Introduction

Welcome to SemEval-2018!

The Semantic Evaluation (SemEval) series of workshops focuses on the evaluation and comparison of systems that can analyse diverse semantic phenomena in text with the aim of extending the current state of the art in semantic analysis and creating high quality annotated datasets in a range of increasingly challenging problems in natural language semantics. SemEval provides an exciting forum for researchers to propose challenging research problems in semantics and to build systems/techniques to address such research problems.

SemEval-2018 is the twelfth workshop in the series of International Workshops on Semantic Evaluation. The first three workshops, SensEval-1 (1998), SensEval-2 (2001), and SensEval-3 (2004), focused on word sense disambiguation, each time growing in the number of languages offered, in the number of tasks, and also in the number of participating teams. In 2007, the workshop was renamed to SemEval, and the subsequent SemEval workshops evolved to include semantic analysis tasks beyond word sense disambiguation. In 2012, SemEval turned into a yearly event. It currently runs every year, but on a two-year cycle, i.e., the tasks for SemEval-2018 were proposed in 2017.

SemEval-2018 was co-located with the 16th Annual Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (NAACL HLT 2018) in New Orleans, Louisiana, US. It included the following 12 shared tasks organized in five tracks:

- Affect and Creative Language in Tweets
 - Task 1: Affect in Tweets
 - Task 2: Multilingual Emoji Prediction
 - Task 3: Irony Detection in English Tweets
- Coreference
 - Task 4: Character Identification on Multiparty Dialogues
 - Task 5: Counting Events and Participants within Highly Ambiguous Data covering a very long tail
- Information Extraction
 - Task 6: Parsing Time Normalizations
 - Task 7: Semantic Relation Extraction and Classification in Scientific Papers
 - Task 8: Semantic Extraction from Cybersecurity Reports using Natural Language Processing (SecureNLP)
- Lexical Semantics
 - Task 9: Hypernym Discovery
 - Task 10: Capturing Discriminative Attributes
- Reading Comprehension and Reasoning
 - Task 11: Machine Comprehension using Commonsense Knowledge
 - Task 12: Argument Reasoning Comprehension Task

This volume contains both Task Description papers that describe each of the above tasks, and System Description papers that present the systems that participated in these tasks. A total of 12 task description papers and 184 system description papers are included in this volume.

We are grateful to all task organizers as well as to the large number of participants whose enthusiastic participation has made SemEval once again a successful event. We are thankful to the task organizers who also served as area chairs, and to task organizers and participants who reviewed paper submissions. These proceedings have greatly benefited from their detailed and thoughtful feedback. We also thank the NAACL HLT 2018 conference organizers for their support. Finally, we most gratefully acknowledge the support of our sponsor, the ACL Special Interest Group on the Lexicon (SIGLEX).

The SemEval-2018 organizers, Marianna Apidianaki, Saif M. Mohammad, Jonathan May, Ekaterina Shutova, Marine Carpuat, Steven Bethard

Organizers:

Marianna Apidianaki, LIMSI, CNRS, Université Paris-Saclay & University of Pennsylvania
Saif M. Mohammad, National Research Council Canada
Jonathan May, University of Southern California Information Sciences Institute
Ekaterina Shutova, University of Cambridge
Steven Bethard, University of Alabama at Birmingham
Marine Carpuat, University of Maryland

Task Selection Committee:

Eneko Agirre, University of the Basque Country
Isabelle Augenstein, University of Copenhagen
Timothy Baldwin, University of Melbourne
Paul Buitelaar, National University of Ireland
Alberto Barrón-Cedeño, Qatar Computing Research Institute
Yonatan Belinkov, MIT
Kalina Bontcheva, University of Sheffield
Georgeta Bordea, National University of Ireland
Daniel Cer, Google
Wanxiang Che, Harbin Institute of Technology
Keith Cortis, University of Passau
Danilo Croce, University of Rome Tor Vergata
Mrinal Das, University of Massachusetts Amherst
Noura Farra, Columbia University
Dimitris Galanis, ILSP, "Athena" Research Center
Christian Hempelmann, Texas A&M University-Commerce
Anders Johannsen, University of Copenhagen
Maria Liakata, University of Warwick
Montse Maritxalar, University of the Basque Country
Jonathan May, University of Southern California Information Sciences Institute
Rada Mihalcea, University of Michigan
Tristan Miller, Technische Universität Darmstadt
Hamdy Mubarak, Qatar Computing Research Institute
Haris Papageorgiou, ILSP, "Athena" Research Center
Mohammad Taher Pilehvar
Maria Pontiki, ILSP, "Athena" Research Center
Peter Potash, University of Massachusetts Lowell
Alan Ritter, The Ohio State University
Alexey Romanov, University of Massachusetts Lowell
Sara Rosenthal, IBM Watson
Nathan Schneider, University of Edinburgh
Parinaz Sobhani, University of Ottawa
Xiaodan Zhu, National Research Council Canada
Arkaitz Zubiaga, University of Warwick

Task Organizers:

Miguel Ballesteros, IBM Watson, USA
Francesco Barbieri, Universitat Pompeu Fabra, LaSTUS lab, Spain
Valerio Basile, Sapienza University, Italy
Steven Bethard, University of Arizona
Felipe Bravo-Marquez, The University of Waikato
Davide Buscaldi, LIPN, UMR CNRS, Université Paris 13
Jose Camacho-Collados, Sapienza University of Rome
Thierry Charnois, LIPN, UMR CNRS, Université Paris 13
Henry Y. Chen, Snap Inc.
Jinho D. Choi, Emory University
Claudio Delli Bovi, Sapienza University of Rome
Ahmed S. Elsayed, University of Colorado
Luis Espinoza-Anke, Universitat Pompeu Fabra, LaSTUS lab, Spain
Kata Gábor, LIPN, UMR CNRS, Université Paris 13
Iryna Gurevych, UKP TU-Darmstadt
Ivan Habernal, UKP TU-Darmstadt
Véronique Hoste, LT3, Faculty of Arts and Philosophy, Ghent University
Filip Ilievski, Vrije Universiteit Amsterdam
Svetlana Kiritchenko, National Research Council Canada
Alicia Krebs, Textkernel BV, Amsterdam, Netherlands
Egoitz Laparra, University of Arizona
Els Lefever, LT3, Faculty of Arts and Philosophy, Ghent University
Alessandro Lenci, Department of Philology, Literature, and Linguistics of the University of Pisa, Italy
Wei Lu, Singapore University of Technology and Design
Ashutosh Modi, Saarland University
Saif M. Mohammad, National Research Council Canada
Roberto Navigli, Sapienza University of Rome
Sergio Oramas, Universitat Pompeu Fabra
Simon Ostermann, Saarland University
Martha Palmer, University of Colorado
Denis Paperno, Lorraine Laboratory of Computer Science and its Applications, CNRS, France
Tommaso Pasini, Sapienza University of Rome
Viviana Patti, University of Torino, Italy
Peter Phandi, Singapore University of Technology and Design
Manfred Pinkal, Saarland University
Marten Postma, Vrije Universiteit Amsterdam
Behrang QasemiZadeh, DFG Collaborative Research Centre 991, Heinrich-Heine University Düsseldorf
Francesco Ronzano, Universitat Pompeu Fabra, LaSTUS lab, Spain
Michael Roth, Saarland University
Horacio Saggion, Universitat Pompeu Fabra, LaSTUS lab, Spain
Mohammad Salameh, Carnegie Mellon University, Qatar
Enrico Santus, Singapore University
Anne-Kathrin Schumann, ProTechnology GmbH, Dresden, former: Department of Applied Linguistics, Translation and Interpreting, Saarland University
Vered Shwartz, Bar-Ilan University
Benno Stein, Webis, Bauhaus-Universität Weimar
Isabelle Tellier, Laboratoire Lattice, CNRS and Université Sorbonne Nouvelle
Stefan Thater, Saarland University

Cynthia Van Hee, LT3, Faculty of Arts and Philosophy, Ghent University
Piek Vossen, Vrije Universiteit Amsterdam
Henning Wachsmuth, Webis, Bauhaus-Universität Weimar
Dongfang Xu, University of Arizona
Haïfa Zargayouna, LIPN, UMR CNRS, Université Paris 13

Invited Speaker:

Ellie Pavlick, Brown University

Invited Talk: Why should we care about linguistics?

Ellie Pavlick

(Joint Invited Speaker with *SEM 2018)

Brown University

Abstract

In just the past few months, a flurry of adversarial studies have pushed back on the apparent progress of neural networks, with multiple analyses suggesting that deep models of text fail to capture even basic properties of language, such as negation, word order, and compositionality. Alongside this wave of negative results, our field has stated ambitions to move beyond task-specific models and toward "general purpose" word, sentence, and even document embeddings. This is a tall order for the field of NLP, and, I argue, marks a significant shift in the way we approach our research. I will discuss what we can learn from the field of linguistics about the challenges of codifying all of language in a "general purpose" way. Then, more importantly, I will discuss what we cannot learn from linguistics. I will argue that the state-of-the-art of NLP research is operating close to the limits of what we know about natural language semantics, both within our field and outside it. I will conclude with thoughts on why this opens opportunities for NLP to advance both technology and basic science as it relates to language, and the implications for the way we should conduct empirical research.

Biography

Ellie Pavlick is currently a Post Doc at Google Research in NY. She will join Brown University as an Assistant Professor in July. Ellie received her PhD from University of Pennsylvania under the supervision of Chris Callison-Burch. Her current research focus is on semantics, pragmatics, and building cognitively-plausible computational models of natural language inference.

Table of Contents

<i>SemEval-2018 Task 1: Affect in Tweets</i>	
Saif Mohammad, Felipe Bravo-Marquez, Mohammad Salameh and Svetlana Kiritchenko	1
<i>SeerNet at SemEval-2018 Task 1: Domain Adaptation for Affect in Tweets</i>	
Venkatesh Duppada, Royal Jain and Sushant Hiray	18
<i>SemEval 2018 Task 2: Multilingual Emoji Prediction</i>	
Francesco Barbieri, Jose Camacho-Collados, Francesco Ronzano, Luis Espinosa Anke, Miguel Ballesteros, Valerio Basile, Viviana Patti and Horacio Saggion	24
<i>Tübingen-Oslo at SemEval-2018 Task 2: SVMs perform better than RNNs in Emoji Prediction</i>	
Çağrı Çöltekin and Taraka Rama	34
<i>SemEval-2018 Task 3: Irony Detection in English Tweets</i>	
Cynthia Van Hee, Els Lefever and Veronique Hoste	39
<i>THU_NGN at SemEval-2018 Task 3: Tweet Irony Detection with Densely connected LSTM and Multi-task Learning</i>	
Chuhan Wu, Fangzhao Wu, Sixing Wu, Junxin Liu, Zhigang Yuan and Yongfeng Huang	51
<i>SemEval 2018 Task 4: Character Identification on Multiparty Dialogues</i>	
Jinho D. Choi and Henry Y. Chen	57
<i>AMORE-UPF at SemEval-2018 Task 4: BiLSTM with Entity Library</i>	
Laura Aina, Carina Silberer, Ionut-Teodor Sorodoc, Matthijs Westera and Gemma Boleda	65
<i>SemEval-2018 Task 5: Counting Events and Participants in the Long Tail</i>	
Marten Postma, Filip Ilievski and Piek Vossen	70
<i>KOI at SemEval-2018 Task 5: Building Knowledge Graph of Incidents</i>	
Paramita Mirza, Fariz Darari and Rahmad Mahendra	81
<i>SemEval 2018 Task 6: Parsing Time Normalizations</i>	
Egoitz Laparra, Dongfang Xu, Ahmed Elsayed, Steven Bethard and Martha Palmer	88
<i>Chrono at SemEval-2018 Task 6: A System for Normalizing Temporal Expressions</i>	
Amy Olex, Luke Maffey, Nicholas Morgan and Bridget McInnes	97
<i>NEUROSENT-PDI at SemEval-2018 Task 1: Leveraging a Multi-Domain Sentiment Model for Inferring Polarity in Micro-blog Text</i>	
Mauro Dragoni	102
<i>FOI DSS at SemEval-2018 Task 1: Combining LSTM States, Embeddings, and Lexical Features for Affect Analysis</i>	
Maja Karasalo, Mattias Nilsson, Magnus Rosell and Ulrika Wickenberg Bolin	109
<i>NLPZZX at SemEval-2018 Task 1: Using Ensemble Method for Emotion and Sentiment Intensity Determination</i>	
Zhengxin Zhang, Qimin Zhou and Hao Wu	116
<i>LT3 at SemEval-2018 Task 1: A classifier chain to detect emotions in tweets</i>	
Luna De Bruyne, Orphee De Clercq and Veronique Hoste	123

