w_{+1}$ ,  $w_{-1-w}$ ,  $w_{-w+1}$ . The clusters are acquired based on the Chinese giga-word data with the MKCLS tool. The number of total clusters is set to 500, which is tuned by (Sun and Uszkoreit, 2012).

### 3.3 Evaluation

Table 3 summarizes the tagging accuracy of different stacking models. From this table, we can clearly see that the new features derived from the outputs of other models lead to substantial improvements over the baseline LLM/LGLM. The output structures provided by the PCFGLA model are most effective in improving the LLM/LGLM baseline systems. Among different stacking models, the syntax-free hybrid one (i.e., stacking LLM/LGLM with HMMLA) does not need any treebank to train their systems. For the situations that parsers are not available, this is a good solution. Moreover, the decoding algorithms for linear-chain Markov models are very fast. Therefore the syntax-free hybrid system is more appealing for many NLP applications.

Table 5 is the F1 scores of the DEC/DEG prediction which are obtained by different stacking models. Compared to Table 1, we can see that the hybrid sequence model is still not good at handling long-distance ambiguities. As a result, it harms the parsing performance (see Table 4), though it achieves higher overall precision.

Devel.	DEC	DEG
1or LGLM(HMMLA)	82.93	86.64
1or LGLM(PCFGLA)	88.11	91.12
1or LGLM(DEP)	87.46	89.86

Table 5: F1 score of the *DEC/DEG* prediction of different stacking models on the development data.

### 3.4 Related Work

(Sun and Uszkoreit, 2012) introduced a Bagging model to effectively combine the outputs of individual systems. In the training phase, given a training set  $D$  of size  $n$ , the Bagging model generates  $m$  new training sets  $D_i$ 's by sampling examples from  $D$ . Each  $D_i$  is separately used to train  $k$  individual models. In the tagging phase, the  $km$  models outputs  $km$  tagging results, each word is assigned one POS label. The final tagging is the voting result of these  $km$  labels. Although this model is effective, it is too expensive in the sense

that it uses parser multiple times. We also implement their method and compare the results with our stacking model. We find the accuracy performance produced by the two different methods are comparable.

(Rush et al., 2010) introduced dual decomposition as a framework for deriving inference algorithms for serious combinatorial problems in NLP. They successfully applied dual decomposition to the combination of a lexicalized parsing model and a trigram POS tagger. Despite the effectiveness, their method iteratively parses a sentence many times to achieve convergence, and thus is not as efficient as stacking.

## 4 Improving Tagging Efficiency through Unlabeled Data

### 4.1 The Idea

Hybrid structured models often achieve excellent performance but can be slow at test time. In our problem, it is obviously too inefficient to improve POS tagging by parsing a sentence first. In this section, we explore unlabeled data to transfer the predictive power of hybrid models to sequence models. The main idea behind this is to use a fast model to approximate the function learned by a slower, larger, but better performing ensemble model. Unlike the true function that is unknown, the function learned by a high performing model is available and can be used to label large amounts of pseudo data. A fast and expressive model trained on large scale pseudo data will not overfit and will approximate the function learned by the high performing model well. This allows a slow, complex model such as massive ensemble to be compressed into a fast sequence model such as a first order LGLM with very little loss in performance.

This idea to use unlabeled data to transfer the predictive power of one model to another has been investigated in many areas, for example, from high accuracy neural networks to more interpretable decision trees (Craven, 1996), from high accuracy ensembles to faster and more compact neural networks (Bucila et al., 2006), or from structured prediction models to local classification models (Liang et al., 2008),

### 4.2 Reducing Hybrid Models to Sequence Models

For English POS tagging, Liang, Daumé and Klein (2008) have done some experiments to

Size of data	HMMLA	win size=3		win size=4		Voting	
		LLM	LGLM	LLM	LGLM	DEC/DEG	
+100k	94.72%	95.05%	95.07%	95.04%	95.10%	95.36%	--
+200k	94.77%	95.06%	95.18%	95.20%	95.23%	95.43%	--
+500k	94.97%	95.11%	95.21%	95.15%	95.23%	95.43%	--
+1000k	95.09%	95.19%	95.23%	95.22%	95.31%	95.49%	85.75/89.01

Table 6: Tagging accuracies of different re-compiled models on the development data.

transfer the power of a chain conditional random field to a logistic regression model. Similarly, we do some experiments to explore the feasibility of reducing hybrid tagging models to a HMMLA, LLM or LGLM, for Chinese POS tagging. The large-scale unlabeled data we use in our experiments comes from the Chinese Gigaword (LDC2005T14), which is a comprehensive archive of newswire text data that has been acquired over several years by the Linguistic Data Consortium (LDC). We choose the Mandarin news text, i.e. Xinhua newswire. We tag giga-word sentences by applying the stacked first order LGLMs with all other models. In other words, the HMMLA, PCFGLA and DEP systems are applied to tag unlabeled data features and their outputs are utilized to define features for first-order and second-order LGLMs which produce pseudo training data. Both original gold standard training data and pseudo training data are used to re-train a HMMLA, a LLM/LGLM with extended features.

The key for the success of hybrid tagging models is the existence of a large diversity among learners. Zhou (2009) argued that when there are lots of labeled training examples, unlabeled instances are still helpful for hybrid models since they can help to increase the diversity among the base learners. The author also briefly introduced a preliminary theoretical study. In this paper, we also combine the re-trained models to see if we can benefit more. We utilize voting as the strategy for final combination. In the tagging phase, the re-trained LLM, LGLM and HMMLA systems outputs 3 tagging results, each word is assigned one POS label. The final tagging is the voting result of these 3 labels.

## 4.3 Experiments

### 4.3.1 Reducing Hybrid Models to HMMLA

With the increase of (pseudo) training data, a HMMLA may learn better latent variables to sub-categorize POS tags, which could significantly im-

prove a purely supervised HMMLA. In our experiments, all HMMLA models are trained with 8 iterations of split, merge, smooth. The second column of Table 6 shows the performance of the re-trained HMMLAs. The first column is the number of sentences of pseudo sentences. The pseudo sentences are selected from the beginning of the Chinese gigaword. We can clearly see that the idea to leverage unlabeled data to transfer the predictive ability of the hybrid model works. Self-training can also slightly improve a HMMLA (Huang et al., 2009). Our auxiliary experiments show that self-training is not as effective as our methods.

### 4.3.2 Reducing Hybrid Models to LLM/LGLM

To increase the expressive power of a discriminative classification model, we extend the feature templates. This strategy is proposed by (Liang et al., 2008). In our experiments, we increase the window size of word uni/bi-gram features to approximate long distance dependencies. For window size 3, we will add  $w_{-3}$ ,  $w_3$ ,  $w_{-3}w_{-2}$  and  $w_2w_3$  as new features; for size 4, we will add  $w_{-4}$ ,  $w_{-3}$ ,  $w_3$ ,  $w_4$ ,  $w_{-4}w_{-3}$ ,  $w_{-3}w_{-2}$ ,  $w_2w_3$  and  $w_3w_4$ ; Column 3 to 6 of Table 6 show the performance of the re-compiled LLMs/LGLMs. Similar to the generative model, the discriminative LLM/LGLM can be improved too.

### 4.3.3 Voting

The last two columns of Table 6 are the final voting results of the HMMLA, LLM and LGLM. The window size of word uni/bi-gram features for the LLM and LGLM is set to 4. Obviously, the re-trained models are still diverse and complementary, so the voting can further improve the sequence models. The result of the best hybrid sequence model is very close to the best stacking models. Furthermore, the F1 scores of the DEC/DEG prediction are 85.75 and 89.01, which are very close to parsers too.

#### 4.3.4 Improving Parsing

Purely supervised sequence models are not good at predicting function words, and accordingly are not good enough to be used as front modules to parsers. The re-compiled models can mimic some behaviors of parsers, and therefore are suitable for parsing. Our evaluation shows that the significant improvement of the POS tagging stop harming syntactic parsing. Results in Table 7 indicate that the parsing accuracy of the Berkeley parser can be simply improved by inputting the Berkeley parser with the re-trained sequential tagging results. Additionally, the success to separate tagging and parsing can improve the whole syntactic processing efficiency.

Devel.	LP	LR	F1
HMMLA	82.18	81.16	81.66↑
LLM	81.86	80.93	81.40↑
LGLM	82.07	81.21	81.64↑
Voting	82.34	81.42	81.88↑

Table 7: Accuracies of parsing based on re-compiled tagging.

#### 4.3.5 Final results

Table 8 shows the performance of different systems evaluated on the test data. Our final sequence model achieve the state-of-the-art performance, which is once obtained by combining multiple parsers as well as sequence models.

Systems	Acc.
(Sun and Uszkoreit, 2012)	95.34%
Our system	95.33%

Table 8: Tagging accuracies on the test data.

## 5 Conclusion

In this paper, we study two techniques to build accurate and fast sequence models for Chinese POS tagging. In particular, our goal is to capture long-distance dependencies in sequence models. To improve tagging accuracy, we study stacking to integrate multiple models with heterogeneous views. To improve tagging efficiency at test time, we explore unlabeled data to transfer the predictive power of hybrid models to simple sequence or even local classification models. Hybrid systems are utilized to create large-scale pseudo training data for cheap models. By applying complex

machine learning techniques, we are able to build good sequential POS taggers. Another advantage of our system is that it serves as a front-end to a parser very well. Our study suggests that complicated structured models can be well simulated by simple sequence models through unlabeled data.

## Abstract

In this paper, we present our efforts towards incorporating external knowledge from Hindi WordNet to aid dependency parsing. We conduct parsing experiments on Hindi, an Indo-Aryan language, utilizing the information from concept ontologies available in Hindi WordNet to complement the morpho-syntactic information already available. The work is driven by the insight that concept ontologies capture a specific real world aspect of lexical items, which is quite distinct and unlikely to be deduced from morpho-syntactic information such as morph, POS-tag and chunk. This complementing information is encoded as an additional feature for data driven parsing and experiments are conducted. We perform experiments over datasets of different sizes. We achieve an improvement of 1.1% (LAS) when training on 1,000 sentences and 0.2% (LAS) on 13,371 sentences over the baseline. The improvements are statistically significant at  $p < 0.01$ . The higher improvements on 1,000 sentences suggest that the semantic information could address the data sparsity problem.

## 1 Introduction

Last decade has witnessed several efforts towards developing robust data driven dependency parsing techniques (Kübler et al., 2009). The efforts, in turn, initiated a parallel drive for building dependency annotated treebanks (Tsarfaty et al., 2013), which serve as a data source for training data driven dependency parsers. The annotations are often multi-layered and furnish information on part of speech category of word forms, their morphological features, related word groups and the

syntactic relations. The availability of such rich resources have considerably improved the parsing performance of syntactic parsers (Collins et al., 1999). However, the error analysis studies carried out on these parsers later revealed that certain syntactic relations are difficult to deduce and disambiguate with the syntactic information available in the annotated treebanks.

The need for richer information invoked several efforts in the direction of annotating higher order linguistic information in treebanks. It was felt that semantics can be leveraged for syntactic disambiguation and thus semantic annotation was performed in syntactic treebanks to complement the morpho-syntactic annotations (Kingsbury et al., 2002; Montemagni et al., 2003). Fujita et al. (2007) and MacKinlay et al. (2012) illustrated that semantic annotation delivers a significant improvement in parsing, confirming the hypothesis that semantics can assist syntactic analysis.

Among Indian languages, notable efforts on using semantic information in dependency parsing are on *Hindi*. Bharati et al. (2008) illustrated that mere *animacy* (human, non-human and inanimate) of a nominal significantly improves the accuracy of the parser. Later studies on extending such information with finer semantic distinctions like *time*, *place*, *abstract* reconfirmed the substantial role of semantics in syntactic parsing (Ambati et al., 2009). These studies are carried out on a dataset with hand annotated semantics. Although these studies provide deep insights on the role of semantics in parsing, they are limited in application as such information can not be automatically generated while parsing new sentences.

In this work, we make an effort to supply the aforementioned semantic information by employing concept hierarchy available in Hindi WordNet (henceforth HWN).

## 2 Related Work

Attempts have been made to utilize hand annotated semantic information for *constituency parsing* (Fujita et al., 2007; MacKinlay et al., 2012) as well as *dependency parsing* (Øvrelid and Nivre, 2007; Bharati et al., 2008; Ambati et al., 2009). However, acquiring such information for new sentences remains a challenge. This leads us to the exploration of lexical databases and ontologies for accessing semantic information useful for parsing. Xiong et al. (2005) used two lexical resources *HowNet*<sup>1</sup> (Dong and Dong, 2000) and *TongYiCi CiLin* (Mei and Gao, 1996) for parsing Penn Chinese Treebank (Xue et al., 2002). Agirre et al. (2008) demonstrated that semantic classes obtained from English WordNet (Miller, 1995) help to obtain significant improvements in both PP attachment and PCFG parsing. Similarly, for dependency parsing, Agirre et al. (2011) utilized the English WordNet semantic classes and improved parsing accuracies.

## 3 Background and Challenges

Hindi is an Indo-Aryan language with richer morphology as compared to English. It exerts a relatively free word order with SOV being the default configuration. Due to the flexible word order, dependency representations are preferred over constituency for its syntactic analysis (Bharati and Sangal, 1993). The dependency representations do not constrain the order of words in a sentence and thus are better suited for flexible ordering of words. The dependency grammar formalism, used for Hindi is *Computational Paninian Framework* (CPG) (Begum et al., 2008; Bharati et al., 2009). The dependency relations in CPG formalism are closer to semantics and hence they are also denoted as *syntactico-semantic* relations.

The most important feature explored for dependency parsing is ‘case clitics’ that largely governs the relations nominals bear with their heads. Several efforts in past, on parsing Hindi, have greatly benefited by utilizing these clitics as a feature (Ambati et al., 2010a; Ambati et al., 2010b). However, case markers and case roles do not have a one-to-one mapping, each case marker is distributed over a number of case roles. Among the six case markers only Ergative case marker is unambiguous (Mohanan, 1994). Although case

markers are good indicators of the relation a nominal bears in a sentence, their ambiguous nature bars their ability in effectively identifying the role of a nominal while parsing. Consider the examples from (1a-e), the instrumental *se* is extremely ambiguous. It can mark the instrumental adjuncts as in (1a), source expressions as in (1b), material as in (1c), comitatives as in (1d), and causes as in (1e).

- (1a) मोहन ने चाबी से ताला खोला ।  
Mohan-Erg key-Inst lock-Nom open  
‘Mohan opened the lock with a key.’
- (1b) गीता ने दिल्ली से सामान मंगवाया ।  
Geeta-Erg Delhi-Inst luggage-Nom procure  
‘Geeta procured the luggage from Delhi.’
- (1c) मूर्तिकार ने पत्थर से मूर्ति बनायी ।  
sculptor-Erg stone-Inst idol-Nom make  
‘The sculptor made an idol out of stone.’
- (1d) राम की श्याम से बात हुई ।  
Ram-Gen Shyaam-Inst talk-Nom happen  
‘Ram spoke to Shyaam.’
- (1e) बारिश से कई फसलें तबाह हो गयीं ।  
rain-Inst many crops-Nom destroy  
happen-Perf  
‘Many crops were destroyed due to the rain.’

Not all instances of a nominal in Hindi are case marked, as shown in Table 1. In appropriate contexts, a nominal can also bear a nominative case which is morphologically null (henceforth referred as unmarked nominals). It is possible, in fact quite frequent, to have more than one unmarked nominal within a single clause and due to the relative free word order, the movement can result in different surface configurations.

- (2a) चिड़िया दाना चुग रही है ।  
bird-Nom grain-Nom peck-Prog
- (2b) दाना चिड़िया चुग रही है ।  
grain-Nom bird-Nom peck-Prog  
‘A bird is pecking grain.’

	Patient-Unmarked	Patient-Marked
Agent-Unmarked	1276	741
Agent-Marked	5373	966

Table 1: Co-occurrence of Marked and Unmarked verb arguments in Hindi Dependency Treebank. *Source:* training-set, shared task MTPIL 2012

A conventional parser has no cues for the disambiguation of instrumental case marker *se* in examples (1a-e) and similarly, in example (2a-b), it

<sup>1</sup><http://www.keenage.com>

is hard for the parser to know whether ‘bird’ or ‘grain’ is the agent of the action ‘peck’. Apart from lexical and structural ambiguity, there are also data sparsity and out of vocabulary (OOV) problems when parsing out-of-domain text. Traditionally, syntactic parsing has largely been limited to the use of only a few lexical features. Features like POS-tags are way too coarse to provide deep information valuable for syntactic parsing. So in order to assist the parser for better judgments, we need to complement the morphology somehow.

#### 4 Hindi WordNet and Concept Ontologies

Hindi WordNet is a lexical database developed on the lines of English Wordnet, under the Indo WordNet project (Narayan et al., 2002). For each lexical item, Hindi WordNet defines a synset which enlists its synonyms. Further, each synset is mapped to a concept ontology. The concept ontology is a hierarchical organization of concepts like entities, actions etc. which defines the semantic properties of lexical items of a given synset. The ontology consists of around 200 different concepts. The lexical item is the leaf node in this hierarchical construct. As we move up the hierarchy, the specific semantic aspects of a given lexical item are unraveled. The hierarchy terminates, immediately after capturing the syntactic category of a word, at the *TOP* node. The *TOP* acts as a *root*, holding the hierarchies of all the lexical items listed in HWN. Figure 1 illustrates a typical hierarchy in this ontology, where *Ape* is the most explanatory node. As we move up, it becomes more and more generic. Further, the relations between different synsets are captured based on the following paradigms :

- Semantic (hypernymy, hyponymy, meronymy etc.)
- Lexical (antonymy, synonymy etc.)
- Gradience (size, quality, manner etc.).

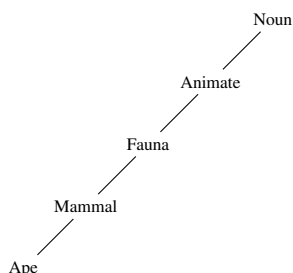

Figure 1: Sample Hierarchy of Concepts in Hindi Wordnet

Type	Sentence Count	Token Count	Chunk <sup>4</sup> Count
Training	12,038	268,009	142,445
Development	1,233	26,416	13,945
Testing	1,828	39,775	21,165

#### 5 Hindi Dependency Treebank

In this section, we give an overview of Hindi Treebank (HTB ver-0.51) (Bhatt et al., 2009; Palmer et al., 2009) a part of which was released for Hindi Dependency Parsing shared task, MTPIL, (Sharma et al., 2012). It is a multi-layered dependency treebank with morphological, part-of-speech and dependency annotations based on the Computational Paninian Framework (henceforth CPG). In the dependency annotation, relations are mainly verb-centric. The relation that holds between a verb and its arguments is called a ‘*karaka*’ relation. Besides *karaka* relations, dependency relations also exist between nouns (genitives), between nouns and their modifiers (adjectival modification, relativization), between verbs and their modifiers (adverbial modification including subordination). CPG provides an essentially syntactico-semantic dependency annotation, incorporating *karaka* (e.g., agent, theme, etc.), *non-karaka* (e.g. possession, purpose) and other (part of) relations. A complete tag-set of dependency relations based on CPG can be found in (Bharati et al., 2009). The ones starting with ‘*k*’ are largely Paninian *karaka* relations, and are assigned to the arguments of a verb. The data is released in two formats, SSF (Bharati et al., 2007) and CoNLL-X<sup>2</sup> formats (details in Table 2). It has also been released in UTF-8 encoding and roman readable WX<sup>3</sup> notation. We are using the CoNLL-X format and UTF-8 encoding.

#### 6 Incorporating Knowledge from Concept Ontologies

In this section, we present our approach to incorporate semantic knowledge from HWN into the parsing model. We transform the hierarchical information in the concept ontology listed in HWN, into a string feature (henceforth WN feature) for

<sup>2</sup><http://ilk.uvt.nl/conll/#dataformat>

<sup>3</sup><http://sanskrit.inria.fr/DATA/wx.html>

<sup>4</sup>A chunk is a set of adjacent words which are in dependency relation with each other, and are connected to the rest of the words by a single incoming arc.

all the tokens in our data. Given a lexical item, we extract the information using its syntactic category from the ontological hierarchy corresponding to the most appropriate sense selected. In the following, we discuss in detail the selection and incorporation of this information with the challenges posed.

## 6.1 Feature Extraction

In this section, we explore the extraction of features from HWN corresponding to the lexical items in our data. We also address the issues like sense selection and coverage.

### 6.1.1 Sense Selection

Attributed to the phenomenon of lexical ambiguity, a lexical item can have senses varying across different contexts. Although HWN lists all the possible senses of a lexical item, to choose the contextually appropriate sense is a challenging task. Here, we discuss our approach to select the sense of a lexical item best suited in a given context.

- *Category Based Sense Selection*: Consider a word *chaat*, it can either mean ‘lick’ or ‘snacks’. The former corresponds to a verb while the latter is a nominal as depicted in Figure 2. The syntactic category of a lexical item provides an initial cue for the sense selection. Among the varied senses, we filter out the senses that do not fall into its syntactic category.

Figure 2: Nominal and Verb Sense of *chaat*

- *Intra – Category Sense Selection*: As a matter of fact, words are ambiguous not only across different syntactic categories but also within same category as depicted in Figure 3. Once the senses of a lexical item are filtered based on its syntactic category, within category senses, if many, are investigated for the best sense based on the following strategies:

- *First Sense*: Among the varied senses, we select the first sense listed

in HWN corresponding to the POS-tag of a given lexical item. The choice is motivated by our observation that the senses of a lexical item are ordered in the descending order of their frequencies of usage i.e., the first sense listed in HWN is the predominant sense of a given lexical item.

- *WSD*: Although first sense captures the predominant usage of a lexical item, it is inappropriate for its other infrequent usages. We, therefore, need to pick the contextually appropriate sense of a lexical item. To this end, we exercise Extended Lesk, a classical word sense disambiguation algorithm (Banerjee and Pedersen, 2003).

Figure 3: Two senses for the nominal *chaat*

### 6.1.2 Numeric Expressions

As is obvious, no lexical resource can have an exhaustive coverage because of the evolving nature of human language. In the context of HWN, the problem further intensifies as it restricts the entry to only words of open class syntactic categories. Apart from that, it also has a limited coverage for numeric expressions as these expressions belong to an infinite set. Numerals can be used in wide range of senses. Apart from their simple ordinal or cardinal usages, they can also be used as nominals in expressions like time and measurement. In their adjectival sense, WN features can be extracted corresponding to the head word they modify e.g., the temporal sense of an expression 10 *saal* can be identified by the head word *saal* ‘year’. However, to identify the temporal sense of a numeral, used as nominal, like 2013 is challenging. We use a numeric-expression recognizer, built in-house, to identify measurement and temporal expressions. The tool makes use of regular expressions and cue words. Once identified, we assign them an appropriate HWN ontological hierarchy which either corresponds to *time*, *measurement* or *number*.

### 6.1.3 Complex Predicate as a Feature

Complex predicates (CPs, also known as complex verbs) are highly frequent in South Asian languages (Mohan, 1997). They occur in the form of nominal+verb combinations (called conjunct verbs) and verb+verb combinations (called compound verbs). For example, in (5), ‘शरण लेना’ (refuge take) is a complex predicate composed of a nominal ‘शरण’ and a light verb ‘लेना’. The constituents of a complex predicate are related by a dependency relation *poF* in HDT. In Hindi dependency parsing, the major chunk of parse errors is attributed to the low learnability of complex predicates (Husain and Agrawal, 2012). Begum et al. (2011) addressed the identification of these expressions using some linguistic rules. Fortunately, HWN has listed a finite set of these expressions in its database (Chakrabarti et al., 2007). We first extract the multi word expressions listed in HWN if the last word in the expression is a verb. Then from the list only 2-word expressions are selected and treated as complex predicates. Instead of adding WN features to the nominal of a complex predicate, we assign a separate *CP* tag to it. The semantics of light verbs is, however, kept as such.

## 6.2 Feature Design

After the extraction of WN features, we explore possibilities of their design and incorporation in the parsing framework, as follows.

### 6.2.1 Grouping Similar Features

We observed that few concept ontological lineages are semantically similar. For example, the six lineages depicted below address the notion of time.

- *Time*
- *Descriptive*→*Time*
- *Inanimate*→*Abstract*→*Time*
- *Inanimate*→*Abstract*→*Time*→*Period*
- *Inanimate*→*Abstract*→*Time*→*Season*
- *Inanimate*→*Abstract*→*Time*→*Mythological Period*

Since our focus is on adding representative semantic features which can assist parsing, we believe that such divergences should be grouped together. In the listed example, first, second and the last four differ in terms of their origin and belong to different branches in the hierarchy. Thus they can not be grouped by optimal depth selection (described later in Section 6.2.3) and requires a manual scrutiny. We studied the possible lineages in the concept ontology and performed

merging wherever necessary, furnishing a semantically well diverse set of concept lineages.

### 6.2.2 Split Vs Conjoined

The concept lineage, derived for a word from HWN concept ontology, contains diverse concepts at each level of the lineage. The choice of using each of these concepts as independent features or the complete lineage as a single feature demands exploration. In the context of parsing, each independent concept from the lineage can potentially capture a specific aspect of syntax, depending on the fineness of the concept. The down side of this proposition is the increase in the feature dimensions, as each level adds a new dimension in the feature space. Whereas, using the complete lineage as a single feature does not add any additional dimension in the feature space but captures only a specific concept. This trade off is difficult to comprehend on theoretical grounds, hence we explore both choices of feature design in our experiments.

### 6.2.3 Ontology Depth

Hindi WordNet concept ontology furnishes a ‘generalization hierarchy’ for a lexical item, where the specificity of concepts increases as we move down the hierarchy. It may look intuitive to use fully expanded concept lineage, as it contains more detailed description of the lexical unit. However, opting for a highly fine-grained concept lineage leads to the problem of sparseness. It becomes less and less probable to find ample training examples as the feature becomes more fine-grained. At the same time, too much generalization is also unrewarding since the richer information is cast away in the excessive coarser lineage. This calls for measures to obtain an optimal depth of concept lineage for each lexical item. On one hand it should be generalized enough to give significant examples of its respective type while on the other hand, it should be fine enough to capture the rich ontological concept associated with the lexical unit. In order to quantify the trade-off we resort to statistical correlation measures and employed *Gini Coefficient* (Gini, 1912). We computed the coefficient against all possible concept lineages in the training set and set a threshold. The lineages that fall below the threshold are generalized till they are above the threshold. For example, in Figure 1 the concept *ape* is suppressed to give the lineage till *mammal* only. So in future if a word gives the lineage as in Figure 1 it will be

replaced with its one level up generalization i.e. *Animate*→*Fauna*→*Mammal*.

## 7 Experiments and Results

In our experiments, we focus on establishing dependency relations between the chunk heads which we henceforth denote as *inter-chunk* parsing. The relations between the tokens of a chunk (*intra-chunk* dependencies) are not considered for experimentation. In example (3), dotted line shows an *intra-chunk* relation while the bold lines show *inter-chunk* dependency relations<sup>5</sup>. The decision is motivated by the fact that the *intra-chunk* dependencies can easily be predicated automatically using a finite set of rules (Kosaraju et al., 2012). Moreover we also observed the high learnability of *intra-chunk* relations from an initial experiment. We found the accuracies of *intra-chunk* dependencies to be more than 99.00% for both Labeled Attachment and Unlabeled Attachment.

In this section, we present our parsing experiments incorporating the features extracted from HWN, as discussed in Section 6. First we setup our baseline parser followed by the detailed discussion on the impact of the individual features, extracted from HWN, on the overall parsing performance.

We setup our baseline parser on the lines of (Singla et al., 2012) with minor modifications in the parser *feature model*. We employ MaltParser version-1.7<sup>6</sup> (Nivre et al., 2007) and Nivre’s Arc Eager algorithm for all our experiments reported in this work. All the results reported are evaluated using *eval07.pl*<sup>7</sup>. We use MTPIL (Sharma et al., 2012) dependency parsing shared task data described in Section 5. Among the features available in the FEATS column of the CoNLL format data, we only consider *Tense*, *Aspect*, *Modality (tam)* and *postpositions* while training the baseline parser. Other columns like POS, LEMMA, etc. are used as such. After the baseline, the parsing framework is further enriched with the semantic features extracted from HWN to address the problems raised in Section 3. These features are added in the FEATS column of the data, separated by ‘|’. In a pilot experiment split form of features, as discussed in Section 6.2.2, are found to per-

<sup>5</sup>k1: Doer, k1s: Noun Complement, k5: Source, k7p: Place, k7t: Time, pof: part-of (complex predicate), lwg\_psp: local-word-group postposition

<sup>6</sup><http://www.maltparser.org/download.html>

<sup>7</sup><http://nextens.uvt.nl/depparse-wiki/SoftwarePage/#eval07.pl>

form better than conjoined form, which motivate us to use WN feature in split form in all our experiments. The experimentation proceeds in the order as listed in Table 3 which also presents the consolidated results of our parsing experiments using the MTPIL training and testing sets. In order to see the impact of semantic information on data sparsity, we split the MTPIL training set into datasets of different sizes. We experiment with 6 data sets of different sizes. The results are produced on MTPIL test set and are plotted on Graph (Figure 4). The increase in LS and LAS, as the training size decreases, shows the impact of semantic information on data sparsity. The improvement of 1.1 (LAS) by semantics upon reducing the training examples to 1000 implies that semantics can address the data sparsity and OOV problems when working with out-of-domain text.

Next we discuss the impact of WN features on the accuracy of our parsing results produced on datasets of different sizes:

- *Sense Selection*: As discussed in Section 6.1.1, we perform two experiments to extract the WN features corresponding to the most appropriate sense of a lexical item. In the first experiment, the first sense of each lexical item is selected while in the second, WSD is used to pick the contextually most appropriate sense. These features corresponding to the chosen sense are coupled with the features already present in the baseline. As depicted in Graph (Figure 4), there is a average increase of 0.38 (LAS) on all datasets using the first sense strategy from the baseline. However, using WSD the accuracy decreased across all datasets. As is obvious, the fall in accuracy can be attributed to the wrong sense selection. The problem can be addressed by using better WSD algorithms for Hindi.
- *Numeric Expressions and Grouping*: As discussed in Section 6.1.2, numeric expressions and sense grouping increases the coverage of HWN. This obvious reason is clearly depicted in the improvement in parsing results as shown in Table 3. More the semantic information available in the data, more will be its impact on the parsing.
- *Depth of Information*: The optimality of feature coarseness is put to test in this ex-

periment. This experiment is run on numeric expression data with feature pruning done as described in Section 6.2.3. An increment of average 0.03% LAS across datasets is observed from the previous experiment. In the test set, there are only a few cases that are updated by choosing an optimal lineage depth which explains the minimal increase in accuracy.

- *Complex Predicate*: As pointed in (Begum et al., 2011), addressing the low learnability of complex predicates can improve the parsing results. The improvements are particularly seen in the core arguments of a verb. The similar syntactic distribution of adjectival or nominal element of a complex predicate and the syntactic arguments of a verb particularly *objects*, make these expressions highly ambiguous. Identifying these expressions beforehand, as suggested in (Begum et al., 2011), improves the parsing performance. The incorporation of this crucial information from HWN is rewarding as we achieve an improvement of  $\sim 0.4\%$  in LAS on a dataset of 1,000 sentences.

	Experiments	LAS(%)	UAS(%)	LS(%)
E1	Baseline	83.69	92.43	86.58
E2	E1 + First Sense	83.78	92.4	86.73
E3	E1 + WSD (Extended Lesk)	83.6	92.34	86.57
E4	E2 + Numeric Expressions & Grouping	<b>83.88</b>	<b>92.45</b>	<b>86.87</b>
E5	E4 + Ontological Depth	83.84	92.4	86.79
E6	E4 + Complex Predicate	83.75	92.39	86.72
E7	E5 + E6 (Complex Predicate + Ontological Depth)	83.74	92.39	85.7

## 8 Discussion

In this section, we discuss further, how well the issues raised in Section 3 are handled by the incorporation of semantic information in the parsing framework of Hindi. In Section 3, we stated that ambiguities in morphological cases in Hindi bar their efficient exploitation while parsing. Also we noted that unmarked nominals may as well affect the performance of a parser. So we propose semantics as a complementing information that can fill these gaps. Below we discuss whether semantic information has bridged these gaps or not.

- *Case Ambiguity*: Including the semantics from HWN to help disambiguate the con-

fusion present in a case marker, has improved parsing accuracy. Particularly confusion among the roles of concrete vs abstract time and place, and direct vs indirect object relations has been removed. In example (3), the dependency relation between nodes *Karachi* and *do* has been corrected from *k2* ‘Theme’ to *k5* ‘Source’. The post-position *from* can either mark a theme or a source relation. Semantics has removed this confusion.

- *Lack of Case Marker*: In absence of case marking lexical semantics acted as a complementing information. The improvement has been, as observed during error analysis, particularly for agents and patients. Thus semantics can be seen here as pseudo case markers. This is clearly visible from the example (4). The dependency relation between the nodes *then* and *do* has been corrected to *k7t* ‘time of action’ from *k1* ‘subject’.

- *Complex Predicates*: As we discussed, complex predicates are identified using HWN, so that the similar syntactic distributions of verb arguments and the nominal or adjectival part of a CP can be disambiguated. Identifying the complex predicates has turned to be rewarding. As was expected, the prior identification of CPs has significantly improved the joint identification of label and attachment. The system trained on 1,000 sentences has shown an improvement of 0.34% (LAS) and 0.2% (UAS) by prior identification of complex predicates. The confusion that has been removed is among the arguments of a verb and the nominal part of the CP i.e., between agent, patient vs nominal,

Figure 4: Impact of WN Features on Different Data Sizes

adjectival part of CP. In example below, baseline incorrectly identifies *refuge* as an argument of verb *take*. ‘*refuge take*’ is a complex predicate which is correctly identified upon incorporation of complex predicates in our parsing module.

## 9 Conclusion and Future Work

We present our efforts on exploring lexical resources, Hindi WordNet in our case, to discover features which complement the available morphosyntactic feature conventionally explored for parsing. We find concept ontology available in HWN quite resourceful in furnishing features which can essentially break syntactic ambiguity, resulting in better accuracies for parsing. In future we would like to investigate other hierarchies like hypernymy, hyponymy, meronymy etc. We would also like to substitute lexical units with their respective synsets as proposed in (Agirre et al., 2011).

CIS, University of Munich  
inquiries@cislmu.org

## Abstract

We investigate the robustness of domain adaptation (DA) representations and methods across target domains using part-of-speech (POS) tagging as a case study. We find that there is no single representation and method that works equally well for all target domains. In particular, there are large differences between target domains that are more similar to the source domain and those that are less similar.

## 1 Introduction

Domain adaptation (DA) is the problem of adapting a statistical classifier that was trained on a source domain (SD) to a target domain (TD) for which no or little training data is available. We present a case study that investigates the robustness of DA across six different TDs for POS tagging. Most prior work on DA has either been on a single TD, on two or more tasks – which results in an experimental setup in which two variables change at the same time, task and TD – or has not systematically investigated how robust different features and different DA approaches are.

The two main information sources in POS tagging are *context* – which POS's are possible in a particular syntactic context – and *lexical bias* – the prior probability distribution of POS's for each word. We address DA for lexical bias in this paper, focusing on unknown words; they are most difficult to handle in DA because no direct information about their possible POS is available in the SD training set. Since typical TDs contain a high percentage of unknown words, a substantial gain in the overall performance can be achieved by improving tagging for these words.

We address a problem setting where – in addition to *labeled SD data* – a large amount of *unlabeled TD data* is available, but *no labeled TD*

*data*. This setting is often called unsupervised domain adaptation (cf. (Daumé III, 2007)).

We make three contributions in this paper. First, we systematically investigate the cross-TD robustness of different representations and methods. We show that there are some elements of DA setups used in the literature that are robust across TDs – e.g., the use of distributional information – but that many others are not, including dimensionality reduction and shape information.

Second, we present an analysis that shows that there are two important factors that influence cross-TD variation: (i) the magnitude of the difference in distributional properties between SD and TD – more similar TDs require other methods than less similar TDs and (ii) the evaluation measures used for performance. Since in unsupervised DA we optimize learning criteria on a SD that can be quite different from the TD, different TD evaluation measures can diverge more in DA than in standard supervised learning settings when comparing learning methods.

Our third contribution is that we show that if we succeed in selecting an appropriate DA method for a TD, then performance improves significantly. We establish baselines for unknown words for the five TDs of the SANCL 2012 shared task and present the best DA results for unknown words on the Penn BioTreebank. Our improvements on this data set (by 10% compared to published results) are largely due to a new DA technique we call training set filtering. We restrict the training set to long words whose distribution is more similar to unknown words than that of words in general.

The next section describes experimental data and setup and Section 3 experimental results. Section 4 presents analysis and discussion. Section 5 reviews related work. Section 6 concludes.

## 2 Experimental data and setup

**Data.** Our SD is the Penn Treebank (Marcus et

al., 1993) of Wall Street Journal (WSJ) text. Following Blitzer et al. (2006), we use sections 2-21 for training. We also use 100,000 WSJ sentences from 1988 as unlabeled data in training.

We evaluate on six different TDs. The first TD is the Penn BioTreebank data set distributed by Blitzer. It consists of development and test sets of 500 sentences each and an unlabeled set of 100,000 sentences of BIO text.

The remaining five TDs (newsgroups, weblogs, reviews, answers, emails) are from the SANCL shared task (Petrov and McDonald, 2012). We will use WEB to refer to these five TDs collectively. Each WEB TD has an unlabeled training set of 100,000 sentences and development and test sets of about 1000 labeled sentences each. WEB and BIO tag sets differ slightly; we use them as published without modifications to make our results directly comparable to the benchmarks.

We define the *target domain repository* (TD-R) for a TD as the union of development set and unlabeled data available for that TD. SD+TD-R is the union of the source data (labeled and unlabeled WSJ) and TD-R.

**Classification setup.** In contrast to most other work on POS DA, we adopt a simple approach of *word classification*. The objects to be classified are words and the classes are the POS's of the SD. The gold label of a word in training is the majority tag in the SD. A prediction for an unknown word is then made by computing its feature representation and applying the learned classifier.

We adopt word classification instead of the more common sequence labeling setup because word classification is much more efficient to train and allows us to run a large number of experiments efficiently. Our experiments demonstrate that word classification accuracies are comparable with or higher than sequence labeling in POS DA for unknown words (cf. Table 2).

We use LIBSVM (Chang and Lin, 2011) to train  $\binom{k}{2}$  one-vs-one classifiers on the training set, where  $k$  is the number of POS tags in the latter. The SVMs were trained with untuned default parameters; in particular,  $C = 1$ . For sequence classification, we use CRFSuite (Okazaki, 2007), a Conditional Random Field (CRF) toolkit. Apart from the word features described below, we use the base feature set of Huang and Yates (2009) for CRFs, including features for state, emission and transition probabilities. CRFs are trained until

convergence with a limit of 300 iterations.

**Features.** There are in principle two sources of information to predict the POS of an unknown word in an unsupervised setting: the word itself (sequence of letters, shape etc) and the context(s) in which it occurs. For syntactic categorization, the immediate left and right neighbors of a word are the most informative aspect of context. Based on this reasoning, we create a feature representation for each word that has three components: left context information, right context information and shape information. We will refer to left/right context information as *distributional information*. Let  $f$  be the function that maps a word  $w$  to its (full) feature vector. We then define  $f$  as follows:

$$f(w) = \begin{bmatrix} f_{\text{left}}(w) \\ f_{\text{right}}(w) \\ f_{\text{shape}}(w) \end{bmatrix}$$

Based on the intuition that each of the three sources of information is equally important, each of the three component vectors is normalized to unit length.

For both distributional and shape features, we have a choice of either using *all possible features* or *a subset consisting of the most frequent features*. We directly compare these two possibilities, using recommended values from the literature for the subset condition: the 250 most frequent features (indicator words) for distributional vectors (Schütze, 1995) and the 100 most frequent features (suffixes) for shape vectors (Müller et al., 2012). Each component vector has an additional binary feature that is set to 1 if the rest of the vector is zero, and 0 otherwise to avoid numerical issues with zero vectors.

**Distributional features.** The  $i^{\text{th}}$  entry  $x_i$  of  $f_{\text{left}}(w)$  is the number of times that the *indicator word*  $t_i$  occurs immediately to the left of  $w$ :

$$x_i = \text{freq}(\text{bigram}(t_i, w))$$

where  $t_i$  is the word with frequency rank  $i$  in the corpus.  $f_{\text{right}}(w)$  is defined analogously.

Many different ways of defining and transforming distributional features have been proposed in the literature. We systematically investigate the following variables: (i) weighting (ii) dimensionality reduction and (iii) selection of data that distributional vectors are based on.

We experiment with three different *weighting functions* that transform non-zero counts as follows. (i) tf:  $w_{\text{tf}}(x) = 1 + \log(x)$ , (ii) tf-idf:

$w_{\text{tf-idf}}(x) = (N/\log \text{df}_{t_i})(1 + \log(x))$  (where  $N$  is the total number of words and  $\text{df}_{t_i}$  the number of words that indicator word  $t_i$  is a non-zero feature of) and (iii) binary:  $w_{\text{bin}}(x) = 1$ .

Transformation operations like *dimensionality reduction* (Deerwester et al., 1990) can be effective in improving generalization in machine learning, in particular in nonstandard settings like DA where a labeled random sample of the TD is not available. We test singular value decomposition (SVD) here because it has been used in prior work on POS (Huang and Yates, 2009). We apply SVD to the matrix of all feature vectors and keep the dimensions corresponding to the  $d = 100$  largest singular values.

We compute distributional vectors either on target data only (i.e., on TD-R) or on the union of source and target data (i.e., SD+TD-R). We compare these two alternatives and show in our experiments that SD distributional information does not consistently improve performance.

**Shape features.** Suffixes are likely to be helpful because regular processes of inflectional and derivational morphology do not change in English when going from one domain to the next. Many POS taggers incorporate information from suffixes to build robust features (Miller et al., 2007). For a selected suffix  $s$ , we simply set the dimension corresponding to  $s$  in  $f_{\text{shape}}(w)$  to 1 if  $w$  ends in  $s$  and to 0 otherwise. We either select all suffixes or the top 100, depending on the experiment.

In addition to suffixes, we investigate two other representational variables related to shape: case and digits. For case, we compare keeping case information as is with converting all uppercase characters to lowercase characters. For digits, we compare keeping digits as is with converting all digits to the digit 0; e.g., \$1,643 is converted to \$0,000). We call these two transformations *case normalization* and *digit normalization*.

**Training set filtering.** The key challenge in DA is that the distributions of source and target are different. One simple trick we can apply to make the distributions more similar is to eliminate all short words from the training set. We call this (training set) *filtering*. The reason this is promising is that longer words are more likely to be examples of productive linguistic processes than short words – even if this is only a statistical tendency with many exceptions.

In future work, we would like to test other fil-

tering options that are based on similar principles, including filtering based on word frequency and open/closed tag classes. Filtering on word length is simple and we show below that it is able to improve accuracy by several percentage points on one TD.

### 3 Experimental results

We train  $\binom{k}{2}$  binary SVM classifiers on the feature representations we just defined. The training set consists of all words that occur in the WSJ training set (in condition SD+TD-R) or all words that occur in both the WSJ training set and TD-R (in condition TD-R). An unknown word is classified by building its feature vector, running the classifiers on it and then assigning it to the POS class returned by the LIBSVM one-vs-one setup.

We divide our experiments into two parts. In the *basic experiment*, we investigate four parameters of the model that are likely to interact with each other: dimensionality of shape vectors (ALL vs. 100 most frequent suffixes), dimensionality of distributional vectors (ALL vs. 250 most frequent indicator words), use of dimensionality reduction (SVD: yes or no) and weighting of distributional vectors (bin, tf, tf-idf).

In the *extended experiment*, we then investigate the effect of other parameters on the best performing model from the basic experiment: distributional vectors based on SD+TD-R vs TD-R, case normalization, digit normalization, completely omitting either shape or distributional information and training set filtering. For the basic experiment, these parameters are set to the following values: distributional vectors are computed on TD-R, case normalization is used, digit normalization is not used, and the training set is not filtered (i.e., all words are included in the training set).

**Basic experiment.** Table 1 gives the results of the basic experiment: the 24 possible combinations of number of shape features, number of distributional features, use of dimensionality reduction and weighting scheme. In each column, the best three accuracies are underlined and the best accuracy is doubly underlined; the results significantly different from the best result are marked with a dagger.<sup>1</sup>

The goal of the basic experiment is to exhaus-

<sup>1</sup> $p < .05$ , 2-sample test for equality of proportions with continuity correction. We use the same test and level for all significance results in this paper.

Table 1: Accuracy of unknown word classification in the basic experiment. The performance of the best (three best) parameter combinations per column are doubly (singly) underlined. A dagger indicates a result significantly worse than the column’s best result.

tively investigate combinations of the four parameters that we suspect to have the strongest interaction with each other and then find a parameter combination that is a good basis for testing the remaining parameters in the extended experiment. The guiding principle in this investigation is that when in doubt, we select the simpler or default setting for the extended experiment in order to make as few assumptions as possible.

For the number of shape features, ALL generally does better than 100. Five TDs have their best result for ALL: rev, blog, answer, email (line 14) and BIO (line 24). The exception is grp (best result on line 3). The reason seems to be that the newsgroups TD contains a larger number of unknown words with suffixes that do not support POS generalization well. E.g., the suffixes -ding, -eding, -eeding, -breeding of a newsgroup name like “alt.animals.horses.breeding” (mistagged as VBG, gold tag: NN) are misleading. Despite these problems, the best 100 result for newsgroups is not significantly better than the best ALL result (lines 3 vs. 20). This argues for using the setting ALL for the extended experiment.

For the number of distributional features, there is a similar tendency for the WEB TDs (grp, rev, blog, answer, email) to do slightly better for fewer

features (250) than ALL features. However, BIO clearly benefits from using the full dimensionality of the distributional feature space: all 250 results are statistically worse than the best ALL result and the gap to the best 250 result is large (line 24 vs line 6, a difference of  $74.39 - 70.95 = 3.44$ ). The gap between best 250 result and best ALL result is smaller for the other five TDs (although only slightly smaller for email) and for each of the five TDs there is an ALL result that is statistically indistinguishable from the best 250 result. For this reason, we choose dist=ALL for the extended experiment. Simply using ALL indicator words also has the advantage of eliminating the need to optimize an additional parameter, the number of indicator words selected.

In a way similar to distributional features, the behaviors of WEB and BIO TDs also diverge for dimensionality reduction. The top three results for the WEB TDs are always achieved without SVD (lines 1, 3, 13, 14, 15, 19, 20), the top three results for the BIO TD are all SVD results (lines 6, 22, 24). We opt for the simpler option (no SVD) for the extended experiment in the absence of strong consistent cross-TD evidence for the need of dimensionality reduction. We will also see in the extended experiment that we can recover and surpass the best BIO result (74.39, line 24) by optimizing other parameters.

The results on weighting argue against using binary weighting: the six best results in the table all use tf weighting, either by itself or in conjunction with idf (lines 3, 14, 24). Apparently, the distinction between lower and higher frequencies of indicator word occurrences is beneficial for unknown word classification. Whether tf or tf-idf is better, is less clear. For two TDs, tf-idf yields the best result (grp on line 3, BIO on line 24), for four TDs tf (rev, blog, answer, email: line 14). The difference between best tf-idf and best tf result is not significant for grp; we will get tf results for BIO that are better than the best tf-idf result of 74.39 in Table 1. For this reason, we choose the setting tf for the extended experiment. Again, we are selecting the simpler of two options (tf vs tf-idf) when faced with somewhat mixed evidence.

In summary, based on the results of the base experiment, we choose the following settings for the extended experiment: shape = ALL, dist = ALL, svd = n, wght = tf. For shape, dist, and svd this is the simpler of two possible settings. For

weighting, we choose tf (instead of the simpler binary option) because of clear evidence that some form of frequency weighting is beneficial across TDs. These settings correspond to line 20 in Table 1. This line is repeated as the baseline on line 1 in Table 2. Admittedly, choosing this as a baseline setting is somewhat arbitrary as one could always weigh the optimization criteria – peak performance, robustness, simplicity – differently.

Table 2: Extended experiment. The effect of various parameter changes on accuracy of unknown word classification. “NRM” = “normalization.

**Extended experiment.** In the extended experiment, we investigate the effect of additional parameters. Results are shown in Table 2. Underlining conventions and statistical test setup are identical to Table 1. The CRF baseline used a parameter setting similar to word classification with two exceptions: we set dist=250 because we were not able to run dist=ALL due to memory limitations; and we convert all features to binary due to space restrictions.

Using sequence classification instead of word classification for unknown word prediction does not consistently improve results (line 2). For grp and answer, the CRF achieves the best overall accuracy, but the difference to the baseline is not significant. For the other four TDs, the best result occurs in a different parameter setting. For BIO, a large drop in performance occurs (from 65.64 to 56.62), perhaps suggesting that word classification is more robust than sequence classification for unknown words.

Calculating distributional vectors on both source and target (as opposed to target only) has similarly inconsistent effects (line 3). Perfor-

mance compared to the baseline decreases for four TDs and increases for two. Based on this evidence, SD distributional information is not robust cross-TD and should probably not be used.

Omitting case normalization (line 4) consistently hurts for WEB TDs, but helps for BIO. In other words, for BIO it is better not to case-normalize words. This result is plausible because case conventions vary considerably in different TDs. Whether keeping case distinctions is helpful or not depends on how similar source and target are in this respect and is therefore not stable in its effect across TDs.

Digit normalization (line 5) has a minor positive or negative effect on the first four TDs, but increases accuracy by more than 2% in the last two, email and BIO. The makeup of the WSJ tag set makes it unlikely that differences between digits could result in POS differences that are predictable in unsupervised DA. This argues for using digit normalization when WSJ is the SD.

The clearest result of the table is that distributional information is necessary for good performance. Performance compared to the baseline drops in all cases and all accuracies on lines 6&7 are significantly worse than the best result. Moreover, distributional features seem to encode more meaningful information for POS tagging than shape features; results on lines 6&7 are consistently lower than results on lines 8&9.

The evaluation is similarly consistent for shape information in the WEB TDs (lines 8 and 9). All accuracies are below the baseline, with some of the drops being quite large, e.g., about 7% for answer and email. Surprisingly, omitting shape information results in a large *increase* of accuracy for the BIO TD. We will further investigate this puzzling result below.

Finally, training set filtering – only training the classifier on words above a threshold length  $k$  – is beneficial for all TDs except for blog; and even for blog, moderate filtering has only a negligible negative effect on accuracy (lines 10–11). In principle, the idea of restricting training to longer words because they are most likely to be representative of unknown words seems to be a good one. However, the effect of filtering is sensitive to the threshold length  $k$ . We leave it to future work to find properties of the TD that could be used as diagnostics for finding a good value for  $k$ .

The motivation of splitting the experiments into

basic experiment and extended experiments was to find a stable point in parameter space for the parameters that are most likely to interact and then look at the effect of the remaining parameters using this stable point as starting point. In Table 2, we see that for the WEB TDs, all variations of experimental conditions either hurt performance or produce only small positive changes in accuracy in comparison to the baseline. This is evidence that our strategy of splitting experiments into basic and extended was sound for these TDs.

		BIO

19	$ w  > 10$	80.52 <sup>†</sup>

Table 3: Extended experiment for BIO without shape information. Dist=ALL.

However, the situation for BIO is different. Two parameter changes result in large performance gains for BIO: omitting shape information (increase by 8%, lines 1 vs 8) and filtering out short training words (increase by 14%, lines 1 vs 17). This indicates that the base configuration of the extended experiment is not a good starting point for exploring parameter variation for BIO.

For this reason, we repeat parts of the extended experiment without any shape information. As we would expect, we obtain results for WEB TDs that are consistently worse than those in Table 2 (not shown), with one exception: a slight increase for  $|w| > 8$  in email. However, the results for BIO are much improved as shown in Table 3.

To conclude, we found that shape information is helpful for the WEB TDs, but it decreases performance by about 10% for BIO. We will analyze the reason for this discrepancy in the next section.

As a last set of experiments, we run the optimal parameter combination ( $|w| > 7$  in Table 3, 84.46) on the BIO test set and obtained an accuracy of 88.13. This is more than 10% higher than the best number for unknown word prediction on BIO published up to this point (76.3 by Huang and Yates (2010)). For the experimental conditions with the best WEB results in Table 2

(double underlining), we get the following test accuracies: grp=56.66, rev=67.79, blog=64.80, answer=66.51, email=65.51. These are either better than dev or slightly worse except for blog; the blog result can be explained by the fact that the blog base model (line 1) also is a lot worse on test than on dev (66.08 vs 71.86). We interpret these test set results as indicating that we did not overfit to the development set in our experiments.

**Summary.** We have investigated the cross-TD robustness of a number of configurational choices in DA for POS tagging. Based on our results, the following choices are relatively robust across TDs: using ALL indicator words (as opposed to a subset) for distributional features, no dimensionality reduction, tf weighting, digit normalization, target-only distributional features, and formalization of the problem of unknown word prediction as word classification (as opposed to sequence classification).

We found other choices to be dependent on the TD, in particular the use of shape features, case normalization and training set filtering.

The most important lesson from these results is that many aspects of DA are highly dependent on the TD. Given our results, it is unlikely that a single DA setup will work in general. Instead, criteria need to be developed that allow us to predict which features and methods work for different TDs.

## 4 Analysis and discussion

The biggest TD differences we found in the experiments are those between WEB and BIO: they behave differently with respect to dimensionality reduction (bad for WEB, good for BIO), shape information (good for WEB, bad for BIO) and sequence classification (neutral for WEB, bad for BIO).

One hypothesis that could explain these results is that the difference between BIO and WSJ is larger than the difference between WEB and WSJ. For example, dimensionality reduction creates more generalized representations, which may be appropriate for TDs with large source-target differences like BIO; and WSJ suffixes may not be helpful for BIO because biomedical terminology has suffixes specific to scientific vocabulary and is rare in newspaper text. In contrast, WEB suffixes may not diverge as much from WSJ since both are “non-technical” genres.

One way to assess the difference between two

TD	tags	suffixes	transitions
grp	.009	.275	.068
rev	.057	.352	.212
blog	.009	.295	.074
answer	.048	.337	.158
email	.036	.273	.139
BIO	.096	.496	.385

Table 4: JS divergences between WSJ and TDs.

domains is to compare various characteristic probability distributions. The distance of two domains under a representation  $R$  has been shown to be important for DA (Ben-David et al., 2007). Similar to Huang and Yates (2010), we use Jensen-Shannon (JS) divergence as a measure of divergence. Table 4 shows the JS divergences between WSJ and the six TDs for different distributions.

The results confirm our hypothesis. BIO is indeed more different from WSJ than the other TDs. Tag distribution divergence is 0.096 for BIO and ranges from 0.009 to 0.057 for WEB. Suffix distribution divergence of BIO is 0.496, almost 50% more than rev, the WEB TD with highest suffix divergence. The underlying probability distributions here are  $P(\text{suffix}|t)$ , where  $t \in \{\text{NN}, \text{NNP}, \text{JJ}\}$  – most unknown words are in these three classes and accuracy is therefore mostly a measure of accuracy on NN, NNP and JJ. Finally, transition probability divergence of BIO for NN, NNP, JJ is also much larger than for WEB. The distribution investigated here is  $P(t_{i-1}|t_i)$ ; we compute the divergence between, say, BIO and WSJ for the three tags and then average the three divergences.

We do not have space to show detailed results on all tags, but the divergences are more similar for closed class POS. E.g., there is virtually no difference in transition probability divergence for modals between BIO and WEB. This observation prompted us to investigate whether some TD differences might depend on the evaluation measure used. Accuracy – a type of microaveraging – is mostly an evaluation of the classes that are frequent for unknown words: NN, NNP, JJ. If most of the higher divergence of BIO is caused by these categories, then a macroaveraged evaluation, which gives equal weight to each POS tag, should show less divergence.

This is indeed the case as the macroaveraged results in Table 4 show. These results are more consistent across TDs than those evaluated with accuracy. Removing shape and distributional information now hurts performance for all TDs (lines

Table 5: Selected conditions of the extended experiment (Table 2), evaluated using macroaveraged  $F_1$ .

6&8). WEB and BIO behave more similarly with respect to training set filtering: the large outliers for BIO we obtained in the accuracy evaluation are gone. SD distributional information has a more beneficial effect on  $F_1$  than on accuracy, probably because the classification of POS that are more stable across TDs like verbs and adverbs benefits from SD information. The CRF produces the best result for all WEB TDs. For less frequent POS classes (those that dominate the macroaveraged measure, especially verbal POS), sequence information and “long-distance” context is probably more stable and can be exploited better than for NN, NNP and JJ. However, there is still a drop-off from the baseline for BIO; we attribute this to the larger differences in the transition probabilities for BIO vs WEB (Table 4); the sequence classifier is at a disadvantage for BIO, even on a macroaveraged measure, because the transition probabilities change a lot.

It is important to note that even though  $F_1$  results are more consistent for DA, accuracy is the appropriate measure to use for POS tagging: the usefulness of a tagger to downstream components in the processing pipeline is better assessed by accuracy than by  $F_1$ .

## 5 Related work

Most work on POS tagging takes a standard supervised approach and assumes that source and target are the same (e.g., (Toutanova et al., 2003)). At the other end of the spectrum is the unsupervised setting (e.g., (Schütze, 1995; Goldwater and Griffiths, 2007)). Other researchers have addressed the task of adapting a known tagging dictionary to a TD (e.g., (Merialdo, 1994; Smith and Eisner, 2005)), which we view as complementary to methods for words about whose tags nothing is known. Subramanya et al. (2010) perform DA without using any unlabeled TD text. All of these applica-

tions scenarios are reasonable; however, it can be argued that the scenario we address is – apart from standard supervised learning – perhaps more typical of what occurs in practice: there is labeled SD text available for training; there is plenty of unlabeled TD text available; and there is a substantial number of TD words that do not occur in the SD. Frequently, researchers make the assumption that a small labeled target text has been created (e.g., (Daumé III, 2007)); in the process, a small number of unknown words may also be labeled, but this is not an alternative to handling unknown words in general.

Work by Das and Petrov (2011) is also a form of DA for POS tagging, using universal POS tag sets and parallel corpora. It is likely that best performance for TDs without training data can be achieved by combining our approach with a multilingual approach if appropriate parallel data is available. Ganchev et al. (2012) use another source of additional information, search logs. Again, it should be possible to integrate search-log based features into our framework.

Blitzer et al. (2006) learn correspondences between features in source and target. Our results suggest that completely ignoring source features (and only using source labels) may be a more robust approach for unknown words.

Cholakov et al. (2011) point out that improving tagging accuracy does not necessarily improve the performance of downstream elements of the processing pipeline. However, improved unknown word classification will have a positive impact on most downstream components.

Choi and Palmer (2012) perform DA by training two separate models on the available data, a generalized one and a domain-specific one. During tagging, an input sentence is tagged by the model that is most similar to the sentence. Since their approach is not conditioned on the underlying tagging model, it would be interesting to integrate their approach with ours.

Huang and Yates (2009) evaluate CRFs with distributional features. Besides raw feature vectors, they examine lower dimensional feature representations using SVD or a special HMM-based method. In our experiments, we did not find an advantage to using SVD.

Huang and Yates (2010) use sequence labeling to predict POS of unknown words. Huang and Yates (2012) extend this work by inducing latent

states that are shown to improve prediction. As we argued above, a word classification approach has several advantages compared to a sequence labeling approach. Since latent sequence states can be viewed as a form of dimensionality reduction, it would be interesting to compare them to the non-sequence-based dimensionality reduction (SVD) we have investigated in our experiments.

Zhang and Kordoni (2006) use a classification approach for predicting POS for in-domain unknown words. They achieve an accuracy of 61.3%. Due to differences in the data sets used, these results are not directly comparable with ours.

Miller et al. (2007) and Cucerzan and Yarowsky (2000) have both investigated the use of suffixes for DA. Miller et al. characterized words by a list of hand-built suffix classes that they appear in. They then used a 5-NN classifier along with a custom similarity measure to find initial lexical probabilities for all words. We also ran extensive experiments with kNN, but found that one-vs-one SVM performs better.

Cucerzan and Yarowsky (2000) use distribution as a backoff strategy if no helpful suffix information is available. They address unknown word prediction for new languages. We have found that for within-language prediction, distributional information is generally more robust than shape information, including suffixes.

Van Asch and Daelemans (2010) find that DA performance is the higher, the more similar the unigram distribution of the TD is to that of the SD. However, we cannot compute unigram distributions in the case of unknown words.

## 6 Conclusions and Future Work

In this paper, we have investigated the robustness of DA representations and methods for POS tagging and shown that there are large differences in robustness across TDs that need to be taken into account when performing DA for a TD. We found that the divergence between source and target is an important predictor of what elements of DA will work; e.g., higher divergence makes it more likely that generalization mechanisms like dimensionality reduction will be beneficial.

In future work, we would like to develop statistical measures of source-target divergence that accurately predict whether a feature type or DA technique supports high-performance DA for a particular TD.

## Abstract

Light verb constructions (LVCs) are verb and noun combinations in which the verb has lost its meaning to some degree and the noun is used in one of its original senses. They often share their syntactic pattern with other constructions (e.g. verb-object pairs) thus LVC detection can be viewed as classifying certain syntactic patterns as light verb constructions or not. In this paper, we explore a novel way to detect LVCs in texts: we apply a dependency parser to carry out the task. We present our experiments on a Hungarian treebank, which has been manually annotated for dependency relations and light verb constructions. Our results outperformed those achieved by state-of-the-art techniques for Hungarian LVC detection, especially due to the high precision and the treatment of long-distance dependencies.

## 1 Introduction

Multiword expressions (MWEs) are lexical items that can be decomposed into single words and display lexical, syntactic, semantic, pragmatic and/or statistical idiosyncrasy (Kim, 2008). Light verb constructions (LVCs) form a subtype of MWEs: they are verb and noun combinations in which the verb has lost its meaning to some degree and the noun is used in one of its original senses (e.g. *make a decision* or *take a walk*). In several NLP applications like information retrieval or machine translation it is important to identify LVCs in context since they require special treatment, particularly because of their semantic features. Thus, LVCs should be identified to help these applications.

Light verb constructions (e.g. *make a mistake*) often share their syntactic pattern with literal verb + noun combinations (e.g. *make a cake*). Thus,

specific syntactic constructions – e.g. verb-object pairs – can be separated into two classes: one where the noun behaves as a real object (*cake*) and one where the noun functions as the light verb object (*mistake*). Thus, LVC detection can be viewed as classifying certain syntactic patterns as LVCs or not and assigning a specific syntactic label to the argument of the light verb.

In this paper, we explore a novel way to LVC detection: we apply a dependency parser to carry out the task. Although the usability of identified multiword expressions has been investigated in the literature (see Section 4), and many MWE detection systems rely on syntactic information, we are not aware of any approach that aimed at applying a dependency parser for the dedicated task of identifying LVCs. Our approach requires a treebank annotated for syntactic and LVC information at the same time. Due to the availability of annotated resources, we focus on light verb constructions in Hungarian, a morphologically rich language. Thus, we present our experiments on the legal subcorpus of the Szeged Dependency Treebank annotated for LVCs (Vincze and Csirik, 2010) as well as dependency relations (Vincze et al., 2010). We will pay special attention to non-contiguous LVCs in our investigations as there are quite a few non-contiguous LVCs in Hungarian due to the free word order. Our results empirically prove that LVCs can be detected as a “side effect” of dependency parsing.

## 2 Light Verb Constructions in Hungarian

Hungarian is an agglutinative language, which means that a word can have hundreds of word forms due to inflectional or derivational morphology (É. Kiss, 2002). Hungarian word order is related to information structure, e.g. new (or emphatic) information (focus) always precedes the verb and old information (topic) precedes the

focus position. Thus, the position relative to the verb has no predictive force as regards the syntactic function of the given argument. In English, the noun phrase before the verb is most typically the subject whereas in Hungarian, it is the focus of the sentence, which itself can be the subject, object or any other argument.

The grammatical function of words is determined by case suffixes. Hungarian nouns can have about 20 cases, which mark the relationship between the verb and its arguments (subject, object, dative etc.) and adjuncts (mostly adverbial modifiers). Although there are postpositions in Hungarian, case suffixes can also express relations that are expressed by prepositions in English. Verbs are inflected for person and number and the definiteness of the object. There are several other linguistic phenomena that are syntactic in nature in English but they are encoded morphologically in Hungarian. For instance, causation and modality are expressed by derivational suffixes.

The canonical form of a Hungarian light verb construction is a bare noun + third person singular verb, for instance, *tanácsot ad* advice-ACC give “to give advice”. Due to the above features, they may occur in non-canonical versions as well: the verb may precede the noun, or they may be not adjacent, moreover, the verb may occur in different surface forms inflected for tense, mood, person and number.

LVCs may occur in several forms due to their syntactic flexibility. Besides the prototypical verbal form in Hungarian, they can have a participial form (e.g. *figyelembe vevő* account-INE taking “taking into account”) and they may also undergo nominalization, yielding a nominal compound (e.g. *életbe lépés* life-INE step “entering into force”).<sup>1</sup>

From a morphological perspective, LVCs can also be divided into groups. First, the nominal component is the object of the verb, i.e. it bears an accusative case in Hungarian (e.g. *döntést hoz* decision-ACC bring “to make a decision” or *tanácsot ad* advice-ACC give “to give advice”). Second, the nominal component can bear other (oblique) cases as well (e.g. *zavarba*

<sup>1</sup>Due to some orthographical rules, certain nominal or participial occurrences of LVCs should be spelt as one word in Hungarian (such as *tanácsadó* advice.giver “consultant”). These latter cases are not identifiable with syntax-based methods, only with morphological methods, thus we omit them from our investigations.

*hoz* embarrassment-ILL bring “to embarrass” or *figyelemmel kísér* attention-INS follow “to pay attention”). Third, – although rarely – a postpositional phrase can also occur in the construction (e.g. *uralom alá jut* rule under get “to get under rule” or *hatás alatt áll* effect under stand “to be under effect”).

### 3 Light Verb Constructions as Complex Predicates

Although light verb constructions are made of two parts, namely, the nominal component and the verb, thus, they show phrasal properties, it can be argued that from a semantic point of view they form one unit. First, many light verb constructions have a verbal counterpart with the same meaning (e.g. *döntést hoz* decision-ACC bring “to make a decision” – *dönt* “to decide”). Second, there are meanings that can only be expressed through a light verb construction (e.g. *házkutatást tart* (search.of.premises-ACC hold) ‘to conduct search of premises’ in Hungarian). Third, there are languages that abound in verb + noun constructions or multiword verbs (such as Estonian (Muischnek and Kaalep, 2010) or Persian (Mansoori and Bijankhan, 2008)): verbal concepts are mostly expressed by combining a noun with a light verb (Mansoori and Bijankhan, 2008).

On the other hand, there are views that the relationship between the verbal and the nominal component is not that of a normal argument. For instance, Meyers et al. (2004) assume that support verbs (a term related to light verbs) share their arguments with a noun. Chomsky (1981, p.37) calls *advantage* a quasi-argument of *take* in the idiom *take advantage of*.<sup>2</sup> Alonso Ramos (1998) proposes the role of quasi-object: this relationship holds between parts of idiomatic constructions, which is in accordance with Chomsky’s usage of the term *idiom*. In this spirit, the term *quasi-argument* might be extended to signal the relationship between the verbal and the nominal components of light verb constructions as well since they behave as a semantic unit, forming one complex predicate.

Higher-level NLP applications can also profit from this solution because the identification of light verb constructions can be enhanced in this way, which has impact on e.g. information extrac-

<sup>2</sup>In our view, *take advantage of* is a light verb construction rather than an idiom.

tion (IE). For instance, in event extraction the parser should recognize the special status of the quasi-argument and treat it in a specific way as in the following sentence:

Pete **made a decision** on his future.

Thus, the following data can be yielded by the IE algorithm:

EVENT: decision-making  
ARGUMENT<sub>1</sub>: Pete  
ARGUMENT<sub>2</sub>: his future

Instead of:

\*EVENT: making  
ARGUMENT<sub>1</sub>: Pete  
ARGUMENT<sub>2</sub>: decision  
ARGUMENT<sub>3</sub>: his future

Thus, there is an event of **decision-making**, **Pete** is its subject and it is about **his future** (and not an event of **making** with the arguments **decision**, **Pete** and **his future** as it would be assumed if *decision* was not marked as a quasi-argument of the verb).

In order to reach this way of representation, there are two possibilities. First, we employ linguistic preprocessing of the data (including dependency parsing), then an LVC detector is used and in a post-processing step after syntactic parsing, the special relation of the nominal and the verbal component should be marked, i.e. certain syntactic labels are overwritten. Second, we execute parsing in a way that the training dataset already contains LVC-specific syntactic labels, that is, it is the dependency parser that carries out LVC detection. In this paper, we experiment with both ways and present and evaluate our results.

## 4 Related Work

There have been a considerable number of studies on LVC detection for several languages. They have been automatically identified in several languages such as English (Cook et al., 2007; Tu and Roth, 2011), Dutch (Van de Cruys and Moirón, 2007), Basque (Gurrutxaga and Alegria, 2011) and German (Evert and Kermes, 2003) just to mention a few.

We are aware of one machine learning system that identifies Hungarian LVCs in texts: the system described in Vincze et al. (2013) selects LVC

candidates from texts on the basis of syntactic information, then in a second step it classifies them as genuine LVCs or not, using morphological, lexical, syntactic and semantic features.

Regarding the methods they use, Fazly and Stevenson (2007), Van de Cruys and Moirón (2007) and Gurrutxaga and Alegria (2011) used statistical features for identifying LVCs. Others employed rule-based systems (Diab and Bhutada, 2009; Nagy T. et al., 2011), which usually make use of (shallow) linguistic information. Some hybrid systems integrated both statistical and linguistic information as well (Tan et al., 2006; Tu and Roth, 2011).

As we aim at identifying LVCs by applying a dependency parser, next we concentrate on studies that are based on syntactic information and are related to MWE extraction. Seretan (2011) developed a method for collocation extraction based on syntactic constraints. Wehrli et al. (2010) argued that collocations can highly contribute to the performance of the parser since many parsing ambiguities can be excluded if collocations are known and treated as one syntactic unit. Nivre and Nilsson (2004) analyzed the influence of (previous) MWE recognition on dependency parsing and showed that known MWEs have a beneficial effect on parsing results. Korkontzelos and Manandhar (2010) investigated whether known MWEs improve the performance of statistical shallow parsers and found that they can significantly contribute to the efficiency of parsing. Eryiğit et al. (2011) analysed the impact of extracting MWEs on improving the accuracy of a dependency parser in Turkish. They found that the integration of compound verb and noun formations (which concept is similar to the one of light verb constructions applied here) has a detrimental effect on parsing accuracy since it increases lexical sparsity.

As can be seen, many previous studies examined the effects of already identified MWEs on the efficiency of parsing. On the other hand, there have been some current studies that aim at experimenting in the other direction, namely, using parsers for identifying MWEs: constituency parsing models are employed in identifying contiguous MWEs in French and Arabic (Green et al., 2013). Their method relied on a syntactic treebank, an MWE list and a morphological analyzer.

In this paper, we also experiment in this area: we employ a dependency parser for identifying

LVCs in Hungarian texts as a “side effect” of parsing sentences. Our dependency parser based method for identifying Hungarian LVCs is novel since to the best of our knowledge, dependency parsers have not been directly applied to identify LVCs. Moreover, it requires only a syntactic treebank enhanced with LVC annotation, in other words, there is no need to implement a separate LVC detector from scratch. In the following, we present our experiments and discuss our results.

## 5 Experiments

In this section, we will present our corpus, our methodology for detecting light verb constructions and we will show our results.

### 5.1 The Corpus

The Szeged Constituency Treebank has been manually annotated for light verb constructions (Vincze and Csirik, 2010). This treebank exists in another manually annotated version, namely, with dependency annotation (Vincze et al., 2010). Thus, manual annotations for LVCs and dependency structures are available for the same bunch of texts, which made it possible to map the two manual annotations. Thus, dependency relations were enhanced with LVC-specific relations that can be found between the two members of the constructions. For instance, instead of the traditional OBJ (object) relation, which occurred in the original version of the Szeged Dependency Treebank, the relation OBJ-LVC can be found between the words *döntést* (decision-ACC) and *hoz* “bring”, members of the LVC *döntést hoz* “to make a decision” in the version used in this experiment. Here we provide a list of LVC-specific relations that occurred in our data (neglecting a handful of cases which were mislabeled due to some annotation errors in the dependency treebank):

- ATT-LVC – relation between a noun and a participial occurrence of a light verb:

*(a tegnapi) adott tanács*

(the yesterday) given advice

“(the) advice that was given (yesterday)”

- OBJ-LVC – relation between a light verb and its object:

*bejelentést tesz*

announcement-ACC makes

“to make an announcement”

- OBL-LVC – relation between a light verb and its nominal argument (which is not the subject or object or dative):

*életbe lép*

life-ILL step

“to take effect”

- SUBJ-LVC – relation between a light verb and its subject:

*sor kerül (vmire)*

turn get sg-SUB

“the time has come for sg”

When mapping the LVC annotations and the dependency structures, we paid attention to the fact that it is only LVCs spelt as two tokens that could be identified with our methodology since no internal structure of compound words are marked in the Hungarian treebank and thus no dependency relation can be found among the members of the compound. So, we neglect LVCs spelt as one word and focus only on verbal and participial LVCs that consist of two members (cf. Footnote 1).

Figure 1 shows an example of a sentence with and without LVC-specific dependency labels. As can be seen, we have the light verb construction *döntést hoz* decision-ACC bring “to make a decision” in the sentence. However, it is parsed as a “normal” object of the verb in the first case (OBJ) and as a light verb object (OBJ-LVC) in the second case. Moreover, it is also seen that the two components of the LVC are not adjacent hence there are crossing branches in the dependency graph.

Although the entire Szeged Corpus contains manual LVC and dependency annotation, for the purpose of our study, we just selected texts from the law domain since they contain the biggest number of LVCs. Sentences in the law subcorpus were further filtered due to the fact that state-of-the-art dependency parsers cannot adequately treat verbless sentences, hence verbless sentences were ignored (see Farkas et al. (2012) for a detailed discussion of the problem). After this filtering step, we experimented with 6173 sentences, which consist of 156,744 tokens and contain 1101 LVCs. We present statistical data on the frequency of the LVC-specific relations in Table 1.

As Hungarian is a free word order language, the two components of LVCs, namely, the noun and the light verb, may not be adjacent in all cases,

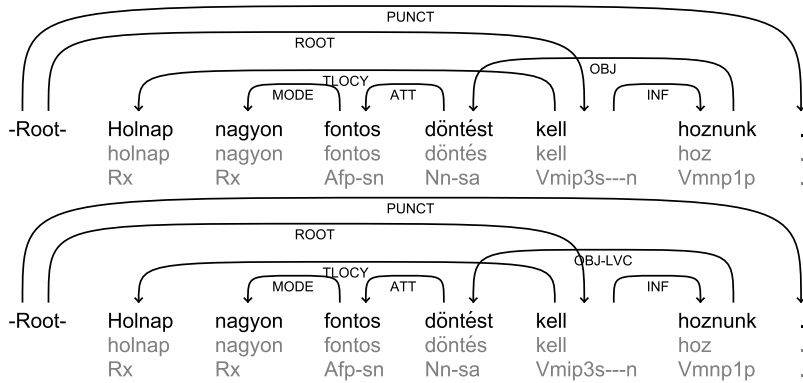

Figure 1: Dependency graph of the sentence *Holnap nagyon fontos döntést kell hoznunk* “Tomorrow we will have to make a very important decision” with or without LVC-specific dependency relations.

Relation	#	Non-contiguous	%
ATT-LVC	142	60	42.3
OBJ-LVC	587	231	39.4
OBL-LVC	266	50	18.8
SUBJ-LVC	102	4	3.9
Other-LVC	4	2	50
Total	1101	347	31.5

Table 1: Distribution of relations in the gold standard data and the frequency of non-contiguous LVCs.

which has a potentially detrimental effect on their identification in texts. Thus, we investigated the frequency of such cases in the data. Table 1 reveals that it is a quite frequent phenomenon in the corpus: almost one third of LVCs are non-contiguous. The largest distance between the noun and the verb is 21 tokens and the average distance between the two non-adjacent components is 4.28 tokens. All this suggests that sequence labeling approaches for LVC detection may not be as effective on the data as expected, however, a dependency parser that is able to identify long-distance dependencies may deal with the problem of non-adjacent but grammatically dependent elements in a more accurate way, which we will test below.

## 5.2 Dependency Parsing for LVC Detection

Farkas et al. (2012) carried out the first experiments on Hungarian dependency parsing. They empirically showed that state-of-the-art dependency parsers achieve similar results – in terms of attachment scores – on Hungarian and English.

Although the results are not directly comparable due to domain differences and annotation schema divergences, they concluded that the difficulty of parsing Hungarian is very similar to parsing English and statistical dependency parsing is a viable way of parsing Hungarian, a morphologically rich language with free word order.

As their results indicated, the Bohnet dependency parser (Bohnet, 2010) proved to be the most effective on Hungarian data (Farkas et al., 2012), thus we applied it in our experiments too. It is an efficient second order dependency parser that models the interaction between siblings as well as grandchildren. Its decoder works on labeled edges, i.e. it uses a single-step approach for obtaining labeled dependency trees. It uses a rich and well-engineered feature set and it is enhanced by a Hash Kernel, which leads to higher accuracy.

Due to the free word order, there are quite many long-distance dependencies in Hungarian sentences, where a word and its parent are not adjacent (see also Figure 1). However, these linguistic phenomena are reasonably well-treated by dependency parsers. Furthermore, there seem to be quite a lot of non-contiguous LVCs in Hungarian. Hence, we think that these facts justify our experiments on applying a dependency parser for identifying LVCs.

## 5.3 Methodology

We trained and evaluated the Bohnet parser on the data in a ten-fold cross validation manner. To evaluate the quality of the dependency parsing, we applied the Labeled Attachment Score (LAS) and Unlabeled Attachment Score (ULA) metrics, taking into account punctuation as well. On the other hand, we also employed  $F_{\beta=1}$  scores inter-

Method	Precision	Recall	F-score
Dictionary matching	0.7849	0.1229	0.2125
Classification	0.8284	0.6760	0.7445
Dependency parser	0.8660	0.6712	0.7563

Table 2: Results on LVC detection.

preted on the LVC-specific relations to evaluate the performance of detecting LVCs in the corpus and we evaluated our system on contiguous and non-contiguous LVCs as well.

As baselines, we made use of the methods described in Vincze et al. (2013). They first employed dictionary matching, where LVCs collected from a parallel corpus annotated for Hungarian LVCs (Vincze, 2012) were mapped to the lemmatized texts. We also applied dictionary matching as one of our baselines. The main method of Vincze et al. (2013) first parsed each sentence and extracted potential LVCs on the basis of the dependency relations found between verb-object, verb-subject, verb-prepositional object, verb-other argument and noun-modifier pairs. The dependency labels were provided by `magyarlan` (Zsibrita et al., 2013). Later, C4.5 decision trees were applied to classify candidate LVCs, which exploits a rich feature set. For instance, morphological features exploited the fact that the nominal component of LVCs is typically derived from a verbal stem or coincides with a verb, on the other hand, the POS tags of the words and surrounding words were also used as features. As for semantic features, the `activity` or `event` semantic senses were looked for among the upper level hyperonyms of the head of the noun phrase in the Hungarian WordNet<sup>3</sup>. As lexical features, fifteen typical light verbs were selected from the list of the most frequent verbs taken from the Szeged ParalellFX corpus (Vincze, 2012) and it was checked whether the lemmatized verbal component of the candidate was one of these fifteen verbs. The lemma of the noun was also applied as a lexical feature.

We evaluated our database with this system too in a ten-fold cross validation manner (using the same data splits as previously) and as evaluation metrics, we employed  $F_{\beta=1}$  scores. The results of our experiments are shown in Tables 2 and 3.

Method	Precision	Recall	F-score
Contiguous LVCs			
Classification	0.8746	0.7854	0.8276
Dependency parser	0.9008	0.7357	0.8099
Non-contiguous LVCs			
Classification	0.7103	0.5188	0.6000
Dependency parser	0.7940	0.5362	0.6401

Table 3: Results on detecting contiguous and non-contiguous LVCs.

## 6 Results

As Table 2 shows, the dependency parser with the LVC-specific relations achieved an F-score of 0.7563 (recall: 0.6712, precision: 0.8660) interpreted on the LVC-specific relations. This result exceeds the ones obtained by the baselines: it outperforms the dictionary matching method by 54.38% in terms of F-score with a considerably better recall value, and, on the other hand, it also performs better than the classification method with a 1.18% gain in F-score – the results are significant (ANOVA,  $p = 0.012$ ). In the latter case, the improvement is due to the higher precision value.

The identification of non-contiguous LVCs proved to be more difficult for both methods than that of contiguous LVCs. The classification approach significantly outperforms the dependency parser on the contiguous LVC class (ANOVA,  $p = 0.0455$ ) but on the non-contiguous class the dependency parser performs significantly better with an F-score of 0.6401 (ANOVA,  $p = 0.0343$ ).

In order to analyze the performance in more detail, we compared the precision, recall and F-scores for each LVC-specific label. Data in Table 4 reveal that SUBJ-LVCs are the easiest ones to predict (with both high precision and recall values) and participial uses of LVCs are the most difficult to identify (ATT-LVC) relation between the noun and the participle, mostly due to the low recall value. Although the precision value is rather low in the case of objects (OBJ-LVC), objects and other arguments (OBL-LVC) can be detected reasonably well. Table 5 shows results for (non-)contiguous LVC classes. It is revealed that for OBL-LVCs, there is no substantial difference between contiguous and non-contiguous LVCs but for objects and participial LVCs, the dis-

tance between the two components of the LVC has an essential effect on the efficiency.<sup>4</sup>

As for the performance on dependency parsing, we got 90.38 (LAS) and 92.12 (ULA) when training with LVC-specific relations. If these results are compared to those achieved with traditional (i.e. non-LVC-specific) relations, then it is revealed that in the latter case LAS is 90.63, i.e. 0.25 percentage point higher, which can be considered negligible.

## 7 Discussion

As the results show, the dependency parsing approach achieved the best results on LVC detection, especially due to the high precision score. This is probably due to the rich feature set applied by the Bohnet parser. Furthermore, our approach to solve the problem of LVC detection as a classification of syntactic constructions by using a dependency parser is also justified by these results.

A comparison with previous parser-based approach to MWE detection might also prove use-

<sup>4</sup>As there were hardly any non-contiguous SUBJ-LVCs in the dataset, we cannot draw any conclusions on the difficulty level of identifying non-contiguous light verb subjects.

ful. Green et al. (2013) employed constituency parsers to identify contiguous MWEs in French and Arabic. As a main difference between our approach and theirs, we applied a dependency parser for the task of LVC detection, which proved especially effective since we worked with a free word order language, thus we had to deal with non-contiguous LVCs as well. Our dependency parser approach could adequately identify them as well, however, experimenting with a constituency parser will be a possible way to continue our work.

In Hungarian, it sometimes happens that a sequence that looks like an LVC is actually not an LVC in the specific context as in *A dékán újabb előadást tartott szükségesnek* the dean new-COMP presentation-ACC hold-PAST-3SG necessary-DAT “The dean thought that another presentation was necessary”. In other contexts, *előadást tart presentation-ACC hold* “to have a presentation” would most probably function as an LVC. However, in this case we encounter with another fixed grammatical construction of Hungarian, namely, *valamilyennek tart valamit* somewhat-DAT hold something-ACC “to regard something as something”, e.g. *szépnek tartja a lányt* beautiful-DAT hold-3SG-OBJ the girl-ACC “he thinks that the girl is beautiful”. Thus, there is no LVC in the above example, but approaches that heavily build on MWE lexicons may falsely identify this verb-object pair as a light verb object-light verb pair since they hardly consider contextual information. In contrast, dependency parsers have access to information about other dependents of the verb hence they may learn that in such cases the presence of a dative dependent argues against the identification of the verb-object pair as an LVC.

As for the specific LVC-relations, our approach was most successful on LVCs where the noun fulfilled the role of the subject (i.e. it had the relation SUBJ-LVC). This may be attributed to the fact that these LVCs are the least diverse in the corpus: there are only a handful of such types, and each LVC type has several occurrences in the data thus they can be easily identified. On the other hand, participial uses of LVCs (ATT-LVC) were the hardest to detect, which is partly due to their lexical divergence and partly due to the fact that currently adjectives and participles are not distinguished in Hungarian morphological parsing, i.e. they have the same morphological codes. Thus, the parser, which heavily builds on morpho-

logical information, has no chance to learn that it is only participles that tend to occur as parts of LVCs but adjectives do not. A distinction of participles and adjectives in the Hungarian computational morphology would most probably have beneficial effects on identifying LVCs.

Our results empirically prove that a dependency parser may be effectively applied to identify LVCs in free texts, provided that we have a dependency model trained on LVC-specific relations, which itself requires a treebank manually annotated for dependency relations and LVCs. Although the LAS scores are somewhat lower than in the case of LVC-less dependency relations, the task of LVC detection can be also performed by the parser. On the other hand, the classification approach needs a trained dependency model since it classifies LVC candidates selected on the basis of syntactic information. It also uses LVC lists gathered from annotated corpora and in order to denote LVC-specific relations (i.e. quasi-arguments) in the case of complex predicates, an extra post-processing step is needed in the workflow. Thus, the resources needed by the two approaches are the same but with the dependency parsing approach, the implementation of a new LVC-detector from scratch might be saved and complex predicates are provided immediately by the parser. Moreover, another advantage of the dependency parser is that it performs better on non-contiguous LVCs, which are frequent in Hungarian.

We also carried out an error analysis in order to compare the two methods. It was difficult for both the dependency parser and the classifier to recognize rare LVCs or those that included a non-frequent light verb. A typical source of error for the dependency parser was that sometimes an LVC-specific relation was proposed for non-nouns (e.g. adverbs or conjunctions) as well, like in *akár írnia* (either write-INF.3SG) “either he should write”, where *akár* was labeled as an LVC-object of the verb instead of a conjunction. Furthermore, the classifier often made an error in cases where the sentence included an LVC but another argument of the verb was labeled as part of the LVC, e.g. *filmet forgalomba hoz* (film-ACC circulation-INE bring) “to put a film into circulation”, where the gold standard LVC is *forgalomba hoz* “to put something into circulation” but *filmet hoz* “to bring a film” was labeled as a false positive LVC. Since different phenomena proved to be difficult for the

two systems, a possible direction for future work may be to combine the two approaches in order to minimize prediction errors.

Here we experimented with Hungarian, a morphologically rich language. Nevertheless, we believe that the method of applying a dependency parser for LVC detection is not specific to this typological class of languages and it can be employed for any language that has a dependency treebank which contains annotation for LVCs.

## 8 Conclusions

In this paper, we empirically showed that a dependency parser can be employed to detect LVCs in free texts. For this, we used a Hungarian treebank, which has been manually annotated for dependency relations and light verb constructions. Our results outperformed those achieved by state-of-the-art techniques for Hungarian LVC detection and the main advantages of our system is its high precision on the one hand and the adequate treatment of non-contiguous LVCs on the other hand.

The error analysis of the systems applied suggests that since the two systems make errors in different cases, combining them may lead to more precise results. Another possible way of improving the system is to explore methods for the treatment of participial LVCs. Furthermore, as future work we aim at experimenting with the dependency parser in other scenarios (e.g. the newspaper subcorpus of the Szeged Dependency Treebank) in order to make further generalizations on the role of dependency parsing in LVC detection.

# Written Dialog and Social Power: Manifestations of Different Types of Power in Dialog Behavior

## Abstract

Dialog behavior is affected by power relations among the discourse participants. We show that four different types of power relations (hierarchical power, situational power, influence, and power over communication) affect written dialog behavior in different ways. We also present a system that can identify power relations given a written dialog.

## 1 Introduction

The recent increase in online social interactions has triggered great interest in computationally analyzing such interactions to gain insights about the discourse participants (DPs). Within the field of analyzing online interactions, there is a growing interest in finding how social power relations between participants are reflected in the various facets of interactions, and whether the power relations can be detected using computational means (Rowe et al., 2007; Bramsen et al., 2011). More recent work has shown that an analysis of the dialog structure (and not just the message content) helps detecting power relations (Biran et al., 2012; Danescu-Niculescu-Mizil et al., 2012).

Understanding the relation between dialog and power may help in various applications. For example, if a dialog system is engineered to behave appropriately given the user’s expectation of relative power (for different types of power), then the user may experience the interaction with the system as more natural. Turning to dialog analysis rather than generation, we can build a computational system to analyze power relations between participants in an interaction. Such a system could have various applications. Power analysis in online forums and communities could be useful in

determining relevance to a user searching the forum. For example, a user may want to limit his search to posts authored by the DPs with higher power. Power analysis may also aid law enforcement agencies to detect leaders and influencers in suspicious online communities. This is especially useful since the real identities of the members of such communities are often not revealed and their hierarchies may not be available to the law enforcement agencies.

The power differential between the DPs may be based on a multitude of factors such as status, authority, role, knowledge and so on. Early computational approaches to analyzing power in interactions relied solely on static power structures such as corporate hierarchies as the source of the power differential (Rowe et al., 2007; Bramsen et al., 2011). More recent studies have looked into dynamic notions of power as well, such as influence (Biran et al., 2012). However, not much work has been done to understand how different types of power differ in the ways they affect how people interact in dialog.

In this paper, we study four different types of power — hierarchical power, situational power, influence and power over communication. We investigate whether all four social power relations are manifested in dialog behavior; we restrict our attention to written dialog, specifically email exchanged in an American corporation. By “dialog behavior”, we mean the choices a DP makes while engaging in dialog. Dialog behavior includes choices that affect dialog structure, such as the choice of when to participate (e.g., does the DP initiate the dialog?), how much to contribute (e.g., is the DP terse or loquacious?), what sort of contribution to make (e.g., which dialog acts does the DP perform? how does the contribution link

to previous dialog contributions?), and what form the contribution should take (e.g., whether to make an overt display of power). The main contribution of this paper is to show that the four types of power we consider are in fact different from one another and that they affect the DPs' behavior in written dialog in different but predictable ways. We analyze these manifestations in the language as well as the dialog structure of interactions. We also present a system to detect the DPs with one of these types of power from threaded email interactions.

In Section 2, we discuss related work in the field. Section 3-4 presents the data, annotations, and inter-rater agreement studies on the annotations. Section 5 summarizes the dimensions of interactions we analyze. We then present the main contributions of this paper: Section 6 analyzes the variations in the manifestations of power among the four types, and Section 7 describes a system to predict persons with any of the four types of power. We then conclude and discuss future work.

## 2 Related Work

Within the dialog community, researchers have studied notions of control and initiative in dialogs (e.g. (Walker and Whittaker, 1990; Jordan and Di Eugenio, 1997)). Walker and Whittaker (1990) define "control of communication" in terms of whether the discourse participants are providing new, unsolicited information. They use utterance level rules to determine which discourse participant (whether the speaker or the hearer) is in control, and extend it to segments of discourse. Their notion of control differs from our notion of power over communication. They model control locally over discourse segments. What we are interested in (and what our annotations capture) is the possession of controlling power by one (or more) participant(s) across the entire dialog, i.e. how a participant controls the communication in a dialog thread in order to achieve its intended goals. Despite this difference in definition, we show in Section 6 that our notion of power over communication correlates with Walker and Whittaker (1990)'s notion of control over discourse segments. Jordan and Di Eugenio (1997) suggest that "initiative" applies to the level of problem solving, just as "control" applies to the dialog level. We leave the investigation into the relation between initiative and situational power for future work.

In social sciences, different typologies of power have been proposed. Wartenberg (1990) makes the distinction between power-over and power-to in the context of interactions. Power-over refers to relationships between interactants set by external power structures, while power-to refers to the ability an interactant possesses within the interaction, even if it is temporary. Our notions of hierarchical power and influence are special cases of power-over. Hierarchical power is determined by organizational hierarchy, while influence is determined by knowledge, expertise etc. Similarly, our notions of situational power and power over communication are special cases of power-to. Situational power applies to the situation or task at hand, while power over communication applies to the interaction itself. French and Raven (1959) proposed five bases of power: Coercive, Reward, Positional, Referent, and Expert. They are widely used to study power in sociology. We consider hierarchical power, situational power and power over communication to be positional in nature; although the former two can also have bases in coercion and rewards. The bases of influence are mainly referent and expert power.

Studies in sociolinguistics have also explored the relation between dialog behavior and social power. O'Barr (1982) shows that power relations are manifested in language use in courtroom dialogs. Locher (2004) studies politeness in dialogs in relation to the exercise of power. The correlation between discourse structure and perceived influence of participants has also been studied (Ng et al., 1993; Ng et al., 1995). Specifically, factors such as frequency of contribution, proportion of turns, and number of successful interruptions have been identified as important indicators of influence (Reid and Ng, 2000). This work was done entirely on spoken dialog. In our work, we show that the core insight — conversation is a resource for influence — carries over to written dialog; we also show that it carries over to other forms of power. However, some of the characteristics of spoken dialog do not carry over directly to written dialog, most prominently among them the issue of interruptions: there is no interruption in written dialog.

We now look at various computational approaches to extract power relations from online dialogs. Several studies have used Social Network Analysis (e.g., (Rowe et al., 2007)) to extract social relations from online communication.

Researchers have also applied NLP techniques on message content to detect power relations. Earlier approaches used simple lexical features (e.g. (Bramsen et al., 2011; Gilbert, 2012)) while later studies have performed deeper discourse analysis and used features such as linguistic coordination (Danescu-Niculescu-Mizil et al., 2012), language uses such as attempts to persuade and various other dialog patterns (Biran et al., 2012). We present a more detailed discussion of the above mentioned studies and how they differ from our line of research in (Prabhakaran et al., 2012c).

Our research also falls into the category of studies that go beyond pure lexical features and use dialog structure based features to extract social power relations. In (Prabhakaran et al., 2012c), we studied the notion of situational power in depth and presented a system to detect persons with situational power using dialog features. In this paper as well, we use the system described in (Prabhakaran et al., 2012c). However, this work differs from (Prabhakaran et al., 2012c) and other studies described above in that our focus is on how different types of power are manifested differently in the dialog behavior of the participants. We show that the types of power we consider are in fact different and vary in the ways they manifest in dialogs (Section 6). We also present a system that predicts different types of power (Section 7), not just hierarchical or situational power.

### 3 Data and Annotations

We use the subset of the Enron email corpus with power annotations presented in Prabhakaran et al. (2012a) for our experiments. The corpus also contains manual dialog act annotations by Hu et al. (2009), which enable us to perform the analysis of how power affects dialog behavior. The corpus contains 122 email threads with a total of 360 messages and 20,740 word tokens. There are about 8.5 participants per thread. There are 221 active participants (participants of a thread who has sent at least one email message in the thread) in the corpus. Table 1 presents the counts and percentages of active participants with each type of power in the corpus. We now define the four types of power we investigate in this paper.

**Hierarchical Power (HP):** We use the gold organizational hierarchy for Enron released by Agarwal et al. (2012) to model hierarchical power. It contains relations between 1,518 employees, and

Type of power	Count	Percentage
Hierarchical Power (HP)	18	8.1
Situational Power (SP)	81	36.7
Power over Communication (PC)	127	57.5
Influence (INFL)	11	5.0

Table 1: Annotation statistics

13,724 dominance pairs (pairs of employees such that the first dominates the second in the hierarchy, not necessarily immediately). We labeled a participant to have hierarchical power within a thread if there exist a dominance pair in the gold hierarchy such that he/she dominates any other participant in the same thread.

For the other three types of power — situational power, power over communication, and influence, we utilize the manual annotations present in the corpus of (Prabhakaran et al., 2012a).<sup>1</sup> We labeled a participant to have one of these types of power within a thread if he or she was judged to have that type of power over any other participant in the same thread. We explain the annotations in detail below with an example thread and corresponding annotations shown in Table 2; the email body contains dialog act and link annotations in [square brackets] which will be explained in Section 3.1.

**Situational Power (SP):** Person<sub>1</sub> is said to have situational power over person<sub>2</sub> if person<sub>1</sub> has power or authority to direct and/or approve person<sub>2</sub>’s actions in the current situation or while a particular task is being performed, based on the communication in the current thread. Situational power is independent of organizational hierarchy: person<sub>1</sub> with situational power may or may not be above person<sub>2</sub> in the organizational hierarchy (or there may be no organizational hierarchy at all). In our example thread, our annotator judged Kathryn to possess situational power over Leslie, Sara and Brent because Kathryn is following up on and assigning a task to others, and because Kathryn uses language that shows that she is in charge of the situation.

**Power over Communication (PC):** A person is said to have power over communication if he actively attempts to achieve the intended goals of the communication.<sup>2</sup> These are people who ask questions, request others to take action, etc., and not

<sup>1</sup>The manual annotations also capture the perception of hierarchical power. In this work, we use only the actual gold hierarchy (Agarwal et al., 2012) as described above.

<sup>2</sup>In (Prabhakaran et al., 2012a), power over communication was called “control of communication”.

Table 2: Example thread with power annotations

people who simply respond to questions or perform actions when directed to do so. There could be multiple such participants in a given thread. In our example thread, no one was judged to have power over communication since the communication is broken into two separate interactions of just one message each — one from Kathryn to everyone and the other between Brent and Mark.

**Influence (INFL):** A person is defined to have influence if she 1) has credibility in the group, 2) persists in attempting to convince others, even if some disagreement occurs, 3) introduces topics/ideas that others pick up on or support, and 4) is a group participant but not necessarily active in the discussion(s) where others support/credit her. In addition, the influencer's ideas or language may be adopted by others and others may explicitly recognize influencer's authority. In our example,

our annotator judged Mark to have influence over Brent since the latter seeks advice from the former on how to deal with the situation.

### 3.1 Dialog Act Annotations

The corpus we used contains manual dialog act annotations as described in Hu et al. (2009). We use these annotations to model the dialog structure of the communication thread. For each message, Hu et al. (2009) assign a Dialog Act (DA) label to each segment of text with a coherent communicative function. The label could be one of the following: ReqAction, ReqInfo, Inform, InformOffline,<sup>3</sup> Conventional, and Commit. In addition, the segments are linked by three types of links to reflect the dialog structure. These links capture the patterns of local alternation between an initiating dialog act and a responding one. A **forward link** (Flink) is the analog of a “first pair-part” of an adjacency pair, is restricted to ReqInfo and ReqAction segments. The responses to such requests are assigned a **backward link** (Blink). If an utterance can be interpreted as a response to a preceding segment, it gets a Blink even where the preceding segment has no Flink. The preceding segment taken to be the “first pair-part” of the link is assigned a **secondary forward link** (SFlink).

### 3.2 Overt Display of Power

Our corpus also contains the **overt display of power** (ODP) (Prabhakaran et al., 2012b) annotations. An utterance is defined to have an ODP if it is interpreted as creating additional constraints on the response beyond those imposed by the general dialog act. Syntactically, an ODP can be an imperative, a question, or a declarative sentence. In our example thread, utterance M1.2 is an instance of ODP. The inter-annotator agreement value ( $\kappa$ ) of ODP annotations was 0.67.

## 4 Reliability of Annotations

The power annotations in the corpus are performed by a single annotator and capture her perception of the overall power structure among the participants of the interaction. To verify the reliability of these annotations, we performed an independent inter-annotator agreement (IAA) study on a subset of 47 threads from the corpus. We trained

<sup>3</sup>Sometimes, the Inform act refers to a previous act of communication which did not happen in the email thread itself. Such cases are marked as Offline.

two annotators — AnnA and AnnB — using the same annotation manual described in (Prabhakaran et al., 2012a) and compared the annotations they produced on the selected threads. Annotators were asked to read the entire thread before performing the annotations. They are also asked to provide, in free-form English, a short “power narrative” which describes their perception of the overall power structure among the discourse participants of that thread. Annotators build a fairly consistent mental image of a power narrative — an outline of the power structure between the participants — based on various indicators from across the thread. Their individual power annotations are based on this power narrative. Hence, the cognitive process behind labeling a participant to have a particular type of power is not a binary decision the annotator makes for each participant. However, evaluating agreement on such a formulation is not straightforward. Thus, for the purpose of this IAA study, we port this task into a binary decision task of identifying whether participant X has power of type P or not.