<i>SINAI at SemEval-2018 Task 1: Emotion Recognition in Tweets</i> Flor Miriam Plaza del Arco, Salud María Jiménez-Zafra, Maite Martin and L. Alfonso Urena Lopez	128
<i>UWB at SemEval-2018 Task 1: Emotion Intensity Detection in Tweets</i> Pavel Přibáň, Tomáš Hercig and Ladislav Lenc	133
<i>AttnConvnet at SemEval-2018 Task 1: Attention-based Convolutional Neural Networks for Multi-label Emotion Classification</i> Yanghoon Kim, Hwanhee Lee and Kyomin Jung	141
<i>INGEOTEC at SemEval-2018 Task 1: EvoMSA and μTC for Sentiment Analysis</i> Mario Graff, Sabino Miranda-Jiménez, Eric S. Tellez and Daniela Moctezuma	146
<i>Epita at SemEval-2018 Task 1: Sentiment Analysis Using Transfer Learning Approach</i> Guillaume Daval-Frerot, Abdesselam Boucekif and Anatole Moreau	151
<i>KDE-AFFECT at SemEval-2018 Task 1: Estimation of Affects in Tweet by Using Convolutional Neural Network for n-gram</i> Masaki Aono and Shinnosuke Himeno	156
<i>RNN for Affects at SemEval-2018 Task 1: Formulating Affect Identification as a Binary Classification Problem</i> Aysu Ezen-Can and Ethem F. Can	162
<i>Tw-StAR at SemEval-2018 Task 1: Preprocessing Impact on Multi-label Emotion Classification</i> Hala Mulki, Chedi Bechikh Ali, Hatem Haddad and Ismail Babaoglu	167
<i>DL Team at SemEval-2018 Task 1: Tweet Affect Detection using Sentiment Lexicons and Embeddings</i> Dmitry Kravchenko and Lidia Pivovarova	172
<i>EmoIntens Tracker at SemEval-2018 Task 1: Emotional Intensity Levels in #Tweets</i> Ramona-Andreea Turcu, Sandra Maria Amarandei, Iuliana-Alexandra Fleşcan-Lovin-Arseni, Daniela Gifu and Diana Trandabat	177
<i>uOttawa at SemEval-2018 Task 1: Self-Attentive Hybrid GRU-Based Network</i> Ahmed Hussein Orabi, Mahmoud Hussein Orabi, Diana Inkpen and David Van Bruwaene	181
<i>THU_NGN at SemEval-2018 Task 1: Fine-grained Tweet Sentiment Intensity Analysis with Attention CNN-LSTM</i> Chuhan Wu, Fangzhao Wu, Junxin Liu, Zhigang Yuan, Sixing Wu and Yongfeng Huang	186
<i>EiTAKA at SemEval-2018 Task 1: An Ensemble of N-Channels ConvNet and XGboost Regressors for Emotion Analysis of Tweets</i> Mohammed Jabreel and Antonio Moreno	193
<i>CENTEMENT at SemEval-2018 Task 1: Classification of Tweets using Multiple Thresholds with Self-correction and Weighted Conditional Probabilities</i> Tariq Ahmad, Allan Ramsay and Hanady Ahmed	200
<i>Yuan at SemEval-2018 Task 1: Tweets Emotion Intensity Prediction using Ensemble Recurrent Neural Network</i> Min Wang and Xiaobing Zhou	205

<i>AffecThor at SemEval-2018 Task 1: A cross-linguistic approach to sentiment intensity quantification in tweets</i>	
Mostafa Abdou, Artur Kulmizev and Joan Ginés i Ametllé	210
<i>Amobee at SemEval-2018 Task 1: GRU Neural Network with a CNN Attention Mechanism for Sentiment Classification</i>	
Alon Rozental and Daniel Fleischer	218
<i>deepSA2018 at SemEval-2018 Task 1: Multi-task Learning of Different Label for Affect in Tweets</i>	
Zi Yuan Gao and Chia-Ping Chen	226
<i>ECNU at SemEval-2018 Task 1: Emotion Intensity Prediction Using Effective Features and Machine Learning Models</i>	
Huimin Xu, Man Lan and Yuanbin Wu	231
<i>EMA at SemEval-2018 Task 1: Emotion Mining for Arabic</i>	
Gilbert Badaro, Obeida El Jundi, Alaa Khaddaj, Alaa Maarouf, Raslan Kain, Hazem Hajj and Wassim El-Hajj	236
<i>NTUA-SLP at SemEval-2018 Task 1: Predicting Affective Content in Tweets with Deep Attentive RNNs and Transfer Learning</i>	
Christos Baziotis, Athanasiou Nikolaos, Alexandra Chronopoulou, Athanasia Kolovou, Georgios Paraskevopoulos, Nikolaos Ellinas, Shrikanth Narayanan and Alexandros Potamianos	245
<i>CrystalFeel at SemEval-2018 Task 1: Understanding and Detecting Emotion Intensity using Affective Lexicons</i>	
Raj Kumar Gupta and Yinping Yang	256
<i>PlusEmo2Vec at SemEval-2018 Task 1: Exploiting emotion knowledge from emoji and #hashtags</i>	
Ji Ho Park, Peng Xu and Pascale Fung	264
<i>YNU-HPCC at SemEval-2018 Task 1: BiLSTM with Attention based Sentiment Analysis for Affect in Tweets</i>	
You Zhang, Jin Wang and Xuejie Zhang	273
<i>UG18 at SemEval-2018 Task 1: Generating Additional Training Data for Predicting Emotion Intensity in Spanish</i>	
Marloes Kuijper, Mike van Lenthe and Rik van Noord	279
<i>ISCLAB at SemEval-2018 Task 1: UIR-Miner for Affect in Tweets</i>	
Meng Li, Zhenyuan Dong, Zhihao Fan, Kongming Meng, Jinghua Cao, Guanqi Ding, Yuhan Liu, Jiawei Shan and Binyang Li	286
<i>TCS Research at SemEval-2018 Task 1: Learning Robust Representations using Multi-Attention Architecture</i>	
Hardik Meisheri and Lipika Dey	291
<i>DMCB at SemEval-2018 Task 1: Transfer Learning of Sentiment Classification Using Group LSTM for Emotion Intensity prediction</i>	
Youngmin Kim and Hyunju Lee	300
<i>DeepMiner at SemEval-2018 Task 1: Emotion Intensity Recognition Using Deep Representation Learning</i>	
Habibeh Naderi, Behrouz Haji Soleimani, Saif Mohammad, Svetlana Kiritchenko and Stan Matwin	305

<i>Zewen at SemEval-2018 Task 1: An Ensemble Model for Affect Prediction in Tweets</i>	
Zewen Chi, Heyan Huang, Jianguai Chen, Hao Wu and Ran Wei	313
<i>Amrita_student at SemEval-2018 Task 1: Distributed Representation of Social Media Text for Affects in Tweets</i>	
Nidhin A Unnithan, Shalini K, Barathi Ganesh H. B., Anand Kumar M and Soman K P	319
<i>SSN MLRG1 at SemEval-2018 Task 1: Emotion and Sentiment Intensity Detection Using Rule Based Feature Selection</i>	
Angel Deborah S, Rajalakshmi S, S Milton Rajendram and Mirnalinee T T	324
<i>CENNLN at SemEval-2018 Task 1: Constrained Vector Space Model in Affects in Tweets</i>	
Naveen J R, Barathi Ganesh H. B., Anand Kumar M and Soman K P	329
<i>TeamCEN at SemEval-2018 Task 1: Global Vectors Representation in Emotion Detection</i>	
Anon George, Barathi Ganesh H. B., Anand Kumar M and Soman K P	334
<i>IIT Delhi at SemEval-2018 Task 1 : Emotion Intensity Prediction</i>	
Bhaskar Kotakonda, Prashanth Gowda and Brejesh Lall	339
<i>Mutex at SemEval-2018 Task 1: Exploring Impacts of Context Information On Emotion Detection</i>	
Pan Du and Jian-Yun Nie	345
<i>TeamUNCC at SemEval-2018 Task 1: Emotion Detection in English and Arabic Tweets using Deep Learning</i>	
Malak Abdullah and Samira Shaikh	350
<i>RIDDL at SemEval-2018 Task 1: Rage Intensity Detection with Deep Learning</i>	
Venkatesh Elango and Karan Uppal	358
<i>ARB-SEN at SemEval-2018 Task1: A New Set of Features for Enhancing the Sentiment Intensity Prediction in Arabic Tweets</i>	
El Moatez Billah Nagoudi	364
<i>psyML at SemEval-2018 Task 1: Transfer Learning for Sentiment and Emotion Analysis</i>	
Grace Gee and Eugene Wang	369
<i>UIUC at SemEval-2018 Task 1: Recognizing Affect with Ensemble Models</i>	
Abhishek Avinash Narwekar and Roxana Girju	377
<i>KU-MTL at SemEval-2018 Task 1: Multi-task Identification of Affect in Tweets</i>	
Thomas Nyegaard-Signori, Casper Veistrup Helms, Johannes Bjerva and Isabelle Augenstein .	385
<i>EmoNLP at SemEval-2018 Task 2: English Emoji Prediction with Gradient Boosting Regression Tree Method and Bidirectional LSTM</i>	
Man Liu	390
<i>UMDSub at SemEval-2018 Task 2: Multilingual Emoji Prediction Multi-channel Convolutional Neural Network on Subword Embedding</i>	
Zhenduo Wang and Ted Pedersen	395
<i>UMDuluth-CS8761 at SemEval-2018 Task 2: Emojis: Too many Choices?</i>	
Jonathan Beaulieu and Dennis Asamoah Owusu	400
<i>The Dabblers at SemEval-2018 Task 2: Multilingual Emoji Prediction</i>	
Larisa Alexa, Alina Lorent, Daniela Gifu and Diana Trandabat	405

<i>THU_NGN at SemEval-2018 Task 2: Residual CNN-LSTM Network with Attention for English Emoji Prediction</i>	
Chuhan Wu, Fangzhao Wu, Sixing Wu, Zhigang Yuan, Junxin Liu and Yongfeng Huang	410
<i>#TeamINF at SemEval-2018 Task 2: Emoji Prediction in Tweets</i>	
Alison Ribeiro and Nádia Silva	415
<i>EICA Team at SemEval-2018 Task 2: Semantic and Metadata-based Features for Multilingual Emoji Prediction</i>	
Yufei Xie and Qingqing Song	419
<i>EmojiIt at SemEval-2018 Task 2: An Effective Attention-Based Recurrent Neural Network Model for Emoji Prediction with Characters Gated Words</i>	
Chen Shiyun, Wang Maoquan and He Liang	423
<i>Peperomia at SemEval-2018 Task 2: Vector Similarity Based Approach for Emoji Prediction</i>	
Jing Chen, Dechuan Yang, Xilian Li, Wei Chen and Tengjiao Wang	428
<i>ECNU at SemEval-2018 Task 2: Leverage Traditional NLP Features and Neural Networks Methods to Address Twitter Emoji Prediction Task</i>