There were 289 participants in the selected 47 threads. The  $\kappa$  values obtained for each type of power is shown in Table 3 under Round 1. Since the  $\kappa$  values obtained in round 1 were only fair to moderate, we performed another round of training and inter annotator study. For this round, AnnB was not available, and we hired another annotator AnnC. The  $\kappa$  values obtained between AnnA and AnnC on another set of 10 threads is presented in Table 3 under Round 2.

Type of power	Round 1	Round 2
Situational Power (SP)	0.47	0.47
Power over Communication (PC)	0.27	0.76
Influence (INFL)	0.50	0.79

Table 3: Inter Rater Agreement ( $\kappa$ )

The  $\kappa$  values obtained in both round 1 and round 2 are in the range of those previously reported for similar tasks (e.g., 0.18 for managerial influence and 0.52 for establishing solidarity (Bracewell et al., 2012); 0.72 for influence (Biran et al., 2012)). The agreement in round 2 improved considerably for both PC and INFL after the second round of training. The issue of moderate agreement for SP and its possible reasons are discussed in detail in (Prabhakaran et al., 2012c). For the rest of this paper, we use the original annotations that were present in the corpus.

## 5 Dialog Behavior

We use five sets of features to capture the dialog behavior of participants: dialog act percentages (**DAP**), dialog link counts (**DLC**), positional (**PST**), verbosity (**VRB**), and overt displays of power (**ODP**). The specific features within each set are listed in Table 4. PST and VRB are readily derivable from the data, without any annotations.

Set	Features
DAP	ReqAction, ReqInform, Inform, InformOffline, Conventional, Commit
DLC	Flink, Slink, Blink, Clink, Dlink, DlinkRatio
PST	Initiator, FirstMsg, LastMsg
VRB	MsgCount, MsgRatio, TokenCount, TokenRatio, TokensPerMsg
ODP	ODPCount

Table 4: Feature Sets

DAP captures the percentages of each dialog act labels in each participant’s utterances. DLC captures the metrics on various kinds of links in each participant’s messages. Flink, Slink and Blink corresponds to counts of respective link annotations in participants’ messages. We refer to Flinks with one or more backward links as connected links (Clink) and those with no matching Blink as dangling links (Dlink). A dangling link denotes a request that was ignored. The DlinkRatio is the ratio of Dlinks to Flinks for a participant. This captures what percentage of a participant’s requests went unanswered. PST captures the positions within the thread where the participant joined and left the conversation. Initiator is a binary feature capturing whether the participant initiated the thread or not. FirstMsg and LastMsg are real valued features between 0 and 1, capturing the relative position of the first and last messages by the participant. VRB features are self explanatory. ODP captures the number of instances of ODP in the messages by each participant.

## 6 Variations in Manifestations of Power

In this section, we present the results of a statistical analysis of the dialog features with respect to people with the four types of power. For each type of power (HP, SP, INFL and PC), we consider two populations of people who participated in the dialog:  $\mathcal{P}$ , those judged to have that type of power, and  $\mathcal{N}$ , those not judged to have that power. Then, for each feature, we perform a two-sample, two-tailed t-test comparing means of feature values of

Set	Features	HP	SP	PC	INFL

Features - DAP: Dialog acts, DLC: Dialog links, PST: Positional, VRB: Verbosity, ODP: Overt display of power

$\mathcal{P}$  and  $\mathcal{N}$ . Table 5 presents means of each feature value for both populations  $\mathcal{P}$  and  $\mathcal{N}$  (as “ $\text{mean}(\mathcal{P}) | \text{mean}(\mathcal{N})$ ”) along with the p-value associated with the t-test as the subscript. For  $p < 0.05$ , we reject the null hypothesis and consider the feature to be statistically significant (boldfaced in Table 5).

We find many features which are statistically significant, which suggests that power types are reflected in the dialog structure. The t-test results also show that significance of features differ considerably from one type of power to another, which suggests that different power types are reflected differently in the dialog structure, and that they are thus indeed different types of power.

For HP, we find that people with HP are less active in threads than those without. For example, persons with hierarchical power tend to talk less within a thread (TokenRatio). They tend to start participating much later in the threads (FirstMsg) and do not initiate threads often (Initiator). SP and PC manifest in stark contrast from HP. Persons with SP and persons with PC both tend to talk more within a thread (TokenRatio). They also tend to be the initiators of the thread (Initiator) or start participating in the thread closer to the beginning (FirstMsg). SP and PC have many other features which are also statistically significant. For

example, they send significantly more messages (MsgCount). They also have significantly more instances of overt displays of power (ODPCount) than others. It is interesting to note that ODPCount was not a significant feature for HP. It suggests that bosses don’t always display their power overtly when they interact. SP and PC also differ from one another. For example, those with SP tend to request actions (ReqAction) significantly more than those without. However, this was not significant in case of PC. Similarly, the number of back links (Blink) was not a significant feature for SP. But, people with PC tend to have significantly fewer back links (Blink) than those without.

This finding — people with PC have fewer back links — is interesting, since it aligns PC with the characterization of control by Walker and Whittaker (1990). According to them, control over a discourse segment is determined by whether the participant provide unsolicited information in the dialog or not. In the dialog act annotation scheme we use, solicited information (in other words, responses to requests and commands) places an obligatory Blink on the corresponding text segment. Hence, the fact that people with PC have significantly larger contributions to the dialog (VRB features), but with fewer back

links, suggest that most of their contribution is unsolicited information. This is in line with Walker and Whittaker (1990)’s definition of control over discourse segments.

Although INFL has fewer data points, we found a few significant features for INFL. People with INFL never request actions (ReqAction) as opposed to those with SP who request actions more frequently than others. Also, people with INFL tend to have significantly more inform utterances (Inform). They also have significantly fewer overt displays of power (ODPCount) than others, a stark contrast to those with SP and PC.

The statistical measures presented in previous section are exploratory in nature, presenting tests on all combinations of features and power types. We do not draw theoretical conclusions from the specific combination of interactions that are found statistically significant. Hence, we did not apply any corrections for multiple tests in statistical significance for individual features. When we apply, the Bonferroni correction for multiple tests to adjust the p-value for number of test performed (threshold =  $0.05/84 = 6.0E-4$ ), 10 features would still remain statistically significant. Hence the global null hypothesis that the features we considered do not interact with the power types would still be rejected.

## 7 Predicting Persons with Power

In this section, we present a system to predict whether a person has a given type of power in the context of an email thread. We show that different sets of features are helpful to detect different types of power. We build a separate binary classifier for each power type predicting whether or not a given participant in a communication thread has that type of power or not. Since our dataset is skewed especially for HP & INFL (with very few persons with power), we balanced our dataset by up-sampling minority class instances in the training step. This has proven useful in cases of unbalanced datasets (Japkowicz, 2000). All results presented below have been obtained after balancing the training folds in cross validation; the test folds remain unchanged. We used the tokenizer, POS tagger, lemmatizer and SVMLight (Joachims, 1999) wrapper in the ClearTK (Ogren et al., 2008) package. The ClearTK wrapper for SVMLight internally shifts the prediction threshold based on a posterior probabilistic score calcu-

Type	Feature set	P	R	F

PC: Power over communication, INFL: Influence  
VRB: Verbosity, PST: Positional, DAP: Dialog acts, DLC: Dialog links, LEX: Lexical, ODP: Overt display of power

lated using Lin et al. (2007)’s algorithm.

We first find the best performing subset of features for each feature set by exhaustive search within the set. Once we have the best subset of each feature set, we do another round of exhaustive search combining best performers of each set to find the overall best performing feature subset. We report micro-averaged (P)recision, (R)ecall and (F)-measure on 5-fold cross validation for each power type. We experimented with a linear kernel and a quadratic kernel; the latter performed better. All results presented in this paper are obtained using a quadratic kernel.

Table 6 shows cross validation results for all

four types of power for each set of features.<sup>4</sup> The corpus was split into folds at the thread level. We present two simple baseline measures - **Random** and **AlwaysTrue** and a language-based baseline, **LEX**. In the Random baseline, we predict an active participant to have the particular type of power at random. In AlwaysTrue baseline, we always predict an active participant to have power. For LEX, we use only lexical features (unigrams and bigrams) from messages sent by each participant to train the SVM model described above. For each power type, the table also lists (in the last row) the best performing feature subset combination and corresponding results.

HP is hard to predict, which could partly be due to the very small number of positive training examples in the corpus. For the LEX baseline using purely word ngrams, the system did not get any correct predictions. All feature subsets outperformed the other baselines of 11.3% and 15.0% (for Random and AlwaysTrue respectively), and a combination of VRB, PST and ODP gave the best model obtaining an F measure of 29.5%.

For SP, the best performing individual feature sets are ODP and DLC, both at or near 60.0%. While ODP gave a high precision (71.2%) model, DLC gave a high recall (75.3%) model, the combination of both gave the best performing system with an F measure of 64.4%.

For PC, the best single feature was FirstMsg (relative position of first message). This is because the person with the power over communication is almost always the initiator of the thread. Note that the notion of PC is not defined in terms of positional features: annotators were asked to find the participants who “actively attempt to achieve the intended goals of the communication”. It is our finding that those who are in PC were also the ones who did initiate the thread. It is also worth noting that ODP is the worst performer for PC which is in contrast with the case of SP, supporting the claim that these two types of power are in fact different.

INFL is another very hard class to predict, again, possibly partly due to the very small number of positive training examples. The simple baseline F measures were both 9.5, while the LEX did not produce any correct predictions at all. All feature sets except PST outperformed these baseline measures. The best performance was obtained

by DLC with counts of Blinks, Flinks, Dlinks and SFlinks as features.

For assessing statistical significance of F measure improvements over baseline, we used the Approximate Randomness Test (Yeh, 2000). We found the improvements to be statistically significant for SP ( $p = 0.001$ ), HP ( $p=0.001$ ) and PC ( $p = 0.01$ ) with a threshold for significance at  $p = 0.05$ . However, for INFL, the improvement was not statistically significant ( $p = 0.3$ ). The statistical significance of SP, HP and PC would hold even after applying Bonferroni correction for multiple tests.

## 8 Conclusion and Future Work

We studied four types of power between participants of written dialog. We have shown that these types of power are manifested very differently with respect to the features we are using, which validates our claim that these are indeed different types of power. We also presented a supervised learning system to predict persons with one of the types of power in written dialog yielding encouraging results. We have shown that dialog features are very significant in predicting power relations in online written communication.

In future work, we intend to try predicting power relations between pairs of participants. It would be interesting to see how dialog features correlate with the other direction of power; that is from a submitter to an exerciser of power. We will investigate the use of additional features related to the dialog participants, such as gender. We will also investigate using a dialog act tagger, link predictor and an ODP tagger to build a fully automatic power predicting system. We would also like to extend this work to other genres of written communication like discussion forums and blogs.

# Evaluation of the *Scusi?* Spoken Language Interpretation System – A Case Study

Thomas Kleinbauer, Ingrid Zukerman and Su Nam Kim

Faculty of Information Technology, Monash University  
Clayton, Victoria 3800, Australia

## Abstract

We present a performance evaluation framework for Spoken Language Understanding (SLU) modules, focusing on three elements: (1) characterization of spoken utterances, (2) experimental design, and (3) quantitative evaluation metrics. We then describe the application of our framework to *Scusi?*— our SLU system that focuses on referring expressions.

## 1 Introduction

We present a performance evaluation framework for Spoken Language Understanding (SLU) modules, and describe its application to the evaluation of *Scusi?* — an SLU system that focuses on the interpretation of descriptions of household objects (Zukerman et al., 2008). Our contributions pertain to (1) the characterization of spoken utterances, (2) experimental design, and (3) quantitative evaluation metrics for an N-best list.

**Characterization of spoken utterances.** According to (Jokinen and McTear, 2010), “in diagnostic-type evaluations, a representative test suite is used so as to produce a system’s performance profile with respect to a taxonomy of possible inputs”. In addition, one of the typical aims of an evaluation is to identify components that can be improved (Paek, 2001). These two factors in combination motivate a characterization of input utterances along two dimensions: *accuracy* and *knowledge* (Section 4).

- **Accuracy** indicates whether an utterance describes an intended object precisely and unambiguously. For instance, when intending a blue plate, “the blue plate” is an accurate description if there is only one such plate in the room, while “the *green* plate” is inaccurate.
- **Knowledge** indicates how much the SLU module knows about different factors of the interpretation process, e.g., vocabulary or geometric

relations. For instance, “CPU” in “the *CPU* under the desk”<sup>1</sup> is *Out of Vocabulary (OOV)* for *Scusi?*, and the “of” in “the picture *of* a face”<sup>\*</sup> is an unknown relation.

The frequency of different values for these dimensions influence the requirements from an SLU system, and the components that necessitate additional resources, e.g., vocabulary extension.

**Experimental design.** It is generally accepted that an SLU system should exhibit reasonable behaviour by human standards. At present, in experiments that evaluate an SLU system’s performance, people speak to the system, and the accuracy of the system’s interpretation is assessed. However, this mode of evaluation, which we call *Generative*, does not address whether a system’s interpretations are plausible (even if they are wrong). Thus, in addition to a *Generative* experiment, we offer an *Interpretive* experiment. Both experiments are briefly described below. Their implementation in our SLU system is described in Section 5.

- In the *Interpretive* experiment, trial subjects and the SLU system are addressees, and are given utterances generated by a third party. The SLU system’s confidence in its interpretations is then compared with the preferences of the participants.
- In the *Generative* experiment, trial subjects are speakers, generating free-form utterances, and the SLU module and expert annotators are addressees. Gold standard interpretations for these descriptions are produced by annotators on the basis of their understanding of what was said, e.g., an ambiguous utterance has more than one correct interpretation. The SLU system’s performance is evaluated on the basis of the rank of the correct interpretations.

<sup>1</sup>Examples from our trials are marked with asterisks (\*).

These two experiments, in combination with our characterization of spoken utterances, enable the comparison of system and human interpretations under different conditions.

**Quantitative evaluation metrics.** Automatic Speech Recognizers (ASRs) and parsers often return N-best hypotheses to SLU modules, while many SLU systems return only one interpretation (DeVault et al., 2009; Jokinen and McTear, 2010; Black et al., 2011). However, maintaining N-best interpretations at the semantic and pragmatic level enables a Dialogue Manager (DM) to examine more than one interpretation, and discover features that guide appropriate responses and support error recovery. This ranking requirement, together with our experimental design, motivates the following metrics (Section 6).

- For *Interpretive* experiments, we propose correlation measures, such as Spearman rank or Pearson correlation coefficient, to compare participants' ratings of candidate interpretations with the scores given by an SLU system.
- For *Generative* experiments, we provide a broad view of an SLU system's performance by counting the utterances that it *CantRepresent*, and among the remaining utterances, counting those for which a correct interpretation was *NotFound*. We obtain a finer-grained view using fractional variants of the Information Retrieval (IR) metrics *Recall* (Salton and McGill, 1983) and *Normalized Discounted Cumulative Gain (NDCG)* (Järvelin and Kekäläinen, 2002), which handle equiprobable interpretations in an N-best list. We also compute @*K* versions of these metrics to represent the relation between rank and performance.

In the next section, we discuss related work, and in Section 3, we outline our system *Scusi?*. In Section 4, we present our characterization of descriptions, followed by our experimental design and evaluation metrics. The results obtained by applying our framework to *Scusi?* are described in Section 7, followed by concluding remarks.

## 2 Related Work

As mentioned above, our contributions pertain to the characterization of spoken utterances, experimental design, and quantitative metrics.

**Characterization of spoken utterances.** Most evaluations of SLU systems characterize input

utterances in terms of ASR *Word Error Rate (WER)*, e.g., (Hirschman, 1998; Black et al., 2011). Möller (2008) provides a comprehensive collection of interaction parameters for evaluating telephone-based spoken dialogue services, which pertain to different aspects of an interaction, viz communication, cooperativity, task success, and spoken input. Our characterization of spoken utterances along the accuracy and knowledge dimensions is related to Möller's task success category. However, in our case, these features pertain to the context, rather than the task. In addition, our characterization is linked to system development effort, i.e., how much effort should be invested to address utterances with certain characteristics; and to evaluation metrics, in the sense that the assessment of an interpretation depends on the accuracy of an utterance, and takes into account the capabilities of an SLU system.

**Experimental design.** Evaluations performed to date are based on Generative experiments (Hirschman, 1998; Gandrabur et al., 2006; Thomson et al., 2008; DeVault et al., 2009; Black et al., 2011), which focus on correct or partially correct responses. They do not consider human interpretations for utterances with diverse characteristics, as done in our Interpretive trials.

**Quantitative evaluation metrics.** Most SLU system evaluations use IR-based metrics, such as recall, precision and accuracy, to compare the components of one interpretation of a perfect request to the components of a reference interpretation (Hirschman, 1998; Möller, 2008; DeVault et al., 2009; Jokinen and McTear, 2010). In contrast, we consider the rank of completely correct interpretations of perfect requests and partially correct interpretations of imperfect requests in an N-best list. Thomson *et al.* (2008) analyzed metrics for N-best lists, such as *Receiver Operator Characteristic*, *Weighted Semantic Error Rate* and *Normalized Cross Entropy* (Gandrabur et al., 2006); and offered the *Item Level Cross Entropy (ICE)* metric, which combines the confidence score and correctness of each of N-best interpretations. In this paper, we adapt IR-based metrics to handle equiprobable interpretations in an N-best list, and offer the *CantRepresent* and *NotFound* metrics to give a broad view of system performance. In the future, we intend to incorporate confidence/accuracy metrics, such ICE.

Figure 1: Sample UCG and ICG for “the blue mug on the large table”.

### 3 The *Scusi?* System

*Scusi?* is a system that implements an anytime, probabilistic mechanism for the interpretation of spoken utterances, focusing on a household context. It has four processing stages, where each stage produces multiple outputs for a given input, early processing stages may be probabilistically revisited, and only the most promising options at each stage are explored further.

The system takes as input a speech signal, and uses an ASR (Microsoft Speech SDK 6.1) to produce candidate texts. Each text is assigned a probability given the speech wave. The second stage applies Charniak’s probabilistic parser ([bllip.cs.brown.edu/resources.shtml#software](http://bllip.cs.brown.edu/resources.shtml#software)) to syntactically analyze the texts in order of their probability, yielding at most 50 different parse trees per text. The third stage applies mapping rules to the parse trees to generate *Uninstantiated Concept Graphs (UCGs)* that represent the semantics of the utterance (Sowa, 1984). The final stage produces *Instantiated Concept Graphs (ICGs)* that match the concepts and relations in a UCG with objects and relations within the current context (e.g., a room), and estimates how well each instantiation matches its “parent” UCG and the context. For example, Figure 1(a) shows one of the UCGs returned for the description “the blue mug on the large table”, and Figure 1(b) displays one of the ICGs generated for this UCG. Note that the concepts in the UCG have generic names, e.g., *mug*, while the ICG contains specific objects, e.g., *mug03* or *cup01*, which are offered as candidate matches for *lex=mug*, *color=blue*.

#### 3.1 *Scusi?*’s capabilities

*Scusi?* aims to understand requests for actions involving physical objects (Zukerman et al., 2008). Focusing on object descriptions, *Scusi?* has a vocabulary of lexical items pertaining to objects, colours, sizes and positions. For object names, this vocabulary is expanded with synonyms and near

synonyms obtained from WordNet (Fellbaum, 1998) and word similarity metrics from (Leacock and Chodorow, 1998). However, this vocabulary is not imposed on the ASR, as we do not want *Scusi?* to hear only what it wants to hear. In addition, *Scusi?* was designed to understand the colour and size of objects; the topological positional relations *on*, *in*, *near* and *at*, optionally combined with *center*, *corner*, *edge* and *end*, e.g., “the mug *near the center* of the table”; and the projective positional relations *in front of*, *behind*, *to the left/right*, *above* and *under* (topological and projective relations are discussed in detail in (Coventry and Garrod, 2004; Kelleher and Costello, 2008)). By “understanding a description” we mean mapping attributes and positions to values in the physical world. For instance, the CIE colour metric (CIE, 1995) is employed to understand colours, Gaussian functions are used to represent sizes of things compared to the size of an average exemplar, and spatial geometry is used to understand positional relations.

At present, *Scusi?* does not understand (1) *OOV* words, e.g., “the *opposite* wall”\*; (2) more than one meaning of polysemous positional relations, e.g., “*to the left of* the table”\* as “*to the left and on* the table” as well as “*to the left and next to* the table”; (3) positional relations that are complex, e.g., “*in the left near corner of* the table”\*, or don’t have a landmark, e.g., “the ball *in the center*”\*; and (4) descriptive prepositional phrases starting with “of” or “with”, e.g., “the picture *of* the face”\* and “the plant *with* the leaves”\*. However, contextual information sometimes enables the system to overcome *OOV* words. For example, *Scusi?* may return the correct ICG for “the *round* blue plate on the table” at a good rank.

Clearly, these problems can be solved by programming additional capabilities into our system. However, people will always say things that an SLU system cannot understand. Our evaluation framework can help distinguish between situations in which it is worth investing additional development effort, and situations for which other coping mechanisms should be developed, e.g., asking a clarification question or ignoring the unknown portions of an utterance (while being aware of the impact of this action on comprehension).

#### 3.2 ASR capabilities

The WER of the ASR used by *Scusi?* is 30% when trained on an open vocabulary in combination with a small language model for our corpus.

This WER is consistent with the WER obtained in the 2010 Spoken Dialogue Challenge (Black et al., 2011). In addition to the obvious problem of mis-recognized entities or actions, which yield OOV words, ASR errors often produce ungrammatical sentences that cannot be successfully parsed. For instance, one of the alternatives produced by the ASR for “the blue plate at the front of the table”<sup>\*</sup> is “*to build played* at the front *door* the table”. Further, disfluencies are often mis-heard by the ASR or cause it to return broken sentences.

#### 4 Characterization of Spoken Utterances

When describing an object or action, speakers may employ a wrong lexical item, or use a wrong attribute. For instance, “the green *couch*”<sup>\*</sup> was described when intending a green bookcase. In addition, when describing objects, speakers may under-specify them, e.g., ask for “the pink mug” when there are several such mugs; provide inconsistent specifications that do not match any object perfectly, yielding no candidates or several partial candidates, e.g., request “the large blue mug” when there is a large pink mug and a small blue mug; omit a landmark, e.g., “the ball in the center”<sup>\*</sup>; or employ words or constructs unknown to an SLU module, e.g., “the *exact* center”<sup>\*</sup>.<sup>2</sup> These situations, which affect the performance of an SLU system, are characterized along the following two dimensions: *accuracy* and *knowledge*.

- **Accuracy** – We distinguish between *Perfect* and *Imperfect* utterances. An utterance is perfect if it matches at least one object or action in the current context in every respect. In this case, an SLU module should produce one or more interpretations that match perfectly the utterance. If every object or action in the context mismatches an utterance at least in one aspect, the utterance is *imperfect*. In this case, we consider *reasonable* interpretations (that match the request well but not perfectly) to be the Gold standard. The **number** of Gold interpretations is an attribute of accuracy: an utterance may match (perfectly or imperfectly) 0, 1 or more than 1 interpretation.
- **Knowledge** – If all the words and syntactic constructs in an utterance are understood by an SLU module (Section 3.1), the utterance is deemed *known*, otherwise, it is *unknown*.

<sup>2</sup>People often over-specify their descriptions, e.g., “the large red mug” when there is only one red mug (Dale and Reiter, 1995). Such over-specifications are not problematic.

To illustrate these concepts, a description that contains only known words, and matches two objects in the context in every respect, is classified as *known-perfect*>1.

### 5 Experimental Design

We devised two experiments to assess an SLU system’s performance: *Interpretive*, where the participants and the SLU system are the addressees (Section 5.1), and *Generative*, where the participants are the speakers and the SLU module is the addressee (Section 5.2).

In both experiments, we evaluate the performance of an SLU system on the basis of complete interpretations of an utterance, which in *Scusi?*’s case is a description. For example, given “the pink ball near the table”, all the elements of an ICG must try to match this description and the context. That is, if `ball01` is pink, but it is *on* `table02`, the ICG `ball01-location_near-table02` will have a good description match but a bad reality match, while the opposite happens for ICG `ball01-location_on-table02`.

#### 5.1 Interpretive trial

This experiment tests whether *Scusi?*’s understanding matches the understanding of a relatively large population under different accuracy conditions. We focus on imperfect and ambiguous descriptions, as they pose a greater challenge to people than perfect descriptions. The trial consists of a Web-based survey where participants were given a picture of a room and 9 descriptions generated by the authors (Figure 2). For each description, participants were asked to rate each of 20 labeled objects based on how well they match the description, where a rating of 10 denotes a “perfect match” and a rating of 0 denotes “no match”.

Our Web survey was done by 47 participants, resulting in  $47 \times 20$  scores for each description. These scores were averaged across participants, yielding a single score for each labeled object for each of our 9 descriptions.

#### 5.2 Generative trial

In this experiment, trial subjects generated free-form, spoken descriptions to identify three designated objects in each of four scenarios. The scenarios, which were designed to test different functionalities of *Scusi?*, contain between 8 and 16 objects (Figure 3 shows two scenarios). The annotators provided the Gold standard interpretations for

(a) Room with labeled objects

1. *the plate next to the ball* *perfect*>1
2. *the large blue box* *imperfect*>1
3. *the red dish* *perfect*=1
4. *the brown bookcase under the portrait* *imperfect*>1
5. *the orange mug near the vase* *imperfect*>1
6. *the large plate* *perfect*>1
7. *the large green bookcase near the chest* *imperfect*=1
8. *the large ball on the table* *imperfect*>1
9. *the portrait above the bookcase* *perfect*=1

(b) Descriptions with their characterization

Figure 2: Context visualization and object descriptions used in the Interpretive experiment.

(a) Projective relations and “end, edge, corner” and “center” of a table

(b) Colour, size, positional relation and intervening object in a room

Figure 3: Two of the scenarios used in the Generative experiments.

a description on the basis of what they understood (rather than using the designated referents). Each annotator handled half of the descriptions, and the other annotator verified the annotations. Disagreements were resolved by consensus.

Our study had 26 participants, who generated a total of 432 spoken descriptions (average length was 10 words, median 8, and the longest description had 21 words). We manually filtered out 32 descriptions that were broken up by the ASR due to pauses made by the speakers, and 105 descriptions that *Scusi?* *CantRepresent* (Section 6.2). Two sets of files were submitted to *Scusi?*: a set containing textual transcriptions of the remaining 295 descriptions, and a set containing textual alternatives produced by the ASR for each of these descriptions.

This experiment enables us to observe the frequencies of descriptions with different characteristics (Section 4), and determine their influence on performance, as well as the effect of ASR versus textual input. Table 3 displays the frequencies of the four accuracy classes of descriptions (*perfect* =1 and >1 and *imperfect* =1 and >1), and two knowledge classes (*known* and *unknown-OOV*) (Section 4). For instance, the top row shows that 197 descriptions are *known-perfect*=1 (Col-

umn 2), and 25 descriptions are *unknown-OOV* (Column 3). 18 *unknown-non-OOV* descriptions were omitted from Table 3. These descriptions have Gold ICGs, but contain word combinations that are not known to *Scusi?*, e.g., “on top of” and “at the front of”. Note the low frequencies of three of the *unknown-OOV* categories, and of the *imperfect*>1 classes. The latter suggests that, unlike our Interpretive trial, people rarely generate descriptions that are both ambiguous and inaccurate. Table 3 also displays the results obtained for the performance metrics *NotFound@K*, *FRecall@K* and *NDCG@K* (Section 6) for each accuracy-knowledge combination and for Text and ASR input; the results are described in Section 7.

## 6 Evaluation Metrics

We first consider the Interpretive trial followed by the Generative trial.

### 6.1 Interpretive trial

*Scusi?*’s understanding of each description was compared with that of our trial subjects by calculating the Spearman rank correlation coefficient and Pearson correlation coefficient between the average of the scores of the subjects’ ratings for each object, and the probability assigned

Table 1: Descriptions that cannot be represented.

	Positional relation			Others and Prep. Phrase “with”/“of”
	Poly- semous	Complex	No Landm.	
<i>perfect=1</i>	9	29	0	9
<i>perfect&gt;1</i>	5	15	0	4
<i>imperfect=1</i>	6	13	18	3
<i>imperfect&gt;1</i>	2	2	1	0
TOTAL	22	59	19	16

by *Scusi?* to the top-ranked correct interpretation with the corresponding head object, e.g., `plate16-near-ball09` for the first description in Figure 2(b). The results for the Spearman rank and Pearson correlation coefficient appear in Section 7.1.

## 6.2 Generative trial

We first describe our broad metrics, followed by the fine-grained metrics.

**CantRepresent** counts the number of utterances that an SLU system cannot represent, which are a subset of the *unknown* utterances, and are excluded from the rest of the evaluation. Table 1 displays the frequencies of such descriptions and their causes (11 descriptions had more than one problem). As shown in Table 1, complex positional relations, e.g., “*the left front corner*”\*, account for most of the problems.

**NotFound@K** counts the number of representable utterances for which no correct interpretation was found within rank  $K$ . **NotFound@∞** considers all the interpretations returned by an SLU system. It is worth noting that *NotFound* utterances are included when calculating the following metrics.

**Precision@K and Recall@K.** The @ $K$  versions of precision and recall evaluate performance for different cut-off ranks  $K$ .

**Precision@K** is simply the number of correct interpretations at rank  $K$  or better divided by  $K$ . **Recall@K** is defined as follows:

$$\text{Recall@}K(d) = \frac{|CF(d) \cap \{I_1, \dots, I_K\}|}{|C(d)|},$$

where  $C(d)$  is the set of correct interpretations for utterance  $d$ ,  $CF(d)$  is the set of correct interpretations found by an SLU module, and  $I_j$  denotes an interpretation with rank  $j$ .

Contrary to IR settings, where typically there are many relevant documents, in language understanding situations, there is often one correct interpretation for an utterance (Table 3). If this interpretation is ranked close to the top, **Precision@K**

will be constantly reduced as  $K$  increases. Hence, we eschew this measure when evaluating the performance of an SLU system.

An SLU module may return several equiprobable interpretations, some of which may be incorrect. The relative ranking of these interpretations is arbitrary, leading to non-deterministic values for **Recall@K** — a problem that is exacerbated when  $K$  falls within a set of such equiprobable interpretations. This motivates a variant of **Recall@K**, denoted **FRecall@K** (*Fractional Recall*), that allows us to represent the arbitrariness of the ranked order of equiprobable interpretations, as follows:

$$\text{FRecall@}K(d) = \frac{\sum_{j=1}^K fc(I_j)}{|C(d)|}, \quad (1)$$

where  $fc$  is the fraction of correct interpretations among those with the same probability as  $I_j$  (this is a proxy for the probability that  $I_j$  is correct):

$$fc(I_j) = \frac{c_j}{h_j - l_j + 1}, \quad (2)$$

where  $l_j$  is the lowest rank of all the interpretations with the same probability as  $I_j$ ,  $h_j$  the highest rank, and  $c_j$  the number of correct interpretations between rank  $l_j$  and  $h_j$  inclusively.

**Normalized Discounted Cumulative Gain (NDCG@K).** A shortcoming of **Recall@K** is that it considers the rank of an interpretation only in a coarse way (at the level of  $K$ ). A finer-grained account of rank is provided by **NDCG@K** (Järvelin and Kekäläinen, 2002), which discounts interpretations with higher (worse) ranks.

**DCG@K** allows the definition of a relevance measure for a result, and divides this measure by a logarithmic penalty that reflects the rank of the result. Using  $fc(I_j)$  as a measure of the relevance of interpretation  $I_j$ , we obtain

$$\text{DCG@}K(d) = fc(I_1) + \sum_{j=2}^K \frac{fc(I_j)}{\log_2 j}.$$

This score is normalized to the  $[0, 1]$  range by dividing it by the score of an ideal answer where  $|C(d)|$  correct interpretations are ranked in the first  $|C(d)|$  places, yielding

$$\text{NDCG@}K(d) = \frac{\text{DCG@}K(d)}{1 + \sum_{j=2}^{\min\{|C(d)|, N\}} \frac{1}{\log_2 j}}. \quad (3)$$

Note that **FRecall@K** is computed in relation to the number of correct interpretations, while **NDCG@K** considers the minimum of  $K$  and this number (Equations 1 and 3 respectively).

Table 2: Results of the Interpretive trials.

## 7 Results

We first discuss the results of our Interpretive trials followed by those of our Generative trials.

### 7.1 Interpretive Trials

Table 2 compares the results of the Web survey with *Scusi?*’s performance for the Interpretive trials. Column 2 indicates the object preferred by the trial subjects, and Columns 3-5 show the top-three interpretations preferred by *Scusi?* ( $I_1$ – $I_3$ ). Matches between the system’s output and the averaged participants’ ratings are boldfaced.

As seen in Table 2, *Scusi?*’s ratings generally match those of our participants, achieving a strong Pearson correlation of 0.77, and a weaker Spearman correlation of 0.63. This is due to the fact that implausible interpretations get a score of 0 from *Scusi?*, while some people still choose them, thus yielding different ranks for them.

*Scusi?*’s top-ranked interpretation matches our participants’ preferences in 5.5 cases, and its second-ranked interpretation in 2.5 cases (the fractions are for equiprobable interpretations). The discrepancies between *Scusi?*’s choices and those of our trial subjects are explained as follows: (desc. 3) “the red dish” – according to Leacock and Chodorow’s similarity metric (Section 3.1), a mug is more similar to a dish than a dinner plate, while our trial subjects thought otherwise; (desc. 4) “the brown bookcase under the portrait” – *Scusi?* penalizes heavily attributes that do not match reality (Zukerman et al., 2008), hence `bookcase14` is penalized, as it is not under any portrait; (desc. 6) “the large plate” – our participants perceived `plate28` to be larger than `plate16` although they are the same size, and hence equiprobable; (desc. 7) “the large green bookcase near the chest” – like description 4, `bookcase10` (which is green) is ranked second due to its low probability of being considered large.

Thus, according to this trial, *Scusi?*’s performance satisfies our original requirement for rea-

sonable behaviour and plausible mistakes, but perhaps it should be more forgiving with respect to mis-matched attributes.

### 7.2 Generative Trials

Table 3 displays the results for *NotFound@K*, *FRecall@K* and *NDCG@K* for  $K = 1, 3, 10, \infty$  for Text and ASR input, the four accuracy classes, and the *known* and *unknown-OOV* knowledge categories. There are 277 descriptions in total (instead of 295), as 18 *unknown-non-OOV* descriptions were omitted from Table 3 (Section 5.2). As mentioned in Section 5.2, the vast majority of the utterances belong to the *perfect=1* class (with *known* or *unknown-OOV* words), and to the *known perfect>1* and *imperfect=1* categories.

**ASR versus Text.** The *NotFound@1,3*, *FRecall@1,3* and *NDCG@1,3* metrics show that *Scusi?* yields at least one correct interpretation at the lowest (best) ranks for the vast majority of Text inputs (the discrepancy between *FRecall* and *NDCG* at low ranks is due to the way these measures are calculated, Section 6.2). This suggests that in the absence of ASR errors, if correct interpretations are found, the system’s confidence in its output is justified. As expected, the *NotFound* values are substantially higher, and the *FRecall* and *NDCG* values lower, for inputs obtained from the ASR (23% of the descriptions had one wrong word in the best ASR alternative, 21% had two wrong words, 12.5% had three, and 8.5% more than three). There is a substantial improvement in *FRecall* and *NDCG* as ranks increase, which shows that contextual information can alleviate some ASR errors. The improvement in these metrics for the *perfect>1* class, without affecting *NotFound*, indicates that *Scusi?* finds more correct interpretations for the same descriptions.

The ASR results compared to those of Text indicate that, unsurprisingly, speech recognition quality must be improved. This may be achieved through advances in ASR technology, or by pre-

Table 3: Description breakdown in terms of accuracy and knowledge, performance metrics and results.

venting ASR errors (Gorniak and Roy, 2005; Sugiyura et al., 2009) or correcting them (López-Cózar and Callejas, 2008; Kim et al., 2013).

**Known versus Unknown-OOV.** *Perfect=1* is the only class with a substantial number of OOV words (25). Note the increase in *FRecall* up to rank @∞ for *known* ASR and *unknown-OOV* Text and ASR, which indicates that correct interpretations are returned at very high ranks when input words are not identified (*NDCG* increases only modestly, as it penalizes high ranks). The difference in performance between *known-perfect=1* and *unknown-OOV-perfect=1* suggests that it is worth improving *Scusi?*'s vocabulary coverage.

## 8 Conclusion

We offered a framework for the evaluation of SLU systems that comprises a characterization of spoken utterances, experimental design and evaluation metrics. We described its application to the evaluation of *Scusi?*—our SLU module for the interpretation of descriptions in a household context.

Our characterization of descriptions identifies frequently occurring cases, such as *perfect=1*, and rare cases, such as *imperfect>1*; and highlights the influence of vocabulary coverage on performance.

Our two types of experiments enable the evaluation of an SLU system's performance from two viewpoints: Interpretive trials support the comparison of an SLU module's performance with that of people as addressees, and Generative trials assess the performance of an SLU system when interpreting descriptions commonly spoken by users. The results of the Interpretive trial were encouraging, but they indicate that *Scusi?*'s "punitive" at-

titude to attributes that do not match reality, such as a bookcase not being under any portrait, may need to be moderated. However, as stated above, *imperfect>1* descriptions were rare in our Generative trials. The results of these trials show that development effort should be invested in (1) ASR accuracy (Kim et al., 2013); (2) vocabulary coverage; and (3) ability to represent complex, polysemous and no-landmark positional relations. In contrast, descriptive prepositional phrases starting with "with" or "of" may be judiciously ignored, or the referent may be disambiguated by asking a clarification question.

Our *CantRepresent* and *NotFound* evaluation metrics provide an overall view of an SLU system's performance. IR-based metrics have been used in the evaluation of SLU systems to compare an interpretation returned by an SLU module with a reference interpretation. In contrast, we employ *FRecall* and *NDCG* in the traditional IR manner, i.e., to assess the rank of correct interpretations in an N-best list. The relevance measure *fc* (Equation 2), which is applied to both metrics, enables us to handle equiprobable interpretations. However, rank-based evaluation metrics do not consider the absolute quality of an interpretation, i.e., the top-ranked interpretation might be quite bad. In the future, we propose to investigate confidence/accuracy metrics, such as ICE (Thomson et al., 2008), to address this problem.

# A Noisy Channel Approach to Error Correction in Spoken Referring Expressions

Su Nam Kim, Ingrid Zukerman, Thomas Kleinbauer and Farshid Zavareh  
Faculty of Information Technology, Monash University  
Clayton, Victoria 3800, Australia

## Abstract

We offer a noisy channel approach for recognizing and correcting erroneous words in referring expressions. Our mechanism handles three types of errors: it removes noisy input, inserts missing prepositions, and replaces mis-heard words (at present, they are replaced by generic words). Our mechanism was evaluated on a corpus of 295 spoken referring expressions, improving interpretation performance.

## 1 Introduction

One of the main stumbling blocks for Spoken Dialogue Systems (SDSs) is the lack of reliability of Automatic Speech Recognizers (ASRs) (Pellegrini and Trancoso, 2010). Recent research prototypes of ASRs yield Word Error Rates (WERs) between 15.6% (Pellegrini and Trancoso, 2010) and 18.7% (Sainath et al., 2011) for broadcast news. However, the commercial ASR employed in this research had a WER of 30% and a Sentence Error Rate (SER) (proportion of sentences for which no correct textual transcription was produced) of 65.3% for descriptions of household objects.

In addition to mis-recognized entities or actions, ASR errors often yield ungrammatical sentences that cannot be processed by subsequent interpretation modules of an SDS, e.g., “the blue plate” being mis-heard as “*to build played*”, and hesitations (e.g., “ah”s) being mis-heard as “and” or “on” — all of which happened in our trials.

In this paper, we offer a general framework for error detection and correction in spoken utterances that is based on the noisy channel model, and present a first-stage implementation of this framework that performs simple corrections of referring expressions. Our model is implemented as a pre-processing step for the *Scusi?* spoken language interpretation system (Zukerman et al., 2008; Zukerman et al., 2009).

Table 1: Spoken, heard and labeled descriptions.

Spoken:	the stool	<i>to</i>	the left of	the table
Heard:	the <i>storm</i>		the left of	the table
Labels:	<b>Object</b>	<b>Prep</b>	<b>Specifier</b>	<b>Landmark</b>
Spoken:	the plate		in	the microwave
Heard:	<i>to play</i>	<i>it</i>	in	the microwave
Labels:	<b>Object</b>	<b>Noise</b>	<b>Prep</b>	<b>Landmark</b>

The idea of the noisy channel model is that a message is sent through a channel that introduces errors, and the receiver endeavours to reconstruct the original message by taking into account the characteristics of the noisy channel and of the transmitted information (Ringger and Allen, 1996; Brill and Moore, 2000; Zwarts et al., 2010). The system described in this paper handles three types of errors: noise (which is removed), missing prepositions (which are inserted), and mis-heard words (which are replaced). Table 1 shows two descriptions that illustrate these errors. The first row for each description displays what was spoken, the second row displays what was heard by the ASR, and the third row shows the semantic labels assigned to each segment in the description by a shallow semantic parser (Section 3.2). Specifically, in the first example, the preposition “*to*” is missing, and the object “stool” is mis-heard as “*storm*”; and in the second example “the plate” is mis-heard as “*to play*”, and the noisy “*it*” has been inserted by the ASR.

Ideally, we would like to replace mis-heard words with phonetically similar words, e.g., use “plate” instead of “*play*”. However, at present, as a first step, we replace mis-heard words with generic options, e.g., “thing” for an object or landmark. Further, we insert the generic preposition “at” for a missing preposition. Thus, we deviate from the noisy channel approach in that we do not quite reconstruct the original message. Instead, we construct a grammatically correct version of this message that enables the generation of reasonable interpretations (rather than no interpretation or non-

sensical ones). For example, the mis-heard description “to play it in the microwave” in Table 1 is modified to “the thing in the microwave”. Clearly, this is not what the speaker said, but hopefully, this modified text, which describes an object, rather than an action, enables the identification of the intended object, e.g., a plate, or at least a small set of candidates, in light of the rest of the description.

Our mechanism was evaluated on a corpus of 295 spoken referring expressions, significantly improving the interpretation performance of the original *Scusi?* system (Section 6.3).

The rest of this paper is organized as follows. In the next section, we discuss related work. In Section 3, we outline the design of our system. Our probabilistic model is described in Section 4, followed by the noisy channel error correction procedure. In Section 6, we discuss our evaluation, and then present concluding remarks.

## 2 Related Research

This research combines three main elements: correction of ASR output, noisy channel models and shallow semantic parsing.

López-Cózar and Griol (2010) used lexical approaches to replace, insert or delete words in a textual ASR output, and syntactic approaches to modify tenses of verbs and grammatical numbers to better match grammatical expectations. However, these actions make *ad hoc* changes.

The noisy channel model has been employed for various NLP tasks, such as ASR output correction (Ringger and Allen, 1996), spelling correction (Brill and Moore, 2000), and disfluency correction (Johnson and Charniak, 2004; Zwarts et al., 2010). Our approach differs from the traditional noisy channel approach in that it uses a word-error classifier to model the noisy channel, and semantic information to model the input characteristics.

Shallow semantic parsers for SDSs have been used in (Coppola et al., 2009; Geertzen, 2009). Coppola *et al.* (2009) used FrameNet (Baker et al., 1998) to detect and filter the frames for target words, and employed a Support Vector Machine (SVM) classifier to perform semantic labeling. Geertzen (2009) used a shallow parser to detect semantic units only when a dependency parser failed to produce a parse tree. In contrast, our shallow semantic parser is part of a noisy channel model that post-processes the output of an ASR.

## 3 System Design

Our error correction procedure (Section 5) receives as input alternatives produced by an ASR, and generates modified versions of these alternatives. It employs the following modules: (1) a classifier that determines whether a word in a text produced by the ASR is correct; (2) a shallow semantic parser (SSP) that assigns semantic labels to segments in the text; and (3) a noisy channel error correction mechanism that decides which alterations should be made to the ASR output on the basis of the information provided by the other two modules. The resultant texts are given as input to the *Scusi?* spoken language interpretation system.

In this section, we describe the word error classifier and SSP together with our semantic labels, and report on their performance. We also provide a brief outline of the *Scusi?* system.

The performance of the classifier and SSP was evaluated in terms of accuracy over the corpus constructed to evaluate the *Scusi?* system (Kleinbauer et al., 2013). This corpus comprises 400 spoken descriptions generated by 26 speakers. We performed 13-fold cross-validation, where each fold contains two speakers (Section 6.1).

### 3.1 Word error classifier

We investigated three classifiers to determine whether a word in the ASR textual output is correct: the Weka implementation of Decision Trees (Quinlan, 1993) and Naïve Bayes classifiers (Domingos and Pazzani, 1997) ([cs.waikato.ac.nz/ml/weka/](http://cs.waikato.ac.nz/ml/weka/)), and the Mallet implementation of the linear chain Conditional Random Fields (CRF) algorithm (Lafferty et al., 2001) ([mallet.cs.umass.edu](http://mallet.cs.umass.edu)).

The best performance was obtained by the Decision Tree, which yielded an average accuracy of 80.9% over the 13 folds. The most influential features were  $rr(w, d)$  and Part-of-Speech (PoS) tag of the current word  $w$  in levels 1 and 2 of the Decision Tree respectively, where  $rr$  is the *repetition ratio* of the current word  $w$  in the textual ASR outputs for description  $d$ :

$$rr(w, d) = \frac{\# \text{ of ASR outputs for } d \text{ that contain } w}{\# \text{ of alternative ASR outputs for } d}.$$

### 3.2 Shallow Semantic Parser (SSP)

We found the following semantic labels useful for referring expressions:

- **Object** – a lexical item designating an object, optionally preceded by a determiner and one

or more gerunds, adjectives or nouns, e.g., “*the blue ceramic drinking mug*”.

- **Preposition** – a preposition or prepositional expression, e.g., “*on*” or “*further away from*”.
- **Landmark** – same pattern as Object, but a description may contain more than one landmark, e.g., “*the mug on the table in the corner*”.
- **Noise** – sighs or hesitations that are often misheard by the ASR as “*and*”, “*on*” or “*in*”.
- **Specifier** – a further specification that normally precedes a Landmark, e.g., “*the center of*”, “*front of*” or “*the left of*”. The preposition “*of*” at the end of a Specifier that precedes a Landmark is always required.
- **Additional** – words that are often superfluous, e.g., “*the mug that is on the table*”.

We employed the Mallet implementation of the linear chain Conditional Random Fields (CRF) algorithm (Lafferty et al., 2001) to learn sequences of semantic labels ([mallet.cs.umass.edu](http://mallet.cs.umass.edu)).

Accuracy over texts and segments was respectively measured as follows:

$$\frac{\text{\# of texts with perfectly matched label sequences}}{\text{total \# of texts}}$$
$$\frac{\text{\# of segments with perfectly matched labels}}{\text{total \# of segments}}$$

The CRF was trained separately for textual transcriptions of spoken descriptions and for ASR outputs. Two annotators labeled the 400 transcribed texts, and 800 samples from the ASR output: 400 from the best output and 400 from the worst. The first annotator segmented and labeled the descriptions, and the second annotator verified the annotations; disagreements were resolved by consensus.

We considered the features found useful in the CoNLL2001 shared task (<http://www.cnts.ua.ac.be/conll2000/chunking/>). The features that yielded the best performance were *current word*, *current PoS* and *previous word*, achieving an accuracy of 92% over the 400 textual transcriptions, and 76.13% over the 800 ASR outputs. Accuracy over segments was higher, at 96.26% for texts, and 87.28% for ASR outputs. However, SSP’s performance for the identification of Noise was rather poor, with an average accuracy of 54.75%.

### 3.3 Scusi?

*Scusi?* is a system that implements an anytime, probabilistic mechanism for the interpretation of

spoken utterances, focusing on a household context. It has four processing stages, where each stage produces multiple outputs for a given input, early processing stages may be probabilistically revisited, and only the most promising options at each stage are explored further.

The system takes as input a speech signal, and uses an ASR (Microsoft Speech SDK 6.1) to produce candidate texts. Each text is assigned a probability given the speech wave. The second stage applies Charniak’s probabilistic parser (<http://bllip.cs.brown.edu/resources.shtml#software>) to syntactically analyze the texts in order of their probability, yielding at most 50 different parse trees per text. The third stage applies mapping rules to the parse trees to generate concept graphs (Sowa, 1984) that represent the semantics of the utterance. The final stage instantiates the concept graphs within the current context. For example, given a parse tree for “*the blue mug on the table*”, the third stage returns the uninstantiated concept graph *mug(COLOR: blue) – on – table*. The final stage then returns candidate instantiated concept graphs, e.g., *mug1-location\_on-table2*, *mug2-location\_on-table1*. The probability of each instantiated concept graph depends on (1) how well the objects and relations in this graph match the corresponding objects and relations in the uninstantiated concept graph (e.g., whether *mug1* is a mug, and whether it is blue); and (2) how well the relations in this graph match the relations in the context (e.g., whether *mug1* is indeed on *table2*).

## 4 Probability Estimation

We use a distance measure inspired by the *Minimum Message Length (MML)* principle (Wallace, 2005) to estimate the goodness of a message and its semantic model. This principle is normally used for model selection, based on the following formulation:

$$\Pr(\text{data}\&\text{model}) = \Pr(\text{data}|\text{model}) \times \Pr(\text{model})$$

, which strikes a balance between model complexity and data fit, i.e., the highest-probability model that best explains the data is the best model overall. That is, the best model is not necessarily the model that fits the data best, as such a model may over-fit the data; the model itself must also have a high prior probability. In our case, the data is a text, either heard by the ASR or modified, and the model is a sequence of semantic labels. At present,

our model is restricted to semantic labels for segments in referring expressions, but in the future we will use this formalism to compare models representing different dialogue acts, e.g., commands.

Our use of the MML principle differs from its normal usage in that we employ it to compare a text and its semantic model with a modified version of this text and its own semantic model (rather than comparing two models that try to account for the same text). Modifications attract a penalty that depends on the probability that they are required (the higher the probability, the lower the penalty). This penalty is applied to prevent arbitrary modifications where a system hears what it expects.

Below we describe the estimation of the probability of a text and its semantic model. The next section describes the combination of the noisy channel model with the word-error classifier, SSP, and the modifications made to texts.

The joint probability of a Text and its Semantic Model is estimated as follows:

$$\Pr(\text{Text}\&\text{SemModel}) = \Pr(\text{Text}|\text{SemModel}) \times \Pr(\text{SemModel}),$$

where

- $\Pr(\text{SemModel}) = \Pr(\text{SSP}) \times \prod_{i=0}^{N+2} \Pr(L_i|L_0, \dots, L_{i-1}),$

where  $\Pr(\text{SSP})$  reflects SSP’s confidence in the sequence of semantic labels it produced for *Text*,  $N$  is the number of segments in the sequence,  $L_i$  is the label for segment  $i$ ,  $L_{-1}$  and  $L_0$  are the special labels **Beginning**, and  $L_{N+1}$  and  $L_{N+2}$  are the special labels **End**. To make this calculation tractable, we employ trigrams, i.e.,  $\Pr(L_i|L_0, \dots, L_{i-1}) \cong \Pr(L_i|L_{i-2}, L_{i-1}).$

- $\Pr(\text{Text}|\text{SemModel}) = \prod_{i=1}^N \Pr(\text{text}_i|L_i),$

where  $\text{text}_i$  is the sequence of words in segment  $i$ , and  $\Pr(\text{text}_i|L_i)$  is estimated as follows:

$$\Pr(\text{text}_i|L_i) = \prod_{j=1}^{M_i} \Pr(\text{HWord}_{ji}|L_i),$$

where  $M_i$  is the number of words in  $\text{text}_i$ , and  $\text{HWord}_{ji}$  is the  $j$ th heard word in  $\text{text}_i$ .

Owing to the relatively small size of our corpus,  $\Pr(\text{HWord}_{ji}|L_i)$  is roughly estimated as follows:

$$\Pr(\text{HWord}_{ji}|L_i) = \frac{\sum_{k=1}^{T_{ji}} \Pr(\text{HWord}_{ji}|\text{XpctPoS}_{kji})\Pr(\text{XpctPoS}_{kji}|L_i),$$

where  $\text{XpctPoS}_{kji}$  is a PoS expected at position  $j$  in *segment* <sub>$i$</sub> , and  $T_{ji}$  is the number of PoS expected

at position  $j$  in *segment* <sub>$i$</sub> .  $\Pr(\text{HWord}_{ji}|\text{XpctPoS}_{kji})$  is obtained from a corpus, and  $\Pr(\text{XpctPoS}_{kji}|L_i)$  is estimated from our textual transcriptions of spoken descriptions, except for the PoS associated with Noise, which are estimated from our spoken corpus (there is no Noise in texts). We obtain a rough estimate of  $\Pr(\text{XpctPoS}_{kji}|L_i)$  by considering three positions in a segment: first, middle (intermediate positions) and last. For instance, the possible PoS for the first position of an Object or Landmark are determiner, adjective, gerund, verb(past) or noun.

To illustrate this calculation, consider the second description in Table 1, which is heard as “to play it in the microwave”. The probability of the Semantic Model for this description is

$$\Pr(\text{SemModel}) = \Pr(O|B, B) \Pr(N|O, B) \Pr(P|N, O) \Pr(L|P, N) \Pr(E|L, P) \Pr(E|E, L).$$

All the probabilities involving Noise are set to an arbitrarily low  $\epsilon$ , which yields

$$\Pr(O|B, B) \Pr(E|L, P) \Pr(E|E, L) \epsilon^3.$$

The probability of the Text given the Semantic Model is

$$\Pr(\text{Text}|\text{SemModel}) = \Pr(\text{“to play”}|O) \Pr(\text{“it”}|N) \Pr(\text{“in”}|P) \Pr(\text{“the microwave”}|L),$$

which is quite high for “it”|N, “in”|P and “the microwave”|L, but is reduced due to the mismatch between the PoS of “to play” (TO VB) and the PoS expected by an Object, which are: DT/JJ/VBG/VBD/NN for the first position, and NN for the last position (Section 5.1.3).

Our system modifies this heard description by replacing “to play” with “the thing” and removing the noisy “it”, which yields “the thing in the microwave” (Section 5). The probability of the Semantic Model for this modified sentence is

$$\Pr(\text{SemModel}') = \Pr(O|B, B) \Pr(P|O, B) \Pr(L|P, O) \Pr(E|L, P) \Pr(E|E, L),$$

which is higher than that of the original Semantic Model, as is the probability of the new Text given the new Semantic Model:

$$\Pr(\text{Text}'|\text{SemModel}') = \Pr(\text{“the thing”}|O) \Pr(\text{“in”}|P) \Pr(\text{“the microwave”}|L).$$

However, this gain is offset by the penalties incurred by the modifications. The estimation of these penalties is described in the next section.

## 5 Noisy Channel Error Correction

Given a textual output produced by an ASR, we apply Algorithm 1 to remove noise, insert prepo-

sitions and replace wrong words. The probability of the resultant text and its semantic model is recalculated after each change as described in Section 4, and is moderated by the probability of the penalty for the change. Since a modification may yield a text where SSP identifies Noise, the Noise removal step is repeated after every change.

After each modification, the probability of the original text and semantic model is compared with the probability of the new text, its semantic model and any incurred penalties. The winning text and semantic model (without penalties) are then taken as the originals for the next modification. Upon completion of this process, all the incurred penalties are re-incorporated into the final probability of a modified text, in order to enable a fair comparison with other texts that were not altered.

The application of this process to all the texts produced by an ASR for a particular utterance may yield identical texts (e.g., when words with unexpected PoS are converted to “thing”). These texts are merged, and their probabilities are recalculated. The resultant texts are ranked in descending order of probability and ascending order of the number of replaced words (i.e., texts with fewer replacements are ranked ahead of texts with more replacements, irrespective of their probability). The final probabilities are adjusted to reflect the ranking of a text.

## 5.1 Estimating penalties from modifications

The modifications performed by our system attract a penalty that depends on the probability that the relevant portion of a heard utterance is wrong. The higher this probability, the lower the penalty, which is implemented as a multiplier of  $\Pr(\text{Text}\&\text{SemModel})$ .

### 5.1.1 Removing noise

The penalty for removing a heard word  $j$  in  $\text{segment}_i$  that is labeled as Noise by SSP is estimated on the basis of its probability of being Wrong (obtained from the word-error classifier, Section 3.1), as follows:

$$\Pr(\text{remove } H\text{Word}_{ji}) = \begin{cases} \Pr(\text{IsW}(H\text{Word}_{ji}))\Pr(\text{Class}) & \text{if label} = \text{W} \\ (1 - \Pr(\text{IsC}(H\text{Word}_{ji})))\Pr(\text{Class}) & \text{if label} = \text{C} \end{cases} \quad (1)$$

where  $\Pr(\text{Class})$  is the accuracy of the classifier (on training data),  $\Pr(\text{IsW}(H\text{Word}_{ji}))$  is the probability assigned by the classifier to heard word  $j$  in  $\text{segment}_i$  being Wrong, and  $\Pr(\text{IsC}(H\text{Word}_{ji}))$