<i>KLUEunicorn at SemEval-2018 Task 3: A Naive Approach to Irony Detection</i> Luise Dürlich	607
<i>NTUA-SLP at SemEval-2018 Task 3: Tracking Ironic Tweets using Ensembles of Word and Character Level Attentive RNNs</i> Christos Baziotis, Athanasiou Nikolaos, Pinelopi Papalampidi, Athanasia Kolovou, Georgios Paraskevopoulos, Nikolaos Ellinas and Alexandros Potamianos	613
<i>YNU-HPCC at SemEval-2018 Task 3: Ensemble Neural Network Models for Irony Detection on Twitter</i> Bo Peng, Jin Wang and Xuejie Zhang	622
<i>Binarizer at SemEval-2018 Task 3: Parsing dependency and deep learning for irony detection</i> Nishant Nikhil and Muktabh Mayank Srivastava	628
<i>SSN MLRG1 at SemEval-2018 Task 3: Irony Detection in English Tweets Using MultiLayer Perceptron</i> Rajalakshmi S, Angel Deborah S, S Milton Rajendram and Mirnalinee T T	633
<i>NLPRL-IITBHU at SemEval-2018 Task 3: Combining Linguistic Features and Emoji pre-trained CNN for Irony Detection in Tweets</i> Harsh Rangwani, Devang Kulshreshtha and Anil Kumar Singh	638
<i>ValenTO at SemEval-2018 Task 3: Exploring the Role of Affective Content for Detecting Irony in English Tweets</i> Delia Irazú Hernández Farías, Viviana Patti and Paolo Rosso	643
<i>#NonDicevoSulSerio at SemEval-2018 Task 3: Exploiting Emojis and Affective Content for Irony Detection in English Tweets</i> Endang Wahyu Pamungkas and Viviana Patti	649
<i>KNU CI System at SemEval-2018 Task4: Character Identification by Solving Sequence-Labeling Problem</i> Cheoneum Park, Heejun Song and Changki Lee	655

<i>NewsReader at SemEval-2018 Task 5: Counting events by reasoning over event-centric-knowledge-graphs</i>	
Piek Vossen	660
<i>FEUP at SemEval-2018 Task 5: An Experimental Study of a Question Answering System</i>	
Carla Abreu and Eugénio Oliveira	667
<i>NAI-SEA at SemEval-2018 Task 5: An Event Search System</i>	
Yingchi Liu, Quanzhi Li and Luo Si	674
<i>SemEval-2018 Task 7: Semantic Relation Extraction and Classification in Scientific Papers</i>	
Kata Gábor, Davide Buscaldi, Anne-Kathrin Schumann, Behrang QasemiZadeh, Haifa Zargayouna and Thierry Charnois	679
<i>ETH-DS3Lab at SemEval-2018 Task 7: Effectively Combining Recurrent and Convolutional Neural Networks for Relation Classification and Extraction</i>	
Jonathan Rotsztein, Nora Hollenstein and Ce Zhang	689
<i>SemEval-2018 Task 8: Semantic Extraction from CybersecUrity REports using Natural Language Processing (SecureNLP)</i>	
Peter Phandi, Amila Silva and Wei Lu	697
<i>DM_NLP at SemEval-2018 Task 8: neural sequence labeling with linguistic features</i>	
Chunping Ma, Huafei Zheng, Pengjun Xie, Chen Li, Linlin Li and Luo Si	707
<i>SemEval-2018 Task 9: Hypernym Discovery</i>	
Jose Camacho-Collados, Claudio Delli Bovi, Luis Espinosa Anke, Sergio Oramas, Tommaso Pasini, Enrico Santus, Vered Shwartz, Roberto Navigli and Horacio Saggion	712
<i>CRIM at SemEval-2018 Task 9: A Hybrid Approach to Hypernym Discovery</i>	
Gabriel Bernier-Colborne and Caroline Barriere	725
<i>SemEval-2018 Task 10: Capturing Discriminative Attributes</i>	
Alicia Krebs, Alessandro Lenci and Denis Paperno	732
<i>SUNNYNLP at SemEval-2018 Task 10: A Support-Vector-Machine-Based Method for Detecting Semantic Difference using Taxonomy and Word Embedding Features</i>	
Sunny Lai, Kwong Sak Leung and Yee Leung	741
<i>SemEval-2018 Task 11: Machine Comprehension Using Commonsense Knowledge</i>	
Simon Ostermann, Michael Roth, Ashutosh Modi, Stefan Thater and Manfred Pinkal	747
<i>Yanfudao at SemEval-2018 Task 11: Three-way Attention and Relational Knowledge for Commonsense Machine Comprehension</i>	
Liang Wang, Meng Sun, Wei Zhao, Kewei Shen and Jingming Liu	758
<i>SemEval-2018 Task 12: The Argument Reasoning Comprehension Task</i>	
Ivan Habernal, Henning Wachsmuth, Iryna Gurevych and Benno Stein	763
<i>GIST at SemEval-2018 Task 12: A network transferring inference knowledge to Argument Reasoning Comprehension task</i>	
HongSeok Choi and Hyunju Lee	773
<i>LightRel at SemEval-2018 Task 7: Lightweight and Fast Relation Classification</i>	
Tyler Renslow and Günter Neumann	778

<i>OhioState at SemEval-2018 Task 7: Exploiting Data Augmentation for Relation Classification in Scientific Papers Using Piecewise Convolutional Neural Networks</i>	
Dushyanta Dhyani	783
<i>The UWNLP system at SemEval-2018 Task 7: Neural Relation Extraction Model with Selectively Incorporated Concept Embeddings</i>	
Yi Luan, Mari Ostendorf and Hannaneh Hajishirzi	788
<i>UC3M-NII Team at SemEval-2018 Task 7: Semantic Relation Classification in Scientific Papers via Convolutional Neural Network</i>	
Víctor Suárez-Paniagua, Isabel Segura-Bedmar and Akiko Aizawa	793
<i>MIT-MEDG at SemEval-2018 Task 7: Semantic Relation Classification via Convolution Neural Network</i>	
Di Jin, Franck Dernoncourt, Elena Sergeeva, Matthew McDermott and Geeticka Chauhan	798
<i>SIRIUS-LTG-UiO at SemEval-2018 Task 7: Convolutional Neural Networks with Shortest Dependency Paths for Semantic Relation Extraction and Classification in Scientific Papers</i>	
Farhad Nooralahzadeh, Lilja Øvrelid and Jan Tore Lønning	805
<i>IRCMS at SemEval-2018 Task 7: Evaluating a basic CNN Method and Traditional Pipeline Method for Relation Classification</i>	
Zhongbo Yin, Zhunchen Luo, Luo Wei, Mao Bin, Tian Changhai, Ye Yuming and Wu Shuai ..	811
<i>Bf3R at SemEval-2018 Task 7: Evaluating Two Relation Extraction Tools for Finding Semantic Relations in Biomedical Abstracts</i>	
Mariana Neves, Daniel Butzke, Gilbert Schönfelder and Barbara Grune	816
<i>Texterra at SemEval-2018 Task 7: Exploiting Syntactic Information for Relation Extraction and Classification in Scientific Papers</i>	
Andrey Sysoev and Vladimir Mayorov	821
<i>UniMa at SemEval-2018 Task 7: Semantic Relation Extraction and Classification from Scientific Publications</i>	
Thorsten Keiper, Zhonghao Lyu, Sara Pooladzadeh, Yuan Xu, Jingyi Zhang, Anne Lauscher and Simone Paolo Ponzetto	826
<i>GU IRLAB at SemEval-2018 Task 7: Tree-LSTMs for Scientific Relation Classification</i>	
Sean MacAvaney, Luca Soldaini, Arman Cohan and Nazli Goharian	831
<i>ClaiRE at SemEval-2018 Task 7: Classification of Relations using Embeddings</i>	
Lena Hettinger, Alexander Dallmann, Albin Zehe, Thomas Niebler and Andreas Hotho	836
<i>TakeLab at SemEval-2018 Task 7: Combining Sparse and Dense Features for Relation Classification in Scientific Texts</i>	
Martin Gluhak, Maria Pia di Buono, Abbas Akkasi and Jan Šnajder	842
<i>NEUROSENT-PDI at SemEval-2018 Task 7: Discovering Textual Relations With a Neural Network Model</i>	
Mauro Dragoni	848
<i>SciREL at SemEval-2018 Task 7: A System for Semantic Relation Extraction and Classification</i>	
Darshini Mahendran, Chathurika Brahmana and Bridget McInnes	853

<i>NTNU at SemEval-2018 Task 7: Classifier Ensembling for Semantic Relation Identification and Classification in Scientific Papers</i>	
Biswanath Barik, Utpal Kumar Sikdar and Björn Gambäck	858
<i>Talla at SemEval-2018 Task 7: Hybrid Loss Optimization for Relation Classification using Convolutional Neural Networks</i>	
Bhanu Pratap, Daniel Shank, Oladipo Ositelu and Byron Galbraith	863
<i>TeamDL at SemEval-2018 Task 8: Cybersecurity Text Analysis using Convolutional Neural Network and Conditional Random Fields</i>	
Manikandan R, Krishna Madgula and Snehanshu Saha	868
<i>HCCL at SemEval-2018 Task 8: An End-to-End System for Sequence Labeling from Cybersecurity Reports</i>	
Mingming Fu, Xuemin Zhao and Yonghong Yan	874
<i>UMBC at SemEval-2018 Task 8: Understanding Text about Malware</i>	
Ankur Padia, Arpita Roy, Taneeya Satyapanich, Francis Ferraro, Shimei Pan, Youngja Park, Anupam Joshi and Tim Finin	878
<i>Villani at SemEval-2018 Task 8: Semantic Extraction from Cybersecurity Reports using Representation Learning</i>	
Pablo Loyola, Kugamoorthy Gajananan, Yuji Watanabe and Fumiko Satoh	885
<i>Flytxt_NTNU at SemEval-2018 Task 8: Identifying and Classifying Malware Text Using Conditional Random Fields and Naïve Bayes Classifiers</i>	
Utpal Kumar Sikdar, Biswanath Barik and Björn Gambäck	890
<i>Digital Operatives at SemEval-2018 Task 8: Using dependency features for malware NLP</i>	
Chris Brew	894
<i>Apollo at SemEval-2018 Task 9: Detecting Hypernymy Relations Using Syntactic Dependencies</i>	
Mihaela Onofrei, Ionut Hulub, Diana Trandabat and Daniela Gifu	898
<i>SJTU-NLP at SemEval-2018 Task 9: Neural Hypernym Discovery with Term Embeddings</i>	
Zhuosheng Zhang, Jiangtong Li, Hai Zhao and Bingjie Tang	903
<i>NLP_HZ at SemEval-2018 Task 9: a Nearest Neighbor Approach</i>	
Wei Qiu, Mosha Chen, Linlin Li and Luo Si	909
<i>UMDuluth-CS8761 at SemEval-2018 Task9: Hypernym Discovery using Hearst Patterns, Co-occurrence frequencies and Word Embeddings</i>	
Arshia Zernab Hassan, Manikya Swathi Vallabhajosyula and Ted Pedersen	914
<i>EXPR at SemEval-2018 Task 9: A Combined Approach for Hypernym Discovery</i>	
Ahmad Issa Alaa Aldine, Mounira Harzallah, Giuseppe Berio, Nicolas Béchet and Ahmad Faour	919
<i>ADAPT at SemEval-2018 Task 9: Skip-Gram Word Embeddings for Unsupervised Hypernym Discovery in Specialised Corpora</i>	
Alfredo Maldonado and Filip Klubička	924
<i>300-sparsans at SemEval-2018 Task 9: Hypernymy as interaction of sparse attributes</i>	
Gábor Berend, Márton Makrai and Péter Földiák	928