---

```

---

is the probability of this word being Correct (the last two probabilities add up to 1).

The rationale for this formula is that if SSP deems a heard word to be Noise, and the classifier labels it Wrong with high probability, then its removal should cause only a small reduction in  $\Pr(\text{Text}\&\text{SemModel})$ . Conversely, if a heard word deemed to be Noise by SSP is labeled Correct by the classifier with high probability, then its removal should cause a large reduction in  $\Pr(\text{Text}\&\text{SemModel})$ . In both cases, the probabilities assigned to the labels by the classifier are moderated by the classifier’s accuracy.

To illustrate this process, let’s return to the example “to play it in the microwave”, where “it” is labeled Noise by SSP, and Wrong by the classifier with probability  $\Pr(\text{IsW}(\text{“it”}))$ . A new text *Text'* is obtained as a result of the removal of “it”, and the penalty  $\Pr(\text{IsW}(\text{“it”}))\Pr(\text{Class})$  is multiplied by the new  $\Pr(\text{Text}'\&\text{SemModel}')$ .

### 5.1.2 Inserting a preposition

If a preposition is not found in a position where one is expected, e.g., between an Object and Landmark or between an Object and a Specifier, we insert a generic preposition “at”. The penalty

for the insertion of a preposition depends on the probability that the ASR failed to hear an uttered preposition, which is estimated as follows:

$\Pr(\text{insert } P_i) = \Pr(P_i \text{ appears in } \textit{Text} \text{ and doesn't appear in the ASR output for } \textit{Text})$ , where  $P_i$  is a preposition in position  $i$  in  $\textit{Text}$ .

To determine the frequency of this event, we employ an edit distance algorithm that aligns the texts produced by the ASR with their corresponding textual transcriptions. This was done for 800 alternatives produced by the ASR (400 best and 400 worst), yielding a probability of 0.02 of the ASR dropping a preposition. The corresponding penalty for inserting a preposition (0.02) is hopefully offset by the increase in  $\Pr(\textit{SemModel}')$  as a result of this insertion. For instance, the probability of the Semantic Model for the heard description (without a preposition) in the first example in Table 1 is

$$\Pr(\textit{SemModel}) = \Pr(O|B, B) \Pr(S|O, B) \Pr(L|S, O) \Pr(E|L, S) \Pr(E|E, L),$$

where  $\Pr(S|O, B)$  and  $\Pr(L|S, O)$  are low, as they are ungrammatical. After adding the preposition,

$$\Pr(\textit{SemModel}') = \Pr(O|B, B) \Pr(P|O, B) \Pr(S|P, O) \Pr(L|S, P) \Pr(E|L, S) \Pr(E|E, L).$$

Although the new expression has an extra factor, the probabilities of the new factors are higher than those of their original counterparts.

### 5.1.3 Replacing a word

The decision to replace a word is based on the match between expected PoS and the PoS of a heard word. If they match, no replacement is performed. Otherwise, replacements are performed by applying the following rules, which are based on the PoS expected by the different types of segments at each position (first, middle, last).

- **Objects and Landmarks** – The expected PoS for Objects and Landmarks are: DT/JJ/VBG/VBD/NN for the first word, JJ/VBG/VBD/NN for the middle words, and NN for the last word. Thus, if there is a PoS mismatch, we perform the following replacements (if there is only one word in an Object or Landmark, we replace it with “thing” (NN)):

- $HWord_1 \Rightarrow$  “the” (DT)
- $HWord_{mid} \Rightarrow$  “unknown” (JJ) (multiple times)
- $HWord_{last} \Rightarrow$  “thing” (NN)

To illustrate this process, consider the heard Object “to:TO battle:NN played:VB”, which

is replaced with “the:DT battle:NN thing:NN”. Even though “battle” is incorrect, it is not modified, as its PoS is expected. However, *Scusi?* can cope with such unknown object attributes.

- **Prepositions and Prepositional Phrases** – This segment is more restricted than Objects and Landmarks, as it is largely composed of closed class words. We therefore use edit distance to find the prepositional phrase in the corpus of textual transcriptions that best matches the words in a heard prepositional phrase. The phrase from the corpus then replaces the heard segment. If there is no best-matching prepositional phrase, the generic “at” is used as a replacement. For example, “for the wave from” is replaced with “further away from” (with “from” being the next-best match), while “a all” is replaced with “at”.
- **Specifiers** – This segment is similar to Objects and Landmarks plus a final “of” when it precedes a Landmark (about 5% of the descriptions had Specifiers without Landmarks). In addition, the head noun, which is normally the penultimate word in a Specifier, must be a positional noun, such as “center”, “edge” or “corner”. Thus, a word is replaced if a PoS mismatch occurs or the penultimate word is not an expected positional noun, as follows:

- $HWord_1 \Rightarrow$  “the” (DT)
- $HWord_{mid} \Rightarrow$  “unknown” (JJ) (multiple times)
- $HWord_{last-1} \Rightarrow$  “position” (NN)
- $HWord_{last} \Rightarrow$  “of” (IN, preposition)

For instance, given the Specifier “the:DT ride:NN into:IN” followed by a Landmark, “of:IN” is appended, and “into:IN” is replaced with “position:NN”, yielding “the:DT ride:NN position:NN of:IN”. Clearly, other replacement options are possible, which will be investigated in the future.

In principle, the penalty for replacing a word should depend on both the probability that it is wrong (as for noise removal) and on the similarity between the wrong word and the proposed replacement. That is, the higher the probability that a word is wrong, and the higher the similarity between the original word and the replacement, the lower the penalty for the replacement. However, at present, we replace words that do not match an

expected PoS only with generic options, e.g., “unknown” for expected adjectives, “thing” for expected nouns in Objects and Landmarks, and “position” for expected positional nouns in Specifiers. Thus, our penalty consists only of the first of the above factors moderated by a generic similarity factor  $\delta (= 0.5)$ , as follows:

$$\Pr(\text{replace } H\text{Word}_{ji}) = \quad (2)$$

$$\begin{cases} \delta \Pr(\text{IsW}(H\text{Word}_{ji}))\Pr(\text{Class}) & \text{if label} = \text{W} \\ \delta (1 - \Pr(\text{IsC}(H\text{Word}_{ji})))\Pr(\text{Class}) & \text{if label} = \text{C} \end{cases}$$

In the future, the generic  $\delta$  will be replaced by a function of the similarity between an original word and its candidate replacements.

## 6 Evaluation

In this section, we describe our corpus and evaluation metrics, and compare the results obtained with *Scusi?* plus error correction with those obtained by the original *Scusi?* system.

### 6.1 Corpus

Our model’s performance was evaluated using part of the corpus constructed to evaluate the *Scusi?* system (Kleinbauer et al., 2013). The original corpus comprises 432 free-form descriptions spoken by 26 trial subjects to refer to 12 designated objects in four scenarios (three objects per scenario, where a scenario contains between 8 and 16 objects; participants repeated or rephrased some descriptions). 32 descriptions could not be processed by the ASR, and 105 contained constructs that could not be represented by *Scusi?*. The remaining 295 descriptions were used in our evaluation.

The descriptions, which varied in length and complexity, had an average description length of 10 words. Sample descriptions are: “the green plate next to the screwdriver at the top of the table”, “the large pink ball in the middle of the room”, “the plate on the corner of the table” and “the computer under the table”.

### 6.2 Evaluation metrics

We use the evaluation metrics discussed in (Kleinbauer et al., 2013), viz *%NotFound@N*, the percentage of descriptions that have no correct interpretation within the top  $N$  ranks; *Fractional Recall@N* (*FRecall@N*), which represents the fact that the ranked order of equiprobable interpretations is arbitrary; and *Normalized Discounted Cumulative Gain@N* (*NDCG@N*), which discounts interpretations with higher (worse) ranks (Järvelin

and Kekäläinen, 2002). The last two metrics are defined as follows:

$$F\text{Recall}@N(d) = \frac{\sum_{j=1}^N fc(I_j)}{|C(d)|},$$

where  $d$  is a description,  $C(d)$  is the set of correct interpretations for  $d$ ,  $I_j$  is an interpretation generated by *Scusi?* at rank  $j$ , and  $fc$  is the fraction of correct interpretations among those with the same probability as  $I_j$  (this is a proxy for the probability that  $I_j$  is correct):

$$fc(I_j) = \frac{c_j}{h_j - l_j + 1},$$

where  $l_j$  is the lowest rank of all the interpretations with the same probability as  $I_j$ ,  $h_j$  the highest rank, and  $c_j$  the number of correct interpretations between rank  $l_j$  and  $h_j$  inclusively.

*DCG@N* allows the definition of a relevance measure for a result, and divides this measure by a logarithmic penalty that reflects the rank of the result. Using  $fc(I_j)$  as a measure of the relevance of interpretation  $I_j$ , we obtain

$$DCG@N(d) = fc(I_1) + \sum_{j=2}^N \frac{fc(I_j)}{\log_2 j}.$$

This score is normalized to the  $[0, 1]$  range by dividing it by the score of an ideal answer where  $|C(d)|$  correct interpretations are ranked in the top  $|C(d)|$  places, yielding

$$NDCG@N(d) = \frac{DCG@N(d)}{1 + \sum_{j=2}^{\min\{|C(d)|, N\}} \frac{1}{\log_2 j}}$$

### 6.3 Results

Table 2 compares the performance of the original *Scusi?* system with that of *Scusi?* plus error correction, and displays the performance obtained for three types of modifications: N+P, P+R and N+P+R, where N stands for noise removal, P for preposition insertion, and R for word replacement (preposition insertion was folded into all the options, as it happens in only 2% of the cases). The table shows the average of *%NotFound*, *FRecall* and *NDCG* for the 295 descriptions in our corpus. The best performance is boldfaced.

As seen in Table 2, *Scusi?* plus error correction with word replacement generally outperforms the original *Scusi?* system (the Object/Landmark replacement has the greatest impact on performance among the three types of word replacements). *Scusi?*+N+P+R yields the best overall performance for *FRecall@∞* and

Table 2: Performance comparison: original *Scusi?* versus *Scusi?* + Noisy Channel Error Correction.

Average of	<i>Scusi?</i> Noisy Channel Error Correction			
		N+P	P+R	N+P+R
<i>%NotFound@∞</i>	22.37%	22.03%	14.24%	<b>13.90%</b>
<i>%NotFound@20</i>	28.14%	28.47%	<b>23.39%</b>	24.41%
<i>%NotFound@10</i>	31.86%	31.19%	<b>24.75%</b>	26.78%
<i>%NotFound@3</i>	37.97%	40.00%	<b>32.88%</b>	36.27%
<i>%NotFound@1</i>	44.75%	47.80%	<b>40.00%</b>	44.41%
<i>FRecall@∞</i>	0.776	0.778	0.858	<b>0.859</b>
<i>FRecall@20</i>	0.709	0.699	<b>0.753</b>	0.741
<i>FRecall@10</i>	0.667	0.662	<b>0.731</b>	0.712
<i>FRecall@3</i>	0.598	0.567	<b>0.636</b>	0.600
<i>FRecall@1</i>	0.488	0.462	<b>0.508</b>	0.481
<i>NDCG@∞</i>	0.641	0.626	<b>0.688</b>	0.666
<i>NDCG@20</i>	0.628	0.610	<b>0.669</b>	0.644
<i>NDCG@10</i>	0.617	0.601	<b>0.663</b>	0.636
<i>NDCG@3</i>	0.589	0.562	<b>0.624</b>	0.591
<i>NDCG@1</i>	0.516	0.490	<b>0.538</b>	0.511

*%NotFound@∞* (statistically significantly better than *Scusi?* with  $p < 0.01$  for the Wilcoxon signed rank test), while *Scusi?*+P+R yields the best performance for the remaining measures (statistically significantly better than *Scusi?* for *FRecall@∞,20,10,3*, *NDCG@∞,20,10,3* and all values of *%NotFound*; and statistically significantly better than *Scusi?*+N+P+R for *FRecall@3,1*, all values of *NDCG* and *%NotFound@3,1*,  $p \leq 0.05$ ). The fact that *Scusi?*+N+P+R outperforms *Scusi?*+P+R only for *%NotFound@∞* and *FRecall@∞* indicates that while the combination of noise removal with the other corrections enables *Scusi?* to find additional correct interpretations, these interpretations tend to appear in high (bad) ranks. The performance of *Scusi?*+N+P is generally worse than that of the original *Scusi?* system — a disappointing outcome that may be attributed to the low accuracy of SSP in the identification of Noise (54.75%, Section 3.2).

Further examination of our results reveals the following types of errors: (1) ASR errors that rendered a description unprocessable by other stages, e.g., “the green plate next to the hammer” heard as “*degree in applied next to him are*”, and “the picture above the table” heard as “the picture *of the that*”; (2) ASR errors that were not corrected, as the PoS was expected, e.g., “the center *off/IN* the table”; (3) wrong expression replacements, e.g., “the plate:O | next to *scholar of:P*” corrected as “the plate:O | next to:P”; and (4) out of vocabulary terms, e.g., “motherboard” and “frame”.

An interesting pattern emerges when considering ASR errors. Both *Scusi?*+N+P+R and *Scusi?*+P+R outperform the original version of

Table 3: Performance broken down by SER.

ASR output	Average of	<i>Scusi?</i>	P+R	N+P+R
all wrong (193 desc.)	<i>%NotFound@1</i>	61.66%	<b>52.85%</b>	54.40%
	<i>%NotFound@10</i>	44.56%	<b>33.68%</b>	35.75%
one correct (102 desc.)	<i>%NotFound@1</i>	<b>12.75%</b>	15.69%	25.50%
	<i>%NotFound@10</i>	<b>7.84%</b>	<b>7.84%</b>	9.80%

*Scusi?* for the 193 descriptions with no correct textual interpretation (SER = 65.3%, Section 1), while the original version of *Scusi?* performs at least as well as the best option, *Scusi?*+P+R, for the 102 descriptions where a correct textual interpretation was found (Table 3). This indicates that SSP is over-zealous in finding errors, and its performance must be further investigated, or another mode of operation considered (e.g., retaining both the original and the modified ASR output).

## 7 Discussion and Future Work

We have offered a noisy channel approach for error correction in spoken utterances, with a first-stage implementation that corrects errors by removing noise, inserting prepositions, and replacing wrong words with generic terms. Our approach yields significant improvements in interpretation performance, and shows promise for achieving further improvements with more sophisticated interventions.

The structure of referring expressions is rather rigid in terms of the order of the semantic segments. To test the general applicability of our noisy channel model, we propose to consider other types of dialogue acts, and take into account the expectations from the dialogue, e.g., “to play a CD” is modified when it is considered a mis-heard description, but if it were a response to the question “what would you like me to do?”, no changes would be required. In addition, we will extend our approach to propose specific, rather than generic, word replacements, and to handle superfluous information (i.e., information that is meaningless to the language interpretation module) or missing information (e.g., missing landmarks). Another avenue of research involves versions of *Scusi?* that employ SSP as an alternative to or in combination with a syntactic parser.

# Natural Language Query Refinement for Problem Resolution from Crowd-Sourced Semi-Structured Data

Rashmi Gangadharaiah and Balakrishnan Narayanaswamy

IBM Research,

India Research Lab

{rashgang,murali.balakrishnan}@in.ibm.com

## Abstract

We study the problem of natural language query generation for decision support systems (DSS) in the problem resolution domain. In this domain, a user has a task he is unable to accomplish (eg. *bluetooth headphone not playing music*), which we capture using language structures. We show how important units that define a problem can robustly and automatically be extracted from large noisy online forum data, with no labeled data or query logs. We also show how these units can be selected to reduce the number of interactions and how they can be used to generate natural language interactions for query refinement.

## 1 Introduction

Decision Support Systems (DSSs) that help decision makers extract useful knowledge from large amounts of data have found widespread application in areas ranging from clinical and medical diagnosis (Musen et al., 2006) to banking and credit verification (Palma-dos Reis et al., 1999). IBM's Watson Deep Question Answering system (Ferrucci et al., 2010), can be applied to DSSs to diagnose and recommend treatments for lung cancer and to help manage health insurance decisions and claims<sup>1</sup>. Motivated by the rapid explosion of contact centres, we focus on the application of DSSs to assist technical contact center agents.

Contact center DSSs should be designed to assist an agent in the *problem resolution* domain. This domain is characterized by a user calling in to a contact center with the problem of being unable to perform an action with their product (e.g. *I am unable to connect to youtube*). Currently contact center DSSs are essentially search engines for

technical manuals. However, this has two shortcomings : (i) in most cutting edge consumer technology, like software and smart devices, the range of possible applications and use cases makes it impossible to list all of them in the manuals- limiting their usefulness under the heavy tailed nature of customer problems, (ii) contact centers are known to suffer from high churn due to pressures and difficulties of the jobs, particularly the need for rapid resolution, making ease of use essential since users of these DSSs are somewhere between experts (in using the system) and novices (in the actual technology customers need help with).

With the birth and growth of the Web 2.0 and in particular, large and active online product forums, such as, Yahoo! Answers<sup>2</sup>, Ubuntu Forums<sup>3</sup> and Apple Support Communities<sup>4</sup>, there is the hope that other technology savvy users will find and resolve large number of problems within days of the release of a product. However, these forums are *noisy*, i.e. they contain many throw-away comments and erroneous solutions. The first important question we address in this paper is, how can we mine relevant information from online forums and, in essence, *crowdsource* the creation of contact center DSSs? In particular, we show how many problems faced by consumers can be captured by *actions on attributes* (e.g. *bluetooth headphone not playing music*).

In order to address the second shortcoming, we study the problem of automatic *interactive* query refinement in DSSs. When DSSs are used by non-computer scientists, natural language understanding and interaction problems take center-stage (Alter, 1977). Since both customers and agents are not experts in a technical area, mis-understandings are common. As agents are evaluated based on the number of problems resolved, it is often the case

<sup>1</sup><http://www.ihealthbeat.org/articles/2013/2/11/ibm-offering-two-new-decision-support-tools-based-on-watson.aspx>

<sup>2</sup><http://answers.yahoo.com/>

<sup>3</sup><http://ubuntuforums.org/>

<sup>4</sup><https://discussions.apple.com/>

that queries entered by an agent are underspecified. In response to such a query, a search engine may return a large number of documents. For complicated technical queries, the time taken by an agent to read the long list of returned information and possibly reformulate the query could be significant. The second question we address in this paper is how can a DSS make *natural language* suggestions that assist the agent in acquiring additional information from a caller to resolve her problem in the shortest amount of time? Finally, for rapid prototyping and deployment, we develop a system and architecture that *does not use any form of labeled data or query logs*, a big differentiator from prior work. Query Logs are not always available for enterprise systems that are not on the web and/or have a smaller user base (Bhatia et al., 2011). When software and hardware change rapidly over time, it is infeasible to quickly collect large query logs. Also, logs may not always be accessible due to privacy and legal constraints.

To the best of our knowledge, this paper presents the first interactive system (and detailed evaluation thereof) for natural language problem resolution in the absence of manually labeled logs or pre-determined dialog state sequences. Concretely, our primary contributions are:

- **Problem Representation and Unit Extraction:** We define and automatically extract units that best represent a problem. We show how to do this robustly from noisy forum threads, allowing us to use abundant online user generated content.
- **Unit selection for Interaction:** We propose and evaluate a complete interactive system for users to quickly find a resolution based on semi-structured online forum data. Follow up questions are generated automatically from the retrieved results to minimize the number of interactions.
- **Natural Language Question Generation:** We demonstrate that, in a dialog system it is possible and useful to automatically generate fluent interactions based on the units we define *using appropriate templates*. We use these to create follow up questions to the user, which have much needed context, and show that this improves precision.

## 2 Proposed System

In online forums, people facing issues with their product (thread initiators) post their problems and other users write subsequent posts discussing solutions. These threads form a rich data source that

could contain problems similar to what a user who calls in to the contact center faces, and can be used to find an appropriate solution. Our system (Figure 1) has two phases. In the offline phase, the system extracts units that describe the problem being discussed. In the online phase, the interaction engine selects the most appropriate units that best divide the space of search results obtained, to minimize the number of interactions. The system then generates follow up interactions by inserting the units into appropriate unit type dependent templates. The answers to these follow up questions are used to improve the search results.

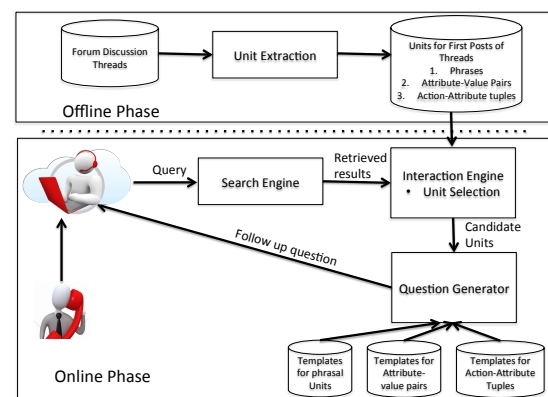

Figure 1: System Description

### 2.1 Representational Units

It is important to select representational units that capture the signature, or the most important characteristics of the information that users search for. This signature should be sufficient to find relevant results. In order to understand the right units for the problem resolution domain, we conducted the following user study. Five annotators analyzed the first posts from 50 threads from the Apple Discussion Forum, and were asked to mark the most relevant short segments of the post that best described the problem (an example in Table 1).

<p>I cannot hear the notifications on my bluetooth now. it's at normal volume when i send a message, if i receive an email or text volume is very low yet I have all volumes up all the way. Is there a new bluetooth volume i have to turn up? or did another update screw the bluetooth . Was working just great before i updated to ios - 4 . please help me.</p>
--

Table 1: Relevant short segments for a forum post.

Based on the user study, the first kind of units we considered were **phrases**, which are consecutive words that occur very frequently in the thread.

Phrases as query suggestions have been shown to improve user experience when compared to just showing terms (Kelly et al., 2009) since longer phrases tend to provide more context information. One shortcoming of these contiguous phrasal units is that they are sensitive to typography, i.e. small changes in phrasing (e.g. *ios - 4* and *ios 4*) lead to different phrases and the occurrence counts are divided among these variations. This causes difficulties both in the problem representation as well as in the search for problem resolution which are exacerbated by the noisy, casual syntax in forums. Motivated by Probst et al. (2007), we extract **attribute-value pairs**. These units provide both robustness as well as more configurational context to the problem. Another observation from the segments marked was that many of them involved a user wanting to perform an action (*I cannot hear notifications on bluetooth*) or the problems caused by a user’s action (*working great before I updated*). We capture them using **action-attribute tuples** (details in Section 3.1.1).

Thread initiators describe the same problem in different ways leading to multiple threads discussing the same problem. Ideally, we want the representation of the problem to be the same for all these threads to build robust statistics. Consider the following examples, *sync server has failed*, *sync server failed*, *sync server had failed*, *sync server has been failing*. While the phrasing is different, we see that their dependency parse trees (Figure 2) show a common relation between the verb or action, *fail*, and the attribute *sync server* (the base form of the verbs are obtained from their corresponding lemmas with TreeTagger (Schmid, 1994)). Motivated by this, we use dependency parse trees for extracting action-attribute tuples.

Figure 2: Dependency Parse Trees for various forms of the same problem.

### 3 Detailed System Description

We now give a detailed description, showing how the three types of units can be robustly extracted and used from noisy online forums.

## 3.1 Offline Component

In the offline phase we first extract candidate units that describe a problem (and its solution) from the forum threads. We then filter this description, using the thread itself, to retain the important units.

### 3.1.1 Candidates for Problem Description

Sentences are tagged and parsed using the Stanford dependency parser (de Marneffe et al., 2006). The following units are then obtained from the first post of the discussion thread.

**Phrasal units:** defined to be Noun Phrases satisfying the regular expression,  $(Adjective)^* (Number/Noun/Proper\ Noun)^+$ , (eg., *interactive web sites*, *osx widgets*, *2007 outlook calendar*). These are extracted from the discussion thread along with their frequencies of occurrence.

**Attribute-Value pairs:** The dependency relations *amod* (adjectival modifier of a noun phrase) and *num* (numeric modifier of a noun) in the parsed output are used for this purpose. In the case of *amod*, the attribute is the noun that the adjective modifies and its value is the adjective. For example, with *amod(signal, strong)*, the attribute is *signal* and its value is *strong*. In the case of *num*, the attribute is the noun and its value is the numeric modifier. For example, with *num(digits, 10)*, the attribute is *digits* and its value is *10*. As mentioned in Section 2.1, these pairs capture more context of the problem being discussed. Additional attribute-value pairs are extracted by expanding the attributes with the adjacent nouns and adjectives that occur with it. For the example in Figure 3, the attribute *signal* is modified to *cell phone signal* and added to the list of attribute-value pairs along with their frequencies of occurrence.

**Action-Attribute tuples:** The dependency relations used for these units are given in Table 3 with examples. Many of these units help describe the user’s problem while others provide contextual information behind the problem being discussed. These units are described with 4-tuples  $(Arg_1-verb-Arg_2-Arg_3)$ , three of which are the arguments of the verb or attributes of an action. The relations given in the first column of Table 3 form fillers for the attributes of the action. The example in Figure 3 gives the tuple, *I-entered-dns-null*, where, *I* is the subject, *entered* is the action performed, *dns* is the object. If the verb has a *prt* relation, the particle is appended to the verb. For example, *turned* has a *prt* relation in *prt(turned, off)*,

First Post	I cannot hear the notifications on my bluetooth now. it's at normal volume when i send a message but if i receive an email or text the volume is very low yet I have all volumes up all the way. Is there a new bluetooth volume i have to turn up with ios - 4? or is it that another update screwed with the bluetooth again. Was working just great before i updated ios - 4. please help me. thanks!
Phrases	volume, bluetooth volume, bluetooth, notifications, update, ios, normal volume, work, text, way, email, message, new bluetooth volume,
Phrases + Att-Val pairs	volume, bluetooth volume, bluetooth, notifications, update, ios, normal volume, work, text, way, email, message, new bluetooth volume, ios 4
Phrases + Att-Val pairs + Act-Att tuples	volume, bluetooth volume, bluetooth, notifications, update, ios, normal volume, work, text, way, email, message, new bluetooth volume, ios 4, low volume, I hear notifications on bluetooth, update screwed bluetooth, I send message, I receive email, it is at normal volume, working great before updated, I missed emails, *I volumes way.

Table 2: Problem representations for a forum post.

hence, the verb is now modified to *turned off*. Since *entered* in this example takes only a subject and an object as arguments, the third argument is *null*. Consider another example, *I removed the wep password in the router settings*, the tuple is now *I-removed-password-in the settings*. The last row in Table 3 gives an example of the usage of the *xcomp* relation. As done with Attribute-Value pairs, the attributes in these units are also expanded with the adjacent nouns and adjectives and added to the list of Action-Attribute tuples along with their frequencies of occurrence in the entire thread.

### 3.1.2 Scoring and Filtering

Since the problem is defined by the thread initiator in the first post of the thread, units in the first post are scored and ranked based on tf-idf (Manning et al., 2008). We treat each thread as a document and the top 50 highest scoring candidates form the problem description for the thread. Units are extracted from the rest of the thread in order to obtain frequency statistics for the units in the first post. Pronouns, prepositions and determiners are dropped from the units while obtaining the counts. In addition, verbs in the action-attribute tuples are converted to their base form using the lemma information obtained from TreeTagger (Schmid, 1994), to obtain counts. This makes the scores robust to small variations in the units.

Examples of extracted units are shown in Table 2. We see that errors in the parse (*volumes* was tagged as a verb) cause erroneous units (*\*I volumes up*). For this reason, we use frequency statistics from the rest of the discussion thread, to determine if a unit is valid or not. The tf-idf based scheme also removes commonly used phrases such as, *please help me, thank you*, etc.

## 3.2 Online Phase

The system searches for a set of initial documents based on the user's initial query. Next, the follow-up candidate units are selected (Section 3.2.1) from the units extracted in the offline phase for the

Figure 3: Dependency parse: *I entered the dns because I do not have a strong cell phone signal*.

retrieved documents and natural language interactions are further generated by filling the templates (Section 3.2.2) with the selected units.

### 3.2.1 Selection of candidate units for Question Generation

Interactions should be selected to (i) understand the user's requirements better by making the query more specific and reduce the number of results returned by the search engine, and (ii) reduce the number of interactions required. We use information gain to find the best unit that reduces the search space, motivated by its near optimality (Golovin et al., 2010). If  $S$  is the set of all retrieved documents,  $S_1 \subseteq S$  containing  $unit_i$  and  $S_2$  is a subset of  $S$  that do not contain  $unit_i$ , the gain from branching (or interacting) on  $unit_i$  is,

$$Gain(S, unit_i) = E(S) - \frac{|S_1|}{|S|} E(S_1) - \frac{|S_2|}{|S|} E(S_2) \quad (1)$$

$$E(S) = \sum_{k=1, \dots, |S|} -p(doc_k) \log_2 p(doc_k) \quad (2)$$

Where, each document is assigned a probability based on its rank in the search results:

$$p(doc_j) = \frac{\frac{1}{rank(doc_j)}}{\sum_{k=1, \dots, |S|} \frac{1}{rank(doc_k)}} \quad (3)$$

The unit that gives the highest information gain forms the candidate for question generation. Information gain has been widely used in Decision Trees (Mitchell, 1997), where the nodes represent attributes and the edges indicate values, and is known to result in short trees. In our case, the nodes represent the follow up questions and the edges indicate whether the user's answer is *yes* or

Relation	Example	Attributes(Arg <sub>1</sub> /Arg <sub>2</sub> /Arg <sub>3</sub> )	Action(Verb)
nsubj	nsubj(entered,I)	I (Arg <sub>1</sub> )	entered
dobj	dobj(entered,dns)	dns (Arg <sub>2</sub> )	entered
iobj	iobj(give, address)	address (Arg <sub>3</sub> )	address
pobj	prep(connect,to), pobj(to,wifi)	wifi(Arg <sub>2</sub> )	connect
prep_(to,into, etc)	prep_in(removed,settings)	in the settings (Arg <sub>3</sub> if Arg <sub>2</sub> not present, else Arg <sub>2</sub> )	removed
xcomp	xcomp(prompt, connect), prep_to(connect,wifi), nsubj (prompt, password)	password(Arg <sub>1</sub> ), to wifi (Arg <sub>2</sub> )	prompt to connect

Table 3: Dependency relations used to extract Action-Attribute tuples

*no*. The goal in decision trees is to quickly exhaust the space of examples with fewer steps, resulting in shorter trees. The goal in this paper is to traverse the space of results obtained with the initial query to reach the most relevant document with the fewest interactions. Since the dialog problem can be easily mapped to decision trees, the choice of information gain allows the user to arrive at the most relevant document with the smallest number of interactions in the online phase.

### 3.2.2 Question Generation

Questions are generated based on the type, number and tense information present in the units. The list of templates used for question generation is given in Table 4. Once a candidate unit is selected, a template is chosen based on its type. Phrasal units have a single template. If an attribute has two values with very similar information gains, the template for Attribute-Value pairs accommodates the different values. For example, if the pairs, *Outlook:2003* and *Outlook:2007* have very similar gains, the question would then be *Is your outlook: Option<sub>1</sub>:2003 Option<sub>2</sub>:2007 ?* and the user has the option to click on the one that is relevant to his query. For Action-Attribute tuples, the templates are chosen based on the the person, number and tense information from the verbs (Table 4). *null* in the table (for example, *null-send-emails-null*) indicates that a particular argument does not exist or was not found and hence the argument will not be added to the appropriate template. Certain templates require converting the verb to a different form (e.g., *VBD* to *VBN*). This mapping is stored as a dictionary obtained by running the TreeTagger on the entire dataset and various forms are automatically obtained by linking them to the lemmas of the verbs (for example, *give(VB/lemma) gave(VBD) given(VBN) gives(VBZ)*).

## 4 Results and Discussion

To evaluate our system, we built and simulated a contact center DSS for iPhone problem resolution.

### 4.1 Description of Dataset

We crawled threads created during the period 2007-2011 from the Apple Discussion Forum resulting in about 147,000 discussion threads. In order to create a test data set, threads were clustered treating each discussion thread as a data point using a tf-idf representation. The thread nearest the centroid from the 60 largest clusters were marked as the ‘most common’ problems.

<p>Underspecified Query 1: “cannot sync calendar”  Forms 6 specific queries</p> <ol style="list-style-type: none"> <li>1. because iphone disconnected</li> <li>2. because the sync server failed to sync</li> <li>3. because the sync session could not be started</li> <li>4. because the phone freezes</li> <li>5. error occurred while mingling data</li> <li>6. error occurred while merging data</li> </ol>
--

Table 5: Specific and under-specified queries

To generate specific and under-specified queries on this data set, in our experiments, we use the first post as a proxy for the problem description. An annotator created one short query (underspecified) from the first post of each of the 60 selected threads. These queries were given to the Lemur search engine (Strohman et al., 2005) to retrieve the 50 most similar threads from an index built on the entire set of 147,000 threads. He manually analyzed the first posts of the retrieved threads to create contexts, resulting in 217 specific queries. To understand this process we give an example from our data creation in Table 5. Starting from an under-specified query *cannot sync calendar*, the annotator found 6 specific queries. Two other annotators, were given these specific queries along with the search engine’s results from the corresponding under-specified query. They were asked to choose the most relevant results for the specific queries. The intersection of the choices of the annotators formed our ‘gold standard’.

### 4.2 User based analysis of the problem representation and unit extraction

We conducted two user studies to determine the (subjective) value of our problem representation,

Unit's Type	Template (with examples)
Phrases	Is your query related to <i>[unit]</i> ? eg: Is your query related to <i>osx widgets</i> ?
Attribute-Value pairs (if single value)	Is your <i>[attribute]</i> <i>[value]</i> ? eg: Is your <i>wifi signal strong</i> ?
Attribute-Value pairs (if multiple values)	Is your <i>[attribute]</i> : Option <sub>1</sub> : <i>[value<sub>1</sub>]</i> ... Option <sub>n</sub> : <i>[value<sub>n</sub>]</i> ? eg: Is your <i>outlook calendar</i> : Option <sub>1</sub> : <i>2003</i> Option <sub>2</sub> : <i>2007</i> ?
Action-Attribute tuples (Verb/Action is VB: base form)  ARG <sub>1</sub> is empty / ARG <sub>1</sub> is a pronoun	Does the <i>[ARG<sub>1</sub>(sg)] [VERB]</i> the <i>[ARG<sub>2</sub>] [ARG<sub>3</sub>]</i> ? Do the <i>[ARG<sub>1</sub>(pl)] [VERB]</i> the <i>[ARG<sub>2</sub>] [ARG<sub>3</sub>]</i> ? Do you want to <i>[VERB]</i> the <i>[ARG<sub>2</sub>] [ARG<sub>3</sub>]</i> ? eg: Does the <i>wifi network prompt</i> the <i>password</i> ? from the tuple: <i>wifi network-prompt-password-null</i>
Action-Attribute (Verb/Action is VBP: non-3rd person, singular, present) ARG <sub>1</sub> is empty / ARG <sub>1</sub> is a pronoun	<i>[ARG<sub>1</sub>] [VERB] [ARG<sub>2</sub>] [ARG<sub>3</sub>]</i> ? Do you want to <i>[VERB]</i> the <i>[ARG<sub>2</sub>] [ARG<sub>3</sub>]</i> ? eg: Do you want to <i>send</i> the <i>emails</i> ? from the tuple: <i>null-send-emails-null</i>
Action-Attribute (Verb/Action is VBN: past participle) ARG <sub>1</sub> is empty / ARG <sub>1</sub> is a pronoun ARG <sub>2</sub> and ARG <sub>3</sub> are empty ARG <sub>2</sub> and ARG <sub>3</sub> are empty	Have you <i>[VERB] [ARG<sub>2</sub>] [ARG<sub>3</sub>]</i> ? Has the <i>[ARG<sub>1</sub>(sg)]</i> been <i>[VERB]</i> ? Have the <i>[ARG<sub>1</sub>(pl)]</i> been <i>[VERB]</i> ? Has the <i>[ARG<sub>1</sub>(sg)] [VERB]</i> the <i>[ARG<sub>2</sub>] [ARG<sub>3</sub>]</i> ? Have the <i>[ARG<sub>1</sub>(pl)] [VERB]</i> the <i>[ARG<sub>2</sub>] [ARG<sub>3</sub>]</i> ? eg: Has the <i>update caused</i> the <i>phone to crash</i> ? from the tuple: <i>update-caused-phone-to crash</i>
Action-Attribute (Verb/Action is VBZ: 3rd person, singular, present) ARG <sub>1</sub> is empty	Does the <i>[ARG<sub>1</sub>] [VERB<sub>VB</sub>]</i> the <i>[ARG<sub>2</sub>] [ARG<sub>3</sub>]</i> ? Does the <i>phone [VERB<sub>VB</sub>]</i> the <i>[ARG<sub>2</sub>] [ARG<sub>3</sub>]</i> ? eg: Does the <i>iphone use idol support</i> from the tuple: <i>iphone-uses-idol support-null</i>
Action-Attribute (Verb/Action is VBD: past tense) ARG <sub>1</sub> is empty ARG <sub>1</sub> is empty ARG <sub>1</sub> is a pronoun	Has the <i>[ARG<sub>1</sub>(sg)] [VERB<sub>VBN</sub>] [ARG<sub>2</sub>] [ARG<sub>3</sub>]</i> ? Have the <i>[ARG<sub>2</sub>(pl)] [ARG<sub>3</sub>]</i> been <i>[VERB<sub>VBN</sub>]</i> ? Is the <i>[ARG<sub>2</sub>(sg)] [ARG<sub>3</sub>] [VERB<sub>VBN</sub>]</i> ? Have you <i>[VERB<sub>VBN</sub>] [ARG<sub>2</sub>] [ARG<sub>3</sub>]</i> ? Have the <i>[ARG<sub>1</sub>(pl)] [VERB<sub>VBN</sub>] [ARG<sub>2</sub>] [ARG<sub>3</sub>]</i> ? eg: Has the <i>iphone found several networks</i> ? from the tuple: <i>iphone-found-several networks-null</i>
Action-Attribute (Verb/Action is VBG: gerund/present participle)  ARG <sub>1</sub> is empty	Is the <i>[ARG<sub>1</sub>(sg)] [VERB]</i> the <i>[ARG<sub>2</sub>] [ARG<sub>3</sub>]</i> ? Are the <i>[ARG<sub>1</sub>(pl)] [VERB]</i> the <i>[ARG<sub>2</sub>] [ARG<sub>3</sub>]</i> ? Is the <i>phone [VERB]</i> the <i>[ARG<sub>2</sub>] [ARG<sub>3</sub>]</i> ? eg: Is the <i>site delivering</i> the <i>flash version</i> ? from the tuple: <i>site-delivering-flash version-null</i>

Table 4: Templates for the follow up Question Generation .

focusing on action-attribute tuples. In the first user study, 5 users were given the first post of 20 threads with three problem representations for the first post, (1) phrasal units only, (2) phrasal units and attribute-value (Att-Val) pairs and (3) phrasal units, attribute-value pairs and action-attribute (Act-Att) tuples. They were asked to indicate which representation best represented the problem. All users preferred the third representation on all the first posts. An example first post and units are in Table 2.

In the second study, the same 5 users were asked to indicate how many units in Representation 3 were not relevant to the problem discussed in the first post, for a subset of 10 threads. We defined ‘not relevant’ as noisy components which do not aid in the problem representation e.g. *oh boy* and *thanks!* (see Table 2). All users marked 2 examples

(*sort* and *way*) as not relevant, out of 110 units that the algorithm generated for these threads.

These two user studies taken together show that the combined set of units, is able to capture the problem description well and that our algorithm is able to filter out noise in the thread to create a robust and useful representation of the problem. The results in Section 4.3 (Tables 6 and 7), show the value of our problem representation, in a complete end-to-end system, with objective metrics.

### 4.3 Unit selection for interaction

We evaluate a complete system with both user (or agent) and search engine in the loop. We focus on measuring the value of the interactions by an analysis of which results ‘rise to the top’. The experiment was conducted as follows. Annotators were given a specific query and its underspecified query

Figure 4: Success at N.

Figure 5: MAP at N.

(as created in Section 4.1) along with the results obtained when the underspecified query was input to the search engine. They were presented with the  $Top = 1, 3$  or  $5$  scoring follow up questions. E.g., for the underspecified query in Table 5 and specific query 2, the generated question was (see Table 4), *Has the sync server failed to sync?*. The user then selected the most appropriate follow up question, reducing the number of results. We then measured the relevance of the reduced result, with respect to the gold standard (see Section 4.1) for that specific query, using metrics commonly used in Information Retrieval - MRR, Mean Average Precision (MAP) and Success at rank  $N$  (Baeza-Yates et al., 1999). We restrict  $N = 5$  (small) since the rapid resolution time required of contact center agents does not allow them to look at many results.

In Figures 4, 5 and Table 6, we compare our system against a baseline system, which is the set of results obtained with the underspecified query, and a system where 5 interaction units are selected at random from the initial search results. Note that, as the number of follow up questions presented increases, the scores will improve since it is more likely that the ‘correct’ choice is presented. However, there is a trade-off here since the agent has to again peruse more questions, which increases

time spent, and so we limit this value to 5 as well. In terms of all three measures, our system is able

Unit’s Type	MRR
Baseline	0.3997
Random	0.4021
Phrases (with Top=5)	0.6548
Phrases, Pairs (with Top=5)	0.6745
Phrases, Pairs, Tuples (with Top=5)	0.7362

Table 6: MRR for different unit types.

to give a substantial improvement in performance. E.g., one intelligently chosen interaction performs better than 5 randomly chosen ones. These results show the value of the units we select and the choice of information gain as a metric. To measure the importance of each unit type, we analyzed the selected follow up questions ( $Top = 5$ ) for each underspecified query. Table 7 lists the fraction of queries whose origin was a specific unit type.

Unit’s Type	Preference
Phrases	51%
Attribute-Value Pairs	12%
Action-Attribute Tuples	37%

Table 7: Fraction of follow up questions selected that originated from a specific unit type

#### 4.4 Evaluating Templates for Question Generation

Finally, an annotator was given 100 generated follow up questions from the previous experiment and asked to label them as understandable or not. The annotator marked 13% as not understandable. Examples were, *does the phone connect*, *has the touchscreen stopped*, *does the message connect* (which were due to errors in parsing) and *do you want to leave the car* (due to a filtering error).

## 5 Related Work

Our work is related to three somewhat distinct areas of research, dialog systems, question answering (QA) systems and interactive search. Unlike most QA systems, we continue a sequence of interactions where the system and the user are active participants. The primary contribution of this work is a combined DSS, search, natural language dialog and query refinement system built automatically from semi-structured forum data. No prior work on interactive systems deals with problem resolution from large scale, noisy online forums.

Many speech dialog systems exist today for tasks including, obtaining train information (RAILTEL) (Bennacef et al., 1996), airline information (Rudnicky et al., 2000) and weather information (Zue et al., 2000). These systems perform simple database retrieval tasks, where, the keywords and their possible values are known apriori.

In general document retrieval tasks, when a user's query is under-specified and a large number of documents are retrieved, interactive search engines have been designed to assist the user in narrowing down the search results (Bruza et al., 2000). Much research has concentrated on query reformulation or query suggestions tasks. Suggestions are often limited to terms or phrases either extracted from query logs (Guo et al., 2008; Baeza-Yates et al., 2004) or from the documents obtained in the initial search results (Kelly et al., 2009). Bhogal et al. (2007) require rich ontologies for query expansion, which may be difficult and expensive to obtain for new domains. Leung et al. (2008) identify related queries from the web snippets of search results. Cucerzan and White (2007) use users' post-query navigation patterns along with the query logs to provide query suggestions. Mei et al. (2008) rank query suggestions using the click-through (query-url) graph. Boldi et al. (2009) provide query suggestions based on short random walk on the query flow graph. The main drawback behind these approaches is the dependence on query logs and labeled data to train query selection classifiers. We show how certain units are robust representations of documents in the problem resolution domain which can automatically be extracted from semi-structured data.

Feuer et al. (2007) use a proximity search-based system that suggests sub and super phrases. Cutting et al. (1993; Hearst and Pedersen (1996; Kelly et al. (2009) cluster retrieved documents and make suggestions based on the centroids of the clusters. Kraft and Zien (2004) and Bhatia et al. (2011) use  $n$ -grams extracted from the text corpus to suggest query refinement. Although these techniques do not rely on query logs for providing suggestions, the suggestions are limited to *contiguous* phrases. They also do not generate follow up questions, but instead provide a list of suggestions and require the user to select one among them or use them manually to reformulate the initial queries.

Automatically framing natural language questions as follow up questions to the user is still a

challenging task since, (1) Diriye et al. (2009) and Kelly et al. (2009) showed that interactive query expansion terms are poorly used, and tend to lack information meaningful to the user, thus emphasizing the need for larger context to best capture the actual query/problem intent (2) finding a few question/suggestions that would narrow the search results will lead to fewer interactions as opposed to displaying the single best result (3) particularly for non-technical users, interactions and clarifications need to be fluent enough for the user to understand and continue his interaction with the system (Alter, 1977). In this paper, we show how to extract important representative contextual units (which do not necessarily contain contiguous words) and use these to generate contextual interactions.

Sajjad et al. (2012) consider a data set where objects belong to a known category, with textual descriptions of objects and categories collected from human labelers, using which  $n$ -gram based attributes of objects are defined. Subsets of these attributes are filtered, again using labeled data. Kotov and Zhai (2010) frame questions with the help of handmade templates for the problem of factoid search from a subset of Wikipedia. However, they do not select queries with the goal of minimizing the number of interactions. To extend these approaches to problem-resolution finding, (as opposed to factoids or item descriptions) simple most common noun phrases (as used in Sajjad et al. (2012) and Kotov and Zhai (2010)) are insufficient, since they do not capture the problem or intent of the user. As motivated in Section 1, this requires a better representation of candidate phrases. Our paper also suggests an approach that does not need any human labelled or annotated data. Suggestions are selected using units such that the problem intent is well captured and also ensure that fewer interactions take place between the user and the system. Follow-up questions are framed using templates designed for these units, allowing us to move beyond simple terms and phrases.

## 6 Conclusion and Future Work

This paper proposed an interactive system for natural language problem resolution in the absence of manually labelled logs or pre-determined dialog state sequences. As future work, we would like to use additional information such as, the trustworthiness of the posters, quality of solutions in the threads, etc., while scoring the documents.

{razmara,anoop}@sfu.ca

## Abstract

State-of-the-art statistical machine translation systems rely heavily on training data and insufficient training data usually results in poor translation quality. One solution to alleviate this problem is *triangulation*. Triangulation uses a third language as a pivot through which another source-target translation system can be built. In this paper, we dynamically create multiple such triangulated systems and combine them using a novel approach called *ensemble decoding*. Experimental results of this approach show significant improvements in the BLEU score over the direct source-target system. Our approach also outperforms a strong linear mixture baseline.

## 1 Introduction

The objective of current statistical machine translation (SMT) systems is to build cheap and rapid corpus-based SMT systems without involving human translation expertise. Such SMT systems rely heavily on their training data. State-of-the-art SMT systems automatically extract translation rules (e.g. phrase pairs), learn segmentation models, re-ordering models, etc. and find tuning weights solely from data and hence they rely heavily on high quality training data. There are many language pairs for which there is no parallel data or the available data is not sufficiently large to build a reliable SMT system. For example, there is no Chinese-Farsi parallel text, although there exists sufficient parallel data between these two languages and English. For SMT, an important research direction is to improve the quality of translation when there is no, insufficient or poor-quality parallel data between a pair of languages.

\*This research was partially supported by an NSERC, Canada (RGPIN: 264905) grant and a Google Faculty Award to the second author.

One approach that has been recently proposed is *triangulation*. Triangulation is the process of translating from a source language to a target language via an intermediate language (aka pivot, or bridge). This is very useful specifically for low-resource languages as SMT systems built using small parallel corpora perform poorly due to data sparsity. In addition, ambiguities in translating from one language into another may disappear if a translation into some other language is available.

One obvious benefit of triangulation is to increase the coverage of the model on the input text. In other words, we can reduce the number of out-of-vocabulary words (OOVs), which are a major cause of poor quality translations, using other paths to the target language. This can be especially helpful when the model is built using a small amount of parallel data.

Figure 1 shows how triangulation can be useful in reducing the number of OOVs when translating from French to English through three pivot languages: Spanish (*es*), German (*de*) and Italian (*it*). The solid lines show the number of OOVs for a direct MT system with regard to a multi-language parallel test set (Section 6.2 contains the details about the data sets) and the dotted lines show the OOVs in the triangulated ( $src \rightarrow pvt \rightarrow tgt$ ) systems. The number of OOVs on triangulated paths can never be less than the first edge (i.e.  $src \rightarrow pvt$ ) and it is usually higher than the second edge (i.e.  $pvt \rightarrow tgt$ ) as well. Thus, the choice of intermediate language is very important in triangulation.

Figure 1 also shows how combining multiple triangulated systems can reduce this number from 2600 (16%) OOVs to 1536 (9%) OOVs. Thus, combining triangulated systems with the original  $src \rightarrow tgt$  system is a good idea. When combining multiple systems, the upper bound on the number of OOVs is the minimum among all OOVs in the different triangulations. These OOV rates provide useful hints, among other clues, as to which pivot

languages will be more useful. In Figure 1, we can expect Italian (*it*) to help more than Spanish (*es*) and both to help more than German (*de*) in translation from French (*fr*) to English (*en*), which we confirmed in our experimental results (Table 1).

In addition to providing translations for otherwise untranslatable phrases, triangulation can find new translations for current phrases. The conditional distributions used for the translation model have been estimated on small amounts of data and hence are not robust due to data sparseness. Using triangulation, these distributions are smoothed and become more reliable as a result.

For each pivot language for which there exists parallel data with the source and the target language, we can create a  $src \rightarrow tgt$  system by bridging through the pivot language. If there are a number of such pivot languages with corresponding data, we can use mixture approaches to combine them in order to build a stronger model. We propose to apply the ensemble decoding approach of (Razmara et al., 2012) in this triangulation scenario. Ensemble decoding allows us to combine hypotheses from different models dynamically at the decoder. We experimented with 12 different language pairs and 3 pivot languages for each of them. Experimental results of this approach show significant improvements in the BLEU and METEOR scores over the direct source-target system in all the 12 language pairs. We also compare to a strong linear mixture baseline.

## 2 Related Work

Use of pivot languages in machine translation dates back to the early days of machine translation. Boitet (1988) discusses the choice of pivot languages, natural or artificial (e.g. interlingua), in machine translation. Schubert (1988) argues that a proper choice for an intermediate language for high-quality machine translation is a natural language due to the inherent lack of expressiveness in artificial languages. Previous work in applying pivot languages in machine translation can be categorized into these divisions:

### 2.1 System Cascades

In this approach, a  $src \rightarrow pvt$  translation system translates the source input into the pivot language and a second  $pvt \rightarrow tgt$  system takes the output of the previous system and translates it into the target language. Utiyama and Isahara (2007) use this

direct ( $fr-en$ )	2600 (16%)
triangulated ( $fr-\{es, de, it\}-en$ )	2066 (12%)
direct + triangulated	1536 (9%)

Figure 1: Number of OOVs when translating directly from *fr* to *en* (solid lines), triangulating through *es*, *de* or *it* individually (dotted lines), and when combining multiple triangulation systems with the direct system. OOV numbers are based on a multi-language parallel test set and the models are built on small corpora (10k sentence pairs), which are not multi-parallel.

approach to triangulate between Spanish, German and French through English. However, instead of using only the best translation, they took the  $n$ -best translations and translated them into the target language. MERT (Och, 2003) has been used to tune the weights for the new feature set which consists of  $src \rightarrow pvt$  and  $pvt \rightarrow tgt$  feature functions. The highest scoring sentence from the target language is used as the final translation. They showed that using 15 hypotheses in the  $pvt$  side is generally superior to using only one best hypothesis.

### 2.2 Corpus Synthesis

Given a  $pvt \rightarrow tgt$  MT system, one can translate the pivot side of a  $src-pvt$  parallel corpus into the target language and create a noisy  $src-tgt$  parallel corpus. This can also be exploited in the other direction, meaning that a  $pvt \rightarrow src$  MT system can be used to translate the pivot side of a  $pvt-tgt$  bitext. de Gispert and Marino (2006), for example, translated the Spanish side of an English-Spanish bitext into Catalan using an available Spanish-Catalan SMT system. Then, they built an English-Catalan MT system by training on this new parallel corpus.

### 2.3 Phrase-Table Triangulation

In this approach, instead of translating the input sentences from a source language to a pivot language and from that to a target language, triangulation is done on the phrase level by triangulating two phrase-tables:  $src \rightarrow pvt$  and  $pvt \rightarrow tgt$ :

$$(\bar{f}, \bar{e}) \in T_{\mathcal{F} \rightarrow \mathcal{E}} \iff \exists \bar{i} : (\bar{f}, \bar{i}) \in T_{\mathcal{F} \rightarrow \mathcal{I}} \wedge (\bar{i}, \bar{e}) \in T_{\mathcal{I} \rightarrow \mathcal{E}}$$

where  $\bar{f}, \bar{i}$  and  $\bar{e}$  are phrases in the source  $\mathcal{F}$ , pivot  $\mathcal{I}$  and target  $\mathcal{E}$  languages respectively and  $T$  is a set representing a phrase table.

Utiyama and Isahara (2007) also experimented with phrase-table triangulation. They compared both triangulation approaches when using Spanish, French and German as the source and target languages and English as the only pivot language. They showed that phrase-table triangulation is superior to the MT system cascades but both of them did not outperform the direct  $src \rightarrow tgt$  system.

The phrase-table triangulation approach with multiple pivot languages has been also investigated in several work (Cohn and Lapata, 2007; Wu and Wang, 2007). These triangulated phrase-tables are combined together using linear and log-linear mixture models. They also successfully combined the mixed phrase-table with a  $src-tgt$  phrase-table to achieve a higher BLEU score.

Bertoldi et al. (2008) formulated phrase triangulation in the decoder where they also consider the phrase-segmentation model between  $src-pvt$  and the reordering model between  $src-tgt$ .

Beside machine translation, the use of pivot languages has found applications in other NLP areas. Gollins and Sanderson (2001) used a similar idea in cross-lingual information retrieval where query terms were translated through multiple pivot languages to the target language and the translations are combined to reduce the error. Pivot languages have also been successfully used in inducing translation lexicons (Mann and Yarowsky, 2001) as well as word alignments for resource-poor languages (Kumar et al., 2007; Wang et al., 2006). Callison-Burch et al. (2006) used pivot languages to extract paraphrases for unknown words.

### 3 Baselines

In this paper, we compare our approach with two baselines. A simple baseline is the direct system

between the source and target languages which is trained on the same amount of parallel data as the triangulated ones. In addition, we implemented a phrase-table triangulation method (Cohn and Lapata, 2007; Wu and Wang, 2007; Utiyama and Isahara, 2007). This approach presents a probabilistic formulation for triangulation by marginalizing out the pivot phrases, and factorizing using the chain rule:

$$\begin{aligned} p(\bar{e} | \bar{f}) &= \sum_{\bar{i}} p(\bar{e}, \bar{i} | \bar{f}) \\ &= \sum_{\bar{i}} p(\bar{e} | \bar{i}, \bar{f}) p(\bar{i} | \bar{f}) \\ &\approx \sum_{\bar{i}} p(\bar{e} | \bar{i}) p(\bar{i} | \bar{f}) \end{aligned}$$

where  $\bar{f}, \bar{e}$  and  $\bar{i}$  are phrases in the source, target and intermediate language respectively. In this equation, a conditional independence assumption has been made that source  $\bar{f}$  and target phrases  $\bar{e}$  are independent given their corresponding pivot phrase(s)  $\bar{i}$ . The equation requires that all phrases in the  $src \rightarrow pvt$  direction must also appear in  $pvt \rightarrow tgt$ . All missing phrases are simply dropped from the final phrase-table.

Using this approach, a triangulated source-target phrase-table is generated for each pivot language. Then, linear and log-linear mixture methods are used to combine these phrase-tables into a single phrase-table in order to be used in the decoder. We implemented the linear mixture approach, since linear mixtures often outperform log-linear ones (Cohn and Lapata, 2007). We then compare the results of these baselines with our approach over multiple language pairs (Section 6.2). In linear mixture models, each feature in the mixture phrase-table is computed as a linear interpolation of corresponding features in the component phrase-tables using a weight vector  $\vec{\lambda}$ .

$$\begin{aligned} p(\bar{e} | \bar{f}) &= \sum_i \lambda_i p_i(\bar{e} | \bar{f}) \\ p(\bar{f} | \bar{e}) &= \sum_i \lambda_i p_i(\bar{f} | \bar{e}) \\ \forall \lambda_i > 1 \quad \sum_i \lambda_i &= 1 \end{aligned}$$

Following Cohn and Lapata (2007), we combined triangulated phrase-tables with uniform weights into a single phrase table and then interpolated it with the phrase-table of the direct system.

## 4 Ensemble Decoding

SMT log-linear models (Koehn, 2010) find the most likely target language output  $e$  given the source language input  $f$  using a vector of feature functions  $\phi$ :

$$p(e|f) \propto \exp(\mathbf{w} \cdot \phi)$$

Ensemble decoding combines several models dynamically at the decoding time. The scores are combined for each partial hypothesis using a user-defined mixture operation  $\odot$  over component models.

$$p(e|f) \propto \exp(\mathbf{w}_1 \cdot \phi_1 \odot \mathbf{w}_2 \cdot \phi_2 \odot \dots)$$

Razmara et al. (2012) successfully applied ensemble decoding to domain adaptation in SMT and showed that it performed better than approaches that pre-compute linear mixtures of different models. Several mixture operations were proposed, allowing the user to encode belief about the relative strengths of the component models. These mixture operations receive two or more probabilities and return the mixture probability  $p(\bar{e}|\bar{f})$  for each rule  $\bar{f} \rightarrow \bar{e}$  used in the decoder. Different options for these operations are:

- **Weighted Sum (wsum)** is defined as:

$$p(\bar{e}|\bar{f}) \propto \sum_m^M \lambda_m \exp(\mathbf{w}_m \cdot \phi_m)$$

where  $m$  denotes the index of component models,  $M$  is the total number of them and  $\lambda_m$  is the weight for component  $m$ .

- **Weighted Max (wmax)** is defined as:

$$p(\bar{e}|\bar{f}) \propto \max_m (\lambda_m \exp(\mathbf{w}_m \cdot \phi_m))$$

- **Model Switching (Switch)**: Each cell in the CKY chart is populated only by rules from one of the models and the other models' rules are discarded. Each component model is considered an expert on different spans of the source. A binary indicator function  $\delta(\bar{f}, m)$  picks a component model for each span:

$$\delta(\bar{f}, m) = \begin{cases} 1, & m = \operatorname{argmax}_{n \in M} \psi(\bar{f}, n) \\ 0, & \text{otherwise} \end{cases}$$

The criteria for choosing a model for each cell,  $\psi(\bar{f}, n)$ , is based on max top score, i.e.

for each cell, the model that has the highest weighted best-rule score wins:

$$\psi(\bar{f}, n) = \lambda_n \max_{\bar{e}} (\mathbf{w}_n \cdot \phi_n(\bar{e}, \bar{f}))$$

The probability of each phrase-pair  $(\bar{e}, \bar{f})$  is then:

$$p(\bar{e}|\bar{f}) = \sum_m^M \delta(\bar{f}, m) p_m(\bar{e}|\bar{f})$$

## 5 Our Approach

### 5.1 Dynamic Triangulation

Given a  $src \rightarrow pvt$  and a  $pvt \rightarrow tgt$  system which are independently trained and tuned on their corresponding parallel data, these two systems can be triangulated dynamically in the decoder.

For each source phrase  $\bar{f}$ , the decoder consults the  $src \rightarrow pvt$  system to get its translations on the pivot side  $\bar{i}$  with their scores. Consequently, each of these pivot-side translation phrases is queried from the  $pvt \rightarrow tgt$  system to obtain their translations on the target side with their corresponding scores. Finally a  $(\bar{f}, \bar{e})$  pair is constructed from each  $(\bar{f}, \bar{i})$  and  $(\bar{i}, \bar{e})$  pair, whose score is computed as:

$$p_{\mathcal{I}}(\bar{f}|\bar{e}) \propto \max_{\bar{i}} \exp \left( \underbrace{w_1 \cdot \phi_1(\bar{f}, \bar{i})}_{\mathcal{F} \rightarrow \mathcal{I}} + \underbrace{w_2 \cdot \phi_2(\bar{i}, \bar{e})}_{\mathcal{I} \rightarrow \mathcal{E}} \right)$$

This method requires the language model score of the  $src \rightarrow pvt$  system. However for simplicity we do not use the pivot-side language models and hence the score of the  $src \rightarrow pvt$  system does not include the language model and word penalty scores. In this formulation for a given source and target phrase pair  $(\bar{f}, \bar{e})$ , if there are multiple bridging pivot phrases  $\bar{i}$ , we only use the one that yields the highest score. This is in contrast with previous work where they take the sum over all such pivot phrases (Cohn and Lapata, 2007; Utiyama and Isahara, 2007). We use *max* as it outperforms *sum* in our preliminary experiments.

It is noteworthy that in computing the score for  $p_{\mathcal{I}}(\bar{f}|\bar{e})$ , the scores from  $src \rightarrow pvt$  and  $pvt \rightarrow tgt$  are added uniformly. However, there is no reason why this should be the case. Two different weights can be assigned to these two scores to highlight the importance of one against the other one.

A naive implementation of phrase-triangulation in the decoder would require  $O(n^2)$  steps for each source sub-span, where  $n$  is the average number of translation fan-out (i.e. possible translations) for each phrase. However, since the phrase candidates from both  $src \rightarrow pvt$  and  $pvt \rightarrow tgt$  are already sorted, we use a lazy algorithm that reduces the computational complexity to  $O(n)$ .

## 5.2 Combining Triangulated Systems

If we can make use of multiple pivot languages, a system can be created on-the-fly for each pivot language by triangulation and these systems can then be combined together in the decoder using *ensemble decoding* discussed in Section 4. Following previous work, these triangulated phrase-tables can also be combined with the direct system to produce a yet stronger model. However, we do not combine them in two steps. Instead, all triangulated systems and the direct one are combined together in a single step.

Ensemble decoding is aware of full model scores when it compares, ranks and prunes hypotheses. This includes the language model, word, phrase and glue rule penalty scores as well as standard phrase-table probabilities.

Since ensemble decoding combines the scores of common hypotheses across multiple systems rather than combining their feature values as in mixture models, it can be used to triangulate heterogeneous systems such as phrase-based, hierarchical phrase-based, and syntax-based with completely different feature types. Considering that ensemble decoding can be used in these diverse scenarios, it offers an attractive alternative to current phrase-table triangulation systems.

## 5.3 Tuning Component Weights

Component weights control the contribution of each model in the ensemble. A tuning procedure should assign higher weights to the models that produce higher quality translations and lower weights to weak models in order to control their noise propagation in the ensemble. In the ensemble decoder, since we do not have explicit gradient information for the objective function, we use a direct optimizer for tuning. We used *Condor* (Vanden Berghen and Bersini, 2005) which is a publicly available toolkit based on Powell’s algorithm.

The ensemble between three triangulated models and a direct one requires tuning in a 4-

dimensional space, one for each system. If, on average, the tuner evaluates the decoder  $n$  times in each direction in the optimization space, there needs to be  $n^4$  ensemble decoder evaluations, which is very time consuming. Instead, we resorted to a simpler approach for tuning: each triangulated model is separately tuned against the direct model with a fixed weights (we used a weight of 1). In other words, three ensemble models are created, each on a single triangulated model plus the direct one. These ensembles are separately tuned and once completed, these weights comprise the final tuned weights. Thus, the total number of ensemble evaluations reduces from  $O(n^4)$  to  $O(3n)$ .

In addition to this significant complexity reduction, this method enables parallelism in tuning, since the three individual tuning branches can now be run independently. The final tuned weights are not necessarily a local optima and one can run further optimization steps around this point to get to even better solutions which should lead to higher BLEU scores.

# 6 Experiments & Results

## 6.1 Experimental Setup

For our experiments, we used the Europarl corpus (v7) (Koehn, 2005) for training sets and ACL/WMT 2005<sup>1</sup> data for dev/test sets (2k sentence pairs) following Cohn and Lapata (2007). Our goal in this paper was to understand how multiple languages can help in triangulation, the improvement in coverage of the unseen data due to triangulation, and the importance of choosing the right languages as pivot languages. Thus, we needed to run experiments on a large number of language pairs, and for each language pair we wanted to work with many pivot languages. To this end, we created small sub-corpora from Europarl by sampling 10,000 sentence pairs and conducted our experiments on them. As we will show, using larger data than this would result in prohibitively large triangulated phrase tables. Table 2 shows the number of words on both sides of used language pairs in our corpora.

The ensemble decoder is built on top of an in-house implementation of a Hiero-style MT system (Chiang, 2005) called Kriya (Sankaran et al., 2012). This Hiero decoder obtains BLEU

scores equal to or better than the state-of-the-art in phrase-based and hierarchical phrase-based translation over a wide variety of language pairs and data sets. It uses the following standard features: forward and backward relative-frequency and lexical TM probabilities; LM; word, phrase and glue-rules penalty. GIZA++ (Och and Ney,

2000) has been used for word alignment with phrase length limit of 10. In both systems, feature weights were optimized using MERT (Och, 2003). We used the target sides of the Europarl corpus (2M sentences) to build 5-gram language models and smooth them using the Kneser-Ney method. We used SRILM (Stolcke, 2002) as the language model toolkit.

## 6.2 Results

Table 1 shows the BLEU scores when using two languages from  $\{fr, en, es, de\}$  as source and target, and the other two languages plus *it* as intermediate languages. The first group of numbers are BLEU scores for triangulated systems through the specified pivot language. For example, translating from *de* to *es* through *en* (i.e.  $de \rightarrow en \rightarrow es$ ) gets 15.94% BLEU score. The second group shows the BLEU scores of the baseline systems including the direct system between the source and target languages and the linear mixture baseline of the three triangulated systems. The BLEU scores of ensemble decoding using different mixture op-

direct	478K	393K	403K	665K	1,084K	1,155K	479K	927K	1,319K	394K	743K	976K
tri + direct	83M	102M	132M	113M	103M	133M	129M	101M	152M	141M	109M	129M

Figure 2: Coverage for i) direct system; ii) combined triangulated system with three 3 languages; and iii) the combination of the triangulated phrase-tables and the direct one. The table shows the number of rules for each system and language pair after filtering based on the source side of the test set.

erations are illustrated at the bottom.

As the table shows, our approach outperforms the direct systems in all the 12 language pairs while the mixture model systems fail to improve over the direct system baseline for some of the language pairs. Our approach also outperforms the mixture models in most cases. Overall, ensemble decoding with *wmax* as mixture operation performs the best among the different systems and baselines. Figure 3 shows the average of the BLEU score of the direct system, mixture models and *wmax* on all 12 systems. On average the *wmax* method obtains 0.33 BLEU points higher than the mixture models.

Figure 3: The average BLEU scores of the direct system, mixture models and *wmax* ensemble triangulation approach over all 12 language pairs.

We also computed the Meteor scores (Denkowski and Lavie, 2011) for all systems

and the results are summarized in Figure 4. As the figure illustrates, our ensemble decoding approach with *wmax* outperforms the mixture models in 11 of 12 language pairs based on Meteor scores.

### 6.3 Phrase table coverage

Figure 2 shows the phrase-table coverage of the test set for different language pairs. The coverage is defined as the percentage of unigrams in the source side of the test set for which the corresponding phrase-table has translations for. The first set of bars shows the coverage of the direct systems and the second one shows that of the combined triangulated systems for three pivot languages. Finally, the last set of bars indicate the coverage when the direct phrase-table is combined with the triangulated ones. In all language pairs, the combined triangulated phrase-tables have a higher coverage compared to the direct phrase-tables. As expected, the coverage increases when these two phrase-tables are aggregated. The table below the figure shows the number of rules for each system and language pair after filtering out based on the source side of the test set. This illustrates why running experiments on larger sizes of parallel data is prohibitive for hierarchical phrase-based models.

Figure 4: Meteor score difference between mixture models and direct systems as well as the difference between ensemble decoding approach with *wmax* and the direct system.

### 6.3.1 Choice of Pivot Language

Cohn and Lapata (2007) showed that the pivot language should be close to the source or the target language in order to be effective. For example, when translating between Romance languages (Italian, Spanish, etc.), the pivot language should also be a Romance language. In addition to those findings, based on the results presented in Table 1, here are some observations for these five European languages:

- When translating from or to *de*, *en* is the best pivot language;
- Generally *de* is not a suitable pivot language for any translation pair;
- When translating from *en* to any other language, *fr* is the best pivot;
- *it* is the best intermediate language when translating from *fr* or *es* to other languages; except when translating to *de* for which *en* is the best pivot language (c.f. first finding);

## 7 Conclusion and Future Work

In the paper, we introduced a novel approach for triangulation which does phrase-table triangulation and model combination on-the-fly in the decoder. Ensemble decoder uses the full hypothesis score for triangulation and combination and hence is able to mix hypotheses from heterogeneous systems.

Another advantage of this method to the phrase-table triangulation approach is that our method is

applicable even when there exists no parallel data between source and target languages for tuning because we only use the *src-tgt* tuning set to optimize hyper-parameters, though phrase-table triangulation methods use it to learn MT log-linear feature weights for which having a tuning set is much more essential. Empirical results also showed that this method with *wmax* outperforms the baselines.

Future work includes imposing restrictions on the generated triangulated rules in order to keep only ones that have a strong support from the word alignments. By exploiting such constraints, we can experiment with larger sizes of parallel data. Specifically, a more natural experimental setup for triangulation which we would like to try is to use a small direct system with big *src*  $\rightarrow$  *pvt* and *pvt*  $\rightarrow$  *tgt* systems. This resembles the actual situation for resource-poor language pairs. We will also experiment with higher number of pivot languages.

Currently, most research in this area focuses on triangulation on paths containing only one pivot language. We can also analyze our method when using more languages in the triangulation chain and see whether there would any gain in doing such.

Finally, in current methods all  $(\bar{f}, \bar{i})$  phrase pairs of the *src*  $\rightarrow$  *pvt* systems, for which there does not exist any  $(\bar{i}, \bar{e})$  pair in *pvt*  $\rightarrow$  *tgt* are simply discarded. However in most cases, such  $\bar{i}$  phrases can be segmented into smaller phrases (or rules for Hero systems) to be triangulated via them. This segmentation is a decoding problem which requires an efficient algorithm to be practical.

## Abstract

We present a high-precision, language-independent transliteration framework applicable to bilingual lexicon extraction. Our approach is to employ a bilingual topic model to enhance the output of a state-of-the-art grapheme-based transliteration baseline. We demonstrate that this method is able to extract a high-quality bilingual lexicon from a comparable corpus, and we extend the topic model to propose a solution to the out-of-domain problem.

## 1 Introduction

A large, high-quality bilingual lexicon is of great utility to any dictionary-based system that processes bilingual data. The ability to automatically generate such a lexicon without relying on expensive training data or pre-existing lexical resources allows us to find translations for rare and unknown words with high efficiency.

Transliteration<sup>1</sup> is particularly important as new words are often created by importing words from other languages, especially English. It would be an almost impossible task to create and maintain a dictionary of such words by hand, as new words appear rapidly, especially in online texts, and word usage can vary over time.

In this paper we construct a language-independent transliteration framework. Our model builds on previous transliteration work, improving extraction and generation precision by including semantic as well as purely lexical features. The proposed model can be trained

<sup>1</sup>This paper considers both ‘transliteration’ (EN–XX) and ‘back-transliteration’ (XX–EN). For simplicity we refer to both tasks as ‘transliteration’.

on comparable corpora, thereby not relying on expensive or often unavailable parallel data.

The motivation behind the approach of combining lexical and semantic features is that these two components are largely independent, greatly improving the effectiveness of their combination. This is particularly important for word-sense disambiguation. For example, a purely lexical approach is not sufficient to transliterate the Japanese ソース (*soosu*), as it can mean either ‘sauce’ or ‘source’ depending on the context.

## 2 Previous Work

Previous work has considered various methods for transliteration, ranging from simple edit distance and noisy-channel models (Brill et al., 2001) to conditional random fields (Ganesh et al., 2008) and finite state automata (Noeman and Madkour, 2010). We construct a baseline by modelling transliteration as a Phrase-Based Statistical Machine Translation (PB-SMT) task, a popular and well-studied approach (Matthews, 2007; Hong et al., 2009; Antony et al., 2010).

The vast majority of previous work on transliteration has considered only lexical features, for example spelling similarity and transliteration symbol mapping, however we build on the inspiration of Li et al. (2007) and later Hagiwara and Sekine (2012), who introduced semantic features to a transliteration model.

Li et al. (2007) proposed the concept of ‘semantic transliteration’, which is the consideration of inherent semantic information in transliterations. Their example is the influence of the source language and gender of foreign names on their transliterations into Chinese. Hagiwara and Sekine (2012) expanded upon this idea by considering a ‘latent class’

transliteration model considering transliterations to be grouped into categories, such as language of origin, which can give additional information about their formation. For example, if we know that a transliteration is of Italian origin, we are more likely to recover the letter sequence ‘gli’ than if it were originally French.

While these methods consider limited semantic features, they do not make use of the rich contextual information available from comparable corpora. We show such contextual information, in the form of bilingual topic distributions, to be highly effective in generating transliterations.

Bilingual lexicon mining from non-parallel data has been tackled in recent research such as Tamura et al. (2012) and Haghghi et al. (2008), and we build upon the techniques of multilingual topic extraction from Wikipedia pioneered by Ni et al. (2009). Previous research in lexicon mining has tended to focus on semantic features, such as context similarity vectors and topic models, but these have yet to be applied to the task of transliteration mining. We use the word-topic distribution similarities explored in Vulić et al. (2011) as baseline word similarity measures.

In some cases it is possible to use monolingual corpora for transliteration mining, as English is often written alongside transliterations (Kaji et al., 2011), however we consider the more general setting where such information is unavailable.

### 3 Baseline Transliteration Model

We begin by constructing a baseline transliteration system trained only on lexical features. This baseline system will allow us to compare directly the effectiveness of the addition of a semantic model to a traditional transliteration framework.

Our baseline model is a grapheme-based machine transliteration system. We model transliteration as a machine translation task on a character rather than word level, treating character groups as phrases. The model is trained by learning phrase alignments such as that shown in Figure 1. The field of phrase-based SMT has been well studied and there exists a standard toolset enabling the construc-

Figure 1: Example of Japanese–English transliteration phrase alignment.

tion of an easily reproducible baseline system.

We use the default configuration of Moses (Koehn et al., 2007) to train our baseline system, with the distortion limit set to 1 (as transliteration requires monotonic alignment). Character alignment is performed by GIZA++ (Och and Ney, 2003) with the ‘grow-diag-final’ heuristic for training. We apply standard tuning with MERT (Och, 2003) on the BLEU (Papineni et al., 2001) score. The language model is built with SRILM (Stolcke, 2002) using Kneser-Ney smoothing (Kneser and Ney, 1995).

The system described above has been implemented as specified in previous work such as Matthews (2007) (Chinese and Arabic), Hong et al. (2009) (Korean), and Antony et al. (2010) (Kannada). We demonstrate that this standard, highly-regarded baseline can be greatly improved with our proposed method.

## 4 Semantic Model

Having set up the baseline system, we turn to the task of combining a semantic model with our transliteration engine. We employ the method of bilingual LDA (Mimno et al., 2009), an extension of monolingual Latent Dirichlet Allocation (LDA) (Blei et al., 2003) as the semantic model.

Monolingual LDA takes as its input a set of monolingual documents and generates a word-topic distribution  $\phi$  classifying words appearing in these documents into semantically similar topics. Bilingual LDA extends this by considering pairs of comparable documents in each of two languages, and outputs a pair of word-topic distributions  $\phi$  and  $\psi$ , one for each input language. The graphical model for bilingual LDA is illustrated in Figure 2.

Figure 2: Graphical model for Bilingual LDA with  $K$  topics,  $D$  document pairs and hyperparameters  $\alpha$  and  $\beta$ . Topics for each document are sampled from the common distribution  $\theta$ , and the two languages have word-topic distributions  $\phi$  and  $\psi$ .

#### 4.1 Motivation for Bilingual LDA

We choose to employ a bilingual topic model to measure semantic similarity (i.e. topic similarity) of word pairs rather than the more intuitive method of comparing monolingual context similarity vectors (Rapp, 1995) for reasons of robustness and scalability.

Measuring context similarity on a word level requires a bilingual lexicon to match cross-language word pairs and such bilingual data is often expensive or unavailable. There are also problems with directly comparing collocations and word concurrence of distant language pairs as they do not always correspond predictably. Therefore our proposed method provides a more robust approach using coarser semantic features.

The use of topic models as a semantic similarity measure is a scalable method because document-aligned bilingual training data is growing ever more widely available. Examples of such sources are Wikipedia, multilingual newspaper articles and mined Web data.

#### 4.2 Semantic Similarity Measures

In order to apply bilingual topic models to a transliteration task, we must construct an effective word similarity measure for source and target transliteration candidates. We improve upon three natural similarity measures, Cos, Cue and KL, based on those considered in Vulić et al. (2011), by proposing two methods of feature combination: reordering and SVM

combination.

The reranking method considers hybrid scores Base+Cos, Base+Cue and Base+KL. These are generated by reranking the top-10 baseline (Base) transliteration candidates by their respective semantic scores (Cos, Cue or KL). We used 10 candidates for filtering as we found this gave the best balance between volume and accuracy in preliminary experiments. Approximately 75–85% of correct transliterations (depending on language pair) were within the top-10 candidates and this is therefore an upper bound for the hybrid model accuracy. As a comparison, the top-100 candidates contained roughly 80–85% of correct transliterations, the remainder failing to be identified by the baseline.

We additionally consider the combination of all three semantic features with the baseline (Moses) transliteration scores using a Support Vector Machine (SVM) (Vapnik, 1995). The SVM is used to classify candidate pairs as ‘transliteration’ (positive) or ‘not transliteration’ (negative), and we rerank the candidates by SVM predicted values. The features used for SVM training are baseline, Cos, Cue and KL scores.

The similarity measures Cos, Cue and KL are defined below.

##### 4.2.1 Cos Similarity

The **Cos** method calculates the cosine similarity of the topic distribution vectors  $\psi_{k,w_e}$  and  $\phi_{k,w_f}$  for transliteration pair candidates  $w_e$  and  $w_f$ .

$$\text{Cos}(w_e, w_f) = \frac{\sum_{k=1}^K \psi_{k,w_e} \phi_{k,w_f}}{\sqrt{\sum_{k=1}^K \psi_{k,w_e}^2} \sqrt{\sum_{k=1}^K \phi_{k,w_f}^2}} \quad (1)$$

##### 4.2.2 Cue Similarity

The **Cue** method expresses the mean of the two probabilities  $P(w_e | w_f)$  of a transliteration  $w_e$  given some source language string  $w_f$  and  $P(w_f | w_e)$  of the reverse. We define:

$$P(w_e | w_f) = \sum_{k=1}^K \psi_{k,w_e} \frac{\phi_{k,w_f}}{\text{Norm}_\phi}$$

and likewise for  $P(w_e | w_f)$ , with the

normalization factors given by  $Norm_\phi = \sum_{k=1}^K \phi_{k,w_f}$  and  $Norm_\psi = \sum_{k=1}^K \psi_{k,w_e}$ .

Finally, we consider:

$$Cue(w_e, w_f) = \frac{1}{2}(P(w_e | w_f) + P(w_f | w_e)) \quad (2)$$

### 4.2.3 KL Similarity

The **KL** method considers the averaged Kullback-Leibler divergence:

$$KL(w_e, w_f) = \frac{1}{2}(KL_{e,f} + KL_{f,e}) \quad (3)$$

$$KL_{e,f} = \sum_{k=1}^K \frac{\phi_{k,w_e}}{Norm_\phi} \log \frac{\phi_{k,w_e}/Norm_\phi}{\psi_{k,w_f}/Norm_\psi}$$

$$KL_{f,e} = \sum_{k=1}^K \frac{\psi_{k,w_f}}{Norm_\psi} \log \frac{\psi_{k,w_f}/Norm_\psi}{\phi_{k,w_e}/Norm_\phi}$$

using the same normalization factors as for Cue similarity.

## 5 Experiments

In order to demonstrate the effectiveness of our proposed model, we constructed an evaluation framework for a transliteration extraction task. The language pairs English–Japanese (EN–JA), Japanese–English (JA–EN), English–Korean (EN–KO) and Korean–English (KO–EN) were chosen to verify that this method is effective for a variety of languages and in both transliteration directions. Indeed, the methods introduced in this paper could also be applied directly to other languages with many transliterations, such as Chinese, Arabic and Hindi.

While it is possible to make language-specific optimizations, we decided only to pre-process the data minimally (such as removing punctuation) in order to demonstrate that our model works effectively in a language-independent setting. Examples of language-specific preprocessing techniques that we did not perform include segmentation of Japanese compound nouns (Nakazawa et al., 2005) and splitting of Korean syllabic blocks (*eumjeols*) into smaller components (*jamo*) (Hong et al., 2009).

Language Pairs	Train	Tune	Test
EN–JA/JA–EN	59K	1K	1K
KO–EN/EN–KO	21K	1K	1K

Table 1: Number of aligned word pairs in each fold of data.

## 5.1 Data Set

We chose to build our data set from Wikipedia articles, as they provide document-aligned comparable data across a variety of languages. Figure 3 shows how the Wikipedia data was split.

### 5.1.1 Baseline Training Data

We trained our baseline system on aligned Wikipedia page titles. This data consisted of pairs of English and Japanese/Korean words extracted from the freely available Wikipedia XML dumps. The aligned titles were filtered with hand-written rules<sup>2</sup> to extract only transliteration pairs, and the test data was verified for correctness by hand. This data will be made available to encourage comparison for future transliteration research<sup>3</sup>.

The composition of this data is shown in Table 1. Aligned word pairs were shuffled randomly before splitting into the three folds to ensure an even topic distribution across each of ‘Train’, ‘Tune’ and ‘Test’.

### 5.1.2 Bilingual Topic Model

The bilingual topic model was trained on the body text of Wikipedia articles aligned with Wikipedia inter-language links. These correspond to articles covering the same content, however they are rarely of similar length and not necessarily close transliterations.

We first pre-processed the most recent Wikipedia XML dumps to remove all tags and data other than plain text sentences, then aligned articles with language links to generate comparable document pairs. Words occurring fewer than 10 or more than 100K times were also removed to reduce noise and computation time.

<sup>2</sup>Heuristic rules included extraction of Japanese katakana, a script used primarily for transliterations, and words aligned with proper nouns as defined in a name dictionary.

<sup>3</sup><http://orchid.kuee.kyoto-u.ac.jp/~john>

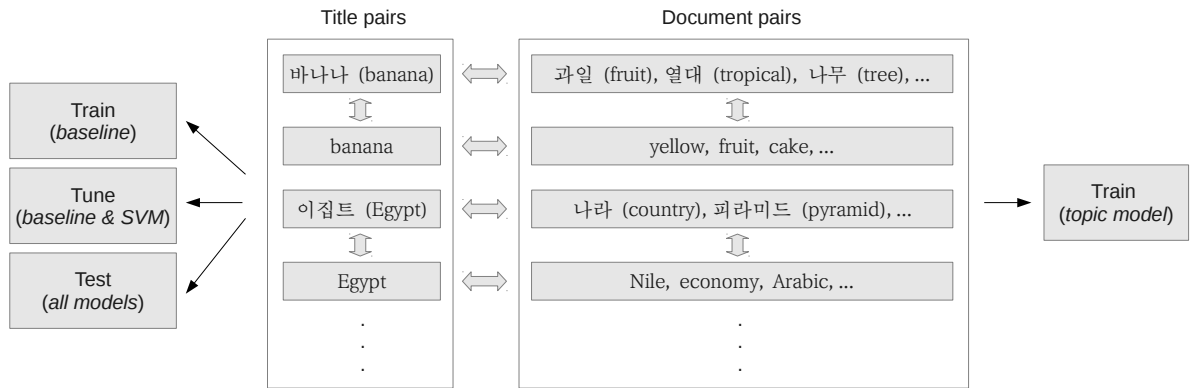

Figure 3: We extracted aligned title pairs (only transliterations) and aligned document pairs from Wikipedia using inter-language links. The baseline was trained and tuned on title pairs (‘Train’ and ‘Tune’), the topic model was trained on document pairs and the SVM was trained on the title pairs ‘Tune’ fold.

### 5.1.3 SVM Hybrid Model

The training data for the proposed SVM hybrid model was built from the same data used for the baseline (tuning fold). We first generated the top-10 distinct transliteration candidates for the tuning data using the ‘n-best-list’ option in Moses. These candidates were then labeled as ‘transliteration’ or ‘not-transliteration’ and feature scores (Base, Cos, Cue, KL) were generated for each candidate. The SVM model was trained using these labels and feature scores.

## 5.2 LDA Implementation Details

PolyLDA++, our implementation of multilingual LDA, was based on GibbsLDA++ (Phan et al., 2007), a toolkit for monolingual LDA. This software is available for free<sup>4</sup>.

Each topic model was trained over 1000 iterations, and the standard Dirichlet prior hyperparameters for the LDA model were set as  $\alpha = 50/K$  for  $K$  topics and  $\beta = 0.1$ .

The choice of number of topics is important, as demonstrated in Figure 4, which shows the top-1 accuracy of the SVM hybrid model using various numbers of topics  $K$ . The optimal value of  $K$  seems to be between around 100 for this data.

The model accuracy gradually decreases with adding more than 100 topics. We believe that this is because the granularity of

Figure 4: Top-1 accuracy of SVM for various  $K$ .

the topics becomes too fine to accommodate for the wide differences in semantic usage of English and Japanese/Korean transliteration pairs. A higher number of topics could be more suitable for more closely related language pairs, such as Italian and English (Vulić et al., 2011), because the higher similarity of word usage would allow for topics of more limited semantic scope. Such experiments are to be considered in future work. The results below are for  $K = 100$ .

## 5.3 Results

Table 2 compares the top-1 accuracy of our proposed hybrid models to the baseline perfor-

<sup>4</sup><http://orchid.kuee.kyoto-u.ac.jp/~john>

	JA-EN	EN-JA	KO-EN	EN-KO
Base	0.334	0.363	0.296	0.421
Base+Cos	0.608	0.559	0.494	0.516
Base+Cue	0.608	0.551	<b>0.507</b>	0.504
Base+KL	0.365	0.398	0.261	0.373
SVM	<b>0.610</b>	<b>0.572</b>	0.504	<b>0.551</b>

Table 2: Top-1 accuracy of proposed model for each hybrid scoring method.

Figure 5: Precision-recall curve for SVM hybrid model.

mance. The SVM hybrid model outperformed the baseline for every language pair, by as much as 0.276 for JA-EN. This suggests that the addition of a bilingual topic model significantly improves transliteration accuracy.

In general the SVM was the most effective hybrid score, outperforming Base+Cos, Base+Cue and Base+KL in all but KO-EN, where it performed very slightly worse than Base+Cue.

Figure 5 shows the precision-recall curve for the SVM hybrid model over the test set. We vary recall by ranking the hybrid model scores for all test pairs and selecting only the highest scoring fraction to evaluate. This simulates a lexicon extraction task where we wish to sacrifice recall for precision. The results demonstrate that it is possible to improve significantly the precision of a set of extracted transliterations by reducing the recall. This large improvement is made possible because the topic similarity scores are particularly effective at measuring confidence in each transliteration candidate, allowing effective selection of the correct transliterations.

## 5.4 Comparison with Previous Work

The results compare favorably to the top-1 accuracy of similar existing systems, such as DIRECTL+ (Jiampojarn et al., 2010), which also used Wikipedia titles (EN-JA 0.398), and Hagiwara and Sekine (2012) (EN-JA 0.349).

Our baseline transliteration system can be measured against previous work using Moses and GIZA++ alignment, such as Matthews (2007) (EN-AR 0.43, AR-EN 0.39, EN-ZH 0.38, ZH-EN 0.35) and Hong et al. (2009) (EN-KO 0.45). These scores are consistent with our baseline results.

While it is difficult to compare directly the accuracy of transliteration systems across different languages and data sets, especially since we use additional data to train the semantic model, the results above show that our model has made a considerable improvement over the state-of-the-art baseline.

## 6 Extension to Out-of-Domain Words

The model described in this paper revolves around the use of a bilingual topic model to improve transliteration quality. What happens then when a source word is not covered by the topic model? This is a very important problem in a practical setting, and we show that even in such cases our model can improve considerably upon the baseline system. We define ‘out-of-domain’ words as source language words that did not appear in the topic model training data and hence do not have a known topic distribution.

### 6.1 Model Details

Our proposed approach is to consider not the word-topic distribution of the source word  $w_e$  itself, but rather that of the words in the surrounding context. We consider two methods for calculating the modified topic similarity

scores over the set of words  $W_e$  in the same context as the source word.

Let  $S(w_e, w_f)$  be a basic topic similarity score Cos, Cue or KL, then we define the extended scores  $ExtMean(W_e, w_f)$  and  $ExtWeight(W_e, w_f)$  as follows:

$$ExtMean(W_e, w_f) = \frac{\sum_{w_e \in W_e} S(w_e, w_f)}{|W_e|} \quad (4)$$

$$ExtWeight(W_e, w_f) = \frac{\sum_{w_e \in W_e} c'_{w_e} S(w_e, w_f)}{\sum_{w_e \in W_e} c'_{w_e}} \quad (5)$$

where  $c'_{w_e} = (\log c_{w_e})^{-1}$  for the frequency  $c_{w_e}$  of  $w_e$  appearing in the semantic model training data.

ExtMean corresponds to the mean topic similarity for each word in the context  $W_e$ . ExtWeight is weighted by the inverse log frequency of each word, allowing consideration of their semantic importance. These extended scores are used to train the SVM in place of the original scores.

## 6.2 Out-of-Domain Experiment

We performed an additional experiment where we transliterated a set of 25 Japanese words unknown to the topic model into English. These words appeared in Wikipedia fewer than 10 times and therefore were not included in our training data. We extracted the sentences and documents in which these words occurred, and back-transliterated the Japanese words into English by hand. We considered both sentence-level and document-level contexts for  $W_e$ , and evaluated each extended metric ExtMean and ExtWeight.

The results of the out-of-domain experiment are shown in Table 3, which gives the top-1 accuracy of the SVM hybrid model trained on the ExtMean and ExtWeight counterparts of Cos, Cue and KL similarities. Base is the top-1 accuracy using only the Moses baseline.

The most effective settings were to use ExtWeight on a sentence level context. There is a balance between size and relevance of context, with document-level context containing too many misleading words. The improvement of ExtWeight over ExtMean shows the impor-

	Base	ExtMean	ExtWeight
Document	0.27	0.44	0.48
Sentence		0.48	0.52

Table 3: Top-1 accuracy for out-of-domain model extension (JA-EN).

tance of weighting contextual words based on their importance (i.e. inverse log frequency).

The results show a large improvement (+0.25) over the baseline scores that is comparable to that of the in-domain model (+0.28, see Table 2). This suggests that the proposed model is an effective solution to the out-of-domain problem.

## 7 Discussion and Error Analysis

An example of the top candidates for a successful and an incorrect transliteration are given in Tables 4 and 5 respectively. We can see that the topic model has succeeded in finding the correct transliteration of ‘batik’, a traditional Javanese fabric, however a low score was given to the Korean transliteration of the name ‘Bernard’ appearing in the training data.

The benefits of the addition of a topic model is made clear with the example of ‘batik’ in Table 4. The semantic similarity measures give a higher score to ‘batik’ than ‘Batic’, a Slavic surname, despite ‘Batic’ being the more likely transliteration according to the baseline.

The improvement over the baseline for back-transliteration (XX-EN), on average +0.24, was considerably greater than that for transliteration (EN-XX), on average +0.17. We believe that this is due to the vast range of transliteration spelling variations in the non-English target languages. Since there is only one correct spelling variation defined in our test data and the topic distributions for each spelling variation are very similar, it is not possible to guess correctly. For an example of this problem, see Table 5.

### 7.1 Topic Alignment Difficulties

The majority of transliteration errors were caused by unsuccessful topic alignment between the source and target words. This was partly caused by the differences in usage of the original English words and the transliterated Japanese or Korean. For example, the

Candidate	Baseline	Cos	Cue	KL	SVM
<b>batik</b>	-1.29	<b>0.989</b>	<b>2.54e-04</b>	<b>-0.327</b>	<b>1.10</b>
baetic	-1.32	0.0764	1.67e-06	-1.65	-1.39
batic	<b>-0.708</b>	0.00	0.0	0.0	-1.48
batick	-0.788	0.00	0.0	0.0	-1.53
butic	-1.09	0.00	0.0	0.0	-1.68

Table 4: A good transliteration – バティック (*batikku* / ‘batik’) → batik.

Candidate	Baseline	Cos	Cue	KL	SVM
베르나르 <i>bereunareu</i>	-2.96	<b>0.642</b>	<b>4.78e-04</b>	<b>-1.72</b>	<b>0.112</b>
베르나르드 <i>bereunareudeu</i>	-3.65	0.243	3.84e-05	-2.41	-0.909
베른하르트 <i>bereunhareuteu</i>	-3.58	0.188	7.64e-05	-1.81	-0.969
<b>베르나르트 <i>bereunareuteu</i></b>	-4.24	0.217	8.24e-05	-2.69	-1.02
버나드 <i>beonadeu</i>	<b>-2.78</b>	0.123	4.33e-05	-3.01	-1.23

Table 5: An incorrect transliteration – bernard → 베르나르트 (*bereunareuteu*).

Japanese バイキング (*baikingu*) is a transliteration of ‘Viking’, however it is almost always used to mean ‘buffet’, deriving from the Scandinavian smorgasbord. In this case, we can expect the Japanese to be associated with food-related topics, quite different from ‘Viking’.

There are also many cases where words that do not clearly fit into one topic have unclear distributions across many groups. For example, the word 로마 (*roma* / ‘Rome’) could be more strongly categorized with ‘cities’ and ‘sightseeing’ in English but ‘history’ and ‘classical civilization’ in Korean, giving a low overall topic correlation.

## 7.2 Effect of Word Length and Frequency

We found that our model was more successful at finding the correct transliteration of longer words, as smaller words tend to have more spelling variations and are orthographically more similar to other words. By removing words of length 5 characters or less from the test data, we were able to improve the top-1 accuracy (SVM) to 0.593 (KO–EN, +0.089) and 0.721 (JA–EN, +0.111). In a practical lexicon extraction task over the entirety of Wikipedia this would cover roughly 35–45% of words (depending on language).

There was almost no variation in transliteration accuracy based on word frequency. The baseline is relatively unaffected by word frequency, with the exception of finding very rare character phrases not in the training data, and

the topic model proved to be robust across words of both high and low frequency.

## 8 Conclusion and Future Work

In this paper we demonstrated that the addition of semantic features can significantly improve transliteration accuracy. Specifically, it is possible to outperform the top-1 accuracy of a state-of-the-art phrase-based SMT transliteration baseline through the addition of a bilingual topic model.

Furthermore, our extended model is able to produce a considerable improvement in accuracy even for out-of-domain source words that have an unknown topic distribution. The experimental data set was constructed to simulate the task of extracting unknown word pairs from a comparable corpus, however our extension model results suggest that it will be possible to extract high-quality transliterations from larger and less comparable corpora than ever before.

In the future we would like to explore in depth the improvements to machine translation made possible by this approach.

## Abstract

We present a novel system combination of machine translation and text summarization which provides high quality summary translations superior to the baseline translation of the entire document. We first use supervised learning and build a classifier that predicts if the translation of a sentence has high or low translation quality. This is a reference-free estimation of MT quality which helps us to distinguish the subset of sentences which have better translation quality. We pair this classifier with a state-of-the-art summarization system to build an MT-aware summarization system. To evaluate summarization quality, we build a test set by summarizing a bilingual corpus. We evaluate the performance of our system with respect to both MT and summarization quality and, demonstrate that we can balance between improving MT quality and maintaining a decent summarization quality.

## 1 Introduction

Machine Translation (MT) has been championed as an effective technology for knowledge transfer from English to languages with less digital content. An example of such efforts is the automatic translation of English Wikipedia to languages with smaller collections. However, MT quality is still far from ideal for many of the languages and text genres. While translating a document, there are many poorly translated sentences which can provide incorrect context and confuse the reader. Moreover, some of these sentences are not as *informative* and could be summarized to make a more cohesive document. Thus, for tasks in which complete translation is not mandatory, MT can be effective if the system can provide a

more informative subset of the content with higher translation quality.

In this work, we demonstrate a framework of MT and text summarization which replaces the baseline translation with a proper summary that has higher translation quality than the full translation. For this, we combine a state of the art English summarization system and a novel framework for prediction of MT quality without references.

Our research contributions are:

- (a) We extend a classification framework for reference-free prediction of translation quality at the sentence-level.
- (b) We incorporate MT knowledge into a summarization system which results in high quality translation summaries.
- (c) For evaluation purposes, we conduct a bilingual manual summarization of a parallel corpus.<sup>1</sup>

Our English-Arabic system reads in an English document along with its baseline Arabic translation and outputs, as a summary, a subset of the Arabic sentences based on their informativeness and also their translation quality. We demonstrate the utility of our system by evaluating it with respect to both its MT and the summarization quality. For summarization, we conduct both reference-based and reference-free evaluations and observe a performance in the range of the state of the art system. Moreover, the translation quality of the summaries shows an important improvement against the baseline translation of the entire documents.

This MT-aware summarization can be applied to translation of texts such as Wikipedia articles.

<sup>1</sup>The bilingually summarized corpora could be found at: <http://nlp.qatar.cmu.edu/resources/SuMT>

For such domain-rich articles, there is a large variation of translation quality across different sections. An intelligent reduction of the translation tasks results in improved final outcome. Finally, the framework is mostly language independent and can be customized for different target languages and domains.

## 2 Related work

Our approach draws on insights from problems related to text summarization and also automatic MT evaluation. Earlier works on Arabic summarization in campaigns and competitions such as DUC (Litkowski, 2004) or Multi-Ling (Gianakopoulos et al., 2011) were focused on abstractive summarization which involves the generation of new sentences from the original document. The fluency of such generated summaries might not be perfect. However, having a noisy source language text for an MT system can degrade the translation quality dramatically. Thus, extractive summarization like our framework is more suitable for MT summarization. In retrospect our annotated Arabic-English summaries is a unique bilingual resource as most other Arabic-English summarization corpora (e.g. DUC) are abstractive summaries.

There has been a body of recent work on the reference-free prediction of translation quality both as confidence estimation metrics and also direct prediction of human judgment scores (Bojar et al., 2013; Specia, 2012) or the range of the BLEU score (Soricut and Echiabi, 2010; Mohit and Hwa, 2007). These works mostly use supervised learning frameworks with a rich set of source and target language features. Our binary classification of MT quality is closer to the classification system of Mohit and Hwa (2007) to estimate translation difficulty of phrases. However, there are several modifications such as the method of labeling, the focus on sentence level prediction and finally the use of a different metric for both the labeling and final evaluation (which reduces the metric bias). For learning features, we cumulatively explore and optimize most of the reported features, and add document-level features to model the original document properties for each sentence.

Another line of research constrained by the lack of access to reference translations is confidence estimation for MT which is simply system's judg-

ments of its own performance. The confidence measure is a score for N-grams (substrings of the hypothesis) which are generated by an MT system. Confidence estimation is performed at the word level (Blatz et al., 2003) or phrase level (Zens and Ney, 2006). The measure is based on feature values extracted from the underlying SMT system and also its training data. There are many overlaps between the features used in confidence estimation and the MT quality prediction. However, the two frameworks use different learning methods. Confidence estimation systems usually do not have gold standard data and are mostly a linear interpolation of a large group of scores. In contrast, MT quality predictors such as our framework usually use supervised learning and rely on gold standard data.

Text summarization has been successfully paired with different NLP applications such as MT in cross-language summarization. Wan et al. (2010) and Boudin et al. (2011) proposed cross-language summarization frameworks in which for each sentence, in a source language text, an MT quality and informativeness scores are combined to produce summary in a target language (Chinese and French, respectively). In the latter, sentences are first translated, ranked and then summaries are generated. Differently, in Wan et al. (2010), each sentence of the source document is ranked based on an *a posteriori* combination of both scores. The selected summarized sentences are then translated to the target language using Google Translate. In contrast, we go a step further and design a hybrid approach in which we incorporate our MT quality classifier into the state-of-the-art summarization system. Moreover, we use SMT beyond a black-box and actually incorporate its knowledge in prediction of translation quality along with other set of features such as document-related and Arabic morphological information. Finally we demonstrate that our approach outperforms Wan et al. (2010) by conducting automatic evaluation of MT and summarization systems.

## 3 An overview of the approach

Given a source language document and its translation, our aim is to find a high quality summary of the translation with a quality superior to translating the entire document. Figure 1 illustrates an overview of our framework composed of the following major components: (a) a standard

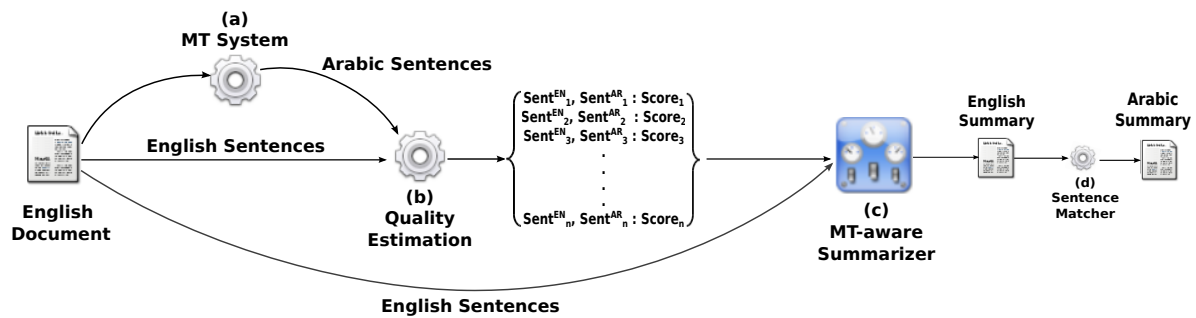

Figure 1: An overview of our MT-aware summarization system

SMT system; (b) our reference-free MT quality estimation system; (c) our MT-aware summarization system; and (d) the English-Arabic sentence matcher. Our system provides the translation summary through the following steps:

1. We translate an input English document into Arabic using the SMT system.
2. The quality estimation system (b) predicts if a translated sentence has high or low translation quality and assigns a quality score to each sentence.
3. We summarize the English document using our MT-aware summarization system (c), which incorporates the translation quality score (output of (b)) in its sentence selection process.
4. We produce the final Arabic translation summary by matching the English summarized sentences with the corresponding Arabic translations (d).
5. We automatically evaluate the quality of our MT-aware summarization system using MT and summarization metrics.

Our contributions are mainly related to the second and third components which will be discussed in Sections 4 and 5.

#### 4 Reference-free quality estimation of MT

Our system needs to estimate the translation quality without access to the Arabic reference translations. The reference-free MT evaluation has been investigated extensively in the past decade. A valuable gold-standard resource for many of these studies are human judgment scores which have

been developed in evaluation programs like NIST, and workshops such as WMT (Koehn and Monz, 2006). Since such human judgments do not exist for English to Arabic translations, we adapt the framework of Mohit and Hwa (2007) for predicting the translation quality. This framework uses only reference translations and the automatic MT evaluation scores to create labeled data for training a classifier. The binary classifier reads in a source language sentence, with its automatically obtained translation and predicts if the target sentence has *high* or *low* translation quality. We describe details of this framework in the following section.

##### 4.1 Labeling gold-standard data

In order to train the binary classifier, we need gold standard data with English source sentences labeled as having high or low translation quality when translated into Arabic. For this labeling, we estimate translation quality by the Translation Edit Rate TER metric (Snover et al., 2006).<sup>2</sup> We deliberately use two different metrics for gold standard labeling (TER) and the final MT evaluation (using BLEU (Papineni et al., 2002)) to reduce the bias that a metric can introduce to the framework. In this task, we use a parallel corpus that is composed of a set of documents. We automatically translate each document and label its sentences based on the following procedure:

- (a) Measure the TER score of the document against its reference translation.
- (b) For each sentence within the document, measure its TER score: If this score is higher than the document score, it has *low* translation quality. Otherwise it has *high* translation quality.

<sup>2</sup>This automatic labeling framework exempts us from the manual labeling of translation quality like Wan et al. (2010).

This provides a simple estimate of the translation quality for a source language sentence relative to the document that it belongs to. This document-level relevance is a deliberate choice to build a classifier that ranks the translation quality of a sentence with respect to other sentences in the document (similar to a summarization system). We also note that the quality labeling is obviously non-absolute and relative to the specific SMT engine used in this work.

## 4.2 MT quality classifier

We use a Support Vector Machine (SVM) classifier and exploit a rich set of features to represent a source language sentence and its translation. We use the default configuration with a linear kernel function. In order to estimate a score for the translation quality, we use a normalized form of the classifier's score for each sentence. The score is the distance from the separating surface and is proper estimate of the intensity of the class label.

## 4.3 Learning features

We use a suite of features that have been extensively used in works related to translation quality estimation. We adapt the feature extraction procedure from the Quest framework (Specia et al., 2013) to our English-Arabic translation setup, and extract the following groups of features:

**General features:** For each sentence we use different features modeling its length in terms of words, the ratio of source-target length, source-target punctuation marks, numerical characters, and source-target content words.

**Language model scores:** The likelihood of a target language (Arabic) sentence can be a good indicator of its grammaticality. In our experiments, we used the SRILM toolkit (Stolcke, 2002) to build 5-gram language model using the LDC Arabic Gigaword corpus. We then, apply this model to obtain log-likelihood and perplexity scores for each sentence.

**MT-based scores:** We extract a set of features from the generated MT output. These include the absolute number and the ratios of out of vocabulary terms and the ratio of Arabic detokenization that is performed on the Arabic MT output.

**Morphosyntactic features:** We use features to model the difference of sequences of POS tags

for a pair of source-target sentences. These features measure the POS preservation in the translation process (e.g. measuring if the proper nouns in the source sentence are kept and also translated as proper nouns in Arabic). We compute the absolute difference between the number of different POS tags. The source and target sentences are tagged respectively using the TreeTagger (Schmid, 1994) and AMIRA (Diab, 2009) toolkits. We also, indicate the percentage of nouns, verbs, proper nouns in the source and target sentences.

**Document-level features:** We extend Mohit and Hwa (2007) framework by incorporating a set of document-level features (in addition to the sentence-level ones) which scales the sentence's classification relative to its document. In a linear model, these document-level features rescale and shift the feature space relative to the given document which helps us to classify the sentence with respect to the document. These features consist of the average of the sentence-level features described above.

## 5 MT-aware Summarization

We pair summarization and MT (SUMT) by including information about the MT quality into the summarization system. Our MT-aware summarizer focuses on the linguistic and translation quality of a given sentence, as well as its position, length, and the content in its sentence ranking procedure. The main goal of this system is to obtain an informative summary of a source document with an improved translation quality that could replace the complete, yet less fluent translation of the document.

We explore various configurations and find the sweet spot of the translation and summarization qualities in the system illustrated in Figure 1. This includes converting the MEAD summarizer into an MT-aware summarization framework by including information from the classifier into the sentence ranking procedure.

### 5.1 The MEAD Summarization system

In our experiments, the summary for each document is generated using MEAD (Radev et al., 2004), a state-of-the-art single- and multi-document summarization system. MEAD has been widely used both as a platform for developing summarization systems and as a baseline system for testing novel summarizers. It is a

centroid-based extractive summarizer which selects the most important sentences from a sequence of sentences based on a linear combination of three parameters: the sentence length, the centroid score and the position score (Radev et al., 2001). MEAD also employs a cosine reranker to eliminate redundant sentences. We create summaries at 50% length (a fixed ratio for all documents) using MEAD’s default configurations.

## 5.2 SUMT system

Our MT-aware summarizer (SUMT) represents an approach of adapting the basic sentence scoring/ranking approach of MEAD. We extend the default MEAD sentence ranking procedure by incorporating information about the translation quality of the sentence. This score is provided by our SVM-based classifier. The selected sentences generally correspond to those having high translation quality (estimated by TER).

Typically, the ranking score of a sentence is defined by a linear combination of the weighted sentence position, centroid and length scores. We used the default weights defined for each feature in the default version of MEAD. The additional quality feature weight is optimized automatically towards the improvement of BLEU, using a held-out development set of documents. Finally, sentences in each document are ranked based on the final obtained score. In this work, we take a hard 50% summarization ratio which is applied to MEAD, SUMT and our gold standard summaries.

## 6 Experimental Setup

In this section, we explain details of the data and the general setting for different components of our system.

### 6.1 Translation and Summarization Corpora

For our experiments, we use the standard English-Arabic NIST test corpora which are commonly used MT evaluations.<sup>3</sup> We use the documents provided in NIST 2008 and 2009 for the training and development, and those in the NIST 2005 for testing. Each collection contains an Arabic and four English reference translations. Since we work on English to Arabic translation, we only use the first translation as the reference.

<sup>3</sup>All of the different MT corpora can be accessed from Linguistic Data Consortium (LDC).

### 6.2 Annotation of gold-standard summaries

The automatic summarization should be able to reduce the complexity of documents length wise, while keeping the essential information from the original documents like important events, person names, location, organizations and dates. In order to evaluate the quality of the summaries, we conducted a bilingual summarization of our test corpus (the NIST 2005). This parallel corpus is composed of 100 parallel documents containing each in average 10 sentences. We asked two native speakers (one per language) to summarize each side of the corpora independent of each other and independent of the MT output. We set a hard 50% ratio for annotators to choose approximately half of the sentences per document. Annotators followed a brief guideline to completely understand the entire document and examine and select summary sentences based on the following criteria: (a) Being informative with respect to the main story and the topic (b) minimizing the redundancy of information (c) preserving key information such as the named entities and dates. We obtain as inter-judge agreement a value of  $\kappa = 0.61$  corresponding to a moderate agreement according to the literature.<sup>4</sup>

### 6.3 MT Setup

The baseline MT system is the open-source MOSES phrase-based decoder trained on a standard English-Arabic parallel corpus. This 18 million word parallel corpus consists of the non-UN parts of the NIST corpus distributed by the LDC. We perform the standard preprocessing and tokenization on the English side using simple punctuation-based rules. We also use the MADA+TOKAN morphological analyzer (Habash et al., 2009) to preprocess and tokenize the Arabic side of the corpus. The corpus is word-aligned using the standard setting of GIZA++ and the grow-diagonal-final heuristic of MOSES. We use the 5-gram language model with modified Kneser-Ney smoothing. The language model for our system is trained using the LDC Arabic Gigaword corpus. A set of 500 sentences is used to tune the decoder parameters using the MERT (Och, 2003). After decoding, we use the El Kholy and Habash (2010) Arabic deto-

<sup>4</sup>This Cohen’s kappa value is obtained using the MEAD evaluation tool designed to assess the agreement between two summaries.

kenization framework to prepare the Arabic output for evaluation.

#### 6.4 MT-quality classifier

We use the models described in Section 4 to build a Support Vector Machine (SVM) binary classifier using the LIBSVM package (Chang and Lin, 2011). To train our classifier we use a total of 2670 sentence pairs extracted from 259 documents of NIST 2008 and 2009 data sets. The sentences are labeled following our TER-based procedure. The automatic labeling procedure (section 4.1) enforces a rough 50-50 high and low quality translations. Thus, we obtained 1370 negative examples and 1363 positive ones. For all tests, we use a set of 100 documents from the NIST 2005 test set, containing 1056 sentences.

### 7 Evaluation and results

We experimented with different configurations of the MT and the summarization system with the goal of achieving a balanced performance in both dimensions. We reached the sweet spot of performance in both dimensions in our MT-aware summarization system in which we achieved major (over 4 points BLEU score) improvements while maintaining an acceptable summarization quality. In the following we discuss the performance of the MT and summarization systems.

#### 7.1 MT evaluation

Table 1 presents MT quality for the baseline system and different summarization frameworks measured by BLEU, TER and METEOR (Lavie and Agarwal, 2007) scores.<sup>5</sup>

The remaining MT experiments are conducted on summarized documents. These include summaries provided by: (a) a length-based baseline system that simply chooses the subset of sentences with the shortest length (**Length**); (b) the state of the art MEAD summarizer (**MEAD**); (c) our MT quality estimation classifier (**Classifier**); (d) a linear interpolation of informativeness and MT quality scores in the spirit of Wan et al. (2010) (**Interpol**)<sup>6</sup>; (e) our MT-aware summarizer

<sup>5</sup>Our English to Arabic baseline system shows a performance in the ballpark of the reported score for the state of the art systems (e.g. El Kholly and Habash (2010)).

<sup>6</sup>The overall score of a sentence is defined as follows:  $score = (1 - \lambda) * InfoScore + \lambda * TransScore$  where  $\lambda = 0.3$  and  $TransScore$  and  $InfoScore$  denote the MT quality score and the informativeness score of a sentence.

(**SuMT**); and (f) an oracle classifier which chooses the subset of sentences with the highest translation quality (**Oracle**). This oracle provides an upper bound estimate of room that we have to improve translation quality of the summaries.

	BLEU	TER	METEOR
<i>Baseline</i>	27.52	58.00	28.51
<b>Length</b>	26.33	58.13	27.81
<b>MEAD</b>	28.42	55.00	28.82
<b>Classifier</b>	31.36	52.00	29.22
<b>Interpol</b>	28.45	55.00	29.05
<b>SuMT</b>	<b>32.12</b>	<b>51.00</b>	<b>30.48</b>
<b>Oracle</b>	34.75	47.00	32.42

Table 1: A comparison of MT quality for full and summarized documents.

We are aware that the comparison of the MT baseline system with these summarization systems is not a completely fair comparison as the test sets are not comparable. However, with a ballpark comparison of the baseline (for full documents) with the summarized documents, we demonstrate the average range of improvement in translation quality. Moreover, we compare different summarization systems with each other to reach the best combination of MT and summarization quality.

We set a 50% summarization ratio in all experiments and also in creation of the gold-standard to create similar comparable conditions. For example, for evaluating our quality estimation classifier as a summarizer, we filter out the bottom 50% of the sentences (based on their classification scores) for each document and evaluate the translation quality of the top 50% Arabic translation sentences.

The MT results for the MEAD summarizer indicate that summarization of MT does not necessarily improve MT quality. In contrast, the comparison between the baseline, the oracle summarizer and SuMT system demonstrates a major improvement in MT quality that is competitive with the oracle summarizer (an improvement of almost +5 BLEU scores). The results given in Table 1 show also that our system produce better MT quality sentences than Interpol (+4.67 BLEU points). This could be explained by the higher weight assigned to the informativeness score in the linear interpolation. In the following sections we demonstrate that we maintain a decent summarization quality while we achieve these MT improvements.

	<i>English</i>					<i>Arabic</i>				
	<b>Length</b>	<b>MEAD</b>	<b>Classifier</b>	<b>Interpol</b>	<b>SuMT</b>	<b>Length</b>	<b>MEAD</b>	<b>Classifier</b>	<b>Interpol</b>	<b>SuMT</b>
<b>ROUGE-1</b>	54.21	<b>75.93</b>	67.41	73.72	72.51	36.01	45.66	44.94	45.33	<b>46.43</b>

## 7.2 Model-based summarization evaluation

We evaluate the quality of our summarization systems for both English and Arabic. We first focus on English summaries generated using different summarization configurations, and then evaluate the quality of Arabic summaries obtained by matching the English summarized sentences with the corresponding Arabic translations. It is not surprising that summarizing a noisy Arabic MT output would not produce high quality Arabic summaries. Instead, we use the parallel corpus to project the summarization from the source language (English) to the corresponding Arabic translations.

For evaluating our summarization systems, we use ROUGE (Lin, 2004), a metric based on n-gram similarity scores between a model summary generated by human and an automatically generated peer summary. We use the ROUGE-1, ROUGE-2, ROUGE-SU4 and ROUGE-L F-scores with the two human summaries described in Section 6 as models.<sup>7</sup> We use the same parameters and options in ROUGE as in the DUC 2007 summarization evaluation task.<sup>8</sup> Table 2 presents the ROUGE F-scores obtained on our test datasets for the different summarization systems for both languages.

Similar to section 7.1, we experiment with five summarizers: **Length**, **MEAD**, **Classifier**, **Interpol**, **SuMT**. As expected, the MEAD summarizer shows the best summarization performance. Also, the length-based baseline system generates poor quality summaries (about 22 score ROUGE-1 reduction from MEAD). This is not surprising since the baseline only uses the length of the sentence regardless its content. Furthermore, the perfor-

<sup>7</sup>A study conducted by Lin and Hovy (2003) shows that automatic evaluation using unigram and bigram co-occurrences between summary pairs have the highest correlation with human evaluations and have high recall and precision in significance test with manual evaluation results.

<sup>8</sup><http://duc.nist.gov/duc2007/tasks.html>.

mance of the classifier-based summarizer is lower than the MEAD, because it does not use the summarization feature and only relies on an estimated translation quality to select the sentences.

Reviewing different values of the ROUGE metric in the left side Table 2, we observe that SuMT and Interpol summaries maintain a decent quality, comparable to the state of the art MEAD. For example, they give promising results in terms of ROUGE-L (71.17% and 72.79%, respectively), which consistently indicates that the sentences produced are closer to the reference summary in linguistic surface structure than those of the classifier (65.92). In addition to the quality of the English summaries, we are more interested in assessing the quality of the Arabic summaries. This comes back to our main goal of producing a fluent Arabic summary with good translation quality. We evaluate the Arabic summaries by measuring different ROUGE metrics against our model summaries. The results in the right side of Table 2 show that our MT-aware summarization framework achieves the best results in different ROUGE configurations and outperforms the state-of-the-art summarizer (+1 point ROUGE-1). In other words, our Arabic translated summaries generated using SuMT, are the most fluent and have the most similar structure compared with the Arabic model summaries.

## 7.3 Model-free summarization evaluation

In addition to the reference-based summarization evaluation described above, we conducted model-free experiments evaluating the summary quality for both languages. Recently, Louis and Nenkova (2013) proposed SIMetrix, a framework that does not require gold standard summaries for measuring the summarization quality. The framework is based on the idea that higher similarity with the source document would be indicative of high quality summary. SIMetrix is a suite of model-free similarity metrics for comparing a generated sum-

mary with the source document for which it was produced. That includes cosine similarity, distributional similarity and also use of topic signature words. SIMetrix is shown to produce summary scores that correlate accurately with human assessments.<sup>9</sup>

We used SIMetrix to evaluate the quality of the summaries generated by different systems. We report in Table 3, **%TopicTokens** referring to the percentage of tokens in the summary that are topic words of the input document; the Kullback Leibler divergence (**KL**); and the Jensen Shannon divergence (**JS**) between vocabulary distributions of the input and summary texts, which was found to produce the best predictions of summary quality. Since KL divergence is not symmetric, we measure it both ways Input-Summary (**KL<sub>IS</sub>**) and Summary-Input (**KL<sub>SI</sub>**). Based on these metrics, a good summary is expected to have low divergence between probability distributions of words in the input and summary, and high similarity with the input.

Table 3 illustrates these similarity results for both English and Arabic summaries. The results are consistent with those found in the model-based evaluation. For Arabic, our MT-aware system achieves the best results in terms of different divergence (0.14 JS against 0.17 for MEAD) and topic related scores (73.37% of tokens in the SUMT Arabic summaries are topic words in the input document against 71.78% in MEAD summaries). It is important to note that lower divergence scores indicate higher quality summaries.

	Length	MEAD	Classifier	Interpol	SuMT
<i>English</i>					
<b>%TopicTokens</b>	63.21	63.70	63.28	63.50	63.33
<b>KL<sub>IS</sub></b>	0.37	0.18	0.33	0.19	0.25
<b>KL<sub>SI</sub></b>	0.14	0.02	0.12	0.07	0.09
<b>JS</b>	0.04	0.01	0.03	0.02	0.02
<i>Arabic</i>					
<b>%TopicTokens</b>	71.51	71.61	73.18	72.44	<b>73.37</b>
<b>KL<sub>IS</sub></b>	1.30	1.24	1.28	1.20	<b>1.19</b>
<b>KL<sub>SI</sub></b>	1.11	1.07	1.03	0.96	<b>0.94</b>
<b>JS</b>	0.17	0.15	0.16	0.15	<b>0.14</b>

Table 3: Distribution similarity scores for each system summaries evaluated against the input document for English and Arabic.

<sup>9</sup>SIMetrix is available at: <http://www.seas.upenn.edu/~lannie/IEval2.html>.

## 8 Conclusion and Future work

We presented our approach in pairing automatic text summarization with machine translation to generate a higher quality content. We demonstrated an English to Arabic MT aware summarization framework with high summarization quality and greatly improved translation quality.

We plan to extend our current system in the following directions: (a) We will examine alternative learning frameworks and features to improve our prediction of the translation quality. (b) We will explore different methods to incorporate and optimize the MT quality information with the summarization system. (c) We will explore alternative text domains such as Wikipedia in which there is a larger variation of translation quality in different parts of the document. Considering the poor translation quality of many language pairs, text summarization can provide effective support for MT in various end-user applications. We believe there are many avenues to explore in this direction of research.

## Abstract

In this paper, we consider the tuning of statistical machine translation (SMT) models employing a large number of features. We argue that existing tuning methods for these models suffer serious sparsity problems, in which features appearing in the tuning data may not appear in the testing data and thus those features may be over tuned in the tuning data. As a result, we face an over-fitting problem, which limits the generalization abilities of the learned models. Based on our analysis, we propose a novel method based on feature grouping via OSCAR to overcome these pitfalls. Our feature grouping is implemented within an online learning framework and thus it is efficient for a large scale (both for features and examples) of learning in our scenario. Experiment results on IWSLT translation tasks show that the proposed method significantly outperforms the state of the art tuning methods.

## 1 Introduction

Since the introduction of log-linear based SMT (Och and Ney, 2002), tuning has been a hot topic. Various methods have been explored: their objectives are either error rates (Och, 2003), hinge loss (Watanabe et al., 2007; Chiang et al., 2008) or ranking loss (Hopkins and May, 2011), and they are either batch training or online training methods. In this paper, we consider tuning translation models with a large number of features such as lexical, n-gram level and rule level features, where the number of features is largely greater than the number of bilingual sentences. Practically, existing tuning methods such as PRO and MIRA might

This joint work was done while the first author visited NICT.

be applied in our scenario, however, they will suffer from some pitfalls as well, which have been less investigated in previous works.

One of pitfalls is that these features are so sparse that many features which are potentially useful for a test set may not be included in a given tuning set, and many useless features for testing will be over tuned on the development set meanwhile. As a result, the generalization abilities of features are limited due to the mismatch between the testing data and the tuning data, and over-fitting occurs. One practice is to tune translation models on a larger tuning set, such as the entire training data (Xiao et al., 2011; Simianer et al., 2012), in the hope that more features would be included during tuning. However, tuning robust weights for translation models has additional requirements to a tuning set. Firstly, multiple reference translations in the tuning data are helpful for better tuning, especially when testing data contains multiple reference translations. Secondly, the closeness between the tuning set and a test set is also important for better testing performance (Li et al., 2010). These requirements can explain why tuning on the training data leads to unsatisfactory performance on the IWSLT translation task, as will be shown in our experiments later. Therefore, enlarging a tuning set is not always a sufficient solution for robust tuning, since it would be impractical to create a large scale tuning set with these requirements.

We propose a novel tuning method by *grouping* a large number of features to leverage the above pitfalls. Instead of directly taking the large number of atomic features into translation model, we firstly learn their group structure on the training data to alleviate their serious sparsity. Then, we tune the translation model consisting of grouped features on a multi-reference development set to ensure robust tuning. Unlike unsupervised clustering methods such as k-means (MacQueen, 1967) for feature clustering, we group the features with

the OSCAR (Octagonal Shrinkage and Clustering Algorithm for Regression) method (Bondell and Reich, 2008), which directly relates the objective of feature grouping to translation evaluation metrics such as BLEU (Papineni et al., 2002) and thus grouped features are optimized with respect to BLEU. Due to the large number of features and large number of training examples, efficient grouping is not simple. We apply the online gradient projection method under the FOBOS (forward-backward splitting) framework (Duchi and Singer, 2009) to accelerate feature grouping.

We employ a large number of features by treating each translation rule in a synchronous-CFG as a single feature. Experiments on IWSLT Chinese-to-English translation tasks show that, with the help of grouping these features, our method can overcome the above pitfalls and thus achieves significant improvements.

## 2 Tuning Method

We propose a novel tuning method for translation models with a large number of features, which incorporates feature grouping. Our assumption is that although a feature which is useful for a test set does not appear in the tuning set, another similar feature may exist. Therefore, grouping similar features can alleviate sparsity in this way. The proposed tuning method consists of two steps: first, it tries to learn a group structure for atomic features; second, it treats each feature group as a single feature and tunes the translation model on a given tuning set using off-the-shelf toolkits such as PRO. In the first step, we learn a group structure of atomic features in the large training data for better coverage. In the second step, we tune a translation model with the grouped features on a given development set with multiple references to ensure the robust tuning.

Before describing our tuning algorithm, we present notations for the rest of this paper. Suppose  $\mathcal{H}$  is a feature set consisting of atomic features  $\{h_1, h_2, \dots, h_d\}$  or their index set  $\{1, 2, \dots, d\}$  for simplicity;  $H = \langle h_1, h_2, \dots, h_d \rangle$  is a  $d$ -dimensional feature vector function with respect to  $\mathcal{H}$ , and  $W$  is its weight vector with each component  $W_i$  and dimension  $d$ ;  $\mathcal{G} = \{g_1, g_2, \dots, g_M\}$  is a group of  $\mathcal{H}$ , where each element  $g_i$  is a power set of  $\mathcal{H}$ . Similarly,  $G = \langle g_1, g_2, \dots, g_M \rangle$  is an  $M$ -dimensional feature vector function with respect to  $\mathcal{G}$  and  $W^{\mathcal{G}}$  is

its weight with each component  $W_i^{\mathcal{G}}$ . In this paper, we consider the disjoint  $\mathcal{G}$ , i.e.  $g_i \cap g_j = \emptyset$  if  $i \neq j$ . Further, suppose  $\Delta(W)$  is a set of the index  $i$  such that  $W_i \neq 0$ , and  $|\cdot|$  is either the number of elements in a set  $S$  or the absolute value of a real number  $x$ .

---

### Algorithm 1 Tuning Algorithm

---

**Input:** training data, dev,  $W^{ini}$ ,  $T$

- 1: Initialize  $W^1 = W^{ini}$
- 2: **for all**  $i$  such that  $1 \leq i \leq T$  **do**
- 3:   Decode on training data with  $W^i$  to obtain a k-best-list and merge k-best-lists
- 4:   Update the group set  $\mathcal{G}$  based on the merged k-best-list  $\triangleright$  **Call Algorithm 2**
- 5:   Tune the translation model with  $\mathcal{G}$  as the feature set on dev with PRO to update  $W^{\mathcal{G}}$
- 6:   Unpack  $W^{\mathcal{G}}$  to  $W^{i+1}$
- 7: **end for**
- 8:  $W = W^{T+1}$

**Output:**  $W$

---

Algorithm 1 describes our two-step tuning procedure for a translation model with  $\mathcal{H}$  as its feature set. It inputs a training data set, a development set, initial weight  $W^1$  with respect to  $\mathcal{H}$ , and maximal iterations  $T$ ; and outputs a weight  $W$ . It initializes with  $W^1$  in line 1; from line 2 to line 7, it iteratively obtains a k-best-list by decoding with  $W^i$ , updates the group set  $\mathcal{G}$ , tunes the translation weight  $W^{\mathcal{G}}$  based on  $\mathcal{G}$ , and unpacks the  $W^{\mathcal{G}}$  to obtain  $W^{i+1}$ . At the end, it returns the final weight  $W$ . In particular, the k-best-list is obtained using  $H$  as a feature vector with its weight vector  $W$  derived from grouped weights  $W^{\mathcal{G}}$  through unpacking: if  $h_j \in g_k$ , then  $W_j = W_k^{\mathcal{G}}$ . The grouping algorithm in line 3 will be introduced in the next section.

In this paper, we use a hierarchical phrase based translation model, which consists of 8 default features: translation probabilities, lexical translation probabilities, word penalty, glue rule penalty, synchronous rule penalty and language model. In addition, we also employ a large number rule identify (id) features: each rule itself is a feature, and if a translation contains a rule for  $x$  times, then the value of this rule id feature is  $x$ . In line 4 we group these id features and impose that each default feature itself is a group.

## 3 Online Feature grouping

---

**Algorithm 2 Feature Grouping Algorithm**

---

**Input:**  $\lambda_1, \lambda_2, k$ -best-list,  $W^1, n$ 

- 1: Collect a set of tuples  $\{\langle f, e', e^* \rangle\}$  from  $k$ -best-list
- 2: **for all**  $i$  such that  $1 \leq t \leq n$  **do**
- 3: Randomly select  $\langle f, e', e^* \rangle$  from the tuple set
- 4:  $W^{t+1/2} = W^t + \nabla_W \delta(f, e', e^*, W^t)/t$
- 5: Minimize  $Q(W; W^{t+1/2}, t+1, \lambda_1, \lambda_2)$  to obtain  $(W^{t+1}, \mathcal{G})$

▷ **Group optimization**

- 6: **end for**

**Output:**  $\mathcal{G}$ 

---

Suppose  $f$  is a sentence in a development set,  $C$  is a set of translations for  $f$ , and  $r$  is a set of reference translations for  $f$ . Following PRO, we define ranking loss function as follows:

$$L(W) = \frac{1}{N} \sum_f \sum_{e^*, e'} \delta(f, e', e^*, W), \quad (1)$$

with

$$\delta(f, e', e^*, W) = \max_W \left\{ (H(f, e') - H(f, e^*)) \cdot W + 1, 0 \right\},$$

where  $e', e^* \in C$  such that  $\text{BLEU}(e^*, r) > \text{BLEU}(e', r)$ , and  $N$  is the number of all tuples  $\langle e^*, e', f \rangle$ .

To achieve group structure and avoid the sparsity in  $H$ , we apply the OSCAR over the above loss function, and obtain the function:

$$L(W) + \lambda_1 \sum_{i=1}^d |W_i| + \lambda_2 \sum_{1 \leq i < j \leq d} \max\{|W_i|, |W_j|\}, \quad (2)$$

where  $d$  is the dimension of feature vector  $H$  or its weight  $W$ ,  $\lambda_1$  and  $\lambda_2$  are two hyperparameters for two regularizers taking positive value. Minimization of Eq.2 makes some components in  $W$  equal and thus achieves a feature grouping effect. In other words,  $W_i = W_j$  means that  $h_i$  and  $h_j$  lie in the same group, i.e.  $h_i, h_j \in g_k$  for some  $g_k \in \mathcal{D}(W)$ , where  $\mathcal{D}(W)$  denotes the group derived from  $W$  as follows. Given  $W$ , we first sort its components  $W_i$  to obtain a permutation  $\{i_k\}_{k=1}^d$  such that  $W_{i_1} \leq W_{i_2} \leq \dots \leq W_{i_d}$  with  $1 \leq i_k \leq d$ ; then we can easily obtain  $\mathcal{D}(W)$  after traversing  $\{W_{i_k}\}_{k=1}^d$ . For example,  $W =$

$\langle 1, 3, 1, 3, 1 \rangle$ , then  $\mathcal{D}(W) = \{\{1, 3, 5\}, \{2, 4\}\}$ . One advantage of OSCAR over unsupervised clustering methods (e.g.  $k$ -means) is that it relates the objective of grouping to an error metric, such as BLEU, and thus can achieve an optimal grouping towards BLEU.

Bondell and Reich (2008) firstly proposed two approaches for OSCAR. The first one casts the problem into a quadratic program (QP) consisting of  $O(d^2)$  variables and  $O(d^2)$  constraints. The second one tries to optimize a sequence of (potentially smaller) QP's with more constraints, which can be up to  $O(d!)$  in the worst case. Zhong and Kwok (2011) explored a much faster approach which is based on the accelerated gradient and projection method. Its complexity is reduced to  $O(d \log d)$ . Since the dimension  $d$  of  $H$  is large enough in our scenario where  $d$  is up to hundred of thousands, these existing optimization methods are inefficient to minimize Eq.2. Here, based on (Zhong and Kwok, 2011), we employ an online gradient projection algorithm under the FOBOS framework for faster learning. The framework of FOBOS is a type of online learning, in which it is theoretically guaranteed to solve such a problem as in Equation 2: the objectives consisting of two additive terms, in which one is non-smooth but convex and the other is smooth and convex<sup>1</sup>. FOBOS contains two steps: it first performs a gradient descent operator, and then updates weight by a proximity (or projection) operator.

Algorithm 2 describes the online training of feature grouping. It requires some inputs: two regularizer parameters  $\lambda_1$  and  $\lambda_2$ ; a  $k$ -best-list translations; an initial weight  $W^1$ ; and a maximum iterations  $n$ . It firstly collects a set of tuples encoded with translation pairs from  $k$ -best-list following the strategy implemented in the PRO toolkit in line 1. It repeatedly updates weight  $W^t$  and feature group  $\mathcal{G}$  from line 2 to line 6: it randomly samples a tuple  $\langle f, e', e^* \rangle$  from the collected tuple set in line 3, it performs a gradient descent operator in line 4 where  $\nabla_W \delta(f, e', e^*, W^t)$  denotes the subgradient of  $\delta(f, e', e^*, W^t)$  at current weight  $W^t$ , and it optimizes  $(W^{t+1}, \mathcal{G})$  by a proximity operator for group optimization in line 5. At last it returns the group result  $\mathcal{G}$ .

In particular, the subgradient of  $\delta(f, e', e^*, W^t)$

---

<sup>1</sup>For Eq.2, the non-smooth but convex term is the entire of Eq.2, and the smooth and convex term can be considered as 0.

in line 4 is defined via the following equation:

$$\nabla_W \delta(f, e', e^*, W) = \begin{cases} H(f, e') - H(f, e^*), & \text{if } \delta(f, e', e^*, W) > 0; \\ 0, & \text{else.} \end{cases}$$

The main technique is the proximity operator for group optimization in line 5, which tries to minimize the function  $Q(\cdot; a, t, \lambda_1, \lambda_2)$  with  $a = W^t + \nabla_W \delta(f, e', e^*, W^t)/t$ :

$$Q(W; a, t, \lambda_1, \lambda_2) = (W - a)^\top W + \frac{2}{t} \left( \lambda_1 \sum_{i=1}^d |W_i| + \lambda_2 \sum_{1 \leq i < j \leq d} \max\{|W_i|, |W_j|\} \right). \quad (3)$$

In the next Section, we will present the details of this proximity for group optimization.

#### 4 Group Optimization

To derive an efficient algorithm with large  $d$  for group optimization, we present the following lemma with its proof attached in appendix.

**Lemma 1.** *In Eq.3, if  $a_k=0$ , then its minimal solution  $\hat{W}$  suffices to  $\hat{W}_k = 0$ .*

Suppose  $W^t$  is sparse, i.e.  $d$  is largely greater than the number of its non-zero components ( $|\Delta(W^t)|$ ), then  $W^{t+1/2}$  in line 4 is also sparse since  $H$  is sparse. The above Lemma states that the optimal solution  $W^{t+1}$  in line 5 of Algorithm 2 is also a sparse vector. Therefore, it is desirable to optimize the  $W^{t+1}$  in a low complexity independent on  $d$ . If so, we can easily see that if we set  $W^1$  as a sparse vector,  $W^t$  is sparse for all  $t > 1$  by a mathematical induction. Based on these analysis, the efficiency of proximity operator for group optimization only requires an assumption that its proximity step can be efficiently solved in a low complexity independent on a large  $d$ .

Let  $u = |\Delta(a)|$ , and  $p$  be a one-to-one map<sup>2</sup>  $p : \{1, \dots, u\} \rightarrow \{1, \dots, d\}$ , s.t.  $|a_{p(1)}| \geq |a_{p(2)}| \geq \dots \geq |a_{p(u)}| > 0$ . Followed by Lemma 1, minimizing Eq.2 is equivalent to minimizing the following equation if we ignore the zero compo-

<sup>2</sup>For easier understanding,  $i'(j')$  denotes the index in  $\{1, \dots, u\}$ , while  $i(j)$  denotes the index in  $\{1, \dots, d\}$ .

nents in the optimal solutions of both equations:

$$\begin{aligned} \bar{Q}(W; a, t, \lambda_1, \lambda_2) &= \sum_{i'=1}^u W_{p(i')}^2 - \sum_{i'=1}^u a_{p(i')} W_{p(i')} \\ &+ \sum_{i'=1}^u \frac{2(\lambda_1 + \lambda_2(d-u))}{t} |W_{p(i')}| + \\ &\frac{2\lambda_2}{t} \sum_{1 \leq i' < j' \leq u} \max\{|W_{p(i')}|, |W_{p(j')}|\}. \end{aligned}$$

The advantage of optimizing  $\bar{Q}(W; a, t, \lambda_1, \lambda_2)$  instead of  $Q(W; a, t, \lambda_1, \lambda_2)$  is that it explicitly reduces the size of active components in  $W$  into  $u$  rather than  $d$ , and thus it is more direct to expect a faster optimization algorithm. Further, Proposition 1 in (Zhong and Kwok, 2011) states that the minimal solution  $\hat{W}$  of such an equation as  $\bar{Q}(W; a, t, \lambda_1, \lambda_2)$  suffices to the constraint  $|\hat{W}_{p(1)}| \geq \dots \geq |\hat{W}_{p(u)}|$ . Therefore, minimizing  $Q(W; a, t, \lambda_1, \lambda_2)$  is also equivalent to optimizing the following constraint programming:

$$\begin{aligned} &\underset{W}{\text{minimize}} && \bar{Q}(W; a, t, \lambda_1, \lambda_2) \\ &\text{subject to} && |W_{p(1)}| \geq \dots \geq |W_{p(u)}|, \end{aligned}$$

where  $\bar{Q}(W; a, t, \lambda_1, \lambda_2)$  defined on the constraint is rewritten as

$$\begin{aligned} \bar{Q}(W; a, t, \lambda_1, \lambda_2) &= \sum_{i'=1}^u W_{p(i')}^2 - \sum_{i'=1}^u a_{p(i')} W_{p(i')} \\ &+ \sum_{i'=1}^u \frac{2(\lambda_1 + \lambda_2(d-i'))}{t} |W_{p(i')}|. \quad (4) \end{aligned}$$

Now, we can implement line 5 in Algorithm 2 as summarized by Algorithm 3, after some modifications over the projection algorithm in (Zhong and Kwok, 2011). Algorithm 3 requires some variables  $\lambda_1, \lambda_2, a$  and  $t$ . Firstly, it sorts  $|a_i|$  for the indice in  $\Delta(a)$  to obtain the map  $p$  in line 1, and initializes  $\mathcal{G}$  as  $\{\{p(1)\}\}$  in line 2. From line 3 to line 10, it goes into a merging loop where it repeatedly merges two group members to pre-calculate  $\mathcal{G}$ : for each  $i'$ , it iteratively merges the member  $g$  initialized as  $\{p(i')\}$  and the top member in the stack, updates  $g$  with the merged member, and substitutes the top member in the stack with  $g$ , if the  $v$  value (will be defined later) of  $g$  is greater than that of the top member. Then, it begins to calculate  $W$  initialized as 0 and  $\mathcal{G}$ . For each index  $i$  in each member  $g$  of  $\mathcal{G}$ , it assigns  $W_i$

---

**Algorithm 3 Group Optimization**

---

**Input:**  $\lambda_1, \lambda_2, a, t$ 

```
1: Sort  $\{|a_i| : i \in \Delta(a)\}$  to obtain  $p \triangleright$  See the definition of  $\Delta$  in Section 2
2: Initialize stack of group set  $\mathcal{G} = \{p(1)\}$ 
3: for all  $i'$  such that  $2 \leq i' \leq |\Delta(a)|$  do
4:    $g = \{p(i')\}$ 
5:   while  $\mathcal{G} \neq \emptyset$  and  $v(g) \geq v(\text{top}(\mathcal{G}))$  do
6:      $g = g \cup \text{top}(\mathcal{G}) \triangleright$  Merge  $g$ 
7:     Pop  $\text{top}(\mathcal{G})$ 
8:   end while
9:   Push  $g$  onto  $\mathcal{G}$ 
10: end for  $\triangleright$  Pre-calculate  $\mathcal{G}$ 
11:  $W = 0$ 
12: for all  $g \in \mathcal{G}$  do
13:   for all  $i \in g$  do
14:      $W_i = \text{sign}(a_i)v(g)$ 
15:   end for
16: end for  $\triangleright$  Calculate  $W$ 
17:  $\mathcal{G} = \mathcal{D}(W)$   $\triangleright$  Calculate  $\mathcal{G}$ 
Output:  $W, \mathcal{G}$   $\triangleright$   $W$  minimizes Eq.3
```

---

according to the sign<sup>3</sup> of  $a_i$  and  $v(g)$  in line 14. In line 17 it calculates  $\mathcal{G} = \mathcal{D}(W)$  as discussed in Section 3. At last it returns the pair  $\langle W, \mathcal{G} \rangle$ .

In particular, the  $v$  value  $v(g)$  in line 5 is defined as

$$v(g) = \frac{\sum_{i \in g} \left( |a_i| - 2(\lambda_1 + \lambda_2(d - p^*(i))) / t \right)}{2|g|},$$

where  $p^*(i)$  denotes the inversion of  $p$  such that  $p(p^*(i)) = i$ . And  $v(g)$  can be intuitively interpreted as the group averaged sub-gradient of  $(\sum_{i'=1}^u W_{p(i')}^2 - \bar{Q}(W; a, t, \lambda_1, \lambda_2)) / 2$ . In addition, an intuitive explanation of merging loop is that the value of objective in Eq.4 will be decreased after each merging step in line 6.

In summary, if we use a sparse representation for vector  $a$  in Algorithm 3, then its complexity is  $O(|\Delta(a)| \log(|\Delta(a)|))$ , which is independent of  $d$ . Therefore, the whole tuning algorithm (Algorithm 1) with feature grouping is efficient even with a large value of  $d$ .

## 5 Experiments

We conduct experiments on the IWSLT2008 Chinese-to-English translation tasks, whose training data consists of about 30K bilingual sentence

<sup>3</sup>The reason is attributed to the Eq.5 in (Zhong and Kwok, 2011).

pairs. Test sets 2003, 2004 and 2008 are used as the development set, development test (devtest) set and test set, respectively; and all of them contain 16 references. A 5-gram language model is trained on the training data with the SRILM toolkit, and word alignment is obtained with GIZA++. In our experiments, the translation performances are measured by the case-insensitive BLEU4 metric. The significance testing is performed by paired bootstrap re-sampling (Koehn, 2004).

We use an in-house developed hierarchical phrase-based translation (Chiang, 2005) as our baseline decoder, and we use the state of the art tuning methods MERT and PRO as our comparison methods<sup>4</sup>. Based on our in-house decoder, we implement three translation models with different feature sets: default features (default); default features plus rule id features (+id); and default features plus group features of rule id (+group). On the IWSLT training data, the number of rule id features is 500K, i.e.  $d = 500K$ , which is significantly greater than the number of bilingual sentences 30K. Our proposed tuning method is with the following setting by tuning on the dev-test set:  $\lambda_1 = 1e - 10$ ,  $\lambda_2 = 3e - 8$ , and  $T = 15$ ,  $n = 20 \times N$ , i.e. 20 passes over k-best-lists.

From Table 1, we can see that tuning the translation model on the development set is much better (improvements of 4.3 BLEU scores) than that on the training data under the default features setting. Its main reason, as presented in Section 1, may be that multiple references and closeness<sup>5</sup> of tuning sets are much helpful for translation tasks. Further, the id features do not achieve improvements and even decreases 0.9 BLEU scores when tuned on the development set, due to its serious sparsity. However, after grouping id features, the groups learned by our method can alleviate the feature sparsity and thus significantly obtain gains of 0.7 BLEU scores over default feature setting.

Further, we implement another tuning method<sup>6</sup> for comparison, i.e.  $L_1$  regularization method (Tsuruoka et al., 2009) based on the ranking loss  $L(W)$  defined in Eq.1. We tune the translation

<sup>4</sup>Both of them are derived from the Moses toolkit: <http://www.statmt.org/moses/>.

<sup>5</sup>If the tuning set and test set are close enough or identically distributed, it is possible to get gains by sparse discriminative features without using feature grouping (Chiang et al., 2009).

<sup>6</sup>It is similar to dtrain implemented in the cdec toolkit: <http://cdec-decoder.org/>, except that it does not use the distributed learning framework.

Methods	Tuning set	Feature set	# Features		BLEU4		Runtimes
			Active	Reused	devtest	test	
MERT	dev	default	8	8	45.7	40.6	15
PRO	dev	default	8	8	46.3	41.1	34
PRO	train	default	8	8	42.8	36.8	834
PRO	dev	+id	11081	4534	45.5	40.2	47
L <sub>1</sub>	train	+id	584	71	42.7	36.9	975
L <sub>1</sub>	dev	+id	443	248	46.2	41.0	39
<b>OSCAR</b>	–	<b>+group</b>	<b>503</b>	<b>425</b>	<b>46.9</b>	<b>41.8</b>	1256

Table 1: BLEU scores on the test set and tuning runtimes (minutes) for the different tuning methods with different settings. Tuning sets dev and train denote the development and training data sets, respectively. "Active" denotes the number of active features for all methods except OSCAR or active grouped features for OSCAR; and "Reused" denotes the number of active (or grouped) features which also appear during 1000-best decoding on the test set. Boldface BLEU means our method OSCAR is significantly better than other methods with  $p < 0.05$ .

model with the +id feature setting on both the development set and training data set, respectively, and their hyperparameters are tuned on the dev-test set. As depicted in Table 1, our method significantly outperforms the L<sub>1</sub> method.

In addition, Table 1 presents the number of both active and reused features for each method on different settings. We can see that the active features (503 grouped features) in OSCAR method are much less than those (11081 features) in PRO with +id setting, which means that OSCAR has lower model complexity. Further, most (84.5%) of active features tuned on dev set are be used during testing for OSCAR, which means that OSCAR is more efficient to address feature sparsity problem compared with both L<sub>1</sub> and PRO.

At last, Table 1 also shows the runtimes for each tuning method. Tuning on training data is much inefficient compared with tuning on dev set, since it requires repeatedly decoding on a much larger dataset. Furthermore, the efficiency of our OSCAR method is comparable to that of tuning on training data. Anyway, distributed training is a reasonable approach to improve the efficiency of OSCAR, as suggested by Simianer et al. (2012).

## 6 Conclusion and Future Work

This paper proposes a novel training method for a translation model with a large number of features, which is the main contribution of this paper. This method is based on automatic feature grouping, which is implemented within an online learning method and thus is efficient for large scale training in SMT. The other contribution is that we success-

fully extend OSCAR to a large scale of learning setting. In future work, we will investigate distributed learning for OSCAR and then testify it on larger scale training data.

## Acknowledgments

We would like to thank our colleagues in both HIT and NICT for insightful discussions, and three anonymous reviewers for many invaluable comments and suggestions to improve our paper. ## Appendix

*Proof.* Suppose  $\hat{W}_k \neq 0$ , and thus  $|\hat{W}_k| > 0$ . Set  $\hat{W}'$  as another weight such that  $\hat{W}'_j = \hat{W}_j$  for all  $j (j \neq k)$ , and  $\hat{W}'_k = 0$ . Then, for each  $i, j$  the following equations hold:

$$|\hat{W}_i| \geq |\hat{W}'_i|,$$

and

$$\max\{|\hat{W}_i|, |\hat{W}_j|\} \geq \max\{|\hat{W}'_i|, |\hat{W}'_j|\}.$$

Thus, the following equations hold based on the above equations by simple algebraic operations:

$$\begin{aligned} & Q(\hat{W}; a, t, \lambda_1, \lambda_2) - Q(\hat{W}'; a, t, \lambda_1, \lambda_2) \\ &= \hat{W}_k \times \hat{W}_k + \frac{2\lambda_1}{t} \sum_{i=1}^d (|\hat{W}_i| - |\hat{W}'_i|) + \frac{2\lambda_2}{t} \times \\ & \quad \sum_{1 \leq i < j \leq d} (\max\{|\hat{W}_i|, |\hat{W}_j|\} - \max\{|\hat{W}'_i|, |\hat{W}'_j|\}) \\ & \geq \hat{W}_k \times \hat{W}_k > 0. \end{aligned}$$

Therefore, we conclude that  $Q(\hat{W}; a, t, \lambda_1, \lambda_2) > Q(\hat{W}'; a, t, \lambda_1, \lambda_2)$ . This contradicts the assumption that  $\hat{W}$  is the minimal solution of Eq.3.  $\square$

# Multimodal Comparable Corpora as Resources for Extracting Parallel Data: Parallel Phrases Extraction

Haithem Affi, Loïc Barrault and Holger Schwenk

Université du Maine,

Avenue Olivier Messiaen F-72085 - LE MANS, France

FirstName.LastName@lium.univ-lemans.fr

## Abstract

Discovering parallel data in comparable corpora is a promising approach for overcoming the lack of parallel texts in statistical machine translation and other NLP applications. In this paper we propose an alternative to comparable corpora of texts as resources for extracting parallel data: a multimodal comparable corpus of audio and texts. We present a novel method to detect parallel phrases from such corpora based on splitting comparable sentences into fragments, called phrases. The audio is transcribed by an automatic speech recognition system, split into fragments and translated with a baseline statistical machine translation system. We then use information retrieval in a large text corpus in the target language, split also into fragments, and extract parallel phrases. We compared our method with parallel sentences extraction techniques. We evaluate the quality of the extracted data on an English to French translation task and show significant improvements over a state-of-the-art baseline.

## 1 Introduction

The development of a statistical machine translation (SMT) system requires one or more parallel corpora called bitexts for training the translation model and monolingual data to build the target language model. Unfortunately, parallel texts are a limited resource and they are often not available for some specific domains and language pairs. That is why, recently, there has been a huge interest in the automatic creation of parallel data. Since comparable corpora exist in large quantities and are much more easily available (Munteanu and Marcu, 2005), the ability to exploit them is highly

beneficial in order to overcome the lack of parallel data. The ability to detect these parallel data enables the automatic creation of large parallel corpora.

Most of existing studies dealing with comparable corpora look for parallel data at the sentence level (Zhao and Vogel, 2002; Utiyama and Isahara, 2003; Munteanu and Marcu, 2005; Abdul-Rauf and Schwenk, 2011). However, the degree of parallelism can vary considerably, from noisy parallel texts, to quasi parallel texts (Fung and Cheung, 2004). Corpora from the last category contain none or few good parallel sentence pairs. However, there could have parallel phrases in comparable sentences that can prove to be helpful for SMT (Munteanu and Marcu, 2006). As an example, consider Figure 1, which presents two news articles with their video from the English and French editions of the Euronews website<sup>1</sup>. The articles report on the same event with different sentences that contain some parallel translations at the phrase level. These two documents contain in particular no exact sentence pairs, so techniques for extracting parallel sentences will not give good results. We need a method to extract parallel phrases which exist at the sub-sentential level.

For some languages, text comparable corpora may not cover all topics in some specific domains and languages. This is because potential sources of comparable corpora are mainly derived from multilingual news reporting agencies like AFP, Xinhua, Al-Jazeera, BBC etc, or multilingual encyclopedias like Wikipedia, Encarta etc. What we need is exploring other sources like audio to generate parallel data for such domains that can improve the performance of an SMT system.

In this paper, we present a method for detecting and extracting parallel data from multimodal corpora. Our method consists in extracting parallel

---

<sup>1</sup>[www.euronews.com/](http://www.euronews.com/)

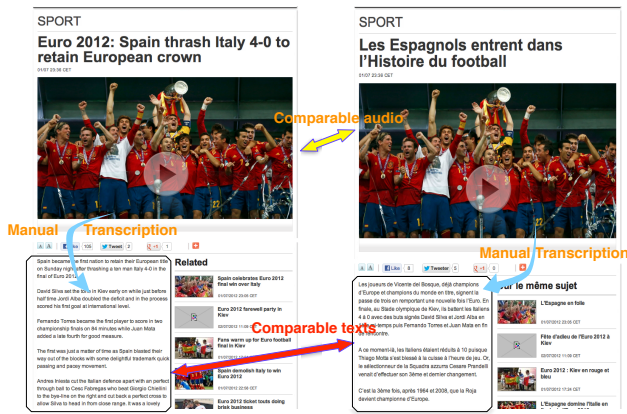

Figure 1: Example of multimodal comparable corpora from the Euronews website.

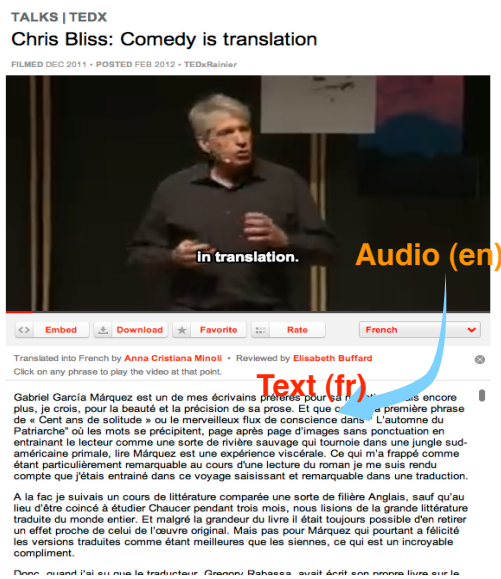

Figure 2: Example of multimodal comparable corpora from the TED website.

phrases.

## 2 Extracting parallel data

### 2.1 Basic Idea

Figure 2 shows an example of multimodal comparable data coming from the TED website<sup>2</sup>. We have an audio source of a talk in English and its text translation in French. We think that we can extract parallel data from this corpora, at the sentence and the sub-sentential level.

In this work we seek to adapt and to improve machine translation systems that suffer from resource deficiency by automatically extracting parallel data in specific domains.

<sup>2</sup><http://www.ted.com/>

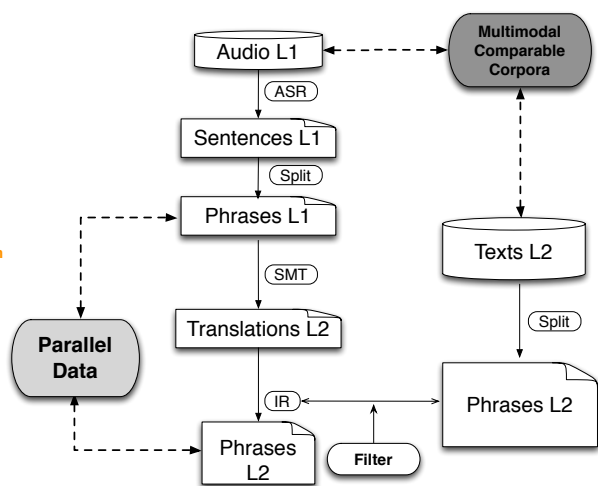

Figure 3: Principle of the parallel phrase extraction system from multimodal comparable corpora.

### 2.2 System Architecture

The basic system architecture is described in Figure 3. We can distinguish three steps: automatic speech recognition (ASR), statistical machine translation (SMT) and information retrieval (IR). The ASR system accepts audio data in the source language L1 and generates an automatic transcription. This transcription is then split into phrases and translated by a baseline SMT system into language L2. Then, we use these translations as queries for an IR system to retrieve most similar phrases in the texts in L2, which were previously split into phrases. The transcribed phrases in L1 and the IR result in L2 form the final parallel data. We hope that the errors made by the ASR and SMT systems will not impact too severely the extraction process.

Our technique is similar to that of (Munteanu and Marcu, 2006), but we bypass the need of the Log-Likelihood-Ratio lexicon by using a baseline SMT system and the TER measure (Snover et al., 2006) for filtering. We also report an extension of the work of (Aflî et al., 2012) by splitting transcribed sentences and the text parts of the multimodal corpus into phrases with length between two to ten tokens. We extract from each sentence on the corpus all combinations of two to ten sequential words.

## 2.3 Baseline systems

Our ASR system is a five-pass system based on the open-source CMU Sphinx toolkit<sup>3</sup>(version 3 and 4), similar to the LIUM'08 French ASR system described in (Deléglise et al., 2009). The acoustic models are trained in the same manner, except that a multi-layer perceptron (MLP) is added using the bottle-neck feature extraction as described in (Grézl and Fousek, 2008). Table 2.3 shows the performances of the ASR system on the development and test corpora.

Corpus	% WER
Development	19.2
Test	17.4

Table 1: Performance of the ASR system on development and test data.

Our SMT system is a phrase-based system (Koehn et al., 2003) based on the Moses SMT toolkit (Koehn et al., 2007). The standard fourteen feature functions are used, namely phrase and lexical translation probabilities in both directions, seven features for the lexicalized distortion model, a word and a phrase penalty and a target language model. It is constructed as follows. First, word alignments in both directions are calculated. We used the multi-threaded version of the GIZA++ tool (Gao and Vogel, 2008). Phrases and lexical reorderings are extracted using the default settings of the Moses toolkit. The parameters of our system were tuned on a development corpus, using the MERT tool (Och, 2003).

We use the Lemur IR toolkit (Ogilvie and Callan, 2001) for the phrases extraction procedure. We first index all the French text (after splitting it into segments) into a database using *Indri Index*. This feature enable us to index our text documents in such a way we can use the translated phrases as queries to run information retrieval in the database, with the specialized *Indri Query Language*. By these means we can retrieve the best matching phrases from the French side of the comparable corpus.

For each candidate phrases pair, we need to decide whether the two phrases are mutual translations. For this, we calculate the TER between them using the tool described in (Servan and

Schwenk, 2011),<sup>4</sup> i.e. between automatic translation, and the phrases selected by IR.

## 3 Experiments

In our experiments, we compare our phrase extraction method (which we call *PhrExtract*) with the sentence extraction method (*SentExtract*) of (Afli et al., 2012). We use the extracted dataset by both methods as additional SMT training data, and measure the quality of the parallel data by its impact on the performance of the SMT system. Thus, the final extracated parallel data is injected into the baseline system. The various SMT systems are evaluated using the BLEU score (Papineni et al., 2002). We conducted experiments on an English to French machine translation task. All the text data is automatically split into phrases of two to ten tokens.

### 3.1 Data description

Our multimodal comparable corpus consists of spoken talks in English (audio) and written texts in French. The goal of the TED task is to translate public lectures from English into French. The TED corpus totals about 118 hours of speech. We call the English transcriptions of the audio part *TEDasr* witch is split into phrases (called *TEDasr\_split*). A detailed description of the TED task can be found in (Rousseau et al., 2011).

The development corpus *DevTED* consists of 19 talks and represents a total of 4 hours and 13 minutes of speech transcribed at the sentence level. The language model is trained with the SRI LM toolkit (Stolcke, 2002), on all the available French data without the TED data. The baseline system is trained with version 7 of the News-Commentary (nc7) and Europarl (eparl7) corpus.<sup>5</sup> The indexed data consist of the French text part of the *TED* corpus which contains translations of the English part of the corpus. We call it *TEDbi*. It is split into phrases (called *TEDbi\_split*). Tables 2 and 3 summarize the characteristics of the different corpora used in our experiments.

### 3.2 Experimental results

We first apply sentence extraction on the TED corpus with a method similar to (Afli et al., 2012). We then apply phrase extraction on the same data split

<sup>3</sup>Carnegie Mellon University:

TEDasr_split	82.7M	yes

Table 3: Comparable data used for the extraction experiments.

as described in 2.2. Then, both methods are compared.

As mentioned in section 2.3, the TER score is used as a metric for filtering the result of IR. We keep only the sentences or phrases which have a TER score below a certain threshold determined empirically. Thus, we filter the selected sentences or phrases in each condition with different TER thresholds ranging from 0 to 100 by steps of 10. The extracted parallel data are added to our generic training data in order to adapt the baseline system. Table 4 presents the BLEU score obtained for these different experimental conditions.

Our baseline SMT system, trained with generic bitexts achieves a BLEU score of 22.93. We can see that our new method of phrase extraction significantly improve the baseline system more than sentences extraction method until the TER threshold of 80 is reached: the BLEU score increases from 22.93 to 23.70 with the best system of our proposed method and from 22.93 to 23.40 with the best system using the classical method of sentence extraction.

The results show that the choice of the appropriate TER threshold depends on the method. We can see that for *PhrExtract* the best threshold is 60 when the best one is 80 for *SentExtract*. This last one is also an important point in the general evaluation of the two methods. In fact, we can see on Figure 4 that from this point our proposed method gives less performing results than *SentExtract* method.

This suggest to apply combination of the two methods. This corresponds to injecting the extracted phrases and sentences into the training

data. The combination method is called *CombExtract*. Figure 4 presents the comparison of the different experimental conditions in term of BLEU score for each TER threshold. We can see that except for threshold 30, the curve of the combination follows in general the same trajectory of the curve of *PhrExtract*. These results show that *SentExtract* has no big impact in combination with the *PhrExtract* method and the best threshold when using *PhrExtract* is at 60.

Figure 4: Performance of *PhrExtract*, *SentExtract* and their combination in term of BLEU score for each TER threshold.

This is because of the big difference on the quantity of data between the two methods as we can see in Table 4. The benefit of our method is that it can generate more quantities of parallel data than the sentence extraction method for each TER threshold, and this difference of quantities improves results of MT system until the TER threshold of 80 is reached. However, we can see in Table 4 that the quality of only 39.35k (TER 80) extracted by *SentExtract* can have exactly the same impact of 25.3M extracted by our new technique. That is why we intend to investigate in the filtering module of our system.

## 4 Related Work

Research on exploiting comparable corpora goes back to more than 15 years ago (Fung and Yee, 1998; Koehn and Knight, 2000; Vogel, 2003; Gaussier et al., 2004; Li and Gaussier, 2010). A lot of studies on data acquisition from comparable corpora for machine translation have been reported (Su and Babych, 2012; Hewavitharana and Vogel, 2011; Riesa and Marcu, 2012).

To the best of our knowledge (Munteanu and

Table 4: Number of tokens extracted and BLEU scores on DevTED obtained with *PhrExtract* and *SentExtract* methods for each TER threshold.

Marcu, 2006) was the first attempt to extract parallel sub-sentential fragments (phrases), from comparable corpora. They used a method based on a Log-Likelihood-Ratio lexicon and a smoothing filter. They showed the effectiveness of their method to improve an SMT system from a collection of a comparable sentences. The weakness of their method is that they filter source and target fragments separately, which cannot guarantee that the extracted fragments are a good translations of each other. (Hewavitharana and Vogel, 2011) show a good result with their method based on on a pairwise correlation calculation which suppose that the source fragment has been detected.

The second type of approach in extracting parallel phrases is the alignment-based approach (Quirk et al., 2007; Riesa and Marcu, 2012). These methods are promising, but since the proposed method in (Quirk et al., 2007) do not improve significantly MT performance and model in (Riesa and Marcu, 2012) is designed for parallel data, it’s hard to say that this approach is actually effective for comparable data.

This work is similar to the work by (Afli et al., 2012) where the extraction is done at the phrase level instead of the sentence level. Our methodology is the first effort aimed at detecting translated phrases on a multimodal corpora.

Since our method can extract parallel phrases from a multimodal corpus, it greatly expands the range of corpora which can be usefully exploited.

## 5 Conclusion

We have presented a fully automatic method for extracting parallel phrases from multimodal comparable corpora, *i.e.* the source side is available as audio stream and the target side as text. We used a framework to extract parallel data witch combine an automatic speech recognition system, a statistical machine translation system and information retrieval system. We showed by experiments conducted on English-French data, that parallel phrases extracted with this method improves significantly SMT performance. Our approach can be improved in several aspects. The automatic splitting is very simple; more advanced phrases generation might work better, and eliminate redundancy. Trying other method on filtering can also improve the precision of the method.

## Abstract

Automatically mining named entities (NE) is an important but challenging task, pattern-based and bootstrapping strategy is the most widely accepted solution. In this paper, we propose a novel method for NE mining using web document titles. In addition to the traditional text patterns, we propose to use url-text hybrid patterns that introduce url criterion to better pinpoint high-quality NEs. We also design a multiclass collaborative learning mechanism in bootstrapping, in which different patterns and different classes work together to determine better patterns and NE instances. Experimental results show that the precision of NEs mined with the proposed method is 0.96 and 0.94 on Chinese and English corpora, respectively. Comparison result also shows that the proposed method significantly outperforms a representative method that mines NEs from large-scale query logs.

## 1 Introduction

The task of named entity mining (NEM) aims to mine named entities (NE) of given categories from raw data. NEM is essential in many applications. For example, NEM can generate NE gazetteers necessary for the task of named entity recognition (NER) (Cohen and Sarawagi, 2004; Kazama and Torisawa, 2008; Talukdar et al., 2006). It can also help improve the search results in web search (Paşca, 2004), and increase the coverage of knowledge graphs.

Extensive research has been conducted on NEM, in which pattern-based methods are the most popular. Handcrafted or automatically learnt patterns are usually used to extract NE instances from various corpora, such as web documents,

search engine's retrieved snippets, and query logs. Bootstrapping strategy is often applied to generate more patterns and instances iteratively so as to improve the coverage of the system.

The method we propose also belongs to the family of pattern-based NEM. However, our method is a departure from the previous ones. It makes contributions from the following aspects: First, we design url-text hybrid patterns instead of the traditional text patterns. We take url criterion into account, so as to measure the quality of the source webpages. Second, we propose Multiclass Collaborative Learning (MCL) mechanism, which globally scores and ranks the patterns and NE instances within multiple classes in bootstrapping.

We evaluate our method in two languages, i.e., Chinese and English, so as to demonstrate the language-independent nature of the method. We mine NEs using the system for five categories in both languages, including *star*, *film*, *TV play*, *song*, and *PC game*. Experimental results show that the average precision of the extracted NEs is 96% in Chinese and 94% in English. Meanwhile, the average coverage computed against a benchmark repository is 61% and 55% for the two languages. Comparative experiments further show that our method significantly outperforms a representative conventional method.

## 2 Related Work

In this section, we review the previous studies on NEM from three aspects: the data resource used, the proposed methods, and particularly the bootstrapping strategy.

Various resources have been exploited for NEM. Many researchers make use of large-scale web corpora and learn NEs surrounded by certain context patterns (Paşca, 2004; Downey et al., 2007). Others mine NEs using web search engines. They submit extraction patterns as queries to search engines, and extract NEs matching the

patterns from the retrieved snippets (Etzioni et al., 2005; Etzioni et al., 2004; ?; Kozareva and Hovy, 2010). There are also studies extracting NEs structured HTML tables (Dalvi et al., 2012). Besides web documents, NEs as well as their attributes can also be mined from search engine query logs, since many users tend to search for named entities in their queries (Paşca, 2007a; Paşca, 2007b).

As an alternative, this paper proposes to mine NEs from vertical websites titles, based on our observation that NEs of a class  $c$  can generally be found in webpage titles of some vertical websites of class  $c$ . Our statistics show that 99% out of 10,000 random NEs appear in webpage titles. Besides, webpage titles have the advantage that they are of better quality than free-text documents, while less noisy than user queries.

Pattern-based methods are the most popular ones in NEM (Riloff and Jones, 1999; Thelen and Riloff, 2002; Etzioni et al., 2004; Paşca, 2004; Talukdar et al., 2006; Paşca, 2007b; Wang and Cohen, 2009; Kozareva and Hovy, 2010). NE extraction patterns in previous papers can be roughly classified into two types, i.e., Hearst patterns and class-specific wrappers. Hearst patterns are named after Hearst (1992), who among the first to design patterns, such as “E is a C”, “C including E”, to extract hyponyms / hypernyms. The surface patterns were later extended to lexico-syntactic patterns (Thelen and Riloff, 2002; Paşca, 2004), so that the pattern-filling instances can be identified more accurately via considered constraints.

Hearst patterns are binary patterns containing two slots. In contrast, class-specific wrappers are unary patterns with a single slot (Paşca, 2007b; Wang and Cohen, 2008). For example, the pattern “the film \* was directed by” is a wrapper for the *film* class, in which the place holder “\*” can be replaced by any film name. Wrappers need to be learnt for each NE class of interest. Our method proposed in this paper is also a pattern-based one. However, we design a novel type of url-text hybrid pattern, which not only benefits from the conventional textual wrappers, but also takes advantage of url constraint.

Most methods mentioned above are weakly-supervised, in which a few patterns, heuristic rules or instances are fed to the system as seeds, and the system enriches patterns and NE instances iteratively. Bootstrapping is widely used in these methods (Riloff and Jones, 1999; Thelen and Riloff-

f, 2002; Paşca, 2007b; Wang and Cohen, 2008). The bootstrapping algorithm can effectively reduce manual intervention in building the system. However, it is prone to noise brought in during iterations. We therefore design a Multiclass Collaborative Learning (MCL, detailed in Section 3.4) mechanism in this paper, which guarantees the quality of the generated new patterns and instances by introducing inter-class and intra-class scoring criteria.

### 3 Named Entity Mining

#### 3.1 Overview of the Method

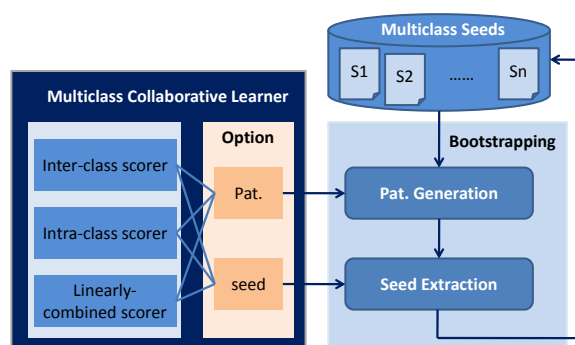

Figure 1: Framework of named entity mining

Named entities of a category are often organized in corresponding vertical websites, where each named entity is displayed in a single webpage. For example, it’s easy to extract film NEs from IMDB<sup>1</sup> web titles with regular expressions.

Our method learns NE extraction patterns from web titles (text pattern) and introduces url constraint (url pattern) to make the extraction results more precise. As described in Figure 1, our method uses bootstrapping strategy in pattern generation and seed extraction. We also propose Multiclass Collaborative Learning (MCL) mechanism to filter noise introduced in iterations.

#### 3.2 URL-Text Hybrid Patterns

##### 3.2.1 Motivation

Text patterns are widely used as wrappers in tasks like information extraction and relation extraction. To improve the accuracy of wrappers, a lot of constraints such as part-of-speech tags (Etzioni et al., 2005) and trigger words (Talukdar et al., 2006) were introduced to tackle the

<sup>1</sup>www.imdb.com

tricky conditions. However, simple wrappers can also acquire high-quality NEs in specific conditions. For example, “ $^(.+?)$$ ” is qualified to extract person name from the titles whose corresponding urls match the regular expression “ $http://www.nndb.com/people/\d+/\d+/$$ ”.

Based on the consideration above, we take the quality of urls into consideration when using wrappers. We use simple text patterns if the websites are of high-quality, and have to use complicated text patterns if the website’s quality is low. We therefore design url-text hybrid patterns to guarantee the capability of the patterns from both url and text aspects.

### 3.2.2 URL Patterns

Similar urls share the same pattern in many websites (Blanco et al., 2011). For example, all IMDB webpages describing video information match pattern “ $http://www.imdb.com/title/tt\d+/$$ ”. Therefore, we can take the url pattern as the identity of the website. Url patterns are globally learned using a large-scale url database. The process is as follows:

1. Given a url, we generate candidate url patterns by replacing the segments separated with “/” from its non-domain parts with slots respectively. For example, for url: “ $www.AAA.com/BBB/123$ ” in which “ $/BBB/123$ ” is the non-domain part, we can generate two candidate patterns “ $www.AAA.com/SLOT/123$ ” and “ $www.AAA.com/BBB/SLOT$ ”.
2. All candidate patterns are accumulated on the url database. The ones with a frequency above a pre-defined threshold  $k$  are retained.
3. For each retained candidate pattern, we generate the final url pattern by replacing the slot with a regular expression based on the statistics of its slot fillers. For instance, for the candidate pattern “ $www.AAA.com/BBB/SLOT$ ”, if the slot can be filled with “123”, “234”, and “456”, then the slot can be replaced with “ $\d+$ ”, meaning that this slot can be filled with any number sequence. Accordingly, the final url pattern should be “ $www.AAA.com/BBB/\d+$ ”.

### 3.2.3 Text Patterns

Text patterns are commonly used in NEM. Here we use a classical method to generate text patterns. Given a seed NE  $s$  in a category  $c$ , and a title  $t$  containing  $s$ , the text patterns are generated as:

1. Segment the title  $t$  into a word sequence.
2. Match the seed  $s$  in  $t$ , and replace  $s$  with the slot “ $^(.+?)$$ ”<sup>2</sup>.
3. Generate patterns that contain the slot as well as words preceding and succeeding the slot within a pre-defined window size. Several patterns can be yielded in this way given different window sizes. We set the window size to 2, 3, 4, and 5 in our experiment.

### 3.2.4 Hybrid Patterns

A url-text hybrid pattern ( $utp$ ), combining both url and text patterns, is defined as a 4-tuple:  $utp = (up, tp, c, f)$ , where  $up$  and  $tp$  are the url pattern and text pattern respectively,  $c$  indicates the category that  $utp$  belongs to, and  $f$  (scored by Eq.(6)) denotes the confidence of  $utp$ .

We use  $UTP$  to denote a set of  $utps$ , and use  $UTP_i$  to denote the  $UTP$  of the  $i$ -th category  $c_i$ . A hybrid pattern is more strict than a url pattern and a text pattern separately. As we will show, the NEs it can extract are of better quality and coverage.

## 3.3 Bootstrapping

As described in Algorithm 1, our method *GenerateUTP* generates raw patterns ( $r\_UTP^k$ ) with seeds ( $Seeds^{k-1}$ ) from web titles (WT) in the  $k$ -th iteration. Likewise, raw NE instances ( $r\_ins^k$ ) are extracted by *ExtractNE* in the following steps. *SelectUTP* and *SelectNE* output high quality patterns and NE instances respectively. These two functions are based on MCL mechanism described in Section 3.4. During these processes, each pattern is scored by Eq.(5) and is kept if its score is above a threshold, and the instances yielded in each iteration are ranked according to Eq.(6), and those ranked in the top  $1/k$  are selected and added (with function *AddSeeds*) into the seed set.

We use  $\#(ins^k)$  to denote the number of instances after the  $k$ -th iteration. The iterations will terminate if  $\#(ins^k)/\#(ins^{k-1}) < \eta$ , where  $\eta$  is

<sup>2</sup>“ $^(.+?)$$ ” is a regular expression used to extract arbitrary strings

---

**Algorithm 1** Bootstrapping for NE Mining

---

**Require:**

$Seeds^0$  for  $n$  categories:  $\{S_1^0, S_2^0, \dots, S_n^0\}$   
webpage titles (WT);  
iteration count  $k = 1$ ;

**Ensure:**

- 1: **while** Terminate criterion is not met **do**
  - 2:  $r\_UTP^k = GenerateUTP(Seeds^{k-1}, WT)$ ;
  - 3:  $UTP^k =$   
 $SelectUTP(r\_UTP^k, Seeds^{k-1}, WT)$ ;
  - 4:  $r\_ins^k = ExtractNE(UTP^k, WT)$ ;
  - 5:  $ins^k = SelectNE(r\_ins^k)$ ;
  - 6:  $Seeds^k = AddSeeds(ins^k, Seeds^{k-1})$ ;
  - 7:  $k = k + 1$ ;
  - 8: **end while**
  - 9: **return**  $ins^k$ : Named entities for  $n$  categories  
 $\{NE_1, NE_2, \dots, NE_n\}$ ;
- 

a threshold ( $\eta = 1.01$  in our experiments). All the extracted NEs after the last iteration are output along with their confidence score computed according to Equ.(6). One can set threshold w.r.t. the confidence score, so as to select high-quality named entities for certain applications.

### 3.4 Multiclass Collaborative Learning (MCL)

In this section, we design collaborative learning mechanism, which contains inter-class and intra-class scoring criteria, to better control the quality of the patterns and NE instances bootstrapped in iterations.

#### 3.4.1 Inter-class Scoring

If an NE of category  $c_i$  can also be extracted with patterns from other categories, it is likely that it is noise, or at least is an ambiguous NE that is unsuitable to be used as a seed of  $c_i$ . Likewise, if a pattern of class  $c_i$  can also be generated by seeds from other categories, this pattern is obviously not a high-quality pattern for category  $c_i$ . Thus, we can score the patterns and seeds of the target category with the help of the other classes, which is termed “inter-class scoring”.

The inter-class score for patterns is defined as:

$$P_1(c_i|utp) = \frac{P(c_i) \times P(utp|c_i)}{\sum_j P(c_j) \times P(utp|c_j)} \quad (1)$$

where:  $P(c_i) = |S_i|/|\bigcup S_j|$ , in which  $S_i$  denotes the seed set of category  $c_i$  and  $|\cdot|$  means the size

of a set. During initialization, we prepare approximately the same number of seeds for each class.  $P(utp|c_i) = |S_i(utp)|/|S_i|$ , in which  $S_i(utp)$  denotes the set of seeds in class  $c_i$  which generate the pattern  $utp$ .

The inter-class score for instances<sup>3</sup> is defined as:

$$P_1(c_i|s) = \frac{P(c_i) \times P(s|c_i)}{\sum_j P(c_j) \times P(s|c_j)} \quad (2)$$

where:  $P(c_i)$  is defined as above, and  $P(s|c_i) = \frac{Freq_i(s)}{\sum_{s' \in S_i} Freq_i(s')}$ ,  $Freq_i(s)$  means the number of  $c_i$ 's patterns that can extract instance  $s$ ,  $S_i$  means all instances of category  $c_i$ .

#### 3.4.2 Intra-class Scoring

Besides inter-class scoring, we also design an intra-class scoring criterion. The basic hypothesis is that, if a pattern generates a lot of instances that cannot be recalled by other patterns in this class, the pattern is likely to be incorrect.

For each class  $c_i$ , and the set of  $m$  patterns in the current iteration  $UTP_i = utp_i^1, utp_i^2, \dots, utp_i^m$ , we compute the intra-class score for  $utp$  (say,  $utp$  is the  $j$ -th pattern  $utp_i^j$ ) as:

$$P_2(c_i|utp) = \frac{|S_i(utp) \cap S_i^H|}{|S_i(utp)|} \quad (3)$$

where  $S_i(utp)$  means the set of instances extracted by  $utp$  in class  $c_i$ ,  $S_i^H$  is a set of high-quality instances extracted with all patterns in class  $c_i$ . Here “high-quality” is guaranteed by discarding the instances with frequency lower than a threshold  $T$ .

Likewise, intra-class scoring can also be defined for instances: the instances matching more patterns in class  $c_i$  are more likely to be correct instances of this class. The intra-class score for a seed  $s$  is computed as:

$$P_2(c_i|s) = \frac{|UTP_i(s)|}{|UTP_i|} \quad (4)$$

where  $UTP_i(s)$  denotes the set of patterns in class  $c_i$  that can extract instance  $s$ , while  $UTP_i$  denotes the set of all patterns in  $c_i$ .

#### 3.4.3 Linearly-combined Scoring

The final score for patterns and instances linearly combines both inter- and intra-class scores as follows:

---

<sup>3</sup>we also use  $s$  to denote an instance generated during bootstrapping.

For patterns:

$$P(c_i|utp) = \lambda P_1(c_i|utp) + (1 - \lambda)P_2(c_i|utp) \quad (5)$$

For instances:

$$P(c_i|s) = \lambda P_1(c_i|s) + (1 - \lambda)P_2(c_i|s) \quad (6)$$

In our experiments,  $\lambda$  is set to 0.5.

## 4 Evaluation

We evaluate our NE extraction method on five classes, i.e., *star*, *film*, *TV play*, *song*, and *PC game*. The reason to select these classes is that they are among the most frequently searched in search engines.

### 4.1 Experimental Data

In the experiments, we mainly evaluate the proposed method on Chinese. However, we also test the effectiveness of the method on English (Section 5.3). We therefore prepare experimental data for both languages.

We run our model on approximately 9.7 billion Chinese web titles and 13 billion English web titles respectively. Chinese web titles were collected from high-quality webpages after spam filtering and pageranking while English web titles were taken from all of our crawled English webpages. Note that, although the English corpus is larger than the Chinese one, it is still noisy and more sparse, given the fact that there are much more English (56.6%) webpages than Chinese (4.5%) on the whole internet<sup>4</sup>. The English titles are lowercased in preprocessing.

### 4.2 Metrics

We evaluate the methods based on precision ( $P$ ), coverage ( $C$ ), as well as the volume ( $V$ ) of the extracted NEs. In particular, precision is defined as the percentage of correct NEs of a given class from the automatically extracted ones. Precision is manually evaluated, in which we randomly sample 100 NEs from each resulting NE set of a given class, and ask two annotators to independently annotate whether each extracted NE belongs to the target class. The samples with different annotations are then reviewed by both annotators to produce the final result.

<sup>4</sup>[http://en.wikipedia.org/wiki/Languages\\_used\\_on\\_the\\_Internet](http://en.wikipedia.org/wiki/Languages_used_on_the_Internet) world.

Recall is more difficult to assess. Inspired by (Etzioni et al., 2004), we evaluate coverage against benchmark NE repositories. More specifically, we select a popular website for each given category in the corresponding language. For example, we use IMDB as the benchmark NE repository for categories *star*, *film* and *TV play* in English. All of the websites for constructing benchmark data on both Chinese (CH) and English (EN) are summarized in Table 1.

	Class	Website	Vol
CH	star	yule.sohu.com/star	4,643
	film	mtime.com	25,457
	TV play	www.mtime.com	4,080
	song	music.baidu.com	126,127
	PC game	pc.pcgames.com.cn	7,711
EN	star	imdb.com/	545,853
	film	imdb.com/	160,188
	tv play	imdb.com/	19,823
	song	spotify.com/	171,270
	pc game	gamespot.com/pc	8,131

Table 1: Benchmark dataset

The benchmark NEs were extracted from the websites using handcrafted patterns. Post-processing is done for the Chinese data, including discarding films and TV plays scored by only one viewer and songs played no more than 10 times. These filtering clues are extracted from the websites along with the NEs. For the English data, NEs are limited to those beginning with English characters and consisting of only English characters and some specific symbols (‘. – ;, !#). All English NEs are lowercased. The last column of Table 1 shows the statistics of the benchmark data. Coverage is computed as the percentage of NEs in a given benchmark set covered by the automatically extracted NEs. Please note that those websites for constructing benchmark data are not used in url patterns in the following experiments.

### 4.3 Results on Chinese

To extract Chinese NEs for the 5 examined classes, we first select 200 seeding NEs for each class. These seeds are randomly sampled from the top-5000 hot NEs for each class from Baidu<sup>5</sup> query logs. The results are shown in Table 2.

<sup>5</sup>[www.baidu.com](http://www.baidu.com), the largest Chinese search engine in the

Category	P	C	$C_{hot}$	Vol
star	0.99	0.85	0.90	7,630
film	0.95	0.76	0.86	24,183
TV play	0.92	0.82	0.93	21,655
song	0.96	0.12	0.33	11,011
PC game	0.96	0.50	0.75	14,049
<b>average</b>	0.96	0.61	0.75	15,706

Table 2: NEM results on the Chinese corpus

	star	film	TV play	song	PC game
CH	0.52	0.53	0.86	0.11	0.79
EN	0.78	0.82	0.87	0.78	0.84

Table 3: Percentage of NEs out of benchmark dataset

As can be seen from the Table 2, the precision of the extracted NEs is pretty high, which exceeds 0.92 on all five classes. On the other hand, the coverage varies across different classes. Especially, the coverage on songs is very low, which is only 0.12. After observing the extraction patterns, we found that the low coverage of songs is mainly due to the complexity of the patterns. Specifically, the titles of music websites usually contain not only the song’s name, but also the singer’s name. For example, the title “青花瓷-周杰伦-在线试听mp3下载-酷我音乐(*Green Flower Porcelain - Jay Chou - online audition mp3 download - kuwo music*)” is from a music website “www.kuwo.cn”, in which “青花瓷(*Green Flower Porcelain*)” is the song’s name, while “周杰伦(*Jay Chou*)” is the singer’s name. The singer’s name may seriously influence the generality of the induced text patterns.

We further evaluate our method’s coverage of hot NEs. Here an NE is deemed hot if its daily search frequency is no less than 10 according to our query logs. The fourth column ( $C_{hot}$ ) of Table 2 depicts the results. We can see that the coverage of hot NEs is evidently higher than that of random NEs for all five categories. The volume of extracted NEs for each class is listed in the last column of Table 2. Furthermore, row 1 of Table 3 depicts the percentage of the extracted Chinese NEs that are out of the benchmark dataset, from which we can see that our method actually mines a lot of NEs that are not covered by the benchmark data. This demonstrates the importance of extracting NEs from multiple websites.

#### 4.4 Comparison Results

In this section, we compare our method with the method proposed by (Paşca, 2007b). Paşca’s method is guided by a small set of seed instances for each class. The method extracts NEs from user queries in 5 steps: (1) generating query patterns matching the seed instances, (2) identifying candidate NEs using the patterns, (3) representing each candidate NE with a vector of patterns extracting it, (4) representing each class with a vector of patterns extracting its seeds, (5) computing the similarity between the representing vectors of each candidate NE and the class, and ranking the candidate NEs according to the similarity. Extracting NEs from query logs is a promising direction since search queries reflect the netizen’s true requirements. In our experiments, we implement Paşca’s method using our query log data, which contains a total of 100 million Chinese queries from Baidu search engine. The seeds used here are the same as in our method.

	Class	P@500	P@5k	P@all	C
Paşca’s method	star	0.83	0.53	0.29	0.62
	film	0.95	0.79	0.73	0.10
	TV play	0.96	0.59	0.39	0.32
	song	0.98	0.92	0.86	0.12
	PC game	0.73	0.34	0.11	0.28
	<b>average</b>	0.89	0.63	0.48	0.29
Our method	star	0.98	0.98	0.99	0.85
	film	1.00	1.00	0.95	0.76
	TV play	0.99	1.00	0.92	0.82
	song	1.00	0.94	0.96	0.12
	PC game	1.00	0.97	0.96	0.50
	<b>average</b>	0.99	0.98	0.96	0.61

Table 4: Comparison with Paşca (2007b)’s method

We compare two methods based on precision at different numbers of extracted NEs, by annotating 100 NEs out of the first 500, 5k and all respectively, as well as coverage. The comparison results are shown in Table 4. We can find from the result that our method significantly outperforms Paşca’s in both precision and coverage (C). Especially, the precision of NEs extracted by Paşca’s method sharply decreases when lower ranked NEs are examined, whereas the quality of NEs extracted by our method seems quite stable.

## 5 Analysis

### 5.1 Analysis of Experiment Settings

This section analyzes the influence of the experimental settings. We first introduce the performance when using text pattern only, and then examine the contribution of the inter- and intra-class scoring in the MCL learning. Finally, we show how the performance varies with different number of iterations. Table 5 shows the P@500, P@5k

Class	P@500	P@5k	P@all	C
star	0.97	0.85	0.62	0.31
film	0.98	0.98	0.97	0.20
song	0.89	0.70	0.37	0.08
TV play	0.96	0.93	0.72	0.23
PC game	0.56	0.18	0.11	0.01

Table 5: Performance when using text pattern only

and P@all performance when only using text patterns. The precision seems relatively good but the coverage is generally low. The precision falls rapidly as the number of selected NEs grows except the category *film*. This table indicates that url patterns play an important role in our method, without which the quality of the extracted NEs cannot be guaranteed.

Table 6 shows the P@500 and P@5k performance of our method when we only use intra-class or inter-class scoring in MCL learning. We can find that there is a dramatic decrease in the performance in both settings, suggesting that both inter-class and intra-class scoring criterion are necessary to guarantee the accuracy of the extracted NEs, and they should be used together.

Table 7 shows the performance after 1, 3, and 5 iterations. The number of url patterns is also listed along with precision and coverage. As can be seen, the average precision only slightly drops from 0.97 to 0.96 after 5 iterations, whereas the average coverage increases significantly from 0.53 to 0.61. This is mainly because the extraction sources grow almost 3 times, from 314 url-patterns to 1129 for each category on average.

### 5.2 Error Analysis

We have analyzed the erroneous NEs extracted by our method. This paragraph analyzes errors regarding precision while the following paragraph describes errors about recall. It turns out that ambiguity is a main reason for the errors. We find

	Category	P@500	P@5k
Using only intra-class estimator in MCL	star	0.11	0.36
	film	0.17	0.18
	TV play	0.12	0.43
	song	0.09	0.12
	PC game	0.43	0.10
	<b>average</b>	0.18	0.24
Using only inter-class estimator in MCL	star	0.07	0.08
	film	0.97	0.97
	TV play	0.98	0.96
	song	0.25	0.35
	PC game	0.75	0.79
	<b>average</b>	0.60	0.63

Table 6: Performance when using only intra-class or inter-class scoring in MCL

it quite common that an NE belongs to more than one class. For example, a TV play might be adapted from a novel with the same name, a biographical film might be named after the protagonist, etc. Statistics reveal that in “www.mtime.com”, which is the benchmark data for extracting Chinese films and TV plays in our work, 12.8% of the TV plays have homonymic films in the same website, while the percentage is 14% in its English counterpart “www.imdb.com”. Our method suffers from the ambiguity problem since the homonymic NEs might yield url-text patterns belonging to other classes, and thereby bring in noisy NEs.

Besides, as pointed out in Section 4.3, title complexity is the main problem that hinders NE extraction. Particularly, some titles contain more than one NE, which makes it difficult to induce text-patterns for a certain class from these titles. Another reason leading to the mismatch of benchmark NEs is that some NEs have different forms in different sources. For instance, we extract the song “*New Years Project*”, but the correct form in the benchmark data is “*New Year’s Project*”.

### 5.3 Language Adaptation

Our method is language-independent. This section presents the evaluation in English. The English data is described in Section 4.1. Table 8 shows the performance of our method.

We can see from the table that the precision of the extracted English NEs is also high. Compared with Table 2 above, we can find that the coverage of the English NEs is lower than that on Chinese. However, the volume of the extracted NEs is al-

#Iteration	measure	star	film	TV play	song	PC game	average
1	Precision	0.98	0.98	0.99	0.98	0.92	0.97
	Coverage	0.86	0.55	0.65	0.12	0.47	0.53
	url-text patterns	296	437	387	243	207	314
3	Precision	0.98	0.96	0.95	0.97	0.91	0.95
	Coverage	0.89	0.75	0.66	0.12	0.53	0.59
	url-text patterns	745	2,041	1,525	324	659	1,059
5	Precision	0.99	0.95	0.92	0.96	0.96	0.96
	Coverage	0.85	0.76	0.82	0.12	0.50	0.61
	url-text patterns	791	2,101	1,593	325	835	1,129

Table 7: Performance for varying number of iterations

Category	P	C	Vol
star	0.98	0.65	1,589,002
film	0.92	0.40	352,152
TV play	0.89	0.59	71,273
song	0.95	0.31	240,335
PC game	0.97	0.80	29,166
<b>average</b>	0.94	0.55	456,386

Table 8: Performance on English corpora

most 30 times larger. This is unsurprising, since there are much more NEs written in English than in Chinese on the internet. Given that the English corpus used in our experiments is only 1.4 times larger than the Chinese corpus, we believe that data sparseness might be a major cause of the low coverage. Likewise, from the row 2 of Table 3, our method also acquires a large proportion of NEs in English which do not exist in the benchmark websites.

To have a better understanding of the coverage problem, we examined the cases not extracted with our method. As we have analyzed the problem of song, we randomly sampled 1000 NEs missed by our method for the other 3 classes with low coverage on the Chinese test dataset, i.e., *star*, *film*, and *TV play*. We then examined whether the missed cases contain a lot of hot NEs according to the following heuristics: (1) If a star has no picture on the imdb page, then it should not be deemed hot. Our statistics show that 97.3% missed stars have no pictures. (2) If a film’s duration is no longer than one hour and the number of viewers grading it on IMDB is less than 10, then the film should not be hot. 90.6% missed films are not hot according to this criterion. (3) Similar to film, if the number of reviewers grading a TV play is less than 10, then

it is not hot. 69.9% of the missed TV plays are not hot accordingly. On the whole, the above numbers suggest that the NEs not covered by our method are mostly unpopular ones, which may seldom be used in real applications.

## 6 Conclusion and Future Work

In this paper, we propose to extract NEs from web document titles using url-text hybrid patterns. A multiclass collaborative learning mechanism is introduced into the bootstrapping algorithm to better perform the quality control. We evaluate our method on five categories popular in real applications, in both Chinese and English. The results reveal that the precision and coverage (against benchmark data) of the extracted NEs are 0.96 / 0.61 in Chinese, and 0.94 / 0.55 in English. Detailed analysis demonstrates that the url-text hybrid patterns are superior to conventional text wrappers, and the multiclass collaborative learning mechanism is effective. Further comparison also shows that our method can significantly outperform a representative method that learns NEs from query logs.

Our future work will be carried out along two directions, i.e. improving the text-pattern induction approach and testing the method in more other languages.

## 7 Acknowledgment

This work is supported by National High-tech R&D Program of China (863 Program) under the grant number: 2011AA01A207. We give warm thanks to Prof. Jian-Yun Nie and other anonymous reviewers for their comments.

## Abstract

Event detection on Twitter is an important and challenging research topic. On the one hand, Twitter provides first-hand information and fast broadcasting. On the other, challenges include short and noisy content, big volume data and fast-changing topics. Dominant approaches for Twitter event detection model events by clustering tweets, words or segments, while segments have been proven to be advantageous over both words and tweets in news event detection. We study segment-based news event detection, for which existing heuristic-based methods suffer from low recall. We propose feature-based event filtering to address this issue. Our filter incorporate a rich family of features that are empirically proven to be valuable. Experimental results show that our event detection system outperforms the state-of-the-art baseline with doubled recall and increased precision.

## 1 Introduction

We study news event detection from Twitter messages (tweets). Generally, tweets can be classified into three groups: 1) *news events*, or breaking news such as “Manchester united Vs Athletic in Jan. 1st”; 2) *hot topics* that spread among a large amount of Twitter users, such as horoscope topics (e.g. “You have recently experienced a phase of expansionism and it’s... More for Sagittarius”); and 3) *heterogeneous collections* or, meaningless non-event tweets, such as “Need buddy wanna chat”. Some previous work (Cataldi et al., 2010; Kasiviswanathan et al., 2011; Diao et al., 2012) regards both news events and hot topics as subjects of detection, while other work (Jackoway et al., 2011; Sakaki et al., 2010; Becker et al., 2012)

only detects news events. We are interested in the latter, for which most previous work detects only specific types of events. For example, Sakaki et al. (2010) detect earthquake events from Twitter. In this paper, we study event detection in general.

Compared with event detection in news texts, Twitter provides more opportunities and challenges. Yom-Tov and Diaz (2011) report that Twitter can broadcast news faster than traditional media, which provides an opportunity for event detection in Twitter. On the other hand, there are challenges in event detection from Twitter data: 1) tweets are too short and sometimes cannot carry enough information; 2) tweets contain many noisy words, which can be harmful for event detection and 3) the volume of Twitter data is very large, which makes event detection a big data problem.

The dominant approach for Twitter event detection is clustering. Similar tweets (Becker et al., 2011; Li et al., 2012c) or words (Platakis et al., 2009; Lee et al., 2012) are group into a cluster, before clusters are classified into either news events or non-events. A recent paper (Li et al., 2012a) showed that segments (i.e. ngrams; see Section 2) can be advantageous over both tweets and words for clustering. As segments have much smaller quantity than tweets and are more semantically meaningful than words, they are better units to be clustered. We take Li’s system (Twevent) as our baseline system.

Twevent apply a heuristic-based method (*newsworthiness*) to filter out hot topics and heterogeneous clusters from news events. *Newsworthiness* is calculated by similarity between edges in a cluster, and whether segments of the cluster frequently appear in Wikipedia. Both similarity of edges and Wikipedia are useful in filtering out heterogeneous collections from news events, while Wikipedia can also separate some news and topics. However, there are several problems with this approach: 1) *newsworthiness* cannot distinguish

news from some topics, includes horoscope topics (“sagittarius; approach; big trouble”) and topics such as “hitler; fox; megan fox; rip; megan; selena gomez”, which contain segments that can also frequently occur in Wikipedia; 2) as a single measure, *newsworthiness* is subject to a tradeoff between precision and recall, while a high precision can be obtained only with an extremely low recall (about 10%).

On the other hand, tweets contain useful information that can address the weakness of *newsworthiness*. For example the “Follow spree” topic, which refers to following-back activities by celebrities to their fans, can be recognized by the common hashtag suffix “followspree”. Another example is that news tweets are more likely to contain url links. We propose a classifier based method for event filtering and define a set of novel features that capture statistical, social and textual information from event clusters. Some of the features are useful in getting rid of heterogeneous collections while others may be useful for recognizing news events from hot topics.

We call our system Feature-Rich segment-based news Event Detection system on Twitter (FRED). Experimental results show that our system FRED outperforms the state-of-the-art event detection system Twevent by significantly increased precision and doubled recall.

## 2 Segment-Based Event Detection

In this section, we introduce the segment-based event detection method of Li et al. (2012a), which consists of three steps: tweet segmentation, bursty segment detection and segment clustering. Tweet Segmentation splits tweet into non-overlapping segments, which maybe unigrams or N-grams (2-5 grams). For a certain time window, segments that show a bursty frequency pattern are selected as bursty segments. Segment clustering groups bursty segments about same event into one cluster regarding them as one event.

### 2.1 Tweet Segmentation

Tweet segmentation can be regarded as a optimization problem to partition tweet with the use of Microsoft Web N-Gram service<sup>1</sup> and Wikipedia<sup>2</sup>.

<sup>1</sup><http://web-ngram.research.microsoft.com/info/>

<sup>2</sup><http://www.wikipedia.org/>

The objective function is defined as:

$$\arg \max_{s_1, \dots, s_m} C(d) = \sum_{i=1}^m C(s_i) \quad (1)$$

where  $d$  is a tweet from Tweet stream,  $\{s_1, \dots, s_m\}$  are the segments in tweet  $d$  and  $C$  is the function which measures the stickiness of a tweet or segment. In particular:

$$C(s) = L(s) \cdot e^{Q(s)} \cdot S(\text{scp}(s)) \quad (2)$$

where the length  $L(s)$  is defined in Eq 3, and a longer  $s$  makes it typically less sticky.  $Q(s)$  is the probability that  $s$  appears as an anchor text in Wikipedia articles; frequently-appearing anchor texts are more semantically meaningful.  $S(\cdot)$  is the sigmoid function.  $\text{scp}(s)$  is a cohesiveness measurement of segment  $s$  defined with symmetric conditional probability, as shown in Eq 4. Better combination of words when forming segments leads to higher cohesiveness value.

$$L(s) = \begin{cases} \frac{|s|-1}{|s|}, & \text{for } |s| > 1 \\ 1, & \text{for } |s| = 1 \end{cases} \quad (3)$$

$$\text{scp}(s) = \log \frac{Pr(s)^2}{\frac{1}{n-1} \sum_{i=1}^{n-1} Pr(w_1^i) Pr(w_{i+1}^n)} \quad (4)$$

In the above equations, a segment  $s$  can be written as  $\{w_1 \dots w_n\} (n > 1)$ , where  $Pr(\cdot)$  is the prior probability derived from the Microsoft Web N-gram service.

### 2.2 Bursty Segment Detection

From the large number of segments resulting from the last step, a small portion of bursty ones are selected for event clustering since segments with a burst frequency are more representative for a breaking news in the data stream. For convenience, we take a time window  $t$  as the time unit for bursty segment detection and segment clustering.  $N_t$  refers to the number of tweets within the time window  $t$ , and  $f_{s,t}$  represents the number of tweets that contain segment  $s$  within  $t$ . If  $f_{s,t} > E[s|t]$ , then a segment  $s$  is a **bursty segment**.  $E[s|t]$  is the expected number of tweets that contain  $s$  within  $t$ . As  $N_t$  is sufficiently large, the Gaussian distribution is used to model the probability of  $f_{s,t}$ .

$$P(f_{s,t}) \sim N(N_t p_s, N_t p_s (1 - p_s)) \quad (5)$$

where  $p_s$  is expected probability of tweets contain  $s$ , calculated as:

$$p_s = \frac{1}{L} \sum_{t=1}^L \frac{f_{s,t}}{N_t} \quad (6)$$

$L$  is number of time windows containing  $s$ .

$E[s|t] = N_t p_s$ . Even after filtering out non-bursty segments, a large amount of bursty segments remain. **Bursty weight**  $w_b(s, t)$  is assigned to each bursty segments and the top  $K$  bursty segments are chosen for further processing.  $K$  is set to  $\sqrt{N_t}$  in Twevent.

$$w_b(s, t) = P_b(s, t) \log(u_{s,t}) \quad (7)$$

$P_b(s, t)$  is the bursty probability and  $u_{s,t}$  means the **user frequency** of  $s$  helping to filter out some noisy segments, as the more users talk about the segment  $s$ , the more popular and meaningful it is.  $u_{s,t}$  is calculated as the number of users who post tweets containing  $s$  within  $t$ .

$$P_b(s, t) = S(10 \times \frac{f_{s,t} - (E[s|t] + \sigma[s|t])}{\sigma[s|t]}) \quad (8)$$

$\sigma[s|t] = \sqrt{N_t p_s (1 - p_s)}$  is the standard deviation of Gaussian distribution in Eq 5.

### 2.3 Segment Clustering

k-Nearest Neighbor graph (kNNgraph) clustering method, is applied to group bursty segments into clusters. The kNNgraph clustering method takes a complete graph of bursty segments with edges representing similarity between segments as input and output event clusters. It groups two segments into same cluster only when they are in each other's k-nearest neighbors.  $k$  is a key parameter to control the size of clusters. We choose value for  $k$  in Section 4. The output of kNNgraph clustering is an event cluster set corresponding to the time window  $t$ , denoted as  $G_{set}(t)$ . All  $G_{set}(t)$  sets are gathered to a whole event cluster set  $G_{set}$ .  $G_{set}$  is manually labeled for further use, introduced in Section 4.2.

Temporal features and text similarity are incorporated when calculating similarity between two segments  $s_1, s_2$ .

$$sim_t(s_1, s_2) = \sum_{m=1}^M w_t(s_1, m) w_t(s_2, m) sim(T_1, T_2) \quad (9)$$

$\langle t_1 \dots t_M \rangle$  are  $M$  sub time windows of the time window  $t$ . Frequency of segment  $s$  in the sub time window  $t_m$  is denoted as  $f_t(s, m)$ .  $w_t(s, m)$  is the frequency weight of  $s$  in  $t_m$ , which serves as a temporal feature and is shown in Eq 10.  $T_i$  denotes a set of tweets containing  $s_i$  within  $t_m$ .  $sim(T_1, T_2)$  measures text similarity between the two sets of tweets  $T_1, T_2$ . Tweets in  $T_i$  are concatenated as a pseudo document, and cosine similarity is applied for calculating distance. Pseudo documents are represented by the Vector Space Model, weighted by TF-IDF. TF value is the number of tweets containing word  $w$  within the sub time window  $t_m$  and DF value is the number of tweets containing  $w$  in the whole twitter corpus.

$$w_t(s, m) = \frac{f_t(s, m)}{\sum_{m'=1}^M f_t(s, m')} \quad (10)$$

## 3 Feature-Rich Event Filter

The clusters in the kNNgraph clustering result  $G_{set}$  contain news events, hot topics and heterogeneous clusters, corresponding to the three types of tweets mentioned in the Introduction. Our goal, which is to recognize news events from other two types of event clusters, is a challenging task because hot topics and news events can both have bursty frequency and share similar characteristics.

### 3.1 Event Filter in Twevent

Twevent utilizes a heuristic-based method for event filtering using information from Wikipedia. A heuristic equation, *newsworthiness*, is used to determine whether an event cluster is a news event or not, whereas all clusters with a high *newsworthiness* score is news events. The *newsworthiness*  $\mu(e)$  of an event cluster  $e$  containing segment set  $S_e$  and edge set  $G_e$  is calculated as follows.

$$\mu(e) = \frac{\sum_{s \in S_e} \mu(s)}{|S_e|} \cdot \frac{\sum_{g \in G_e} sim(g)}{|S_e|} \quad (11)$$

where  $\mu(s)$  of segment  $s$  is calculated as:

$$\mu(s) = \max_{l \in s} e^{Q(l)} - 1 \quad (12)$$

$l$  is sub-phrase of  $s$  and  $Q(l)$  is the probability that  $l$  appears as anchor text in Wikipedia articles.

An event cluster  $e$  is taken as a news event only if it satisfies the condition that  $\mu_{max}/\mu(e) < \tau$ , where  $\tau$  is a threshold for *newsworthiness*,  $\mu_{max}$

is the maximum of  $\mu(e)$  in time window  $t$ . Lower  $\tau$  value leads to high precision and low recall, which is the limitation of *newsworthiness*. Rich information from tweets and clusters themselves can be useful in alleviating this problem.

### 3.2 Event Filter in FRED

In order to incorporate rich features, we take event filtering as a binary classification problem, where class ‘T’ means true news event class includes news events and class ‘F’ represents false news event class containing hot topics and heterogeneous clusters. In our filter, event clusters in  $Gset$  are represented with a set of cluster-level features, and classified into T or F by a SVM<sup>3</sup> classifier. All clusters in class T, represented as  $Eset$ , form the final news event result. Features used to represent event clusters are shown in Section 3.3.

### 3.3 Features

We collect three types of features for the filter, representing statistical, social and textual information related of event clusters, respectively. Some of the features are designed to filter out heterogeneous clusters, while others to distinguish news events from hot topics. Given an event cluster  $e$  and the corresponding time window  $t$  (from which  $e$  is extracted), we have the following information: 1)  $Gset(t)$ , a sub set of  $Gset$  corresponding to  $t$ . 2)  $S_e$ , the set of segments in  $e$  and  $G_e$ , the set of edges in  $e$ . 3)  $T(e)$ , which consists of tweets that are related to  $e$  containing at least one segment of  $S_e$  and being posted in  $t$ . 4)  $relU(e)$ , which represents users who posted the tweets in  $relT(e)$ , and  $U_t$ , which denotes the number of users who published tweets within  $t$ .

#### Statistical Features

For statistical features, we collect direct statistical information from event clusters, such as how many segments and edges it contains, the density of the event graph and so on.

- *seg*, which refers to the segment number of  $e$ , calculated as  $|S_e| / \max_{e' \in Gset(t)} (S_{e'})$ . News events and hot topics contain more segments than heterogeneous clusters generally.
- *edge*, which refers to number of the edges of  $e$ , defined as  $G_e / \max_{e' \in Gset(t)} (G_{e'})$ . Similar

with segment number, heterogeneous clusters usually have less edges than news and topics.

- *wiki*, the average of *newsworthiness* for all segments in  $S_e$ . A higher *wiki* value indicates that the event cluster contains more meaningful and important segments. *wiki* is able to distinguish news events from hot topics and heterogeneous clusters, as shown Li et al. (2012a).
- *dup* is designed to filter out some specific heterogeneous clusters that contains words sharing the same lemma. For example the event cluster  $e7$  in Table 3, which words sharing lemma “feel”. *dup* can be obtained by stemming all unigrams appeared in  $S_e$  and calculating the number of duplicated stemmed unigrams out of all stemmed unigrams.
- *sim*, which refers to average similarity of all edges in  $G_e$ . A bigger *sim* means that the event cluster is more dense, or sticky.
- *df*, which refers to the number of tweets related to  $e$  out of all tweets published in  $t$ , namely  $|relT(e)|/N_t$ . *df* could help to eliminate heterogeneous clusters, which are published by less users in less tweets.
- *udf*, which refers to  $|relU(e)|/U_t$ . The influence of *udf* is similar with *df*.

#### Social Features

Tweets in  $relT(e)$  contain rich Twitter-specific social information, which may reveal the difference between news events and hot topics. For example, the more mentions (@username) exist in  $relT(e)$ , the more likely  $e$  is a topic.

- *rt*, which represent how many tweets in  $relT(e)$  are retweeted. *Retweet* is a forwarding action on a tweet published by other users indicating an interest to the tweet. A retweeted tweet is denoted by a prefix of “RT @username”. *Retweet* functions as a means of sharing and spreading without commenting to show user’s opinion. A news event may have a larger fraction of retweeted tweets than others as users want to spread the news.
- *men*, which refers to the normalized number of tweets containing *mention* (e.g., @username) in  $relT(e)$  specifying one target

<sup>3</sup>We use LibSVM <http://www.csie.ntu.edu.tw/~cjlin/libsvm/> for the experiment.

receiver of tweets (e.g., “@justinbieber”). *Mention* actions occur more frequently in hot topics than in news events, as users prefer showing their opinion about this topic rather than just spreading it.

- *rep*, which refers to the normalized number of reply tweets in  $relT(e)$ . *Reply* means commenting, and a reply tweet is started with a mention. Similar with *mention*, *reply* has strong indication of conversation, and are more related to topics than news.
- *url*, which refers to the normalized number of tweets containing url link in  $relT(e)$ . *Url* shows extra information for tweet. News events contains more information than a topic, which may not be fully expressed in a short tweet, and hence url links are likely used to refer to the original article.
- *tag*, which refers to the normalized number of tweets containing *hashtag* in  $relT(e)$ . A *hashtag* (#gamecocks) is a short description of what’s happening. Generally a popular hashtag indicates a hot topic or an event (e.g., “The game got a little exciting today but we got the win! #gamecocks”).
- *pst*, which measures how many tweets contain words in past tense in  $relT(e)$ , normalized by  $|relT(e)|$ . News events are more likely to be described formally and with more words in past tense.

### Textual Features

Besides above groups of features, text information embedded in hashtag content are another valuable source of information. News events will more likely have common hashtags. For example, many tweets about “National Football League” games have a common hashtag “#NFL”. Twitter topic can have common prefixes or suffixes of hashtag. For example the “Follow spree” topic, which is mentioned earlier, may have a common hashtag suffix “followspree”.

- *fTag*, which represents how many hashtags appear in  $relT(e)$  are frequent hashtags. We extract a frequent hashtag list from whole Twitter data set by taking the top 2000 most frequently used hashtags.
- *psfx*. To obtain frequent hashtag prefixes/suffixes, we first filter out prefixes/suffixes

of all hashtags in the data that satisfy at least one of the following conditions: 1) less than 3 characters, 2) composed by repeating one character, 3) frequency lower than 200. After arranging the prefixes in alphabetical order, we keep only the longest prefixes for the same prefix pattern. Prefixes are ranked by frequency, and the top 2000 are taken as frequent hashtag prefixes. Similarly, we could extract 2000 most frequent hashtag suffixes. *psfx* and *sfx* are used to indicate how many hashtags tweets in  $relT(e)$  contain frequent prefixes or suffixes respectively. *psfx* is the combination of *psfx* and *sfx* by multiplying them.

## 4 Experiments

### 4.1 Data

The Twitter data we use were crawled from Twitter timeline, which is the real-time tweet stream containing all tweets published by Twitter users from January 1st to January 15th, 2013. After removing stops words, filtering out non-English tweets and null content tweets, the data set contains 31,097,528 tweets published by 16,331,133 users with 382,475 words.

Wikipedia data is used as an extra resource in the tweet segmentation tasks (Section 2.1) and event filtering (Section 3). We use the Wikipedia dump data<sup>4</sup> of February 4th, 2013. It includes 13,167,739 pages and 10,507,127 anchor entities that have 5 words length limit. These anchor entities’ anchor probability, i.e. the number of pages that entity  $e$  appears as anchor text divided by the number of pages containing entity  $e$ , are calculated at the very beginning.

### 4.2 Settings

We reproduced Twevent as our baseline system. Parameter  $\tau$  in Twevent and *gamma* in FRED are tuned for best performance on a development set, which consists all event clusters on Jan. 2nd and 5th. Time window  $t$  is set to be a day and  $M$  (in Eq. 9) is 12.  $k$  in kNNgraph clustering method is set to be 5, as a tradeoff of the number of event clusters and average number of segments in clusters.  $\tau$  in Twevent is tuned and set to be 2 and *gamma* in LibSVM of FRED is 5. 10-fold cross validation is

Table 1: Experimental Results Using Different Features.

utilized to get system-generated class labels for all event clusters.

We built a standard gold set for FRED after labeling the event cluster set  $Gset$ , which is the output of the segment-based event detection (Section 2). The labeling method is shown as follows. Given an event cluster  $e$ , the segments in  $e$  and the corresponding time window  $t$ , we use the segments and  $t$  to determine whether  $e$  is related to a news. Google and Twitter search are used to assist manual annotations of events. As a result, 4249 event clusters in  $Gset$  were manually labeled into 804 news events and 3445 non-events. Note that some news events in  $Gset$  may be sub events of one event. For example “The Golden Globe Awards ceremony 2013” happened in January 13th are detected more than once, as people talked about winners for different awards. We have not merged these sub events in this paper, which will be considered for future work.

With the event cluster set  $Gset$ , we use the precision, recall and F1-measure to evaluate the performances of FRED and Twevent, where precision is defined the fraction of news events in system-generated ‘T’ class event clusters ( $Eset$  for FRED), and recall measures how many manually labeled news events are detected out of all news events in  $Gset$ . F1 measure is calculated for an overall evaluation. Note that given our annotations, which is much larger than that of Li (Li et al., 2012a), we can give a better estimation of recall, which Li et al. were not able to report in detail (they used the number of detected news as recall, which did not reveal the real recall notion).

### 4.3 Experimental Results and Analysis

As we show some statistical results of tweet segmentation (Section 2.1), we obtained 1,604,129 distinct segments with 22.3% unigrams, 72% 2-grams and 5.7% 3-5 grams.

#### Effectiveness of Features

In Table 1 we show the results of feature ablation test. ExpID is the experiment id. FeatureSet is the features we used for current experiment. All means all statistical, social and textual features. Diff means the difference between F1 in current experiment and experiment 0, and a smaller Diff indicates that the feature is more valuable.

The experimental results show that nearly all features contribute to event filter on either precision or recall. Features can be partitioned into three groups according to their impact on precision and recall: 1) features that are useful only for precision include  $df$ ,  $udf$ ,  $dup$ ,  $rt$ . 2) features that are useful for both precision and recall includes rest of features such as  $wiki$ ,  $sim$ ,  $url$  etc. 3) feature  $pst$  is slightly harmful for precision and recall.

The most valuable features to our system are  $wiki$ ,  $sim$ ,  $rep$ ,  $url$  and  $tag$ .  $wiki$  is extra resource obtained from Wikipedia, and contributes to valuable segments in event clusters.  $sim$  indicates denser event cluster with stronger connections between segments, while replied tweet number, url number and hashtag number are social features embedded in tweets related to event clusters. Results show there are bigger differences in these features between news events and others clusters when compared to other social features.

#### The Performance of FRED

System	#Evt	P	R	F1
Twevent <sub>u</sub>	114	68.42%	9.7%	16.99%
Twevent	107	75.70%	10.07%	17.78%
FRED	146	83.64%	22.89%	35.94%

Table 2: Experimental Results.

The experimental results of FRED and baseline systems are presented in Table 2. Twevent<sub>u</sub> is a variant of Twevent, which uses unigrams (words) instead of segments in the event detection. #Evt is the number of news events.

The experimental result of Twevent (precision 75.7%) is lower than that reported by Li et al. (2012a) (precision 86.1%). It is likely to be caused by 1) different Twitter data, Li use Singapore Twitter data containing 4.3 million tweets in one month while ours is global Twitter data of 31.1 million tweets in half a month; 2) horoscope topics are very popular in our data, which cannot be filtered out by Twevent. Because horoscope topics greatly influence the performance of Twevent, we performed a manual filtering to them for a better result. Twevent without the extra process yields 125 event clusters with a low precision of 64.8%. No extra filtering process was necessary for FRED.

The results in Table 2 show that, 1) segments are better than words for news event detection as Twevent outperforms Twevent<sub>u</sub>, which brings in more heterogeneous collections; 2) our system FRED performs better than Twevent with significantly increased precision and doubled recall, which proves that feature-rich event filter could alleviate the low recall problem in Twevent.

### Analysis

We show some example event clusters in Table 3. Lm refers to manually annotated class label. Lt and Lf refer to class labels generated by Twevent and FRED, respectively. The labeling results in Table 3 show that Twevent and FRED made different types of mistakes. As mentioned earlier, Twevent (without manual filtering) always fails to distinguish horoscope topics, while FRED can. From e2-e3 and e4-e5, we can also see that Twevent’s labeling result changes for same news events while FRED gives consistent labels. Note that one important difference between FRED and Twevent is that the former uses some supervision. Preliminary experiments show that unsupervised

clustering such as k-means clustering cannot effectively bring the benefits of rich-features.

Football and basketball games, which appear almost everyday, take a large fraction of news events. Events such as the 27th Golden Globes Award ceremony hosted on January 13th, show bursty frequency patterns from late January 13th to 14th. Topics such as horoscope topics are popular everyday. At least from our data, the most popular hobbies of the globe seem to be football games.

Among all events, concert news or gossips about celebrities such as “Justin Bieber” and “Taylor Swift” draw much more and much longer attention. For example, e4 in Table 3, which is a news event related to Justin Bieber, continues to appear as news in many days very longer than e1 (a news related to song). New episode of TV programs and TV series such as “Big Brother” and “Pretty Little Liars” are also popular news events.

## 5 Related Work

Document-pivot clustering methods are frequently used in event detection on social media, in which short messages are regarded as documents (Becker et al., 2011; Li et al., 2012c). Becker et al. (2011) represent text content of a tweet as a TF-IDF weight vector and apply an incremental clustering algorithm to group similar tweets with one cluster regarded as an event. In the following event classification phase, temporal, social, topical and Twitter-centric features are used to represent each cluster and clusters are determined whether they are event-related or topic-related or non-event.

As social media data is on an extremely big scale, document-pivot clustering methods are ineffective as they are time- and memory-consuming. In contrast, in feature-pivot clustering methods, only features (words) that show a burst frequency pattern in a time window are extracted and then clustered into groups to get events. In addition to improving clustering efficiency, detecting bursty features also plays an important role for feature selection as social media messages are very noisy.

In most feature-pivot clustering methods, events are represented as a few representative words showing what happened, which may cause events to be difficult to understand (Li et al., 2012a; Platakis et al., 2009; Lee et al., 2012; Fung et al., 2005). Li et al. (2012a) adopted tweet segmentation in their event detection system Tweven-

ID	Lm	Lt	Lf	Time	Segments	Detail
e1	T	T	T	15th	golden disk awards; 27th; cr; kris; preview	Golden Disk Awards
e2	T	T	F	4th	lead; fans; check; vote; favorite music; peoples choice	peoples choice voting
e3	T	F	F	5th	lead; fans; check; vote; favorite music; peoples choice	related to e4
e4	T	T	T	2nd	paparazzi; chaos; accident; dangerous; fools; princess di	photographer died when chasing justin bieber
e5	T	F	T	3rd	paparazzi; town; sm; went	related to e6
e6	F	T	F	12th	venus; amorous; squares edgy	horoscope topic
e7	F	F	F	7th	feel; feel bad; feel i'm; feel sick	heterogeneous collection

Table 3: Example Events.

t. Tweet segmentation is firstly proposed by Li et al. (2012b) for an named entity recognition system on Twitter. They claim that segments are much more meaningful and easier to read than words. Twevent is the most related work to this paper. We adopt tweet segmentation, and segment tweets into non-overlapping segments that are regarded as bursty feature candidates, and utilize a feature-pivot clustering method to group bursty segments into clusters as events. The difference between this paper and Twevent is that they use a simple measurement (*newsworthiness*) to filter out meaningless twitter topics from events, while we propose a classifier based filter to distinguish news events and twitter topics. The advantage of our system is that it supports the definition of rich features, some of which are helpful to eliminate heterogeneous clusters and others can distinguish news events and hot topics. We will explore their functions in this paper.

In addition to the above group of work, which represents events with a few messages or features showing the topic information, some researchers try to extract structured information for events. Given a set of seed events, Benson et al. (2011) use a factor graph to extract artist and venue information of a concert event. Popescu et al. (2011) extract main entities, actions and audience opinions.

Data from social medias like Twitter are very sparse in presenting thousands of events, while some researchers mainly focus on specific types of events. Sakaki et al. (2010) detected disaster events like earthquakes and typhoons from Twitter. Pohl et al. (2012) tried to detect sub-event to assist disaster management with Flickr and YouTube data. Agarwal et al. (2012) analyzed tweets containing specific keywords and report Fire-in Factory and Labor-Strike events. They

have fixed query words and search for related messages from social media websites for data. The query words are challenges to define as they are vital to the quality of dataset, which will greatly influence the results. Becker et al. (2012) tried to generate queries for a planned event to relax the limitation. Our work mainly focus on news event detection problem on Twitter.

Rich features have been used in other tasks in NLP, such as POS-tagging (Toutanova et al., 2003), parsing (Zhang and Nivre, 2011) and machine translation (Chiang et al., 2009). Our work is in line with these.

## 6 Conclusion

We proposed a feature-rich classifier to recognize news events for segment based event detection, defining novel statistical, social and textual features for the filter. Experiments showed the effectiveness of the method, and in particular some features such as the number of urls and hashtags. The feature-rich event filter led to significantly higher precision and doubled recall when compared to the state-of-the-art baseline system. In our experiments we observed that a news event can be detected more than once in one time window, which each appearance representing one aspects of the event. Building these sub-events into a hierarchy will be explored in the future.

# Building Chinese Event Type Paradigm Based on Trigger Clustering

Xiao Ding, Bing Qin, Ting Liu\*

Research Center for Social Computing and Information Retrieval

Harbin Institute of Technology, China

{xding, qinb, tliu}@ir.hit.edu.cn

## Abstract

Traditional Event Extraction mainly focuses on event type identification and event participants extraction based on pre-specified event type annotations. However, different domains have different event type paradigms. When transferring to a new domain, we have to build a new event type paradigm. It is a costly task to discover and annotate event types manually. To address this problem, this paper proposes a novel approach of building an event type paradigm by clustering event triggers. Based on the trigger clusters, the event type paradigm can be built automatically. Experimental results on three different corpora – ACE (small, homogeneous, open corpus), Financial News and Musical News (large scale, specific domain, web corpus) indicate that our method can effectively build an event type paradigm and can be easily adapted to new domains.

## 1 Introduction

Event extraction techniques have been widely used in several different specific domains, such as musical reports (Ding et al., 2011), financial analysis (Lee et al., 2003), biomedical investigation (Yakushiji et al., 2001) and legal documents (Schilder et al., 2007). Traditional event extraction systems achieved excellent performance in some important information extraction benchmarks, such as MUC (Message Understanding Conference, Chinechor et al., 1994) and ACE (Automatic Content Extraction). However, most of these methods require pre-specified event types as their prior knowledge. For example, ACE defines an event as *a specific occurrence involving participants*, and it annotates 8 types and 33 subtypes of events (LDC, 2005). However, building an event type paradigm in this way not only requires massive human effort but also tends to be very data dependent. As a result, it

may prevent the event extraction from being widely applicable. Since event types among domains are different, the event type paradigm of ACE, which does not define music related events, is useless for the music domain event extraction. So we have to build a totally different event type paradigm for the music domain from scratch.

Recently, some researchers have been aware of the limitations of only considering pre-defined paradigm as well. In the same vein, some studies work on the problem of relation extraction (Chambers and Jurasky, 2011 and 2009; Poon and Domingos, 2009 and 2008; Yates and Etzioni, 2009). Rosenfeld and Feldman (2006) built a high-performance unsupervised relation extraction system without target relations in advance. Hasegawa et al. (2004) discovered relations among named entities from large corpora by clustering pairs of named entities. However, most of the above work focuses on relation extraction rather than event extraction.

In contrast to the well-studied problem of relation extraction, only a few works focused on event extraction. For example, Li (2010) proposed a domain-independent novel event discovery approach. They exploited a cross-lingual clustering algorithm based on sentence-aligned bilingual parallel texts to discover event trigger clusters. Their motivation is to discover novel events for a new domain rather than build a new event type paradigm from scratch. So it takes domain specific event triggers as the input. However, it is also a costly task to annotate triggers for new domains.

To address above issues, this paper proposes a series of novel algorithms to automatically build event type paradigm. The proposed approach is based on the definition of event trigger: *the word that most clearly expresses an event's occurrence*, and our key observations: *triggers are the most important lexical units to represent events. A set of triggers with similar meaning or usage represents the same event type. Event types can*

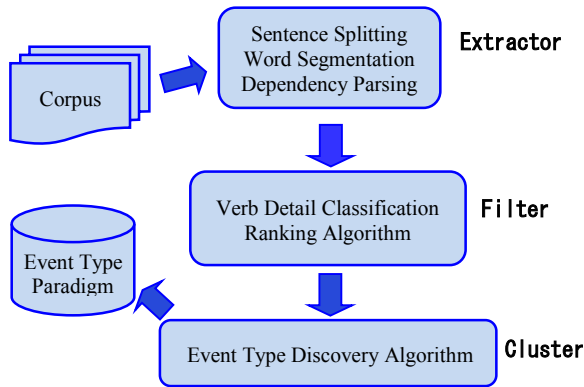

Figure 1. Architecture of the proposed system

be discovered based on trigger clustering. Our approach involves three steps: 1) we introduce a trigger extraction algorithm based on the dependency syntactic structure; 2) a trigger filter is then constructed to remove some noisy candidate triggers; 3) we develop an event type discovery algorithm based on our proposed trigger clustering methods. The clustered event types are used to construct an event type paradigm.

Experimental results show that our approach not only achieve significantly better performances than the baseline method, but also are more stable across different corpora. On the ACE, Financial News and Musical News corpus, the average accuracy is 73%. It shows that trigger clustering based method is effective on building an event type paradigm which is the premise of event extraction. We extract 33 event types for the ACE corpus, nine event types for the Financial News corpus and seven event types for the Musical News corpus.

Our contributions are as follows.

1. In this paper, we put forward the problem of event type paradigm building, and develop a novel framework as the solution.
2. This paper exploits a series of novel algorithms for automatically discovering and clustering domain independent event types.

The remainder of this paper is organized as follows. Section 2 presents our approach for event type paradigm building. Section 3 evaluates the proposed method. The related work on event extraction is discussed in Section 4, and we conclude the paper in Section 5.

## 2 Approach Overview

Since event trigger is the word that most clearly expresses an event’s occurrence, the key idea of this paper is to automatically construct an event type paradigm by clustering event triggers. For example, in the ACE corpus, a set of event triggers {倒闭, 闭门, 关闭, 停业, 解散} ({bankrupt,

10:	<b>End For</b>
11:	<b>End For</b>

Figure 2. The algorithm for trigger extraction

shut down, close, close down, dismiss}) represents the sense of the event type “Business/End-Org”. As shown in Figure 1, our system has three main components: trigger extractor, trigger filter and trigger cluster. The input of the system is a raw corpus, such as the ACE corpus, the Financial News corpus and the Musical News corpus, and the output is the event type paradigms which are shown in Table 2, Table 3 and Table 4.

### 2.1 Trigger Extractor

An event trigger is the center of an event, which is an important feature for recognizing the event type. Kiyoshi Sudo (2003) summarized three classical models for representing events. All of these three models rely on the syntactic tree structure and the trigger is specified as a predicate in this structure. In order to accurately extract event triggers, we employ the predicate-argument model (Yangarder et al., 2000) which is based on a direct syntactic relation between a predicate and its arguments. We extract the syntactic relation for predicate-argument model by means of the HIT (Harbin Institute of Technology) Dependency Parser (Che et al., 2009). Based on the predicate-argument model, we propose a trigger extraction algorithm (TE). The details are shown in Figure 2.

Take the following sentence as an example:

毛泽东 1893 年 出生 于 湖南湘潭。  
<sub>1 2 3 4 5</sub>  
→ Mao Zedong was born in Xiangtan, Hunan  
<sub>1 2 3 4 5</sub>  
Province in 1893.  
<sub>6 7</sub>

The HIT Chinese Dependency Parser dependencies are:

*SBV* (出生-3, 毛泽东-1)  
→ (born-3, Mao Zedong-1)  
*VOB* (出生-3, 湖南湘潭-5)  
→ (born-3, Xiangtan, Hunan Province-5)

ADV (出生-3, 1893 年-2)

→ (born-3, 1893-7)

POB (湖南湘潭-5, 于-4)

→ (Hunan Province-5, in-4)

where each atomic formula represents a binary dependence from the governor (the first token) to the dependent (the second token). The SBV relation, which stands for the *subject-predicate structure*, means that the head is a predicate verb and the dependent is a subject of the predicate verb; the VOB dependency relation, which stands for the *verb-object structure*, means that the head is a verb and the dependent is an object of the verb; the ADV relation, which stands for the *adverbial structure*, means that the head is a verb and the dependent is an adverb of the verb; the POB relation, which stands for the *prep-object structure*, means that the head is an object and the dependent is a preposition of the object.

Since  $V_{SBV} = V_{VOB} = V_t = \text{出生}$  (born) in this case, based on the predicate-argument model, the word “出生” should be extracted as a candidate event trigger.

## 2.2 Trigger Filter

Although we obtain some useful candidate triggers, certain meaningless candidate triggers come along in the results of the trigger extractor as well. Therefore, we introduce a trigger filter which uses heuristic rule and ranking algorithm to filter out these less informative candidates.

These rules are applied in order as follows:

### Rule (1): Subdividing Verbs

Since event trigger words are extracted based on the predicate-argument model, most of these candidate trigger words are verb terms. However, not all of verb terms can be used as trigger words. For example, the copular verb (e.g. “is”) rarely acts as the event trigger. To investigate which categories of verbs can serve as event triggers, we classify Chinese verbs into eight subclasses listed in Table 1. Such classification makes each subclass function as one grammatical role. For example, a modal verb will never be the predicate of a sentence and a nominal verb will always function as a noun.

We perform the verb sub-classification model based on the work by Liu et al. (2007). Statistically, about 94% of ACE Chinese event triggers are general verbs or nominal verbs and other types of verbs are rarely as trigger words. In order to ensure the accuracy of trigger clustering, we stress that the candidate trigger must be general verb or nominal verb.

### Rule (2): Domain Relevance Ranking

Verb	Description	Examples
vx	copular verb	他 <b>是</b> 对的 (He is right)
vz	modal verb	你 <b>应该</b> 努力工作 (You should work hard)
vf	formal verb	他 要求 <b>予以</b> 澄清 (He'd demand an explanation)
vq	directional verb	他 认识 <b>到</b> 困难 (He has realized the difficulties)
vb	resultative verb	他 看 <b>完</b> 了 电影 (He has seen the movie)
vg	<b>general verb</b>	他 <b>喜欢</b> 踢 足球 (He likes playing football)
vn	<b>nominal verb</b>	参加 我们的 <b>讨论</b> (Take part in our discussion)
vd	adverbial verb	产量 <b>持续</b> 增长 (Production increases steadily)

Table 1. The scheme of verb subclass

Domain relevancy degree is an important measure of the trigger’s significance. According to the candidate trigger distribution in the domain corpus and the general corpus, we can compute its domain relevancy degree as follows:

$$DR(V_i) = \text{Freq}_D(V_i) / \text{Freq}_G(V_i) \quad (1)$$

where  $DR(V_i)$  is the domain relevancy degree of the candidate trigger  $V_i$ ,  $\text{Freq}_D(V_i)$  is the frequency count of the candidate trigger  $V_i$  in the domain corpus (financial and musical news), and  $\text{Freq}_G(V_i)$  is the frequency count in the general corpus (People’s Daily corpus). We will rank candidate triggers by their domain relevancy degrees and retain top  $N_t^1$  candidate triggers.

## 2.3 Trigger Clustering and Event Type Paradigm Building

The trigger word is the most important lexical unit to represent events. A set of triggers with the same meaning and usage represents the same event type. Event type can be discovered based on trigger clustering. We propose the event type discovery (ETD) algorithm based on trigger clustering without giving the number of clusters in advance. The algorithm is shown in Figure 3.

For two triggers  $V_i$  and  $V_j$  in ETD, the similarity function  $\text{Sim}(V_i, V_j)$  in clustering is calculated using semantic information provided by HowNet (Dong et al., 2006) as

$$\text{Sim}(V_i, V_j) = \frac{2N_s}{N_i + N_j} \quad (2)$$

where  $N_s$  denotes the number of identical sememes in the DEFs (the concept definition in HowNet) of  $V_i$  and  $V_j$ ;  $N_i$  and  $N_j$  denote the number of sememes in the DEFs of  $V_i$  and  $V_j$ , respect-

<sup>1</sup> We test different  $N_t$  on dev set; and  $N_t$  is 50% of candidate triggers achieved the best gains.

<b>Algorithm 2: ETD algorithm</b>
<b>Input:</b> Candidate triggers from Section 2.2 and Threshold $\theta$ (refer to Section 3.2)
<b>Output:</b> Event trigger clusters
1: <b>ForEach</b> trigger $V_i$ in candidate triggers <b>Do</b>
2:   Compute the similarity ( $Sim$ ) between $V_i$ and the rest of other triggers, using function (2)
3: <b>If</b> $Sim \geq \theta$ <b>Then</b>
4:     add $V_i$ to the related event type $ET_{re} \cup \{V_i\}$
5: <b>Else If</b> $Sim < \theta$ <b>Then</b>
6:     set up a new event type $ET_{new}$
7: <b>End For</b>

Figure 3. The ETD algorithm

<b>Algorithm 3: PAC model</b>
<b>Input:</b> Verb-argument tuples $\langle V_i, Subj, Obj \rangle$ , where $V_i$ is the trigger from Section 2.2 and Subj and Obj are the arguments of $V_i$ ; and Threshold $\theta$ (refer to Section 3.2)
<b>Output:</b> Event trigger and arguments clusters
1: <b>ForEach</b> tuple $p$ in verb-argument tuples $\langle V_i, Subj, Obj \rangle$ <b>Do</b>
2:   Compute the similarity ( $Sim$ ) between $p$ and the rest of other tuples, using function (3) and (4)
3: <b>If</b> $Sim \geq \theta$ <b>Then</b>
4:     add $V_i$ to the related event type $ET_{re} \cup \{V_i\}$
5: <b>Else If</b> $Sim < \theta$ <b>Then</b>
6:     set up a new event type $ET_{new}$
7: <b>End For</b>

Figure 4. The PAC model

tively. Hownet uses sememes to interpret concepts. Sememes are regarded as the basic unit of the meaning. For example, “paper” can be viewed as a concept, and its sememes are “white”, “thin”, “soft”, “flammable”, etc.

As referred in Section 2.1, most of trigger words are verb terms. Polysemic verbs are a major issue in NLP, such as “to *fire* a gun” and “to *fire* a manager”, where “*fire*” has two different meanings. The state-of-the-art verb sense disambiguation approach (Wagner et al., 2009) stresses that verbs which agree on their selectional preferences belong to a common semantic class. For example, “to *arrest* the suspect” and “to *capture* the suspect”. Based on this approach, we propose a PAC (predicate-argument clustering) model which group the verbs based on their subcategorisation and selectional preferences. ETD considers only the verb subcategorisation, whereas PAC involves the verb argument tuple, such as  $\langle \text{bomb}, US\ Army, \text{weapon warehouse} \rangle$ , where “US Army” and “weapon warehouse” are the subject word and the object word of the trigger word “bomb”. The clustering process of PAC which is shown in Figure 4 is the same as ETD, except for the similarity measurement. PAC calculates the similarity between all the verb argument tuples by the following function:

$$Sim(Tuple_i, Tuple_j) = 2Sum_s / (Sum_i + Sum_j) \quad (3)$$

$$Sum_s = N_s + S_s + O_s, Sum_i = N_i + S_i + O_i, Sum_j = N_j + S_j + O_j \quad (4)$$

where  $S_s$  and  $O_s$  denotes the number of identical sememes in the DEFs of  $Subj_i$  and  $Subj_j$ ,  $Obj_i$  and  $Obj_j$ ;  $S_i$  and  $S_j$  denote the number of sememes in the DEFs of  $Subj_i$  and  $Subj_j$ , respectively;  $O_i$  and  $O_j$  denote the number of sememes in the DEFs of  $Obj_i$  and  $Obj_j$ , respectively.

A group of triggers are aggregated to a trigger cluster according to their semantic distance, and we view each trigger cluster as one kind of event type. Then all these event types are finally employed to construct an event type paradigm.

## 3 Experimental Results and Analysis

### 3.1 Experiment Settings

#### 3.1.1 Data Description

In order to test how robust our approach is, we evaluate it using three different data sets: ACE 05, Financial News<sup>2</sup> and Musical News<sup>3</sup>. ACE 05 is a public corpus with a pre-defined event type paradigm. Financial News and Musical News are specific domain corpora collected by ourselves. To justify the effectiveness of our method, we carefully conducted user studies into two specific domain corpora. For each sentence in the data, two annotators were asked to label and cluster all potential triggers. The agreement between our two annotators, measured using Cohen’s kappa coefficient, is substantial (kappa = 0.75). We asked the third annotator to adjudicate the trigger clusters on which the former two annotators disagreed. Each trigger cluster is used to represent one type of event. All these events construct our final event type paradigm. In particular, we carry out experiment on 633 documents from the ACE 05 corpus, 6000 sentences from the Financial News corpus and 6000 sentences from the Musical News corpus, respectively. One third of these data is used as development set and the remaining data is used as test set.

The gold standard event type paradigm of ACE, Financial News and Musical News are shown in Table 2, Table 3 and Table 4.

#### 3.1.2 Evaluation Measure

We adopt *F-Measure* ( $F$ ) and *Purity* (Halkidi et al., 2001) to determine the correctness of an event cluster:

$$p(i, r) = n(i, r) / n_r \quad (5)$$

<sup>2</sup> <http://www.10jqka.com.cn/>

<sup>3</sup> <http://yue.sina.com.cn/>

Method	Corpus	F-Measure (%)	Purity (%)
Baseline	ACE	42.05	61.47
ETD	ACE	63.21	68.17
PAC	ACE	<b>69.57</b>	<b>70.24</b>
ETD	Financial News	71.52	74.81
PAC	Financial News	<b>74.42</b>	<b>76.18</b>
ETD	Musical News	72.23	78.35
PAC	Musical News	<b>75.08</b>	<b>80.28</b>

Table 5. F-Measure and Purity scores on the test set. All the improvements are significant ( $p < 0.05$ )

Types	Subtype
Life	Be-Born, Marry, Divorce, Injure, Die
Movement	Transport
Transaction	Transfer-Ownership, Transfer-Money
Business	Start-Org, Merge-Org, Declare-Bankruptcy, End-Org
Conflict	Attack, Demonstrate
Contact	Meet, Phone-Write
Personnel	Start-Position, End-Position, Nominate, Elect
Justice	Arrest-Jail, Release-Parole, Trial-Hearing, Charge-Indict, Sue, Convict, Sentence, Fine, Execute, Extradite, Acquit, Appeal, Pardon

Table 2. ACE event type paradigm

Event Type	Examples
Start-Org	MIUI is found in 2010 by Xiaomi Tech.
End-Org	Sears closed more stores as holiday sales slide.
Merge-Org	Two of Tucson’s oldest and most respected landscape companies have decided to merge.
Declare Bankruptcy	American airlines are falling sharply for the second straight day on the fears that the company might be forced to file for bankruptcy.
Go-Public	Chinese video site Youku filed to go public on the New York Stock.
Raise-Price	Gold price rises higher in Hong Kong.
Cut-Price	Sony cuts Tablet S price by \$100, 16GB version now \$399.
Cooperation	Nokia and Microsoft announce plans for a broad strategic partnership to build a new global mobile ecosystem.
Investment	Tencent, one of the biggest web companies in China, is investing \$300m in Digital Sky Technologies of Russia.

Table 3. Financial News event type paradigm

Event Type	Examples
Vocal Concert	Chinese rock singer Cui Jian is to hold his first concert in Beijing at the Capital Gymnasium on Aug. 24.
Album	'Super Girls' release 1st album 'Terminal PK' on August 29, 2005.
Awards	Kanye West won best rap album at the 48th annual Grammy Awards in Los Angeles.
Sign-Org	Lady Gaga was signed with Streamline Records by the end of 2007.
Breakup-Org	Singer Chen Chusheng broke up with his agent E.E. Media after September.
Quit-Singing	Hong Kong pop queen and actress Faye Wong will soon quit her singing career.
Return-Stage	Faye Wong returned to the stage in 2010 amidst immense interest in the Sinosphere.

Table 4. Musical News event type paradigm

Figure 5. ETD algorithm with thresholding on the development set

$$r(i, r) = n(i, r) / n_i \quad (6)$$

$$f(i, r) = \frac{2 * p(i, r) * r(i, r)}{p(i, r) + r(i, r)} \quad (7)$$

$$F = \sum_i (n_i / n) \max \{f(i, r)\} \quad (8)$$

$$Purity = \sum_r (n_r / n) \max \{p(i, r)\} \quad (9)$$

where  $i$  is the gold standard event trigger cluster, and  $r$  is the event trigger cluster which has the most identical triggers with  $i$ . So  $n_i$  is the number of triggers in cluster  $i$ ;  $n_r$  is the number of triggers in cluster  $r$ ;  $n$  is the number of all triggers; and  $n(i, r)$  is the number of identical triggers between  $i$  and  $r$ . For every cluster we first compute  $p(i, r)$ ,  $r(i, r)$  and  $f(i, r)$ , then we obtain *F-Measure* and *Purity* for the whole clustering result. Note that the evaluation is based on word instances rather than word types.

### 3.2 Selection of Trigger Cluster Threshold

During development, we tuned the trigger clustering threshold to find the best value. Figure 5 presents the effect on F-Measure of varying the threshold for trigger clustering. This figure shows that the best performance on the development set can be obtained by selecting threshold 0.6 for the ACE corpus, 0.7 for the Financial News corpus and 0.9 for the Musical News corpus. Figure 5 suggests that the performance did not dramatically change with the threshold when  $\theta$  from 0.6 to 0.9. Hence, we can firstly set  $\theta = 0.6$  for new domains. We also test different threshold values for PAC, the result of which is the same as ETD. Then we directly use 0.6 as threshold value to the blind test.

### 3.3 Comparative Experiments

All the evaluation results are shown in Table 5. We *first* compare our approach with Li et al., 2010 (denoted as baseline) on the ACE 05 corpus. They exploit a cross-lingual clustering algorithm based on sentence-aligned bilingual parallel texts to discover event trigger clusters. The baseline approach can generate both English and Chinese event trigger clusters. We only compare with its Chinese result. Our approach achieves better performance than the baseline approach (about 8% significant improvement on Purity and more than 20% significant improvement on F-Measure). In addition, the baseline approach uses 1233 gold standard English event triggers and 852 gold standard Chinese event triggers in the ACE 05 as the input. However, we automatically extract event triggers based on our trigger extraction algorithm.

We carry out the *second* comparison experiment between ETD algorithm which is based on trigger clustering and PAC model which is based on predicate-argument clustering. The trigger and its corresponding arguments (selectional preferences) play an important role in our approach. We observe that the F-Measure score is boosted from 63.21% to 69.57% on the ACE corpus by using the PAC model. This can be explained by the reason that single trigger is not quite enough for representing event. Trigger’s arguments can contribute to trigger disambiguation. The experiment results also confirm the assumption (Wagner et al., 2009) that verbs which agree on their selectional preferences belong to a common semantic class.

We also run the *third* comparison experiment using three different corpora (ACE 05, Financial News and Musical News) to evaluate the robustness and domain adaptiveness of our system. The performances on the specific domain corpora are better than that on the ACE corpus (about 5% absolute improvement on F-Measure and 6%-10% on Purity). The main reason is that the events in specific domain are more specific. In addition, the experiment results on both specific domain corpora can achieve good performance. This indicates that our system is domain independent.

In order to evaluate whether the filter rules used in Section 2.2 are effective, we introduce the *fourth* comparison experiment. We use the Purity score to evaluate the effectiveness of the two filter rules. The evaluation results are shown in Table 6. We find that the average improvement using only rule (1) is 6.93% absolute for

Method	Performance		
	Purity (%)		
	ACE	Finance	Music
ETD	55.59	60.82	62.31
ETD+Rule(1)	65.13	66.51	69.37
ETD+Rule(2)	58.22	68.26	70.25
ETD+Rule(1)+Rule(2)	<b>68.17</b>	<b>74.81</b>	<b>78.35</b>
PAC	60.17	62.45	66.24
PAC+Rule(1)	68.04	69.24	72.38
PAC+Rule(2)	62.86	70.32	73.21
PAC+Rule(1)+Rule(2)	<b>70.24</b>	<b>76.18</b>	<b>80.28</b>

Table 6. The performance for filter rules

	Error types	Proportion
1	Trigger Extraction	33.0%
2	Trigger ambiguous	28.3%
3	Trigger Filter	19.5%
4	Others	19.2%

Table 7. Error types in the experiment

three corpora compared with the performance without using rule; using only rule (2) is 5.84% absolute; and using both rules, the average improvement is 12.61% absolute. This indicates that our two filter rules can improve the experiment performance significantly.

### 3.4 Discussion

#### Analysis of Experimental Errors

We first inspect the errors produced by our approach. The errors are mainly caused by the sparse event triggers in corpus. Table 7 shows the distribution of the errors in detail.

After error analysis, we found that the most number of errors are caused by trigger extraction. The main reasons are: firstly, not all of event triggers are verbs, such as “婚姻 (marriage)” for “Life/Marry” event, although it is reasonable to assume that event triggers are verbs because on average, there are more than 95% event triggers are verbs in our three different data sets. Secondly, since only verbs with subject and object are extracted, non-predicate verbs and the verbs without subject/object will not be extracted as candidate triggers. However, the coverage of possible triggers by our trigger extraction algorithm is reasonable good (more than 85%), because most of the trigger words appear repeatedly in the corpus, and their usages are varied. As long as one of their usages is fit for our extraction algorithm, they can be extracted as candidate triggers. Note that the goal of this paper is to build an event type paradigm for new domains. We concern more on the coverage of event type rather than event triggers. The event triggers extracted by us can cover all of event types. We will exploit more effective trigger extraction algorithm in future work.

Trigger ambiguity also accounts for a big proportion of the errors. As discussed in Section 2.3, we cannot judge the event type only by the trigger itself, such as “撤 (withdraw/dismiss)” for both “Personnel/End-Position” event and “Movement/Transport” event. This kind of errors can be partially fixed by the PAC model. For example, we cluster “撤职务 (dismiss duties)” for “Personnel/End-Position” event and “撤军队 (withdraw troop)” for “Movement/Transport” event. These examples indicate that selectional preferences seem to be a reasonable feature even for highly ambiguous verbs like “撤” which encourages to improve argument extraction.

There are still some errors caused by trigger filter. This is mainly due to the fact that not all of triggers are general verb or nominal verb. Domain relevance ranking filter rule will ignore the common event types, which might also be very important for general event extraction, such as “Life/Die” event in the ACE corpus. More effective filter rules will be exploited in future.

Some other errors are caused by NLP tools, such as word segmentation, part-of-speech tagging and dependency parsing. We believe that our algorithms can be improved with the improvement of these NLP tools. In addition, there are about 10% of good event triggers extracted but put into the wrong cluster by trigger cluster.

#### **Analysis of Different Corpus Sources**

The third comparison experiment shows that the performance of our approach on three corpora is not very consistent (F-Measure 69.57%, 74.42% and 75.08% on the ACE, Financial and Musical corpus, respectively). The F-Measure on the ACE corpus is lower than that on the other two domain corpora. The performances on the other two domain corpora are comparable. The main reasons are as follows: firstly, the discrimination between some event types in the ACE paradigm is very small, such as the “Justice/Charge-Indict” event and the “Justice/Sue” event; the “Personnel/Nominate” event and the “Personnel/Start-Position” event; the “Life/Die” event and the “Conflict/Attack” event. Secondly, some events rarely occur in the ACE corpus, such as “Justice/Extradite” event occurs only three times in the ACE corpus. Thirdly, some events have a lot of triggers in the ACE corpus, but not all of these event triggers appear frequently. For example, the “Movement/Transport” event has 188 triggers and 64.89% of its triggers appear only once. As compared to ACE corpus, the similarity among event types in the other two

corpora is low. Finally, we analyze that the quantity of event types also results in the different performance between the ACE corpus and the domain-specific corpus. There are 33 subtypes of events in the ACE corpus which are far more than the number of events in the Financial and Musical corpus.

#### **Analysis of Different Filter Rules**

The fourth comparison experiment indicates that both the filter rules are effective. As shown in Table 4, the improvement obtained using rule (1) is 7.87%, 6.79% and 6.14% on the ACE, Financial and Musical News corpus, respectively. The experiment result verifies that verb subdividing is helpful for the Chinese event extraction task. The improvement obtained using rule (2) is 2.69%, 7.87% and 6.97% on the ACE, Financial and Musical News corpus, respectively. The performances on all these three different corpora are improved by rule (2); however, it is obvious that rule (2) is not much effective on the ACE corpus (2.69%) compared with the other two domain-specific corpora (7.87% and 6.97%). The main reason is that the ACE corpus contains many common events and the domain-specific information is not very useful. For the other two domain-specific corpora, rule (2) has improved the performance more than rule (1) did. This is due to the fact that rule (2) is more effective on the domain-specific corpus.

## **4 Related Work**

### **4.1 Word Cluster Discovery**

Our approach of automatically building an event type paradigm is related to some prior work on word cluster discovery (e.g. Barzilay and McKeown, 2001; Ibrahim et al., 2003; Pang et al., 2003). Most of these works are based on machine translation techniques to solve paraphrase extraction problem. However, several recent researches have stressed the benefits of using word clusters to improve the performance of information extraction tasks. For example, Miller et al., (2004) proved that word clusters could significantly improve English name tagging performance. In the same vein, some studies work on the problem of relation extraction (Chambers and Jurasky, 2011 and 2009; Poon and Domingos, 2009 and 2008; Yates and Etzioni, 2009). In these work, “relation words” were extracted and clustered. In this paper, our work confirmed that trigger clusters are also effective for event type paradigm building. The problem of event trigger

words extraction and clustering is also a challenge problem.

#### 4.2 Traditional Event Extraction

The commonly used approaches for most event extraction systems are the knowledge engineering approach and the machine learning approach. Grishman et al., (2005) used a combination of pattern matching and statistical modeling techniques. They extract two kinds of patterns: 1) the sequence of constituent heads separating anchor and its arguments; and 2) a predicate argument sub-graph of the sentence connecting anchor to all the event arguments. In conjunction, they used a set of Maximum Entropy based classifiers for 1) Trigger labeling, 2) Argument classification and 3) Event classification. Ji and Grishman, (2008) further exploited a correlation between senses of verbs (that are the triggers for events) and topics of documents. They first proposed refining event extraction through unsupervised cross-document inference. Following Ji's work, Liao et al., (2010) used document level cross-event inference to improve event extraction. Chen and Ji, (2009) combined word-based classifier with character-based classifier; and explored effective features for the Chinese event extraction task. Liao and Grishman, (2010) ranked two semi-supervised learning methods for adapting the event extraction system to new event types. Hong et al, (2011) proposed a blind cross-entity inference method for event extraction, which well uses the consistency of entity mention to achieve sentence-level trigger and argument (role) classification. Lu and Roth, (2012) presented a novel model based on the semi-Markov conditional random fields for the challenging event extraction task. The model takes in coarse mention boundary and type information and predicts complete structures indicating the corresponding argument role for each mention.

However, for all the above approaches, it is necessary to specify the target event type in advance. Defining and identifying those types heavily rely on expert knowledge, and reaching an agreement among the experts or annotators requires a lot of human labor. Li et al., (2010) proposed a domain-independent novel event discovery approach. They exploited a cross-lingual clustering algorithm based on sentence-aligned bilingual parallel texts to discover event trigger clusters. Their motivation is to discover novel events for a new domain rather than build a new event type paradigm from scratch. Therefore, it takes domain specific event triggers as the input.

However, it is also a costly task to annotate triggers for new domains. The motivation of this paper is to build event type paradigm from scratch rather than discover novel events based on the existing event type paradigm.

#### 5 Conclusion and Future Work

Traditionally, in the topic of event detection, we have to categorize the events into various pre-defined event-types. In this paper, we aim to tackle the situation when the category of event-type is undefined, and we try to derive the event-types from the corpus. In particular, we automatically build an event type paradigm by using a trigger clustering algorithm: 1) we introduce a trigger extraction algorithm based on the dependency syntactic structure; 2) a trigger filter is then constructed to remove some noisy candidate triggers; 3) we develop an event type discovery algorithm based on our proposed trigger clustering methods. The clustered event types are used to construct an event type paradigm. Experimental results on three different corpora – ACE (small, homogeneous, open corpus), Financial News and Musical News (large scale, specific domain, web corpus) indicate that our method can effectively build an event type paradigm and that it is easy to adapt the proposed method to new domains.

In the future, more sophisticated algorithm will be exploited. Furthermore, a bottom-up event extraction system can be built based on our event type paradigm.

## Abstract

Normalizing named entity abbreviations to their standard forms is an important preprocessing task for question answering, entity retrieval, event detection, microblog processing, and many other applications. Along with the quick expansion of microblogs, this task has received more and more attentions in recent years. In this paper, we propose a novel entity abbreviation generation method using first-order logic to model long distance constraints. In order to reduce the human effort of manual annotating corpus, we also introduce an automatically training data construction method with simple strategies. Experimental results demonstrate that the proposed method achieves better performance than state-of-the-art approaches.

## 1 Introduction

Twitter and other social media services have received considerable attentions in recent years. Users provide hundreds of millions microblogs through them everyday. The informative data has been relied on by many applications, such as sentiment analysis (Jiang et al., 2011; Meng et al., 2012), event detection (Sakaki et al., 2010; Lin et al., 2010), stock market predication (Bollen et al., 2011), and so on. However, due to the constraint on the length of characters, abbreviations frequently occur in microblogs. According to a statistic, approximately 20% of sentences in news articles have abbreviated words (Chang and Lai, 2004). The frequency of abbreviation has become even more popular along with the rapid increment of user generated contents. Without pre-normalizing these abbreviations, most of the natural language processing systems may heavily suffer from them.

The goal of entity abbreviation generation is to produce abbreviated equivalents of the original entities. Table 1 shows several examples of entities and their corresponding abbreviations. A few of approaches have been done on this task. Li and Yarowsky (Li and Yarowsky, 2008b) introduced an unsupervised method used to extract phrases and their abbreviation pair using parallel dataset and monolingual corpora. Xie et al. (2011) proposed to use weighted bipartite graph to extract definition and corresponding abbreviation pairs from anchor texts. Since these methods rely heavily on lexical/phonetic similarity, substitution of characters and portion may not be correctly identified through them. Yang et al. (2009) studied the Chinese entity name abbreviation problem. They formulated the abbreviation task as a sequence labeling problem and used the conditional random fields (CRFs) to model it. However the long distance and global constraint can not be easily modeled thorough CRFs.

Entity	Abbr.
北京大学 (Peking University)	北大
中国石油天然气集团公司 (China National Petroleum Corporation)	中石油
中国国际航空公司 (Air China)	国航

Table 1: Abbreviation examples

To overcome these limitations, in this paper, we propose a novel entity abbreviation generation method, which combines first-order logic and rich linguistic features. To the best of our knowledge, our approach is the first work of using first-order logic for this entity abbreviation. Abbreviation generation is converted to character deletion and

keep operations which are modeled by logic formula. Linguistic features and relations between different operations are represented by local and global logic formulas respectively. Markov Logic Networks (MLN) (Richardson and Domingos, 2006) is adopted for learning and predication. To reduce the human effort in constructing the training data, we collect standard forms of entities from online encyclopedia and introduce a few of simple patterns to extract abbreviations from documents and search engine snippets with high precision as training data. Experimental results show that the proposed methods achieve better performance than state-of-the-art methods and can efficiently process large volumes of data.

The remainder of the paper is organized as follows: In section 2, we review a number of related works and the state-of-the-art approaches in related areas. Section 3 presents the proposed method. Experimental results in test collections and analyses are shown in section 4. Section 5 concludes this paper.

## 2 Related Work

The proposed approach builds on contributions from two research communities: text normalization, and Markov Logic Networks. In the following of this section, we give brief description of previous works on these areas.

### 2.1 Text Normalization

Named entity normalization, abbreviation generation, and lexical normalization are related to this task. These problems have been recognized as important problems for various languages. Since different languages have their own peculiarities, many approaches have been proposed to handle variants of words (Aw et al., 2006; Liu et al., 2012; Han et al., 2012) and named entities (Yang et al., 2009; Xie et al., 2011; Li and Yarowsky, 2008b).

Chang and Teng (2006) introduced an HMM-based single character recovery model to extract character level abbreviation pairs for textual corpus. Okazaki et al. (2008) also used discriminative approach for this task. They formalized the abbreviation recognition task as a binary classification problem and used Support Vector Machines to model it. Yang et al. (2012) also treated the abbreviation generation problem as a labeling task and used Conditional Random Fields (CRFs) to do it. They also proposed to re-rank candidates by a

length model and web information.

Li and Yarowsky (2008b) proposed an unsupervised method extracting the relation between a full-form phrase and its abbreviation from monolingual corpora. They used data co-occurrence intuition to identify relations between abbreviation and full names. They also improved a statistical machine translation by incorporating the extracted relations into the baseline translation system. Based on the data co-occurrence phenomena, they introduced a bootstrapping procedure to identify formal-informal relations informal phrases in web corpora (Li and Yarowsky, 2008a). They used search engine to extract contextual instances of the given an informal phrase, and ranked the candidate relation pairs using conditional log-linear model. Xie et al. (2011) proposed to extract Chinese abbreviations and their corresponding definitions based on anchor texts. They constructed a weighted URL-AnchorText bipartite graph from anchor texts and applied co-frequency based measures to quantify the relatedness between two anchor texts.

For lexical normalisation, Aw et al. (2006) treated the lexical normalisation problem as a translation problem from the informal language to the formal English language and adapted a phrase-based method to do it. Han and Baldwin (2011) proposed a supervised method to detect ill-formed words and used morphophonemic similarity to generate correction candidates. Liu et al. (2012) proposed to use a broad coverage lexical normalization method consisting three key components enhanced letter transformation, visual priming, and string/phonetic similarity. Han et al. (2012) introduced a dictionary based method and an automatic normalisation-dictionary construction method. They assumed that lexical variants and their standard forms occur in similar contexts.

In this paper, we focused on named entity abbreviation generation problem and treated the problem as a labeling task. Due to the flexibilities of Markov Logic Networks on capturing local and global linguistic feature, we adopted it to model the supervised classification procedure. To reduce the human effort in constructing training data, we also introduced a sample rule based method to find relations between standard forms and abbreviations.

<b>Predicates about characters in the entity</b>	
<i>character(i,c)</i>	The <i>i</i> th character is <i>c</i> .
<i>isNumber(i)</i>	The <i>i</i> th character is a number.
<b>Predicates about words in the entity</b>

<i>cwPosition(i,j)</i>	The <i>i</i> th character of the entity is the <i>j</i> th character in the corresponding word.

Table 2: Descriptions of observed predicates.

## 2.2 Markov Logic Networks

Richardson and Domingos (2006) proposed Markov Logic Networks (MLN), which combines first-order logic and probabilistic graphical models. MLN framework has been adopted for several natural language processing tasks and achieved a certain level of success (Singla and Domingos, 2006; Riedel and Meza-Ruiz, 2008; Yoshikawa et al., 2009; Andrzejewski et al., 2011; Jiang et al., 2012; Huang et al., 2012).

Singla and Domingos (2006) modeled the entity resolution problem with MLN. They demonstrated the capability of MLN to seamlessly combine a number of previous approaches. Poon and Domingos (2008) proposed to use MLN for joint unsupervised coreference resolution. Yoshikawa et al. (2009) proposed to use Markov logic to incorporate both local features and global constraints that hold between temporal relations. Andrzejewski et al. (2011) introduced a framework for incorporating general domain knowledge, which is represented by First-Order Logic (FOL) rules, into LDA inference to produce topics shaped by both the data and the rules.

## 3 The Proposed Approach

In this section, firstly, we briefly describe the Markov Logic Networks framework. Then, we present the first-order logic formulas including local formulas and global formulas we used in this work.

### 3.1 Markov Logic Networks

A MLN consists of a set of logic formulas that describe first-order knowledge base. Each formula consists of a set of first-order predicates, logical connectors and variables. Different with first-order logic, these hard logic formulas are softened and can be violated with some penalty (the weight of formula) in MLN.

We use  $\mathcal{M}$  to represent a MLN and  $\{(\phi_i, w_i)\}$  to represent formula  $\phi_i$  and its weight  $w_i$ . These weighted formulas define a probability distribution over sets of possible worlds. Let  $y$  denote a possible world, the  $p(y)$  is defined as follows (Richardson and Domingos, 2006):

$$p(y) = \frac{1}{Z} \exp \left( \sum_{(\phi_i, w_i) \in \mathcal{M}} w_i \sum_{c \in C^{n_{\phi_i}}} f_c^{\phi_i}(y) \right),$$

where each  $c$  is a binding of free variable in  $\phi_i$  to constraints;  $f_c^{\phi_i}(y)$  is a binary feature function that

returns 1 if the true value is obtained in the ground formula we get by replacing the free variables in  $\phi_i$  with the constants in  $c$  under the given possible world  $y$ , and 0 otherwise;  $C^{n_{\phi_i}}$  is all possible bindings of variables to constants, and  $Z$  is a normalization constant.

Many methods have been proposed to learn the weights of MLNs using both generative and discriminative approaches (Richardson and Domingos, 2006; Singla and Domingos, 2006). There are also several MLNs learning packages available online such as thebeast<sup>1</sup>, Tuffy<sup>2</sup>, PyMLNs<sup>3</sup>, Alchemy<sup>4</sup>, and so on.

### 3.2 MLN for Abbreviation Generation

In this work, we convert the abbreviation generation problem as a labeling task for every characters in entities. Predicate  $drop(i)$  indicates that the character at position  $i$  is omitted in the abbreviation. Previous works (Chang and Lai, 2004; Yang et al., 2009) show that Chinese named entities can be further segmented into words. Words also provide important information for abbreviation generation. Hence, in this work, we also segment named entities into words and propose an observed predict to connect words and characters.

#### 3.2.1 Local Formulas

The local formulas relate one or more observed predicates to exactly one hidden predicate. In this work, we define a list of observed predicates to describe the properties of individual characters. Table 2 shows the list. For this task, there is only one hidden predicate  $drop$ .

Table 3 lists the local formulas used in this work. The “+” notation in the formulas indicates that the each constant of the logic variable should be weighted separately. For example, formula  $character(2, \bar{\quad}) \wedge isNumber(2) \Rightarrow drop(2)$  and  $character(2, +) \wedge isNumber(2) \Rightarrow drop(2)$  may have different weights as inferred by formula  $character(i, c+) \wedge isNumber(i) \Rightarrow drop(i)$ .

Three kinds of local formulas are introduced in this work. Lexical features are used to capture the context information based on both character and word level information. Distance and position features are helpful in determining which parts of a entity may be removed. Hence, we

also incorporate position information of word into local formulas. For example, “大学(University)” is usually omitted when it is at the end of the entity. In practice, abbreviations of some kinds of entities can be generated through several strategies. So we introduce several local formulas to handle a group of related entities with similar suffix.

#### 3.2.2 Global Formulas

Global formulas are designed to handle deletion of multiple characters. Since in this work, we only have one hidden predicate,  $drop$ , the global formulas incorporate correlations among different ground atoms of the  $drop$  predicate.

We propose to use global formulas to force the abbreviations to contain at least 2 characters and to make sure that at least one character is deleted. The following formulas are implemented:

$$\begin{aligned} &|character(i, c) \wedge drop(i)| \text{ all } i \geq 1 \\ &|character(i, c) \wedge \neg drop(i)| \text{ all } i \geq 2 \end{aligned}$$

Another constraint is that for the characters in some particular words should by dropped or kept simultaneously. So we add two formulas to model this:

$$\begin{aligned} &character(i, c1) \wedge cwMap(i, j) \wedge drop(i) \wedge \\ &character(i + 1, c2) \wedge cwMap(i + 1, j) \\ &\Rightarrow drop(i + 1) \end{aligned}$$

$$\begin{aligned} &character(i, c1) \wedge cwMap(i, j) \wedge \neg drop(i) \wedge \\ &character(i + 1, c2) \wedge cwMap(i + 1, j) \\ &\Rightarrow \neg drop(i + 1) \end{aligned}$$

## 4 Experiments

In this section, we first describe the dataset construction method, evaluation metrics, and experimental configurations. We then describe the evaluation results and analysis.

### 4.1 Data Set

For training and evaluating the performance the proposed method, we need a large number of abbreviation and corresponding standard form pairs. However, manually labeling is a laborious and time consuming work. To reduce human effort, we propose to construct annotated dataset with two steps. Firstly, we collect entities from Baidu

简称: A (abbreviation name: A)
A是E(的)?(中文)?简称 (A is the (Chinese)? abbreviation name of E)
E(的)?(中文)?简称(是)?A (the (Chinese)? abbreviation name of E is A)
A是E的同义词 (A is a synonym of E)
E和A是同义词 (E and A are synonyms)
A和E是同义词 (A and E are synonyms)
E represents the entity
A represents the candidate abbreviation

Table 4: The lexical level regular expressions used to match entity and abbreviation pairs.

Baike<sup>5</sup>, which is one of the most popular wiki-based Chinese encyclopedia and contains more than 6 millions items. Secondly, we use several simple regular expressions to extract abbreviation of entities from the crawled encyclopedia and snippets of search engine.

We crawled 3.2 millions articles from Baidu Baike. After that, we cleaned the HTML tags and extracted title, category and textual content from each articles. the structure of Baidu Baike is similar to that of Wikipedia, where titles are the name of the subject of the article, or may be a description of the topic. Hence, titles can be considered as the standard forms of entities. We select titles whose categories belong to location, organization, and facility to construct the standard forms list. It contains 302,633 items in total.

The next step is to use titles and corresponding articles to extract abbreviations. Through analyzing the dataset, we observe that most of abbreviations with the explicit description can be matched through a few of lexical level regular expressions. Table 4 shows the regular expressions we used in this work. Through this step, 30,701 abbreviation and entity pairs are extracted. We randomly select 500 pairs from them and manually check their correctness. The accuracy of the extracted pairs is around 98.2%.

To further increase the number of extractions, we propose to use Web as corpus and extract abbreviation and entity pairs from snippets of

search engine results. For each entity whose abbreviation cannot be identified through the regular expressions described above, we combine entity and “简称 (abbreviation)” as queries for retrieving. The first three regular expressions in Table 4 are used to match abbreviation and entity pairs. Through this step, we get another 19,531 abbreviations. We also randomly select 500 pairs from them and manually check their correctness. The accuracy is around 95.2%. Finally, we merge the pairs extracted from Baike and search engine snippets and construct a list containing 50,232 abbreviation entity pairs. The accuracy of the list is 97.03%.

## 4.2 Experimental Settings

For evaluating the performance of the proposed method, we conducted experiments on the automatical constructed data. Total instances are randomly split with 75% for training, 5% for development and the other 20% for testing.

We compare the proposed method against start-of-the-art systems. Yang et al. (2009) proposed to use CRFs to model this. In this work, firstly, we re-implement the features they proposed. To fairly compare the two models, we also extend their work by including all local formulas we used in this work as features.

In our setting, we use FudanNLP<sup>6</sup> toolkit and thebeast<sup>7</sup> Markov Logic engine. FudanNLP is developed for Chinese natural language processing. We use the Chinese word segmentation of it under the default settings. The detailed setting of thebeast engine is as follows: The inference algorithm is the MAP inference with a cutting plane approach. For parameter learning, the weights for formulas is updated by an online learning algorithm with MIRA update rule. All the initial weights are set to zeros. The number of iterations is set to 10 epochs.

For evaluation metrics, we use precision, recall, and F-score to evaluate the performance of character deletion operation. To evaluate the performance of the entire generated abbreviations, we also propose to use accuracy to do it. It means that the generated abbreviation is considered as correct if all characters of its standard form are correctly classified.

Table 5: The lexical level regular expressions used to match entity and abbreviation pairs.

### 4.3 Results

To evaluate the performance of our method, we set up several variants of the proposed method to compare with performances of CRFs. The *MLN-LF* method uses only the lexical features described in the Table 3. The *MLN-LF+DPF* method uses both lexical features and distance and position features. The *MLN-Local* method uses all local formulas described in the Table 3. The *MLN-Local+Global* methods combine both local formulas and global formulas together. For Yang’s system, we use *CRFs-Yang* to represent the re-implemented method with feature set proposed by them and *CRFs-LF*, *CRFs-LF+DPF*, and *CRFs-Local* to represent feature sets similar as used by MLN.

Table 5 shows the performances of different methods. We can see that *MLN-Local+Global* achieve the best accuracy of entire abbreviation among all the methods. Although, the F-score of *MLN-Local+Global* is slightly worse than *MLN-Local*. We think that the global formulas contribute a lot for the entire accuracy. However, since the constraint of simultaneously dropping or keeping characters does not consider context, it may also bring some false matches. We can also see that, the methods modeled by MLN significantly outperform the performances of CRFs no matter which feature sets are used (based on a paired 2-tailed t-test with  $p < 0.05$ ). We think that overfitting may be one of the main reasons.

From the perspective of entire accuracy, comparing the performances of *MLN-LF+DPF* and *MLN-Local*, we can see that features for entities with special suffixes contribute a lot. The relative improvement of *MLN-Local* is around 19.7%. It shows that the explicit rules are useful for improv-

ing the performance. However, these explicit rules only bring a small improvement to the accuracy of CRFs.

Comparing the performances of CRFs and MLNs, we can observe that CRFs achieve slightly better performance in classifying single characters. However MLNs achieve significantly better results of the entire accuracies. We think that these kinds of long distance features can be well handled by MLNs. These features are useful to capture the global constraints. Hence, MLNs can achieve better accuracy of the entire abbreviations.

In this paper, we also investigate the performance of different methods as the training data size are varied. Figure 1 shows the results. All full lines show the results of MLNs with different feature sets. The dot dash lines show the results of CRFs. From the results, we can observe that MLNs perform better than CRFs in most of cases. Except that MLNs with only lexical features work slightly worse than CRFs with small number of training data. From the figure, we also observe that the performance improvement of CRFs are not significant when the number of training data is larger than 35,000. However, methods using MLNs benefit a lot from the increasing data size. If more training instances are given, the performance of MLNs can still be improved.

Figure 1: The impacts of training data size.

From the training procedures, we also empirically find that the training iterations of MLNs are small. It means that the convergence rate

of MLNs is fast. To evaluate the convergence rate, we also evaluate the dependence of the performances of MLNs on the number of training epochs. Figure 2 shows the results of *MLN-Local* and *MLN-Local+Global*. From the results, we can observe that the best performances can be achieved when the number of training epochs is more than nine. Hence, in this work, we set the number of iterations to be 10.

Figure 2: The performance curves on the number of training epochs.

## 5 Conclusions

In this paper, we focus on named entity abbreviation generation problem. We propose to use first-order logic to model rich linguistic features and global constraints. We convert the abbreviation generation to character deletion and keep operations. Linguistic features and relations between different operations are represented by local and global logic formulas respectively. Markov Logic Network frameworks is adopted for learning and predication. To reduce the human effort in constructing the training data, we also introduce an automatical training data construction methods with sample strategies. We collect standard forms of entities from online encyclopedia, use a few simple patterns to extract abbreviations from documents and search engine snippets with high precision as training data. Experimental results show that the proposed methods achieve better performance than state-of-the-art methods and can efficiently process large volumes of data.

## Abstract

The identification of light verb constructions (LVC) is an important task for several applications. Previous studies focused on some limited set of light verb constructions. Here, we address the full coverage of LVCs. We investigate the performance of different candidate extraction methods on two English full-coverage LVC annotated corpora, where we found that less severe candidate extraction methods should be applied. Then we follow a machine learning approach that makes use of an extended and rich feature set to select LVCs among extracted candidates.

## 1 Introduction

A multiword expression (MWE) is a lexical unit that consists of more than one orthographical word, i.e. a lexical unit that contains spaces and displays lexical, syntactic, semantic, pragmatic and/or statistical idiosyncrasy (Sag et al., 2002; Calzolari et al., 2002). Light verb constructions (LVCs) (e.g. *to take a decision*, *to take sg into consideration*) form a subtype of MWEs, namely, they consist of a nominal and a verbal component where the verb functions as the syntactic head (the whole construction fulfills the role of a verb in the clause), but the semantic head is the noun (i.e. the noun is used in one of its original senses). The verbal component (also called a light verb) usually loses its original sense to some extent.<sup>1</sup> The meaning of LVCs can only partially be computed on the basis of the meanings of their parts and the way they are related to each other (semi-compositionality). Thus, the result of translating their parts literally can hardly be considered as