<i>UWB at SemEval-2018 Task 10: Capturing Discriminative Attributes from Word Distributions</i> Tomáš Brychcín, Tomáš Hercig, Josef Steinberger and Michal Konkol	935
<i>Meaning_space at SemEval-2018 Task 10: Combining explicitly encoded knowledge with information extracted from word embeddings</i> Pia Sommerauer, Antske Fokkens and Piek Vossen.....	940
<i>GHH at SemEval-2018 Task 10: Discovering Discriminative Attributes in Distributional Semantics</i> Mohammed Attia, Younes Samih, Manaal Faruqui and Wolfgang Maier.....	947
<i>CitiusNLP at SemEval-2018 Task 10: The Use of Transparent Distributional Models and Salient Contexts to Discriminate Word Attributes</i> Pablo Gamallo	953
<i>THU_NGN at SemEval-2018 Task 10: Capturing Discriminative Attributes with MLP-CNN model</i> Chuhan Wu, Fangzhao Wu, Sixing Wu, Zhigang Yuan and Yongfeng Huang.....	958
<i>ALB at SemEval-2018 Task 10: A System for Capturing Discriminative Attributes</i> Bogdan Dumitru, Alina Maria Ciobanu and Liviu P. Dinu.....	963
<i>ELiRF-UPV at SemEval-2018 Task 10: Capturing Discriminative Attributes with Knowledge Graphs and Wikipedia</i> José-Ángel González, Lluís-F. Hurtado, Encarna Segarra and Ferran Pla	968
<i>Wolves at SemEval-2018 Task 10: Semantic Discrimination based on Knowledge and Association</i> Shiva Taslimipoor, Omid Rohanian, Le An Ha, Gloria Corpas Pastor and Ruslan Mitkov.....	972
<i>UNAM at SemEval-2018 Task 10: Unsupervised Semantic Discriminative Attribute Identification in Neural Word Embedding Cones</i> Ignacio Arroyo-Fernández, Ivan Meza and Carlos-Francisco Meéndez-Cruz	977
<i>Luminoso at SemEval-2018 Task 10: Distinguishing Attributes Using Text Corpora and Relational Knowledge</i> Robert Speer and Joanna Lowry-Duda.....	985
<i>BomJi at SemEval-2018 Task 10: Combining Vector-, Pattern- and Graph-based Information to Identify Discriminative Attributes</i> Enrico Santus, Chris Biemann and Emmanuele Chersoni	990
<i>Igevorse at SemEval-2018 Task 10: Exploring an Impact of Word Embeddings Concatenation for Capturing Discriminative Attributes</i> Maxim Grishin	995
<i>ECNU at SemEval-2018 Task 10: Evaluating Simple but Effective Features on Machine Learning Methods for Semantic Difference Detection</i> Yunxiao Zhou, Man Lan and Yuanbin Wu	999
<i>AmritaNLP at SemEval-2018 Task 10: Capturing discriminative attributes using convolution neural network over global vector representation.</i> Vivek Vinayan, Anand Kumar M and Soman K P.....	1003
<i>Discriminator at SemEval-2018 Task 10: Minimally Supervised Discrimination</i> Artur Kulmizev, Mostafa Abdou, Vinit Ravishankar and Malvina Nissim.....	1008

<i>UNBNLP at SemEval-2018 Task 10: Evaluating unsupervised approaches to capturing discriminative attributes</i>	
Milton King, Ali Hakimi Parizi and Paul Cook	1013
<i>ABDN at SemEval-2018 Task 10: Recognising Discriminative Attributes using Context Embeddings and WordNet</i>	
Rui Mao, Guanyi Chen, Ruizhe Li and Chenghua Lin	1017
<i>UMD at SemEval-2018 Task 10: Can Word Embeddings Capture Discriminative Attributes?</i>	
Alexander Zhang and Marine Carpuat	1022
<i>NTU NLP Lab System at SemEval-2018 Task 10: Verifying Semantic Differences by Integrating Distributional Information and Expert Knowledge</i>	
Yow-Ting Shiue, Hen-Hsen Huang and Hsin-Hsi Chen	1027
<i>ELiRF-UPV at SemEval-2018 Task 11: Machine Comprehension using Commonsense Knowledge</i>	
José-Ángel González, Lluís-F. Hurtado, Encarna Segarra and Ferran Pla	1034
<i>YNU_AI1799 at SemEval-2018 Task 11: Machine Comprehension using Commonsense Knowledge of Different model ensemble</i>	
Liu Qingxun, Yao Hongdou, Zhou Xiaobing and Xie Ge	1038
<i>YNU_Deep at SemEval-2018 Task 11: An Ensemble of Attention-based BiLSTM Models for Machine Comprehension</i>	
Peng Ding and Xiaobing Zhou	1043
<i>ECNU at SemEval-2018 Task 11: Using Deep Learning Method to Address Machine Comprehension Task</i>	
Yixuan Sheng, Man Lan and Yuanbin Wu	1048
<i>CSReader at SemEval-2018 Task 11: Multiple Choice Question Answering as Textual Entailment</i>	
Zhengping Jiang and Qi Sun	1053
<i>YNU-HPCC at Semeval-2018 Task 11: Using an Attention-based CNN-LSTM for Machine Comprehension using Commonsense Knowledge</i>	
Hang Yuan, Jin Wang and Xuejie Zhang	1058
<i>Jiangnan at SemEval-2018 Task 11: Deep Neural Network with Attention Method for Machine Comprehension Task</i>	
Jiangnan Xia	1063
<i>IUCM at SemEval-2018 Task 11: Similar-Topic Texts as a Comprehension Knowledge Source</i>	
Sofia Reznikova and Leon Derczynski	1068
<i>Lyb3b at SemEval-2018 Task 11: Machine Comprehension Task using Deep Learning Models</i>	
Yongbin Li and Xiaobing Zhou	1073
<i>MITRE at SemEval-2018 Task 11: Commonsense Reasoning without Commonsense Knowledge</i>	
Elizabeth Merkhofer, John Henderson, David Bloom, Laura Strickhart and Guido Zarrella ..	1078
<i>SNU_IDS at SemEval-2018 Task 12: Sentence Encoder with Contextualized Vectors for Argument Reasoning Comprehension</i>	
Taeuk Kim, Jihun Choi and Sang-goo Lee	1083

<i>ITNLP-ARC at SemEval-2018 Task 12: Argument Reasoning Comprehension with Attention</i> Wenjie Liu, Chengjie Sun, Lei Lin and Bingquan Liu	1089
<i>ECNU at SemEval-2018 Task 12: An End-to-End Attention-based Neural Network for the Argument Reasoning Comprehension Task</i> Junfeng Tian, Man Lan and Yuanbin Wu	1094
<i>NLITrans at SemEval-2018 Task 12: Transfer of Semantic Knowledge for Argument Comprehension</i> Timothy Niven and Hung-Yu Kao	1099
<i>BLCU_NLP at SemEval-2018 Task 12: An Ensemble Model for Argument Reasoning Based on Hierarchical Attention</i> Meiqian Zhao, Chunhua Liu, Lu Liu, Yan Zhao and Dong Yu	1104
<i>YNU-HPCC at SemEval-2018 Task 12: The Argument Reasoning Comprehension Task Using a Bi-directional LSTM with Attention Model</i> Quanlei Liao, Xutao Yang, Jin Wang and Xuejie Zhang	1109
<i>HHU at SemEval-2018 Task 12: Analyzing an Ensemble-based Deep Learning Approach for the Argument Mining Task of Choosing the Correct Warrant</i> Matthias Liebeck, Andreas Funke and Stefan Conrad	1114
<i>YNU Deep at SemEval-2018 Task 12: A BiLSTM Model with Neural Attention for Argument Reasoning Comprehension</i> Peng Ding and Xiaobing Zhou	1120
<i>UniMelb at SemEval-2018 Task 12: Generative Implication using LSTMs, Siamese Networks and Semantic Representations with Synonym Fuzzing</i> Anirudh Joshi, Tim Baldwin, Richard O. Sinnott and Cecile Paris	1124
<i>Joker at SemEval-2018 Task 12: The Argument Reasoning Comprehension with Neural Attention</i> Sui Guobin, Chao Wenhan and Luo Zhunchen	1129
<i>TakeLab at SemEval-2018 Task12: Argument Reasoning Comprehension with Skip-Thought Vectors</i> Ana Brassard, Tin Kuculo, Filip Boltuzic and Jan Šnajder	1133
<i>Lyb3b at SemEval-2018 Task 12: Ensemble-based Deep Learning Models for Argument Reasoning Comprehension Task</i> Yongbin Li and Xiaobing Zhou	1137
<i>TRANSRW at SemEval-2018 Task 12: Transforming Semantic Representations for Argument Reasoning Comprehension</i> Zhimin Chen, Wei Song and Lizhen Liu	1142

Workshop Program

5 June 2018

09:00–09:15 *Welcome / Opening Remarks*

09:15–10:30 *Invited Talk: Why should we care about linguistics?*
Ellie Pavlick

10:30–11:00 *Coffee*

11:00–12:30 **Tasks 1, 2 and 3**

11:00–11:15 *SemEval-2018 Task 1: Affect in Tweets*
Saif Mohammad, Felipe Bravo-Marquez, Mohammad Salameh and Svetlana Kiritchenko

11:15–11:30 *SeerNet at SemEval-2018 Task 1: Domain Adaptation for Affect in Tweets*
Venkatesh Duppada, Royal Jain and Sushant Hiray

11:30–11:45 *SemEval 2018 Task 2: Multilingual Emoji Prediction*
Francesco Barbieri, Jose Camacho-Collados, Francesco Ronzano, Luis Espinosa Anke, Miguel Ballesteros, Valerio Basile, Viviana Patti and Horacio Saggion

11:45–12:00 *Tübingen-Oslo at SemEval-2018 Task 2: SVMs perform better than RNNs in Emoji Prediction*
Çağrı Çöltekin and Taraka Rama

12:00–12:15 *SemEval-2018 Task 3: Irony Detection in English Tweets*
Cynthia Van Hee, Els Lefever and Veronique Hoste

12:15–12:30 *THU_NGN at SemEval-2018 Task 3: Tweet Irony Detection with Densely connected LSTM and Multi-task Learning*
Chuhan Wu, Fangzhao Wu, Sixing Wu, Junxin Liu, Zhigang Yuan and Yongfeng Huang

12:30–14:00 *Lunch*

5 June 2018 (continued)

14:00–15:30 Tasks 4, 5 and 6

14:00–14:15 *SemEval 2018 Task 4: Character Identification on Multiparty Dialogues*

Jinho D. Choi and Henry Y. Chen

14:15–14:30 *AMORE-UPF at SemEval-2018 Task 4: BiLSTM with Entity Library*

Laura Aina, Carina Silberer, Ionut-Teodor Sorodoc, Matthijs Westera and Gemma Boleda

14:30–14:45 *SemEval-2018 Task 5: Counting Events and Participants in the Long Tail*

Marten Postma, Filip Ilievski and Piek Vossen

14:45–15:00 *KOI at SemEval-2018 Task 5: Building Knowledge Graph of Incidents*

Paramita Mirza, Fariz Darari and Rahmad Mahendra

15:00–15:15 *SemEval 2018 Task 6: Parsing Time Normalizations*

Egoitz Laparra, Dongfang Xu, Ahmed Elsayed, Steven Bethard and Martha Palmer

15:15–15:30 *Chrono at SemEval-2018 Task 6: A System for Normalizing Temporal Expressions*