<sup>1</sup>*Light verbs* may also be defined as semantically empty support verbs, which share their arguments with a noun (see the NomBank project (Meyers et al., 2004)), that is, the term *support verb* is a hypernym of *light verb*.

the proper translation of the original expression. Moreover, the same syntactic pattern may belong to a LVC (e.g. *make a mistake*), a literal verb + noun combination (e.g. *make a cake*) or an idiom (e.g. *make a meal (of something)*), which suggests that their identification cannot be based on solely syntactic patterns. Since the syntactic and the semantic head of the construction are not the same, they require special treatment when parsing. On the other hand, the same construction may function as an LVC in certain contexts while it is just a productive construction in other ones, compare *He gave her a ring made of gold* (non-LVC) and *He gave her a ring because he wanted to hear her voice* (LVC).

In several natural language processing (NLP) applications like information extraction and retrieval, terminology extraction and machine translation, it is important to identify LVCs in context. For example, in machine translation we must know that LVCs form one semantic unit, hence their parts should not be translated separately. For this, LVCs should be identified first in the text to be translated.

As we shall show in Section 2, there has been a considerable amount of previous work on LVC detection, but some authors seek to capture just verb-object pairs, while others just verbs with prepositional complements. Actually, many of them exploited only constructions formed with a limited set of light verbs and identified or extracted just a specific type of LVCs. However, we cannot see any benefit that any NLP application could get from these limitations and here, we focus on the full-coverage identification of LVCs. We train and evaluate statistical models on the Wiki50 (Vincze et al., 2011) and Szeged-ParalellFX (SZPFX) (Vincze, 2012) corpora that have recently been published with full-coverage LVC annotation.

We employ a two-stage procedure. First,

we identify potential LVC candidates in running texts – we empirically compare various candidate extraction methods –, then we use a machine learning-based classifier that exploits a rich feature set to select LVCs from the candidates.

The main contributions of this paper can be summarized as follows:

- We introduce and evaluate systems for **identifying all LVCs and all individual LVC occurrences** in a running text and we do not restrict ourselves to certain specific types of LVCs.
- We systematically **compare and evaluate different candidate extraction methods** (earlier published methods and new solutions implemented by us).
- We defined and evaluated several **new feature templates** like semantic or morphological features to select LVCs in context from extracted candidates.

## 2 Related Work

Two approaches have been introduced for LVC detection. In the first approach, LVC candidates (usually verb-object pairs including one verb from a well-defined set of 3-10 verbs) are extracted from the corpora and these tokens – without contextual information – are then classified as LVCs or not (Stevenson et al., 2004; Tan et al., 2006; Fazly and Stevenson, 2007; Van de Cruys and Moirón, 2007; Gurrutxaga and Alegria, 2011). As a gold standard, lists collected from dictionaries or other annotated corpora are used: if the extracted candidate is classified as an LVC and can be found on the list, it is a true positive, regardless of the fact whether it was a genuine LVC in its context.

In the second approach, the goal is to detect individual LVC token instances in a running text, taking contextual information into account (Diab and Bhutada, 2009; Tu and Roth, 2011; Nagy T. et al., 2011). While the first approach assumes that a specific candidate in all of its occurrences constitutes an LVC or not (i.e. there are no ambiguous cases), the second one may account for the fact that there are contexts where a given candidate functions as an LVC whereas in other contexts it does not, recall the example of *give a ring* in Section 1.

The authors of Stevenson et al. (2004), Fazly and Stevenson (2007), Van de Cruys and Moirón

(2007) and Gurrutxaga and Alegria (2011) built LVC detection systems with statistical features. Stevenson et al. (2004) focused on classifying LVC candidates containing the verbs *make* and *take*. Fazly and Stevenson (2007) used linguistically motivated statistical measures to distinguish subtypes of verb + noun combinations. However, it is a challenging task to identify rare LVCs in corpus data with statistical-based approaches, since 87% of LVCs occur less than 3 times in the two full-coverage LVC annotated corpora used for evaluation (see Section 3).

A semantic-based method was described in Van de Cruys and Moirón (2007) for identifying verb-preposition-noun combinations in Dutch. Their method relies on selectional preferences for both the noun and the verb. Idiomatic and light verb noun + verb combinations were extracted from Basque texts by employing statistical methods (Gurrutxaga and Alegria, 2011). Diab and Bhutada (2009) and Nagy T. et al. (2011) employed ruled-based methods to detect LVCs, which are usually based on (shallow) linguistic information, while the domain specificity of the problem was highlighted in Nagy T. et al. (2011).

Both statistical and linguistic information were applied by the hybrid LVC systems (Tan et al., 2006; Tu and Roth, 2011; Samardžić and Merlo, 2010), which resulted in better recall scores. English and German LVCs were analysed in parallel corpora: the authors of Samardžić and Merlo (2010) focus on their manual and automatic alignment. They found that linguistic features (e.g. the degree of compositionality) and the frequency of the construction both have an impact on the alignment of the constructions.

Tan et al. (2006) applied machine learning techniques to extract LVCs. They combined statistical and linguistic features, and trained a random forest classifier to separate LVC candidates. Tu and Roth (2011) applied Support Vector Machines to classify verb + noun object pairs on their balanced dataset as candidates for true LVCs<sup>2</sup> or not. They compared the contextual and statistical features and found that local contextual features performed better on ambiguous examples.

---

<sup>2</sup>In theoretical linguistics, two types of LVCs are distinguished (Kearns, 2002). In true LVCs such as *to have a laugh* we can find a noun that is a converse of a verb (i.e. it can be used as a verb without any morphological change), while in vague action verbs such as *to make an agreement* there is a noun derived from a verb (i.e. there is morphological change).

Some of the earlier studies aimed at identifying or extracting only a restricted set of LVCs. Most of them focus on verb-object pairs when identifying LVCs (Stevenson et al., 2004; Tan et al., 2006; Fazly and Stevenson, 2007; Cook et al., 2007; Bannard, 2007; Tu and Roth, 2011), thus they concentrate on structures like *give a decision* or *take control*. With languages other than English, authors often select verb + prepositional object pairs (instead of verb-object pairs) and categorise them as LVCs or not. See, e.g. Van de Cruys and Moirón (2007) for Dutch LVC detection or Krenn (2008) for German LVC detection. In other cases, only true LVCs were considered (Stevenson et al., 2004; Tu and Roth, 2011). In some other studies (Cook et al., 2007; Diab and Bhutada, 2009) the authors just distinguished between the literal and idiomatic uses of verb + noun combinations and LVCs were classified into these two categories as well.

In contrast to previous works, we seek to identify all LVCs in running texts and do not restrict ourselves to certain types of LVCs. For this reason, we experiment with different candidate extraction methods and we present a machine learning-based approach to select LVCs among candidates.

### 3 Datasets

In our experiments, three freely available corpora were used. Two of them had fully-covered LVC sets manually annotated by professional linguists. The annotation guidelines did not contain any restrictions on the inner syntactic structure of the construction and both true LVCs and vague action verbs were annotated. The Wiki50 (Vincze et al., 2011) contains 50 English Wikipedia articles that were annotated for different types of MWEs (including LVCs) and Named Entities. SZPFX (Vincze, 2012) is an English–Hungarian parallel corpus, in which LVCs are annotated in both languages. It contains texts taken from several domains like fiction, language books and magazines. Here, the English part of the corpus was used.

In order to compare the performance of our system with others, we also used the dataset of Tu and Roth (2011), which contains 2,162 sentences taken from different parts of the British National Corpus. They only focused on true LVCs in this dataset, and only the verb-object pairs (1,039 positive and 1,123 negative examples) formed with the

verbs *do*, *get*, *give*, *have*, *make*, *take* were marked. Statistical data on the three corpora are listed in Table 1.

Corpus	Sent.	Tokens	LVCs	LVC lemma
Wiki50	4,350	114,570	368	287
SZPFX	14,262	298,948	1,371	706
Tu&Roth	2,162	65,060	1,039	430

Table 1: Statistical data on LVCs in the Wiki50 and SZPFX corpora and the Tu&Roth dataset.

Despite the fact that English verb + prepositional constructions were mostly neglected in previous research, both corpora contain several examples of such structures, e.g. *take into consideration* or *come into contact*, the ratio of such LVC lemmas being 11.8% and 9.6% in the Wiki50 and SZPFX corpora, respectively. In addition to the verb + object or verb + prepositional object constructions, there are several other syntactic constructions in which LVCs can occur due to their syntactic flexibility. For instance, the nominal component can become the subject in a passive sentence (*the photo has been taken*), or it can be extended by a relative clause (*the photo that has been taken*). These cases are responsible for 7.6% and 19.4% of the LVC occurrences in the Wiki50 and SZPFX corpora, respectively. These types cannot be identified when only verb + object pairs are used for LVC candidate selection.

Some researchers filtered LVC candidates by selecting only certain verbs that may be part of the construction, e.g. Tu and Roth (2011). As the full-coverage annotated corpora were available, we were able to check what percentage of LVCs could be covered with this selection. The six verbs used by Tu and Roth (2011) are responsible for about 49% and 63% of all LVCs in the Wiki50 and the SZPFX corpora, respectively. Furthermore, 62 different light verbs occurred in the Wiki50 and 102 in the SZPFX corpora, respectively. All this indicates that focusing on a reduced set of light verbs will lead to the exclusion of a considerable number of LVCs in free texts.

Some papers focus only on the identification of true LVCs, neglecting vague action verbs (Stevenson et al., 2004; Tu and Roth, 2011). However, we cannot see any NLP application that can benefit if such a distinction is made since vague action verbs and true LVCs share those properties that are relevant for natural language processing (e.g. they must be treated as one complex predicate (Vincze,

2012)). We also argue that it is important to separate LVCs and idioms because LVCs are semi-productive and semi-compositional – which may be exploited in applications like machine translation or information extraction – in contrast to idioms, which have neither feature. All in all, we seek to identify all verbal LVCs (not including idioms) in our study and do not restrict ourselves to certain specific types of LVCs.

## 4 LVC Detection

Our goal is to identify each LVC occurrence in running texts, i.e. to take input sentences such as *'We often have lunch in this restaurant'* and mark each LVC in it. Our basic approach is to syntactically parse each sentence and extract potential LVCs with different candidate extraction methods. Afterwards, a binary classification can be used to automatically classify potential LVCs as LVCs or not. For the automatic classification of candidate LVCs, we implemented a machine learning approach, which is based on a rich feature set.

### 4.1 Candidate Extraction

As we had two full-coverage LVC annotated corpora where each type and individual occurrence of a LVC was marked in running texts, we were able to examine the characteristics of LVCs in a running text, and evaluate and compare the different candidate extraction methods. When we examined the previously used methods, which just treated the verb-object pairs as potential LVCs, it was revealed that only 73.91% of annotated LVCs on the Wiki50 and 70.61% on the SZPFX had a verb-object syntactic relation. Table 2 shows the distribution of dependency label types provided by the Bohnet parser (Bohnet, 2010) for the Wiki50 and Stanford (Klein and Manning, 2003) and the Bohnet parsers for the SZPFX corpora. In order to compare the efficiency of the parsers, both were applied using the same dependency representation. In this phase, we found that the Bohnet parser was more successful on the SZPFX corpora, i.e. it could cover more LVCs, hence we applied the Bohnet parser in our further experiments.

We define the extended **syntax-based candidate extraction** method, where besides the *verb-direct object* dependency relation, the *verb-prepositional*, *verb-relative clause*, *noun-participial modifier* and *verb-subject of a passive construction* syntactic relations were also investi-

gated among verbs and nouns. Here, 90.76% of LVCs in the Wiki50 and 87.75% in the SZPFX corpus could be identified with the extended syntax-based candidate extraction method.

It should be added that some rare examples of split LVCs where the nominal component is part of the object, preceded by a quantifying expression like *he **gained much of his fame*** can hardly be identified by syntax-based methods since there is no direct link between the verb and the noun. In other cases, the omission of LVCs from candidates is due to the rare and atypical syntactic relation between the noun and the verb (e.g. *dep* in *reach conform*). Despite this, such cases are also included in the training and evaluation datasets as positive examples.

Edge type	Wiki50		SZPFX			
			Stanford		Bohnet	
dobj	272	73.91	901	65.71	968	70.6
pobj	43	11.69	93	6.78	93	6.78

sum	368	100.0	1,371	100.0	1,371	100.0

Table 2: Edge types in the Wiki50 and SZPFX corpora. dobj: object. pobj: preposition. nsubjpass: subject of a passive construction. rmod: relative clause. partmod: participial modifier. other: other dependency labels. none: no direct syntactic connection between the verb and noun.

Our second candidate extractor is the **morphology-based candidate extraction** method (Nagy T. et al., 2011), which was also applied for extracting potential LVCs. In this case, a token sequence was treated as a potential LVC if the POS-tag sequence matched one pattern typical of LVCs (e.g. VERB-NOUN). Although this method was less effective than the extended syntax-based approach, when we **merged the extended syntax-based and morphology-based methods**, we were able to identify most of the LVCs in the two corpora.

The authors of Stevenson et al. (2004) and Tu and Roth (2011) filtered LVC candidates by selecting only certain verbs that could be part of the construction, so we checked what percentage of LVCs could be covered with this selection when we treated just the verb-object pairs as LVC candidates. We found that even the least stringent selec-

tion covered only 41.88% of the LVCs in Wiki50 and 47.84% in SZPFX. Hence, we decided to drop any such constraint.

Table 3 shows the results we obtained by applying the different candidate extraction methods on the Wiki50 and SZPFX corpora.

Method	Wiki50		SZPFX

## 4.2 Machine Learning Based Candidate Classification

For the automatic classification of the candidate LVCs we implemented a machine learning approach, which we will elaborate upon below. Our method is based on a rich feature set with the following categories: statistical, lexical, morphological, syntactic, orthographic and semantic.

**Statistical features: Potential LVCs** were collected from 10,000 Wikipedia pages by the union of the morphology-based candidate extraction and the extended syntax-based candidate extraction methods. The number of their **occurrences** was used as a feature in case the candidate was one of the syntactic phrases collected.

**Lexical features:** We exploit the fact that the **most common verbs** are typically light verbs, so we selected fifteen typical light verbs from the list of the most frequent verbs taken from the corpora. In this case, we investigated whether the lemmatised verbal component of the candidate was one of these fifteen verbs. The **lemma of the head of the noun** was also applied as a lexical feature. The nouns found in LVCs were collected from the corpora, and for each corpus the noun list got from the union of the other two corpora was used. Moreover, we constructed **lists of lemmatised LVCs** from the corpora and for each corpus, the list got from the union of the other two corpora was utilised. In the case of the Tu&Roth dataset, the list got from Wiki50 and SZPFX was

filtered for the six light verbs and true LVCs they contained.

**Morphological features:** The POS candidate extraction method was used as a feature, so when the POS-tag sequence in the text matched one typical **‘POS-pattern’** of LVCs, the candidate was marked as *true*; otherwise as *false*. The **‘Verbal-Stem’** binary feature focuses on the stem of the noun. For LVCs, the nominal component is typically one that is derived from a verbal stem (*make a decision*) or coincides with a verb (*have a walk*). In this case, the phrases were marked as *true* if the stem of the nominal component had a verbal nature, i.e. it coincided with a stem of a verb. *Do* and *have* are often light verbs, but these verbs may occur as auxiliary verbs too. Hence we defined a feature for the two verbs to denote whether or not they were **auxiliary verbs** in a given sentence.

**Syntactic features:** The **dependency label** between the noun and the verb can also be exploited in identifying LVCs. As we typically found in the candidate extraction, the syntactic relation between the verb and the nominal component in an LVC is *doj*, *pobj*, *rcmod*, *partmod* or *nsubjpass* – using the Bohnet parser (Bohnet, 2010), hence these relations were defined as features. The **determiner** within all candidate LVCs was also encoded as another syntactic feature.

**Orthographic features:** in the case of the **‘suffix’** feature, it was checked whether the lemma of the noun ended in a given character bi- or trigram. It exploits the fact that many nominal components in LVCs are derived from verbs. The **‘number of words’** of the candidate LVC was also noted and applied as a feature.

**Semantic features:** In this case we also exploited the fact that the nominal component is derived from verbs. *Activity* or *event* semantic senses were looked for among the hypernyms of the noun in WordNet (Fellbaum, 1998).

We experimented with several learning algorithms and our preliminary results showed that decision trees performed the best. This is probably due to the fact that our feature set consists of a few compact – i.e. high-level – features. We trained the J48 classifier of the WEKA package (Hall et al., 2009), which implements the decision trees algorithm C4.5 (Quinlan, 1993) with the above-mentioned feature set. We report results with Support Vector Machines (SVM) (Cortes and Vapnik, 1995) as well, to compare our methods with Tu &

Method	Wiki50						SZPFX

Roth.

As the investigated corpora were not sufficiently big for splitting them into training and test sets of appropriate size, besides, the different annotation principles ruled out the possibility of enlarging the training sets with another corpus, we evaluated our models in 10-fold cross validation manner on the Wiki50, SZPFX and Tu&Roth datasets. But, in the case of Wiki50 and SZPFX, where only the positive LVCs were annotated, we employed  $F_{\beta=1}$  scores interpreted on the positive class as an evaluation metric. Moreover, we treated all potential LVCs as negative which were extracted by different extraction methods but were not marked as positive in the gold standard. The resulting datasets were not balanced and the number of negative examples basically depended on the candidate extraction method applied.

However, some positive elements in the corpora were not covered in the candidate classification step, since the candidate extraction methods applied could not detect all LVCs in the corpus data. Hence, we treated the omitted LVCs as false negatives in our evaluation.

## 5 Experiments and Results

As a baseline, we applied a context-free dictionary matching method. First, we gathered the gold-standard LVC lemmas from the two other corpora. Then we marked candidates of the union of the extended syntax-based and morphology-based methods as LVC if the candidate light verb and one of its syntactic dependents was found on the list.

Table 4 lists the results got on the Wiki50 and SZPFX corpora by using the baseline dictionary matching and our machine learning approach with different machine learning algorithm and different candidate extraction methods. The dictionary matching approach got the highest precision on SZPFX, namely 72.65%. Our machine learning-based approach with different candidate extraction

methods demonstrated a consistent performance (i.e. an F-score over 50) on the Wiki50 and SZPFX corpora. It is also seen that our machine learning approach with the union of the morphology- and extended syntax-based candidate extraction methods is the most successful method in the case of Wiki50 and SZPFX. On both corpora, it achieved an F-score that was higher than that of the dictionary matching approach (the difference being 10 and 19 percentage points in the case of Wiki50 and SZPFX, respectively).

In order to compare the performance of our system with others, we evaluated it on the Tu&Roth dataset (Tu and Roth, 2011) too. Table 5 shows the results got using dictionary matching, applying our machine learning-based approach with a rich feature set, and the results published in Tu and Roth (2011) on the Tu&Roth dataset. In this case, the dictionary matching method performed the worst and achieved an accuracy score of 61.25. The results published in Tu and Roth (2011) are good on the positive class with an F-score of 75.36 but the worst with an F-score of 56.41 on the negative class. Therefore this approach achieved an accuracy score that was 7.27 higher than that of the dictionary matching method. Our approach demonstrates a consistent performance (with an F-score over 70) on the positive and negative classes. It is also seen that our approach is the most successful in the case of the Tu&Roth dataset: it achieved an accuracy score of 72.51%, which is 3.99% higher than that got by the Tu&Roth method (Tu and Roth, 2011) (68.52%).

Method	Accuracy	F1+	F1-
DM	61.25	56.96	64.76
Tu&Roth Original	68.52	<b>75.36</b>	56.41
J48	<b>72.51</b>	74.73	<b>70.5</b>

Table 5: Results of applying different methods on the Tu&Roth dataset. DM: dictionary matching. Tu&Roth Original: the results of Tu and Roth (2011). J48: our model.

## 6 Discussion

The applied machine learning-based method extensively outperformed our dictionary matching baseline model, which underlines the fact that our approach can be suitably applied to LVC detection. As Table 4 shows, our presented method proved to be the most robust as it could obtain roughly the same recall, precision and F-score on the Wiki50 and SZPFX corpora. Our system’s performance primarily depends on the applied candidate extraction method. In the case of dictionary matching, a higher recall score was primarily limited by the size of the dictionary, but this method managed to achieve a fairly good precision score.

As Table 5 indicates, the dictionary matching method was less effective on the Tu&Roth dataset. Since the corpus was created by collecting sentences that contain verb-object pairs with specific verbs, this dataset contains a lot of negative and ambiguous examples besides annotated LVCs, hence the distribution of LVCs in the Tu&Roth dataset is not comparable to those in Wiki50 or SZPFX. In this dataset, only one positive or negative example was annotated in each sentence, and they examined just the verb-object pairs formed with the six verbs as a potential LVC. However, the corpus probably contains other LVCs which were not annotated. For example, in the sentence *it have been held that a gift to a charity of shares in a close company gave rise to a charge to capital transfer tax where the company had an interest in possession in a trust*, the phrase *give rise* was listed as a negative example in the Tu&Roth dataset, but *have an interest*, which is another LVC, was not marked either positive or negative. This is problematic if we would like to evaluate our candidate extractor on this dataset since it would identify this phrase, even if it is restricted to verb-object pairs containing one of the six verbs mentioned above, thus yielding false positives already in the candidate extraction phase.

Moreover, the results got with our machine learning approach overperformed those reported in Tu and Roth (2011). This may be attributed to the inclusion of a rich feature set with new features like semantic or morphological features that was used in our system, which demonstrated a consistent performance on the positive and negative classes too.

To examine the effectiveness of each individual feature of the machine learning based candidate

classification, we carried out an ablation analysis. Table 6 shows the usefulness of each individual feature type on the SZPFX corpus.

Feature	Precision	Recall	F-score	Diff
Statistical	60.55	55.88	58.12	-1.81
Lexical	71.28	28.6	40.82	-19.11
Morphological	62.3	54.77	58.29	-1.64
Syntactic	59.87	55.8	57.77	-2.16
Semantic	60.81	54.77	57.63	-2.3
Orthographic	63.3	56.25	59.56	-0.37
All	<b>63.29</b>	<b>56.91</b>	<b>59.93</b>	-

Table 6: The usefulness of individual features in terms of precision, recall and F-score using the SZPFX corpus.

For each feature type, we trained a J48 classifier with all of the features except that one. We then compared the performance to that got with all the features. As our ablation analysis shows, each type of feature contributed to the overall performance. The most important feature is the list of the most frequent light verbs. The most common verbs in a language are used very frequently in different contexts, with several argument structures and this may lead to the bleaching (or at least generalization) of its semantic content (Altmann, 2005). From this perspective, it is linguistically plausible that the most frequent verbs in a language largely coincide with the most typical light verbs since light verbs lose their original meaning to some extent (see e.g. Sanromán Vilas (2009)).

Besides the ablation analysis we also investigated the decision tree model yielded by our experiments. Similar to the results of our ablation analysis we found that the lexical features were the most powerful, the semantic, syntactic and orthographical features were also useful while statistical and morphological features were less effective but were still exploited by the model.

Comparing the results on the three corpora, it is salient that the F-score got from applying the methods on the Tu&Roth dataset was considerably better than those got on the other two corpora. This can be explained if we recall that this dataset applies a restricted definition of LVCs, works with only verb-object pairs and, furthermore, it contains constructions with only six light verbs. However, Wiki50 and SZPFX contain all LVCs, they include verb + preposition + noun combinations as well, and they are not restricted to six verbs. All these characteristics demonstrate that identifying LVCs in the latter two corpora is a more realistic

and challenging task than identifying them in the artificial Tu&Roth dataset. For example, the very frequent and important LVCs like *make a decision*, which was one of the most frequent LVCs in the two full-coverage LVC annotated corpora, are ignored if we only focus on identifying true LVCs. It could be detrimental when a higher level NLP application exploits the LVC detector.

We also carried out a manual error analysis on the data. We found that in the candidate extraction step, it is primarily POS-tagging or parsing errors that result in the omission of certain LVC candidates. In other cases, the dependency relation between the nominal and verbal component is missing (recall the example of objects with quantifiers) or it is an atypical one (e.g. *dep*) not included in our list. The lower recall in the case of SZPFX can be attributed to the fact that this corpus contains more instances of nominal occurrences of LVCs (e.g. *decision-making* or *record holder*) than Wiki50, which were annotated in the corpora but our morphology-based and extended syntax-based methods were not specifically trained for them since adding POS-patterns like NOUN-NOUN or the corresponding syntactic relations would have resulted in the unnecessary inclusion of many nominal compounds.

As for the errors made during classification, it seems that it was hard for the classifier to label longer constructions properly. It was especially true when the LVC occurred in a non-canonical form, as in a relative clause (*counterargument that can be made*). Constructions with atypical light verbs (e.g. *cast a glance*) were also somewhat more difficult to find. Nevertheless, some false positives were due to annotation errors in the corpora. A further source of errors was that some literal and productive structures like *to give a book (to someone)* – which contains one of the most typical light verbs and the noun is homonymous with the verb *book* “to reserve” – are very difficult to distinguish from LVCs and were in turn marked as LVCs. Moreover, the classification of idioms with a syntactic or morphological structure similar to typical LVCs – *to have a crush on someone* “to be fond of someone”, which consists of a typical light verb and a deverbal noun – was also not straightforward. In other cases, verb-particle combinations followed by a noun were labeled as LVCs such as *make up his mind* or *give in his notice*. Since Wiki50 contains annotated ex-

amples for both types of MWEs, the classification of verb + particle/preposition + noun combinations as verb-particle combinations, LVCs or simple verb + prepositional phrase combinations could be a possible direction for future work.

## 7 Conclusions

In this paper, we introduced a system that enables the full coverage identification of English LVCs in running texts. Our method detected a broader range of LVCs than previous studies which focused only on certain subtypes of LVCs. We solved the problem in a two-step approach. In the first step, we extracted potential LVCs from a running text and we applied a machine learning-based approach that made use of a rich feature set to classify extracted syntactic phrases in the second step. Moreover, we investigated the performance of different candidate extraction methods in the first step on the two available full-coverage LVC annotated corpora, and we found that owing to the overly strict candidate extraction methods applied, the majority of the LVCs were overlooked. Our results show that a full-coverage identification of LVCs is challenging, but our approach can achieve promising results. The tool can be used in preprocessing steps for e.g. information extraction applications or machine translation systems, where it is necessary to locate lexical items that require special treatment.

In the future, we would like to improve our system by conducting a detailed analysis of the effect of the features included. Later, we also plan to investigate how our LVC identification system helps higher level NLP applications. Moreover, we would like to adapt our system to identify other types of MWE and experiment with LVC detection in other languages as well.

## Abstract

We propose using profile compatibility to differentiate genuine and fake product reviews. For each product, a *collective* profile is derived from a separate collection of reviews. Such a profile contains a number of aspects of the product, together with their descriptions. For a given unseen review about the same product, we build a *test* profile using the same approach. We then perform a bidirectional alignment between the *test* and the *collective* profile, to compute a list of aspect-wise compatible features. We adopt Ott et al. (2011)'s *op\_spam\_v1.3* dataset for identifying *truthful* vs. *deceptive* reviews. We extend the recently proposed N-GRAM+SYN model of Feng et al. (2012a) by incorporating profile compatibility features, showing such an addition significantly improves upon their state-of-art classification performance.

## 1 Introduction

With the rapid development of e-commerce and the increasing popularity of various product review websites, people are more and more used to making purchase decisions based on the reported experience of other customers. A product rated positively by its previous users is able to attract potential new customers, while a poorly rated product is certainly not a good option for most new customers. Given this influential power of product reviews, there comes a huge potential for *deceptive opinion spam* to distort the true evaluation of a product. The promoters of a product may post false complimentary reviews, and competitors may post false derogatory reviews.

Although the task of detecting *deceptive opinion spam* can be formulated as a traditional bi-

nary classification problem with two classes, *deceptive* and *truthful*, where supervised learning can be applied, it is essentially very challenging. Its major difficulty arises from the lack of reliably labeled data, because it is extremely difficult for humans to identify through reading (see discussion in Section 4). Therefore, much previous work on detecting deceptive opinions usually relies on some meta-information, such as the IP address of the reviewer or the average rating of the product, rather than the actual content of the review Liu (2012). However, thanks to the release of the *op\_spam\_v1.3* dataset by Ott et al. (2011), a gold-standard dataset composed of 400 truthful and 400 deceptive hotel reviews (see Section 3), we are now at an appropriate stage for conducting supervised learning and reliable evaluation of the task.

In their work, Ott et al. proposed to use *n*-grams as features, and trained an SVM classifier to classify whether a given review is deceptive or truthful, achieving nearly 90% accuracy. More recently, Feng et al. (2012a) extended Ott et al.'s *n*-gram feature set by incorporating deep syntax features, i.e., syntactic production rules derived from Probabilistic Context Free Grammar (PCFG) parse trees, and obtained 91.2% accuracy on the same dataset.

While both Ott et al. and Feng et al.'s cues of deception come purely from the surface realization in the reviews, we propose the use of additional signals of truthfulness by characterizing the degree of *compatibility* between the personal experience described in a test review and a product profile derived from a collection of reference reviews about the same product. Our intuition comes from the hypothesis that since the writer of a deceptive review usually does not have any actual experience with that product, the resulting review might contain some contradictions with facts about the product, or the writer might fail to mention those as-

pects of the product that are commonly mentioned in truthful reviews. Conversely, a writer of a truthful review is more likely to make similar comments about some particular aspects of the product as other truthful reviewers. In other words, we postulate that by aligning a the profile of a product and the description of the writer’s personal experience, some useful clues can be revealed to help identify possible deception.

In line with the intuition above, we want to capture two types of compatibility: (1) Compatibility with the existence of some *distinct* aspect of the product, such as the mention of the famous art museum nearby the hotel; (2) Compatibility with the description of some *general* aspect of the product, such as commenting that the breakfast at the hotel is charged for.

We show that, by incorporating our computed profile alignment features with Feng et al.’s *n*-grams and deep syntax features, we significantly improve on the state-of-art performance presented by their N-GRAM+SYN model.

## 2 Related work

Before the existence of gold-standard datasets which include both truthful and deceptive product reviews, several attempts were made to detect deceptive opinions.

With regard to unsupervised approaches, previous work was primarily based on various patterns of atypical behaviors. Lim et al. (2010) proposed several behavior models to identify unusual reviewer patterns; e.g., spammers may contribute a fake review soon after product launch to maximally affect subsequent reviewers. Each of these individual models assigns a numeric score indicating the extent to which the reviewer has engaged in apparent spam behaviors, and these scores are then combined to product a final spam score. Jindal et al. (2010) employed data-mining techniques to discover unexpected class association rules; e.g., reviewers who give all high ratings to products of a brand while most other reviews are generally negative about the brand. Wu et al. (2010) proposed to use the distortion of popularity rankings as an indicator of opinion spamming, in the sense that deleting a set of random reviews should not overly disrupt the popularity ranking of a list of entities, while deleting fake reviews should significantly distort the overall rankings, under the assumption that deceptive reviews usually express a

sentiment at odds with legitimate reviews. Feng et al. (2012b) postulated that for a given domain, there exists a set of representative distributions of review rating scores, and fake reviews written by hired spammers will distort such natural distributions. Experimenting with a range of pseudo-gold-standard datasets, they provided quantitative insights into the characteristics of natural distributions of opinions in various product review domains.

With respect to supervised approaches, Jindal and Liu (2008) first conducted a tentative study of detecting deceptive opinions. In the absence of gold-standard datasets, they trained models using features from the review texts, as well as from meta-information on the reviewer and the product, to distinguish between *duplicate* reviews (regarded as deceptive), i.e., reviews whose major content appears more than once in the corpus, and *non-duplicate* reviews (regarded as truthful). However, these (near-)duplicate reviews are often not sophisticated in their composition, and therefore are relatively easy to identify, even by off-the-shelf plagiarism detection software (Ott et al., 2011).

Yoo and Gretzel (2009) constructed a small gold-standard dataset with 40 truthful and 42 deceptive hotel reviews, and manually inspected the statistical differences of psychologically relevant linguistic features for truthful and deceptive reviews.

Ott et al. (2011) released the *op\_spam\_v1.3* dataset (see Section 3), a much larger dataset with 400 truthful and 400 deceptive hotel reviews with *positive* comments, which allows the application of machine learning techniques for training models to automatically detect deceptive opinions. In their work, Ott et al. focused on the textual content of the reviews, and approached the task of detecting deceptive opinions by finding any *stretch of imagination* in the text — they treated fake reviews as imaginative writing, and used standard computational approaches of *genre identification*, *psycholinguistic deception detection*, and *text categorization* to identify them. Among the set of features explored in their classification experiments, they discovered that the features traditionally employed in either psychological studies of deception or genre identification were both significantly outperformed by a much simpler N-GRAM model with *n*-grams only as features, which achieved

nearly 90% accuracy. Later, Feng et al. (2012a) proposed a strengthened model, N-GRAM+SYN, by incorporating syntactic production rules derived from Probabilistic Context Free Grammar (PCFG) parse trees. They obtained 91.2% accuracy on the `op_spam_v1.3` dataset, which is a 14% error reduction.

More recently, Ott et al. released a new version, the `op_spam_v1.4` dataset, with gold-standard *negative* reviews included as well (Ott et al., 2013), which offers an opportunity to more extensively study the problem of detecting deceptive reviews. However, the work described in this paper is focused on *positive* review spam, and based directly on the work of Feng et al. We extend their N-GRAM+SYN model by incorporating potential signals of truthfulness, derived from aligning the description in a test review with the product profile constructed from a large collection of reference reviews about the same product. Somewhat orthogonal to Feng et al.’s *n*-grams and deep syntax features, which are focused on the surface realization of a given product review, our alignment features are able to employ useful information from the product itself.

### 3 The `op_spam_v1.3` Dataset

Due to the difficulty for humans to identify deceptive opinions, traditional approaches to constructing annotated corpora by recruiting human judges to label a given set of texts does not apply to the task of deception detection. Consequently, crowdsourcing services such as Amazon Mechanical Turk<sup>1</sup> (AMT) have been adopted as a better solution (Ott et al., 2011; Rubin and Vashchilko, 2012). By asking paid subjects on AMT to compose deceptive and/or truthful texts, corpora with reliable labels can be constructed.

In this work, we use Ott et al.’s `op_spam_v1.3` dataset<sup>2</sup>, which contains **positive** reviews for the 20 most-rated hotels on TripAdvisor<sup>3</sup> (TA) in Chicago. For each hotel, Ott et al. selected 20 deceptive reviews from submissions on AMT, and 20 truthful reviews from 5-star reviews on TA, resulting in 800 reviews in total for 20 hotels. The average length of deceptive reviews is 115.75 words, while the truthful reviews are chosen to have roughly the same average length.

<sup>2</sup><http://www.cs.cornell.edu/~myleott>

<sup>3</sup><http://tripadvisor.com>.

## 4 Difficulty of the Task

It has been shown that humans can differentiate truthful reviews from deceptive ones with only a modest accuracy. With respect to the `op_spam_v1.3` dataset used in our work, human judges were only able to achieve 60% accuracy, and the inter-annotator agreement was low: 0.11 computed by Fleiss’s kappa (Ott et al., 2011). Since as humans, we do not have a tangible intuition of what signals deception and what characterizes truthfulness, we have great difficulty designing features for automatic identifying deceptive opinions.

In addition, there is difficulty with regard to the construction of gold-standard datasets for the task of deception detection. On one hand, although crowdsourcing provides a relatively cheap and reliable approach, gathering deceptive data is still nevertheless laborious. On the other hand, since for truthful reviews, we are able to select a small subset for which we have high confidence only by using a combination of various heuristics, the constructed dataset is inherently biased. Therefore, given the limited number and size of currently available gold-standard datasets, in the process of developing more sophisticated models involving a larger number of features, we may inevitably face the issue of overfitting on a relatively small set of data.

## 5 Methodology

### 5.1 Baseline features

We adopt Feng et al.’s N-GRAM+SYN model as the baseline system, which employs two distinct sets of features.

**N-GRAM features:** As shown by Ott et al., the bag-of-words model is effective for identifying deceptive reviews. However, the optimal choice of *n* is not consistent in Ott et al.’s original implementation and Feng et al.’s strengthened model: Ott et al. used the union of unigrams and bigrams, while Feng et al. obtained their best performance using unigrams alone, together with deep syntax features. Therefore, for a fair comparison, we consider using unigrams, bigrams, and the union of both, and choose the best combination with deep syntax features as our baseline system.

**SYN features:** Following Feng et al., deep syntax features are encoded as production rules derived from PCFG parse trees. These production

rules include lexicalized ones, i.e., POS-tag-to-word rules, and are combined with the grandparent node.

All baseline features are encoded as their tf-idf weights, with features appearing only once in the dataset eliminated.

## 5.2 Product profile construction

### 5.2.1 Aspects and compatibility

As introduced in Section 1, we postulate that by aligning the profile of a product with the description of the writer’s personal experience, we can characterize the degree of compatibility between them. Such alignment features could serve as useful signals to differentiate between deception and truthfulness.

In particular, we define compatibility for two types of aspects of a product — *distinct* aspects and *general* aspects. Distinct aspects are special features of the product. For hotels, those distinct aspects are usually realized as proper noun phrases in the text, typically the names of the landmarks nearby the hotel, including museums, parks, restaurants, bars, and shopping malls. On the other hand, general aspects are common features which typically appear in any product of this particular kind. For hotels, **location**, **service**, and **breakfast** are typical general aspects. The method we use to identify and extract distinct and general aspects from reviews is described in Section 5.2.4.

Compatibility for distinct and general aspects is defined as follows:

1. Compatibility with the **existence** of some *distinct* aspect of the product, e.g., truthful reviews of this Chicago hotel often mention the famous nearby Field Museum, and the test review also mentions this museum.
2. Compatibility with the **description** of some *general* aspect of the product. For example, breakfast at most Chicago hotels is complimentary; however, the breakfast at this hotel is charged for, and the test review describes it as “the breakfast is kinda expensive”.

### 5.2.2 Definition of product profile

A product’s profile  $P$  is composed of a set of its aspects  $A = \{a_1, \dots, a_N\}$ , where each  $a_i$  is an individual aspect of the product. Each aspect  $a_i$  is associated with a description  $D_i = \{p_1 : w_1, \dots, p_m : w_m\}$ , in which each element is a unique word  $p_j$

Aspect	Description
Bathroom	{ <i>clean</i> : 3.0, <i>comfortable</i> : 3.0, <i>pleasant</i> : 5.0, <i>high-end</i> : 1.0, <i>European</i> : 1.0}
Room	{ <i>wonderful</i> : 4.0, <i>deluxe</i> : 2.0, <i>huge</i> : 2.0}
Service	{ <i>average</i> : 2.0, <i>slow</i> : 2.0}
Michigan Ave.	{ <i>existence</i> : 5.0}

Table 1: An example fragment of the profile of a hotel.

to describe the aspect, along with the weight  $w_j$  assigned to that word.

Distinct aspects,  $a_{i,d}$ , and general aspects,  $a_{i,g}$ , are treated differently when it comes to their descriptions. For a distinct aspect, its description can contain only one word, *existence*, because we only care about whether this aspect is mentioned in the text, not the particular words used to describe this aspect. In fact, most of these distinct aspects do not occur with any associated adjectives or adverbs.

An example fragment of a hotel’s profile is shown in Table 1, in which the last aspect **Michigan Ave.** is a distinct aspect, and thus only one word, *existence*, appears in its description.

### 5.2.3 Data for profile construction

To establish a profile  $P$  for each target hotel in the op\_spam\_v1.3 dataset, we first gather all its reviews on TripAdvisor, from which we choose up to 200 reviews, subject to the following criteria:

1. It is not present in the op\_spam\_v1.3 dataset.
2. Its rating is five stars (the highest).
3. Its language is English.
4. It contains at least 150 characters.
5. The author has written at least 10 reviews.
6. The author has written reviews for at least 5 different hotels.
7. The author has received at least 5 helpfulness votes from other users.

If there are more than 200 reviews satisfying the above criteria, we choose the 200 with the highest number of helpfulness votes received by their authors. Most of the above criteria are consistent

<b>Reviews</b>			
	<i>Min</i>	<i>Max</i>	<i>Mean</i>
Reviews per hotel	44	200	160.6
Characters	150	8,995	848.3
<b>Authors</b>			
	<i>Min</i>	<i>Max</i>	<i>Mean</i>
Total reviews	10	506	37.8
Reviewed hotels	5	278	17.8
Helpfulness votes	5	2,280	33.3

Table 2: The statistics of the collection of reviews used in constructing profiles and their distinct authors.

with the original setup of collecting the truthful reviews in the `op_spam_v1.3` dataset. However, we add the last three strong criteria to ensure the quality of the collected reviews.

Table 2 lists the statistics of the reviews used in our profile construction. The statistics are categorized into (1) the information about the reviews themselves, including the total number of qualified reviews for each hotel, and the length (in characters) of each review; and (2) the information about the distinct authors of these reviews, including the total number of reviews each author has written on TripAdvisor, the total number of hotels each author has reviewed, and the total number of helpfulness votes that each author has received from other users.

#### 5.2.4 Aspect extraction

**Raw aspect extraction** For each particular hotel  $h$ , from the set of its corresponding reviews  $R_h$ , we extract the aspects  $A_h = \{a_{1,t_1,h}, \dots, a_{M,t_M,h}\}$  (e.g., **room**, **service**, and **Michigan Ave.** in Table 1) to be included into  $h$ 's profile  $P_h$ , where  $t_i$  is the type, *distinct* or *general*, of each aspect. For the sake of notational clarity, from now on, when talking about a specific hotel  $h$ , we will omit the subscript  $h$ . We first extract all noun phrases present in  $R$ , and use these noun phrases as raw aspects. For each raw aspect extracted, we identify whether it is a *distinct* or *general* aspect: if the aspect is extracted as a proper noun phrase (as tagged by the Stanford parser (Klein and Manning, 2003)), then the aspect is labeled as *distinct*, and *general* otherwise.

Noun phrase extraction is performed solely on

the syntactic parse trees. We do not attempt to resolve coreferences for the following two reasons: (1) since most coreference resolution tools are trained on news texts, their performance on product reviews might not be reliable; (2) we observe that authors of these product reviews rarely employ coreference in their writing, and therefore the impact of resolving coreference might be minor after all.

**Aspect clustering** Due to the flexibility of natural languages, it is common to see people express the same concept through different lexical usage. For example, both “price” and “rate” can refer to the price of the hotel. In addition to synonyms, semantically related words can also be adopted to describe the same aspect of the product, for example, “lighting” and “painting” can both describe the decoration of the hotel.

In order to deal with the use of these (near-) synonyms in text, we perform separate clustering for the sets of distinct and general aspects.

For distinct aspects  $\{a_{i,d}\}$ , the distance between a pair of aspects is defined by the length of their longest common substring divided by the average length of the two aspects. The motivation for this definition is to bring *distinct* aspects such as **Michigan Ave.** and **Michigan Avenue** into the same cluster.

For general aspects  $\{a_{i,g}\}$ , the distance between a pair of aspects is defined as their Lin Similarity (Lin, 1998), implemented by NLTK’s similarity package (Bird et al., 2009).

For both types of aspects, we perform hierarchical agglomerative clustering with average linkage. Cluster merging is terminated once the distance between all pairs of clusters is greater than 0.3.

**Sorting aspects by occurrences** After clustering distinct and general aspects separately, we keep track of the total occurrences of each aspect across the entire set  $R$ . Then, we let  $A$  be the set of the most common  $N$  aspects<sup>4</sup>.  $N$  is a parameter identical for all hotels, indicating how many aspects are included in each profile. We expect that the choice of  $N$  is affected by the particular type of product, and we experiment with several values of  $N$ .

<sup>4</sup> $N$  is usually much smaller than  $M$ , the total number of raw aspects.

### 5.2.5 Description extraction

For a hotel  $h$ , each of its aspects  $a_i$  is then associated with a description

$$D_i = \{p_{i,1} : w_{i,1}, \dots, p_{i,m} : w_{i,m}\},$$

which has two components: description words  $p_{i,j}$  and their weights  $w_{i,j}$ , for  $1 \leq j \leq m$ .

**Description words** The list  $\{p_{i,1}, \dots, p_{i,m}\}$  is composed of the description words used to modify the particular aspect  $a_i$ , e.g.,  $\{\text{wonderful}, \text{deluxe}, \text{and huge}\}$  for the aspect **room** in Table 1.

For each *distinct* aspect  $a_{i,d}$ , as discussed in Section 5.2.2, there can be only one description word, *existence*, indicating the presence of this aspect in the profile.

For each *general* aspect  $a_{i,g}$ , its description words are automatically extracted from the dependencies in the set of reviews  $R$ . From the dependencies output by the Stanford dependency parser (de Marneffe et al., 2006), for a particular aspect  $a_i$ , we first locate all relevant dependency relations which have  $a_i$  (or the head noun of  $a_i$  if  $a_i$  is a noun phrase) as the governors (or dependents, depending on the particular dependency types). Then from these relevant dependency relations, we extract the words that appear in the dependent (or governor) slots to be the description words, provided that those words are tagged as adjectives or adverbs.

**Weight assignment** Each description word  $p_{i,j}$  is assigned a weight  $w_{i,j}$  to indicate the *reliability* of that particular description word. There are many possibilities for these weight assignment functions. Here, as a preliminary study, for *distinct* aspects  $\{a_{i,d}\}$ , we simply use the number of occurrences of the aspect in the review collection  $R$  as the assigned weight  $w_{i,j}$ , and for *general* aspects  $\{a_{i,g}\}$ , we use the number of occurrences of  $p_{i,j}$  in  $R$  as  $w_{i,j}$ .

### 5.3 Computing profile compatibility

Once we establish a profile  $P$  for each hotel  $h$  from the set of relevant reviews  $R$ , then given an unseen test review  $r$  about  $h$ , we can perform a *bidirectional* alignment with  $P$ , and compute a list of compatibility features.

Using the same approach as described in Sections 5.2.4 and 5.2.5, we construct a profile  $Q$  from this single review. For the sake of clarity, we call  $Q$  the *test profile*, in contrast to  $P$ , the *collective*

*profile*, which is constructed from a collection of reviews.

#### 5.3.1 Bidirectional alignment

We perform a *bidirectional* alignment between the test profile  $P$  and the collective profile  $Q$ . The *direction* of an alignment is defined as the following.

When aligning the test profile  $Q$  with the collective profile  $P$  ( $Q \rightarrow P$ ), we compute *aspect-wise* compatibility features (to be defined in Section 5.3.2) **for each aspect  $a_i$  in  $P$** . Similarly, when aligning the collective profile  $P$  with the test profile  $Q$  ( $P \rightarrow Q$ ), we compute **for each aspect  $a_i$  in  $Q$** .

The  $Q \rightarrow P$  alignment captures whether the aspects that most reviewers would describe in their reviews are mentioned in the test review, and whether there exist any similarity or conflicts between the common opinions represented in the collective profile  $P$  and the test review.

The  $P \rightarrow Q$  alignment captures whether the test review falsely includes some imaginary extra aspects about the product, such as an indoor pool in the hotel, while the collective profile  $P$  does not include this aspect.

#### 5.3.2 Aspect-wise compatibility features

For each direction of the bidirectional alignment, we compute a list of aspect-wise compatibility features. Without loss of generality, assume that the direction of the alignment is  $Q \rightarrow P$ . Thus, for each aspect  $a_i$  in  $P$ , we include three features to indicate the compatibility between  $P$  and  $Q$ :

1.  $m_{a_i}$ : a boolean value indicating whether  $a_i$  is mentioned in  $Q$  or not. If  $a_i$  does appear in  $Q$ , we then compute the following two values, based on  $a_i$ 's description  $D_i$  in  $P$ , and its description  $D'_i$  in  $Q$ .
2.  $s_{a_i} \in [0, 1]$ : a numeric value indicating the *similarity* between  $P$  and  $Q$  with respect to  $a_i$ .  $S_{a_i}$  is computed as the cosine similarity between  $D_i$  and  $D'_i$ . We treat  $D_i$  and  $D'_i$  as two vectors following the bag-of-words model, where the description words are the words, and the weights are their corresponding frequencies.
3.  $c_{a_i} \in [0, 1]$ : a numeric value indicating the *conflicts* between  $P$  and  $Q$  with respect to  $a_i$ . For each description word  $p_i$  in  $D_i$ , we determine whether  $D'_i$  includes its antonym.

Antonyms are determined using the lexical relations defined in WordNet<sup>5</sup>.  $c_{a_i}$  is computed as the fraction of description words in  $D_i$  that have corresponding antonyms in  $D'_i$ .

Clearly, when computing aspect-wise similarity score  $s_{a_i}$ , we do not consider any synonyms or semantic similarity between two description words — the similarity is based solely on the use of exact words. Our strategy of exact word matching is a simplification, but since similarity of adjectives and adverbs is not as well-studied as that of nouns (various similarity metrics for nouns are available for WordNet, but none of those work on adjectives and adverbs), clustering description words is not as trivial as clustering aspects<sup>6</sup>.

#### 5.4 C+N-GRAM+SYN model

To test whether a given review  $r$  about the hotel  $h$  is deceptive or not, we extend Feng et al.’s N-GRAM+SYN model by incorporating our aspect-wise compatibility features into it. We call this extension the C+N-GRAM+SYN model, which includes the following two categories of features:

1. Alignment compatibility features
  - (a) Compatibility features for alignment  $Q \rightarrow P$ , including  $m_{a_i}$ ,  $s_{a_i}$ , and  $c_{a_i}$  for each of the  $N$  aspects  $\{a_1, \dots, a_N\}$  with the highest occurrences in  $P$ .
  - (b) Compatibility features for alignment  $P \rightarrow Q$ , including  $m_{a'_i}$ ,  $s_{a'_i}$ , and  $c_{a'_i}$  for each of the  $N$  aspects  $\{a'_1, \dots, a'_N\}$  with the highest occurrences in  $Q$ .
2. Baseline features: 3,009 unigrams, 10,538 bigrams, and 6,571 syntactic production rules, as described in Section 5.1.

The resulting dimension of our full feature set is  $20,118 + 2N$ , where  $N$  ranges from 10 to 100 in our experiments (see Section 6.2). For all experiments, we use SVM<sup>perf</sup> (Joachims, 2006) to train all the linear SVM classifiers.

## 6 Results and discussion

### 6.1 Reimplementing baseline models

We first demonstrate the performance of our reimplemented baseline models. We conduct 5-fold

<sup>5</sup><http://wordnet.princeton.edu/wordnet/>

<sup>6</sup>In fact, we have experimented with using LSA-based word vectors to cluster description words, but the performance is slightly lower than using exact word matching.

Features	Prec	Rec	$F_1$	Acc
SYN	87.2	88.8	88.0	87.9
N-GRAM	89.7	89.5	89.6	89.6
1-GRAM+SYN	88.0	90.0	89.0	88.9
2-GRAM+SYN	87.9	90.5	89.2	89.0
N-GRAM+SYN	89.2	91.3	90.2	90.1

Table 3: Results (in %) of our reimplemented baseline models. Performance is reported using 5-fold cross-validation over the op\_spam\_v1.3 dataset (800 reviews of 20 hotels).

cross-validation experiments over the 800 reviews of 20 hotels, in which each fold contains all reviews from four hotels, such that the learned models are always tested against unseen hotels. Performance is reported by accuracy and the micro-averaged precision, recall, and F-score of retrieving *deceptive* reviews (see Ott et al. (2013) for details). We experiment with five different baseline feature sets: (1) SYN: syntax features, (2) N-GRAM: unigram and bigram features, (3) 1-GRAM+SYN: unigram and syntax features, (4) 2-GRAM+SYN: bigram and syntax features, and (5) N-GRAM+SYN: unigram, bigram and syntax features, where the second is Ott et al.’s model<sup>7</sup>, and the third is Feng et al. (2012a)’s model.

The results are shown in Table 3. Our reimplemented Ott et al.’s model (N-GRAM) obtains 89.6% accuracy, while the accuracy of our reimplemented Feng et al. model (1-GRAM+SYN) is noticeably lower (88.9%). Though its improvement over the N-GRAM model is not significant, the N-GRAM+SYN model performs the best (90.1%) among all baseline models, and thus is chosen to be the baseline in our later experiments.

### 6.2 Comparison with baseline models

We now demonstrate the performance achieved by our profile alignment compatibility features. We experiment with using our profile alignment features in combination with baseline features, i.e., the C+N-GRAM+SYN model. We first study the

<sup>7</sup>Actually, the best performance reported by Ott et al. was obtained using their LIWC + N-GRAM model, which is the combination of N-GRAM features and 80 features output by the Linguistic Inquiry and Word Count (LIWC) software (Pennebaker et al., 2007). However, since the improvement over  $n$ -gram features alone was small and insignificant (0.2% absolute improvement in accuracy), and we were not able to successfully reproduce the improvement, the comparison with our model is based on using N-GRAM features alone.

effect of the number of reviews used in constructing collective profiles (see Section 5.2.3). We experiment with using the top 50, 100, 150, and 200 reviews written by authors with the highest helpfulness votes (for some hotels, the total number of available reviews is less than 200). For each set of constructed profiles, we tried different values of  $N$ , the number of aspects included in each profile (both collective and test profiles), ranging from 10 to 100, and determine the optimal number by conducting 4-fold cross-validation experiments using 80% of the training data.

The results are shown in Table 4. First, we see that the best overall performance, in terms of  $F_1$  score and accuracy, is achieved using the top 50 or 100 reviews for profile construction. This suggests that using a fairly small amount of reliable data is sufficient to recognize compatibility between collective profiles and test reviews. In fact, using a larger number of reviews is slightly detrimental to the overall performance, since more noise might be included in the process.

Moreover, we see that our best model, achieved using 50 or 100 reviews for profile construction, outperforms the best baseline model, N-GRAM+SYN, on all four metrics, by over 1%, which is a 12.1% error reduction rate. The improvement is confirmed to be statistically significant ( $p < .05$ ) using the Wilcoxon sign-rank test. In addition, we inspect each model’s predictions on individual test instances, and discover that our C+N-GRAM+SYN model correctly classifies some instances on which the baseline model makes an error, and at the same time does not make any additional errors that the baseline model does not make.

Finally, with respect to the value of  $N$ , which is the number of aspects included in each profile, we discover that smaller values of  $N$ , i.e., 10 or 20, consistently give the most satisfying results.

## 7 Conclusions and perspectives

In this paper we proposed the use of profile alignment compatibility as an indicator of truthfulness in product reviews. We defined two types of compatibility between product profiles, and designed a methodology to tackle them by extracting aspects and associated descriptions from reviews. We adopted Ott et al.’s op\_spam.v1.3 dataset of hotel reviews, and improved the N-GRAM+SYN model of Feng et al. (2012a). Our approach was

Reviews used	$N$	Prec	Rec	$F_1$	Acc
50	10	90.2*	92.5*	<b>91.4*</b>	<b>91.3*</b>
100	10	90.0*	<b>92.8*</b>	<b>91.4*</b>	<b>91.3*</b>
150	20	<b>90.6*</b>	92.0*	91.3*	<b>91.3*</b>
200	20	90.4*	91.8*	91.1*	91.0*

Table 4: Results (in %) of our profile alignment compatibility models. Performance is reported using 5-fold cross-validation over the op\_spam.v1.3 dataset (800 reviews of 20 hotels). The best result of each metric is shown in bold face. All numbers are significantly better (denoted by \*) than the baseline in Table 3, using the Wilcoxon sign-rank test ( $p < .05$ ).

shown to significantly improve the performance of identifying deceptive reviews.

In future work, it is critical to know how well our methodology of extracting aspects and their descriptions from hotel reviews generalizes on other kinds of reviews. We suspect that the approach should work equally well on other domains, as long as the aspects are realized mainly by noun phrases, especially that distinct aspects are realized by proper noun phrases.

Another particularly interesting direction is to explore how our C+N-GRAM+SYN model performs on identifying fake *negative* reviews, as recently released by Ott et al. (2013), rather than the *positive* reviews used in this work. While negative opinion spam is more hazardous to a brand’s fame compared to positive ones, and thus identifying fake negative reviews might be more crucial, one potential difficulty of our approach is that genuine extremely negative reviews written by renowned reviewers are much more sparse than extremely positive ones, especially for famous products, such as the most popular Chicago hotels in the op\_spam.v1.3 dataset.

## Acknowledgments

This work was financially supported by the Natural Sciences and Engineering Research Council of Canada and by the University of Toronto. We would like to thank Myle Ott from Cornell University for kindly providing us with the op\_spam.v1.3 dataset.

# *Behind the Times: Detecting Epoch Changes using Large Corpora*

Octavian Popescu and Carlo Strapparava

FBK-irst, Trento, Italy

{popescu, strappa}@fbk.eu

## Abstract

Using large corpora of chronologically ordered language, it is possible to explore diachronic phenomena, identifying previously unknown correlations between language usage and time periods, or epochs. We focused on a statistical approach to epoch delimitation and introduced the task of epoch characterization. We investigated the significant changes in the distribution of terms in the Google N-gram corpus and their relationships with emotion words. The results show that the method is reliable and the task is feasible.

## 1 Introduction

Traditionally, scholars of history define epochs according to their deep knowledge and understanding of facts over a long stretch of time. Intuitively, in order to define a new epoch, both a big social impact of a series of events and new issues, which arouse the social interest, must be observed. However, it is hard to define what makes a feature “distinctive” or an event a “great change”. It is even harder to evaluate and measure the impact of a series of changes in society in an objective way. Since the advent of regular newspapers and the industry of mass media, written information has represented a mirror of the interests of society. A social event is relevant only if people pay attention to it and comment on it. A major change in society is reflected in the frequencies with which a set of topics is mentioned in mass media, some of them becoming mentioned more often than previously, while some others are no more of interest. Furthermore, specific epochs typically develop a particular form of wording or rhetorical style.

In this paper we describe a computational approach to *epoch delimitation* on the basis of word distribution over certain periods of time. A big

quantity of data, chronologically ordered, allows accurate statistical statements regarding the covariance between the frequencies of two or more terms over a certain period of time. By discovering significant statistical changes in word usage behavior, it is possible to define epoch boundaries. We show that it is possible to distinguish a series of limited periods of time, spanning at most three years, within which non-random changes affect the joint distribution of terms. Between two such short periods (i.e. the boundaries) no statistical significant changes are observed for decades, and thus we can refer to it as an epoch. The distributions of the considered terms before and after boundaries are distinctly different.

We also introduce the task of *epoch characterization*. Certain words carry with them an emotional charge, like *joy*, *fear*, *disgust* etc. Within a given epoch, we can analyze the distribution of emotion words and their co-occurrences with the set of terms considered indicative for epoch definition. The pattern of these co-occurrences constitutes a blueprint of emotional tendencies with respect to some particular topics in the society within a certain period. Given an arbitrary sample of data from a given, but unknown period of time, the task consists in correlating the emotional pattern of the data with the one of an epoch from which the data comes. The experiments reported here show that this task is feasible and sensible results are obtained.

The corpus used in the current experiments is the Google 5-grams made of all tuples of consecutive 5 words, coming from English books printed roughly from 1614 to 2009.

For the purpose of the present paper, we compiled a lexicon of political and social terms. The lexicon contains 761 words, such as: *capitalism*, *civil disobedience*, *demagogue*, *democracy*, *dictator*, *chickenhawk*, *education*, *government*, *peace*, *war* etc. These terms come from the lists

compiled for the political and sociological domain publicly available<sup>1</sup>. The frequency of these terms and their covariance is analyzed over the years and non-random changes are found according to the methodology presented in Section 3. The methodology itself is purely statistical and it does not depend in any way on what the list contains. We could have equally chosen terms from art or sport domain, obtaining epoch boundaries specific to each domain.

The emotion words used in epoch characterization come primarily from the NRC Word-Emotion Association Lexicon (Mohammad and Turney, 2010) to which the list of emotion words extracted from WordNet-Affect (Strapparava and Valitutti, 2004), distributed in the Semeval 2007 Affective Text task (Strapparava and Mihalcea, 2007), has been added. The lexicon is made up of English words to which eight possible tags are attached: *anger*, *anticipation*, *disgust*, *fear*, *joy*, *sadness*, *surprise* and *trust*. All in all there are 14,000 words for which at least one affective tag is given.

The paper is organized as follows. In Section 2 we review the relevant literature. Section 3 presents the statistical apparatus employed in epoch determination and epoch characterization. In Section 4 we present the experiments and the results we have obtained. In the last section we highlight the contribution of this paper and make an overview of further immediate work.

## 2 Related Work

In (Michel et al., 2011), besides a complete introduction to the Google Books corpus, a limited diachronic study of words meaning and form is also carried out. The authors introduce the term ‘culturomic’ and show that quantitative analyses may lead to interesting results. They show that it is possible to determine censorship and suppression by comparing the frequencies of proper names in bilingual Google books corpora. However, the authors did not proceed to a systematic studies of epochs.

Regarding semantic change, the task of sense disambiguation over the years is introduced in (Mihalcea and Nastase, 2012). In their paper, the authors refer to definite periods of time as epochs but they considered them prior defined.

In (Wang and McCallum, 2006) an analysis of topics over time is carried out. The paper fo-

cuses on rather fixed topics, which are expressed by frozen compounds, such as “mexican war”, “CVS operation”, and determines how these topics evolve during the years. However, because the scope of their paper is not global, the corpus used comes from 19 months of personal emails. It is hard to see how this method could generalize. A similar approach is described in (Wang et al., 2008). The authors use LDA to facilitate the search into large corpora by automatically organizing them.

In (Yu et al., 2010), the statistics tests and the google N-gram corpus are used for (semi) automatic creation and validation of a sense pool. The frequencies extracted from Google N-gram corpus are filtered with an appropriate statistical test and further verified by human experts.

The richness and complexity of cultural information contained in the Google N-gram corpus is analyzed in (Joula, 2012). By considering the degree of interdependence as a measure for complexity, the author used the 2-gram corpus to analyze the complexity of American culture. However, there is no the epoch distinction and statistical support.

Regarding Sentiment analysis, text categorization according to affective relevance, opinion exploration for market analysis, etc. are just some examples of application this NLP area (Pang and Lee, 2008). While positive/negative valence checking is an active field of sentiment analysis, a fine-grained emotion checking is nowadays an emerging research topic. For example, SemEval task on Affective Text (Strapparava and Mihalcea, 2007) focussed on the recognition of six emotions in a corpus of news headlines.

## 3 Methodology

In this section we present the statistical tests we used to analyze the data. We do not assume any prior distribution of the frequencies in the corpus and we employ both non parametric and parametric tests. In this section we present the statistical tests we used to analyze the data. We do not assume any prior distribution of the frequencies in the corpus and we employ both non parametric and parametric tests. The Google N-gram corpus is made up of a number of text files which contain N-grams, where N goes from 1 to 5, and which are obtained from English books published over the years. In Table 1 we present a snippet from the

<sup>1</sup>E.g. [www.democracy.org.au/glossary.html](http://www.democracy.org.au/glossary.html)

5-gram corpus:

<i>n-grams</i>	<i>year</i>	<i># occ.</i>	<i># pages</i>	<i># books</i>
democracy at work	1996	1	1	1
democracy at work	1997	5	5	5
democracy at work	1998	2	2	2

Table 1: 5-Gram Google files

### 3.1 Statistical tests

**Normalization.** Due to the exponential growth of the published data, it is better to normalize the number of occurrences for a meaningful comparison. We considered all the content nouns, including proper names, and we computed for each term of interest the percentage of occurrences of that term with respect to the sum of frequencies of all content nouns (considering lemmata). In this paper, when we refer to frequency of a term we mean the normalized figure, unless explicitly stated otherwise. The percentage is in fact very informative on what the public opinion is concerned about in certain periods and substantial differences may be observed within a short period of time. For example, *democracy* was 25 times less a probable topic at the begin of twenty-first century than 50 years before. In such cases, one can clearly talk about a change of interest in society, see Figure 1.

**Welch’s test.** Welch test is a variant of t-student test to check whether two different samples come from the same population or not (Sawilowsky, 2001). The Welch test fits our purposes because it does not assume that the sample have equal variance, thus it can be applied where the other similar tests, such as classical t-student or F-test, do not. The initial conditions for Welch test does not include (1) the equality of the sample sizes and (2) either the homogeneity of population, thus the data may not come from a population having a distribution with a unique variance. In fact for this reason we prefer to use non parametric test in the present paper.

In practice, we apply the Welch’s test to sample size representing contiguous periods of time . To exemplify, let us consider here the term “war” and two different periods 1800-1900 and 1900-2000. Each period is split in two sub-periods, 1800-1850 vs. 1850-1900, and 1900-1950 vs. 1950-2000 respectively. We test whether the samples 1800-1850 vs. 1850-1900 have the same mean, and we also test whether the samples 1900-1950 vs. 1950-

2000 have the same mean. In Table 2 we present the results obtained.

<i>Sample</i>	<i>t</i>	<i>Outcome</i>
1800-1850 vs. 1850-1900 $\mu_1 = .078$ vs. $\mu_2 = .081$	0.23	No Rejection at $\alpha = 0.1$
1900-1950 vs. 1950-2000 $\mu_1 = .184$ vs. $\mu_2 = .098$	-5.163	Rejection at $\alpha = 0.01$

Table 2: Welch’s test for term *war*.

The null hypothesis, that the two sample come from a population with the same mean cannot be rejected at  $\alpha = 0.1$  in the first case. The same null hypothesis is rejected with a very high confidence,  $\alpha = 0.01$  in the second case.

**Run Test.** Run test is a non parametric test, which determines whether the a sequence of numbers is likely to be the result of a random process or there might be an inner pattern in data (Gibbons and Chakraborti, 1992; Lindgren, 1993). For example let us suppose that we have a Bernoulli process with “+” and “-” possible outcomes and probabilities 1/4, 3/4 respectively. A sequences like ++++-----+----- is very unlikely to be a random generated sequences of this process. The run test is designed to detect such cases. A set of real values, as the frequencies of a term over a period of time are, is converted into a run sequences by considering the median of the sequence and obtaining a new sequences by marking with a “+” if the value is bigger than the median and with a “-” if not.

In practice we apply the run statistics on frequencies of a set of given terms. For example for the term *government*, considering two periods we obtain the results in Table 3, where  $p_1=1800-1850$ ,  $p_2=1850-1900$ , and  $p_3=1900-1950$ .

	<i>run</i>	<i>run-test</i>
$p_1$	+++-----++-++++-----	.29839
$p_2$	+++++++-----+-----	.32603
$p_3$	-----+-----+-----	.00001

Table 3: Run test for term *government*

The null hypothesis, which is that the run sequence is randomly generated can be rejected at a significance level  $\alpha = 0.1$  for the third sample, namely from 1900-1950.

**Least Squares.** The least squares method is used to find the line with the smallest sum of square of the difference between the data and the line points ,(Björck, 1996).

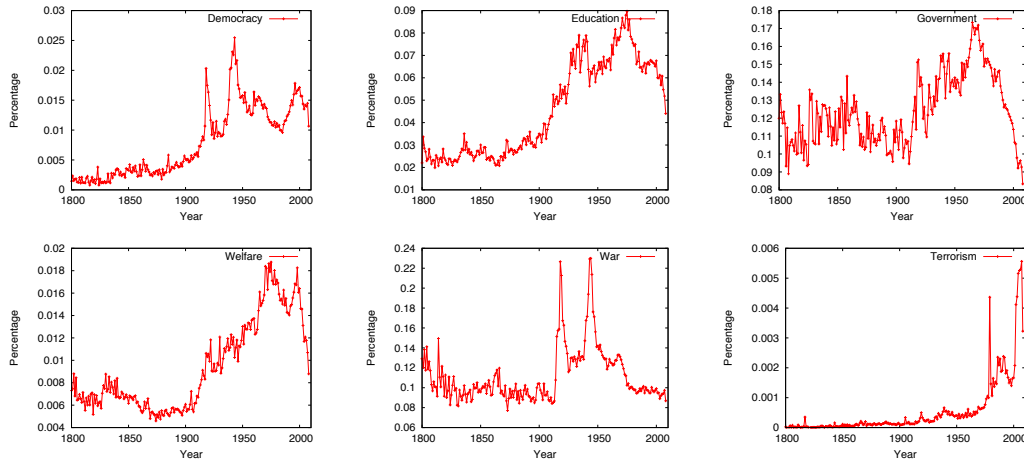

Figure 1: *democracy, government, education, welfare, war and terrorism* percentage

In practice we try to determine the longest period of time in which the data could be fit to a line, imposing that the sum of squares is bond by a small value. For example least squares method applied to the term *government* from 1968 to 2008 produce the optimal line plotted in Figure 2. The line has the equation:  $y = 3.807 - 0.001x$ . The sum of residuals is less than 0.002 ( $ss = 0.0014$ ), which means that the average variance around the line points is 0.00036. This represents a remarkable fit of data to a line.

Figure 2: Least squares applied to the frequencies for term *government*

**Ratio.** It is usual to find in the distribution of frequencies increasing or decreasing sequences. For a definite period of time where a particular direction of growth is observed, we take into account also the rate of growth defined as the ratio between the difference of a three consecutive values:  $\frac{(x_i - x_{i-1})}{(x_{i+1} - x_i)}$ . In practice we use the growth ratio for (C1) characterizing a whole period of time and, (C2) for detecting similarities among distributions for different/same terms over the same/different periods.

**C1** The same growth rate may characterize a whole period of time. A change in the growth rate may signal the beginning of a new epoch. In Table 4, we report the median growth rate for the term *democracy* over two periods.

year	growth rate series						average
1850-1900	1.119	1.227	1.227	1.231	1.136	1.23	1.183
1900-1940	1.218	1.298	1.559	1.69	1.751	1.791	1.802

Table 4: Growth Rate for *democracy* over two periods

**C2** Considering the difference of frequencies of two terms and using the run test we can observe if the growth rate remain the same or changed. In Table 5 we present two runs from two different period of times for the ratio of the differences between the terms *education* and *democracy*. We observe that we have the same growth ratio pattern in different periods.

year	growth rate of difference	
1850-1900	+	+++++
1900-1950	+	+++++

Table 5: Growth rates patterns of the difference between *education* and *democracy*

**Spearman and Kendall Test.** Spearman and Kendall tests are two non parametrical tests for measuring the statistical dependencies between two variables. In practice the time line is always one of the variable and a positive answer from one of this tests shows a non-random evolution of the frequencies within a that period of time. Usually we consider the difference between the frequencies of two terms and apply the Spearman and Kendall test against the timeline. In Table 6 we

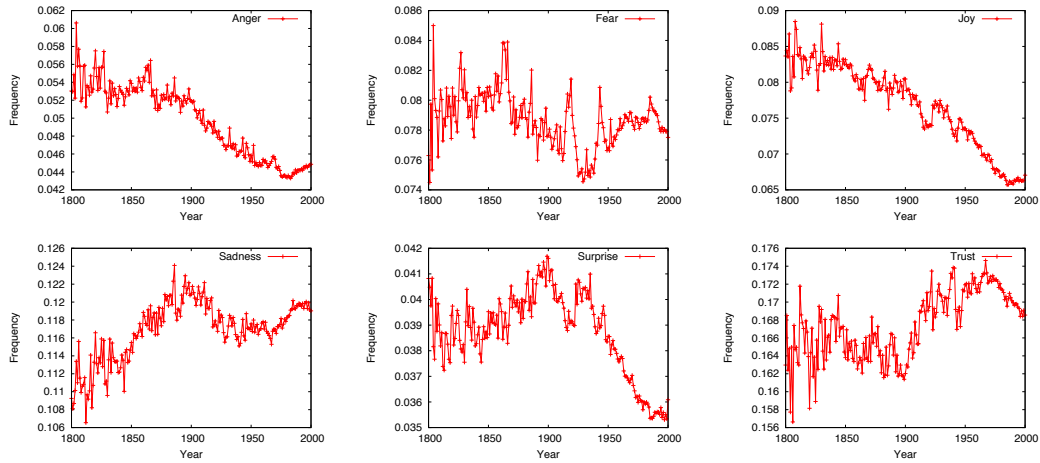

Figure 3: *anger, fear, joy, sadness, surprise and trust* percentage

give an example of the output of the two tests applied to difference between *government* and *welfare*.

year	Spearman	Kendall
1800-1850	0.9689	0.8530
1850-1900	0.7243	0.5510
1900-1950	-0.293	-0.2081
1950-2000	0.7493	0.5934

Table 6: Spearman and Kendall test for time vs. difference between *government* and *welfare*

Figure 4: Emotion percentages in 1921 and 1945

The results above show that from the point of view of the relationship between the frequencies of *government* and *welfare* we can clearly distinguish four different patterns. There is a strong statistical evidence that the frequencies two terms were correlated in the period 1800-1850 and independent between 1900-1950.

Before concluding this section we also plot the frequencies of the emotion terms and two examples of emotion blue-print for years 1921 and 1945. The counts were normalized taking into account the emotion words (see Figures 4 and 3).

### 3.2 Epoch: Decision Procedure

In Section 3.1 we presented the statistical procedures we use for epoch determination. Each of these tests is able individually to find non-random changes in the distribution of the frequencies of terms over the years and to find the beginning and the end of the time periods where the same statistically relevant pattern - linear, same growth rate, dependency - is observed. However, noticing a change in the distribution is not enough for declaring the begin or the end of an epoch. The fact that many of the terms considered are affected by a change in their distribution more or less concomitantly must be observed in order to decide on the epoch boundaries. For now, we preferred a conservative view therefore in the experiments we carried we impose that significantly more than 50% of the terms change their distribution and that the period in which this is happening is at most three years. The algorithm for epoch determination using the tests introduced above is:

---

#### Algorithm Epoch Detection

---

**Require:** Google N-grams with time info

**Ensure:** Epoch

- 1: Apply *Welch's* and *Run* test for non-random changes
  - 2: Choose *start\_year* and *end\_year* spanning several decades
  - 3: **if** number of terms positive to line 1 tests in the time interval  $\pm 3$  years around *start\_year* and *end\_year*  $\leq 50\%$  **then**
  - 4:     **goto** line 2
  - 5: **end if**
  - 6: Apply Least Square, Ratio, Spearman and Kendall
  - 7: **if** number of terms positive to line 6 tests  $\leq 50\%$  **then**
  - 8:     **goto** line2
  - 9: **end if**
  - 10: epoch  $\leftarrow [start\_year, end\_year]$
-

At step 6, the order in which the tests are applied is exactly as specified. If Least Square is positive then also the others are positive as well. An so on: if Ratio holds also the last two tests hold. Condition 7 is satisfied if at least Kendall is positive.

## 4 Experiments

We considered a list of 761 political terms and we applied the decision procedure presented in Section 3.2. The output of the decision procedure is a set of years around which statistically significant changes in the distribution of frequencies for the majority of the terms considered occur. The epoch identified for the chosen list of terms and the decision procedure detailed in Section 3 identified the following 6 epochs epochs between 1800 and 2009, see Table 7.

<i>epoch 1</i>	1800-1860	<i>epoch 4</i>	1950-1975
<i>epoch 2</i>	1860-1900	<i>epoch 5</i>	1975-1999
<i>epoch 3</i>	1900-1950	<i>epoch 6</i>	1999-2009

Table 7: Epochs between 1800-2009

<i>term</i>	<i>change year</i>	<i>positive test</i>
two party system	1975	run, ratio
two party system	1999	Welch's, ratio
patriotism	1975	Welch's, ratio
patriotism	1999	Welch's, squares
too big to fail	1975	ratio
too big to fail	1999	squares

Table 8: Statistical significant changes

Table 8 lists a few examples of terms affected by a statistical change at epoch boundaries. In Table 9 we present the number of terms which changed their distribution for each boundary, on the second column the absolute value and on the third column the percentage relative to the total number of terms considered, 761. We can see that the number of terms which are positive to statistical tests varies substantially. However, it is not by chance that the changes occur.

<i>year</i>	<i>number of terms</i>	<i>percentage</i>
1860	518	68%
1900	491	64%
1950	579	76%
1975	682	89%
1999	607	78%

Table 9: The number of terms defining an epoch

There is a tolerance of a couple of years around the boundaries. For example, if a term's distribution changes  $\pm 3$  years around 1975, then this

change is considered for epoch boundary delimitation. Especially in the last 60 years, it seems that the changes occur more frequently and they are more clearly delimited. During these times, the changes between two different trends occur within a couple of year in the great majority of cases. The dynamic of change is different in the nineteenth century, when it is more likely to observe a buffer zone for several years. In the buffer zone, the distribution around a mean value is quasi normal.

In fact, by running Spearman and Kendall tests we discovered interesting dependencies between the distribution of certain terms and the time line. We computed the differences between the frequencies of pair of terms. For example, for the pair *socialism* and *capitalism* the results of the statistical tests show a strong correlation within each epoch, see Table 10 and Figure 5.

Figure 5: Socialism vs. Capitalism through the epochs

<i>epoch</i>	<i>Spearman Test</i>	<i>Kendall Test</i>	<i>Dependent</i>
1800-1860	0.9741	0.9138	yes
1860-1900	0.9402	0.8429	yes

Table 12: The average of emotion frequencies over the epochs

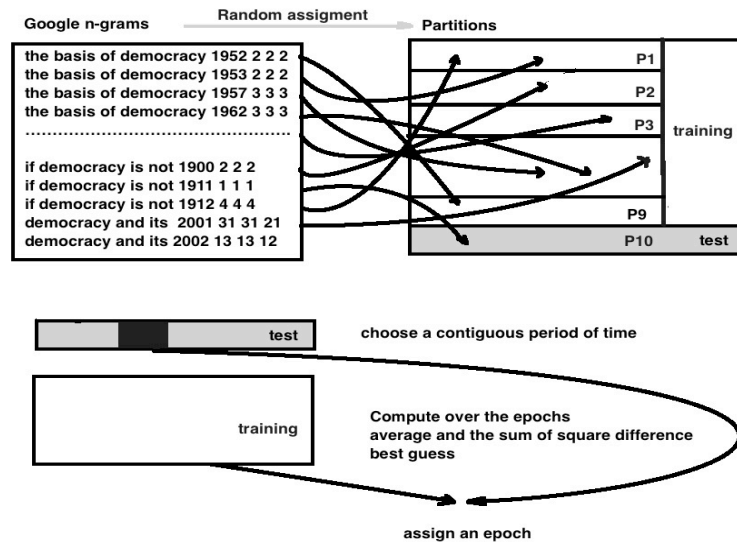

Figure 6: 10-fold validation

To each epoch an emotional blueprint can be attached. An emotional blueprint is obtained by taking into consideration the emotion denoting terms. There are 7 emotion words; *anger*, *anticipation*, *disgust*, *fear*, *joy*, *sadness*, *surprise*, *trust* and two opinion words, *negative* and *positive*. The corpus we consider in this section is the part of Google 5-grams in which each 5-gram contains at least an emotion word. In Table 11 we present their distribution in Google-gram corpus.

The epoch characterization task consists in using the epochs as categories and assigning an unseen sample covering a continuous, but unknown, period of time to one of the categories. For the experiments in this paper, we used the average values of each emotion term computed over the epochs as epoch blueprint, thus each epoch is characterized by a unique value for each emotion term, see Table 12.

For evaluation we used a k-fold cross validation approach. The k-partitions were obtained by

choosing randomly for each occurrence in google corpus its partition, so in average each partition had an equal number of terms. The training was carried on  $k - 1$  partitions and tested on a single partition, thus there are  $k$  independent evaluation experiments. The training  $k - 1$  partitions were joined into a unique corpus which was split into epochs and for each epoch we computed the average for each emotion term. The test partition, the k-partition was split in ten contiguous sub-partitions. For each test sub-partition, the average of the emotion terms was computed and compared against the averages from training corpus to find the most similar ones, resulting in  $10k$  experiments (see Figure 6).

The procedure of finding the most similar epoch can be implemented in different ways. We discuss here two approaches. The first method computes the average over the training corpus for each emotion term and, separately, the average for the test corpus and sums up the squares of the differences

experiment	first run	second run	third run	fourth run	fifth run
all occurrences squares sum	46%	51%	46%	48%	50%
all occurrences best guess	60%	56%	60%	59%	60%
co-occurrences squares sum	53%	58%	59%	57%	59%
co-occurrences best guess	65%	69%	67%	66%	66%

Table 13: 5-partition cross-validation results

for each particular epoch. The category assigned is the one with the least sum of squares. The second method compares the averages computed over the training for each epoch and chooses a representative for each epoch, let us call it best guess. The test sample compares only the averages against the best guess for each epoch and it is assigned to the epoch which has the closest best guess.

To measure the accuracy, we simply count how many times there was only one epoch chosen and that it was indeed the correct one. The figures reported in Table 13 represent the accuracy, as all the sub-partitions were checked and consequently the recall was 1. The last two experiments we carried out on considered political terms. Instead of considering all occurrences of the emotion terms inside a particular epoch, we considered only the co-occurrences of the emotion words with a set of political terms. For this purpose we chose a set of 20 from the list of 761 of political terms considered: *capitalism, community, common good, democracy, education, free market, government, heresy hunting, individual rights, justice, middle class, money, nepotism, politics, public interest, savings, socialism, social system, technology, and war*. The averages for each corpus, training and test respectively, were computed only for these terms and the two approaches above, squares sum and best guess were applied.

In order to understand whether the results above are informative, we run a simple baseline over the same data. The baseline decision was to consider for each subpartition a random epoch. The accuracy of the baseline is around 15%.

## 5 Conclusion and Further Research

The possibility to analyze automatically the changes over the time in the usage of certain terms is an open window into sociological studies carried from a language perspective with computational methods.

During the experiments, some interesting research directions have been revealed. Firstly, although we made no attempt here to make the con-

nection between certain changes and real historical events, it seemed that this was indeed possible. Sharply distinctive changes are observed for certain terms around global war dates. Secondly, while we used the ratio as a parameter which may signal a change, we carried no analyses on the typology of rates themselves. Such analyses may bring to light patterns into the dynamic of interests within a society. Thirdly, the methodology we presented can be easily used for prediction. Such studies could predict future changes. A striking example is represented by the covariance between socialism and capitalism, which seemed to indicate the collapse of political regimes in East Europe several years before it actually happened, see Figure 5. We plan to investigate further the distribution of terms over the time going in the directions above.

## Abstract

While various claims have been made about text in social media text being noisy, there has never been a systematic study to investigate just how linguistically noisy or otherwise it is over a range of social media sources. We explore this question empirically over popular social media text types, in the form of YouTube comments, Twitter posts, web user forum posts, blog posts and Wikipedia, which we compare to a reference corpus of edited English text. We first extract out various descriptive statistics from each data type (including the distribution of languages, average sentence length and proportion of out-of-vocabulary words), and then investigate the proportion of grammatical sentences in each, based on a linguistically-motivated parser. We also investigate the relative similarity between different data types.

## 1 Introduction

Various claims have been made about social media text being “noisy” (Java, 2007; Becker et al., 2009; Yin et al., 2012; Preotiuc-Pietro et al., 2012; Eisenstein, 2013, *inter alia*). However, there has been little effort to quantify the extent to which social media text is more noisy than conventional, edited text types. Moreover, social media comes in many flavours — including microblogs, blogs, and user-generated comments — and research has tended to focus on a specific data source, such as Twitter or blogs. A natural question to ask is how different the textual content of the myriad of social media types are from one another. This is an important first step towards building a general-purpose suite of social media text processing tools.

Most research to date on social media text has used very shallow text processing (such as

keyword-based time-series analysis), with natural language processing (NLP) tools such as part-of-speech taggers and parsers tending to be disfavoured because of the perceived intractability of applying them to social media text. However, there has been little analysis quantifying just how hard it is to apply NLP to social media text, or how intractable the data is for NLP tools.

This paper addresses the two issues above. We build corpora from a variety of popular social media sources, including microblogs, user-generated comments, user forums, blogs, and collaboratively-authored content. We then compare these corpora to more conventional texts through a variety of statistical and linguistic analyses to quantitatively assess the relative extent to which they are “noisy”, and quantify similarities between them. Our findings indicate that there are certainly differences between social media sites, but that if we focus our attention on English text, there are striking similarities, and that even sources such as Twitter may be more “NLP-tractable” than they are often portrayed.

## 2 Background

Natural language processing (NLP) has been applied to a wide range of applications on social media, especially Twitter. Numerous studies have attempted to go beyond simple keyword and burstiness models to identify real-world events from Twitter (Benson et al., 2011; Ritter et al., 2012; Petrovic et al., 2012). Recent efforts have considered identifying user location based on the textual content of tweets (Wing and Baldrige, 2011; Roller et al., 2012; Han et al., 2012b) and user metadata (Han et al., 2013). Related work has examined models of the relationships between words and locations for the purpose of identifying and studying regional linguistic variation (Eisenstein et al., 2010; Eisenstein et al., 2012).

Given the abundance of non-standard language

on social media, including lexical variants (e.g. *supa* for *super*) and acronyms (e.g. *smh* for *shaking my head*), as well as genre-specific phenomena such as the usage of hashtags and mentions on Twitter, standard NLP tools cannot be immediately applied. Efforts to address this problem have taken two main approaches: modifying social media data to more closely resemble standard text, and building social media-specific tools.

Lexical normalisation is the task of converting non-standard forms such as *tlkin* and *touchdoown* to their standard forms (*talking* and *touchdown*, respectively), in the hopes of making text more tractable to NLP (Eisenstein, 2013). Approaches to normalisation have exploited various sources of information including the context in which a given instance of a lexical variant occurs (Gouws et al., 2011; Han and Baldwin, 2011), although the best results to date have been achieved by automatically discovering lexical variant–standard form pairs from a large Twitter corpus (Han et al., 2012a). This latter approach is particularly appealing because it allows for very fast normalisation, suitable for processing large volumes of text.

Conversely, Owoputi et al. (2013) and Ritter et al. (2011) developed part-of-speech (POS) taggers for Twitter that are better able to handle properties of this text type such as the higher out-of-vocabulary rate compared to conventional text. Ritter et al. further developed a Twitter shallow parser and named-entity recogniser. Foster et al. (2011) evaluated standard parsers on social media data, and found them to perform particularly poorly on Twitter, but showed that their performance can be improved through a retraining strategy.

Another natural question to ask is how similar the characteristics of social media text are to those of other domains. More specifically, we may be interested in a numerical measurement of how closely the language used in one corpus matches that of another. Kilgarriff (2001) proposed a method for calculating both inter-corpus similarity and intra-corpus homogeneity, and language modelling has also been used as the basis for calculating how well one corpus models another. We discuss both of these options below.

### 3 Datasets

In order to evaluate the characteristics of text in different social media sources, we assembled the

following datasets from across the spectrum of popular social media sites, varying in terms of document length, the number of authors/editors per document, and the level of text editing:

**TWITTER-1/2:** micro-blog posts from Twitter, crawled using the Streaming API over two discrete time periods (TWITTER-1 = 22 September 2011 and TWITTER-2 = 22 February 2012) to investigate the temporal-specificity of the data — documents up to 140 characters in length, single author per document, and no facility for post-editing

**COMMENTS:** comments from YouTube, based on the dataset of O’Callaghan et al. (2012), but expanded to include all comments on videos in the original dataset<sup>1</sup> — documents up to 500 characters in length, single author per document, and no facility for post-editing

**FORUMS:** a random selection of posts from the top-1000 valid vBulletin-based forums in the Big Boards forum ranking<sup>2</sup> — documents of variable length (with a site-configurable restriction on maximum post length), single author per document, and optional facility for post-editing (depending on the site configuration)

**BLOGS:** blog posts from tier one of the ICWSM-2011 Spinn3r dataset (Burton et al., 2011) — generally no restriction on length, single author per document, and facility for post-editing

**WIKIPEDIA:** text from the body of documents in a dump of English Wikipedia — no restriction on document length, usually multiple authors/editors per document, and facility for post-editing

As a reference corpus of English from a non-social media source, we also include documents from the British National Corpus (Burnard, 2000):

**BNC:** all documents from the written portion of the British National Corpus (BNC) — documents of up to 45K words from a variety of sources, mostly by a single author, with editing.

We present the number of documents and average document size for each dataset in Table 1.

<sup>1</sup>We post-processed the retrieved comments to remove all occurrences of the unicode U+FEFF codepoint (which is used either as a byte order marker at the start of messages or a zero-width no-break space when used elsewhere in a document), as it skewed the results of the language identification.

<sup>2</sup><http://rankings.big-boards.com>

Corpus	Documents	Average words per document
TWITTER-1	1 000 000	11.8 ± 8.3
TWITTER-2	1 000 000	11.6 ± 8.1
COMMENTS	874 772	15.8 ± 18.6
FORUMS	1 000 000	23.2 ± 29.3
BLOGS	1 000 000	147.7 ± 339.3
WIKIPEDIA	200 000	281.2 ± 363.8
BNC	3141	31 609.0 ± 30 424.3

Table 1: Number of documents and average document size (mean±standard deviation, in words) for each dataset

TWITTER-1/2 and COMMENTS, predictably, contain the shortest documents, with 12–16 words per document on average. Forum posts are around twice the length on average (but the spread of document lengths is considerably greater). Blog posts, on average, contain around ten times the number of words of a forum post, with a greater spread again of document lengths and longer sentences. Amongst our social media sources, Wikipedia documents are by far the longest, but considerably shorter than BNC documents.

## 4 Corpus Pre-processing

We first pre-process each dataset using the following standardised methodology.<sup>3</sup> In the case that the corpus comes with tokenisation and POS information, we strip this and perform automatic pre-processing to ensure consistency in the quality and composition of the tokens/tags.

We first apply `langid.py` (Lui and Baldwin, 2012) — an off-the-shelf language identifier — to each document to detect its majority language. We then extract all documents identified as English for further processing.

We next perform sentence tokenisation. In line with the findings of Read et al. (2012a) based on experimentation with a selection of sentence tokenisers over user-generated content, we sentence-tokenise with `tokenizer`.<sup>4</sup>

Finally, we tokenise and POS tag the datasets using `TweetNLP 0.3` (Owoputi et al., 2013).

One particularly important property of `TweetNLP` is that it identifies content such as mentions, URLs, and emoticons that aren’t typically syntactic elements of a sentence. More-

<sup>3</sup>Acknowledging that superior domain-specific approaches exist, e.g. for Wikipedia sentence tokenisation using markup (Flickinger et al., 2010).

<sup>4</sup><http://www.cis.uni-muenchen.de/~wastl/misc/>

over, it is able to distinguish between usages of hashtags which are elements of a sentence, and those which are not, as in the case of Examples (1) and (2) below, respectively.

(1) love this #awesome view out of my window

(2) Swinging with the besties! #awesome

We POS tag each sentence in each corpus using `TweetNLP`, and remove all tokens identified as non-linguistic.<sup>5</sup> In our examples above, e.g., we remove the token `#awesome` from (2) but not (1).

To normalise for corpus size, we extract a random sample of sentences totalling 5M tokens from each dataset, and further partition this sample into 5 equal-sized sub-corpora.

## 5 Analysis

In this section, we analyse the characteristics of the language used in the respective data sources.

### 5.1 Language Mix

First, we analyse the breakdown of languages found in each data source based on the predictions of `langid.py`, as detailed in Table 2. Note that these results are based on the full datasets without language filtering. Also note that WIKIPEDIA and the BNC are intended to be monolingual English collections, and that FORUMS has a strong bias towards English due to the crawling methodology. For the remainder of the datasets, we expect the results to be representative of the language bias of the respective data sources.

All data sources are dominated by English documents, although in the case of TWITTER-1/2, less than half of the documents are in English (`en`), with Japanese being the second most popular language, and strong representation from languages such as Portuguese (`pt`), Spanish (`es`), Indonesian (`id`), Dutch (`nl`) and Malay (`ms`). These results are largely consistent with earlier studies on the language distribution in Twitter (SemioCast, 2010; Hong et al., 2011).

That the BNC is predicted to be 100% English is a validation of the accuracy of `langid.py`. WIKIPEDIA is more interesting, with tiny numbers (around 0.2% in total) of documents which are predicted to have a majority language of Latin (`la`), German (`de`), etc. Manual analysis of these

<sup>5</sup>Specifically, we remove any token tagged as `#`, `@`, `~`, `U`, or `E`.

TWITTER-1		TWITTER-2		COMMENTS		FORUMS		BLOGS		WIKIPEDIA		BNC

it	.013	fr	.015	nl	.006	sv	.002	sv	.008	pt	.000		

Table 2: Top-10 languages (by ISO-639-1 identifier) in each dataset

documents reveals that most are made up of lists of different types: names of people from a variety of ethnic backgrounds, foreign place names, or titles of artworks/military honours in various languages. As such, the language tags are actually overwhelmingly correct,<sup>6</sup> in the sense that the predominant language is indeed that indicated.

The implications of these results for text processing of social media are profound. While English clearly dominates the data, there are significant amounts of non-English text in all our social media sources, with Twitter being the most extreme case: the majority of documents are *not* English. Additionally for TWITTER-1/2 and COMMENTS, instances of all 97 languages modelled by `langid.py` were found in the dataset. At the very least, this underlines the importance of language identification as a means of determining the source language in cases where language-specific NLP tools are to be used.

## 5.2 Lexical Analysis

Next, we analyse the lexical composition of the English documents. Hereafter, we focus exclusively on the 5M token subsample of each dataset.

In Table 3 we present simple statistics on the average word length (in characters) and average sentence length (in words) for each dataset. We also analyse the relative occurrence of out-of-vocabulary (OOV) words, based on the GNU `aspell` dictionary v0.60.6.1 with case folding. We strip all “online-specific” markup (hashtags, user mentions and URLs), on the basis of the output of the POS tagger (i.e. any hashtags etc. that are *not* part of the syntactic structure of the text are removed).<sup>7</sup> To filter out common mis-

<sup>6</sup>With the notable exception of Latin, where many of the documents contain lists of names from a variety of European language backgrounds, but little that is identifiable as Latin.

<sup>7</sup>This step reduced the OOV rate in TWITTER-1/2 by

Corpus	Word length	Sentence length	%OOV	
			-norm	+norm
TWITTER-1	3.8±2.4	9.2±6.4	.246	.225
TWITTER-2	3.8±2.4	9.0±6.3	.240	.222
COMMENTS	3.9±3.2	10.5±10.1	.198	.184
FORUMS	3.8±2.3	14.2±12.7	.181	.171
BLOGS	4.1±2.8	18.5±24.8	.206	.203
WIKIPEDIA	4.5±2.8	21.9±16.2	.190	.188
BNC	4.3±2.8	19.8±14.5	.169	.168

Table 3: Average word and sentence length, and proportion of OOV words (optionally with lexical normalisation) in each dataset

spellings/social media usages such as *ur* for *your*, we optionally include a pre-step of “lexical normalisation” based on the dictionary of Han et al. (2012a) which gives the standard form for a given OOV, based on combined information from slang dictionaries and automatically-learned correspondences (“+norm”).

There is remarkably little difference in word length between datasets, but sentence length in TWITTER-1/2 and COMMENTS is around half that of the more formal WIKIPEDIA/BNC and also BLOGS, with FORUMS splitting the difference. The average word length for all of TWITTER-1/2, COMMENTS and FORUMS is remarkably similar. In terms of OOV words, FORUMS and COMMENTS are comparable to WIKIPEDIA and the BNC (where OOV words are dominated by proper nouns), and actually lower than BLOGS. TWITTER-1/2 has the highest OOV rate of all our datasets, although when we include lexical normalisation, it is only 2–4 percentage points higher than the other social media sources. The impact of lexical normalisation is most noticeable for TWITTER-1/2 and COMMENTS, indicating that informal text and “ad hoc” spellings are more prevalent in them than the other data sources.

about one third; it also reduced the OOV rate in COMMENTS by around 10%.

These results are broadly in agreement with the findings of Rello and Baeza-Yates (2012), who used the relative frequency of a set of common misspellings to estimate the lexical quality of social media, and arrived at the conclusion that social media text is on average “cleaner” than many other web sites, and becoming progressively cleaner over time.

### 5.3 Grammaticality

A natural next question to ask is how grammatical the text in each of our datasets is. We measure this using the English Resource Grammar (ERG: Flickinger et al. (2000)), a broad-coverage HPSG-based grammar. One aspect of the ERG which makes it highly suited to testing grammaticality is that, unlike most NLP parsers, it is “generative”, i.e. it explicitly models grammaticality, and is developed relative to both positive and negative test items to ensure it does not “overgenerate”. We can therefore use it as a proxy for grammaticality judgements. Further to this, the ERG makes active use of ‘root conditions’ to indicate how much the grammar had to relax particular assumptions to produce a derivation for the sentence. These conditions vary on the dimensions of: (1) strict versus informal (corresponding to whether the sentence uses standard punctuation and capitalisation, or not); and (2) full sentences vs. fragments (e.g. isolated noun phrases). All of our experiments are based on the ‘1111’ version of the grammar, and the CHEAP parsing engine (Callmeier, 2002).

In order to maximise the lexical coverage of the ERG, we used POS-conditioned generic lexical types (Adolphs et al., 2008), whereby a generic lexical entry is created for each OOV word on the basis of the output of a POS tagger. To accommodate the *TweetNLP* POS tags, we manually created a new set of mappings to generic lexical entries.<sup>8</sup> We additionally re-tokenised the output of *TweetNLP* to split apart contractions (e.g. *won’t* and possessive clitics (e.g. *Kim’s*), in line with the Penn Treebank tokenisation strategy.

In Table 4 we show the results of parsing 4000 randomly selected English sentences from each corpus using the ERG with the parsing setup we have described.<sup>9</sup>

The highest parse coverage was observed for

<sup>8</sup>The original POS mappings are based on the Penn POS tagset and have been tested and fine-tuned extensively; our POS mapping for the *TweetNLP* POS tags is much more immature, and has potentially contributed to a slight loss in

WIKIPEDIA	48.7	4.5	18.9	1.5	26.2
BNC	38.4	12.0	24.0	2.2	23.2

Table 4: Percentage of sentences (from a random sample of 4000) which can be parsed using the ERG, broken down by the root condition of the top-ranked parse for the parseable sentences

the BNC (with only 23.2% not able to be parsed), closely followed by WIKIPEDIA. At the other end of the scale are the TWITTER-1 and TWITTER-2 variants, which are most likely to contain ungrammatical sentences, with up to 15% more sentences unable to be parsed, although this is only marginally higher than FORUMS and BLOGS, all of which contain more ungrammatical text than COMMENTS.

Between these extremes are some mild surprises — BLOGS and FORUMS, which contain data produced in a more enduring and editable format than TWITTER-1/2, are, according to our metric, only marginally more grammatical. In addition, the non-editable and relatively transient COMMENTS sentences are substantially more likely to be grammatical than either FORUMS or BLOGS. A large part of this effect however is probably due to the sentence length differences between the corpora. As shown in Table 3, the average length for COMMENTS is only 10.5 words, on par with TWITTER-1/2 (but according to this evidence, more carefully constructed). However, in the longer sentences of FORUMS and BLOGS, there is more scope for the authors to introduce anomalies into the text, increasing the chances of the sentence being unparseable.

Examining the root conditions related to formality and fragment analyses also gives us im-

parser accuracy relative to the “canonical” ERG.

<sup>9</sup>Note that the reported results differ significantly from the coverage numbers reported by Read et al. (2012b) for WIKIPEDIA in particular, through a combination of a generic sentence and word tokenisation strategy, a potentially lower-accuracy/coarser-grained POS tagger, and a less mature POS mapping. The impact of these factors should be constant across datasets, however, meaning that the relative numbers should be truly indicative of the relative grammaticality of their text content.

Corpus	Fragment	Preprocessor error	Resource limitations	Ungrammatical inputs	Extra-grammatical	Grammar gaps
TWITTER-1	0.16	0.24	0.00	0.32	0.09	0.18
TWITTER-2	0.19	0.22	0.00	0.31	0.10	0.17
COMMENTS	0.13	0.32	0.00	0.31	0.04	0.20
FORUMS	0.05	0.31	0.01	0.36	0.03	0.24
BLOGS	0.09	0.22	0.11	0.11	0.22	0.25
WIKIPEDIA	0.08	0.11	0.10	0.06	0.06	0.59
BNC	0.15	0.05	0.15	0.04	0.05	0.56

Table 5: A breakdown of the causes of parser error in the unparseable sentences for each dataset

portant insights into the corpora. WIKIPEDIA has by far the highest percentage of sentences with a strict, non-fragment analysis, much higher (10.3%) than the BNC even. In the less-edited corpora, of those sentences which are able to be parsed, a much smaller percentage are strict or full analyses, with the strict fragment analyses being most prevalent in TWITTER-1/2 and informal full analyses dominating in COMMENTS and FORUMS.

The spread of grammaticality numbers is perhaps not as large as we might have expected. There are a few reasons for this. One important point is that the POS-tagging using a very coarse-grained tag set has inevitably led to very general lexical entries for handling unknown words (so we are not even sure of the person, number and tense associated with a verb). This means that it is possible that some of the sentences have been spuriously identified as grammatical, since the very general types for unknown words give the grammar great flexibility in fitting a parse tree to the sentence, even where it may not be appropriate. Secondly it is possible that this POS-tagging has led to an explosion in the number of candidate parse trees, which can paradoxically lead to a small decrease in coverage over longer sentences of WIKIPEDIA and the BNC due to the risk of exceeding the parser timeout or memory limit.

In line with Baldwin et al. (2005), it is possible to shed further light on the quality of the grammaticality judgements, and also stylistic differences between the different corpora by manually analysing the unparseable sentences according to the cause for parse failure, as being due to: (1) a syntactic fragment (not explicitly handled by the ERG; e.g. noun and verb phrase fragments such as *coming home ...*, or standalone expletives such as *wow!*); (2) a preprocessor error (e.g. in sentence tokenisation or POS tagging); (3) parser resource limitations (usually caused by the

grammar running out of edges in the chart, or timing out); (4) ungrammatical strings; (5) extragrammatical strings (where non-linguistic phenomena associated with the written presentation, such as bullets or HTML markup, interface unpredictably with the grammar); and (6) lexical and constructional gaps in the grammar. A breakdown of parse failure over a randomly-selected subset of 100 unparseable sentences from each of the datasets, carried out by the first author, is presented in Table 5.

It is clear that the proportion of ungrammatical sentences is an underestimate, especially in the case of WIKIPEDIA and the BNC, where more than half of the “failures” are attributable to lexical or constructional gaps in the grammar.<sup>10</sup> For TWITTER-1/2, COMMENTS and FORUMS, however, the proportion of grammar gaps and genuinely ungrammatical inputs, respectively, is roughly equivalent, suggesting that our original findings for these datasets are an underestimate of the actual proportion of ungrammaticality, but that the relative proportions are accurate.

An additional observation that can be made from Table 5 is that preprocessing is a common cause of parser failure, primarily in sentence tokenisation (with multiple sentences tokenised into one), and to a lesser extent in POS tagging, and also occasional errors in language identification (only observed in the TWITTER-1/2 data).

Reflecting back over the combined results for grammaticality, we can conclude that there is less syntactic “noise” in social media text than we may have thought, and that while there is no doubt that WIKIPEDIA and the BNC contain less ungrammatical text than the other datasets, the relative occurrence of syntactically “noisy” text in TWITTER-1/2, COMMENTS, FORUMS and

<sup>10</sup>Or, indeed, shortcomings in our POS mapping for unknown words, although again, the relative impact of this should be constant across datasets.

Corpus	Homogeneity
TWITTER-1	549
TWITTER-2	553
COMMENTS	613
FORUMS	570
BLOGS	716
WIKIPEDIA	575
BNC	542

Table 7: Corpus homogeneity using  $\chi^2$  (smaller values indicate greater self-similarity)

BLOGS is relatively constant.

There is partial concordance between these findings and those of Hu et al. (2013), who examined textual properties of Twitter messages relative to blog, email, chat and SMS data, and also a newspaper. They found that Twitter messages were more formal than chat and SMS messages, and more similar to email and blog text in composition, in making prevalent use of standard constructions and lexical items.

#### 5.4 Corpus Similarity

So far we have examined the datasets individually. Next, we investigate how intrinsically similar in style and content the different datasets are. One possible approach to this is via calculation of “corpus similarity” between datasets and homogeneity within a given dataset. In one of the very few studies of measuring corpus similarity and homogeneity, Kilgarriff (2001) introduced a method based on  $\chi^2$ , whereby we measure the similarity of two corpora as the  $\chi^2$  statistic over the 500 most frequent words in the union of the corpora. One limitation of Kilgarriff’s method is that it is only applicable to corpora of equal size. We therefore use the five 1M token sub-corpora of each corpus in these experiments. We measure the similarity of two corpora as the average pairwise  $\chi^2$  similarity between their sub-corpora. We measure the homogeneity (or self-similarity) of a corpus as the average pairwise similarity between sub-corpora of that corpus.

The homogeneity scores in Table 7 indicate that social media text exhibits greater lexical variation (as captured by the  $\chi^2$  measure), and hence is less homogenous, than conventional text types (i.e. the BNC). TWITTER-1 and TWITTER-2 are the most homogenous of the social media corpora, and only fractionally less homogeneous than the BNC. BLOGS are much more diverse than the other corpora.

Turning to corpus similarity (Table 6), there appears to be a roughly linear partial ordering in the relative similarity between the corpora: TWITTER-1/2  $\equiv$  COMMENTS < FORUMS < BLOGS < BNC < WIKIPEDIA (as in, TWITTER-1/2 is more similar to FORUMS than it is to BLOGS, but more similar to BLOGS than the BNC, etc.). This can be observed most clearly based on the similarities of each other corpus with TWITTER-1/2 and WIKIPEDIA, but the similarities for all corpus pairs are consistent with this ordering. TWITTER-1 and TWITTER-2 are unsurprisingly the most similar corpora, with very little difference between the two crawls, suggesting that despite the real-time nature of Twitter, it is reasonably homogenous across time. We further see relatively high similarity between TWITTER-1/2 and COMMENTS, COMMENTS and FORUMS, and FORUMS and BLOGS.

#### 5.5 Language Modelling

Language modelling provides an alternative to estimating corpus similarity, based on the perplexity of a dataset relative to language models (LMs) trained over other partitions from the same dataset, and also partitions from other datasets. We construct open-vocabulary trigram LMs with Good-Turing smoothing using SRILM (Stolcke, 2002).

For each corpus, we build 5 LMs, each trained on 4 of the available 1M word sub-corpora. We then use each model to compute the perplexity of the held-out sub-corpus from the same dataset, as well as all sub-corpora for each other dataset. The results are presented in Figure 1 in the form of a box plot over the 5 LMs for a given training corpus (although the variance between LMs is usually so slight that the “box” appears as a single point).

For each corpus, the lowest perplexity is obtained on the held-out data from the same corpus. Overall, these results agree with those for  $\chi^2$  similarity, namely that there is a continuous spectrum, with TWITTER-1/2 and WIKIPEDIA as the two extremes and COMMENTS, FORUMS, BLOGS and the BNC between them, in that order. Along this spectrum, COMMENTS, FORUMS and BLOGS form a cluster, as do the BNC and WIKIPEDIA.

Combining these results with those for  $\chi^2$  similarity, it would appear that FORUMS is the “median” dataset, which is most similar to each of the other datasets. The implication of this finding is that if a statistical model (e.g. for POS dis-

	TWITTER-1	TWITTER-2	COMMENTS	FORUMS	BLOGS	WIKIPEDIA

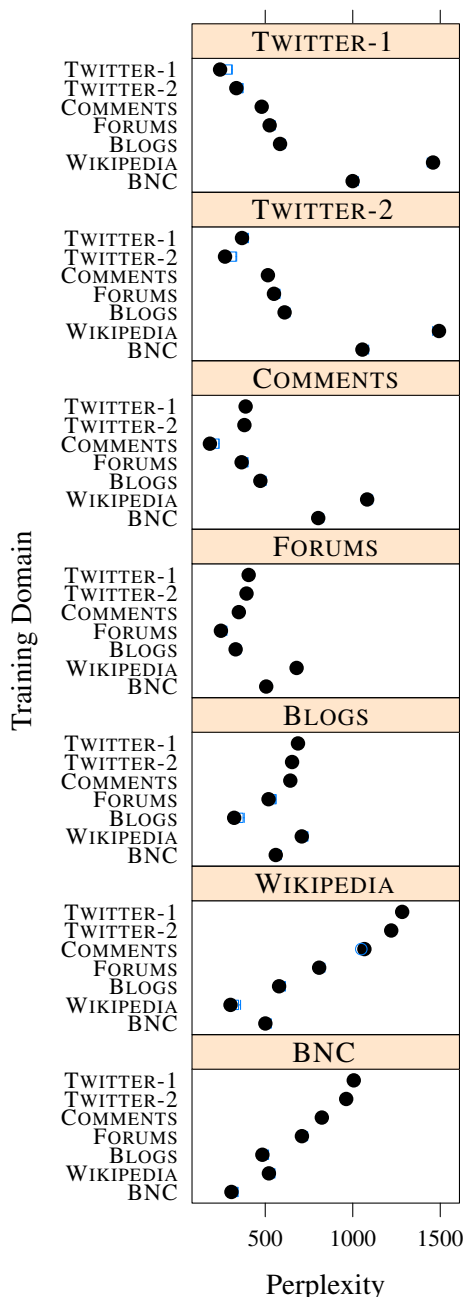

Figure 1: Trigram language model perplexity of test data conditioned on a given training corpus

ambiguation or parse selection) were to be trained on a single data type and applied to the other

data types, FORUMS should be the data of choice, as with the possible exception of WIKIPEDIA, it models the other corpora remarkably well. It also provides evidence for why methods based on edited text collections such as the BNC or newswire text perform badly on Twitter data.

## 6 Conclusions

In this paper we built corpora from a range of social media sources — microblogs, user-generated comments, user forums, blogs, and collaboratively-authored content — and compared them to each other and a reference corpus of more-conventional, edited documents. We applied a variety of linguistic and statistical analyses, specifically: language distribution, lexical analysis, grammaticality, and two measures of corpus similarity. This is the first such systematic analysis and cross-comparison of social media text.

We analysed the widely-acknowledged “noisiness” of social media texts from a number of perspectives, and showed that NLP techniques — including language identification, lexical normalisation, and part-of-speech tagging — can be applied to reduce this noise. Crucially, this suggests that although social media is indeed noisy, it appears to be possible to use NLP to “cleanse” it. Moreover, once rendered less noisy, (further) NLP on social media text might be more tractable than it is conventionally believed to be.

In terms of grammaticality, our results confirmed that social media text is less grammatical than edited text, but also suggested that the disparity is relatively small.

Both of our more-general corpus similarity analyses revealed that the social media text types analysed appear to lie on a continuum of similarity ranging from microblogs to collaboratively-authored content. This finding has potential implications on the selection of training data for statistical NLP systems.

## Abstract

In this paper, we present an automatic system to rank participants of an interaction in terms of their relative power. We find several linguistic and structural features to be effective in predicting these rankings. We conduct our study in the domain of political debates, specifically the 2012 Republican presidential primary debates. Our dataset includes textual transcripts of 20 debates with 4-9 candidates as participants per debate. We model the power index of each candidate in terms of their relative poll standings in the state and national polls. We find that the candidates' power indices affect the way they interact with others and the way others interact with them. We obtained encouraging results in our experiments and we expect these findings to carry across to other genres of multi-party conversations.

## 1 Introduction

Recently, there has been a rapid increase in social interactions being stored on the World Wide Web. In addition to those interactions that are inherently online such as discussion forums and social networks, offline interactions such as broadcast events, debates and speeches are also captured in real time and stored online in repositories such as YouTube and news media outlets. This growing mass of public data representing various modes of interactions enables researchers to computationally analyze social interactions at a scale which was not feasible previously. Within the field of analyzing online social interactions, there is a growing interest to study how the power or status difference between participants is reflected in

the various facets of interactions and if it can be detected using computational means (Diesner and Carley, 2005; Rowe et al., 2007; Bakshy et al., 2011; Bramsen et al., 2011; Biran et al., 2012; Danescu-Niculescu-Mizil et al., 2012).

When people interact with one another, there is often a power differential that affects the way they interact. This differential may be drawn from a multitude of factors such as social status, authority, experience, age etc. Identifying the dominant participants of an interaction through a power ranking system could have various applications. It could help improve effectiveness of advertisements within online communities. For example, targeting an advertisement to powerful and influential members within an online community might increase its effectiveness and reach to the community members. Power analysis can also help in information retrieval systems. Revealing power dynamics within stored interactions could be useful in determining relevance for a user with information needs. For example, a user may want to limit his search to posts authored by interactants with higher power. Power analysis may also aid intelligence agencies to detect leaders and influencers in suspicious online communities. This is especially useful since the real identities of the members of such communities are often not revealed and the hierarchies of such communities may not be available to the intelligence agencies.

Most computational efforts to analyze or predict power differentials between participants of interactions have relied on static power structures or hierarchies as sources for the power differential (Rowe et al., 2007; Bramsen et al., 2011; Gilbert, 2012). However, many interactions happen outside the context of a pre-defined static power structure or hierarchy. Examples for such interactions

include political debates, online discussions, and email interactions outside organizational boundaries. Although the participants of these interactions may not be part of an established power structure, there is often a power differential between them drawn from various other factors such as popularity, experience, knowledge etc. In such situations, the interaction itself plays an important role as a medium for the interactants to pursue, gain and maintain power over others. Consequently, the manifestations of power in such interactions will also inherently differ from the cases where a hierarchy is present. However, most computational studies on power within interactions have not explored such a dynamic notion of power.

In this paper, we analyze political debates where the power differential is dynamic. Specifically, we analyze the 2012 Republican presidential primary debates. We present an automatic ranking system to rank debate participants in terms of their relative power. We model the power of each candidate in terms of their relative standings in the polls released prior to the debate. We find that the candidates' power indices affect the way they interact with others and the way others interact with them. To our knowledge, our work is the first to do an in-depth computational analysis of the structure of interactions, modeling patterns of interruptions and mentions of participants, in relation to power. Moreover, the domain we study is particularly interesting since the primary objective of the debate participants is to pursue and maintain power over each other, as opposed to operating within a static power structure. Lastly, the findings of this study are note-worthy as they relate to the domain of political debates, an area which has not been well-studied in this fashion before. We will release the dataset with annotations to the research community to drive more research in this direction.

Next, we review the background and related computational work in the area of power analysis. Section 3 presents the domain of presidential debates and details how we model power in this domain. Section 4 presents the data and Section 5 presents the power ranker and describes features, experiments and results.

## 2 Background and Related Work

Social power and how it affects the ways people behave in interactions have been studied extensively in social sciences and psychology. Bales

and Slater (1955) studied interactions in small group conversations and suggested language as a reflection and resource of power and influence. Later, Bales (1970) identified the importance of the structure of conversations (e.g. frequency of turns) and argued that "to take up time speaking in a small group is to exercise power over the other members for at least the duration of the time taken, regardless of the content". Ng et al. (1993) found that conversational turns gained by interruptions are stronger indicators of power than turns gained otherwise. In further work Ng and Bradac (1993), they argued that the content also plays a role in influence; a view contrary to (Bales, 1970). More indicators of power in the content of interactions were studied later on. Sexton and Helmreich (1999) found linguistic indicators that could help identify relative status between individuals in social interactions. Locher (2004) studies politeness in interactions in relation to the exercise of power. Our work draws inspiration from many of these studies and looks for correlates of power in both the content and structure of interactions.

Due to the easy availability of data, most of these studies have been performed on written interactions, whereas our study is done on spoken interactions. Early computational approaches to analyze power in interactions relied on network-based approaches. There have been several studies using Social Network Analysis (Diesner and Carley, 2005; Rowe et al., 2007) for extracting social relations from emails. These approaches rely on collections of interactions between a set of individuals to build interaction networks and use various centrality metrics on those networks in order to deduce power relations between interactants. These studies mainly use the meta-data about messages: who sent how many messages to whom and when. Researchers have also analyzed the content of messages using NLP techniques to detect power differentials. For example, Bramsen et al. (2011) and Gilbert (2012) utilize a text classification approach and classify messages in the Enron email corpus as messages sent from a superior to a subordinate, and *vice versa*. Both studies model static hierarchical relationships; our work models a dynamic notion of power in interactions happening outside organizational boundaries. Also, the studies described above consider messages or collections of messages in isolation, but not in the context of the entire interaction.

More recently, a deeper analysis of interactions is shown to be useful in detecting power or influence in interactions. Danescu-Niculescu-Mizil et al. (2012) focus on the notion of language coordination — a metric that measures the extent to which a discourse participant adopts another’s language — in relation to various social attributes such as power, gender, etc. They perform their study on Wikipedia discussion forums and Supreme Court hearings — both of which have enforced power structures. Prabhakaran et al. (2012a) analyze the notion of overt displays of power (ODP) in dialog. Prabhakaran et al. (2012b) and Prabhakaran and Rambow (2013) study how the ODP and other dialog act analysis based features of organizational email interactions correlate with different types of power possessed by the participants. Biran et al. (2012) and Bracewell et al. (2012) use lower-level dialog constructs to model power relations. Biran et al. (2012) use dialog constructs such as attempts to persuade, agreement, disagreement and various dialog patterns in order to find influencers in Wikipedia discussion forums and LiveJournal blogs. Bracewell et al. (2012) try to identify participants pursuing power in discussion forums. They devise a set of eight *social acts* which largely overlaps with the dialog constructs used by (Biran et al., 2012).

Our work also falls into the above category of studies in the sense that we also go beyond pure lexical features and use dialog structure based features in our analysis. However, our work differs in few major ways. Firstly, our domain — political debates — contains spoken interactions while most studies discussed above are performed on written interactions (except Danescu-Niculescu-Mizil et al. (2012) which studies Supreme Court hearings). Secondly, in our domain, the primary purpose of the interactions is to pursue and maintain power, while most studies mentioned earlier deal with domains which are task oriented (Enron, Wikipedia and Supreme Court). Thirdly, in our domain, candidates may gain or lose power in the course of interactions, whereas power is more stable in the studies discussed above. Lastly, our interactions are time-bound, in contrast to online discussions such as Wikipedia forums.

We now turn our attention to related computational work on analyzing conversations in our domain of political debates. Rosenberg and Hirschberg (2009) analyze speeches made in the

context of 2004 Democratic presidential primary election and identify lexical and prosodic cues that signal charisma. More recently, Nguyen et al. (2012) analyze 2008 presidential and vice presidential debates to study how speaker identification helps topic segmentation and how candidates exercise control over conversations by shifting topics. While our domain is also presidential debates, our focus is on how the candidate’s power or confidence affects interactions within the debates.

### 3 Domain: Political Debates

Before the United States presidential election, a series of presidential primary elections are held in each U.S. state by both major political parties (Republican and Democratic) to select their respective presidential nominees. In recent times, it has become customary that candidates of both parties engage in a series of debates prior to and during their respective parties’ primary elections. In this study, we explore how the power differential between the candidates manifests in these debates. Specifically, we use the 20 debates held between May 2011 and February 2012 as part of the 2012 Republican presidential primaries.<sup>1</sup> There were a total of 10 candidates who took part in these primary debates; some of whom participated only in one or two debates. Interactions in these debates are fairly well structured and follow a pattern of the moderator asking questions and the candidates responding, with some disruptions due to interruptions from other candidates.

Presidential debates serve an important role during the election process. It serves as a platform for candidates to discuss their stances on policy issues and contrast them with other candidates’ stances. In addition, it also serves as a medium for the candidates to pursue and maintain power over other candidates. This makes it an interesting domain to investigate how power dynamics between participants are manifested in an interaction. In addition, the 2012 Republican presidential election campaign was one of the most volatile ones in recent times. Most candidates held the front runner position at some point during the campaign. This prevents the analysis of power dynamics in these debates from being biased on the personal characteristics of a single candidate or a small set of can-

---

<sup>1</sup>There were no Democratic presidential primary debates in 2012, since the incumbent President Barack Obama was the de-facto nominee.

didates. Figure 2 shows the trend of how power indices of candidates (to be defined formally in Section 3.1) varied across debates.

### 3.1 Modeling Power in Debates

We use the term *Power Index* to denote the power or confidence with which a candidate comes into the debate. The Power Index of a candidate can be influenced by various factors. For example, during the presidential primary election campaigns, candidates get endorsed by various political personalities, newspapers and businesses. We think that such endorsements as well as the funds raised through campaigns positively affect the Power Index of the candidate. However, a more important source of a candidate’s power is their relative standing in recent poll scores. It gives the candidate a sense of how successful he/she is in convincing the electorate of his/her candidature. In this study, we model the Power Index of each candidate based solely on their recent state or national poll standings because we think that this is the most dominant factor. Other components such as the funds raised can be included in a similar fashion in the calculation of Power Index. We leave this to future work.

For each debate  $D$ , we denote the set of candidates participating in that debate by  $C_D$ . Let  $date(D)$  denote the date on which debate  $D$  was held and  $state(D)$  denote the state in which it was held. Debates from December 2011 onwards were held in states where the primaries were to be held in the near future. In these debates, we assume that their standings in the respective state polls, rather than national polls, would be the dominating factor affecting the power or confidence of candidates. Hence, for those debates, we chose the respective state’s poll scores as the reference. For others, we chose the national polls as the reference. Let  $refType$  denote the type of the reference poll we consider for debate  $D$ .

$$refType = \begin{cases} state(D), & \text{if } date(D) > 12/01/11 \\ NAT, & \text{otherwise} \end{cases}$$

We show the  $refType$  for each debate in Figure 1. For each debate, we find the poll results (national or state) released most recently and use the percentage of electorate supporting each candidate as the power index. If there are multiple polls released on the day the most recent poll was released, then we take the mean of poll scores

Figure 1: Timeline of Debates and Primaries

Number of debates	20
Interaction time	30-40 hrs
Average number of Candidates per debate	6.6
Average number of Turns per debate	245.2
Average number of Words per debate	20466.6

Table 1: Debate statistics

from all those polls to find the power index. Let  $RefPolls(D)$  be the set of polls of type  $refType$  released on the most recent date on which one or more such polls were released before  $Date(D)$ . We define the *Power Index*,  $\mathcal{P}(X)$ , of candidate  $X \in C_D$  as below

$$\mathcal{P}(X) = \frac{1}{|RefPolls(D)|} \sum_{i=1}^{|RefPolls(D)|} p_i$$

where  $p_i$  denote the poll percentage  $X$  got in the  $i^{th}$  poll in  $RefPolls(D)$ .

## 4 Data

We obtained the manual transcripts of presidential debates from The American Presidency Project.<sup>2</sup> The transcripts of all debates follow similar formats, except for a few exceptions. Each debate’s transcript lists the presidential candidates who participated and the moderator(s) of the debate. Transcripts demarcate speaker turns and also contain markups to denote applause, laughter, booing and crosstalk during the debates. Table 1 shows various statistics on the debates. We obtained the state and national poll results from the corresponding Wikipedia pages which kept track of polls from various sources including Gallup, various national and regional news agencies etc.<sup>3,4</sup> Figure 2 shows the trend of how the power indices of candidates varied across debates. Of the ten candidates, seven of them (everyone except Johnson, Huntsman and Pawlenty) were among the top 3 candidates for at least three debates.

Figure 2: Power Index  $P(X)$  variations across debates  
 Note: Plots for Pawlenty and Johnson are not shown since they participated only in one or two debates.

## 5 Automatic Power Ranker

In this section, we present a supervised learning system to rank the participants of the debates based on their power indices. Formally, given a debate  $D$  with a set of participants  $C_D = \{X_1, X_2, \dots, X_n\}$  and corresponding power indices denoted by  $P(X_i)$  for  $1 < i < n$ , we want to find a ranking function  $r : C_D \rightarrow \{1 \dots n\}$  such that for all  $1 < i, j < n$ ,

$$r(X_i) > r(X_j) \iff P(X_i) > P(X_j)$$

We use an SVM based supervised learning system to estimate the ranking function  $r'$  that gives an ordering of participants  $\{X'_1, X'_2, \dots, X'_n\}$ , optimizing on the number of inversions between the orderings produced by  $r'$  and  $r$ .

### 5.1 Features

One of the primary ways power is manifested in an interaction is the manner in which people participate. By this, we are referring to the conscious and subconscious choices a participant makes while engaging in interactions. These include the lexical choices of each participant as well as other choices that affect the structure of the interaction - such as how much a participant speaks and on what topics. We used features to capture the language used in the debates as well as the structure of debates. Specifically, we analyze each debate participant in 4 dimensions — what they said (lexical features), how much they spoke (verbosity features), how they argued (argument features), and how they were talked about (mention features). Some structural features such as turns information are readily available from the transcripts, while for some others like arguments and candidate mentions, we use simple heuristics or perform deeper NLP analysis. The features we used are described in detail below

and are summarized in Table 2.

Code	Feature Description
Lexical: What they spoke	
WN	WordNgrams: word sequence of length 1 to 5
PN	PosNgrams: POS sequence of length 1 to 5
Verbosity: How much they spoke	
WD	WordDev: % of words spoken by $X - 1/ C_D $
TD	TurnDev: % of turns by $X - 1/ C_D $
QD	QuestionDev: % of questions to $X - 1/ C_D $
LT	LongestTurn: # of words in the longest turn
WT	WordsPerTurn: average # of words per turn
WS	WordsPerSent: average # of words per sentence
Argument: How they argued	
IOT	InterruptOthersPerTurn: % of candidate $X$ 's turns that were interrupting others
OIT	OthersInterruptPerTurn: % of candidate $X$ 's turns that others interrupted
Mentions: How they were talked about	
MP	MentionPercent: % of candidate $X$ mentions
FN	FirstNamePercent: % of candidate $X$ mentions that were first name mentions
LN	LastNamePercent: % of candidate $X$ mentions that were last name mentions
FLN	FirstAndLastNamePercent: % of candidate $X$ mentions that were first and last name mentions
TN	TitleAndNamePercent: % of candidate $X$ mentions that were mentions using titles

Table 2: Features with respect to candidate  $X$

**Lexical - What they said:** Ngram based features have been used in previous studies to analyze power in written interactions (Bramsen et al., 2011; Gilbert, 2012). It is expected to capture lexical patterns that denote power relations. We aggregated all turns of a participant and extracted counts for word lemma ngrams (WN) and POS tag ngrams (PN).

**Verbosity - How much they spoke:** We used features to capture each candidate's proportion of turns, time duration they talked, and number of questions posed to them. We approximated the time duration each speaker spoke by the total number of words spoken by him/her in the entire debate. To find the number of questions asked, we used the heuristic — instances where the candidate spoke right after the moderator are questions the moderator posed to the candidate. The percentage values of these features are dependent on the number of participants in each debate, which varied from 9 to 4. To handle this, for each feature, we measured the deviation of each candidate's percentage for that feature from its expected fair share percentage in the debate. We define the fair share percentage of a feature in a given debate to be  $1/|C_D|$  — the percentage each candidate would