Amy Olex, Luke Maffey, Nicholas Morgan and Bridget McInnes

15:30–16:00 Coffee

16:00–16:30 Discussion

5 June 2018 (continued)

16:30–17:30 Poster Session

- 16:30–17:30 *NEUROSENT-PDI at SemEval-2018 Task 1: Leveraging a Multi-Domain Sentiment Model for Inferring Polarity in Micro-blog Text*
Mauro Dragoni
- 16:30–17:30 *FOI DSS at SemEval-2018 Task 1: Combining LSTM States, Embeddings, and Lexical Features for Affect Analysis*
Maja Karasalo, Mattias Nilsson, Magnus Rosell and Ulrika Wickenberg Bolin
- 16:30–17:30 *NLPZZX at SemEval-2018 Task 1: Using Ensemble Method for Emotion and Sentiment Intensity Determination*
Zhengxin Zhang, Qimin Zhou and Hao Wu
- 16:30–17:30 *LT3 at SemEval-2018 Task 1: A classifier chain to detect emotions in tweets*
Luna De Bruyne, Orphee De Clercq and Veronique Hoste
- 16:30–17:30 *SINAI at SemEval-2018 Task 1: Emotion Recognition in Tweets*
Flor Miriam Plaza del Arco, Salud María Jiménez-Zafra, Maite Martin and L. Alfonso Urena Lopez
- 16:30–17:30 *UWB at SemEval-2018 Task 1: Emotion Intensity Detection in Tweets*
Pavel Přibáň, Tomáš Hercig and Ladislav Lenc
- 16:30–17:30 *AttnConvnet at SemEval-2018 Task 1: Attention-based Convolutional Neural Networks for Multi-label Emotion Classification*
Yanghoon Kim, Hwanhee Lee and Kyomin Jung
- 16:30–17:30 *INGEOTEC at SemEval-2018 Task 1: EvoMSA and μ TC for Sentiment Analysis*
Mario Graff, Sabino Miranda-Jiménez, Eric S. Tellez and Daniela Moctezuma
- 16:30–17:30 *Epita at SemEval-2018 Task 1: Sentiment Analysis Using Transfer Learning Approach*
Guillaume Daval-Frerot, Abdesselam Bouchekif and Anatole Moreau
- 16:30–17:30 *KDE-AFFECT at SemEval-2018 Task 1: Estimation of Affects in Tweet by Using Convolutional Neural Network for n-gram*
Masaki Aono and Shinnosuke Himeno
- 16:30–17:30 *RNN for Affects at SemEval-2018 Task 1: Formulating Affect Identification as a Binary Classification Problem*
Aysu Ezen-Can and Ethem F. Can

5 June 2018 (continued)

- 16:30–17:30 *Tw-StAR at SemEval-2018 Task 1: Preprocessing Impact on Multi-label Emotion Classification*
Hala Mulki, Chedi Bechikh Ali, Hatem Haddad and Ismail Babaoglu
- 16:30–17:30 *DL Team at SemEval-2018 Task 1: Tweet Affect Detection using Sentiment Lexicons and Embeddings*
Dmitry Kravchenko and Lidia Pivovarova
- 16:30–17:30 *EmoIntens Tracker at SemEval-2018 Task 1: Emotional Intensity Levels in #Tweets*
Ramona-Andreea Turcu, Sandra Maria Amarandei, Iuliana-Alexandra Fleşcan-Lovin-Arseni, Daniela Gifu and Diana Trandabat
- 16:30–17:30 *uOttawa at SemEval-2018 Task 1: Self-Attentive Hybrid GRU-Based Network*
Ahmed Hussein Orabi, Mahmoud Hussein Orabi, Diana Inkpen and David Van Bruwaene
- 16:30–17:30 *THU_NGN at SemEval-2018 Task 1: Fine-grained Tweet Sentiment Intensity Analysis with Attention CNN-LSTM*
Chuhan Wu, Fangzhao Wu, Junxin Liu, Zhigang Yuan, Sixing Wu and Yongfeng Huang
- 16:30–17:30 *EiTAKA at SemEval-2018 Task 1: An Ensemble of N-Channels ConvNet and XG-boost Regressors for Emotion Analysis of Tweets*
Mohammed Jabreel and Antonio Moreno
- 16:30–17:30 *CENTEMENT at SemEval-2018 Task 1: Classification of Tweets using Multiple Thresholds with Self-correction and Weighted Conditional Probabilities*
Tariq Ahmad, Allan Ramsay and Hanady Ahmed
- 16:30–17:30 *Yuan at SemEval-2018 Task 1: Tweets Emotion Intensity Prediction using Ensemble Recurrent Neural Network*
Min Wang and Xiaobing Zhou
- 16:30–17:30 *AffecThor at SemEval-2018 Task 1: A cross-linguistic approach to sentiment intensity quantification in tweets*
Mostafa Abdou, Artur Kulmizev and Joan Ginés i Ametllé
- 16:30–17:30 *Amobee at SemEval-2018 Task 1: GRU Neural Network with a CNN Attention Mechanism for Sentiment Classification*
Alon Rozental and Daniel Fleischer
- 16:30–17:30 *deepSA2018 at SemEval-2018 Task 1: Multi-task Learning of Different Label for Affect in Tweets*
Zi Yuan Gao and Chia-Ping Chen
- 16:30–17:30 *ECNU at SemEval-2018 Task 1: Emotion Intensity Prediction Using Effective Features and Machine Learning Models*
Huimin Xu, Man Lan and Yuanbin Wu

5 June 2018 (continued)

- 16:30–17:30 *EMA at SemEval-2018 Task 1: Emotion Mining for Arabic*
Gilbert Badaro, Obeida El Jundi, Alaa Khaddaj, Alaa Maarouf, Raslan Kain, Hazem Hajj and Wassim El-Hajj
- 16:30–17:30 *NTUA-SLP at SemEval-2018 Task 1: Predicting Affective Content in Tweets with Deep Attentive RNNs and Transfer Learning*
Christos Baziotis, Athanasiou Nikolaos, Alexandra Chronopoulou, Athanasia Kolovou, Georgios Paraskevopoulos, Nikolaos Ellinas, Shrikanth Narayanan and Alexandros Potamianos
- 16:30–17:30 *CrystalFeel at SemEval-2018 Task 1: Understanding and Detecting Emotion Intensity using Affective Lexicons*
Raj Kumar Gupta and Yinping Yang
- 16:30–17:30 *PlusEmo2Vec at SemEval-2018 Task 1: Exploiting emotion knowledge from emoji and #hashtags*
Ji Ho Park, Peng Xu and Pascale Fung
- 16:30–17:30 *YNU-HPCC at SemEval-2018 Task 1: BiLSTM with Attention based Sentiment Analysis for Affect in Tweets*
You Zhang, Jin Wang and Xuejie Zhang
- 16:30–17:30 *UG18 at SemEval-2018 Task 1: Generating Additional Training Data for Predicting Emotion Intensity in Spanish*
Marloes Kuijper, Mike van Lenthe and Rik van Noord
- 16:30–17:30 *ISCLAB at SemEval-2018 Task 1: UIR-Miner for Affect in Tweets*
Meng Li, Zhenyuan Dong, Zhihao Fan, Kongming Meng, Jinghua Cao, Guanqi Ding, Yuhan Liu, Jiawei Shan and Binyang Li
- 16:30–17:30 *TCS Research at SemEval-2018 Task 1: Learning Robust Representations using Multi-Attention Architecture*
Hardik Meisheri and Lipika Dey
- 16:30–17:30 *DMCB at SemEval-2018 Task 1: Transfer Learning of Sentiment Classification Using Group LSTM for Emotion Intensity prediction*
Youngmin Kim and Hyunju Lee
- 16:30–17:30 *DeepMiner at SemEval-2018 Task 1: Emotion Intensity Recognition Using Deep Representation Learning*
Habibeh Naderi, Behrouz Haji Soleimani, Saif Mohammad, Svetlana Kiritchenko and Stan Matwin
- 16:30–17:30 *Zewen at SemEval-2018 Task 1: An Ensemble Model for Affect Prediction in Tweets*
Zewen Chi, Heyan Huang, Jianguai Chen, Hao Wu and Ran Wei
- 16:30–17:30 *Amrita_student at SemEval-2018 Task 1: Distributed Representation of Social Media Text for Affects in Tweets*
Nidhin A Unnithan, Shalini K, Barathi Ganesh H. B., Anand Kumar M and Soman K P

5 June 2018 (continued)

- 16:30–17:30 *SSN MLRG1 at SemEval-2018 Task 1: Emotion and Sentiment Intensity Detection Using Rule Based Feature Selection*
Angel Deborah S, Rajalakshmi S, S Milton Rajendram and Mirnalinee T T
- 16:30–17:30 *CENNLP at SemEval-2018 Task 1: Constrained Vector Space Model in Affects in Tweets*
Naveen J R, Barathi Ganesh H. B., Anand Kumar M and Soman K P
- 16:30–17:30 *TeamCEN at SemEval-2018 Task 1: Global Vectors Representation in Emotion Detection*
Anon George, Barathi Ganesh H. B., Anand Kumar M and Soman K P
- 16:30–17:30 *IIT Delhi at SemEval-2018 Task 1 : Emotion Intensity Prediction*
Bhaskar Kotakonda, Prashanth Gowda and Brejesh Lall
- 16:30–17:30 *Mutex at SemEval-2018 Task 1: Exploring Impacts of Context Information On Emotion Detection*
Pan Du and Jian-Yun Nie
- 16:30–17:30 *TeamUNCC at SemEval-2018 Task 1: Emotion Detection in English and Arabic Tweets using Deep Learning*
Malak Abdullah and Samira Shaikh
- 16:30–17:30 *RIDDL at SemEval-2018 Task 1: Rage Intensity Detection with Deep Learning*
Venkatesh Elango and Karan Uppal
- 16:30–17:30 *ARB-SEN at SemEval-2018 Task1: A New Set of Features for Enhancing the Sentiment Intensity Prediction in Arabic Tweets*
El Moatez Billah Nagoudi
- 16:30–17:30 *psyML at SemEval-2018 Task 1: Transfer Learning for Sentiment and Emotion Analysis*
Grace Gee and Eugene Wang
- 16:30–17:30 *UIUC at SemEval-2018 Task 1: Recognizing Affect with Ensemble Models*
Abhishek Avinash Narwekar and Roxana Girju
- 16:30–17:30 *KU-MTL at SemEval-2018 Task 1: Multi-task Identification of Affect in Tweets*
Thomas Nyegaard-Signori, Casper Veistrup Helms, Johannes Bjerva and Isabelle Augenstein
- 16:30–17:30 *EmonLP at SemEval-2018 Task 2: English Emoji Prediction with Gradient Boosting Regression Tree Method and Bidirectional LSTM*
Man Liu

5 June 2018 (continued)

- 16:30–17:30 *UMDSub at SemEval-2018 Task 2: Multilingual Emoji Prediction Multi-channel Convolutional Neural Network on Subword Embedding*
Zhenduo Wang and Ted Pedersen
- 16:30–17:30 *UMDuluth-CS8761 at SemEval-2018 Task 2: Emojis: Too many Choices?*
Jonathan Beaulieu and Dennis Asamoah Owusu
- 16:30–17:30 *The Dabblers at SemEval-2018 Task 2: Multilingual Emoji Prediction*
Larisa Alexa, Alina Lorent, Daniela Gifu and Diana Trandabat
- 16:30–17:30 *THU_NGN at SemEval-2018 Task 2: Residual CNN-LSTM Network with Attention for English Emoji Prediction*
Chuhan Wu, Fangzhao Wu, Sixing Wu, Zhigang Yuan, Junxin Liu and Yongfeng Huang
- 16:30–17:30 *#TeamINF at SemEval-2018 Task 2: Emoji Prediction in Tweets*
Alison Ribeiro and Nádia Silva
- 16:30–17:30 *EICA Team at SemEval-2018 Task 2: Semantic and Metadata-based Features for Multilingual Emoji Prediction*
Yufei Xie and Qingqing Song
- 16:30–17:30 *EmojiIt at SemEval-2018 Task 2: An Effective Attention-Based Recurrent Neural Network Model for Emoji Prediction with Characters Gated Words*
Chen Shiyun, Wang Maoquan and He Liang
- 16:30–17:30 *Peperomia at SemEval-2018 Task 2: Vector Similarity Based Approach for Emoji Prediction*
Jing Chen, Dechuan Yang, Xilian Li, Wei Chen and Tengjiao Wang
- 16:30–17:30 *ECNU at SemEval-2018 Task 2: Leverage Traditional NLP Features and Neural Networks Methods to Address Twitter Emoji Prediction Task*
Xingwu Lu, Xin Mao, Man Lan and Yuanbin Wu
- 16:30–17:30 *NTUA-SLP at SemEval-2018 Task 2: Predicting Emojis using RNNs with Context-aware Attention*
Christos Baziotis, Athanasiou Nikolaos, Athanasia Kolovou, Georgios Paraskevopoulos, Nikolaos Ellinas and Alexandros Potamianos
- 16:30–17:30 *Hatching Chick at SemEval-2018 Task 2: Multilingual Emoji Prediction*
Joël Coster, Reinder Gerard van Dalen and Nathalie Adrienne Jacqueline Stierman
- 16:30–17:30 *EPUTION at SemEval-2018 Task 2: Emoji Prediction with User Adaption*
Liyuan Zhou, Qiongkai Xu, Hanna Suominen and Tom Gedeon

5 June 2018 (continued)

- 16:30–17:30 *PickleTeam! at SemEval-2018 Task 2: English and Spanish Emoji Prediction from Tweets*
Daphne Groot, Rémon Kruizinga, Hennie Veldthuis, Simon de Wit and Hessel Haagsma
- 16:30–17:30 *YNU-HPCC at SemEval-2018 Task 2: Multi-ensemble Bi-GRU Model with Attention Mechanism for Multilingual Emoji Prediction*
Nan Wang, Jin Wang and Xuejie Zhang
- 16:30–17:30 *DUTH at SemEval-2018 Task 2: Emoji Prediction in Tweets*
Dimitrios Effrosynidis, Georgios Peikos, Symeon Symeonidis and Avi Arampatzis
- 16:30–17:30 *TAJJEB at SemEval-2018 Task 2: Traditional Approaches Just Do the Job with Emoji Prediction*
Angelo Basile and Kenny W. Lino
- 16:30–17:30 *SyntNN at SemEval-2018 Task 2: is Syntax Useful for Emoji Prediction? Embedding Syntactic Trees in Multi Layer Perceptrons*
Fabio Massimo Zanzotto and Andrea Santilli
- 16:30–17:30 *Duluth UROP at SemEval-2018 Task 2: Multilingual Emoji Prediction with Ensemble Learning and Oversampling*
Shuning Jin and Ted Pedersen
- 16:30–17:30 *CENNLP at SemEval-2018 Task 2: Enhanced Distributed Representation of Text using Target Classes for Emoji Prediction Representation*
Naveen J R, Hariharan V, Barathi Ganesh H. B., Anand Kumar M and Soman K P
- 16:30–17:30 *Manchester Metropolitan at SemEval-2018 Task 2: Random Forest with an Ensemble of Features for Predicting Emoji in Tweets*
Luciano Gerber and Matthew Shardlow
- 16:30–17:30 *Tweety at SemEval-2018 Task 2: Predicting Emojis using Hierarchical Attention Neural Networks and Support Vector Machine*
Daniel Kopev, Atanas Atanasov, Dimitrina Zlatkova, Momchil Hardalov, Ivan Koychev, Ivelina Nikolova and Galia Angelova
- 16:30–17:30 *LIS at SemEval-2018 Task 2: Mixing Word Embeddings and Bag of Features for Multilingual Emoji Prediction*
Gaël Guibon, Magalie Ochs and Patrice Bellot
- 16:30–17:30 *ALANIS at SemEval-2018 Task 3: A Feature Engineering Approach to Irony Detection in English Tweets*
Kevin Swanberg, Madiha Mirza, Ted Pedersen and Zhenduo Wang
- 16:30–17:30 *NEUROSENT-PDI at SemEval-2018 Task 3: Understanding Irony in Social Networks Through a Multi-Domain Sentiment Model*
Mauro Dragoni

5 June 2018 (continued)

- 16:30–17:30 *UWB at SemEval-2018 Task 3: Irony detection in English tweets*
Tomáš Hercig
- 16:30–17:30 *NIHRIO at SemEval-2018 Task 3: A Simple and Accurate Neural Network Model for Irony Detection in Twitter*
Thanh Vu, Dat Quoc Nguyen, Xuan-Son Vu, Dai Quoc Nguyen, Michael Catt and Michael Trenell
- 16:30–17:30 *LDR at SemEval-2018 Task 3: A Low Dimensional Text Representation for Irony Detection*
Bilal Ghanem, Francisco Rangel and Paolo Rosso
- 16:30–17:30 *IIDYT at SemEval-2018 Task 3: Irony detection in English tweets*
Edison Marrese-Taylor, Suzana Ilic, Jorge Balazs, Helmut Prendinger and Yutaka Matsuo
- 16:30–17:30 *PunFields at SemEval-2018 Task 3: Detecting Irony by Tools of Humor Analysis*
Elena Mikhalkova, Yuri Karyakin, Alexander Voronov, Dmitry Grigoriev and Artem Leoznov
- 16:30–17:30 *HashCount at SemEval-2018 Task 3: Concatenative Featurization of Tweet and Hashtags for Irony Detection*
Won Ik Cho, Woo Hyun Kang and Nam Soo Kim
- 16:30–17:30 *WLV at SemEval-2018 Task 3: Dissecting Tweets in Search of Irony*
Omid Rohanian, Shiva Taslimipoor, Richard Evans and Ruslan Mitkov
- 16:30–17:30 *Random Decision Syntax Trees at SemEval-2018 Task 3: LSTMs and Sentiment Scores for Irony Detection*
Aidan San
- 16:30–17:30 *ELiRF-UPV at SemEval-2018 Tasks 1 and 3: Affect and Irony Detection in Tweets*
José-Ángel González, Lluís-F. Hurtado and Ferran Pla
- 16:30–17:30 *IronyMagnet at SemEval-2018 Task 3: A Siamese network for Irony detection in Social media*
Aniruddha Ghosh and Tony Veale
- 16:30–17:30 *CTSys at SemEval-2018 Task 3: Irony in Tweets*
Myan Sherif, Sherine Mamdouh and Wegdan Ghazi
- 16:30–17:30 *Irony Detector at SemEval-2018 Task 3: Irony Detection in English Tweets using Word Graph*
Usman Ahmed, Lubna Zafar, Faiza Qayyum and Muhammad Arshad Islam

5 June 2018 (continued)

- 16:30–17:30 *Lancaster at SemEval-2018 Task 3: Investigating Ironic Features in English Tweets*
Edward Dearden and Alistair Baron
- 16:30–17:30 *INAOE-UPV at SemEval-2018 Task 3: An Ensemble Approach for Irony Detection in Twitter*
Delia Irazú Hernández Farías, Fernando Sánchez-Vega, Manuel Montes-y-Gómez and Paolo Rosso
- 16:30–17:30 *ECNU at SemEval-2018 Task 3: Exploration on Irony Detection from Tweets via Machine Learning and Deep Learning Methods*
Zhenghang Yin, Feixiang Wang, Man Lan and Wenting Wang
- 16:30–17:30 *KLUEnicorn at SemEval-2018 Task 3: A Naive Approach to Irony Detection*
Luise Dürlich
- 16:30–17:30 *NTUA-SLP at SemEval-2018 Task 3: Tracking Ironic Tweets using Ensembles of Word and Character Level Attentive RNNs*
Christos Baziotis, Athanasiou Nikolaos, Pinelopi Papalampidi, Athanasia Kolovou, Georgios Paraskevopoulos, Nikolaos Ellinas and Alexandros Potamianos
- 16:30–17:30 *YNU-HPCC at SemEval-2018 Task 3: Ensemble Neural Network Models for Irony Detection on Twitter*
Bo Peng, Jin Wang and Xuejie Zhang
- 16:30–17:30 *Binarizer at SemEval-2018 Task 3: Parsing dependency and deep learning for irony detection*
Nishant Nikhil and Muktabh Mayank Srivastava
- 16:30–17:30 *SSN MLRG1 at SemEval-2018 Task 3: Irony Detection in English Tweets Using MultiLayer Perceptron*
Rajalakshmi S, Angel Deborah S, S Milton Rajendram and Mirnalinee T T
- 16:30–17:30 *NLPRL-IITBHU at SemEval-2018 Task 3: Combining Linguistic Features and Emoji pre-trained CNN for Irony Detection in Tweets*
Harsh Rangwani, Devang Kulshreshtha and Anil Kumar Singh
- 16:30–17:30 *ValenTO at SemEval-2018 Task 3: Exploring the Role of Affective Content for Detecting Irony in English Tweets*
Delia Irazú Hernández Farías, Viviana Patti and Paolo Rosso
- 16:30–17:30 *#NonDicevoSulSerio at SemEval-2018 Task 3: Exploiting Emojis and Affective Content for Irony Detection in English Tweets*
Endang Wahyu Pamungkas and Viviana Patti
- 16:30–17:30 *KNU CI System at SemEval-2018 Task4: Character Identification by Solving Sequence-Labeling Problem*
Cheoneum Park, Heejun Song and Changki Lee

5 June 2018 (continued)

- 16:30–17:30 *NewsReader at SemEval-2018 Task 5: Counting events by reasoning over event-centric-knowledge-graphs*
Piek Vossen
- 16:30–17:30 *FEUP at SemEval-2018 Task 5: An Experimental Study of a Question Answering System*
Carla Abreu and Eugénio Oliveira
- 16:30–17:30 *NAI-SEA at SemEval-2018 Task 5: An Event Search System*
Yingchi Liu, Quanzhi Li and Luo Si

6 June 2018

09:00–09:30 *SemEval 2019 Tasks*

09:30–10:30 *State of SemEval Discussion*

10:30–11:00 *Coffee*

11:00–12:30 **Tasks 7, 8 and 9**

- 11:00–11:15 *SemEval-2018 Task 7: Semantic Relation Extraction and Classification in Scientific Papers*
Kata Gábor, Davide Buscaldi, Anne-Kathrin Schumann, Behrang QasemiZadeh, Haifa Zargayouna and Thierry Charnois
- 11:15–11:30 *ETH-DS3Lab at SemEval-2018 Task 7: Effectively Combining Recurrent and Convolutional Neural Networks for Relation Classification and Extraction*
Jonathan Rotsztein, Nora Hollenstein and Ce Zhang
- 11:30–11:45 *SemEval-2018 Task 8: Semantic Extraction from Cybersecurity Reports using Natural Language Processing (SecureNLP)*
Peter Phandi, Amila Silva and Wei Lu
- 11:45–12:00 *DM_NLP at SemEval-2018 Task 8: neural sequence labeling with linguistic features*
Chunping Ma, Huafei Zheng, Pengjun Xie, Chen Li, Linlin Li and Luo Si
- 12:00–12:15 *SemEval-2018 Task 9: Hypernym Discovery*
Jose Camacho-Collados, Claudio Delli Bovi, Luis Espinosa Anke, Sergio Oramas, Tommaso Pasini, Enrico Santus, Vered Shwartz, Roberto Navigli and Horacio Sag-gion

6 June 2018 (continued)

12:15–12:30 *CRIM at SemEval-2018 Task 9: A Hybrid Approach to Hypernym Discovery*
Gabriel Bernier-Colborne and Caroline Barriere