```

...
SANTORUM: ... I would ask Governor Romney, do
you believe people who have -- who were felons,
who served their time, who have extended --
exhausted their parole and probation, should
they be given the right to vote?

WILLIAMS: Governor Romney?

ROMNEY: First of all, as you know, the PACs
that run ads on various candidates, as we
unfortunately know in this --

SANTORUM: I'm looking for a question -- an
answer to the question first. [applause]

ROMNEY: We have plenty of time. I'll get there.
I'll do it in the order I want to do. [...]
the super PACs run ads. [...] they said that
you voted to make felons vote? Is that it?

SANTORUM: That's correct. That's what the ad
says.

ROMNEY: And you're saying that you didn't?

SANTORUM: Well, first, I'm asking you to answer
the question, because that's how you got the
time. It's actually my time. [...] should
they be given the right to have a vote?

```

Figure 3: Excerpt from the debate held at Myrtle Beach, SC on January 16 2012

have gotten for that feature if it was equally distributed. We calculate the deviation of each feature — TurnDev (TD), WordDev (WD) and QuestionDev (QD) — as the difference between observed percentage for that feature and  $1/|C_D|$ . We also investigated three additional structural features - longest turn length (LT), words per turn (WT) — whether they had longer turns on average, and words per sentence (WS) — whether they used shorter sentences.

**Argument - How they argued:** Modeling arguments and interruptions in interactions is not a straight-forward task. There has been work in the NLP community to detect arguments and interruptions in spoken as well as written interactions (Somasundaran et al., 2007). However, the well-structured nature of interactions that is expected in the debates allows us to use some simple heuristics to detect arguments and interruptions for the purposes of this study. We leave deeper NLP processing of candidate turns to detect interruptions and arguments for future work.

Debates follow a pattern where the candidate is expected to speak only after a moderator prompts him or her to either answer a question or to respond to another candidate. Hence, if a candidate talks immediately after another candidate, he is disrupting the expected pattern of the debate. This holds true even if such an out-of-turn talk may

not have interrupted the previous speaker mid-sentence. We considered such instances where the candidate spoke out-of-turn after another candidate as interruptions to the previous candidate. In most cases, such interruptions lead to back-and-forth exchanges between the candidates until a moderator steps in. We define such exchanges between candidates where they talk with one another without the moderator intervening as an argument. Arguments can extend to many number of turns. In counting interruptions, we counted only the first interruption by each candidate in the series of turns that constitute an argument. An example argument is given in Figure 3 where we counted only one instance of interruption for both Santorum and Romney. We used features to capture interruptions by candidate  $X$  as well as interruptions by others while candidate  $X$  was speaking. Since the raw counts of these measures are dependent on the number of turns, we used the normalized counts to find the *per-turn* value of these measures as features — InterruptOthersPerTurn (IOT) and OthersInterruptPerTurn (OIT).

**Mentions - How they were talked about:** Intuitively, how often a candidate was mentioned or referred to by others in the debate is a good indicator of his or her power. The more a candidate is mentioned, the more central he or she is in the context of that debate. We use the mention count normalized across the total number of mentions of all candidates in a given debate (MP) as a feature.

In addition, we look at the form of addressing used while referring to each candidate. Previous studies in social sciences and linguistics have looked at the form of addressing in relation to the social relations (Brown and Ford, 1961; Dickey, 1997). Building on insights from these studies, we investigated if the modes of addressing candidates change with respect to their power. Specifically, we looked at four modes of addressing — FN (First Name), LN (Last Name) FLN (First and Last Name) and TN (Title followed by Name, first, last or full). As titles, we included common titles such as Mr., Ms. etc. as well as a set of domain-specific titles: Governor, Speaker, Senator, Congresswoman and Congressman. About 68.6% of total candidate mentions across debates were TN mentions, while the other types of mentions accounted for close to 10% each. FN, LN, TN and FLN capture the distribution of each candidate's mentions across these four types of mentions as

percentage of their total mentions.

## 5.2 Correlation Analysis and Significance

Figure 4 shows the Pearson’s product correlation between each structural feature and candidate’s power index  $P(X)$ . The darker bars denote statistically significant ( $p < 0.05$ ) correlations. Applying Bonferroni correction for multiple tests, the threshold for p-value for significance would be reduced to 0.0025. Even then, the statistically significant features would retain their significance. We consider three correlation windows — weak (0.2 - 0.39), moderate (0.4 - 0.69) and high (0.7 and above).

Figure 4: Pearson Correlations for Structural Features  
Correlation windows: Weak (0.2 - 0.39); Moderate (0.4 - 0.69); High ( $\geq 0.7$ )

We obtained statistically significant moderate positive correlation between the word and turn features and candidates’ power indices. Candidates with higher power indices spoke for significantly more time than others (WD) and they also got significantly more number of turns (TD). This finding is in line with the empirical findings in sociology literature (Ng et al., 1993; Reid and Ng, 2000). We also obtained moderate positive correlation between questions posed to the candidate and his or her power index, which suggests that the candidates with higher power indices were asked significantly more questions by the moderators.

Another interesting observation was on the interruption patterns. We obtained no significant correlation between how powerful a candidate was and how often he/she interrupted others (IOT). Instead, we found statistically significant positive correlation (although weak) for OIT, which means that the candidates with more power were interrupted significantly more by others. This is counter-intuitive and in contrast with previous findings by (Ng et al., 1995) that those who interrupt are more influential or powerful. We believe

that this is a manifestation of the participants pursuing power over each other rather than operating within a static power structure.

We found statistically significant high positive correlation between the power indices of candidates and how often they were referenced/mentioned by others (MP). In other words, as candidates gain more power, they are referenced significantly more by others. However, the distribution of mentions of a candidate across different forms of addressing (FN, LN, TN, FLN) did not have any correlation with the power indices of the candidate. This suggests that while forms of addressing is found to be correlated with power relations by previous studies (Brown and Ford, 1961; Dickey, 1997), they are not affected by the short term variations of power as in our domain.

## 5.3 Implementation

To build the ranker, we used the ClearTk’s *SVM<sup>rank</sup>* (Joachims, 2006) wrapper package. We also used the ClearTk wrapper for the Stanford CoreNLP package to perform basic NLP analysis on the speaker turn texts. The basic steps we performed include - tokenization, sentence segmentation, parts-of-speech tagging, lemmatization and named entity tagging.

## 5.4 Evaluation

We report results on 5-fold cross validation. We report three commonly used evaluation metrics for ranking tasks — Kendall’s Tau,  $nDCG$  and  $nDCG_3$ . Kendall’s Tau measures the similarity between two rankings based on the number of rank inversions (discordant pairings) between original and predicted ranking.  $nDCG$  employs a normalized discounted cumulative gain method which penalizes the inversions happening in the top of the ranked list more than those happening in the bottom.  $nDCG_3$  focuses only on the top 3 candidates from each debate.  $nDCG$  based metrics are more suitable for our purposes since it provides a way to factor in the magnitude of ranking metric (in our case, power index) in the performance assessment. E.g., under  $nDCG$ , the penalty for swapping a pair of candidates with  $P(X)$  values 35.0 and 5.0 will be higher than that for a pair with  $P(X)$  values 12.0 and 15.0. Tau treats these mistakes equally if the swaps generate the same number of inversions.

## 5.5 Results and Discussion

We first find the best performing set of lexical features (Word and POS ngrams) by varying the ngram length from 1 to 5. We then find the best performing feature subset of structural features among all subsets. The small cardinality of the set of structural features makes this feasible. We then use the combination of the best feature subsets from both settings. The results obtained are presented in Table 3. We present a baseline system using word unigrams as features.

	<b>Tau</b>	<b>nDCG</b>	<b>nDCG-3</b>
<i>Baseline (Unigrams)</i>	0.25	0.860	0.733
<i>WN+PN</i>	0.36	0.880	0.779
<i>WD+QD+MP</i>	<b>0.47</b>	<b>0.961</b>	<b>0.921</b>
<i>WD+QD+OIT</i>	0.45	0.960	<b>0.921</b>
<i>WN+PN+WD+QD+MP</i>	0.37	0.902	0.818
<i>WN+PN+WD+QD+OIT</i>	0.37	0.902	0.826

Table 3: Ranker results

We obtain the best configuration of lexical features to be WN+PN, with values of  $n$  as 1 and 2 respectively. The PN features improve the performance of the baseline system (unigrams) from 0.25 to 0.36  $Tau$ . Similar improvements are observed in  $nDCG$  and  $nDCG_3$  as well. The structural features outperform the lexical features and obtain the best overall result of 0.961 for  $nDCG$  and 0.921 for  $nDCG_3$  for a combination of WordDeviation, QuestionDeviation and MentionPercent. Another feature subset — WordDeviation, QuestionDeviation and OthersInterruptPerTurn — obtained the same performance in  $nDCG_3$ , but slightly lower numbers for  $Tau$  and  $nDCG$ . The overall best performing features were WD, QD, MP and OIT, which is in line with the findings in the correlation study in Section 5.2. WD suggests that people with more power tend to and/or are allowed to talk more. QD, MP and OIT are reflections of how others’ perception of a candidates power affected the way they interacted with him/her. Surprisingly, combining lexical and structural features did not yield good results. We suspect that this might be due to the high dimensional ngram feature space.

We analyzed the correlation of each structural features with  $P(X)$  in Section 5.2. However, it is not feasible to perform such significance studies on ngram features because of the huge feature space. In order to find the ngram features that are most representative for this task, we inspected

the feature weights of the linear kernel model created for the best performing ngram feature set (WN+PN). Table 4 lists few of the interesting features that came in the top 25 positive and negative weighted features, along with corresponding weights. POS tags are capitalized and `_BOS_` stands for `beginning_of_sentence`. It is hard to infer strong conclusions based purely on the SVM feature weights. However, SVM does pick up some interesting signals. E.g., those with power used `you` more, while those with less power used `we` more. Also, those with power used `agree` more, suggesting that they might be less contentious than others. `UH_`, which captures interjections/pauses was assigned a positive weight, which aligns with the finding that those with power get interrupted more. `_BOS__JJ` (-0.11) suggests that the participant with lower power tend to start sentences using an adjective.

Positive weighted	Negative weighted
<i>VBN_NN (0.30)</i>	<i>tell (-0.24)</i>
<i>agree (0.27)</i>	<i>do (-0.23)</i>
<i>UH_ (.18)</i>	<i>WDT (-0.15)</i>
<i>you (0.09)</i>	<i>we (-0.09)</i>
<i>VBP_TO (0.18)</i>	<i>_BOS__JJ (-0.11)</i>

Table 4: Top weighted features from the ngram based model created for WN + PN

## 6 Conclusion and Future Work

We presented a system to automatically rank participants of an interaction in terms of their relative power. We identified several linguistic and structural features that were effective in predicting these rankings. We conducted this study in the domain of political debates, specifically the 2012 Republican presidential primary debates. We find that candidates’ power indices affected the way they interacted with others in the debates — how much they spoke and how they spoke. We also found that power affected the way others interacted with them — the number of questions directed at them, how often they were interrupted, and how often they were mentioned. Our experiments in this domain yield very encouraging results and we plan to investigate if these findings carry across to other genres of multi-party conversations as a part of our future work. We also plan to perform deeper analysis on the interactions such as looking for dialog patterns which may signal topic control in relation to power.

Universitat Pompeu Fabra, Spain  
horacio.saggion@upf.edu

## Abstract

This paper addresses the problem of automatic evaluation of text simplification systems for Spanish. We test whether already-existing readability formulae would be suitable for this task. We adapt three existing readability indices (two measuring lexical complexity and one measuring syntactic complexity) to be computed automatically, which are then applied to a corpus of original news texts and their manual simplifications aimed at people with cognitive disabilities. We show that there is a significant correlation between each of the three readability indices and several linguistically motivated features which might be seen as reading obstacles for various target populations. Furthermore, we show that there is a significant correlation between the two readability indices which measure lexical complexity.

## 1 Introduction

In recent years, there has been growing effort to simplify written material and make it equally accessible to everyone. Various studies indicate that lexically and syntactically complex texts can be very difficult for non-native speakers and people with various reading impairments (e.g. autistic, aphasic, dyslexic or deaf people). Aphasic people, for instance, may encounter problems with less frequent words and some particular sentence constructions (Devlin, 1999). They also have problems in understanding syntactic constructions which do not follow the canonical subject-verb-object structure (e.g. passive constructions), and especially those sentences which are semantically reversible, e.g. *“The boy was kissed by the girl”* (Carroll et al., 1999). Additionally, aphasic readers may have additional problems with

comprehending newswire texts which have some genre-specific characteristics. These types of texts tend to use long sentences, noun compounds and long sequences of adjectives, e.g. *“Twenty-five-year-old blonde-haired mother-of-two Jane Smith”* (Carroll et al., 1999). People with intellectual disabilities have problem with both lexically and syntactically complex texts, as well as with processing and loading large amounts of information (Feng, 2009).

Since the late nineties, several initiatives which proposed guidelines for producing plain, easy-to-read and more accessible documents have emerged, e.g. “The Plain Language Action and Information Network (PLAIN)”<sup>1</sup>, “Make it Simple, European Guidelines for the Production of Easy-to-Read Information for people with Learning Disability” (Freyhoff et al., 1998), “Am I making myself clear? Mencap’s guidelines for accessible writing”<sup>2</sup>, and “Web content accessibility guidelines”<sup>3</sup>. All these guidelines share similar instructions for accessible writing, some of them more detailed than others. They all advise the writer to use the active voice instead of passive, use the simplest form of a verb (present and not conditional or future), avoid hidden verbs (i.e. verbs converted into a noun), use short, simple words and omit unnecessary words, write short sentences and cover only one main idea per sentence, etc.

Armed with these guidelines and the aim of making written documents equally accessible to everyone, many attempts have been made to completely or at least partially automate the process of text simplification, which is very expensive and time-consuming when performed manually. So far, text simplification systems have been devel-

<sup>1</sup><http://www.plainlanguage.gov/>

<sup>2</sup><http://november5th.net/resources/Mencap/Making-Myself-Clear.pdf>

<sup>3</sup><http://www.w3.org/TR/WCAG20/>

oped for English (Zhu et al., 2010; Coster and Kauchak, 2011; Woodsend and Lapata, 2011; Wubben et al., 2012), Spanish (Saggion et al., 2011), and Portuguese (Aluísio et al., 2008), with recent attempts at Basque (Aranzabe et al., 2012), Swedish (Rybing et al., 2010), and Dutch (Ruiter et al., 2010). With the emergence of these systems, the question we are faced with is how to automatically evaluate their performance given that the access to the target users might be difficult.

This study is an attempt to address this issue. We focus on text simplification systems for Spanish and investigate whether some of the already existing readability indices could be used for the automatic evaluation of these systems. Using a corpus of original news texts and their manual simplifications which followed specific guidelines for writing for people with cognitive disabilities, we show that two lexical complexity indices – one suggested by Anula (2007), and other by Spaulding (1956) – are highly correlated in both these text sets. Furthermore, we show that both these indices and the third readability index concerned with syntactic complexity (Anula, 2007) could be used for automatic evaluation of text simplification systems, as each index is correlated with some subset of the linguistically motivated complexity features considered as obstacles for people with different reading impairments.

The remainder of the article is structured as follows: Section 2 presents the most important previous work on readability prediction and linguistically motivated complexity features considered as obstacles for people with different reading difficulties; Section 3 describes the corpora, features, and readability indices used in this study; Section 4 presents and discusses the results of analysis of three chosen readability indices, twelve linguistically motivated complexity features, and their mutual correlation; while Section 5 concludes the article by summarising the main contributions and proposing possible directions for future work.

## 2 Related Work

Since the 1950s, over 200 readability formulae have been developed (for the English language), with over 1000 studies of their application (DuBay, 2004). Initially, they were used to assess the grade level of textbooks. Later, they were adapted to different domains and purposes, e.g. to measure readability of technical manuals

(Automated Readability Index (Smith and Senter, 1967)), or US healthcare documents intended for the general public (the SMOG grading (McLaughlin, 1969)). Some of these first readability formulae are still widely in use, given their simplicity (they require only the average sentence and word length) and good correlation with the reading tests. One of the most used readability formulae – the Flesch Reading Ease score (Flesch, 1949) – for example, “correlates .70 with the 1925 McCall-Crabbs reading test and .64 with the 1950 version of the same test” (DuBay, 2004). Another set of readability formulae are those which depend on average sentence length and the percentage of words which cannot be found on a list of the “easiest” words, e.g. the Dale-Chall readability formulae (Dale and Chall, 1948). These formulae have been adapted to other languages by changing the coefficient before the factors (e.g. the Flesch-Douma (Douma, 1960) and Leesindex Brouwer (Brouwer, 1963) formulae for Dutch represent the adaptations of the Flesch Reading Ease score, while Spaulding’s Spanish readability formula (Spaulding, 1956) could be seen as an adaptation of the Dale-Chall formula (Dale and Chall, 1948)). Oosten et al. (2010) showed that readability formulae which are solely based on superficial text characteristics (average sentence and word length) seem to be strongly correlated even across different languages (English, Dutch, and Swedish).

With the recent advances of natural language processing (NLP) tools and techniques, new approaches to readability assessment have emerged. Schwarm and Ostendorf (2005), and Petersen and Ostendorf (2009), used statistical language modeling and support vector machines to show that more complex features (e.g. average height of the parse tree, average number of noun and verb phrases, etc.) give better readability prediction than the traditional Flesch-Kincaid readability formula. They based their approach on the texts from Weekly Reader<sup>4</sup>, and two smaller corpora: Encyclopedia Britannica and Britannica Elementary (Barzilay and Elhadad, 2003), and CNN news stories and their abridged versions<sup>5</sup>. Feng et al. (2009) introduced some new cognitively motivated features which should improve automatic readability assessment of texts for people with cognitive dis-

<sup>4</sup><http://www.weeklyreader.com/>

<sup>5</sup><http://literacynet.org/cnnsf/>

abilities. In addition to three previously used corpora (Weekly Reader, Britannica, and CNN news stories) aimed at second language learners or children, Feng et al. (2009) used a corpus of local news articles which were simplified by human editors in order to make them more accessible for people with mild intellectual disabilities (MID). The texts were further rated for readability by people with MID. The study (Feng et al., 2009) showed that their newly introduced cognitively motivated features (e.g. entity mentions, lexical chains, etc.) are better correlated with the user-study comprehension than the Flesch-Kincaid Grade Level index (Kincaid et al., 1975).

Štajner et al. (2012) stated that many features which could be automatically extracted from a parser’s output can indicate the occurrence of the obstacles to reading comprehension faced by people with autism. The authors referred to the syntactic concept of the projection principle (Chomsky, 1986) that “lexical structure must be represented categorically at every syntactic level” which implies “that the number of noun phrases in a sentence is proportional to the number of nouns in that sentence, the number of verbs in a sentence is related to the number of clauses and verb phrases, etc.” (Štajner et al., 2012). Therefore, they automatically extracted nine features which account for indicators of structural complexity (nouns, adjectives, determiners, adverbs, verbs, infinitive markers, coordinating conjunctions, subordinating conjunctions, and prepositions), and three which account for indicators of ambiguity in meaning (pronouns, definite descriptions, and word senses). Štajner et al. (2012) showed that many of these features are significantly correlated with the Flesch Reading Ease score (Flesch, 1949). Given that all of the reading obstacles for people with autism (Štajner et al., 2012) would also be difficult to understand for people with cognitive disabilities (Freyhoff et al., 1998; Feng, 2009), we believe that these features (Section 3.3) could also be a good measure of complexity reduction achieved in a text simplification system.

Motivated by the study of Štajner et al. (2012), we wanted to explore how these features are correlated with the existing readability formulae (this time for Spanish instead of English). These formulae were not initially intended to be used for the evaluation of text simplification systems but

rather to measure the grade level necessary to understand a given text. Therefore, we wanted to establish whether those readability indices could be used in an automatic evaluation of text simplification systems. To the best of our knowledge, this is the first study of this type for Spanish. Unlike the study of Štajner et al. (2012) which uses the Simple Wikipedia<sup>6</sup> as an example of simplified texts (which do not comply totally with easy-to-read guidelines for people with cognitive disabilities, but are rather intended for a much wider audience), our study uses the original news texts and their manual simplifications aimed at people with cognitive disabilities, following specifically tailored easy-to-read guidelines for this target population (Section 3).

### 3 Methodology

The corpora, readability indices and linguistically motivated complexity features used in this study are presented in the next three subsections.

#### 3.1 Corpora

We first compared all features and readability measures on a parallel corpus of original and manually simplified texts (Table 1) in order to investigate whether these complexity measures differ significantly on these two types of texts, thus justifying the idea to use them to measure the degree of the performed simplification. The corpus contains 200 original news articles in Spanish (provided by the Spanish news agency Servimedia<sup>7</sup>) and their manually simplified versions. Simplification was done by trained human editors, familiar with the particular needs of a person with cognitive disabilities and following a series of easy-to-read guidelines suggested by Anula (2007), as a part of the Simplext project<sup>8</sup> (Saggion et al., 2011).

Table 1: Corpora

Corpus	Texts	Sentences	Words
Original	200	1150	37121
Simplified	200	1804	24332

The simplification operations applied by human editors could be classified in the following four categories (Drndarevic et al., 2013):

<sup>6</sup><http://simple.wikipedia.org>

<sup>7</sup><http://www.servimedia.es>

<sup>8</sup><http://www.simplext.es/>

1. **Syntactic operations:** changes applied at the sentence level, such as sentence splitting or quotation inversion.
2. **Lexical operations:** infrequent, long or technical terms are substituted with their simpler synonyms, and certain expressions are paraphrased or otherwise modified.
3. **Content reduction:** a significant portion of original content is eliminated through summarisation and paraphrases, in accordance with the guidelines that indicate that only the most essential piece of information should be preserved.
4. **Clarification:** certain complex terms and concepts, for which no synonym can be found, are explained by means of a definition.

### 3.2 Readability Indices

In this study, we focused on three readability formulae for Spanish: two concerned with the lexical complexity of the text – LC (Anula, 2007) and SSR (Spaulding, 1956); and the third one concerned with the syntactic complexity of the given text – SCI (Anula, 2007).

**The Spaulding’s Spanish Readability index** (SSR) has been used for assessing the reading difficulty of fundamental education materials for Latin American adults of limited reading ability and for the evaluation of text passages of the foreign language tests (Spaulding, 1956). It predicts the relative difficulty of reading material based on the vocabulary and sentence structure, using the following formula:

$$SSR = 1.609 \times \frac{|w|}{|s|} + 331.8 \times \frac{|rw|}{|w|} + 22.0$$

Here,  $|w|$  and  $|s|$  denote the number of words and sentences in the text, while  $|rw|$  denotes the number of rare words in the text. According to Spaulding (1956), *rare words* are those words which cannot be found on the list of 1500 most common Spanish words provided in the same study<sup>9</sup>. Given that the SSR index was used for assessing the reading difficulty of the materials

<sup>9</sup>Detailed instructions on what should be considered as a *rare word* (e.g. special cases of numbers, names of months and days, proper and geographic names, initials, diminutives and augmentatives, etc.) can be found in (Spaulding, 1956). Here we do not apply rules (a)–(g) specified in (Spaulding, 1956).

aimed at adults of limited reading ability, it is reasonable to expect that this formula could be used for estimating the level of simplification performed by text simplification systems aimed at making texts more accessible for this target population.

**The Lexical Complexity index** (LC) was suggested by Anula (2007) as a measure of lexical complexity of literary texts aimed at the second language learners. It is calculated using the following formula:

$$LC = \frac{LDI + ILFW}{2}$$

where *LDI* and *ILFW* represent the *Lexical Density Index* and *Index of Low-Frequency Words*, respectively:

$$LDI = \frac{|dcw|}{|s|},$$

$$ILFW = \frac{|lfw|}{|cw|} \times 100$$

Here,  $|dcw|$ ,  $|s|$ ,  $|lfw|$ , and  $|cw|$  denote the number of distinct content words, sentences, low-frequency words, and content words (nouns, adjectives, verbs, and adverbs), respectively. Anula (2007) considers as *low frequency words* those words whose frequency rank in the Referential Corpus of Contemporary Spanish<sup>10</sup> is lower than 1,000.<sup>11</sup>

**The Sentence Complexity Index** (SCI) was proposed by Anula (2007) as a measure of sentence complexity in a literary text aimed at second language learners. It is calculated by the following formula:

$$SCI = \frac{ASL + ICS}{2}$$

where *ASL* denotes the average sentence length, and *ICS* denotes the index of complex sentences. They are calculated as follows:

$$ASL = \frac{|w|}{|s|},$$

$$ICS = \frac{|cs|}{|s|} \times 100$$

<sup>10</sup><http://corpus.rae.es/lfrecuencias.html>

<sup>11</sup>Both lists (from Referential Corpus of Contemporary Spanish and the Spaulding’s list of 1500 most common Spanish words) were lemmatised using Connexor’s parser in order to retrieve the frequency of the lemma and not a word form (action carried out manually in the two cited works).

Here,  $|w|$ ,  $|s|$ , and  $|cs|$  denote the number of words, sentences and complex sentences in the text, respectively.<sup>12</sup>

### 3.3 Linguistically Motivated Complexity Features

Inspired by the work of Štajner et al. (2012), and easy-to-read guidelines for writing for people with cognitive disabilities (Freyhoff et al., 1998), this study employs twelve linguistically motivated complexity features (Table 2). The first nine features (1–9) are indicators of structural complexity and the final three features (10–12) are indicators of ambiguity in meaning.

Table 2: Linguistically motivated features

#	Code	Feature
1	<i>N</i>	Noun
2	<i>Det</i>	Determiner
3	<i>Adj</i>	Adjective
4	<i>V</i>	Verb
5	<i>Inf</i>	Infinitive
6	<i>Adv</i>	Adverb
7	<i>Prep</i>	Preposition
8	<i>CC</i>	Coordinating conjunction
9	<i>CS</i>	Subordinating conjunction
10	<i>Pron</i>	Pronoun
11	<i>Sens</i>	Number of senses per word
12	<i>Amb</i>	Percentage of ambiguous words

The corpora were parsed with the Connexor’s Machine parser<sup>13</sup> and the features 1–10 (Table 2) were automatically extracted using the parser’s output. Features 11 and 12 were extracted using two lexical resources – the Spanish Open Thesaurus (version 2)<sup>14</sup> and the Spanish EuroWordNet (Vossen, 1998). The Spanish Open Thesaurus lists 21,831 target words (lemmas) and provides a list of word senses for each word. Each word sense is, in turn, a list of substitute words. There is a total of 44,353 such word senses. The Spanish part of EuroWordNet is far more exhaustive containing 50,526 word meanings and 23,370 synsets. For computation of measures related to word sentences we only considered the lemmas present in the lexical resources used. For each text we com-

<sup>12</sup>We consider a complex sentence one that contains multiple finite predicates according to the output of Connexor’s Machine parser.

<sup>13</sup>[www.connexor.eu](http://www.connexor.eu)

<sup>14</sup><http://openthes-es.berlios.de/>

pute the average number of senses per word (code *Sens*, Table 2) as well as the percentage of ambiguous words in the text (code *Amb*, Table 2) producing two measures for each lexical resource used (*SensWN*, *SensOT*, *AmbWN*, *AmbOT*, Section 4). In the computation we consider all occurrences of lemmas including repeated lemmas.

## 4 Results and Discussion

The results of the analysis of readability indices on the corpora and their mutual correlation are presented in Section 4.1, and the results of the analysis of linguistically motivated complexity features are presented in Section 4.2, while their correlation with the readability indices is presented and discussed in Section 4.3.

### 4.1 Analysis of Readability Indices

The results of the comparison of readability indices across the corpora are given in Table 3. Columns ‘Original’ and ‘Simple’ contain the mean value of the corresponding readability indices in each of the two corpora, while the column ‘Rel.diff.’ contain the mean value of the relative differences between the text pairs (original and simplified). Column ‘Sign.’ presents the level of significance at which the differences between the two corpora are statistically significant. For the indices which follow approximately normal distribution, this column contains the result of the paired t-test. For those which do not follow normal distribution, it contains the result of the alternative non-parametric test – the Wilcoxon signed-rank test. All tests of normality and statistical significance were performed in SPSS.

Table 3: Readability indices

Index	Original	Simple	Rel.diff.	Sign.
LC	21.05	12.76	-39.06%	0.001
SSR	184.20	123.82	-32.60%	0.001
SCI	41.36	29.99	-27.43%	0.001

The results presented in Table 3 clearly demonstrate that there is a significant difference between the original and manually simplified texts for all three readability indices. The text pairs show an average relative difference of almost 40% for LC and about 30% for SSR and SCI, thus justifying the idea that those readability indices might be used in an automatic evaluation of text simplifica-

Figure 1: Readability indices across the corpora

tion systems as a measure of the degree of simplification. The distribution of the three readability indices (LC, SSR, and SCI) is presented in Figure 1, which shows that the distribution of all three indices is shifted left in the case of the simplified texts, thus indicating lower level of complexity.

The correlations between each pair of readability indices (LC–SSR, LC–SCI, and SSR–SCI), calculated using both corpora, are given in Table 4. All correlations which were reported as statistically significant at a 0.001 level of significance are presented in bold. As expected, the two readability indices concerned with the lexical complexity (LC and SSR) are significantly correlated, while the third one concerned with the syntactic complexity (SCI) is not significantly correlated with any of the other two (LC and SSR). The linear correlation between LC and SSR (measured by the Pearson’s coefficient) is, however, much less strong than the one among the four readability indices for English: Flesch Reading Ease, Flesch-Kincaid, Fog and SMOG, reported by Štajner et al. (2012).

Table 4: Correlation among readability indices

Corpus	Indices	Pearson	Spearman
Original	LC–SSR	<b>0.445</b>	<b>0.440</b>
	LC–SCI	-0.075	-0.085
	SSR–SCI	0.045	0.043
Simplified	LC–SSR	<b>0.353</b>	<b>0.378</b>
	LC–SCI	0.093	-0.116
	SSR–SCI	-0.159	-0.136

#### 4.2 Analysis of Linguistically Motivated Complexity Features

Occurrences of each feature which is an indicator of structural complexity, and prepositions (*Prep*)

were calculated as number of occurrences per 100 words. Average number of senses per word and percentage of ambiguous words in text were calculated in two different ways – using the Spanish EuroWordNet (SenseWN and AmbWN) and using the Spanish Open Thesaurus (SenseOT and AmbOT). The results of the analysis are presented in Table 5, using the same notation as in the case of readability indices in Table 3.

Table 5: Complexity Features

Feature	Original	Simple	Rel.diff.	Sign.
N	33.12	33.32	+1.13%	no
Det	14.82	17.13	+17.65%	0.001
Adj	7.24	4.89	-31.10%	0.001
V	10.39	14.56	+45.70%	0.001
Inf	1.65	2.22	+38.14%	0.001
Adv	2.27	3.35	+83.45%	0.001
Prep	19.75	17.12	-12.42%	0.001
CC	2.97	1.63	-41.79%	0.001
CS	1.82	2.55	+53.96%	0.001
Pron	19.75	17.12	+11.82%	0.001
SenseWN	3.78	4.01	+6.99%	0.001
AmbWN	66.02	72.19	+9.62%	0.001
SenseOT	3.52	3.65	+4.47%	0.001
AmbOT	78.89	82.71	+5.13%	0.001

The results in Table 5 show that the number of occurrences (per 100 words) of nouns does not differ significantly between the two corpora. Simplified texts have significantly lower number of occurrences (per 100 words) of adjectives, prepositions and coordinating conjunctions. This could be interpreted as an indication of omitting unnecessary information (adjectives), removing/resolving syntactic ambiguity and complexity (prepositions) and sentence splitting (coordinating conjunctions) in the process of simplification. The increased percentage of verbs might be a reflection of omitting

Table 6: Spearman’s correlation between readability indices and complexity features (Original)

Feature	LC	SSR	SCI
V	<b>*-0.178</b>	<b>-0.192</b>	<b>0.423</b>
Inf	<b>*-0.154</b>	<b>*-0.151</b>	<b>0.303</b>
Adj	<b>*-0.159</b>	0.137	-0.100
Adv	-0.024	-0.047	0.123
Det	-0.022	<b>-0.243</b>	-0.076
N	<b>*0.177</b>	<b>0.193</b>	<b>-0.433</b>
Prep	0.088	0.049	-0.122
CC	0.065	0.116	-0.086
CS	-0.092	<b>*-0.150</b>	<b>0.459</b>
Pron	0.072	<b>-0.248</b>	0.097
SensWN	<b>-0.285</b>	<b>-0.231</b>	<b>0.236</b>
AmbWN	<b>-0.243</b>	-0.080	<b>*0.154</b>
SensOT	-0.077	-0.093	0.088
AmbOT	<b>-0.208</b>	-0.083	0.099

the unnecessary words (e.g. adjectives, coordinating conjunctions, prepositions) and leaving only the main ideas expressed by verbs.

It is interesting to note that both the average number of senses per word and the percentage of ambiguous words are higher in simplified than in original texts, using both sources (EuroWordNet and Open Thesaurus). One possible explanation (which would have to be explored further) is that the shorter and more commonly used words are more ambiguous than the original words which they substituted in the process of simplification.

#### 4.3 Correlation between Readability Indices and Complexity Features

The Spearman’s rho coefficient of correlation between readability indices and the twelve linguistically motivated complexity features is given in Table 6 (for original texts) and in Table 7 (for simplified texts). Correlations which are significant at a 0.001 level of significance (2-tailed) are presented in bold, while those which are significant at a 0.05 but not at a 0.001 level of significance are presented in bold with an ‘\*’ preceding. Other correlations are not statistically significant.

From the results presented in Table 6 and Table 7 it can be noted that each of the readability indices is significantly correlated with several linguistically motivated complexity features. LC is, for example, positively correlated with occurrences of nouns (*N*) and negatively correlated with occurrences of adjectives (*Adj*) in both corpora. SSR

Table 7: Spearman’s correlation between readability indices and complexity features (Simplified)

Feature	LC	SSR	SCI
V	0.000	-0.059	<b>0.672</b>
Inf	-0.025	-0.074	<b>0.573</b>
Adj	<b>-0.241</b>	0.086	<b>*-0.145</b>
Adv	-0.113	-0.118	<b>0.246</b>
Det	-0.086	<b>-0.438</b>	0.034
N	<b>*0.161</b>	<b>0.375</b>	<b>-0.606</b>
Prep	<b>*0.156</b>	0.088	<b>*-0.153</b>
CC	0.027	0.108	<b>*-0.150</b>
CS	-0.030	<b>*-0.159</b>	<b>*0.595</b>
Pron	0.002	-0.074	<b>-0.186</b>
SensWN	-0.064	-0.070	<b>0.225</b>
AmbWN	-0.110	-0.075	0.115
SensOT	0.053	0.025	0.113
AmbOT	0.110	0.113	0.045

is positively correlated with occurrences of nouns (*N*) and negatively correlated with occurrences of determiners (*Det*) and subordinating conjunctions (*CS*). SCI is, on the other hand, negatively correlated with the number of occurrences of nouns (*N*), and positively correlated with number of occurrences of verbs (*V*), infinitive forms (*Inf*), subordinating conjunctions (*CS*), and average number of senses per word according to Spanish EuroWordNet (*SensWN*).

These results indicate that there is no one readability index which correlates significantly with all of the linguistically motivated complexity features. However, it seems that they complement each other well as each one of them is significantly correlated with a different subset of features. Each of these three readability indices could, therefore, be seen as a measure of a different kind of complexity reduction performed by a text simplification system and thus be used in an automatic evaluation of a text simplification system. That automatic evaluation would, of course, account only for measuring the complexity reduction performed by the system, while a human-oriented evaluation would be needed for assessing the preservation of meaning and grammaticality of the simplified text generated by the system (Drndarevic et al., 2013).

## 5 Conclusions and Future Work

The results presented in this study revealed that there are significant differences between the val-

ues of the three readability indices (LC, SSR, and SCI) applied to the corpus of original news texts and the same applied to manually simplified versions of those texts (aimed at people with cognitive disabilities). Another set of experiments indicated that the two corpora also significantly differ in all but one of the twelve linguistically motivated complexity features.

The study also revealed that the two readability indices which measure lexical complexity of a given text are highly correlated. It also showed that each of the three readability indices (LC, SSR and SCI) significantly correlates with several linguistically motivated complexity features in both corpora. Each of them could thus be used in an automatic evaluation of a text simplification system, each measuring a different kind of complexity reduction performed. Furthermore, it seems that those three readability indices complement each other very well in terms of their correlation with different complexity features. Therefore, it might be possible to find some combination of all three of them which could be used as a single measure in an automatic evaluation of text simplification systems.

The search for this ideal combination will be one of the directions of our future work. We also plan to repeat all these experiments on a different set of texts, this time aimed at a different target population, in order to see whether these readability indices show the same properties for texts simplified in a different manner, i.e. whether they could be used in automatic evaluation of any text simplification system. Furthermore, we wish to apply these indices on texts which were automatically simplified. We would like to explore how well the conclusions drawn based on differences of readability indices between original and automatically simplified texts correlate with human judgments of the level of simplification performed.

vinczev@inf.u-szeged.hu

## Abstract

Uncertainty is an important linguistic phenomenon that is relevant in many areas of language processing. While earlier research mostly concentrated on the semantic aspects of uncertainty, here we focus on discourse- and pragmatics-related aspects of uncertainty. We present a classification of such linguistic phenomena and introduce a corpus of Wikipedia articles in which the presented types of discourse-level uncertainty – weasel, hedge and peacock – have been manually annotated. We also discuss some experimental results on discourse-level uncertainty detection.

## 1 Introduction

In many areas of natural language processing, it is essential to distinguish between factual and non-factual information. Thus, depending on the precise task, negated or uncertain propositions should be treated separately by e.g. information extraction systems or they should be neglected. For instance, in medicine, if it is uncertain whether the patient suffers from an illness, the doctor should undertake further examinations to determine the final diagnosis. In another case, only those pieces of news are relevant in news media that are true and come from a reliable source. Uncertain information or unreliable sources should not be part of the news. In order to be able to find uncertain propositions in a huge amount of texts, a reliable uncertainty detector is needed, which can be only developed if annotated resources are at hand.

Previous studies on uncertainty detection concentrated mostly on the semantic dimensions. Indeed, in many cases it is the lexical content (meaning) of the uncertainty marker (cue) that is responsible for uncertainty, i.e. it can be identified

in texts with the help of semantic tools. However, there are other types of uncertainty which cannot be described by just concentrating on semantics. For instance, *many* may denote quite different approximations: in the sentence *Many of the students did not read the book*, *many* may signal about 60-70% of the students (or at least more than 50%), while in *This airline loses many suitcases*, *many* may be only 20% but this number is still high enough for passengers to call it *many*. Here, the context and world knowledge determine how the quantifier *many* should be interpreted.

Here, we will focus on pragmatics- and discourse-related aspects of uncertainty. We will examine the concepts of source, fuzziness and subjectivity and their connection with uncertainty. As a first contribution, we will present a language-independent classification of such linguistic phenomena. As another contribution, we will introduce a corpus of Wikipedia articles in which linguistic cues of the presented types of discourse-level uncertainty have been manually annotated, hence empirical data on the frequency of such phenomena can also be provided. We will report the results of our experiments and we will also compare them with those of previous studies.

## 2 Discourse-level Uncertainty

Different concepts and terms that are related to uncertainty phenomena are employed. Modality is usually associated with uncertainty (Palmer, 1986), but the terms factuality (Saurí and Pustejovsky, 2012), veridicality (de Marneffe et al., 2012), evidentiality (Aikhenvald, 2004) and commitment (Diab et al., 2009) are also used. They all represent related but slightly different linguistic phenomena, which lie mostly in the category of semantic uncertainty. Propositions can be uncertain at the semantic level, that is, their truth value cannot be determined just given the speaker's mental state. Szarvas et al. (2012) offer a classi-

fication of semantic uncertainty phenomena.

Here, we use the term uncertainty similar to Szarvas et al. (2012), who aimed at giving a unified framework for the above-mentioned phenomena: “uncertain propositions are those [...] whose truth value or reliability cannot be determined due to lack of information”. They contrast semantic uncertainty with discourse-level uncertainty: if the scheme “*cue x* but it is certain that not *x*” is invalid (where *x* denotes a proposition, and *cue* denotes an uncertainty cue), that is, an uncertain proposition and its negated version cannot be coordinated, it is an instance of semantic uncertainty (e.g. *##It may be raining in New York but it is certain that it is not raining in New York*).

Besides semantic uncertainty, uncertainty can be found at the level of discourse as well. Here, the missing or intentionally omitted information is not related to the propositional content of the utterance but to other factors. In contrast to semantic uncertainty (Szarvas et al., 2012), the truth value of such propositions can be determined, but uncertainty arises if the proposition is analyzed in detail. For instance, the sentence *Some people are running* evokes questions like *Who exactly are those people that are running?* Here, the answer usually depends on the context, the speaker and the discourse and it cannot be determined out of context, thus henceforth such phenomena will be labeled discourse-level uncertainty.

We will carefully analyze discourse-level uncertainty phenomena below which are named after their most typical linguistic markers, i.e. cues. Although for the sake of simplicity we only provide English examples here, our categorization is based on pragmatic and cognitive considerations, and we will implicitly assume that our categories are language-independent. We will focus on Wikipedia articles, which – as indicated by previous studies (Ganter and Strube, 2009; Farkas et al., 2010) – seem to contain a certain amount of uncertainty phenomena like this. We will concentrate on three key aspects of discourse-level uncertainty, namely, sources, fuzziness and subjectivity.

## 2.1 Weasels

The notion of source is important for deciding the reliability of information conveyed (Saurí and Pustejovsky, 2012; Wiebe et al., 2005; Nawaz et al., 2010). It is not a matter of indifference to whom the information / opinion belongs to, espe-

cially in news media: people are more likely to believe a statement if it is communicated by a reliable source as opposed to a piece of sourceless information. In the public mind, experts, scientists, ministers, etc. are viewed as credible sources (cf. Bell (1991)) while unnamed or unidentifiable sources are considered less reliable. If some pieces of information are backed by a credible source, they are more likely to be treated as trustworthy, however, sourceless information is given less credence.

Events with no obvious sources are called *weasels* in Wikipedia<sup>1</sup> (Ganter and Strube, 2009): their source is missing or is specified only vaguely or too generally, hence, it cannot be exactly determined who the holder of the opinion is (undetermined source) as it is either not expressed or expressed by an indefinite noun phrase. Weasel sentences usually invoke questions like *Who said that?* and *Who thinks that?* The following sentence illustrates this:

**Some** have claimed that Bush would have actually increased his lead if state wide recounts had taken place.

The ultimate source of the proposition expressed in the embedded sentence is not known since it is denoted by the pronoun **some**. Thus, it is not known who provided the opinion and therefore it is uncertain whether this is an important (reliable) piece of information (e.g. the opinion of experts) or whether it should be ignored.

Passive constructions which do not express the agent comprise a special type of weasels:

It has been suggested [**by whom?**] that he should have involved Clinton much more heavily in his campaign.

The sentence does not reveal who has suggested the involvement of Clinton in the campaign. Hence, the source of the information is unclear and the source is missing from the sentence.

The basic idea behind weasel phenomena is the lack of a reference: it is not known who the source of the opinion is. This view is supported by the fact that a weasel candidate ceases to be uncertain if it is enhanced by citations:

Most authors now prefer to place it within the genus *Pezoporus*, e.g. Leeton et al. (1998).

<sup>1</sup>[http://en.wikipedia.org/wiki/Wikipedia:Manual\\_of\\_Style/Words\\_to\\_watch](http://en.wikipedia.org/wiki/Wikipedia:Manual_of_Style/Words_to_watch)

The phrase *most authors* would indicate a weasel (it is not clear whose opinion is this) but the citation at the end of the sentence clearly identifies the source.

In this paper, we extend the original notion of *weasel* and we argue that propositions that have an underspecified argument that would be relevant or is not common knowledge in the situation can be also viewed as weasels. Thus, a proposition is considered to be an instance of weasel if any of its relevant arguments is underspecified, i.e. it evokes questions like *Who/what exactly? Which?* Here, we give an example:

While the Skyraider is not as iconic as **some other** aircraft, it has been featured in some Vietnam-era films such as *The Green Berets* (1968) and *Flight of the Intruder* (1991).

The sentence does not determine what kind of aircraft is considered iconic, so it is a vague or underspecified statement: we only know that there are “iconic aircraft”, but no more details are specified. Again, the weasel type of uncertainty is expressed here by the adjectives *some* and *other*. Note that there is another occurrence of the word *some* in the sentence, but it does not denote any uncertainty in this case since the relevant Vietnam-era films are then listed.

## 2.2 Hedges

Another type of discourse-level uncertainty that will be discussed later on is called a hedge. Although a lot of studies used the term *hedge*, it may denote different linguistic phenomena for different authors. For instance, *hedge* means mostly *speculation* in the biomedical domain (see e.g. Medlock and Briscoe (2007), Vincze et al. (2008), and Farkas et al. (2010)). When contrasting epistemic modality and hedging, Rizomilioti (2006) categorizes approximators, passive voice and attribution to unnamed sources, among others, as instances of hedging and Hyland (1996) also cites them among common hedging devices.

Here, we understand *hedge* in the sense introduced by Lakoff (1973). For him, hedges are “words whose job is to make things fuzzier or less fuzzy”, that is, the exact meaning of some qualities or quantities is blurred by them. Intensifiers (*very*, *much*), deintensifiers (*a bit*, *less*) and circumscribers (*approximately*) also belong to this

group. Their effect is to add uncertainty to some elements in the proposition: they shift the value of some quality / quantity and the truth value of the proposition can only be decided if it is known what the reference point in the discourse is as the following example shows:

Specialized services will **very often** provide a **much** more reliable service based on trusted publications.

In this sentence, there are several hedge cues. First, there is *often*, which informs us that it is not always the case that specialized services provide much more reliable service. It is modified by the intensifier *very*, which indicates that it is almost always the case (but still not always). Next, their service is *much* more reliable than any other service (at least those relevant in the context), that is, it is very reliable.

However, it should be noted that there is no absolute way to determine the truth value of this proposition without agreeing on what is meant by e.g. *often*: for now, let us say that *often* means at least seven out of ten times (but not ten times out of ten) and then *very often* may denote eight or nine times out of ten. It depends on the context, the speakers and the event described in the sentence to determine the reference point according to which the quantity or quality of events or entities can be evaluated. In the above example, the reference point may be 70%, and intensifiers denote that the quality or frequency of the event / entity is above the reference point, in this case, above 70%. Deintensifiers, however, assert that the quality or frequency is below the reference point.

Circumscribers – as their name states – circumscribe the exact amount or quality of the event or entity, which can be above or below the reference point. To represent this visually, they denote a set around the reference point in which the exact amount or quality is situated (see Figure 1 below). Here are some linguistic examples:

This may explain why it has a lower than average estimated albedo of **~0.03**.

The duration of attacks averages **3-7** days.

It is interesting to note that in such cases not only cue words but also cue characters are responsible for uncertainty: the tilde and hyphen in these specific cases. Moreover, there are cue words that

Figure 1: Types of hedges.

function as circumscibers as well like *approximately* and another use of *some*:

Amsterdam Zuidoost has **approximately** 86,000 inhabitants and consists of **some** 38,000 houses.

Figure 1 shows the relationship of hedge types relative to the reference point. Thus, each type of hedge denotes a set in which the exact amount, quality or frequency of the relevant event or entity is situated but its exact place remains unclear.

Hedging is also one of the politeness strategies mentioned by Brown and Levinson (1987): they may function as mitigators in order to minimize disagreement, and to acknowledge that the speaker is imposing a task on the hearer. In the request *Could you please sort of correct this very short text for me?* the phrase *sort of* is a hedge, and the “very short” text may in fact be rather long. Here, hedges have pragmatic functions and they do not refer to uncertainty.

### 2.3 Peacocks

Subjectivity by its very nature contains aspects of uncertainty. People’s opinions may differ from each other concerning specific things or events: they do not necessarily agree on what is good, neutral or bad. Thus, we cannot unequivocally determine what is good or what is bad.

Words that express unprovable qualifications or exaggerations are called *peacock* by Wikipedia editors.<sup>2</sup> Their meaning often inherently contain positive or negative subjective judgments, that is, they are polar expressions. Peacock terms include *brilliant*, *excellent* and *best-known*. Although their usage may be acceptable in other contexts, the objective style of Wikipedia editing requires that peacocks should be avoided.

<sup>2</sup>[http://en.wikipedia.org/wiki/Wikipedia:Manual\\_of\\_Style/Words\\_to\\_watch](http://en.wikipedia.org/wiki/Wikipedia:Manual_of_Style/Words_to_watch)

Although they are not called peacocks by Wikipedia editors, we classify other subjective elements as peacocks as well. For instance, editorial remarks that refer to the subjective opinion of the author of the article (like *ironically* and *unfortunately*) or contentious labels (*controversial* and *legendary*) may all express subjectivity in certain contexts, hence we treat them here as peacock terms. The uncertainty in their meaning again lies in the fact that it cannot be objectively judged what can be called *excellent* for instance – it can be only deduced from discourse or contextual information and it may differ from speaker to speaker.

Here is a sentence with some peacock terms:

Through the **ardent** efforts of Rozsnyai, the Philharmonia Hungarica quickly matured into one of Europe’s **most distinguished** orchestras.

The words *ardent* and *most distinguished* are clearly positive in polarity, and again it cannot be objectively decided what level of enthusiasm is called ardent or which orchestras belong to the most distinguished ones.

All peacock terms are similar to hedges to some extent. They can be called scalar uncertainties since in both cases, a scale is involved in the interpretation of the uncertain term. In the case of peacock, there is a scale of polarity on which phrases can be judged as positive or negative whereas in the case of hedges, there is a scale on which there is a reference point, on the basis of which the uncertain part of the utterance is placed. Although they are similar, we suggest that peacocks and hedges be differentiated in our classification because peacocks are related to subjectivity while hedges are more neutral, hence they can be relevant for different NLP applications (e.g. in opinion mining, which seeks to collect subjective opinions on different topics, peacocks may prove more useful than hedges). Still, hedges shift the value of the quantity / quality mentioned in the text while peacocks denote a specific point on the scale, without modifying it, which again suggests that they should not be lumped in the same class.

### 3 Related Work

These days, uncertainty and modality detection is a widely studied area in natural language processing, which manifests itself in a number of corpora annotated for uncertainty in domains like biology

(Medlock and Briscoe, 2007; Kim et al., 2008; Vincze et al., 2008; Nawaz et al., 2010), medicine (Uzuner et al., 2009), news media (Wilson, 2008; Saurí and Pustejovsky, 2009; Rubin, 2010), and encyclopedia texts (Farkas et al., 2010). Although some authors have called attention to the fact that the progressive nature of discourse and dimensions of time should be also taken into account (de Marneffe et al., 2012; Saurí and Pustejovsky, 2012), as can be judged on the basis of available guidelines, most of these corpora make use of semantic uncertainty, with some exceptions that take into account pragmatic or discourse-level information as well (see below).

The concept of source has played a significant role in the literature. FactBank (Saurí and Pustejovsky, 2009) explicitly annotates the factuality of events according to their sources' perspective and Wiebe et al. (2005) also emphasize the role of sources annotated in the MPQA corpus for opinion mining. The notion of perspective – both in Nawaz et al. (2010) and in Morante and Daelemans (2011) – is similar to the one of sources applied in FactBank and MPQA. In Wikipedia, the lack of identifiable sources is explicitly discouraged by editors. They call such phenomena *weasels* (see also Ganter and Strube (2009)) and weasel detection was one of the subtasks of the CoNLL-2010 shared task (Farkas et al., 2010).

The lack of source characteristics to weasels can be paired with a certain strategy that Hyland (1996) calls impersonal constructions. It is a type of writer-oriented hedges<sup>3</sup> in his system. It is interesting to note that in his system, the opposite of this strategy can also be found, which could be called *anti-weasel*: the writer emphasizes his responsibility by using first person pronouns. However, this latter strategy does not represent any form of uncertainty in our view.

Fuzziness is another dimension of uncertainty. Lakoff (1973) gave an account of some lexical items – which he calls hedges – that “make things fuzzier”, that is, words such as *approximately*, *kind of*, *at least* etc. Due to the presence of such words, the quality or quantity under investigation is shifted on a scale. If modified by the adverb *very* for instance, it moves towards one end of the scale on which this quality/quantity is determined. The phenomenon of hedging in scientific articles

---

<sup>3</sup>However, in our classification, it should be called a weasel.

is analyzed and categorized according to the functions it can fulfill in Hyland (1996).

Subjectivity is also related to uncertainty. There is a great diversity among individual views and opinions: a feature of a product may be appreciated by some customers but it might be considered intolerable for others. Thus, what should be considered positive or negative seems subjective. Many approaches to subjectivity or sentiment analysis rely on lexicons and databases of subjective terms. For instance, the database SentiWordNet (Baccianella et al., 2010) contains a subset of the synsets of the Princeton Wordnet with positivity, negativity and neutrality scores assigned to each concept, depending on the use of its sentiment orientation, thus it is a lexicon where subjective terms are listed and ranked. Wilson (2008) defines subjectivity clues as words and phrases that express private states, that is, individual opinions. She distinguishes lexical cues and syntactic cues that are responsible for subjectivity. She lists several modifiers among her syntactic clues of subjectivity like *quite* and *really*. However, in contrast with other subjective elements, we do not regard them as peacock cues since – as Wilson (2008) herself states – they “work to intensify”, so in our system they are classified as hedge cues. On the other hand, some instances of biased language can also be classified as peacocks in our system (Recasens et al., 2013).

Human communication and discourse is incremental in nature (Cristea and Webber, 1997). Information may be added at a later point of the discourse that clarifies a previously missing piece of information. Applying this to discourse-level uncertainty, it may be the case that an apparent weasel phrase is elaborated on later in the discourse, or the exact value of an apparent hedge expression is later provided. In such cases, the phrases should not be marked as uncertain, which indicates the essential role of co-text – i.e. surrounding words in the text (Brown and Yule, 1983) – in detecting discourse-level uncertainty.

## 4 The Annotated Corpus

In order to test the practical applicability of the new classification of discourse-level uncertainty phenomena, and to investigate the frequency of each uncertainty type, we also created an annotated corpus. We selected WikiWeasel, the Wikipedia subset of the CoNLL-2010 Shared

Task corpora (Farkas et al., 2010) for annotation. By doing this, our results could be contrasted with those of the original annotation carried out specifically for the shared task. Moreover, as the corpus has recently been annotated for semantic uncertainty (Szarvas et al., 2012), interesting comparisons can also be made between semantic and discourse-level uncertainty. The annotated corpus is available free of charge for research purposes at [www.inf.u-szeged.hu/rgai/uncertainty](http://www.inf.u-szeged.hu/rgai/uncertainty).

#### 4.1 Statistical Data on the Corpus

The dataset consists of 4,530 Wikipedia articles and 20,756 sentences. Texts were manually annotated by two linguists for linguistic cues denoting all types of discourse-level uncertainty, i.e. weasel, peacock and hedge. 200 articles were annotated by both linguists and the inter-annotator agreement rate for the categories weasel, peacock and hedge were 0.4837, 0.4512 and 0.4606, respectively (in terms of  $\kappa$ -measure), which reflects that identifying discourse-level phenomena is not straightforward, however, it can be reasonably well solved considering the subjective nature of the task. During the annotation, special emphasis was laid on the discourse structure of the text. For instance, weasel cue candidates do not denote uncertainty when the sentence is enhanced with citations. Also, a weasel-like element may be elaborated on in the next sentence, thus it is not to be marked as weasel as in:

Some ship names are references to other games created by Jordan Weisman. The “Black Swan” is a reference to a character from *Crimson Skies*, and also possibly to the ship *Black Pearl* from *Pirates of the Caribbean*.

In order to attain the gold standard for the commonly annotated parts, the two annotators discussed problematic cases and reached a consensus for each case. The final version of the corpus contains these disambiguated cases.

The dataset contains 10,794 discourse-level uncertainty cues<sup>4</sup>, which occur in 7,336 uncertain

<sup>4</sup>We should mention that our corpus contained 680 passive constructions, which were annotated as weasels. As we focus now on lexical cues of discourse-level uncertainty, and they belong to syntactic cues, the investigation of such cases will be subject to further studies.

sentences. A sentence was considered to be uncertain if it contained at least one uncertainty cue. But, as the results show, many sentences include more than one uncertainty cue. Statistical data on the uncertainty cues found in the WikiWeasel corpus are listed in Table 1, together with available data on semantic uncertainty types, taken from Szarvas et al. (2012).

Uncertainty cue	#	%	Diff. cues
Hedge	4,743	35.24	260
Weasel	4,138	30.75	99
Peacock	1,913	14.21	540
Discourse-level total	10,794	80.2	899
Epistemic	1,171	8.7	114
Doxastic	909	6.75	36
Conditional	491	3.65	15
Investigation	94	0.7	12
Semantic level total	2,665	19.8	166
Total	13,459	100	1065

Table 1: Uncertainty cues in WikiWeasel.

As can be seen, most of the uncertainty cues found in the corpus belong to the discourse-level uncertainty class, the ratio of semantic to discourse-level uncertainty cues being 1:4. Among the types of discourse-level uncertainty, hedges are the most frequent, followed by weasels and peacocks. All this suggests that discourse-level uncertainty is very typical of Wikipedia articles, about 35% of the sentences being uncertain at the discourse level. As regards the specific classes, 3,807 (18.3%), 3,497 (16.8%) and 1,359 (6.5%) sentences contain at least one hedge, weasel or peacock cue, respectively.

#### 4.2 Cue Distribution in the Corpus

On the number of different cues, Table 1 tells us that the set of linguistic cues expressing weasels are the most limited, with almost 100 cues. In contrast, peacock cues vary the most with 540 cues. This suggests that weasels have the most restricted vocabulary in contrast to peacocks, and hedges being in the middle. This also means that the average frequency of a weasel cue is much higher than that of a peacock cue: the average frequency of occurrence of weasel, hedge and peacock cues is 41.8, 18.24 and 3.54, respectively.

We did a more detailed analysis on the lexical distribution of the cues as well. The ten most frequent cues for each type are listed in Table 2. These are responsible for about 86%, 45% and 42% of the occurrences of weasel, hedge and peacock cues, respectively. Thus, a limited vocabu-

Weasel	#	%	Hedge	#	%	Peacock	#	%
some	887	25.64	often	539	11.36	most	318	16.62
many	631	18.24	usually	263	5.55	popular	112	5.85
other	539	15.58	many	217	4.58	famous	81	4.23
several	204	5.90	generally	210	4.43	well-known	50	2.61
most	202	5.84	very	206	4.34	notable	50	2.61
various	177	5.12	most	179	3.77	notably	45	2.35

Table 2: The most frequent discourse-level uncertainty cues in the WikiWeasel corpus.

lary can account for over 85% of weasels.

However, some terms can belong to more than one uncertainty type. For example, *most* occurs in all the three types (weasel: *Most agree that this puts her at about 12 years of age*, hedge: *He spent most of his time working on questions of theology* and peacock: *Kathu is the district which covers the most touristical beach of Phuket*), but *some*, *many* and *several* can all be instances of weasels and hedges. This is due to the linguistic variability of these items: e.g. *some* may refer to “an indefinite quantity” or “something unspecified”.

As can be seen, there are some overlapping cues among the types. This is especially so in the case of hedges and weasels: 25 cues can denote hedges or weasels as well, thus 25% of the weasel cues are ambiguous. These cues were also responsible for most of the differences between the two annotations, which indicates that their identification requires special attention both for human annotators and NLP tools: it is mostly the neighbouring words that can determine whether it is a weasel or hedge. For instance, if *some* occurs before a verb and constitutes a noun phrase on its own, then it is almost certainly a weasel cue (*Some think that...*) but if it occurs before a noun denoting time, it is probably a hedge (*some minutes ago*).

## 5 Experiments

We carried out some baseline experiments on the corpus. We divided the corpus into training (80%) and test (20%) sets and applied a simple dictionary-based approach which classified each cue candidate as uncertain if it was tagged as uncertain in at least 50% of its occurrences in the training dataset. For ambiguous cues, the most frequent label was chosen (e.g. *most* was used as a peacock cue). Similar to the CoNLL-2010 shared task, we evaluated our results at the cue level as well as at the sentence level.

	Cue level			Sentence level		
	P	R	F	P	R	F
Weasel	0.7088	0.6724	0.6901	0.7443	0.7183	0.7311
Hedge	0.8780	0.6616	0.7546	0.9185	0.7193	0.8068
Peacock	0.4222	0.4730	0.4462	0.4034	0.5341	0.4597
Micro F	0.7196	0.6348	0.6745	0.7458	0.6924	0.7181

Table 3: Baseline results in terms of precision / recall / F-score.

Table 3 shows that the peacock class is the most difficult to detect, which may be due to the fact that this class has the most diverse cues and thus applying a dictionary-based method leads to a lower recall. Still, the lower precision was due to the higher level of ambiguity concerning the most typical peacock cues (like *most*). As for hedges, a simple lexical approach can result in a good precision score, which suggests that hedge cues are less ambiguous than weasel or peacock cues. It is also seen that sentence-level results are significantly higher than cue-level results (ANOVA,  $p = 0.0026$ ). Uncertain sentences typically contain more than one cue and in the former scenario, it is sufficient to recognize only one cue in the sentence to regard the sentence as uncertain and false negatives do not affect the performance significantly.

If we compare the data with the CoNLL-2010 version of the corpus, it is seen that the new annotation scheme leads to many more cues (6,725 cue phrases in 4,718 uncertain sentences in the original version vs. 10,794 cues in 7,336 sentences in the version described here) and – although the datasets are not directly comparable – it gives a much better performance: the best system achieved an F-score of 60.2 on weasel detection at the sentence level and 36.5 at the cue level and no classes of cues were distinguished there (Farkas et al., 2010). This difference may be attributed to several factors. First, not all hedge phenomena (used in the sense introduced here) were systematically annotated in the CoNLL-2010 corpus.

Second, complex syntactic structures that contained several types of uncertainty were annotated as one complex cue (e.g. the phrase *it has been widely suggested*, which contains epistemic uncertainty (*suggested*), weasel (passive sentence with no agent) and hedge (*widely*) as well). Third, the CoNLL-2010 version did not distinguish subtypes of cues, i.e. semantic uncertainty and weasels were annotated in the same way. It was probably because of this lack of distinction that participants of the shared task got considerably lower results for Wikipedia articles than for biological papers, which contained fewer weasel cues (Farkas et al., 2010). However, the new annotation makes it possible to select those types of uncertainty that are relevant for a given application, see Section 6.

## 6 Discourse-level Uncertainty and NLP

Detecting weasels is of utmost importance in every information extraction application where it should be known who the author/source is. Thus, information extraction applied for the news media may certainly profit from finding weasels, i.e. missing or undeterminable sources. Pieces of information without an identifiable (and reliable) source require special treatment: they will be excluded from the news or they will be communicated to the public in a special form, using phrases such as *according to unnamed sources* etc.

In sentiment analysis and opinion mining, the identification of subjective terms is essential. These terms are often ambiguous hence a subjectivity word sense disambiguation is needed (Wiebe, 2012). In our corpus, peacock terms and intensifiers – a subtype of hedges – are manually annotated, thus it can be used in the development and evaluation of tools that seek to disambiguate elements of a subjectivity lexicon in running texts.

Information retrieval may also be enhanced by detecting discourse-level uncertainty. In order to find relevant documents for queries that contain numbers, more specifically, to improve recall in such cases, it is important to handle numeric hedges. For instance, if someone looks for websites describing games appropriate for ten year old children, he also may be interested in games that are for children over eight. Thus, the search engine should be prepared for recognizing that the number specified in the query (“ten”) is part of other numeric sets (e.g. “over eight”) and in this way, more relevant hits can be retrieved.

The linguistic processing of patents especially requires that hedges should be recognized. There is a tendency to generalize over the scope of the patent (i.e. hedges are used) in order to prevent further abuse (Osenga, 2006). Thus, the scope of the patents can be expanded or other use cases can later be included in the patent. Hence, any NLP system that aims at patent processing must target hedge detection as well.

Document classification may also profit from detecting discourse-level uncertainty since different genres of texts involve different types of uncertainty. For instance, papers in the humanities contain significantly more hedges than papers in sciences (Rizomilioti, 2006). Thus, the frequency of hedges may be indicative of the domain of the text as well, which again may be exploited in document classification.

## 7 Conclusions

In this paper, we presented a classification of discourse-level uncertainty phenomena, and focused on the concepts of source, fuzziness and subjectivity. We also introduced a corpus of Wikipedia articles in which linguistic cues for each type of discourse-level uncertainty – weasel, peacock and hedge – were manually annotated. We carried out some baseline experiments on discourse-level uncertainty detection, which may prove useful in information extraction and retrieval, sentiment analysis and opinion mining.

In the future, we intend to develop a machine-learning based uncertainty detector. We would also like to investigate the distribution of weasels, hedges and peacocks in other types of texts (e.g. news media or scientific papers) and in other languages as our three categories are language-independent. Moreover, to learn how domain-dependent the model is, we plan to do some domain adaptation experiments as well.

## Abstract

This paper presents a methodology to exploit the potential of Arabic Wikipedia to assist in the automatic development of a large Fine-grained Named Entity (NE) corpus and gazetteer. The corner stone of this approach is efficient classification of Wikipedia articles to target NE classes. The resources developed were thoroughly evaluated to ensure reliability and a high quality. Results show the developed gazetteer boosts the performance of the NE classifier on a news-wire domain by at least 2 points F-measure. Moreover, by combining a learning NE classifier with the developed corpus the score achieved is a high F-measure of 85.18%. The developed resources overcome the limitations of traditional Arabic NE tasks by more fine-grained analysis and providing a beneficial route for further studies.

## 1 Introduction

Previous efforts that have been made to develop an Arabic NER either focused on traditional NE classes (Benajiba et al., 2010) or sought to expand only one class at a time (Shaanan and Raza, 2007). Applications such as Question Answering (QA) receive more benefits when a fine-grained NER is developed. This is true when we consider that, the majority of factoid questions are about named entities (Noguera et al., 2005). Having a finer NER, results in the possibility of extracting more semantic knowledge from the context. For example, if we consider the following sentence:

شركة والت ديزني هي أكبر شركات وسائل الإعلام والترفيه في العالم /šrkħ wAlt dyzny hy Okbr šrkAt wsAÿl AllçlAm wAltrfyh fy AlçAlm/ 'Walt Disney is the largest media company in the entertainment world'<sup>1</sup>

We would have more semantic information if we could tag (الت ديزني /wAlt dyzny/ 'Walt Disney')

<sup>1</sup>Throughout this paper, Arabic words are represented in three variants: (Arabic word /HSB transliteration scheme (Habash et al., 2007) / "English translation")

as [ORG-ENTERTAINMENT] rather than just [ORG]. This deeper semantics is very helpful when answering factoid question like "What is the largest entertainment company?"

Supervised machine learning technologies have been successfully adopted for several natural language tasks, including NER. These technologies require a reasonable portion of data to be accessible in the training phase, containing a number of positive and negative examples to learn from and to circumvent the problem of data sparseness. Traditional methods for compiling such data involve recruiting individuals to annotate a certain corpus manually. This is tedious work, as well as costly and time consuming. Moreover, manually annotating a large portion of a relatively open domain corpus beyond a news-wire and across various genres is not easy for an individual to achieve.

Therefore, when developing a reasonable fine-grained NE corpus two questions should be answered. First, *what proper fine-grained semantic classes should be established?* Second, *how to develop a reasonable sized fine-grained NE corpus at minimum cost?* This work answers those questions.

To these ends the methodology we devised was designed to utilise the availability and growth of Arabic Wikipedia to develop a large and extendable fine-grained named entity corpus and gazetteer with minimum human intervention. The contributions of this paper are:

1. It introduces a two-level tagset for Wikipedia NEs;
2. It develops a large fine-grained automatic NE corpus using minimum human intervention;
3. It develops a large fine-grained gazetteer; and
4. It thoroughly evaluates the resulting corpus and gazetteer.

## 2 Arabic Wikipedia and Named Entity

Wikipedia is an extensive collaborative project on the web in which articles are published and reviewed by volunteers from around the world. Wikipedia includes

271 different languages, with the Arabic version ranked 27th with more than 210,000 articles. The annual increase in the number of articles is 30% (Wikipedia, 2013). The actual relationship between the Named Entity and Wikipedia is that a large percentage of Wikipedia articles are about named entities (Alotaibi and Lee, 2012). This provided the motivation to utilise Wikipedia’s underlying structure to produce the target resources.

To this end, it is beneficial to provide an overview of the critical aspects of the Wikipedia structure:

- **Articles:** These can be one of the following:

1. **Normal article:** Each article has a unique title and contains authentic content; i.e. textual data, images, tables, items and links, related to the concept represented in the title. These are in the majority.
2. **Redirected article:** These contain a specific tag to redirect the enquirer to a normal article. For example: for the redirected article titled (بريطانيا العظمى /bryTAnyA AlçĎmý/ ‘Great Britain’), there is a redirected tag to (المملكة المتحدة) /Almmlkĥ AlmtHdĥ/ ‘United Kingdom’. This tag is written thus #REDIRECTED[[المملكة المتحدة]].
3. **Disambiguation article:** These are used to list all the article titles that share ambiguities.

- **Links types:** There are two types of links in Wikipedia and they are described below:

1. **Non-piped links:** this type of links denotes that the display phrase of the link and the article’s title are the same. For example: [[London]].
2. **Piped links:** this type of link allows for the text that appears in the contextual data to be different from the actual article it refers to. For example: [[UK|United Kingdom]], where “UK” appears in the display text, while “United Kingdom” refers to the titles of the article.

Throughout this paper, the terms “link” and “link phrase” are used interchangeably to refer to the same thing.

- **Connectivity:** Used links, of any type, in the contextual data of any normal article, provide connectivity and thereby an underlying structure for Wikipedia; we are seeking to utilise to achieve our goal.

### 3 Transforming Arabic Wikipedia into a Fine-grained NE corpus and Gazetteer

In this section we present in detail the approach advised to automatically develop a tagged fine-grained named entity corpus and gazetteer based on Arabic Wikipedia.

#### 3.1 The Conciseness of the Approach

Our assumption regarding this work is as follows:

If we are able to classify Wikipedia articles into NE classes, we will then be able to map the resultant labelling back into contextualised linked phrases. This involves the following steps:

1. Defining a fine-grained taxonomy suitable to Wikipedia;
2. Classifying Arabic Wikipedia articles into a pre-defined set of fine-grained NE classes;
3. Mapping the results of the classification back to the linked phrases in the text;
4. Detecting successive mentions of NE that have not been associated with links, while taking into account the Arabic morphological variation of the NE phrase; and
5. Selecting sentences to be included in the final corpus.

#### 3.2 Defining Fine-grained Semantic NE Classes

Sekine et al. (2002) proposed a hierarchical named entity taxonomy that is very fine, with 150 subclasses. The methodology they used to construct semantic classes relies on analysing the named entities in a newswire corpus, in addition to analysing the answer type for a set of questions used in a Text Retrieval Conference TREC-QA task. WordNet noun hierarchy is also used to shape the classes further. Two years later, Sekine and Nobat (2004) added an extra 50 classes and decomposed some classes, such as “disease” and numeric expression respectively. Although the spectrum of classes is very wide, the specific descriptions and definitions for each class strives to avoid overlap and ambiguity, making it difficult to define. This taxonomy has been applied to both English and Japanese.

Some NLP applications, such as QA have designed their own named entity classes, based on the criteria they believe to be the most valuable. Harabagiu et al. (2003) developed a named entity recognition component in which one level consists of 20 defined fine grained classes. Knowing that factoid type questions require named entities, Li and Roth (2006) defined a fine grained taxonomy to answer certain types of questions. Although, their two layer taxonomy covered 50 fine grain classes of different types, some types were unrelated to named entities such as definition, description, manner and reason. Based on the same trend, Brunstein (2002) presented a two-level taxonomy in which 29 answer types are subdivided into 105 subtypes. Other researchers have adopted and used their taxonomy for named entity taxonomy (Nothman et al., 2008).

It is evident that there is no widely agreed fine grained taxonomy that can be directly adopted into Arabic; although ACE taxonomy is a reasonable choice

in the sense that it organises granularity into two layers, i.e. coarse and fine grained. In the evaluation of ACE (2008), the number of fine grain classes is 45. This taxonomy is designed in two levels of granularities and frequently used in the news-wire domain. Moreover, two-level taxonomy allows us to map a tagset into different traditional schemes easily, such as CoNLL or MUC.

Thus, ACE (2008) taxonomy was selected and because it is designed for a news-wire domain we applied some amendments to tailor it for use in a relatively open domain corpus, such as Wikipedia. For example, there are many articles in Wikipedia about people in different subclasses, such as scientists, athletes, artists, politicians, etc. These fine classes are not included in ACE, as it only involves three sub-classes: the individual, group and indeterminate. Another modification is performed; a new class called “Product” is added. This modified taxonomy is presented in Table 1.

Coarse-grained Classes	Fine-grained Classes
<i>PER: Person*</i>	<i>Politician*, Athlete*, Businessperson*, Artist*, Scientist*, Police*, Religious*, Engineer*, Group, Other*.</i>
ORG: Organisation	Government, Non-Governmental, Commercial, Educational, Media, Religious, Sports, Medical-Science, Entertainment.
LOC: Location	Address, Boundary, Water-Body, Celestial, Land-Region-Natural, Region-General, Region-International.
GPE: Geo-Political	Continent, Nation, State-or-Province, County-or-District, Population-Center, GPE-Cluster, Special.
FAC: Facility	Building-Grounds, Subarea-Facility, Path, Airport, Plant.
VEH: Vehicle	Land, Air, Water, Subarea-Vehicle, Unspecified.
WEA: Weapon	Blunt, Exploding, Sharp, Chemical, Biological, Shooting, Projectile, Nuclear, Unspecified.
<i>PRO:Product*</i>	<i>Book*, Movie*, Sound*, Hardware*, Software*, Food*, Drug*, Other*.</i>

Table 1: ACE (2008) modified taxonomy. The modified or added classes are represented with italics and asterisks

### 3.3 Wikipedia Document Classification

The aim of classifying Wikipedia articles is to produce a list of two tuples, like <article’s title, fine-grained NE tag>. The following sub sections describe the steps taken to achieve this goal.

#### 3.3.1 Fine-grained Document Annotation and Quality Evaluation

In order to classify Arabic Wikipedia articles into named entity classes, we manually annotated 4000 articles into two levels of granularity, i.e. coarse and fine grained, using the modified taxonomy shown in Table 1. Two Arabic natives were involved in the annotation process and the inter-annotator agreement between the annotators was calculated using Kappa Statistic (Carletta, 1996). Table 2 shows that the inter-annotator agreement was calculated for different sizes of documents, i.e. 500, 2000 and 4000. This revealed difficulties that might be encountered during the annotation process.

Level	<i>Kappa:</i> n=500	<i>Kappa:</i> n=2000	<i>Kappa:</i> n=4000
Coarse-grained	92	98	99
Fine-grained	80	95	97

Table 2: Inter-annotator agreement in coarse and fine grained levels

#### 3.3.2 Features Engineering and Representation

We developed our classification model relying on the set of features proposed by Alotaibi and Lee (2012) as these score 90% on the F-measure for coarse grained level. The features were:

1. **Simple Features (SF):** which represent the raw dataset as a simple bag of words without further processing.
2. **Filtered Features (FF):** involving removing the punctuation and symbols, filtering stop words and normalising digits.
3. **Language-dependent Features (LF):** represent the tokens in their stem form.
4. **Enhanced Language-dependent Features (ELF):** involving tokenising the sentence and assigning parts of speech for each token. This allows filtering of the dataset by involving only nouns (for instance) in the classifier.

In addition, we extended this set of features by extracting two more features:

1. **First paragraph:** Instead of just relying on the first sentence as in (Alotaibi and Lee, 2012), we identified useful features spread across the first paragraph.
2. **Bigram:** By using this feature, we aim to examine the effects of the collocation of tokens. Here we added the representation of a bigram while still preserving the unigram.

We represent the feature space using the term frequency-inverse document frequency (tf-idf).

### 3.3.3 Fine-grained Document Classification Results

The annotated dataset was divided into training and test at 80% and 20% respectively. We chose the Support Vector Machine (SVM) and Stochastic Gradient Descent (SGD) as a probabilistic model for the classifier. In each round of the classification, we tested one set of features and selected the one that performed best.

Table 3 shows the overall results for the fine-grained classification. There are three main findings. First, both classifiers tend to perform in a very similar way; therefore, in practice, use of either classifier to perform the final classification for the whole Wikipedia dataset will be expected to deliver very similar results. The second finding is that, the bigram features have little effect when different features are set. Finally, the best result for both classifiers was achieved using the  $ELF_{Uni}$  feature.

Features set	SVM			SGD		
	P	R	F	P	R	F
$SF_{Uni}$	0.78	0.79	0.78	0.78	0.79	0.78
$SF_{Uni+Bigram}$	0.80	0.81	0.80	0.80	0.81	0.79
$FF_{Uni}$	0.80	0.81	0.80	0.81	0.82	0.80
$FF_{Uni+Bigram}$	0.81	0.82	0.81	0.81	0.82	0.81
$LF_{Uni}$	0.77	0.78	0.77	0.78	0.79	0.78
$LF_{Uni+Bigram}$	0.79	0.80	0.79	0.79	0.80	0.79
$ELF_{Uni}$	0.82	0.83	0.82	0.82	0.83	0.82
$ELF_{Uni+Bigram}$	0.81	0.82	0.81	0.82	0.82	0.81

Table 3: The average fine-grained classification results when using SGD and SVM over different features sets where (tf-idf) is applied

### 3.4 Compiling the Corpus

Compilation of the final corpus was achieved according to the pipeline steps as follows:

1. Prepare and extract the features for all Arabic Wikipedia datasets, according to the method presented in Section 3.3.2;
2. Train an SVM classifier using the training dataset (4000 articles);
3. For each Wikipedia article, classify the article into the target fine-grained NE class;
4. Prepare final list of all articles' titles and their tags; and
5. Detect successive mentions of the named entity that have not been associated with the link:

As a convention, a linking phrase in the text of any Wikipedia article should only be assigned the first time it appears in context; successive mentions of the phrase appear with no link. Therefore, not all NE phrases are linked every time. Detecting successive mentions works by finding and matching

possible NE phrases in the text that share similarity, to a certain extent, with each phrase in the list of linked NE phrases. The main goal of this step is to augment the plain text with NE tags and to address some of the lexical and morphological variations that arise when a named entity is contextualised. For example, a named entity of (سعود الفيصل /sçwd Alfysl/ 'Saud Alfaisal') is expected to be repeated in context with either the first name (سعود /sçwd/ 'Saud') or the last name (الفيصل /Alfysl/ 'Alfaisal') or both together. This can also be difficult when prefixes are used. For example (و لسعود /wlsçwd/ 'and for Saud'). Therefore, we prepare for and match all the variations of prefixes that can be attached to the NE.

6. Produce the NE annotated corpus by selecting sentences to be included in the final corpus.

#### 3.4.1 To Which Extent to Select Sentences to be Involved in the Final Corpus?

We decided to compile two versions of the developed corpus. The first version is called "WikiFANE<sub>Whole</sub>", which means that we retrieved all the sentences from the articles. On the other hand, the second version, i.e. WikiFANE<sub>Selective</sub>, is compiled by selecting only the sentences, which have at least one named entity phrase. This creates a Wikipedia corpus that has as high a density of tags as possible.

In this paper and for evaluation purposes, we compiled the corpus for more than 2 million tokens as shown in Table 4. Meanwhile, this methodology allows all of Arabic Wikipedia to become a tagged fine-grained NE corpus. Moreover, both versions of this dataset were freely distributed to the research community<sup>2</sup>.

Corpus	# of sentences	# of tokens
WikiFANE <sub>Whole</sub>	76821	2,023,496
WikiFANE <sub>Selective</sub>	57126	2,021,177

Table 4: The total number of sentences and tokens for the compiled corpora

## 4 Introducing a Fine-grained Arabic NE Gazetteer

The process of classifying Wikipedia articles into NE classes provides the benefit of compiling a large Arabic NE Gazetteer at two levels of granularity. Based on our best knowledge, the only Arabic NE gazetteer currently available is that produced by Benajiba et al. (2007) covering only three traditional NE classes, i.e. PER, ORG and LOC. The size of this gazetteer

<sup>2</sup>The fine-grained Arabic NE corpora, i.e. WikiFANE<sub>Whole</sub> and WikiFANE<sub>Selective</sub> are freely available at <http://www.cs.bham.ac.uk/~f5a081/resources.html>

is 4132 entities. Table 5 compares the distribution between ANERgazet and WikiFANE<sub>Gazet</sub>. Due to the space limitation, we only present the coarse level distribution of WikiFANE<sub>Gazet</sub>. It is clearly shown that, WikiFANE<sub>Gazet</sub> has superiority in the sense of type and coverage. The gazetteer produced is freely available to the research community to use and extend<sup>3</sup>.

## 5 Evaluation and Results

To evaluate the fine-grained NE corpus and gazetteer produced, we conducted a set of thorough experiments. The aims of the evaluation were to answer the following questions:

- What is the quality of the corpus produced and the gazetteer in terms of annotation?
- How efficient is the NE classifier when used with WikiFANE<sub>Whole</sub> and WikiFANE<sub>Selective</sub> and tested over cross-domain and within-domain datasets?

### 5.1 Evaluating the Annotation Quality

The performance of document classification across all Wikipedia articles is crucial to avoid error propagation from the document classification stage when compiling the final version of the annotated corpus. Therefore, the first evaluation focused on this aspect. After classifying all articles to the target NE classes, we drew another 4000 articles, to be represented as a sample for all Wikipedia articles, and manually annotated them. The selection of the articles was made by selecting the first 4000 articles with identical glyphs to those used most frequently in other Wikipedia articles. This criteria ensured that the most frequent NE were classified properly with a minimum error rate. After this, we calculated the inter-annotation agreement between the manually annotated, gold-standard documents, and that classified based on step 3 in Section 3.4. Table 6 shows the result for both levels of granularity. The overall Kappa for the fine-grained level is 82.6% and this is

<sup>3</sup>The fine-grained Arabic NE gazetteer WikiFANE<sub>Gazet</sub> is freely available at <http://www.cs.bham.ac.uk/~fsa081/resources.html>

Level	Accuracy	Overall Kappa
Coarse-grained	85.8	84.02
Fine-grained	82.9	82.6

Table 7: The set of language dependent and independent features extracted to be used by the classifier

consistent with the results shown in Section 3.3.3. This gives the impression that, the error rate is at a minimum, even when performing the classification across all Wikipedia articles with small amounts of training data.

### 5.2 Evaluating the Corpus Developed by Learning NE Classifier

This evaluation was designed to evaluate the corpus developed by using it as training data to test it over cross-domain and within-domain datasets. Moreover, this assists evaluation of the efficiency of using gazetteer as external knowledge resource. We parsed the different datasets and tokenised the sentences using AMIRA (Diab, 2009) relying on the scheme (Conjunction + Preposition + Prefix). The concept behind using this tokenisation scheme is that, the notable sparseness issues regarding Arabic NE are caused by agglutination of the prefixes. In this scheme, we guaranteed that the named entities like (خالد /xAld/ ‘Khalid’) in the training data also refer to (ولخالد /wlxAld/ ‘and for Khalid’) in the test data. This happens by tokenising the words and splitting the prefixes, so the result will be three different tokens (و /w/ ‘and’), (ل /l/ ‘for’) and (خالد /xAld/ ‘Khalid’).