12:30–14:00 *Lunch*

14:00–15:30 **Tasks 10, 11 and 12**

14:00–14:15 *SemEval-2018 Task 10: Capturing Discriminative Attributes*
Alicia Krebs, Alessandro Lenci and Denis Paperno

14:15–14:30 *SUNNYNLP at SemEval-2018 Task 10: A Support-Vector-Machine-Based Method for Detecting Semantic Difference using Taxonomy and Word Embedding Features*
Sunny Lai, Kwong Sak Leung and Yee Leung

14:30–14:45 *SemEval-2018 Task 11: Machine Comprehension Using Commonsense Knowledge*
Simon Ostermann, Michael Roth, Ashutosh Modi, Stefan Thater and Manfred Pinkal

14:45–15:00 *Yuanfudao at SemEval-2018 Task 11: Three-way Attention and Relational Knowledge for Commonsense Machine Comprehension*
Liang Wang, Meng Sun, Wei Zhao, Kewei Shen and Jingming Liu

15:00–15:15 *SemEval-2018 Task 12: The Argument Reasoning Comprehension Task*
Ivan Habernal, Henning Wachsmuth, Iryna Gurevych and Benno Stein

15:15–15:30 *GIST at SemEval-2018 Task 12: A network transferring inference knowledge to Argument Reasoning Comprehension task*
HongSeok Choi and Hyunju Lee

15:30–16:00 *Coffee*

16:00–16:30 *Discussion*

6 June 2018 (continued)

16:30–17:30 Poster Session

- 16:30–17:30 *LightRel at SemEval-2018 Task 7: Lightweight and Fast Relation Classification*
Tyler Renslow and Günter Neumann
- 16:30–17:30 *OhioState at SemEval-2018 Task 7: Exploiting Data Augmentation for Relation Classification in Scientific Papers Using Piecewise Convolutional Neural Networks*
Dushyanta Dhyani
- 16:30–17:30 *The UWNLP system at SemEval-2018 Task 7: Neural Relation Extraction Model with Selectively Incorporated Concept Embeddings*
Yi Luan, Mari Ostendorf and Hannaneh Hajishirzi
- 16:30–17:30 *UC3M-NII Team at SemEval-2018 Task 7: Semantic Relation Classification in Scientific Papers via Convolutional Neural Network*
Víctor Suárez-Paniagua, Isabel Segura-Bedmar and Akiko Aizawa
- 16:30–17:30 *MIT-MEDG at SemEval-2018 Task 7: Semantic Relation Classification via Convolution Neural Network*
Di Jin, Franck Deroncourt, Elena Sergeeva, Matthew McDermott and Geeticka Chauhan
- 16:30–17:30 *SIRIUS-LTG-UiO at SemEval-2018 Task 7: Convolutional Neural Networks with Shortest Dependency Paths for Semantic Relation Extraction and Classification in Scientific Papers*
Farhad Nooralahzadeh, Lilja Øvrelid and Jan Tore Lønning
- 16:30–17:30 *IRCMS at SemEval-2018 Task 7 : Evaluating a basic CNN Method and Traditional Pipeline Method for Relation Classification*
Zhongbo Yin, Zhunchen Luo, Luo Wei, Mao Bin, Tian Changhai, Ye Yuming and Wu Shuai
- 16:30–17:30 *Bf3R at SemEval-2018 Task 7: Evaluating Two Relation Extraction Tools for Finding Semantic Relations in Biomedical Abstracts*
Mariana Neves, Daniel Butzke, Gilbert Schönfelder and Barbara Grune
- 16:30–17:30 *Texterra at SemEval-2018 Task 7: Exploiting Syntactic Information for Relation Extraction and Classification in Scientific Papers*
Andrey Sysoev and Vladimir Mayorov
- 16:30–17:30 *UniMa at SemEval-2018 Task 7: Semantic Relation Extraction and Classification from Scientific Publications*
Thorsten Keiper, Zhonghao Lyu, Sara Pooladzadeh, Yuan Xu, Jingyi Zhang, Anne Lauscher and Simone Paolo Ponzetto
- 16:30–17:30 *GU IRLAB at SemEval-2018 Task 7: Tree-LSTMs for Scientific Relation Classification*
Sean MacAvaney, Luca Soldaini, Arman Cohan and Nazli Goharian

6 June 2018 (continued)

- 16:30–17:30 *ClaiRE at SemEval-2018 Task 7: Classification of Relations using Embeddings*
Lena Hettinger, Alexander Dallmann, Albin Zehe, Thomas Niebler and Andreas Hotho
- 16:30–17:30 *TakeLab at SemEval-2018 Task 7: Combining Sparse and Dense Features for Relation Classification in Scientific Texts*
Martin Gluhak, Maria Pia di Buono, Abbas Akkasi and Jan Šnajder
- 16:30–17:30 *NEUROSENT-PDI at SemEval-2018 Task 7: Discovering Textual Relations With a Neural Network Model*
Mauro Dragoni
- 16:30–17:30 *SciREL at SemEval-2018 Task 7: A System for Semantic Relation Extraction and Classification*
Darshini Mahendran, Chathurika Brahmana and Bridget McInnes
- 16:30–17:30 *NTNU at SemEval-2018 Task 7: Classifier Ensembling for Semantic Relation Identification and Classification in Scientific Papers*
Biswanath Barik, Utpal Kumar Sikdar and Björn Gambäck
- 16:30–17:30 *Talla at SemEval-2018 Task 7: Hybrid Loss Optimization for Relation Classification using Convolutional Neural Networks*
Bhanu Pratap, Daniel Shank, Oladipo Ositelu and Byron Galbraith
- 16:30–17:30 *TeamDL at SemEval-2018 Task 8: Cybersecurity Text Analysis using Convolutional Neural Network and Conditional Random Fields*
Manikandan R, Krishna Madgula and Snehanshu Saha
- 16:30–17:30 *HCCL at SemEval-2018 Task 8: An End-to-End System for Sequence Labeling from Cybersecurity Reports*
Mingming Fu, Xuemin Zhao and Yonghong Yan
- 16:30–17:30 *UMBC at SemEval-2018 Task 8: Understanding Text about Malware*
Ankur Padia, Arpita Roy, Taneeya Satyapanich, Francis Ferraro, Shimei Pan, Youngja Park, Anupam Joshi and Tim Finin
- 16:30–17:30 *Villani at SemEval-2018 Task 8: Semantic Extraction from Cybersecurity Reports using Representation Learning*
Pablo Loyola, Kugamoorthy Gajananan, Yuji Watanabe and Fumiko Satoh
- 16:30–17:30 *Flytxt_NTNU at SemEval-2018 Task 8: Identifying and Classifying Malware Text Using Conditional Random Fields and Naïve Bayes Classifiers*
Utpal Kumar Sikdar, Biswanath Barik and Björn Gambäck
- 16:30–17:30 *Digital Operatives at SemEval-2018 Task 8: Using dependency features for malware NLP*
Chris Brew

6 June 2018 (continued)

- 16:30–17:30 *Apollo at SemEval-2018 Task 9: Detecting Hypernymy Relations Using Syntactic Dependencies*
Mihaela Onofrei, Ionut Hulub, Diana Trandabat and Daniela Gifu
- 16:30–17:30 *SJTU-NLP at SemEval-2018 Task 9: Neural Hypernym Discovery with Term Embeddings*
Zhuosheng Zhang, Jiangtong Li, Hai Zhao and Bingjie Tang
- 16:30–17:30 *NLP_HZ at SemEval-2018 Task 9: a Nearest Neighbor Approach*
Wei Qiu, Mosha Chen, Linlin Li and Luo Si
- 16:30–17:30 *UMDuluth-CS8761 at SemEval-2018 Task9: Hypernym Discovery using Hearst Patterns, Co-occurrence frequencies and Word Embeddings*
Arshia Zernab Hassan, Manikyha Swathi Vallabhajosyula and Ted Pedersen
- 16:30–17:30 *EXPR at SemEval-2018 Task 9: A Combined Approach for Hypernym Discovery*
Ahmad Issa Alaa Aldine, Mounira Harzallah, Giuseppe Berio, Nicolas Béchet and Ahmad Faour
- 16:30–17:30 *ADAPT at SemEval-2018 Task 9: Skip-Gram Word Embeddings for Unsupervised Hypernym Discovery in Specialised Corpora*
Alfredo Maldonado and Filip Klubička
- 16:30–17:30 *300-sparsans at SemEval-2018 Task 9: Hypernymy as interaction of sparse attributes*
Gábor Berend, Márton Makrai and Péter Földiák
- 16:30–17:30 *UWB at SemEval-2018 Task 10: Capturing Discriminative Attributes from Word Distributions*
Tomáš Brychcín, Tomáš Hercig, Josef Steinberger and Michal Konkol
- 16:30–17:30 *Meaning_space at SemEval-2018 Task 10: Combining explicitly encoded knowledge with information extracted from word embeddings*
Pia Sommerauer, Antske Fokkens and Piek Vossen
- 16:30–17:30 *GHH at SemEval-2018 Task 10: Discovering Discriminative Attributes in Distributional Semantics*
Mohammed Attia, Younes Samih, Manaal Faruqui and Wolfgang Maier
- 16:30–17:30 *CitiusNLP at SemEval-2018 Task 10: The Use of Transparent Distributional Models and Salient Contexts to Discriminate Word Attributes*
Pablo Gamallo
- 16:30–17:30 *THU_NGN at SemEval-2018 Task 10: Capturing Discriminative Attributes with MLP-CNN model*
Chuhan Wu, Fangzhao Wu, Sixing Wu, Zhigang Yuan and Yongfeng Huang

6 June 2018 (continued)

- 16:30–17:30 *ALB at SemEval-2018 Task 10: A System for Capturing Discriminative Attributes*
Bogdan Dumitru, Alina Maria Ciobanu and Liviu P. Dinu
- 16:30–17:30 *ELiRF-UPV at SemEval-2018 Task 10: Capturing Discriminative Attributes with Knowledge Graphs and Wikipedia*
José-Ángel González, Lluís-F. Hurtado, Encarna Segarra and Ferran Pla
- 16:30–17:30 *Wolves at SemEval-2018 Task 10: Semantic Discrimination based on Knowledge and Association*
Shiva Taslimipoor, Omid Rohanian, Le An Ha, Gloria Corpas Pastor and Ruslan Mitkov
- 16:30–17:30 *UNAM at SemEval-2018 Task 10: Unsupervised Semantic Discriminative Attribute Identification in Neural Word Embedding Cones*
Ignacio Arroyo-Fernández, Ivan Meza and Carlos-Francisco Meéndez-Cruz
- 16:30–17:30 *Luminoso at SemEval-2018 Task 10: Distinguishing Attributes Using Text Corpora and Relational Knowledge*
Robert Speer and Joanna Lowry-Duda
- 16:30–17:30 *BomJi at SemEval-2018 Task 10: Combining Vector-, Pattern- and Graph-based Information to Identify Discriminative Attributes*
Enrico Santus, Chris Biemann and Emmanuele Chersoni
- 16:30–17:30 *Igevorse at SemEval-2018 Task 10: Exploring an Impact of Word Embeddings Concatenation for Capturing Discriminative Attributes*
Maxim Grishin
- 16:30–17:30 *ECNU at SemEval-2018 Task 10: Evaluating Simple but Effective Features on Machine Learning Methods for Semantic Difference Detection*
Yunxiao Zhou, Man Lan and Yuanbin Wu
- 16:30–17:30 *AmritaNLP at SemEval-2018 Task 10: Capturing discriminative attributes using convolution neural network over global vector representation.*
Vivek Vinayan, Anand Kumar M and Soman K P
- 16:30–17:30 *Discriminator at SemEval-2018 Task 10: Minimally Supervised Discrimination*
Artur Kulmizev, Mostafa Abdou, Vinit Ravishankar and Malvina Nissim
- 16:30–17:30 *UNBNLP at SemEval-2018 Task 10: Evaluating unsupervised approaches to capturing discriminative attributes*
Milton King, Ali Hakimi Parizi and Paul Cook
- 16:30–17:30 *ABDN at SemEval-2018 Task 10: Recognising Discriminative Attributes using Context Embeddings and WordNet*
Rui Mao, Guanyi Chen, Ruizhe Li and Chenghua Lin