We extracted traditional sets of features at different levels; including lexical, morphological, syntactical and external knowledge. Table 7 summarises the features used where a window of five features are encoded in the classifier including the current position.

The following set of experiments was conducted relying on the Conditional Random Field (CRF) probabilistic model to perform the sequence labelling. In all the experiments, we divided the datasets into training and test at 80% and 20% respectively. We used the three metrics, precision, recall and F-measure, to evaluate the results.

### 5.2.1 Tags Distribution for the Gold-standard Newswire-based NE Corpora and WikiFANE

Different corpora have been used by researchers to develop NER. The first one is ANERcorp, which developed by Benajiba et al. (2007) and is freely accessible. It is a 150K news-wire based corpus tagged with CoNLL traditional coarse classes, i.e. PER, ORG, LOC and MISC. ACE produced two datasets named ACE 2004<sup>4</sup> and ACE 2005<sup>5</sup> which are subject to a costly licence. This prevents us using those corpora in the evaluation. However, ACE also produced a multilingual small corpus called REFLEX Entity Translation Training/DevTest (REFLEX for short), which consists of about 60K of tokens with two levels of classes. This is divided according to its origin into news-wire (NW), treebank (TB) and web blogs (WL). We used both the ANERcorp and the Arabic portion of REFLEX as gold-standard corpora to conduct the evaluation.

Table 8 shows the tag distribution for each corpus per class and the total per token and phrase. We use (NA) as an indication of no availability in the dataset. It is clearly shown that WikiFANE<sub>Selective</sub> has wider distributed tags compared with WikiFANE<sub>Whole</sub>.

### 5.2.2 Gazetteer Evaluation

Using gazetteer as an external knowledge source in NER helps to boost the performance of NER (Carreras et al., 2002). To evaluate the gazetteer produced, we learned the classifier by news-wire dataset one at a time. Each time, we evaluated the presence and absence of WikiFANE<sub>Gazet</sub>. Due to ANERcorp dataset being coarse-grain level, we decided to map the REFLEX dataset to the same scheme used by ANERcorp. In addition, we eliminated the MISC class used by ANERcorp because there is no direct equivalent in REFLEX. Three main points arose from this experiment. First, the F-measure increased by at least 2 points for all datasets, showing the overall positive effect of the developed gazetteer. Second, the recall metric clearly boosted the classifier enabling retrieval of more NE phrases than would be possible without WikiFANE<sub>Gazet</sub>. Third, the TB sub-dataset of REFLEX showed dramatic improvement in comparison with other datasets, because that TB dataset had comparatively less noise.

Table 9: The comparison for using WikiFANE<sub>Gazet</sub> as external knowledge over news-wire dataset

### 5.2.3 Cross-domain Evaluation

The purpose of cross-domain evaluation is to train the classifier on a certain domain and then test this over different datasets with different domains or genres. The aim behind this experiment is to evaluate the effect when using WikiFANE<sub>Whole</sub> and WikiFANE<sub>Selective</sub> as training data versus news-wire domain datasets. This experiment helps to clarify the suitability of using WikiFANE as a relatively open domain corpus. It is evident from Table 10 that, self-training of ANERcorp and REFLEX produces the best performance. Meanwhile, there are some interesting findings. Even though REFLEX is a news-wire based corpus, its performance is dramatically lower when it is used as training dataset and tested over ANERcorp. This is also the case when training ANERcorp and testing it over REFLEX. This implies that, even within the same domain, news-wire, there is less generalisability for the current news-wire dataset across different datasets. Another interesting finding is that, the version of WikiFANE<sub>Selective</sub> performs better than WikiFANE<sub>Whole</sub> on different test sets, except for with ANERcorp. This might be because WikiFANE<sub>Selective</sub> has a greater tag density than WikiFANE<sub>Whole</sub>, which leads to more positive examples in the dataset.

Training	Testing											
	ANERcorp			REFLEX								
				NW			TB			WL		
	P	R	F	P	R	F	P	R	F	P	R	F
ANERcorp	87.86	72.34	79.35	80.60	58.38	67.71	79.31	64.92	71.40	74.23	52.55	61.54
REFLEX	73.57	50.07	59.59	88.21	72.79	79.76	89.20	76.61	82.43	84.69	66.61	74.57
WikiFANE <sub>Whole</sub>	81.53	43.10	56.39	71.43	37.84	49.47	84.11	51.21	63.66	71.43	36.50	48.31
WikiFANE <sub>Selective</sub>	88.10	37.52	52.62	86.99	42.16	56.80	86.49	51.61	64.65	84.43	37.59	52.02

Table 10: The result of cross-domain evaluation

Corpus		P	R	F
ANERcorp + WikiFANE <sub>Selective</sub>		90.40	58.21	70.81
REFLEX + WikiFANE <sub>Selective</sub>	NW	90.55	62.16	73.72
	TB	86.52	62.10	72.30
	WL	86.01	52.74	65.38

Table 11: The result of combining WikiFANE<sub>Selective</sub> with news-wire corpora

To elaborate more on cross-domain evaluation we evaluated the merging of WikiFANE<sub>Selective</sub>, since it performed best in the previous experiment, with both ANERcorp and REFLEX. The idea behind this experiment was to understand how the classifier performs when different domains and genera are combined together. The most notable findings, as shown in Table 11 are that, the recall metric shows a sharp drop in all datasets. However, the precision shows high scores, suggesting the Wikipedia corpus is strong in difference when compared with the news-wire domain.

### 5.2.4 Within-domain Evaluation

The traditional practice of learning NE classifier is to draw the training and test datasets from single domain. Therefore, we divided WikiFANE<sub>Whole</sub> and WikiFANE<sub>Selective</sub> into training and test for 80% and 20% respectively and then training the CRF classifier on WikiFANE<sub>Whole</sub> and WikiFANE<sub>Selective</sub> separately with and without the injection of the WikiFANE<sub>Gazet</sub> as an external knowledge source. Table 12 shows that, the use of WikiFANE<sub>Gazet</sub> creates a notable improvement across datasets by at least 3 points on the F-measure. In addition, WikiFANE<sub>Selective</sub> has a slightly superiority over WikiFANE<sub>Whole</sub> advising that both datasets are performing at a promising level of accuracy.

## 6 Related Work

A promising trend in the research is towards automatically developing an annotated NE corpus that extends beyond both traditional classes and the domain of newswire, in order to create novel resources. One of the earliest of these approaches was presented by An et al. (2003) in which the web was used to build a target corpus, using bootstrapping to build an anno-

tated NE corpus. A further approach utilises parallel corpora to build an NE corpus automatically. This relies on the suggestion that once one corpus is annotated then other parallel corpora can be easily annotated using projection. Ehrmann et al. (2011) developed multilingual NE corpora for English, French, Spanish, German and Czech. Similarly, Fu et al. (2011) developed a Chinese annotated NE corpus exploiting an English aligned corpus. The difference here is that the alignment is conducted between both corpora at the word-level.

Beyond the newswire-based corpora, Wikipedia becomes more attractive for different NLP tasks. Some researchers have exploited the unrestricted accessibility of Wikipedia to establish an automatic fully annotated NE corpus with different granularity; meanwhile others are merely focusing on partially utilising Wikipedia to achieve specific goals, such as developing a NE gazetteer (Attia et al., 2010) or classifying Wikipedia articles into NE semantic classes (Saleh et al., 2010).

Tkatchenko et al. (2011) expanded the classification into an 18 fine-grain taxonomy extracted from (BNN). To prepare training data for use in the classification stage, a small set of seeds is constructed, as undertaken by Nadeau et al. (2006), in which a semi-supervised bootstrapping approach was used to construct long lists of entities in different fine-grain NE classes from the web. After the list is constructed, the entities are then intersected with Wikipedia articles so as to classify each article according to its target class. Therefore, a set of 40 articles per fine-grain class was produced for use in training with the Naïve Bayes and Support Vector Machine (SVM). Several similar features have been selected (e.g. (Saleh et al., 2010; Dakka and Cucerzan, 2008)).

Instead of relying on machine learning, Richman and Schon Richman and Schon (2008) defined a set of heuristics involving using assigned category links to classify articles. Phrasal patterns for each semantic NE class were specified when a matching article was classified; alternatively the procedure searched the upper level of categories to find candidates. These articles are still classified according to traditional coarse grain classes.

Closely related to our work are attempts to build a completely annotated NE corpus free from human in-

Corpus	PER			ORG			LOC			Overall

WikiFANE <sub>Selective</sub>	96.37	88.75	92.40	96.12	91.73	93.87	82.55	75.73	78.99	88.77	81.86	85.18

Table 12: The result for within-domain evaluation

tervention. The first attempt to transform Wikipedia into an annotated NE corpus was made by Nothman et al. (2008); they assumed that many NEs are associated with Wikipedia inter-links, i.e. the hyperlinks associated with a phrase in contexts pointing to another article. Therefore, the procedure first identified NEs using heuristics to exploit capitalisation, and then the target articles were classified into NE semantic classes. A bootstrapping approach is then used to extract seeds from a set of 1300 articles. Two distinguishing features were extracted per article; i.e. the head noun for the category links and the head noun for the definitional sentence. The corpus produced covered 60 fine-grained classes in two layers. An alternative approach to the same data set is presented by Tardif et al. (2009), in which the classification relies on supervised machine learning. Like Dakka and Cucerzan (2008), both Naïve Bayes and the Support Vector Machine (SVM) have been used as statistical interfaces for the purpose of classification. A total of 2311 articles have been manually annotated and a combination of structured and unstructured features extracted.

The corpus produced by Nothman et al. (2008) has been thoroughly experimented with to evaluate the impact of its performance. Three different gold-standard corpora, i.e. MUC, CoNLL and BNN, were used for comparative purposes and separate models built for each corpus. The experiment showed that, when in conjunction with other gold-standard corpora the Wikipedia-based corpus could raise their performance; it also performs well for non-Wikipedia texts (Nothman et al., 2009).

## 7 Conclusion

We presented a methodology to develop a large size fine-grained named entity corpus and gazetteer using an automatic approach. This involved recruiting document classifications. Using this methodology, we produced constantly evolving NE resources that will exploit the yearly growth rate of Arabic Wikipedia.

The freely fine-grained NE corpus and gazetteer produced when used on their own are of a very promising quality and extend the scope of research beyond traditional NE tasks.

# Ranking Translation Candidates Acquired from Comparable Corpora

Rima Harastani and Béatrice Daille and Emmanuel Morin

LINA UMR CNRS 6241 - University of Nantes

2 rue de la Houssinière, BP 92208

{rima.harastani,beatrice.daille,emmanuel.morin}@univ-nantes.fr

## Abstract

Domain-specific bilingual lexicons extracted from domain-specific comparable corpora provide for one term a list of ranked translation candidates. This study proposes to re-rank these translation candidates. We suggest that a term and its translation appear in comparable sentences that can be extracted from domain-specific comparable corpora. For a source term and a list of translation candidates, we propose a method to identify and align the best source and target sentences that contain the term and its translation candidates. We report results with two language pairs (French-English and French-German) using domain-specific comparable corpora. Our method significantly improves the top 1, top 5 and top 10 precisions of a domain-specific bilingual lexicon, and thus, provides a better user-oriented results.

## 1 Introduction

Comparable corpora have been the subject of interest for extracting bilingual lexicons by several researchers (Rapp, 1995; Fung and Mckeown, 1997; Rapp, 1999; Koehn and Knight, 2002; Morin et al., 2008; Bouamor et al., 2013, among others). Rapp (1995) was the first to suggest that if a word  $A$  co-occurs frequently with another word  $B$  in one language, then the translation of  $A$  and the translation of  $B$  should co-occur frequently in another language. Approaches emerging from (Rapp, 1995) make different assumptions to extract bilingual lexicon from comparable corpora. However, they are all based on the assumption that a translation pair shares some similar context in comparable corpora. We refer to such approaches that depend on co-occurrences of

words to extract a bilingual lexicon by *distributional approaches*. Results obtained from distributional approaches vary according to many parameters. For example, one of the parameters that impacts the performance of distributional approaches is the way the context of a word is defined. Various approaches defined contexts differently: windows (Rapp, 1999), sentences or paragraphs (Fung and Mckeown, 1997), or by taking into consideration syntax dependencies based on POS tags (Gamallo, 2007). However, the most common way the context of a word is defined is by choosing words within windows centered around the word (Laroche and Langlais, 2010), usually of small sizes (e.g. a window of size 3 is used by Rapp (1999)).

Domain-specific comparable corpora have been used for bilingual terminology extraction. These corpora are of modest sizes since large domain-specific corpora are not available for many domains (Morin et al., 2008). As a matter of fact, distributional approaches perform best with large comparable corpora, and thus they often give lower precisions when applied to domain-specific comparable corpora (Chiao and Zweigenbaum, 2002).

The goal of our work is to find translations of terms in domain-specific comparable corpora. Taking a list of ranked translation candidates (provided by a distributional method) for a term, we aim to improve the ranking of the correct translations that are not ranked first in the list. Obviously, the more translation candidates for a term are considered, the more correct translations are found. For example, Rapp (1999) obtains a precision of 72% when only the first translation candidate is considered correct. However, he reports an 89% precision when the first 10 translation candidates are provided as translations for a word.

This study proposes to take the best translation candidates provided by a distributional approach,

and tries to re-rank them in order to improve the top 1, top 5 and top 10 precisions. We suggest that a source term and its correct translation appear in comparable sentences. Comparable sentences are sentences that share parallel data (e.g. word overlap, long matched sequences, bilingual compound nouns). We proceed by first extracting sentences for a source term, as well as sentences for each of its provided translation candidates. For each translation pair (i.e. source term and a translation candidate), each extracted source sentence is aligned with at most one of the extracted sentences for the translation candidate. The aligned sentences are used to re-rank the translation candidates of the source term.

Besides being used by our approach to re-rank translations, comparable sentences that contain a term and its translation in corpora are promising, as they may be useful examples to a user or a human translator that needs to verify a translation pair.

In Section 2, we present our approach and assumptions. In Section 3, we describe our method to extract sentences that best represent a term in corpora. In Section 4, we explain a method to score a sentence containing a term with a sentence containing its translation candidate. We evaluate our approach in Section 5 on two domain-specific corpora for the French-English and French-German language pairs, and report improvements in the top 1, top 5, and top 10 precisions. We conclude in Section 6.

## 2 Assumptions and Approach

A term may appear in several contexts, but some can be more interesting and more informative than others. In Table 1, an example of two sentences in which the term “tumor” appears is given. These sentences were extracted from an English corpus related to the domain of “Breast Cancer”. Sentence (A) is considered to be more informative and more representative of the context of “tumor” than sentence (B). It also contains terms that are highly related to the “Breast Cancer” subject (e.g. chemotherapy, histological).

Our assumption is that the best context (represented by sentences) can be extracted for a term as well as for its translation candidates, and that these extracted sentences can be aligned in order to re-rank the translation candidates of the term.

After obtaining some candidate translations for

(A)	<b>Chemotherapy</b> was also administered to patients with smaller primary <u>tumors</u> with <b>histological</b> grade 2 or 3 or with negative hormone receptors.
(B)	The size of any captured image corresponding to the <u>tumor</u> was estimated.

Table 1: Sentence (A) and (B) containing the term “tumor”

a term by applying a distributional method, we score a source term ( $t_s$ ) with its target translation candidate ( $t_t$ ) as follows: we first extract the  $n$  best sentences that contain  $t_s$  in the source corpus as well as the  $n$  best sentences that contain its translation candidate in the target corpus. Then, we align each of the best sentences of  $t_s$  with at most a sentence of  $t_t$  using a method that depends on lexical similarity. Finally, the translation pair ( $t_s, t_t$ ) is scored according to the scores of the aligned sentences between  $t_s$  and  $t_t$ . The scoring method is illustrated in Figure 1. We combine the resulting score with its initial score that is provided by a distributional method. Combined scores are then used to re-rank translation candidates of the specific term.

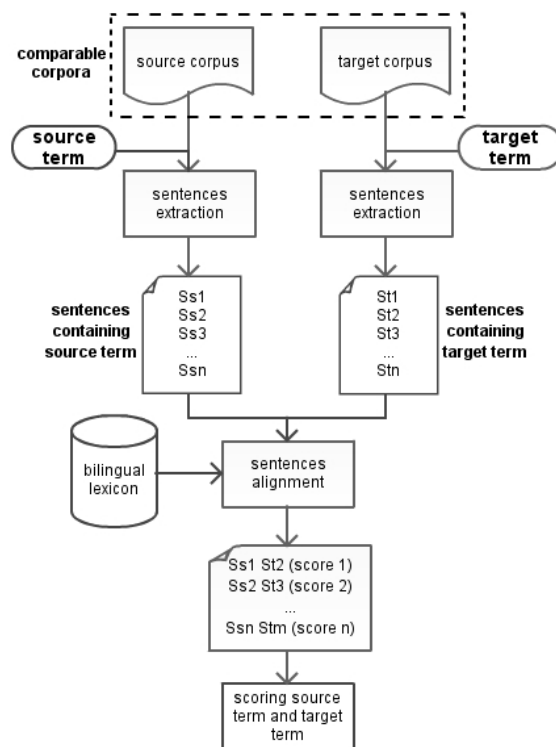

Figure 1: Method to score a translation pair (source term and target term)

Parallel sentence (or fragment) extraction from comparable corpora has received the attention of a number of researchers (Fung and Cheung, 2004; Munteanu and Marcu, 2005; Munteanu and Marcu, 2006; Smith et al., 2010; Hunsicker et al., 2012, among others), to enrich parallel text used by statistical machine translation (SMT) systems. They conducted experiments with large corpora (mainly news stories) which were noisy parallel, comparable (contain topic alignments or articles published in similar circumstances), or very non-parallel (Fung and Cheung, 2004). Usually, these approaches perform document-level alignments before extracting parallel sentences. The domain-specific corpora we use contain few documents (ranging from 38 to 262 documents for each corpus) and no parallel sentences. Furthermore, they are of modest size (about 0.3 M to 0.5 M words), so even if there were some parallel fragments, this phenomenon would be rare. Nevertheless, we assume that some features used in state-of-the-art parallel sentence extraction methods can be used to identify comparable sentences that contain a translation pair.

Our goal is not to extract parallel sentences, but rather we need to find, for a translation pair, bilingual sentences that are comparable. For example, consider that we need to score the correct translation pair (FR<sup>1</sup> clinique, EN<sup>2</sup> clinical), and that we have two sentences, the first contains “clinique” and the second contains “clinical” (see Figure 2). The two sentences are not parallel, however, they both contain the following information: a clinical examination detects the size of a tumor. Finding this kind of comparability in sentences would help in increasing the score of correct translation pairs.

### 3 Best Sentences Extraction for a Term

For a term ( $t$ ), we aim to extract the  $n$  best sentences that represent its context in the corpus. We suggest that sentences that best represent  $t$  contain words that are: (a) strongly associated with  $t$  in the corpus, (b) highly specific to the domain of the corpus. A word in a sentence containing  $t$  is scored by means of two measures: association and domain specificity, that are presented in the following.

1. Association with  $t$ : word associations are computed according to log-likelihood scores

<sup>1</sup>FR signifies French

<sup>2</sup>EN signifies English

that are based on the co-occurrences of words in a window of size ( $s=7$ ) around  $t$ . The top ( $m=30$ ) associated words and their scores with  $t$  are denoted by  $v_m$  (context vector of  $t$  of size  $m$ ). The association between a word ( $w$ ) and  $t$  is computed from occurrences that are resumed in the contingency table (see Table 2), where  $\text{occ}(t,w)$  is the number of occurrences of  $t$  and  $w$ , and  $\neg w$  signifies all words except  $w$ .

	<b>w</b>	<b><math>\neg w</math></b>
<b>t</b>	a=occ( $t,w$ )	b=occ( $t,\neg w$ )
<b><math>\neg t</math></b>	c=occ( $\neg t,w$ )	d=occ( $\neg t,\neg w$ )

Table 2: Contingency table for  $t$  and  $w$

The log-likelihood association measure is computed as follows:

$$\begin{aligned} \text{association}(t, w) = & a \log(a) + b \log(b) \\ & + c \log(c) + d \log(d) + (N) \log(N) \\ & - (a + b) \log(a + b) - (a + c) \log(a + c) \\ & - (b + d) \log(b + d) - (c + d) \log(c + d) \end{aligned} \quad (1)$$

where  $N = a + b + c + d$ . The association between  $w$  and  $t$  is then divided by the biggest association score obtained with  $t$  to have a score  $\in [0,1]$ .

2. Domain specificity: the specificity of a word is its relative frequency in the domain-specific corpus ( $dc = \{w_1, w_2, \dots, w_n\}$ ) divided by its relative frequency in a general language corpus ( $gc = \{w'_1, w'_2, \dots, w'_m\}$ ), it is defined in (Khurshid et al., 1994) as follows:

$$ds(w) = \frac{rvf_{dc}(w)}{rvf_{gc}(w)} \quad (2)$$

where  $rvf_{dc} = \frac{freq_{dc}(w)}{\sum_{w_i \in dc} freq_{dc}(w_i)}$  is the relative frequency in the specific corpus,  $rvf_{gc}(w) = \frac{freq_{gc}(w)}{\sum_{w'_i \in gc} freq_{gc}(w'_i)}$  is the relative frequency in the general corpus, and  $freq$  signifies frequency. The specificity of a term is normalized by being divided by the value of the biggest specificity in the corpus.

To extract the  $n$  best sentences for term  $t$ , we give a score to each sentence  $S$  that contains  $t$  and words

Figure 2: Example of source and target sentences that contain the translation pair (FR clinique and EN clinical)

$w_1, w_2, \dots, w_n$  as follows:

$$score(S) = \sum_{i=1}^n \left( ds(w_i) + association_{(if w_i \in v_m)}(w_i, t) \right) \quad (3)$$

We discard any sentence with a length of less than 5 words (after removing the stop words). All sentences containing  $t$  are then ranked according to their scores. For a translation pair  $(t_s, t_t)$ , the  $n$  best sentences for  $t_s$  as well as for  $t_t$  are extracted following the method explained above.

The next step consists of aligning the  $n$  best sentences of a source term  $t_s$  with  $n$  best sentences of each of its proposed translations.

#### 4 Sentences Alignment for Translation Pairs

We suggest that if a source term ( $t_s$ ) is translated by a target term ( $t_t$ ), then they must share some comparable sentences. The more a translation pair shares sentences with high comparability, the higher its score should be.

The ratio between the lengths of two comparable sentences should be less than 2, following (Munteanu and Marcu, 2005). We also suppose that the overlap between two comparable sentences should be greater than 3 (including the translation pair). Like previous works on extracting parallel sentences from comparable corpora, our approach depends mostly on lexical information between sentences by using a bilingual lexicon.

Suppose that we have a source sentence  $S_s = \{w_1, w_2, t_s, \dots, w_n\}$ <sup>3</sup> and a target sentence  $S_t = \{w'_1, w'_2, t_t, \dots, w'_n\}$ <sup>4</sup> (after removing the stop words), with a set of possible connected words

<sup>3</sup> $t_s$  could be at any position in  $S_s$   
<sup>4</sup> $t_t$  could be at any position in  $S_t$

$M = \{(w_1, w'_1), (w_2, w'_2), \dots, (w_n, w'_n)\}$  obtained using a bilingual dictionary. An optimal alignment  $A$  (each word in the sentence  $S_s$  is connected to at most one word in the sentence  $S_t$ ) is estimated according to a linear function.

Taking the optimal alignment  $A$ , feature functions (where each  $\in [0, 1]$ ) are utilized to compute a score between the two sentences.

1. The cosine similarity between the two sentences (Fung and Cheung, 2004) penalized by the number of unconnected words: each word in  $S_s$  (respectively  $S_t$ ) is weighted by its score in the context vector  $v_m$  (respectively  $v'_m$ ) of  $t_s$  (respectively  $t_t$ ). If a word is missing from the context vector, it would be associated a fixed minimal weight. The first feature function is defined as follows:

$$f_1(S_{t_s}, S_{t_t}) = \frac{\text{cosine}(S_{t_s}, S_{t_t})}{|\text{UnConnectedWords}|} \quad (4)$$

where  $|\text{UnConnectedWords}|$  is the number of unconnected words between the two sentences.

2. Positions of connected words in the source sentence (target sentence respectively) in comparison to the position of source term (target term respectively): the nearer the connected words are from the term  $t$  in the sentence, the greater the score of this feature function will be. Besides, we suppose that for two connected words  $(w_i, w'_i)$ , the distance between  $w_i$  and  $t_s$  should be close to the distance between  $w'_i$  and  $t_t$ . The positions distance is defined as follows:

$$pos_{\text{distance}}(S_{t_s}, S_{t_t}) = \sum_{w_i, w'_i \in A} \frac{(pos_s + pos_t + |pos_s - pos_t|)}{(|S_{t_s}| + |S_{t_t}| + |S_{t_s} - S_{t_t}|)} \quad (5)$$

where  $pos_s = |pos(w_i) - pos(t_s)|$  and  $pos_t = |pos(w'_i) - pos(t_t)|$ .

The  $pos_{distance}$  is then divided by  $|A|$  to be normalized. The positions similarity is computed as follows:

$$f_2(S_{t_s}, S_{t_t}) = 1 - \frac{pos_{distance}}{|A|} \quad (6)$$

3. Longest contiguous span: it is defined by (Munteanu and Marcu, 2005) as being the longest “pair of substrings in which the words in one substring are connected only to words in the other substring”. We assume that the length of a span must be greater than 2. The longest span is divided by the length of the smaller sentence, then:

$$f_3(S_{t_s}, S_{t_t}) = \frac{\text{span}(S_{t_s}, S_{t_t})}{\min(|S_{t_s}|, |S_{t_t}|)} \quad (7)$$

4. Number of connected bi-grams: this feature function is defined as the number of found connected bi-grams divided by the number of connected words in  $A$ , then:

$$f_4(S_{t_s}, S_{t_t}) = \frac{\text{bi-grams}(S_{t_s}, S_{t_t})}{|A|} \quad (8)$$

The optimal alignment  $A$  is the alignment that minimizes the squared Euclidean distance between the two sentence vectors and the  $pos_{distance}$ . Indeed, we choose this minimization function for a matter of optimization.

We follow (Hunsicker et al., 2012) in considering the final score between a sentence pair as the weighted sum of all feature functions, such as the following:

$$\text{score}(S_s, S_t) = \sum_{i=1}^4 (w_i * f_i(S_{t_s}, S_{t_t})) \quad (9)$$

where  $\sum_{i=1}^4 (w_i) = 1$ .

Contrary to previous works that use parallel corpora to train their models and define the weights of feature functions, we define the weights by guesswork. This is because we do not have an annotated parallel corpora. Nevertheless, this should not have a significant impact on our results since our goal is not to extract parallel sentences.

#### 4.1 Reranking translation pairs

For a translation pair  $(t_s, t_t)$ , each sentence of the  $n$  best representing sentences of  $t_s$  is aligned with at

most one of the  $n$  best representing sentences of  $t_t$ . A target sentence can be aligned to multiple source sentences. The score between the translation pair is the average of the scores of the sentence alignments. We refer to this procedure as the sentence alignment method.

The re-ranking is done by combining the score obtained by the sentence alignment method for a translation pair with its initial score that is obtained by a distributional method. The scores are combined by the weighted geometric mean.

## 5 Evaluation

We first need to extract translations for a list of domain-specific terms in comparable corpora. In order to do this, we pre-process corpora and align terms with the free tool TermSuite<sup>5</sup> (Rocheteau and Daille, 2011). The distributional method that is implemented in TermSuite is the one described in (Rapp, 1999). TermSuite provides a chosen number of translations for a term. Translations are ranked according to the scores provided by the distributional method. We try to enhance the top candidate translations of each reference source term by applying our re-ranking method.

### 5.1 Data

To carry out the distributional approach with TermSuite, we need comparable corpora, bilingual dictionaries, and a list of source reference terms to translate. We need the same resources to perform experiments with our method as well as general language monolingual corpora.

- Comparable corpora: we carry out experiments with comparable corpora in two different domains and two language pairs French-English and French-German. The first are medical corpora in the sub-domain of *breast cancer*, these contain approximately 0.37 M to 0.5 M words for each language. The second corpora belong to the renewable energy domain, more specifically, to the sub-domain of *wind energy*, and contain about 0.3 M to 0.35 M words for each language. Breast Cancer corpora were collected from an online medical portal, while Wind Energy corpora have been crawled using Babouk crawler (Groc, 2011). Both corpora have been collected using some seed terms and contain no

<sup>5</sup>This tool is available on <http://code.google.com/p/ttc-project/>

parallel sentences. Table 3 resumes the sizes of monolingual parts of corpora.

Language	Breast Cancer	Wind Energy
French	531,240	313,943
English	528,428	314,549
German	378,474	358,602

Table 3: Sizes in number of words of corpora for each language and for each domain

- Bilingual dictionaries: general language bilingual dictionaries<sup>6</sup> for the French-English and French-German language pairs were obtained. The French-English dictionary contains 145,542 single-word entries and the French-German dictionary contains 118,776 single-word entries.
- General language corpora: for each language, a general language corpus is obtained and used in computing specificities of words to the domain-specific corpora. These contain 12003, 3903 and 44365 unique single words for French, English and German respectively.
- Reference lists: we have built a list of reference single-word terms (SWTs) for each corpora and for each language pair. Each source term in the list is domain-specific with a frequency greater than 5 in the source corpus and has been manually aligned with one golden translation that exists in the target corpus. For Breast Cancer corpora, for each language pair we built a list that contains 122 translation pairs. As for Wind Energy corpora, for each language pair we built a list that includes 96 translation pairs.

## 5.2 Experimental Settings

For the sentence alignment method, we manually define the same parameters for Breast Cancer and Wind Energy corpora. For each term and each translation candidate, we extract the 70 best sentences, where sentences that have the same score are ranked at the same position. However, we take a maximum of 200 sentences for a term. If a term is less frequent than 70 in the corpus, we extract all the sentences that include this term. We do not

<sup>6</sup>The dictionaries were obtained from [http://catalog.elra.info/product\\_info.php?products\\_id=666](http://catalog.elra.info/product_info.php?products_id=666) and [http://catalog.elra.info/product\\_info.php?products\\_id=668](http://catalog.elra.info/product_info.php?products_id=668)

extract a large number of sentences for a term because the alignment process will be computationally expensive, besides, our assumption is that if a translation pair is valid, then its best representative sentences are comparable. When extracting sentences for a term, we discard any sentence with a length of less than 5 words (after removing the stop words). A sentence is supposed to be simply delimited by punctuation marks (“?”, “!”, “.”). We point out that the words, in a sentence containing a term  $t$ , that are used in computing the score of this sentence and as context for  $t$  are the words appearing at maximum in a window of size  $n=20$  around  $t$  (10 words or less appearing before  $t$  in the sentence, and 10 words or less appearing after  $t$  in the sentence, after removing the stop words).

To score a translation pair by aligning its sentences (see equation 9), the biggest weight is set to 0.4 and is attributed to the first feature function (see equation 4). The remainder of weights are set equally to 0.2. When combining the scores of the distributional and the sentence alignment methods by the weighted geometric mean, the weight of the first is set to 0.3, and the weight of the second is set to 0.7.

## 5.3 Evaluation Measures

The precision of a bilingual lexicon is computed at different levels after taking several  $n$  best translations for each term (top 1, top 5, etc.). The precision is the number of the correct translations found divided by the number of source terms in the reference list.

The Mean Reciprocal Rank (MRR) is also used to evaluate the obtained results. The reciprocal rank for a given source term is the multiplicative inverse of the rank of the first correct target translation. The mean reciprocal rank is the average of the reciprocal ranks of the aligned source reference terms. MRR values are between 0 and 1, where higher values indicate a better performance of the system.

$$\text{MRR} = \frac{1}{Q} \sum_{i=1}^{|Q|} \frac{1}{\text{rank}_i} \quad (10)$$

where  $|Q|$  is the number of source terms to be aligned. If a the correct translation of a term has not been found, then its corresponding “ $\frac{1}{\text{rank}_i}$ ” is equal to 0.

## 5.4 Experiments

The results of the distributional approach (baseline) with the language pairs and two corpora are given in Table 4 (P1 signifies the precision when 1 translation candidate is provided for a term). We notice that the results on Breast Cancer corpora are better than those obtained with Wind Energy. This may be justified by the fact that Wind Energy corpora are of smaller sizes and less technical.

The results are also significantly better with the French-English language pair than with the French-German language pair. In fact, domain-specific corpora contain many terms that are compound nouns. In the German language, many compound nouns may be written as single units (e.g. German term “Produktionsstandort” is translated into French by “site de production”). Therefore, the distributional approach may consider such German terms as one word when computing co-occurrences. One way to overcome this problem would be to perform splitting before applying the distributional approach (Macherey et al., 2011).

To analyze the results obtained by the distributional method in more depth, we measured the comparability of Wind Energy corpora for the different language pairs, using the comparability measure presented by Li et al. (2011). For the French-English corpora, we obtained a comparability value of 0.81. As for the French-German corpora, we obtained a comparability value of 0.70. This implies that our French-German corpora are less comparable than the French-English corpora, and partly justifies the reason behind obtaining worse results with the French-German pair using the distributional method.

	Breast Cancer		Wind Energy	
	FR-EN	FR-GR	FR-EN	FR-GR
<b>P1</b>	26.22%	9.16%	16.66%	3.12%
<b>P5</b>	45.08%	18.85%	38.54%	9.37%
<b>P10</b>	53.27%	26.22%	45.83%	10.41%
<b>P15</b>	59.01%	29.50%	50.00%	12.50%
<b>P20</b>	60.65%	31.96%	57.29%	14.58%
<b>P25</b>	61.47%	32.78%	59.37%	14.58%

Table 4: Results obtained with distributional method (baseline). EN-FR signifies English-French, and FR-GR signifies French-German.

In order to improve these results, especially the top 1, top 5 and top 10 precisions, we try to re-rank

the translation candidates for each source term by combining their initial scores with the scores obtained from aligning their sentences.

Let us suppose that for a source term  $t_s$ , we want to re-rank its top 5 translation candidates  $L_{top5}=\{t_{t_1},t_{t_2},t_{t_3},t_{t_4},t_{t_5}\}$  provided by the distributional method. Following the approach presented in Section 3, we extract the best ranked sentences for  $t_s$ . We do the same for each translation candidate in  $L_{top5}$ . Then, for each translation pair (e.g.  $t_s$  and  $t_{t_1}$ ) we try to align each sentence that was extracted for  $t_s$  with one sentence that shares the highest score with it among the sentences extracted for  $t_{t_1}$ , using the approach described in Section 4. A source sentence can be aligned with at most one target sentence and is assigned a score (which is equal to 0 if the sentence is not aligned). The score between  $t_s$  and  $t_{t_1}$  is the average of the scores of the alignments.

Following the above explained procedure, we take the best  $n=20$  translation candidates proposed by the distributional method for each term and re-rank the translation candidates. This evaluation strategy is denoted by RR1 in Tables 5 and 6 which resume the obtained results on our corpora with two language pairs. For example, using the French-English Breast Cancer list, we find that re-ranking the top 20 translation candidates provided for each source term improved the top 1 precision by approximately 5%. Moreover, before re-ranking, 43.24% of the correct translations found in the top 20 results were ranked at the 1<sup>st</sup> position, after re-ranking, this percentage increases to 52.70%. Which means that the re-ranking has significantly improved the ranks of the correct translations. An improvement of approximately 6% in the top 1 precision is obtained when using 20 translation candidates to re-rank the results obtained with the French-English Wind Energy list. However, fewer improvements were obtained with the French-German language pair as there were not many correct translations in the first 20 translations provided for each term by the distributional method.

While performing experiments, we have noticed that re-ranking the first 5 translation candidates for each term may increase the top 1 precision more than if we, for example, re-ranked the first 20 translation candidates for each term. For that, we have decided to follow a different strategy (denoted by RR2) for re-ranking translations. To de-

	Breast Cancer			Wind Energy

<b>P5</b>	18.85%	<b>21.31%</b>	<b>21.31%</b>	9.37%	<b>10.41%</b>	<b>10.41%</b>
<b>P10</b>	26.22%	<b>27.04%</b>	<b>27.04%</b>	10.41%	<b>13.51%</b>	<b>13.51%</b>
<b>MRR</b>	0.139	0.160	<b>0.162</b>	0.051	<b>0.088</b>	0.075

Table 6: Results obtained on both Breast Cancer and Wind Energy French-German Corpora

termine which translation candidate will be ranked at the  $n$  (starting from 1) position for a term, we first re-rank the top  $m = (\text{round}(2(n-1)+5))$  to the nearest multiple of 5) translations proposed for each term. The translation candidate at position 1 will have the position  $n$  in the new ranked list and it will not be further re-ranked. Then, we determine the translation candidate that will be ranked at the position  $(n+1)$  in the new ranked list. We repeat this process until obtaining 10 translation candidates for each term in the new ranked list.

For example, taking a list of translation candidates provided for a term: to determine which translation candidate will be ranked at the first position, we re-rank the list of top 5 ( $L_{top5}$ ) translation candidates provided for the term, we put the translation now ranked in the first position in a list we name  $L_{taken}$ . To determine which translation candidate will be in the second position, we re-rank the list ( $L_{top5} - L_{taken}$ ) and add the translation ranked in the first position to  $L_{taken}$ . Now to determine which translation will be ranked in the third position, we re-rank the (list of top 10 -  $L_{taken}$ ), and put the translation ranked in the first position in  $L_{taken}$ , and so on. Results obtained using this strategy are presented in Tables 5 and 6 (under RR2).

RR2 strategy gave better top 1 precision and MRR than RR1 with French-English Breast Cancer corpora, and better top 10 precision with French-English Wind Energy corpora. RR1 strategy gave better MRR on Wind Energy corpora. In general, the results of the two strategies were

comparable. This means that RR1 gave stable improvements when re-ranking a list of 20 candidates for each term. Both RR1 and RR2 significantly improved the baseline results for French-English and French-German language pairs.

## 6 Conclusion

In this paper, we proposed a method to re-rank the top translation candidates acquired by a distributional method from comparable corpora. We assumed that some sentences are more representative of a term than others, and that a term and its correct translation share comparable sentences that can be extracted from comparable corpora. We suggested aligning sentences that best represent a term with sentences that best represent its translation candidates to re-rank these translation candidates. Our experiments showed improvements in precision and MRR measures for two language pairs and two domains.

Our re-ranking method was tested with SWTs, and we aim to further evaluate it with multi-word terms (MWTs). Moreover, best aligned sentences for a term and its translation candidates can also be proposed for a user-oriented evaluation to see whether the aligned sentences can help in validating a translation pair.

## Abstract

We introduce a novel modality scheme where triggers are words and phrases that convey modality meanings and subcategorize for clauses and verbal phrases. This semantic-syntactic working definition of modality enables us to design practical and replicable annotation guidelines and procedures that alleviate some shortcomings of current purely semantic modality annotation schemes and yield high inter-annotator agreement rates. We use this scheme to annotate a tweet-based Arabic corpus for modality information. This novel language resource, being the first, initiates NLP research on Arabic modality.

## 1 Introduction

Modality is the grammaticalized expression of the "speaker's subjective attitudes" (Bybee et al., 1994:176) and "psychological stances" (Mitchell and al-Hassan, 1994:7) towards propositions and events and their factuality status. In NLP applications and domains, modality is considered as one linguistic means to convey and detect attitudes and opinions (Wiebe et al., 2005; Abdul-Mageed and Diab, 2012), commitments and beliefs (Diab et al., 2009), power relations (Prabhakaran et al., 2012), uncertainties and speculations (Szarvas et al., 2008; Matsuyoshi et al., 2010).

We herein present the first work on Arabic modality annotation, which is part of a larger research project to (1) automatically identify modality triggers (i.e. words and phrases conveying modality meanings), holders (i.e. modality experiencers) and scopes (i.e. the range of linguistic constituents modified by the modality triggers), and (2) automatically detect power re-

lations among participants in the social network of Twitter by using this modality information.

Despite solid work on Arabic modality in theoretical linguistics (Mitchell and al-Hassan, 1994; Brustad, 2000; Moshref, 2012), there are no Arabic corpora annotated for modality, not even the widely used Penn Arabic Treebank. However, there is a plethora of work and annotated corpora for modality in other languages, including English (Saurí et al, 2006; Baker et al., 2010; Prabhakaran et al., 2012; Rubinstein et al., 2013), Portuguese (Hendrickx et al., 2010; Avila and Mello, 2013), Japanese (Matsuyoshi et al. 2010) and Chinese (Cui and Chi, 2013).

Arabic modality annotation involves multiple challenges. First, the paradigm of Arabic modality triggers is complex as it includes auxiliaries, lexical verbs, nominals and particles - like many other languages as well. Second, triggers can be lexically and/or semantically ambiguous: a lexically-ambiguous trigger is a word or phrase that may or may not convey a modality meaning based on context. A semantically-ambiguous trigger is a word or phrase that may convey two or more modality meanings. Third, implicit scopes are common in Arabic and annotators have to be made aware of them. Fourth, Arabic word order flexibility allows triggers - especially adverbials - to occur in the scope's initial, medial or final positions, which makes it challenging for annotators to identify scope spans. Finally, modality scopes are not necessarily adjacent to their triggers, which furthermore complicates the detection of their spans.

The tweets genre on which we work poses an additional challenge due to language variation. We select a random sample of Arabic tweets from the YADAC corpus (Al-Sabbagh and Girju, 2012) posted in Egypt during the first six months

of the 2011 revolution. All selected tweets are about the political situation at that time. Tweets are not only in the Egyptian Arabic (EA) dialect, but also in Modern Standard Arabic (MSA), especially tweets from press agencies and celebrities. Therefore, our annotation scheme has to work on both MSA and EA modality.

Arabic and the tweets genre are not the only original aspects of this paper. We present a novel linguistically-motivated annotation scheme with a semantic-syntactic working definition of modality triggers as *words and phrases that convey modality meanings and subcategorize for clauses and verbal phrases*. Modality meanings are based on Palmer's (1989, 2001) cross-lingual typology of modality, which is proven valid for both MSA and EA (Mitchell and al-Hassan, 1994; Brustad, 2000; Moshref, 2012).

The semantic-syntactic interface between modality triggers and their scopes depicted in our definition is well-established in theoretical linguistics for Arabic (Moshref, 2012) and for English (Jackendoff, 1972; Brennan, 1993; Butler, 2003). Semantics and syntax work simultaneously such that semantics guarantees not to tag all words and phrases that subcategorize for clauses and verbal phrases as modality triggers. Syntax guarantees not to tag words and phrases that share some semantic meanings with modality triggers, but do not subcategorize for clauses and verbal phrases, as modality triggers.

Subcategorization frames of modality triggers are sporadically mentioned in the NLP literature on modality annotation. For English, Saurí et al. (2006) stated in their definition of event modality triggers that "they subcategorize for a that, gerundive or infinitival clause, but also an NP headed by event denoting nouns" (p.334). For Portuguese, Hendrickx et al. (2010) stated that "in the majority of the cases, the target [i.e. scope] is a subordinate clause or a verbal phrase ... in some cases, also main clauses can be targets [i.e. scopes]" (p. 1810). However, no prior work integrates the semantic-syntactic interface into a modality annotation scheme.

Our conceptualization and implementation of this semantic-syntactic interface provide annotators with practical annotation guidelines that yield highly-reliable results, as shown herein. Furthermore, they define modality in terms of concrete syntactic features which we use in our future work for the automatic identification of triggers and their scopes.

The rest of the paper is structured as follows: section 2 briefly reviews related work. Section 3

gives details about Arabic modality and its complexities. Section 4 presents our data, annotation guidelines and procedures. Section 5 reports the annotation results. Finally, we conclude with future work in Section 6.

## 2 Related Work

Recent work on modality annotation focuses on English, Portuguese, Japanese and Chinese. Baker et al. (2010) used an idiosyncratic categorization of English modality that distinguished 8 semantic meanings: requirement, permissive, success, effort, intension, ability, want and belief. They defined each type as a pattern of the form  $H$  (modal)  $P$  where  $H$  is the sentence's agent and  $P$  is the proposition (e.g.  $H$  permits [ $P$  to be true/false]). They obtained an average inter-annotator agreement rate of 0.82. The error analysis of their modality tagger showed that errors resulted primarily from the triggers' lexical ambiguity.

Prabhakaran et al. (2012) focused on 5 semantic meanings of English modality, and used the same  $HP$  patterns as Baker et al. (2010) for annotation guidelines. They reported an inter-annotator agreement rate of 0.95. Their modality tagger yielded a 0.44  $F_1$  score against a gold-standard and 0.79 and 0.91  $F_1$  scores against different testing sets from their crowdsourced data.

Rubinstein et al. (2013) used a more standardized typology of English modality that entailed (1) priority modality divided into bouletic, teleological and deontic triggers; and (2) non-priority modality divided into epistemic, circumstantial and ability triggers. Their purely semantic annotation scheme returned an alpha reliability score of 0.89 only when collapsing the subtypes of priority and non-priority triggers. The scheme yielded an alpha reliability score of 0.65 for scope span annotation.

Cui and Chi (2013) applied Rubinstein et al.'s (2013) scheme for modality annotation to the Penn Chinese Treebank. They obtained a reliability score of 0.94 for triggers' annotation using the collapsed binary typology of modality triggers as priority vs. non-priority. Their error analysis reported vagueness in the annotation guidelines as one disagreement factor.

The lack of previous NLP work on Arabic modality, modality annotation in tweets and syntactically-guided modality annotation schemes render direct comparisons to our work impossible. Yet, the two main distinguishing factors of our work are: (1) to guarantee the replicability of

our study, we avoid idiosyncratic typologies of modality that were used in some previous work; and (2) to better guide our annotators, we use practical guidelines that rely on both semantics and syntax rather than semantics only as in previous annotation schemes.

### 3 Arabic Linguistic Modality

#### 3.1 Background

Among multiple typologies of modality, Palmer's (1989, 2001) was validated for both MSA and EA in theoretical linguistics (Mitchell and al-Hassan, 1994; Brustad, 2000; Moshref, 2012).

Palmer distinguishes two main classes of modality: propositional and event. Propositional modality is concerned with the speaker's attitude to the truth-value of a proposition, and includes:

- Epistemic modality, which expresses the speaker's judgment about the factual status of the proposition as well as the speaker's opinion and attitude towards that proposition.
- Evidential modality, which indicates the evidence the speaker has for his or her judgment or opinion. Evidence can be reported as in hearsay and quotes or sensory.

Event modality refers to events that are not actualized but are merely potential, and includes:

- Deontic modality, which relates to obligations and permissions that emanate from an external source, and commissives, which originate from an internal source as speakers lay an obligation on themselves for a potential event.
- Dynamic modality, which relates to ability, willingness and wishes.

#### 3.2 Challenges

The challenges of Arabic modality annotation are attributed to (1) the complexity of the Arabic modality paradigm, (2) the lexical and semantic ambiguity of Arabic modality triggers, (3) implicit scopes, (4) word order flexibility and (5) potential long dependencies between triggers and their scopes.

The paradigm of Arabic modality triggers includes a large set of auxiliaries, lexical verbs, nominals and particles. Except for auxiliaries, adverbs and some particles, all modality triggers inflect for gender, number, person, tense, aspect and mood. Furthermore, generic modality patterns such as \* *mn Al-\* >n* (it is \* that), where \* is typically an adjective (e.g. *من المهم أن*

*mn Almhm >n* (it's important that)), are common.

Modality triggers can be lexically and/or semantically ambiguous. The noun *zmAn* is one example of a lexically-ambiguous trigger because in 1 it is an epistemic with a clause scope. Yet, in 2 it is a non-modal standing for *era*.

1. *مبارك لسه بيحكنا عندها خيرة*  
*lw smEnA klAm AlnAs Ally EndhA xbrp kAn zmAn mbArk lsh byHkmnA*

If we'd listened to the elite, Mubarak would have been still ruling us.

2. *الحكم الفردي انتهى*  
*zmAn AlHkm Alfrdy AnthY xlAS*

The **era** of individual rulers has come to an end.

The MSA particle *lAbd* is one example of semantically-ambiguous triggers because in 3 it is an epistemic with a clause scope; whereas in 4 it is an obligative with a verbal-phrase scope.

3. *أنه تذكر صدام حسين وهو يستلقي على سريريه الطبي*

*<n mbArk lAbd w>nh tzkr SdAm Hsyn whw ystlqy Ely sryrh AlTby fy qAEp AlmHkmp*

**It must be that Mubarak remembered Saddam Hussein** as he was lying on his medical bed in the court.

4. *يوضع*  
*lAbd An ywDE mbArk fy Alsjn*

Mubarak **must be put in jail**.

Implicit modality scopes are common in Arabic and come in different realizations. In 5, the scope of the permissive *nsmH* (allow) is the deictic \**lk* (that) which refers to the clause *يهان المصري* *In yhAn AlmSrywn* (Egyptians won't be humiliated). That is, the scope of *nsmH* is actually a clause.

5. *يهان مصري*  
*In yhAn AlmSrywn. In nsmH b\*lk.*

Egyptians won't be humiliated. We won't **allow** it.

In 6, the abilitives *AErf* (can) and *EArf* (can) share the same verbal-phrase scope of *A\$wf* (see). To avoid redundancy, the speaker elides the scope of the second abilitive - *AErf* (can) - and does not replace it with any deictic expression. Thus *AErf* modifies an implicit verbal-phrase scope.

6. *m\$ EArf A\$wf HAjp lmA AErf Hklmk*

I can't see anything. When I **can**, I'll call you.

On the surface level, the obligative *lAZm* (must) in 7 is followed by the noun phrase *a real reaction against military trials*. Yet, on a deeper level, the tweet is the short version of *we must*

(take) a real reaction against military trials. This means that *lAz*m has an implicit verbal-phrase scope.

العسكرية ( ) .7

*lAz*m (*naxd*) *mwqf bjd Dd AlmHAKmAt AlEskryp*

We **must** (take) a real reaction against military trials

Word order flexibility allows for some modality triggers - especially adverbials - to occur before, after or in the middle of their scope(s).

Long dependencies between modality triggers and their scope(s) are the last challenge with Arabic modality annotation. The obligative *ATlb* (ask; require) in 8 subcategorizes for a complement clause, which starts 9 words later (affixes excluded).

.8 من عناصر الاجهزة الامنية المصرية المتخفية في ملابس مدنية انهم يتفرجو عشان سلوكهم ولبسهم ونظرتهم مهروشة أوي

*ATlb mn EnASr AlAjhzp Al>mnyp AlmSryp Almtxfyp fy mlAbs mdnyp Anhm ytfrijw Ely kwnAn E\$An slwkhm wlbshw wnZrthm mhrw\$P >wy*

I **ask** Egyptian security individuals disguising in civil outfits to watch Conan because their behavior, outfit and looks are ridiculously revealed.

## 4 Arabic Modality Annotation

### 4.1 Corpus Encoding and Description

We randomly selected a corpus of 1,704 raw tweets (33,349 tokens and 11,013 unique types) from the YADAC corpus (Al-Sabbagh and Girju, 2012). The considered time span ranges from January 25, 2011 to June 30, 2011. All tweets were posted in Egypt by ordinary individuals, celebrities (e.g. politicians, actors, singers, TV hosts), and the press (e.g. newspapers, TV stations, NGOs, election campaigns).

The corpus includes tweets in both MSA and EA because press users always post in MSA, while celebrities and ordinary individuals frequently switch between MSA and EA. Based on our manual annotation of user types, we have 1,318 tweets posted by individuals, 369 tweets by celebrities and 17 tweets by the press.

### 4.2 Annotators and Annotation Units

Two EA native speakers performed the annotation. Being linguistics students, they can be assumed to master MSA. They were given a one-hour video tutorial covering the annotation guidelines and procedures in Sections 4.3 and 4.4, respectively, followed by a 30-minute workshop dedicated to training and discussion.

Each annotator is required to label each (1) modality trigger, (2) its semantic meaning, (3) its scope type(s), and (4) its scope span(s). We keep

holder annotation for future work as it poses additional challenges.

### 4.3 Annotation Guidelines

Our core annotation guidelines are summarized in the semantic-syntactic working definition of modality given in Section 1. We define modality triggers as words and phrases that (1) convey a modality meaning from Palmer's (1989, 2001) typology, (2) and subcategorize for clauses and verbal phrases; representing propositions and events, respectively. We also give the annotators a number of supplementary guidelines.

Annotators have to label each trigger and its scope(s). Multiple triggers may have the same scope as in 9 where the two epistemic triggers *EArf* (I know) and *mt>kd* (I'm sure) share the clause scope of *that Mubarak won't be executed*.

حيثعدم .9

*AnA EArf wmt>kd An mbArk m\$ HytEdm*

I **know** and I'm **sure** that Mubarak won't be executed.

Annotators have to label all the scopes of the modality trigger for type and then identify their spans. In 10, the obligative *lAz*m (must) modifies three verbal-phrase scopes linked by the coordinating conjunction *w* (and).

مانسكتش عليه نجيبه من جوده يحصلش تاني .10

*AHnA lAz m ntAbE AlmwDwE wmAnskt\$ Elyh wnjybh mn jdwrh E\$An mA yHSI\$ tAny*

We **must follow up** with this, **not ignore** it and **investigate** it well so it won't happen again.

Finally, annotators have to retrieve implicit scopes whether they are referred to in-text or using their own real-world knowledge.

### 4.4 Annotation Procedure

Annotation proceeded in four stages. For **Stage 0**, we used our novel, manually-built, large-scale Arabic Modality Lexicon (AML) to automatically pre-highlight candidate modality triggers. AML was built in three steps:

- First, we manually generated the person, gender, number, tense, mood and aspect inflections as well as the present and past participle derivations of 276 lemmas compiled from Mitchell and al-Hassan (1994), Brustad (2000) and Moshref (2012).
- Second, we added a list of triggers including particles, adverbs and multi-word generic expressions that do not inflect for person, gender, number, tense, mood and aspect.
- Finally, we labeled each entry for an English

<entry id="997" token="منهياً" trans="mthy>ly" gloss="I think" ambiguity="NA" dialect="EA" semClass="epistemic" features="NA" </entry>
<entry id="2032" token=" " trans="mn AlmHtm" gloss="it's essential that" ambiguity="NA" dialect="MSA" semClass="obligative" features="MWE" </entry>
<entry id="3423" token=" " trans="Ejz" gloss="failed to" ambiguity="lexical" dialect="MSA/EA" semClass="abilitive" features="inherentlyNeg,Quasi" </entry>

Table 1: An expert from the Arabic Modality Lexicon (AML)

gloss, ambiguities {lexical, semantic, both, NA}, dialects {MSA, EA, both}, modality semantic meaning and special features {quasi; inherently-negative, multi-word expression} as in Table 1.

Currently, AML has 7,584 entries, with the statistical distributions in Table 2. Despite the large size of AML, annotators were instructed to add any words or phrases that match our working semantic-syntactic definition of modality.

Semantic meanings		Ambiguity	
Epistemic	3,144	Lexical	2,363
Sensory	134	Semantic	155
Reported	427	Lexical/Semantic	116
Obligative	1,091	Unambiguous	4,950
Permissive	815		
Commissive	132		
Abilitive	957		
Volitive	884		
Dialects		Special Features	
MSA	2,268	Quasi	777
EA	3,100	Inherently-Neg.	788
MSA/EA	2,216	MWE	276

Table 2: AML statistics

For **Stage 1**, annotators labeled each pre-highlighted modality trigger for its modality semantic meaning. We defined modality semantic annotation as a synonymy judgment task where the annotators, given a number of synsets, had to decide to which synset the pre-highlighted trigger belongs. We used 8 synsets; each of which featured one modality semantic meaning from Palmer's (1989; 2001) typology. The average size of the synsets is 15 words/phrases to represent different shades of meaning. Yet, due to space limitations, we only included sample synsets in Table 3. To avoid fatigue, disinterest, and distraction effects, we used counterbalancing and prompted the annotators to provide their own synonym(s) for the pre-highlighted candidate trigger if none of the given synsets seemed synonymous.

For **Stage 2**, annotators labeled the syntactic type of the linguistic constituents modified by the pre-highlighted modality trigger (i.e. scope type) where applicable. Annotators had to choose whether the modified constituent was a clause, a verbal phrase, or another type of constituency (e.g. a noun phrase, an adjectival phrase). Once

the clause or the verbal phrase option was selected, annotators were prompted to extract that clause or verbal phrase.

<b>Epistemic</b> (opinion, conclusion, possibility)	- - - - في رأيه - - - -
<b>Evidential</b> (reported)	- - - - - - - -
<b>Evidential</b> (sensory)	شاهد بعينه - سمع بنفسه -
<b>Obligative</b> (and necessity)	- - - - يجب - - - -
<b>Permissive</b> (and prohibitive)	- - - - - نهى عن ... - - - -
<b>Commissive</b>	- - - - تعهد - عاهد ... - - - -
<b>Abilitive</b> (incapability)	- - - - تسنى له - - - -
<b>Volitive</b>	- - - - قد النية على - - - -

Table 3: Sample synsets used for modality semantic annotation

For **Stage 3**, we automatically extracted the triggers that followed our semantic-syntactic working definition of modality. That is, triggers labeled as synonymous to one of the synsets in Table 3 AND as modifying a clause or a verbal phrase. In this stage, instances such as *AfkrwA* in 11 were automatically excluded: although it modifies a complement clause, it means *remember* which is a non-modality meaning.

11. نمشي تحقيق مطالبنا بيبيقى

*AfkrwA* <n kl mrp bnm\$y tHqyq mTAlbnA bybqY <SEb  
**Remember** that every time we leave, it becomes harder to achieve our demands!

Similarly, instances such as *>ElnwA* (they announced) in 12 were automatically filtered out. It is synonymous with the evidential reported synset, yet it modifies a prepositional phrase.

12. أخيرا عن أسماء المعتقلين في السجن الحربي

*>ElnwA* >xyrA En >smA' AlmEtqlyn fy Alsjn AlHrby  
They finally **announced** the names of all prisoners in the military jail.

Instances such as *qAdr* (able to) in 13 were automatically admitted as valid modality triggers. It belongs to the dynamic abilitive synset, and modifies the verbal phrase *>n ySnE* (to make).

13. أن يصنع مصيره بيده

*Al\$Eb AlmSry qAdr >n ySnE mSyrh bydh*

The Egyptian people **are able to** make their own destiny.

Our annotation procedure pinpoints the efficiency and applicability of each dimension of our definition of modality. These guidelines also speed up the annotation process and increase annotation reliability because they provide annotators with practical and concrete prompts, and elicit well-structured answers that can be automatically converted into the modality annotation profiles described in Section 4.5.

#### 4.5 Modality Annotation Profiles

Twitter terms of services prohibit redistributing raw tweet texts. Thus at the end of the annotation process, a profile was built for each tweet with its user name, tweet ID, and modality-related information. Associated software is to be given to help reconstruct tweets using their IDs. Although at the time of writing this paper all tweet IDs are still active, there is a potential of degradation if users delete their tweets or make their accounts private. This does not affect the modality-related profile, however, the complete tweet text will not be available. Modality-related information presents chunks of the tweet texts that represent the trigger word/phrase and the scope clause/verbal phrase. Thus we assume that we are not violating the terms of services.

Triggers are marked with 4-character labels. The first character is *T* for Trigger. The second two characters indicate the semantic meaning of the trigger {*Ep*: epistemic, *Rp*: reported, *Sn*: sensory, *Ob*: obligative, *Pr*: permissive, *Cm*: commissive, *Ab*: abilitive, *Vl*: volitive}. The fourth character is an index to indicate whether the trigger is the 1<sup>st</sup>, 2<sup>nd</sup> and so on in the tweet and to relate the trigger to its scope(s).

Scopes are marked with 3-character labels. The first is *S* for Scope. The second represents the syntactic type of the scope - {*C*: clause, *P*: verbal phrase}. The last is an index matching that of its trigger. Table 4 shows the modality annotation profiles for examples 1 and 9, respectively.

## 5 Annotation Results

### 5.1 Inter-Annotator Agreement Rates and Disagreement Factors

AML pre-highlighted 2,892 candidate triggers in our 1,704 tweets. We used the kappa statistics to measure the Inter-Annotator Agreement (IAA) rates for:

- **Modality semantic annotation:** this labels each candidate trigger as synonymous to one of the synsets in Table 3 featuring Palmer's (1989; 2001) typology.
- **Modality syntactic annotation:** this includes (1) **identifying the scope type** as to whether it is a clause, a verbal phrase, or none; and (2) **identifying the scope span** in terms of the beginning and the end of each scope.

Our macro kappa IAA rate for modality semantic annotation is 0.899 (Table 5). It is hard to measure if this rate is significantly higher than rates reported in the literature of modality semantic annotation because direct comparison with prior work is not possible as explained in Section 2. Yet, one point to highlight is that we do not use a collapsed typology of modality semantic meanings as in Rubenstein et al. (2013) and Cui and Chi (2013), who both collapsed modality semantic meanings into two major classes only: priority vs. non-priority.

	Kappa	Percent Agreement
Semantic annotation	0.899	0.918
Scope type	0.846	0.902
Scope span	0.929	0.973

Table 5: Macro kappa inter-annotator agreement rates for modality semantic and syntactic annotations

We attribute our high IAA rate for modality semantic annotation to: (1) the large-scale AML, which provides annotators with an extensive list of candidate triggers; and (2) using synonymy judgments to give annotators practical, self-evident annotation prompts instead of subjective guidelines, defining modality triggers as expressions of alternative states in which the world could be.

There are, however, two limitations to using synonymy judgments for modality semantic annotation. First, the quality of the annotation relies on the quality of the used synsets. It is important to select unambiguous triggers to represent the modality semantic meanings in different contexts. This is because triggers interact with other linguistic features such as modification, negation and grammatical mood. Second, to better guide

the annotators, especially when working on a morphologically-rich language such as Arabic, it is better to have the synset members inflected for the same person, gender, number, tense, mood and aspect as the candidate trigger.

It took us three iterations of annotations - each one with two different annotators - to come up with the best final synsets used in this paper. This process is time and labor consuming. Yet, once the synsets have been created, the annotation process is fast and replicable with a potential to be crowdsourced. We will examine this option in future work.

**Highly-ambiguous lemmas** are the first disagreement factor for modality semantic annotation. Epistemic lemmas such as *\$Af* (saw), *Erf* (knew), *fhm* (understood), *Sdq* (believed) and *qAl* (said) among others have multiple meanings of which one or more might be modality-related. This explains why most of the disagreement scores in Table 6 are between modality and non-modality meanings (i.e. NA).

<i>Ab</i>	0	0	0	0	0	0	124	0	0
<i>VI</i>	0	0	0	0	0	0	0	267	1
<i>NA</i>	98	6	0	0	0	0	0	0	802

Table 6: Confusion matrix for semantic annotation

For one annotator *nfhm* in 14 is synonymous to *n\$RH* (explain) and thus does not belong to any of the modality synsets in Table 3. For the other annotator, this trigger still means *explain*, but not as in explaining factual information, but as in making people adopt a specific point of view or a belief. Thus it is synonymous to *njElhm y&mnwn >n* (make them believe that) and is an epistemic trigger.

14. نفهم إن المجلس العسكري حاجة والجيش حاجة

*lAbd nfhm AlnAs <n Almjls AlEskry HAjp wAljy\$ Hajp*

We must **explain to** people that the Supreme Council of Armed Forces is one thing and the army is another.

The same lemma may also have more than one closely-related modality meaning; (i.e. it is semantically-ambiguous). For one annotator *byqwl* in 15 is an evidential reported trigger meaning *is saying*; whereas it is an epistemic trigger meaning *is thinking* for the other.

15. قفشوا ناس معاهم سلاح وطلعوهم بره الميدان عشان بس اللي بيقول  
إننا بلطجية يعرف إنه غلطان

*qf\$wA nAs mEAhm slAH wTIEwhm brh AlmydAn E\$an Ally byqwl <nnA blTjyp yErf <nh glTAn*

They arrested some people with guns and kicked them out of the square so that those **saying we're thugs** realize that they are wrong.

**Modality triggers not included in AML** are the second disagreement factor for modality semantic annotation. A total of 168 triggers were identified as new; 85 of which were agreed upon by both annotators. For future modality annotation, agreed-upon new triggers will be added to AML and controversial ones are to be examined by experts prior to inclusion.

The macro kappa IAA rate for scope type identification is 0.846 according to Table 5. Main factors of disagreement are:

- **Clauses vs. verbal phrases:** in some contexts, triggers such as *mmkn* (may, it's possible that) and *Drwry* (must; it is necessary that) can be understood either as auxiliaries subcategorizing for verbal phrases or as adjuncts subcategorizing for clauses. Thus *Drwry nnzl nqwl l>* can be either *we must protest and say no or it's necessary that we protest and say no.*
- **Implicit scope recovery:** implicit scopes with deictic expressions or in-text reference were easy to retrieve unlike implicature-based scopes. For instance, *AHnA Sdqna xTABh* (we believed his speech) was perceived by one annotator as *we believed what he said in his speech was true.* Thus the annotator selected the clause option for the scope type. The other annotator did not see such an implicature and thus selected *NA*, meaning that the scope is unrecognizable or is neither a clause nor a verbal phrase.

The macro kappa IAA rate for scope span recognition in Table 5 is 0.929 which is quite high. We attribute this to the simplicity of the tweet genre, which entails short sentences (140 characters or less) and a writing style that resembles short telegraphic notes more than formal and lengthy sentences. Interjections, adjuncts and subordinate conjunctions are the main reasons for disagreement. In 16, one annotator ends the span of the clause-based scope before *El\$An* (so that); while the other includes the entire sentence into the scope span. We will add clearer guidelines for when interjections, adjuncts and subordinate clauses should be considered into the scope span in future work.

16. (علشان اللي في الشارع يحسوا ان فيه حد جنبيهم)

*lAzM AlnAs tnzl (El\$An Ally fy Al\$ArE yHswA An fyh Hd jnbhm)*

People **must** go to protests (so that those already protesting won't feel as if left alone).

As we implemented Stage 3 of our annotation procedure, we sought triggers that adhere to our semantic-syntactic working definition of modality. Triggers labeled as conveying a modality meaning AND subcategorizing for either clauses or verbal phrases were 1,746 and 1,619 triggers by Annotators 1 and 2, respectively. Triggers labeled as not conveying a modality meaning and/or not modifying a clause or a verbal phrase were 1,146 and 1,273 triggers by Annotators 1 and 2, respectively. Exact matches between the two annotators (i.e. triggers labeled similarly for modality meanings, scope type(s) and scope span(s)) amount to 1,343 valid modality triggers according to our definition.

	Modal	Non-Modal
<b>Annotator 1</b>	1,746	1,146
<b>Annotator 2</b>	1,619	1,273
<b>Agreed-Upon (Exact-Match)</b>	1,343	1,034
<b>Total Exact matches</b>	<b>2,377</b>	

Table 7: Exact-match modality annotated corpus

## 5.2 Annotated Corpus Statistics

In this section, we give statistics on candidate triggers labeled identically by both annotators: whether triggers eventually considered as valid modality triggers (i.e. 1,343 triggers) or triggers eventually rejected as invalid modality triggers (i.e. 1,034). Table 8 shows the correlation between modality semantic meanings and their scope types. We conclude that:

- Except for evidential sensory, modality triggers are more likely to modify clauses and verbal phrases than other linguistic constituents such as noun, adjective and adverb phrases. That is, modality triggers subcategorize for clauses and verbal phrases.
- Propositional modality (i.e. epistemic, evidential reported and sensory) subcategorizes more frequently for clauses; whereas event modality (i.e. deontic and dynamic) is more likely to subcategorize for verbal phrases.
- Triggers that were pre-highlighted as candidates by AML and later rejected for being invalid according to our definition correlate more frequently with linguistic constituents other than clauses and verbal phrases.
- Only 2% of scopes are implicit.

Based on AML dialect labels, valid modality triggers are: (1) 77.3% EA-exclusive such as *mthy>ly* (I think) and *EAYz* (I want), (2) 15.6% either MSA or EA based on context such as *qAl* (he said) and *Erf* (he knew),

and (3) 7% MSA-exclusive such as *Astwjib* (it necessitated) and *wddt* (I wanted).

	Clause	V. Phrase	Implicit	NA	Total
<b>Ep</b>	477	23	15	33	<b>548</b>
<b>Rp</b>	197	6	7	33	<b>243</b>
<b>Sn</b>	49	1	2	120	<b>172</b>
<b>Ob</b>	54	77	15	21	<b>167</b>
<b>Pr</b>	15	47	5	11	<b>78</b>
<b>Cm</b>	2	0	0	4	<b>6</b>
<b>Ab</b>	3	97	4	9	<b>113</b>
<b>VI</b>	80	167	0	1	<b>248</b>
<b>NA</b>	36	6	0	760	<b>802</b>
<b>Total</b>	<b>913</b>	<b>424</b>	<b>48</b>	<b>992</b>	<b>2377</b>

Table 8: Modality semantic meanings and scope types

Ambiguity accounts for 37% and 5% of the valid modality lemmas for lexical and semantic ambiguity, respectively. Some of the most frequent lemmas from each ambiguity type are illustrated in Tables 9 and 10.

Lemma	Trans.	Modal Freq.	Non-Modal Freq.
<i>qAl</i>		171	40
<i>nfs</i>		56	186
<i>\$Af</i>		80	129
<i>fhm</i>	فهم	88	45

Table 9: Top frequent lexically-ambiguous lemmas

Lemma	Trans.	Modality meanings	Freq.
<i>\$Af</i>		epistemic (think)	47
		sensory (watch; witness)	95
<i>Erf</i>		epistemic (know)	41
		abilitive (can)	40
<i>mmkn</i>		epistemic (possible that)	28
		abilitive (can)	17

Table 10: Top frequent semantically-ambiguous lemmas

Finally, about 82% of the scope heads are adjacent to their triggers. This is expected given that tweets are typically short.

## 6 Conclusion and Outlook

We presented a novel modality annotation scheme and applied it to the Arabic language in the tweets genre. This work is part of a larger project to use linguistic modality to detect power relations among participants on Twitter. The presented scheme uses both semantics and syntax to increase annotation reliability. Results show that Arabic modality triggers have regular subcategorization patterns that yield high annotation agreement when used as guidelines.

Currently, we are working on an updated version of this corpus with improved guidelines to tackle disagreement factors that emerged here. The new version will also include annotations for modality holders and trigger-related features such as negation, modification and mood.

## Abstract

Nowadays in Tunisia, the Arabic Tunisian Dialect (TD) has become progressively used in interviews, news and debate programs instead of Modern Standard Arabic (MSA). Thus, this gave birth to a new kind of language. Indeed, the majority of speech is no longer made in MSA but alternates between MSA and TD. This situation has important negative consequences on Automatic Speech Recognition (ASR): since the spoken dialects are not officially written and do not have a standard orthography, it is very costly to obtain adequate annotated corpora to use for training language models and building vocabulary. There are neither parallel corpora involving Tunisian dialect and MSA nor dictionaries. In this paper, we describe a method for building a bilingual dictionary using explicit knowledge about the relation between TD and MSA. We also present an automatic process for creating Tunisian Dialect (TD) corpora.

## 1 Introduction

Recently, due to the changes that have occurred in the Arab world, we noticed a new remarkable diversity in the media. The Arabic dialects used in daily life have become progressively used and represented in interviews, news and debate programs instead of Modern Standard Arabic (MSA). In Tunisia, for example, the revolution has affected not only the people but also the media.

For that reason, the media programs have been changed: television channels, political debates and broadcasts news have been multiplied. This gave birth to a new kind of language. Indeed, the majority of speech is no longer made in MSA but alternates between MSA and Tunisian Dialect (TD). Thus, we can distinguish in the same speech, MSA words, TD words and MSA-TD words such as a word with an MSA component (root) and dialectal affixes. This situation poses significant challenges to NLP: In fact, applying NLP tools designed for MSA to TD yields a significantly lower performance, making it imperative to direct research towards building resources and tools that make it possible to process this kind of language. In our case, we aim to convert this new language into text. However, this process presents a series of linguistic and computational challenges. Some of these relate to language modeling: studying large amounts of text to learn about patterns of words in a language. This task is complicated because of the total lack of TD resources, whether parallel TD-MSA text or dictionaries. In this paper, we describe a method that helps to create Tunisian Dialect (TD) text corpora and the associated lexical resources and also build a bilingual MSA-TD dictionary. This paper is organized as follows: After discussing related work, we present our method to deal with the lack of Tunisian resources (Section 3). We then proceed to discuss the method in details: we explain the manner of creating Tunisian verbal

resources (Sections 4 and 5). We present in Section 6 a tool for generating dialectal corpora. We evaluate and discuss the results in Section 7.

## 2 Related work

Arabic dialects have earned the status of living languages in linguistic studies, thus we see the emergence of a serious effort to study patterns and regularities in these linguistic varieties of Arabic (Brustad, 2000; Holes, 2004; Erwin, 1963).

To date, most of these studies have been field studies or theoretical in nature with limited annotated data. In fact, Dialectal Arabic (DA) is emerging as the language of the news and of many varieties of television programs, and also of informal communication online, in emails, blogs, discussion forums, chats, SMS, etc. In current statistical Natural Language Processing (NLP) there is an inherent need for large scale annotated resources for a language (Diab *et al.*, 2010).

But, research on computerization of DA is still in its early stages especially for TD. Several researchers have explored the idea of exploiting existing MSA rich resources to build tools for DA NLP. For example, (Chiang *et al.*, 2006) built syntactic parsers for DA trained on MSA Treebanks. Such approaches typically expect the presence of tools/resources to relate DA words to their MSA variants or translations. Given that DA and MSA do not have much parallel in terms of corpora to help translate DA-to-MSA, (Abo Bakr *et al.*, 2008) introduced a hybrid approach to transfer a sentence from Egyptian Arabic into MSA. This hybrid system consisted of a statistical system for tokenizing and tagging, and a rule-based system for constructing diacritized MSA sentences. Moreover, (Al-Sabbagh and Girju, 2010) described an approach of mining the Web to build an Egyptian-to-MSA lexicon. (Diab *et al.*, 2010) presented an information retrieval project COLABA (Cross Lingual Arabic Blog Alerts) that aims to create resources and processing tools for dialectal Arabic blogs. The COLABA system consists in taking an MSA query and translating it or its component words into DA or alternatively converting all DA documents in the search collection into MSA before searching on them with the MSA query. To do so, they created DIRA (Dialectal Information Retrieval for Arabic), which is a term expansion tool for information retrieval over dialectal Arabic collections, especially the

Egyptian and the Levantine dialects, using Modern Standard Arabic queries. (Habash and Rombow, 2006) presented MAGEAD (Morphological Analyser and Generator of Arabic dialect). MAGEAD works both on analyzing and generating Egyptian and Levantine verbs. The limitation of MAGEAD is that it doesn't deal with verbs that change their roots when moving from MSA to Dialect. (Shaalan *et al.* 2007) proposed a system for translating MSA into the Egyptian dialect. To do so, they tried to build a parallel corpus between the Egyptian dialect and MSA based on mapping rules EGY-MSA.

As a conclusion, for MSA and its dialects, there are no naturally occurring parallel corpora. It is this fact that has led researchers to investigate the use of explicit linguistic knowledge.

### Dialects are under-resourced languages:

Spoken languages which have no written form can be classified as under-resourced languages and as a consequence have no annotated resources. Therefore, several studies have attempted to overcome the problems of lack of resources for these languages. In order to computerize the existing Swiss dialect, (Scherrer, 2008) developed a translation system: standard German to Swiss German. The system developed is based on translating a bilingual lexicon from standard German to any variety of the dialect continuum of German-speaking Switzerland. Moreover, there are several languages from the group of under-resourced languages that do not have a relation with a well-resourced language. Indeed, (Nimaan *et al.* 2006) presented several scenarios to collect corpora in order to automatically process the Somali language: collecting a corpus from the Web, automatic synthesis of texts and machine translation of French into Somali. (SENG, 2010) selected news sites in Khmer to collect data in order to solicit the lack of resources in Khmer.

Related work vs. the Tunisian dialect: The literature shows that there is little work that dealt with the Tunisian dialect, the target language of this work. (Graja *et al.*, 2011) for example, treated the Tunisian dialect for understanding speech. To do so, the researchers relied on manual transcripts of conversations between agents at the train station and travelers. The scope of application is limited and so, the vocabulary is not very rich. However, a limited vocabulary is a problem if we want to model a language model for a system of recognition of

television programs with a wide and varied vocabulary. In addition, (Zribi *et al.*, 2013) presented OTTA (Orthographic Transcription for Tunisian Arabic), a set of guidelines orthography to transcribe Tunisian Arabic. This work is helpful for our case in that it will facilitate the identification of the orthography of the Tunisian words that we will build.

### 3 Method to create a Tunisian Dialect lexicon

In Arabic, there are almost no parallel corpora involving the Tunisian Dialect and MSA. Therefore, Machine Translation (MT) is not easy, especially when there are no MT resources available such as a naturally occurring parallel text or a transfer lexicon. So, to deal with this problem, we propose to leverage the large amount of annotated MSA resources available by exploiting MSA/dialect similarities and addressing known differences. Our approach consists first in studying the morphological, syntactic and lexical differences by exploiting the Penn Arabic Treebank. Second, we present these differences by developing rules and building dialectal concepts. Finally, we define a lexical data base to store these transformations into dictionaries.

#### 3.1 Tunisian Dialect Vs. MSA

The Tunisian Arabic dialect is attached to the Arab Maghreb and is spoken by twelve million people living mainly in Tunisia. It is generally known to its speakers as the 'Darija' or 'Tounsi' which simply means "Tunisian", to distinguish it from Modern Standard Arabic (Baccouche, 1994).

The Tunisian dialect is considered as an under-resourced language. It has neither a standard orthographic or written text nor dictionaries.

Actually, there is no strict separation between Modern Standard Arabic (MSA) and its dialects, but a continuum dominated by mixed forms (MSA-Dialect). In the last two years, this dialect became the language spoken in most of the media instead of standard Arabic. But this dialect has a sophisticated form which mixes MSA and TD forms. Thus, given the similarities between TD and MSA, the resources available to MSA can be advantageously used to create dialectal resources.

#### 3.2 Penn Arabic Treebank corpora to create a bilingual MSA-TD lexicon

Treebanks are important resources that allow for important research in general NLP applications. In the case of Arabic, two important treebanking efforts exist: the Penn Arabic Treebank (PATB) (Maamouri *et al.*, 2004; Maamouri *et al.*, 2009) and the Prague Arabic Dependency Treebank (PADT) (Smrř *et al.*, 2008). The PATB provides tokenization, complex POS tags, and syntactic structure; it also provides empty categories, diacritizations, and lemma choices. The ATB consists of 23,611 parse-annotated sentences (Bies and Maamouri, 2003; Maamouri and Bies, 2004) collected from Arabic newswire texts in Modern Standard Arabic (MSA). The ATB annotation scheme involves 497 different POS-tags with morphological information. In this work, we attempted to mitigate the genre differences by transforming the MSA-ATB to look like TD-ATB. This will allow creating in tandem a bilingual lexicon with different dialectal concepts (Figure1). For this purpose, we

adopted a transformation method based on the parts of speech of ATB's words, as discussed in the following.

Figure1- Method for creating TD resources

#### 4 Mapping rules based on verbal morphological distinction

There's a difference between verb conjugation in MSA and that in TD. We find that in TD, the gender distinction is not marked. Most Tunisian people do not distinguish between masculine and feminine with the second person-singular. Similarly, we mark the absence of the masculine and feminine dual. Another conjugation difference is in the passive form of the TD and MSA verb. In fact, the passive form of most Tunisian verbs is obtained by preceding the verb with the consonant 'ت' [t]. Unlike in MSA, passive verbs in TD cause the transformation of the structure of the sentence: For example, the transformation of the sentence (Active voice) **كلا الطفل التفاحة**/kIA aITfol AltofeHap/The boy ate the

apple/ is in passive voice “التفاحة تاكلت”/AltofeHa teklit/The apple has been eaten/

In the imperfect, the [t] lies between the root and the prefix as in the following:

"يتاكل"/yitekil/ The lunch (M) is edible. *Masculin*

/"تتاكل"/titekil/The apple (F) is edible *Feminin*. In addition to this type of form, the dialect offers another form frequently used as question such as: "تتاكلشي"/titekil\$y/ Is it edible?

In this work, as we aim to build a lexicon for Tunisian verbs, we must take into account these differences. But to define Tunisian inflected forms, we should first define the main concept of “Arabic verb” and we will do this by studying the morphological and lexical differences that may exist between TD verbs and MSA verbs. Indeed, in Arabic there are three principal verbal concepts:

1-Root: It is the basic source of all forms of Arabic verbs. The root is not a real word; rather, it is a sequence of three consonants that can be found in all words that are related to it. Most roots are composed of three letters; very few are composed of four or five consonants.

2-Pattern: In MSA, patterns are models with different structures that are applied to the root to create a lemma. For example, for the root خ ر ج : x r j, we can apply different patterns which give different lemmas with different meanings:

Root1: x r j /خ ر ج / C1C2C3+ verbal pattern1: AistaC1oC2a3 =lemma1 اسْتَخْرَجَ /to extract

Root1: x r j /خ ر ج / C1C2C3+ verbal pattern2 FoEaL (FaEal)=lemma2 خَرَجَ /to go out .

Root1: x r j (خ ر ج) / C1C2C3+ verbal pattern3 >aC1oC2aC3=lemma3 أَخْرَجَ /to eject

3-Lemma: The lemma is a fundamental concept in the processing of texts in at least some languages. An Arabic word can be analyzed as a root inserted into a pattern.

#### 4.1 Verbal concepts for the Tunisian dialect

As we aim to adapt MSA tools to TD, we tried to build for TD verbs the same concepts as those in MSA. Therefore, we focused in this work on the study of correspondences that may exist among the concepts of MSA verbs and dialect verbs. First, we extracted all the verbs that exist in ATB, represented in their inflected forms. Second, we used a lemmatizer to extract lemmas; we obtained as a result 1500 different MSA lemmas. Third, we built manually lemmas

corresponding to TD. Later, we tried to build verbal patterns equivalent to those in MSA. Finally, since there is no standard definition of roots in TD, we opted for a deductive method to define root for dialect verbs. Figure 2 illustrates this method.

Figure 2: From ATB verb to TD-verb

**Building TD-lemmas:** Verbs in the ATB corpus are presented in their inflected forms. So, we extracted lemmas and their roots using the morphological analyzer developed by Elixir FM (Smrz, 2007). As we are native speakers of TD, we associated to each MSA-Lemma a TUN-Lemma. As a result, we found that 60% of the verbs change totally when passing from MSA to TD. This is a preliminary step for building Tunisian patterns from which we will be able to deduct the inflectional forms. So, as we have 1500 TD-Lemmas, and starting from the fact that MSA verbs have patterns describing their morphological behavior during conjugation, we tried, whenever possible, to define to each TD-Lemma a TD-Pattern which is similar to the MSA-pattern.

**Building TD-patterns:** The challenge in building TD-patterns was to find patterns similar to those in MSA. In MSA, patterns are models with different structures that are applied to the root to create a lemma. In fact, for trilateral roots there are in MSA ten patterns I: CCC, II: CaC~aC, III: CACaC, IV: >aCCaC, V: /taCaC~aC, VI: taCACaC, VII: AinCaCaC, VIII: AiCtaCaC, IX : AiCCaC~, X: AistaCCaC.

To classify the lemmas that we have already built, we focused on the creation of verbal patterns for TD verbs. So, we chose three criteria that classify verbs from general (without considering the vowels of the word) to specific (dealing with the different variations of vowels in its conjugation).

#### Classification according to the verb model

Verb model means the form that the root takes after applying the Pattern, for example:

Root :خ ر ج /x r j ; Pattern: CaCaC; Lemma : خَرَجَ /xaraj ; Model : CVCVC

Root: خ ر ج /xrj ; Pattern: AistaCCaC ; Lemma: اسْتَخْرَجَ/Aistaxraj ; Model : AistaCVCVC  
 Classification according to the model of the verb consists in studying similarities between verb models without considering changes in vowels. Indeed, as we have already mentioned, we have 40% of verbs that do not change their root when the pass from MSA to TD. They therefore have the same model without considering vowels. To do this, we assigned to TD-verbs patterns equivalent to those in MSA (1).

For example: MSA-lemma: خَرَجَ / xaraj/go out  
 Pattern-MSA: CaCaC Model: CVCVC

→ TD: lemma: xoraj Model: CVCVC then  
 Pattern-TUN: CoCaC

Moreover, for verbs that change their root when passing to the dialect, we reasoned as follows: For a TD verb whose model looks like the model of a TD-verb for which we have already assigned a Tun-pattern (1), we assign the same Tun-pattern (2).

Example1:

MSA: صَمَتَ /Samat /be silent → TD: سَكَّتَ /sokut  
 Model : CVCVC looks like the model of خَرَجَ / xraj/: go out : CVCVC. (1)

We have already assigned to خَرَجَ / xoraj the -TUN-pattern: CoCaC. Therefore, سَكَّتَ / sokut will have the pattern -TUN: CoCuC (2).

In this way, we classified almost all TD verbs except a few who have a complex form illustrated by a verbal unit plus another lexical unit (particle or other...).

For example, the translation of the MSA verb رَافَقَ /rAfaqa/go with → is in TD: مَشَى-مع /mo\$ay-moEa. We associated this type of verb to patterns that we called "exception patterns"

### **Classification according to the vowel of the second consonant of the pattern**

The vowel of the second consonant of the pattern (vowel letter ع / E) is a fundamental criterion for classifying a verb in MSA (Ouerhani, 2009). In fact, according to this criterion, the MSA pattern I is divided into six patterns due to the variation of the vowel of the second consonant (both in past and present tense). These patterns are respectively: I-au: CaCa-yaCoCuC ; I-ai : CaCaC-yaCiC ; I-aa: CaCaC-yaCoCaC, I-ia: CaCiC-yaCoCaC ; I-uu: CaCuC-yaCoCuC ; I-ii: CaCiC-yaCaCiC.

In TD, this variation is very common and it is marked not only in the pattern I but in all patterns. For this reason, we proposed to divide these patterns and to define new patterns in order

to consolidate the verbs that have the same behavior. For example, for the Pattern-TUN II: MSA: Pattern-TUN II: no TD sub-pattern: New three sub-patterns: II-aa: CaC~aC/yiCaC~aC ; II-ai: CaC~aC /yiCaC~iC ; TUN II-ii: CaC~iC /yiCaC~iC

### **Classification according to the Imperfect mark**

The third classification criterion is based on the imperfect mark. In MSA, this mark remains unchanged in all verbs belonging to the same class. In fact, for the MSA pattern I CaCaL/yaCCAC, the mark is ي/ya ; for example: كَتَبَ /kataba-yaktubu/write. For the pattern III/CACaC/yaCACiC, the mark is يُ/yu; for example يَشَارِكُ-شَارَكَ \$Araka-yu\$Ariqu/participate.

However, we noticed that in TD, this regularity appears especially in the pattern I, so this mark can vary even within the same class. For example, يَخْرُجُ - خَرَجَ / xraj-yuxruj/to go out belongs to theTUN –pattern-I-au; يَقُولُ / قال - QAI-yiquwl/to say belongs to the TUN-pattern-I-au. Note that although these two verbs belong to the same class, their imperfect marks are different. For this reason, we proposed to extend the TUN-pattern-I-au and define more sub-patterns for the pattern I.

In this way, we assigned to يَخْرُجُ - خَرَجَ / xraj-yuxruj the pattern- I -au-u and to يَقُولُ / قال - QAI-yiquwl the pattern- I -au-i.

The result of this classification has allowed distinguishing 32 patterns for dialect verbs while there were 15 in MSA.

### **-TD-root definition**

In Tunisian dialect, there is no standard definition for the root. For this reason, dialect root construction was not obvious, especially when the verb root changes completely from the MSA to the dialect. In fact, to define a root for TUN verbs, we adopted a deductive method. Indeed, in MSA, the rule says: root + pattern =Lemma (1). In our case, we have already defined the TUN-lemma and the Tun-pattern. Following rule (1), the extraction of the root is then made easy. For example, we classified the lemma اِسْتَيْ / Aistan ~ aY / Wait in the pattern AistaCCaC then root(?) + AistaCCaC= Aistan~ Y

Following (1), the root is "نني" [NNY]. In fact, we can say that the definition of roots is a problematic issue which could allow more discussion. According to (1), it was as if we had forced the roots to be [NNY]. However, if we

classify إستنى / Aistann ~ aY under the pattern AiCtaCaC, the root in this case must be سنن / snn. The root can also be quadrilateral سنني / snnY if we classify Aistann ~ aY under the pattern AiCCaCaC. But as there's no standard, we did our best to be as logical as possible to define dialectal root.

## 4.2 Verbal lexicon structure

The various verbal transformations described above are modeled and stored in a dictionary of verbs as follows: to each MSA verbal block containing the MSA-lemma, the MSA-pattern and the MSA-root will correspond a TD- block which contains the TD-lemma, the TD-root- and the TD-pattern. So, knowing the pattern and the root, we will be able to generate automatically various inflected forms of the TUN verbs. That's why we also stored in our dictionary the active and the passive form of the TD-lemma in perfective and imperfective tenses. We also stored the inflected forms in the imperative (CV). Figure 3 shows the structure that we have defined for the dictionary to present the TD-verbal concepts (in Section 4, we will explain how we will automate the enrichment of this dictionary).

```
<DIC_TUN_VERBS_FORM>
<LEXICAL-ENTRY POS="VERB">
<VERB ID-VERB="48">
  <MSA-LEMMA>
    <Headword-sa>عَايَنَ</Headword-MSA
    <Pattern>فاعل</Pattern>
    <Root-Msa>عين</Root-Msa>
    <Gloss lang="ang" > Observe</Gloss>
  </MSA-LEMMA>
  <TUN-VERB Sense= "1" >
    <Cat-Tun-Verb Category=
      TUN-VERB--I-au--yi" />
  <Root-Tun-Verb>شوف</Root-Tun-Verb>
  <Conjug-Tun-Verb>
  <TENSE>
  <FORM Type= "IV" >
  <VOICE Label="Active">
  <Features Val_Number_Gender="1S">
  <Verb_Conj>نشوف</Verb_Conj>
  <Struct-Deriv>∅+شوف+ن</Struct-Deriv>
  </Features>
  </VOICE>
  ...
</DIC_TUN_VERBS_FORM>
```

Figure3- Verbal dictionary structure

## 5 Mapping rules based on syntactic distinction

We identified three areas that reflect the specific syntax of the dialect: word order, grammatical negation and syntactic tools categories. In the following section, we will explain how we define these dialect structures in our lexicon.

### 5.1 Word order

The order of the elements in the dialect sentence seems to be relatively less important than in other languages . However, the canonical word order in Tunisian verbal sentences is SVO (Subject-Verb-Object) (Baccouche, 2003).

In contrast, the MSA word order can have the following three forms: SVO / VSO / VOS (2).

(1) TD: « الطُّفْلُ كَتَبَ الدَّرْسَ ».SVO

(2) MSA: « كتب الطفل درس ».VSO.

This opposition between MSA and the dialect is clearer in the case of proper names. In fact, MSA order is VSO (3) while the order in TD is SVO. (Mahfoudhi, 2002)

(3) MSA : « ضرب موسى عيسى ».

(4) TD : « موسى ضَرَبَ عيسى ».

There are other types of simple dialect sentences named nominal sentences which do not contain a verb. They have the same order in both TD and MSA. For example:

MSA: الطقس حار /TaKs HAR/ The weather is hot

TD: الطَّقْسُ سَخُونُ /TaKs sxuwn/The weather is hot

In our work, we discussed some nominal groups at the syntactic level. The word order is generally reversed when passing to TD. For example

(1) MSA: ADV + ADJ

>ayDaA/Also+مُنَقَّف /muvaK~af/also educated

TD: ADJ +ADV

ADJ/ مُنَقَّف +ADV/زاده

(2) MSA: Noun + ADJ

MSA: كُتُبٌ كَثِيرَةٌ /kutubun kavira/many books->

TD: ADJ + Noun

TD: برشا كُتُب /bar\$A ktub

In the dictionary, we present this kind of rule as shown in Figure 4.

```
<ADV-MSA ID="5">
  <MSA-LEMMA>أَيْضاً</MSA- LEMMA>
  <GLOSS ang="ang">Also</GLOSS>
  <CONTEXT ID="1">
    <CONFIG ID="1" Position="Before" POS="ADJ" />
    <TOKEN>
      <TUN ID="1" DIC="ADJECTIVES" POS="ADJ" />
      <TUN ID="2" />
      <TUN ID="3">زَادَا</TUN>
    </TOKEN>
```

</CONTEXT>

Figure 4- Syntactic rule representation in the dictionary

## 5.2 Grammatical negation

Negation particles are generally set before the verb and can sometimes change the combination. For example, if the word <أكتب> />ktb /Write in MSA is preceded by a negative particle such as لم/lam (Do not), the verb in the dialect will be: mAktibtibti\$/ماكتبتيش= Tun-Neg-Particle(ما)+ Tun-verb (كتب)+ Tun-Neg-enc (ش)

## 5.3 Syntactic tool categories

Tools words or Syntactic tools exist in a large amount in the Treebank and all MSA-texts. However, their transformation was not trivial and required for each tool a study of its different contexts.

A tool word may have different translations depending on its context. For example, the particle حَتَّى/ HatY/so that: we found this particle in ATB in three contexts. This particle gives a new translation whenever it changes context:

- 1- حَتَّى/ HatY + verb = باش (TUN-particle) + TUN\_verb
- 2 حَتَّى/ HatY + NEG\_PART = باش (TUN-particle) + TUN\_NEG\_PART
- 3- حَتَّى/ HatY = حَتَّى/ HatY

So, to deal with these transformations, we converted them into rules and stored them into a lexicon of tool word transformation.

### Context dependent transformation

We mean by context dependent transformation the passage MSA-TD which is based on transformation rules. Indeed, given the word MK, we say that the transformation of MK is based on context if it gives a new translation whenever it changes context. RTK : X + M + Y = TDk

$$X = \sum_{j=1}^m Mj: POSj ; Y = \sum_{i=1}^n Mi: POSi ; k \text{ varies from } 1 \text{ to } z ;$$

RTk: transformation rules n°k; POS : Part of speech ; M: word tool, TDk: Translation n°k

The transformation of a tool word may depend on the words (X) that precede it, or on the following word (Y), or both. If none of the

contexts is presented, then a default translation will be assigned to the tool word. In total, we defined in the tool words dictionary 316 rules for the 146 ATB's tool words.

In the dictionary, we presented a transformation rule. In fact, for each tool word we defined a set of contexts; each context contains one or more configurations. The configuration describes the position and the part of speech of the words of context. Each context corresponds to a new translation of the tool word (Figure 5).

```
<PREP-MSA ID="9">
  <MSA-LEMMA>حَتَّى</MSA-LEMMA>
  <GLOSS lang="ANG ">until </GLOSS>
  <CONTEXT ID="1">
    <CONFIG ID=" 1 " Position="Before" PRC="DET" />
      <CONFIG ID="2" Position=" Before "
        POS="NOUN">ساعة</CONFIG>
  <CONFIG ID="3" Position=" Before" POS="NOUN_NUM" />
  <TOKEN>
    <TUN ID="1">حَتَّى</TUN>
    <TUN ID="2" POS="NOUN_NUM" />
  </TOKEN>
</CONTEXT>
.....
<CONTEXT ID="6">
.....
</Prep-MSA>
```

Figure5- Structure of a context dependent rule in the dictionary

### Context independent transformation

In addition to the context-dependent transformations, the translation of some tool words in the corpus was direct "word to word"; the word remained the same regardless of the context. Figure 6 shows an example of how we represented this kind of translation in the dictionary

```
<SUB_CONJ-MSA ID="7">
  <MSA-LEMMA>كَي</MSA-LEMMA>
  <GLOSS lang="ANG">In order to
</GLOSS>
<TOKEN>
  <TUN ID="1">بَاشْ</TUN>
</TOKEN>
</SUB_CONJ-MSA>
```

Figure 6- Structure of a context independent rule in the dictionary

## 6 Automatic generation of Tunisian Dialect corpora

To test and improve the developed bilingual models, we exploited our dictionaries to

automate the task of converting MSA corpora to corpora with a dialect appearance.

For this purpose, we developed a tool called Tunisian Dialect Translator (TDT) which enables to produce TD texts and to enrich the MSA-TD dictionary (Figure 6). The TDT tool works according to the following steps:

1-Morphosyntactic annotation of MSA texts: TDT annotates each MSA text morphosyntactically by using the MADA analyzer (Morphological Analyser and disambiguator of Arabic) (Habash, 2010). MADA is a toolkit which, given a raw MSA text, adds lexical and morphological information. It disambiguates in one operation part-of-speech tags, lexemes, diacritizations and full morphological analyses.

2-Exploiting MSA-TD dictionaries: Based on each part of speech of the MSA-word, TDT proposes for each MSA structure the corresponding TD translation by exploiting the MSA-TD dictionaries.

3-Enriching the lexicon: As our MSA-TD dictionaries do not cover all Arabic words, texts resulting from the previous step are not totally translated. Therefore, in order to improve the quality of translation and to enrich our dictionaries, enabling them to be well used even in other NLP applications, we added to TDT a semi-automatic enrichment module. This module filters first all MSA words for which a translation has not been provided. Then, TDT assigns to them their corresponding MSA-lemmas and POS. If the POS is a verb or a noun, the user proposes a TD-root and a TD-pattern (described in subsection 3.2) and the TDT generates automatically the appropriate Tunisian lemma and its inflected forms.

Figure7- Automatic process for generating Tunisian corpora

## 7 Evaluation

To evaluate translations of verbs occurring in our MSA-TD dictionary, we asked 47 judges (native speakers) to translate for us a sample containing 10% of verbs extracted from the dictionary. In this sample, there are 52 verbs that don't change their root when passing to TD and 98 do otherwise. The evaluation consists in

comparing what we have proposed as a translation of lexical items taken from the ATB with the proposals of judges who are native speakers of the Tunisian dialect. The percentage of agreement between the judges' translations and the translations proposed in our lexicon is calculated. Table 1 shows the results obtained

Verbs	Unchanged	Changed	Total
Number of verbs in the sample	52	98	150
Agreement	97,17%	63,21%	74,97%

Table 1- Evaluation of verb translation

Moreover, as the translation of the majority of tool words depends on context, we asked 5 judges to translate 89 sentences containing 133 tool words. In this sample, we repeated some tool words in the same sentence but in a different context. Table (2) gives the percentages of agreement between the translations of the judges and those in our dictionaries of tools words. The variation in percentage is due to the fact that for some words, the judges do not agree among themselves. The table shows also the percentage of disagreement between the judges and the dictionaries.

	2 judges	3 judges	4 judges	5 judges
Agreement	72,69 %	74,53 %	71,34 %	71,23 %
<b>Disagreement</b>	18,79 %	15,03 %	14,28 %	12,03 %

Table 2- Evaluation of tool word translation

In fact, disagreement arises when no judge gives a translation similar to the translation proposed in the dictionaries. But, by increasing the number of judges, the disagreement decreases, which proves that our dictionaries contain translations accepted by several judges

## 8 Conclusion

This paper presented an effort to create resources and translation tools for the Tunisian dialect. To deal with the total lack of written resources in the Tunisian dialect, we described first a method that allowed the creation of bilingual dictionaries with in tandem TD-ATB. In fact, TD-ATB will serve as a source of insight on the phenomena that need to be addressed and as corpora to train TD-NLP tools. The verb dictionaries and the verbal concepts that we have developed were also exploited in order to adapt MAGEAD

(Habash *et al.* 2006) (Morphological Analyser and Generator of Arabic Dialect) to the Tunisian dialect (Hamdi *et al.*, 2013).

We focused second on describing TDT, a tool used to generate automatically TD corpora and to enrich semi-automatically the dictionaries we have built.

We plan to continue working on improving the TD-resources by studying the transformation of nouns. We also plan to validate our approach by measuring the ability of a language model, built on a corpus translated by our TDT tool, to model transcriptions of Tunisian broadcast news.

Experiments in progress show that the integration of translated data improves lexical coverage and the perplexity of language models significantly.

## Abstract

Phrase-based machine translation like other data driven approaches, are often plagued by irregularities in the translations of words in morphologically rich languages. The phrase-pairs and the language models are unable to capture the long range dependencies which decide the inflection. This paper makes the first attempt at learning constraints between the language-pair where, the target language lacks rich linguistic resources, by automatically learning classifiers that prevent implausible phrases from being part of decoding and at the same time adds consistent phrases. The paper also shows that this approach improves translation quality on the English-Hindi language pair.

## 1 Introduction

Data driven Machine Translation approaches have gained significant attention as they do not require rich linguistic resources such as, parsers or manually built dictionaries. However, their performance largely depends on the amount of training data available (Koehn, 2005).

When the source language is morphologically rich and when the amount of data available is limited, the number out-of-vocabulary (OOV) increases thereby reducing the translation quality. Popovic and Ney (2004) applied transformations to OOV verbs. Yang and Kirchoff (2006) used a back-off model to transform unknown words, where, the phrase-table entries were modified such that words sharing the same root were replaced by their stems. Others (Freeman et al., 2006; Habash, 2008) found in-vocabulary words that could be treated as morphological variants.

Translating into a language that is rich in morphology from a source language that is not morphologically rich also has limitations. The main

reason for this is that the source language does not usually contain all the information for inflecting the words in the target half. For language-pairs that have limited amounts of training data, it is unlikely that the Translation model comes across all forms of inflections on the target phrases. Hence, some mechanism is required in order to generate these target phrases with all possible inflections and at the same time be able to filter out the implausible hypotheses.

Certain approaches (Toutanova et al., 2008; Minkov et al., 2007; Green et al., 2012) predict inflections using syntactic and rich morphological sources for the target language. This approach cannot be applied on resource poor languages such as, Hindi or other Indian languages, which lack such rich knowledge sources. Ramanathan et al. (2009) use factored models to incorporate semantic relations and suffixes to generate inflections and case markers while translating from English to Hindi but do not consider the problem of agreement between phrases in the target sentence. William and Koehn (2011) suggested an approach to eliminate inconsistent hypotheses in a string-to-tree model by adding unification-based constraints to only the target-side of the synchronous grammar. Although transfer-based MT (Lavie, 2008) uses rich feature structures, grammar rules and constraints are manually developed. In addition, rules formed for one language-pair cannot be applied to another language pair. However, it is possible to model these rules as a classification problem: Given the set of source language features that influence the inflection of the target word, we try to predict the best possible target class. The target class could be the either spontaneous words or inflections of words.

This paper, specifically looks at translating from English to Hindi to predict a) Subject case markers, b) Object case markers and c) Verb phrase inflections. In many PBSMT systems, once the

phrase-pairs have been extracted, it is no longer required to store the training corpus from which the phrase-pairs were extracted. However, while dealing with many morphologically rich languages, the morphological variants of the target phrase not only depend on their source phrase but also on the context in which the source phrase appeared. Hence, it is beneficial to incorporate source-side features while decoding and most PBSMT systems do not use any other information from the input sentence other than the source phrase itself.

This paper presents an approach to improve the translation quality while translating from a morphologically poor language (such as, English) to a target language that is morphologically rich without using any rich resources such as, parsers or morphological analyzers. The contributions of the paper are summarized as follows:

- The approach detects inconsistent hypotheses generated by the translation model by treating the task as a classification problem.
- The approach also predicts plausible target phrases that agree with the features extracted from the input sentence.
- The paper also shows how the incorporation of source-specific features during decoding results in better translations.

Section 2 provides motivating examples to understand the importance of the task at hand.

## 2 Motivation

We demonstrate the usefulness of our approach on Indian languages as they are rich in morphology. They are also considered as resource-poor and low-density languages due to the lack of data availability and the absence of rich knowledge sources like morphological analyzers or syntactic parsers. Hindi has a free word-order where the constituents are identified through case markers.

A few approaches generate the right inflection by a) capturing all possible variations within the target phrase (Gandhe et al., 2011) and b) use the language model to select the most fluent phrases. However, the following problems still remain:

1) Many language models typically use 4-gram or 5-gram models (even lower when the data available is scarce). Example 1a has a subject (Ram) that is masculine (masc)-3rd person (3)-singular(sg)-present progressive(pp) and example

1b, has a subject (Sita) that is feminine (fem)-3rd person(3)-singular(sg)-present progressive(pp). This difference in gender, changes the inflection on the auxiliary Hindi verb *raha*, from ‘a’ (in 1a) to ‘i’ (in 1b). It should be noted that lower order n-gram language models fail to obtain the right translation due to the long distance dependency between the subject (*Ram / Sita*) and the verb phrase (*khel raha hai / khel rahi hai* corresponding to *is playing* in English) in the target language.

### Example 1a:

S: Ram is playing with the grand master .  
 T: *Ram grand master ke saath khel raha hai* .  
 (Ram grand master with play+3+sg+masc+pp)

### Example 1b:

S: Sita is playing with the grand master .  
 T: *Sita grand master ke saath khel rahi hai* .  
 (Sita grand master with play+3+sg+fem+pp)

2) Language models are insufficient to produce the right inflections. Consider the case shown in example 2, where the translation of the English pronouns (*he/she*) is same in Hindi (both translate to *Woh*). The inflection on the auxiliary verb phrase (*raha hai / rahi hai*) is still being decided by the gender of the subject (*he/she*). Even if a higher order language model is employed, the language model gives equal preference to both the translations as the information about the gender of the subject is completely absent in the Hindi translation. Hence, the information that *Woh* corresponds to masculine in example 2a and feminine in example 2b has to come from the source sentence (*He/She*).

### Example 2a:

S: He is playing chess .  
 T: *Woh chess khel raha hai* .  
 (he chess play+3+sg+masc+pp)

### Example 2b:

S: She is playing chess .  
 T: *Woh chess khel rahi hai* .  
 (she chess play+3+sg+fem+pp)

3) Most often in PBSMT systems, the subject and verb phrases are far apart and hence are extracted independently, as in the case of example 1. Since there are no constraints during decoding on which phrases to choose, mis-matched phrases

may get picked. Apart from verb inflections, the presence of the case-marker ‘*ne*’ (shown in example 3) on the subject blocks the transfer of the subject’s gender onto the verb phrase and the verb phrase instead gets inflected with the gender of the object(*apple*). This blocking/presence of case markers is also not captured by traditional PBSMT systems.

#### Example 3a:

S: He ate an apple .

T: *us ne seb khaya* .  
(he apple ate+3+sg+masc+past)

#### Example 3b:

S: She ate an apple .

T: *us ne seb khaya* .  
(she apple ate+3+sg+masc+past)

### 3 Model

The agreement constraints can be applied to either the translation model or the language model, such that implausible combination of phrases are not picked for the best hypothesis. In our approach, we apply the agreement constraints on the translation model by filtering phrase-pairs which have an incorrect inflection on the target phrase. Since the problem of inconsistent output is mainly due to the subject, object and verb phrases, we determine agreement constraints only for these target words. For instance, suppose a ‘female’ gender inflection is expected on the target verb. Then, any phrase that contains ‘male’ gender inflection on the verb will produce an inconsistent translation and hence should be penalized. We can also add phrase-pairs when the correct inflection is not present in the phrase table.

The easiest way to filter the inconsistent phrase-pairs is to create manual rules to look at the English source side that specify the possible set of target translations and discard the rest. For instance, using example 3 in Section 2, we could create a manual rule, “When the English verb tense is ‘*past*’, Hindi subject takes the case marker ‘*ne*’ and the verb phrase takes the gender and number of the ‘subject’ ”. However, this is time consuming and it is difficult to create an exhaustive list of such rules. Hence, it is imperative that we learn these rules from data. In this paper, we use multi-class support vector machine (Crammer and Singer, 2001) classifiers that use features only

from the input source sentence to predict possible target case marker/inflections for the subject, object and verb phrases in the target sentence. We treat these as the allowed inflections on the target phrases and penalize phrase-pairs that do not contain the predicted target inflections. This methodology is expected to prevent implausible sentences being translated and improve the overall fluency of the translated sentence.

## 4 Classification

We model the prediction of the possible target inflections for a given input sentence as a classification problem. We build different classifiers<sup>1</sup> to predict the target inflections of parts of the input sentence for which the translations are dependent on long range morphological rules. The features that we use for the different classifiers are listed in Section 5. The classifiers built are as follows:

**Subject Classifier (SubCM) and Object Classifier (ObjCM):** predicts the case marker on the subject and the object.

**Verb Phrase Classifier (Vp):** is used to predict the inflections on the verbs.

### 4.1 Subject and Object Classifier

Subject and Object phrases, when translated from English into a morphological rich language, often contain inflections of gender and number. Some languages also generate a case marker to denote the subject or the object. If such a case marker is not present, the target sentence often may not make sense. For our experiments from English to Hindi, we looked at predicting the correct case marker. To obtain the possible case markers that can come after a subject or the object in target language (in our case Hindi), we look at all the case markers following a subject and those that follow the object. If a language has linguistic resources such as parsers, this can be done easily. Since Hindi, and many other languages do not have a good parser, we make use of automatic word alignments obtained from bilingual data to project the subject information from English to Hindi, and determine the case markers following the subject and the object on the target side. Using this technique, we found 4 classes for the subject classifier and 3

<sup>1</sup>we use the libsvm library:  
<http://www.csie.ntu.edu.tw/~cjlin/libsvm/>

classes for the object classifier. For the prediction of the classes, we use all the noun phrase features (in Section 5.1), tense feature of the verb phrase (in Section 5.2) and tense conjugate features (in Section 5.3).

SubCM	ObjCM	Vp
NULL	NULL	<i>X raha tha</i> (was X+ing)
<i>ne</i>	<i>ko</i> (of)	<i>X+nA chahiye</i> (should X)
<i>ke</i> (of)	<i>mein</i> (in)	<i>X+nI chahiye</i> (should X)
<i>ki</i> (of)		<i>X+A gayA</i> (was X+ed) ...

Table 1: Classes defined for different classifiers.

## 4.2 Verb Phrase Classifier 1

Verb phrases contain morphological information about the gender, number, person, tense and aspect of the sentence. It is hence important to produce the right inflections and auxiliary verbs. Since it is impractical to have a class for each verb, we convert the verb phrases to an abstract form and also predict the target verb phrase in its abstract form. For instance, the verb phrase ‘was playing’ will be generalized to ‘was X+ing’ form and the corresponding predicted class would be ‘*X raha tha*’.

A simple approach to find the possible output forms of the classifier is to mine the target language data for all the verb phrases, rank them by frequency and filter them based on a threshold to yield the different forms that the verbs can take in the language. The aggregated verb phrases can be normalized by replacing the root verb in these phrases by an ‘X’ tag to obtain the possible abstract forms for the target verb phrases. For Hindi, verb phrases were identified by using a simple part-of-speech (POS) tagger to tag the monolingual data and to capture continuous sequences of ‘V’ tags. We found 120 Hindi verb classes in all. Some of these classes are listed in Table 1. We use all the features listed in Section 5.

## 4.3 Verb Phrase Classifier 2

Having too many classes for verb phrases causes the following problems: a) During our initial experiments we found that out of the 120 verb classes specified by us, only 60 were present in the bilingual training data. This reduces the chances of predicting a correct class since the classifier does not see all classes during training. b) The classifier sees only a few instances of each class. To simplify the verb phrase prediction, we split the prediction such that instead of predicting each verb form, we predict each ‘kind’ of inflection

that modifies the verb phrase. Since each verb phrase in our training data contains information about the gender, number and person, each class now has ample amount of training examples.

**Gender Classifier (VpG):** This classifier predicts the gender inflections on the target verb phrases using features from the source sentence.

**Number Classifier (VpN):** This classifier predicts the number inflections on the target verb phrases using features from the source sentence.

**Person Classifier (VpP):** This classifier predicts the Person information of the target verb phrases given the source sentence features.

The three classifiers have two, two and three classes, respectively. The predicted gender, number and person is then used to select the target verb form:

**Base Verb form Function:** Given the input English verb phrase, this function outputs all possible translations (that is, with all possible inflections and auxiliary verbs) of the given verb form. For example, for the verb phrase ‘is playing’ in the example in Section 1, this function will produce 12 target verb forms, one each for possible combinations of elements from the sets (masculine and feminine), (singular and plural) and (first, second and third person). The function for producing the list of verb forms given the English verb form is implemented using machine alignments and monolingual data as done in Gandhe et al. (2011). It uses parallel data to extract all the source-target verb phrase-pairs from the word-aligned data. These source-target verb phrase-pairs are converted into an abstract form by replacing the root verb with an ‘X’ (as done in Section 4.2). Aggregating this over a large amount of parallel data and filtering out the low frequency phrase-pairs gives us translations of a source verb form into its corresponding target forms. The gender, number and person for each of the target verb forms can be found out by looking at the inflections, suffixes and auxiliary verbs.

## 4.4 Training

We use an English parser to parse the source sentence and obtain the different features. Using the alignments of the subject, object and verb phrase,

we project them onto the target language and extract the expected output case-marker/inflections for each of the three cases (SubCM, ObjCM, Vp) and assign it the corresponding class. Our approach is not limited to hand-alignments. Alignments obtained from automatic aligners can also be used. Since hand-alignments were available beforehand, we made use of these alignments in this work. We will explore the usability of automatic aligners as future work. We now briefly describe the features that we used for the above classifiers.

## 5 Features

Given the parse tree of an English sentence, we determine the subject noun phrases and the object noun phrases for each of the verb phrases present in the input sentence giving *(subject, object, verb)* triples. We also determine the morphological information about the subject, object and verb phrases in sentence (in Sections 5.1 and 5.2). Most of the features described are boolean, unless specified otherwise. Figure 1 shows an example of an English-Hindi word-aligned sentence-pair. The dependency parse of the English sentence is used to determine the source subject (sita), object(chess) and the verb phrase (is playing). Features are calculated over these phrases and the target words aligned to them in the word alignments are used to create the training examples for the three classifiers.

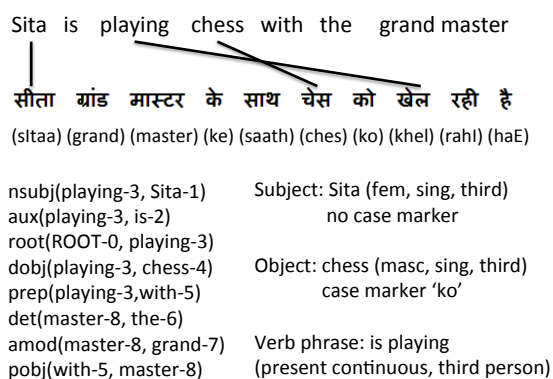

Figure 1: An English parse with features.

### 5.1 Noun Phrase Features

The inflection on the verb phrase is influenced by 3 attributes of a noun phrase:

**Gender:** Unlike English, most Indian languages have a gender (*male/female*) for every

subject and object. To determine the gender of an English word, we take its most common Hindi translation and assign the gender of this translation to the English word. Gender of Hindi words can be determined by mining the Hindi monolingual data for *(noun phrase, verb phrase)* pairs using a simple POS tagger on Hindi data. POS taggers are now easily available for most Indian languages. However, no other rich sources such as, parsers or morphological analyzers are used on the target language. We then assign the gender of the verb phrase suffix (*'a'* for masculine and *'I'* for feminine) to the words in the noun phrase. Doing this over a large amount of data gives us the list of nouns with their gender. For example, the Hindi word *'kItAb'* is seen with verb phrases such as, *'padI'*, *'dI'*, etc. in the monolingual data. Since *'kItAb'* occurs most with verb phrases ending in suffix *'I'*, its gender is *'female'*. The English word *'book'* translates most often to *'kItAb'* and is hence assigned the gender *'female'* and the corresponding feature value of 1. For words like, *'house'*, which are determined to be *'male'*, the value is 0.

**Number:** Similar to the gender, the singularity or plurality of the noun phrase influences the inflection on the verb phrase. The plurality of the English noun can be determined by using a POS tagger and looking for a *'NNS'* tag or in case of pronouns, a finite list of pronouns. Hence, nouns in plural form and the pronouns, *'they'*, *'us'*, *'them'*, were given the feature value as 1. For all other singular words, the value is 0.

**Presence of case marker:** Perhaps the most important feature, the presence or absence of a case marker on the target subject and object phrase decides the transfer of inflections from the noun phrases to the verb phrase (examples of Section 2). This is not a source side feature, since case markers are present on the noun phrases in the target language. We cannot use the case marker information directly as we do not have the target side information. Hence they are used in two steps: a) Subject and Object classifiers (Section 4) are used to predict the noun phrase (*subject, object*) case markers and b) The predicted case markers are used as an input to the verb phrase classifier. This feature is not used as an input to the subject and object classifiers. If a

subject/object case marker is present, the features are valued 1, else 0.

## 5.2 Verb Phrase Features

The verb phrase features influence the tense, aspect and person of the target verb phrase as well as the case marker presence on the noun phrases. The verb phrase extracted from the dependency parse of the input sentence are morphologically segmented (Minnen et al., 2001) and the different aspects of the verb phrase are obtained from it.

**Tense Features:** The tense features tell the presence or absence of *Present, Past and Future* tense. For instance, for the verb phrase ‘was explained’, the present and future features take the value 0 and the past feature takes the value 1.

**Aspect Features:** The aspect features are important in deciding the final form and the auxiliaries in the target sentence. We label the features as *simple, progressive and perfect*. In this case, a verb phrase with a ‘ing’ suffix is said to be progressive, whereas a verb phrase with ‘have’ and its inflections is said to be perfect. For example, the phrase ‘has been explaining’ will have both progressive and perfect features with value 1.

**Mood Features:** The mood features capture the *obligation, conditional and probability* mood in the input English sentence by looking at the modal verbs which are required to produce the corresponding auxiliary verbs in Hindi.

**Number:** English verb forms with plurality inflection translates into plurality of the Hindi verbs.

**Person:** English auxiliary verb ‘am’ denotes the presence of first person. By looking at the subject of the verb in the dependency parser, (*first, second or third*) the person information can be assigned to the verb phrase.

## 5.3 Conjugate Features

These features capture the more language-specific nuances that together decide the transfer of inflections from nouns to verbs. These features try to emulate the behavior of grammar rules.

**Case marker-Gender:** When a case marker is not present on the noun phrase, the inflection from

them is likely to be transferred to the verb phrase. For this case, we assign this feature the same value as the gender of the noun phrase. When a case marker is present, information is blocked and hence we assign a null value to this feature.

**Case marker-Number:** This feature captures blocking of the number information and takes a value 0 or 1 depending on the presence or absence of case marker.

**Tense-Gender:** When the tense of the sentence is past, it is likely that the gender information is blocked. Hence, when the tense is past, this feature is assigned a null value. Otherwise, the value is same as the value of the gender feature.

**Tense-Number:** Similar to the previous one, except that this captures the blocking of number information.

## 6 Decoding

We used a PBSMT system, similar to Tillman et al. (2006), to decode and this required slight modifications to incorporate our approach. The extracted phrase-pairs have phrase translation probabilities and lexical probabilities estimated (similar to Papineni et al. (2002)). The input sentence is passed through a parser to determine the subject, object and the verb phrases in the sentence. Various features mentioned in the previous section are computed during run time and the classifiers are used to predict the subject case marker, object case marker and the verb phrase inflection. The agreement constraints can be applied as:

**Hard Removal:** All phrase-pairs that do not agree with the predicted case marker or inflections are removed from the phrase table before the hypothesis search.

**Soft Removal:** The agreement model outputs the prediction probabilities for different target case markers or inflections. This probability score can be used as a feature in the phrase table and trained on a development data set.

**Addition:** If the predicted case marker or inflection is not present in the original phrase table, the correct phrase-pair can be added by

automatically generating the target phrase.

The input sentence is fed into the agreement model to produce the constraints for the subject, object and verb phrases. We use the hard constraint and addition techniques during decoding. Applying soft constraints will be done in future work. For subject and object phrases, we aggregate the phrase-pairs in the phrase table which contain the English source word. From these, all phrase-pairs that do not agree with the predicted case markers on the target side are filtered. In addition, if the predicted case marker is not present in the phrase table, we add the phrase-pair with the right case marker into the phrase table. This is done by looking for the most common target translations of the source word and appending the predicted case marker to them. For verb phrases, we aggregate the phrase-pairs containing the English verb phrase.

All phrase-pairs which do not have the predicted target verb phrase inflections are filtered. Since we do not know the complete translation of the source verb phrase at this step, we look only for the predicted target verb phrase's inflection and auxiliary verbs. If no correct verb phrase form is found in the phrase table, the target phrase is generated using the most common translation of the English verb and the phrase-pair is added. In order to score these new phrase-pairs, we can make use of the automatically generated bilingual dictionaries created during the automatic word-alignment phase. The phrase-pairs and entries in the dictionaries can be stemmed to their base forms (removing inflections) using Ramanathan et al. (2003). In cases where there are multiple instances of the same verb (caused due to stemming) present in the modified dictionary, the average of the probabilities is taken. The lexical probabilities for the phrase-pairs can then be estimated as given in Papineni et al. (2002) from the modified dictionaries. To obtain the phrase translation probabilities, the scores from the classifiers are converted to a score between 0 and 1 using a logistic function ( $1/(1 + e^{-score})$ , where, *score*: classifier's score) and then re-normalized such that the sum of probabilities of all the target phrases for a particular source phrase is one (and vice versa). In the case of 'Verb Phrase Classifier 2' (Section 4.3), the scores from each of the classifiers is first converted to a score between 0 and 1 using a logistic function, summed and then re-normalized.

## 7 Experiments

We first report the results of prediction of noun phrases and verb phrases and proceed on to report the results of using them in PBSMT.

### 7.1 Prediction Evaluation

To aggregate the classes required for subject, object and verb phrase classifiers, we used 1.4 million Hindi monolingual sentences crawled from the web. We pos-tagged this data using iit kgp Hindi pos tagger<sup>2</sup>. The monolingual data, along with 280,000 automatic alignments of sentence-pairs, was used to apply the technique suggested in Gandhe et al. (2011) to build the base verb form function described in Section 4.2. The svm classifiers were trained and tested using libsvm<sup>3</sup>. To extract the features from manually aligned sentences, we used the Stanford Parser<sup>4</sup> to obtain the English dependency parse trees. The source English side was morphologically segmented using morpha (Minnen et al., 2001) and the target Hindi side was segmented using an approach described in Ramanathan et al. (2003).

Table 2 gives the accuracies of the classifiers when trained with a particular set of features. The conjugate features make a significant improvement to all the three classifiers. Hindi object case markers are easier to predict than subject case markers since the objects usually do not occur with a case marker. Also, the subject case markers show a high dependency on the verb phrase features, which is explained by grammatical rules, according to which tense and structure of the verb phrase decide the case marker on the subject. It is important to remember here that the verb phrase classifier uses the output of the case-markers predicted by noun classifiers as a feature.

Features	SubCM	ObjCM	Vp
NounFeat	0.63	0.81	-
Noun+VerbFeat	0.72	0.84	0.58
Noun+Verb+ConjFeat	<b>0.75</b>	<b>0.87</b>	<b>0.61</b>

Table 2: Prediction accuracy for the classifiers.

The prediction accuracy is low for the **Vp** classifier even with conjugate features due to the large number of classes. Most classes do not have sufficient training examples and a few classes were

<sup>2</sup><http://nltr.org/snltr-software/>

<sup>3</sup><http://www.csie.ntu.edu.tw/~cjlin/libsvm/>

<sup>4</sup><http://nlp.stanford.edu/software/lex-parser.shtml>

even absent in the training data. When we split this classification into separate tasks as explained in Section 4.3 and later combine the output of individual classifiers to obtain the predicted verb phrase, we obtain a much better accuracy. The results of this configuration are shown in Table 3. Since the verb phrase classifier uses case-markers as a feature, we also analyze the importance of these for verb phrase prediction and study 3 different settings: a) Removing the case marker (CM) feature, b) Using Gold case markers from the reference and c) Using the predicted case markers. Although the prediction accuracies are best for GoldCM, using the predicted case markers results in only a slight drop in accuracy.

	VpN	VpG	VpP	Overall
No CM	0.83	0.62	0.95	0.58
Gold CM	<b>0.87</b>	<b>0.86</b>	<b>0.95</b>	<b>0.74</b>
Pred CM	0.85	0.83	0.95	0.70

Table 3: Prediction accuracy for verb phrase inflections.

## 7.2 Machine Translation Evaluation

The system was trained on 285,000 automatically aligned sentences. The baseline system uses the standard decoding algorithm while our approach prunes the phrase table before decoding. We measure the translation quality using a single reference BLEU (Papineni et al., 2002). The test set contains 715 sentences from the News domain. Table 4 gives the comparison of the baseline with the two systems (Note: In both systems, the case marker features are obtained from the predictions of the subject and object classifiers):

**Pred1:** Verb phrase prediction as a single task (Table 2)

**Pred2:** Verb phrase prediction split into individual components (Table 3).

	BLEU	Adequacy	Fluency
Baseline	15.43	3.75	2.23
Pred1	15.45	3.87	2.41
Pred2	<b>15.58</b>	<b>3.93</b>	<b>2.79</b>

Table 4: BLEU score and Human Judgment.

The BLEU score increase is small on Pred1 but was significantly better with Pred2 with  $p < 0.0001$  with the Wilcoxon Signed-Rank test (Wilcoxon, 1945) performed by dividing the test file into 10 equal subfiles (as done in Gangadharaiah et al. (2010)). On analysis of the refer-

ence, we found the tense of the verb phrases in the Hindi reference to be different from that of English. Also, often the presence of auxiliary verbs ‘hona’ in the Hindi reference changed the structure of the verb phrase. The output produced by our system is more literal and in congruence with the grammar of the input sentence. Callison et al. (2006) list the disadvantages of using BLEU. The differences in translations between the proposed approaches and the baseline are most often a correction of inflection, and sometimes this resulted in better selection of neighboring words by the language model. BLEU failed to accommodate these improvements, hence we also performed human evaluation to judge the quality of the translations on adequacy and fluency using a scale of 1-5<sup>5</sup>.

We gave 100 randomly picked sentences from the test set to a single human judge. We see that our approach (Table 4) has a greater impact on fluency, suggesting that grammatical agreement is important for fluency. Adequacy improvement can be attributed to the correct translations of the case markers and the tense information.

## 8 Conclusion and future work

We modeled the task of case marker and inflection prediction as a classification task. The prediction accuracies show that the inflections on the verbs are highly influenced by the case markers on the subjects and objects. Similarly, the case markers on subjects are affected by the tense of the verb phrases. Since all the features are extracted from the source side, this approach can be easily applied for improving translation quality from English to any morphologically rich foreign language. More work can be done on creating features that encode the grammatical rules we might have missed.

Even though the gain in translation quality with the BLEU score was small, human evaluation showed that this approach helps in improving the fluency and adequacy of the sentence and hence makes it more readable. Future work can be on using more than one possible case marker-verb phrase constraints (i.e., as a soft constraint) for a given input and applying this approach for other language-pairs where the target language is morphologically rich.

<sup>5</sup>We used the scale defined in <http://projects.ldc.upenn.edu/TIDES/Translation/TransAssess04.pdf>

## Abstract

We present a Variational-Bayes model for learning rules for the Hierarchical phrase-based model directly from the phrasal alignments. Our model is an alternative to heuristic rule extraction in hierarchical phrase-based translation (Chiang, 2007), which uniformly distributes the probability mass to the extracted rules locally. In contrast, in our approach the probability assigned to a rule is globally determined by its contribution towards all phrase pairs and results in a sparser rule set. We also propose a distributed framework for efficiently running inference for realistic MT corpora. Our experiments translating Korean, Arabic and Chinese into English demonstrate that they are able to exceed or retain the performance of baseline hierarchical phrase-based models.

## 1 Introduction

Hierarchical phrase-based translation (Hiero) as described in (Chiang, 2005; Chiang, 2007) uses a synchronous context-free grammar (SCFG) derived from heuristically extracted phrase pairs obtained by symmetrizing bidirectional many-to-many word alignments (Och and Ney, 2004). The phrase-pairs are constrained by the source-target alignments such that all the alignment links from the source (target) words are connected to the target (source) words *within* the phrase. Given a word-aligned sentence pair  $\langle f_1^j, e_1^I, A \rangle$ , where  $A$  indicate the alignments, the source-target sequence pair  $\langle f_i^j, e_{i'}^{j'} \rangle$  can be a phrase-pair *iff* the following alignment constraint is satisfied.

$$(k, k') \in A : k \in [i, j] \Leftrightarrow k' \in [i', j']$$

Given the phrase-pairs, SCFG rules are extracted by replacing aligned sequences of words in source

\*This research was partially supported by an NSERC, Canada (RGPIN: 264905) grant and a Google Faculty Award to the third author.

and target sides by co-indexed non-terminals and rewriting the replaced source-target word sequences as separate rules. Consider a rule  $X \rightarrow \langle \beta, \gamma \rangle$ , where  $\beta$  and  $\gamma$  are sequences of terminals and non-terminals. Now, given another rule  $X \rightarrow \langle f_i^j, e_{i'}^{j'} \rangle$ , such that  $f_i^j$  and  $e_{i'}^{j'}$  are contained fully within  $\beta$  and  $\gamma$  as sub-phrases, the larger rule could be rewritten to create a new rule.

$$X \rightarrow \langle \beta_p X_k \beta_s, \gamma_p X_k \gamma_s \rangle \quad (1)$$

Here  $\beta_p$  ( $\beta_s$ ) refers to any prefix (suffix) of  $\beta$  that precedes (follows)  $f_i^j$ . Note that the non-terminals are co-indexed with a unique index so that they are rewritten simultaneously.

Figure 1: Chinese-English *phrase-pair* with alignments

As a concrete example, consider the word aligned Chinese-English phrase pair shown in Figure 1. Notice that the phrase 联合国 (united nations) is incorrectly aligned to English determiner *the*, even though in ideal case the entire Chinese phrase 联合国难民专员公署 should be aligned on the English side to *the unhr*. The heuristic approach extracts 32 rules, some of which are shown in Figure 2.

The distribution of the rules is unknown, as the different derivations of the sentences are not explicitly observed. Thus, Chiang (2007) follows an approach similar to that of Bod (1998) and hypothesizes a distribution over the rules. Under this each phrase-pair is assumed to have a unit count, which is uniformly distributed to all the rules extracted from this phrase-pair. The locally assigned rule counts are then aggregated across the entire set of phrase-pairs. The probability for each phrase pair

Translation rule	$P_{Heu}(e f)$	$P_{VB}(e f)$
* $X \rightarrow \langle \text{在中南海} \mid \text{at chong nan hai} \rangle$	0.333	0.003
* $X \rightarrow \langle \text{在中南海} \mid \text{at zhong nan hai} \rangle$	0.333	0.008
$X \rightarrow \langle \text{在中南海} \mid \text{at zhongnanhai} \rangle$	0.333	<b>0.988</b>

Figure 3: Rules extracted for translating the Chinese phrase 在中南海. The probabilities are shown for grammar extracted from heuristic as well our proposed method. The least preferred translations are shown with \*. Our Variational-Bayes method extracts a grammar having a peaked distribution as shown.

* $X \rightarrow \langle \text{联合国} \mid \text{the} \rangle$
* $X \rightarrow \langle \text{数月, 联合国} \mid \text{months, the} \rangle$
$X \rightarrow \langle \text{数月, } X_1 \mid \text{months, } X_1 \rangle$
$X \rightarrow \langle \text{数月} \mid \text{months} \rangle$
$X \rightarrow \langle \text{联合国难民专员公署} \mid \text{the unhcr} \rangle$

Figure 2: Rules extracted for the example phrase-pair in Figure 1. The rules encoding incorrect translations are marked with \*.

is then estimated using relative frequency estimation.

### 1.1 Motivation

A major problem with this heuristic rule extraction method is the lack of *global re-weighting* of the pseudo-counts beyond their local assignments. By assigning uniform weight to the rules, Chiang (2007) assumes all the rules extracted from a given phrase-pair to be equally good. However, some rules might be better than others in terms of generalization, for capturing a syntactic phrase-pair, or being a semantically coherent unit of translation.

Due to this uniform treatment of good and poor translations, probability mass is wasted on poor translation candidates. For example the phrase-pair in Fig 1 would generate several poor translation rules (shown with \* in Fig. 2). This is due to the incorrect alignment link between 联合国 and *the* (note that the word *the* is typically aligned with a large number of words due to its frequency). The heuristic extraction method simply assigns uniform count to all translations and as a result the first translation in Fig. 2 becomes the fourth best translation for this source phrase.

In Chiang (2007) the rule extraction algorithm produces a fairly flat distribution over rules. For example the different translation options of the Chinese phrase 在中南海 (*at zhongnanhai*) all

have the same  $p(e|f)$  probability as shown in Figure 3. In contrast, our method produces a peaked distribution and shifts the probability mass towards *at zhongnanhai*, which is the preferred translation.

In this paper, we propose a method which distributes the probability mass among the rules (generated from a phrase-pair) based on their contribution in explaining the collection of all phrase-pairs in a global manner. This difference in estimation methods can lead to a peaked distribution of rule probabilities. Secondly we also present a distributed framework that enables rule extraction on large datasets that are typical in SMT. Our Variational-Bayes approach for rule extraction improves/ retains the translation quality for the three different language pairs. Finally, we also present a detailed analysis comparing the extracted SCFG with the heuristically extracted SCFG.

## 2 Model

Our model uses the notion of a *derivation*: the set of rules that fully derive an aligned phrase pair, and learns the estimates for the rules contained in the derivations through Variational inference. Setting the notations, we denote the set of derivations for a given phrase pair  $x$  as  $\phi_x$  and the set of all rules as  $\mathcal{G}$ . Given the set of initial phrase pairs  $\mathcal{X}$  and a prior over the grammars  $\mathcal{G}$ , we formulate Hiero grammar extraction as the task of inferring a posterior distribution over Hiero grammars. Using Bayes' rule, we can express the posterior over the grammar  $\mathcal{G}$  given the set of bilingual phrases  $\mathcal{X}$  as:  $P(\mathcal{G}|\mathcal{X}) \propto P(\mathcal{G})P(\mathcal{X}|\mathcal{G})$ .

As mentioned earlier, our model replaces the heuristic rule extraction step in Hiero pipeline. Consequently our model assumes the existence of *initial* phrase-pairs obtained from bidirectional symmetrization of word alignments. We use the following two-step generative story to create an aligned phrase pair from the Hiero rules.

$\phi^z \sim \text{Dirichlet}(\alpha_z)$	[draw derivation type parameters]
$\theta \sim \text{Dirichlet}(\alpha_h p_0)$	[draw rule parameters]
$z_d \sim \text{Multinomial}(\phi^z)$	[decide the derivation type]
$r \mathbf{r} \in d_x \sim \text{Multinomial}(\theta)$	[generate rules deriving phrase-pair $x$ ]

Figure 4: Definition of the proposed model

1. First decide the derivation type  $z_d$  for generating the aligned phrase pair  $x$ . It can either be a terminal derivation or hierarchical derivation with one/two gaps,<sup>1</sup> i.e.  $z_d = \{\text{TERM}, \text{HIER-A1}, \text{HIER-A2}\}$ .
2. Then identify the constituent rules  $\mathbf{r}$  in the derivation to generate the phrase pair.

Under this model the probability of a particular derivation  $d \in \phi_x$  for a given phrase pair  $x$  can be expressed as:

$$p(d) \propto p(z_d) \prod_{r \in d} p(r|\mathcal{G}, \theta) \quad (2)$$

where  $r$  is a rule in grammar  $\mathcal{G}$  and  $\theta$  is the grammar parameter.

Figure 4 depicts the generative story of our generative model. The derivation-type  $z_d$  is sampled from a multinomial distribution parameterized by  $\phi^z$ , where  $\phi^z$  is distributed itself by a Dirichlet distribution with hyper-parameter  $\alpha_z$ . The grammar rules are generated from a multinomial distribution parameterized by  $\theta$ , where  $\theta$  itself is distributed according to a Dirichlet distribution parameterized by a concentration parameter  $\alpha_h$  and a base distribution  $p_0$ . For the base distribution, we use a simple but yet informative prior based on geometric mean of the bidirectional alignment scores. This allows us to only explore the rules that would be consistent with the underlying word alignments.<sup>2</sup> Thus our setting closely resembles that of the Hiero heuristic rule extraction.

Our goal is thus to infer the joint posterior  $p(\theta, \Phi|\alpha_h, p_0, \alpha_z, \mathcal{X})$ , where  $\theta$  are the model parameters and  $\Phi$  the latent derivations over all the phrase pairs.

<sup>1</sup>This refers to the maximum arity of a rule involved in the derivation.

<sup>2</sup>While a non-parametric prior would be better from a Bayesian perspective, we leave it for future consideration.

### 3 Training

For inference we resort to a variational approximation and factorize the posterior distributions over grammar parameters  $\theta$  and latent derivations  $\Phi$  as:

$$p(\theta, \Phi|\alpha_h, p_0, \alpha_z, \mathcal{X}) \approx q(\theta|\mathbf{u})q(\Phi|\pi)$$

where  $\mathbf{u}$  and  $\pi$  are the parameters of the variational distributions.

The inference is then performed in an EM-style algorithm- iteratively updating the parameters  $\mathbf{u}$  and  $\pi$ . We initialize  $\mathbf{u}^0 := \alpha_h p_0$ , which is then updated with expected rule counts in subsequent iterations. The expected count for a rule  $r$  at time-step  $t$  can be written as:

$$\mathbb{E}[r^t] = \sum_{d \in \phi_x} p(d|\pi^{t-1}, x) f_d(r) \quad (3)$$

where  $p(d|\pi^{t-1}, x)$  is the probability of the derivation  $d$  for the phrase pair  $x$  and  $f_d(r)$  is the frequency of the rule  $r$  in derivation  $d$ . The  $p(d|\cdot)$  term in Equation 3 can then be written in terms of  $\pi$  as:

$$p(d|\pi^{t-1}, x) \propto p(z_d) \prod_{r \in d} \pi_r^{t-1} \quad (4)$$

The  $p(d|\cdot)$  are normalized across all the derivations of a given phrase pair to yield probabilities. For each *derivation type*  $z_d$ , its expected count (at time  $t$ ) is the sum of the probabilities of all the derivations of its type.

$$\mathbb{E}[z_d^t] = \sum_x \sum_{\{z_d=z_{d'}|d' \in \phi_x\}} p(d'|\pi^{t-1}, x) \quad (5)$$

We initialize the Dirichlet hyperparameters  $\alpha_{z_d}$  using a Gamma prior ranging between  $10^{-1}$  and  $10^3$ :  $\alpha_{z_d} \sim \text{Gamma}(10^{-1}, 10^3)$ .<sup>3</sup>

<sup>3</sup>In initial experiments we used an initial prior of  $\alpha_z = [10^0, 10, 10^4]$  to compensate for the smaller probabilities for arity-2 derivation resulting from two multiplications. However, our later experiments showed it to be unnecessary and so we used an initial prior that does not prefer any particular outcome.

  **end for**  
  **for**  $r \in \mathcal{G}$  **do**  
    Estimate posterior  $\mathbf{u}^t$ :  $u_r^t \leftarrow u_r^0 + \mathbb{E}[r^t]$   
  **end for**  
**Output:** Posterior distribution  $\mathbf{u}^t$

---

We run inference for a fixed number of iterations<sup>4</sup> and use the grammar along with their posterior counts from the last iteration for the translation table. Following (Sankaran et al., 2011), we use the shift-reduce style algorithm to efficiently encode the word aligned phrase-pair as a normalized decomposition tree (Zhang et al., 2008). The possible derivations (that are consistent with the word alignments) could then be enumerated by simply traversing every node in the decomposition tree and replacing its span by a non-terminal  $X$ .

### 3.1 Distributing Inference

While the above training procedure works well for smaller datasets, it does not scale well for the realistic MT datasets (which have millions of sentence pairs) due to greater memory and time requirements. To address this shortcoming, we distribute the training using a Map-Reduce style framework, where each node works on the local dataset in computing the required statistics and then communicates the statistics to a central aggregator reduce node.

Distributed inference for Expectation Maximization algorithm was studied in (Wolfe et al., 2008). They used three different topologies in

<sup>4</sup>In our experiments, we set the number of iterations to 10.

terms of computation time, bandwidth requirement and so on. While Map-Reduce is substantially slower than the All-pairs and Junction-tree topologies, it takes much lesser bandwidth than the other two apart from being much easier to implement. Furthermore our choice of the Variational inference naturally lends itself to distributed training.

We simply shard the set of aligned phrase pairs and parallelize the training steps for the shards across different nodes. At the end of local computation of the statistics (expected rule counts for example), we need to aggregate the statistics to get a global view, which will then be used in the next iteration/training step. We parallelize this aggregation across several nodes in one or two reduce steps as required. At the end of aggregation we communicate the updated statistics to each node on a need basis.<sup>5</sup>

## 4 Experiments

We experiment with three datasets of varying sizes. We use the University of Rochester Korean-English dataset consisting of almost 60K sentence pairs for the small data setting. For moderate and large datasets we use Arabic-English (ISI parallel corpus) and Chinese-English (Hong Kong parallel text and GALE phase-1) corpora. We use the MTC dataset having 4 references for tuning and testing for our Chinese-English experiments. The statistics of the corpora used in our experiments are summarized in Table 1.

Lang.	Training Corpus	Train/ Tune/ Test
<i>Ko-En</i>	URochester data	59218/ 1118/ 1118
<i>Ar-En</i>	ISI Ar-En corpus	1.1 M/ 1982/ 987
<i>Cn-En</i>	HK + GALE ph-1	2.3 M/ 1928/ 919

Table 1: Corpus Statistics in # of sentences

We follow the standard MT practice and use GIZA++ (Och and Ney, 2003) for word aligning the parallel corpus. We then use the heuristic step that symmetrizes the bidirectional alignments (Och et al., 1999) to extract the initial phrase-pairs up to a certain length, consistent with the word alignments. Finally we employ our proposed Variational-Bayes training to learn rules for

<sup>5</sup>We simulate the Map-Reduce style of computation using a regular high-performance cluster using a mounted filesystem rather than a Hadoop cluster with a distributed filesystem.

Model	Ko-En	Ar-En	Cn-En
<i>Baseline</i>	7.18	<b>37.82</b>	<b>28.58</b>
<i>Variational-Bayes</i>	<b>7.68</b>	37.76	28.40

Table 2: BLEU scores for baseline heuristic extraction and the proposed Variational-Bayes model. Best scores are in **boldface** and statistically significant differences are *italicized*.

Hiero. As a baseline Hiero model, we use the heuristic rule extraction (Chiang, 2007) approach to extract the rules. In both cases the parameters are estimated by the relative frequency estimation.

For decoding we use our in-house hierarchical phrase-based system- Kriya<sup>6</sup> (Sankaran et al., 2012b). We use the following 8 standard features for the log-linear model: translation probabilities ( $p(e|f)$  and  $p(f|e)$ ), lexical probabilities ( $p_l(e|f)$  and  $p_l(f|e)$ ), phrase and word penalties, language model and glue rule penalty.

#### 4.1 Results

The main BLEU score results are summarized in Table 2 and the key aspects are summarized below.

- **Higher BLEU scores:** Our Bayesian model performs better than the baseline heuristic rule extractor for Korean-English. Furthermore, the improvement of 0.5 BLEU is statistically significant at  $p$ -value of 0.01.
- **Large corpora:** Our distributed inference model easily scales to the large corpora and the inference completes in less than a day for Chinese-English. It also retains BLEU scores in the same level as the baseline models for both Arabic-English and Chinese-English.

#### 4.2 Compact Models

Some earlier research on Hiero have explored model size reduction as a means of reducing the time and space complexity of the Hiero decoder as well as for mitigating issues such as *overgeneration* (Setiawan et al., 2009). These approaches use a variety of compression strategies, *viz.* threshold pruning (Zollmann et al., 2008), pattern-based filtering (He et al., 2009; Iglesias et al., 2009) and significance pruning (Yang and Zheng, 2009).

While compact models is not the central idea of our work, we nevertheless explore the effect of

<sup>6</sup><https://github.com/sfu-natlang/Kriya>

a simple threshold pruning strategy on the grammar learned from our proposed model. Table 3 shows the results for the pruned grammars, where we prune the rules having expected count below a mincount threshold. We present the results for specific mincount settings based on our experiments on the held-out tuning set for each language pair.

Model	Ko-En	Ar-En	Cn-En
Model size: <i>VB</i>	2.67	331.6	471.7
BLEU: <i>VB</i>	<b>7.68</b>	<b>37.76</b>	<b>28.40</b>
<i>Pruning mincount</i>	0.25	1.0	1.0
Model size: <i>pruned</i>	1.65	58.9	87.3
Reduction:	38.2%	82.2%	81.5%
BLEU: <i>pruned</i>	<b>7.64</b>	37.58	<b>28.45</b>

Table 3: Model sizes (in millions) and BLEU scores of the full VB and pruned VB grammars. Mincount implies the expected rule count threshold used for pruning the full VB grammar. Best/indistinguishable BLEU scores are shown in **boldface**.

- **Retains score with smaller grammar:** The pruned grammars retain the performance of the full grammar, even while using just 18% of the complete model.
- **Higher reduction for large dataset:** Variational inference reduces the model size over 80% for the large corpora. While this is similar to the findings of Johnson et al. (2007) and that of the pruning strategies mentioned above; the question of whether an intelligent model selection strategy can yield higher BLEU scores is still open.
- **Faster decoding:** The compact grammars naturally result in faster decoding and we observed up to 20-30% speedup in the translation including the time spent for loading the model.

Sankaran et al. (2012a) proposed a model for extracting *compact* Hiero grammar with restricted arity (at most 1 non-terminal). In contrast our model is close the classical Hiero model Chiang (2007) having an arity of two. Though our results are not directly comparable to theirs, we nevertheless find our model to yield a better model size reduction than theirs. While they claim up to 57%

reduction, we achieve over 80% for the two large data conditions and about 38% reduction for the Korean-English small data setting.

### 4.3 Analysis

We now compare the probability distributions of the two grammars at the level of individual rules to understand the differences between them. We considered a set of source phrases that are common in both grammars and analyzed their probability distributions over the translation options.

Specifically we use the Q-Q plot to study the behaviour of two probability distributions as explained below considering the Chinese phrase 联合国 (*united nations*) as a representative example. The Q-Q plot in Figure 5 plots the  $p(e|f)$  probabilities (sorted for the baseline grammar) for different translations of the source phrase. The translations from the baseline grammar are then paired off with the points in the sorted VB curve and the corresponding probabilities are plotted in the same order as the baseline translations. The following conclusions can be drawn from this plot:

- **Penalize poor translations:** Among the low-probability translations, majority of the translations in the VB-grammar have probability less than the corresponding baseline translations. This has the desired property of potentially shifting the probability mass away from poor translations.
- **Reward good translations:** VB-grammar rewards some translations that were deemed to be poor by the heuristic method, by assigning a slightly higher probability than the heuristic grammar. A manual inspection showed that the rules with higher probabilities were objectively better translation rules. For example Table 4 contrasts the probabilities assigned by the two methods for the first four translation options in Fig. 5.
- **Uniform probability is not informative:** The heuristic extraction method tends to assign an uniform probability for groups of translations and this is evident in the flat segments of the baseline curve and is especially dominant in the low probability region. In contrast, the VB-grammar is more peaked (in Fig. 5 the probabilities are sorted for the VB grammar).

Translations	Heu $p(e f)$	VB $p(e f)$
alert the united nations	4.28e-04	3.46e-04
during	4.28e-04	3.20e-04
<i>for un</i>	4.28e-04	<i>5.02e-04</i>
human	4.28e-04	3.20e-04

Table 4: Probabilities assigned by the two methods for the first four translations in Fig. 5. The better translation among four and the higher probability assigned by our model are *italicized*.

We also observe similar trend for several source phrases in both Arabic-English and Chinese-English corpora.

At the macro level, we compare the sizes of the different types of rules in the heuristic and the Variational-Bayes grammar. The baseline grammar extract slightly more rules with arity-1 than the grammar extracted by our model (see Figure 6). Our model extracts rules used in a *derivation* of a phrase-pair, only if *all* its constituent rules are consistent with the Hiero rule constraints (such as restriction on the total number of terminals and non-terminals in the rule). However the heuristic method extracts all the consistent rules and does *not* consider the derivations. While this is a more stricter constraint, the VB model extracts slightly more (about 170K) arity-2 rules as we allow the unaligned words to be attached to different levels of hierarchical rules during the construction of the decomposition tree. This extracts translation rules that are beyond the purview of the heuristic method, since the Viterbi alignments cannot capture them.

We earlier examined the effect of pruning the VB grammar in Section 4.2 and noted that the grammar could be substantially reduced for different language pairs without sacrificing translation quality. In this context, we compare the effects of pruning the heuristic and VB grammars in Figure 6 for Chinese-English. For the same mincount threshold of 1 as the best performing VB setting, the BLEU score of the heuristic grammar drops by over 1 point. However this setting prunes over 99% of the arity-1 and arity-2 rules even while it retains all the terminal rules. This is primarily because of the way the heuristic method estimates rule counts by uniformly distributing the weight among all the rules. The terminal rules are sufficient for coverage but does not capture long distance movements; and the lack of arity-1 and arity-2 rules further restrict the reordering ability of the model. We have to substantially lower the

Figure 5: Q-Q plot comparing the  $p(e|f)$  distributions of the baseline and VB-grammars for the Chinese phrase 联合国 (*united nations*). The points on the two curves represent distinct target translations (the numbers on the  $x$ -axis indicate the indices) and the points are sorted according to VB translation probabilities against the paired-off translation probabilities from the baseline grammar. The  $y$ -axis is clipped to highlight the variations in the low-probability range.

mincount threshold to 0.05, in order to get performance comparable to the pruned VB grammar setting. Interestingly, this uses about 7M more rules (13M more arity-1 rules, but 6M fewer arity-2 rules) than VB-Pr (1.0), but its BLEU score is marginally lower than the latter. This could be ascribed to the missing arity-2 rules, which could be crucial for certain long-distance reordering.

Figure 6: Cn-En: Model sizes and BLEU for different grammars. The pruned models are identified by the suffix 'Pr', whose mincount is shown in the brackets. The  $y$ -axis on the left marks the model sizes and that on the right denotes BLEU. The numbers in the stacked bars denote the # of rules (in millions) for the corresponding rule type.

As the final part of the analysis, we also present the 100 high probability lexical phrases extracted by both rule extraction methods for the Arabic-English corpus in Figure 7. As seen, the heuristic grammar assigns high probability to the rules translating proper nouns and short phrases, whereas the VB method assigns high probability to more generic translations.

## 5 Related Research

Most of the research on learning Hiero SCFG rules has been focussed on inducing phrasal alignments between source and target using Bayesian models (Blunsom et al., 2008; Blunsom et al., 2009; Levenberg et al., 2012; Cohn and Haffari, 2013). Broadly speaking, these generative approaches learn a posterior over parallel tree structures on the sentence pairs. While these methods extract hierarchical rules, they do not conform to Hiero-style rules. Consequently the hierarchical rules are used *only* for learning an alignment model and cannot be used directly in the Hiero decoder. Instead, these approaches employ the standard Hiero heuristics to extract rules to be used by the decoder from the alignments predicted by their model. In this sense, these are similar to Bayesian models for learning alignments using stochastic Inversion transduction grammars (ITG) (Wu, 1997) or linear

Figure 7: 100 high probability Arabic-English lexical rules extracted by the two methods.

ITG (Saers et al., 2010). In addition, most of these works except for Levenberg et al. (2012) use small datasets with fewer than 100K sentence pairs.

More recently Sankaran et al. (2012a) proposed a Bayesian model employing Variational inference for directly extracting Hiero grammar from aligned phrase pairs. While our work is similar to theirs, there are notable differences as well. Firstly their model extracts a simpler arity-1 grammar, where the source and target sides can have at most 1 non-terminal. In contrast the grammar extracted by our model fully conforms to Hiero-style rules and hence can potentially capture larger reordering (than the unary grammar). Secondly, their inference does not scale for the larger datasets and consequently they train only on a subset of initial phrase-pairs thresholded by some high frequency. We further distribute the inference under a simple MapReduce style framework, which allows us to scale to large datasets.

A different line of work focuses on reducing the size of Hiero models, and we discussed these pa-

pers in Section 4.2. While this is not the central aspect of our work, we showed that simple pruning of the grammar (extracted by our model) could reduce the size by more than 80% without sacrificing translation quality.

## 6 Conclusion

This paper introduced a novel Bayesian model for learning Hiero SCFG translation rules which is an alternative to the commonly used heuristic rule extraction approach. For inference, we use Variational-EM along with a Map-Reduce style framework for distributing the training process. This allowed us to efficiently train the model for very large corpora. We provided quantitative results and also a detailed qualitative analysis to demonstrate the superiority of the model trained by our approach. In future work, we would like to extend our model for inference directly on full sentence pairs as has been applied for the syntax-based model (Galley et al., 2006).

## Abstract

Language model is an essential part in statistical machine translation, but traditional  $n$ -gram language models can only capture a limited local context in the translated sentence, thus lacking the global information for prediction. This paper describes a novel topic-triggered language model, which takes into account the topical context by estimating the  $n$ -gram probability under the given topics and online adjusts language model score according to different topic distributions. Experimental results show that our method provides a average improvement of +0.76 B on NIST Chinese-to-English translation task and a reduction in word perplexity of the test-document.

## 1 Introduction

Language model (LM) measures the fluency of translation outputs (Brown et al., 1993), and plays an important role in statistical machine translation (SMT). Traditional language model predicts the next word conditioning only on the preceding  $n-1$  words, thus ignores syntactic structures in the sentence and global information over the document.

One direct approach to handle this problem is to explore sentence-level context, such as syntax-based language model for reranking (Charniak et al., 2003), and dependency language model for String-to-Dependency model (Shen et al., 2008). But these methods are still not robust enough to handle the polysemy and domain changes, as they lack the global-context information.

Another interesting line is to utilize information at document-level. Intuitively, different domains or topics have different  $n$ -gram probability distributions. Thus, we should take into account the topic information when we translate a document. Topic model has been learned in several

parts of SMT, such as word-alignment (Zhao and Xing, 2006; Zhao and Xing, 2007; Gong et al., 2011), translation model (Xiao et al., 2012). All these works show that a particular translation often appears in some specific topical context, so it is reasonable to enhance the prediction ability of language model by incorporating topical information. Tan et al. (2011) introduces a large scale distributed composite language model incorporating document-level information. But they only focus on the target side and explore in  $n$ -best reranking task which has a limited search space, while another promising application is taking account of topical information on both sides and integrate the LM into decoding to online select translation hypotheses. However, the integration is not easy. Since the test-document can be from any topic, it is hard to dynamically estimate language model probability according to various topic distributions.

In this paper, we follow this line and introduce a novel topic-triggered language model. We first estimate the topic distribution for each document in training data, and assign those topic probabilities to each sentence. With target-side topic probabilities, we train a topic-specific language model for each topic. Then, rather than limiting topical context to target side, we utilize the source-side topical information at decoding time and online adjust language model score according to the topic distribution of the translated-document. As there is no explicit correspondence between topics on both sides, we project the source-side topic distribution to the target side as a trigger to our topic specific language models. As compared with previous works, our model takes advantage of the topical information on both sides, thus breaking down the context barrier for language model. Experimental results on various Chinese-English test sets show that our method gains an average improvement of +0.76 B points and a perplexity reduction over

the baseline model.

## 2 Related Work

Previous works devoted to improving language models in SMT mostly focus on utilizing more contextual information, such as syntax-based LMs (Charniak et al., 2003; Schwartz et al., 2011; Shen et al., 2008; Hassan et al., 2009), Forward & MI trigger LM (Xiong et al., 2011), and large-scale language models (Zhang et al., 2006; Brants et al., 2007; Emami et al., 2007; Talbot and Osborne, 2007). Since our philosophy is fundamentally different from them in that we incorporate information at document level to build language models. So we discuss previous works that explore topic information for SMT in this section.

Researchers have been trying to incorporate topic information into language models in several ways. Gildea and Hofmann (1999) use EM algorithm to perform a topic factor decomposition based on a segmented training corpus. They estimate unigram topic-based probability and combine it with standard  $n$ -gram model. Tam et al. (2007) and Ruiz and Federico (2011) introduce topic model for cross-lingual language model adaptation task. They use bilingual topic model to project latent topic distribution across languages. Based on the BLSA, they are able to transfer source-side topic weights into target-side and use them to generate topic-based marginals to adapt  $n$ -gram language model. Our model is different from theirs in that rather than using topic-based probabilities to adapt  $n$ -gram model, we directly calculate LM probability conditioned on topic distributions.

There are also some valuable applications of topic model for machine translation. Zhao and Xing (2006) propose the Bilingual Topic Admixture Model (BiTAM) for word alignment and extract topic-dependent translation model accordingly. Gong et al. (2011) introduce topic model for filtering topic-mismatched phrase pairs. Su et al. (2012) use the topic distribution of in-domain monolingual corpus to adapt the translation model. Xiao et al. (2012) introduce a topic similarity model to select the synchronous rules for hierarchical phrase-based translation. Our work is in the same spirit with those works, but we are interested in LM problem rather than other parts in SMT.

Our work models topic probabilities into training corpus and trains several topic-specific LMs,

so it is in the same spirit of mixture modeling. Heidel et al. (2007) use topic distribution to cluster the training corpora and train LMs accordingly. Our method is different from theirs in that we assign topic probabilities to training sentences rather than segment them into different topics, so our model is more robust to data sparse problem. Besides, Foster and Kuhn (2007), Civera and Juan (2007), Lü et al. (2007) also adapt mixture modeling framework to exploit the full potential of existing corpus. Adopting this framework, the training corpus is first divided into different parts, each of which is used to train a sub model, then these sub models are used together with different weights during decoding. Those works typically use word similarities and sentence level information, while our work extends the context into the document level.

## 3 Topic triggered Language Model

Polysemy is a difficult problem for statistical machine translation. As shown in Figure 1, English sentence "give me a shot" has different meanings in different domains. Using traditional LM, which only considers the local context information in the translated sentence, this ambiguous translation is hard to handle, since these translations are all common in the corpus with different domains. But with the help of topical context information, the difference can be told. For example, the word 'shot' is often translated into "(photo)" in the sentences related to the film topic, and to "(chance)" in sports topic. So as the topic information is concerned, LM allows for more fine-grained distinction of different translations and enjoys stronger prediction power.

In our method, we introduce the topic of current document  $t$  as a hidden variable, and decompose the language model probability as follows:

$$P(\mathbf{e}) = \sum_t P(\mathbf{e}, t) = \sum_t P(\mathbf{e}|t) \cdot P(t) \quad (1)$$

$P(\mathbf{e}|t)$  indicates the probability of the sequence  $\mathbf{e}$  given the topic  $t$ , and  $P(t)$  is the topic distribution of the test-document which is calculated during decoding. In general, our framework to build the topic-trigger language model can be specified into two steps:

- Build topic-specific LMs conditioned on the topic distribution estimated by the target-side topic model

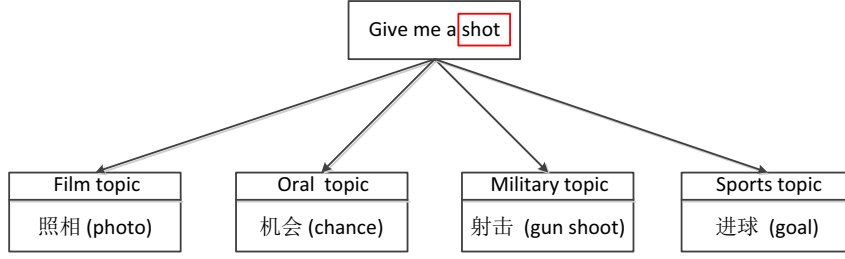

Figure 1: Example of different translations of word "shot" in different topics

- Capture source-side topic information during decoding and online adjust LM score

We will give detailed description of the two parts in the following section.

### 3.1 Topic-specific language model

In this section, we first briefly review the principle of Hidden Topic Markov Model (HTMM) which is the basis of our method, then describe our approach to build topic-specific LMs in detail.

#### 3.1.1 Hidden Topic Markov Model

Topic model is a suite of algorithms aiming to discover the hidden thematic structure in large archives of documents. Recently both Latent Dirichlet Allocation (LDA) (Blei et al., 2003) and Probabilistic Latent Semantic Analysis (PLSA) (Hofmann, 1999) have been successfully applied in various NLP tasks. Based on the "bag-of-words" assumption that the order of words can be ignored, these methods model the corpus as a co-occurrence matrix of words and documents, and build generative models to infer the latent aspect of topics. Using these models, words can be clustered into the derived topics with a probability distribution. and the correlation between words can be automatically captured via topics.