6 June 2018 (continued)

- 16:30–17:30 *UMD at SemEval-2018 Task 10: Can Word Embeddings Capture Discriminative Attributes?*
Alexander Zhang and Marine Carpuat
- 16:30–17:30 *NTU NLP Lab System at SemEval-2018 Task 10: Verifying Semantic Differences by Integrating Distributional Information and Expert Knowledge*
Yow-Ting Shiue, Hen-Hsen Huang and Hsin-Hsi Chen
- 16:30–17:30 *ELiRF-UPV at SemEval-2018 Task 11: Machine Comprehension using Commonsense Knowledge*
José-Ángel González, Lluís-F. Hurtado, Encarna Segarra and Ferran Pla
- 16:30–17:30 *YNU_AII799 at SemEval-2018 Task 11: Machine Comprehension using Commonsense Knowledge of Different model ensemble*
Liu Qingxun, Yao Hongdou, Zhou Xiaobing and Xie Ge
- 16:30–17:30 *YNU_Deep at SemEval-2018 Task 11: An Ensemble of Attention-based BiLSTM Models for Machine Comprehension*
Peng Ding and Xiaobing Zhou
- 16:30–17:30 *ECNU at SemEval-2018 Task 11: Using Deep Learning Method to Address Machine Comprehension Task*
Yixuan Sheng, Man Lan and Yuanbin Wu
- 16:30–17:30 *CSReader at SemEval-2018 Task 11: Multiple Choice Question Answering as Textual Entailment*
Zhengping Jiang and Qi Sun
- 16:30–17:30 *YNU-HPCC at Semeval-2018 Task 11: Using an Attention-based CNN-LSTM for Machine Comprehension using Commonsense Knowledge*
Hang Yuan, Jin Wang and Xuejie Zhang
- 16:30–17:30 *Jiangnan at SemEval-2018 Task 11: Deep Neural Network with Attention Method for Machine Comprehension Task*
Jiangnan Xia
- 16:30–17:30 *IUCM at SemEval-2018 Task 11: Similar-Topic Texts as a Comprehension Knowledge Source*
Sofia Reznikova and Leon Derczynski
- 16:30–17:30 *Lyb3b at SemEval-2018 Task 11: Machine Comprehension Task using Deep Learning Models*
Yongbin Li and Xiaobing Zhou
- 16:30–17:30 *MITRE at SemEval-2018 Task 11: Commonsense Reasoning without Commonsense Knowledge*
Elizabeth Merkhofer, John Henderson, David Bloom, Laura Strickhart and Guido Zarrella

6 June 2018 (continued)

- 16:30–17:30 *SNU_IDS at SemEval-2018 Task 12: Sentence Encoder with Contextualized Vectors for Argument Reasoning Comprehension*
Taeuk Kim, Jihun Choi and Sang-goo Lee
- 16:30–17:30 *ITNLP-ARC at SemEval-2018 Task 12: Argument Reasoning Comprehension with Attention*
Wenjie Liu, Chengjie Sun, Lei Lin and Bingquan Liu
- 16:30–17:30 *ECNU at SemEval-2018 Task 12: An End-to-End Attention-based Neural Network for the Argument Reasoning Comprehension Task*
Junfeng Tian, Man Lan and Yuanbin Wu
- 16:30–17:30 *NLITrans at SemEval-2018 Task 12: Transfer of Semantic Knowledge for Argument Comprehension*
Timothy Niven and Hung-Yu Kao
- 16:30–17:30 *BLCU_NLP at SemEval-2018 Task 12: An Ensemble Model for Argument Reasoning Based on Hierarchical Attention*
Meiqian Zhao, Chunhua Liu, Lu Liu, Yan Zhao and Dong Yu
- 16:30–17:30 *YNU-HPCC at SemEval-2018 Task 12: The Argument Reasoning Comprehension Task Using a Bi-directional LSTM with Attention Model*
Quanlei Liao, Xutao Yang, Jin Wang and Xuejie Zhang
- 16:30–17:30 *HHU at SemEval-2018 Task 12: Analyzing an Ensemble-based Deep Learning Approach for the Argument Mining Task of Choosing the Correct Warrant*
Matthias Liebeck, Andreas Funke and Stefan Conrad
- 16:30–17:30 *YNU Deep at SemEval-2018 Task 12: A BiLSTM Model with Neural Attention for Argument Reasoning Comprehension*
Peng Ding and Xiaobing Zhou
- 16:30–17:30 *UniMelb at SemEval-2018 Task 12: Generative Implication using LSTMs, Siamese Networks and Semantic Representations with Synonym Fuzzing*
Anirudh Joshi, Tim Baldwin, Richard O. Sinnott and Cecile Paris
- 16:30–17:30 *Joker at SemEval-2018 Task 12: The Argument Reasoning Comprehension with Neural Attention*
Sui Guobin, Chao Wenhan and Luo Zhunchen
- 16:30–17:30 *TakeLab at SemEval-2018 Task 12: Argument Reasoning Comprehension with Skip-Thought Vectors*
Ana Brassard, Tin Kuculo, Filip Boltuzic and Jan Šnajder
- 16:30–17:30 *Lyb3b at SemEval-2018 Task 12: Ensemble-based Deep Learning Models for Argument Reasoning Comprehension Task*
Yongbin Li and Xiaobing Zhou

6 June 2018 (continued)

16:30–17:30 *TRANSRW at SemEval-2018 Task 12: Transforming Semantic Representations for Argument Reasoning Comprehension*
Zhimin Chen, Wei Song and Lizhen Liu

SemEval-2018 Task 1: Affect in Tweets

Abstract

We present the SemEval-2018 Task 1: Affect in Tweets, which includes an array of subtasks on inferring the affectual state of a person from their tweet. For each task, we created labeled data from English, Arabic, and Spanish tweets. The individual tasks are: 1. emotion intensity regression, 2. emotion intensity ordinal classification, 3. valence (sentiment) regression, 4. valence ordinal classification, and 5. emotion classification. Seventy-five teams (about 200 team members) participated in the shared task. We summarize the methods, resources, and tools used by the participating teams, with a focus on the techniques and resources that are particularly useful. We also analyze systems for consistent bias towards a particular race or gender. The data is made freely available to further improve our understanding of how people convey emotions through language.

1 Introduction

Emotions are central to language and thought. They are familiar and commonplace, yet they are complex and nuanced. Humans are known to perceive hundreds of different emotions. According to the *basic emotion model* (aka the *categorical model*) (Ekman, 1992; Plutchik, 1980; Parrot, 2001; Frijda, 1988), some emotions, such as joy, sadness, and fear, are more basic than others—physiologically, cognitively, and in terms of the mechanisms to express these emotions. Each of these emotions can be felt or expressed in varying intensities. For example, our utterances can convey that we are very angry, slightly sad, absolutely elated, etc. Here, *intensity* refers to the degree or amount of an emotion such as anger or sadness.¹ As per the *valence–arousal–dominance (VAD) model* (Russell, 1980, 2003), emotions are points in a

three-dimensional space of valence (positiveness–negativeness), arousal (active–passive), and dominance (dominant–submissive). We use the term *affect* to refer to various emotion-related categories such as joy, fear, valence, and arousal.

Natural language applications in commerce, public health, disaster management, and public policy can benefit from knowing the affectual states of people—both the categories and the intensities of the emotions they feel. We thus present the *SemEval-2018 Task 1: Affect in Tweets*, which includes an array of subtasks where automatic systems have to infer the affectual state of a person from their tweet.² We will refer to the author of a tweet as the *tweeter*. Some of the tasks are on the intensities of four basic emotions common to many proposals of basic emotions: anger, fear, joy, and sadness. Some of the tasks are on valence or sentiment intensity. Finally, we include an emotion classification task over eleven emotions commonly expressed in tweets.³ For each task, we provide separate training, development, and test datasets for English, Arabic, and Spanish tweets. The tasks are as follows:

1. Emotion Intensity Regression (EI-reg): Given a tweet and an emotion E, determine the intensity of E that best represents the mental state of the tweeter—a real-valued score between 0 (least E) and 1 (most E);
2. Emotion Intensity Ordinal Classification (EI-oc): Given a tweet and an emotion E, classify the tweet into one of four ordinal classes of intensity of E that best represents the mental state of the tweeter;
3. Valence (Sentiment) Regression (V-reg): Given a tweet, determine the intensity of sentiment or valence (V) that best represents the mental state

¹Intensity is different from *arousal*, which refers to the extent to which an emotion is calming or exciting.

²<https://competitions.codalab.org/competitions/17751>

³Determined through pilot annotations.

of the tweeter—a real-valued score between 0 (most negative) and 1 (most positive);

4. Valence Ordinal Classification (V-oc): Given a tweet, classify it into one of seven ordinal classes, corresponding to various levels of positive and negative sentiment intensity, that best represents the mental state of the tweeter;
5. Emotion Classification (E-c): Given a tweet, classify it as ‘neutral or no emotion’ or as one, or more, of eleven given emotions that best represent the mental state of the tweeter.

Here, E refers to emotion, EI refers to emotion intensity, V refers to valence, reg refers to regression, oc refers to ordinal classification, c refers to classification.

For each language, we create a large single textual dataset, subsets of which are annotated for many emotion (or affect) dimensions (from both the basic emotion model and the VAD model). For each emotion dimension, we annotate the data not just for coarse classes (such as anger or no anger) but also for fine-grained real-valued scores indicating the intensity of emotion. We use Best–Worst Scaling (BWS), a comparative annotation method, to address the limitations of traditional rating scale methods such as inter- and intra-annotator inconsistency. We show that the fine-grained intensity scores thus obtained are reliable (repeat annotations lead to similar scores). In total, about 700,000 annotations were obtained from about 22,000 English, Arabic, and Spanish tweets.

Seventy-five teams (about 200 team members) participated in the shared task, making this the largest SemEval shared task to date. In total, 319 submissions were made to the 15 task–language pairs. Each team was allowed only one official submission for each task–language pair. We summarize the methods, resources, and tools used by the participating teams, with a focus on the techniques and resources that are particularly useful. We also analyze system predictions for consistent bias towards a particular race or gender using a corpus specifically compiled for that purpose. We find that a majority of systems consistently assign higher scores to sentences involving one race or gender. We also find that the bias may change depending on the specific affective dimension being predicted. All of the tweet data (labeled and unlabeled), annotation questionnaires, evaluation scripts, and the bias evaluation corpus are made freely available on the task website.

2 Building on Past Work

There is a large body of prior work on sentiment and emotion classification (Mohammad, 2016). There is also growing work on related tasks such as stance detection (Mohammad et al., 2017) and argumentation mining (Wojatzki et al., 2018; Palau and Moens, 2009). However, there is little work on detecting the *intensity* of affect in text. Mohammad and Bravo-Marquez (2017) created the first datasets of tweets annotated for anger, fear, joy, and sadness intensities. Given a focus emotion, each tweet was annotated for intensity of the emotion felt by the speaker using a technique called *Best–Worst Scaling (BWS)* (Louviere, 1991; Kiritchenko and Mohammad, 2016, 2017).

BWS is an annotation scheme that addresses the limitations of traditional rating scale methods, such as inter- and intra-annotator inconsistency, by employing comparative annotations. Note that at its simplest, comparative annotations involve giving people pairs of items and asking which item is greater in terms of the property of interest. However, such a method requires annotations for N^2 items, which can be prohibitively large.

In BWS, annotators are given n items (an n -tuple, where $n > 1$ and commonly $n = 4$). They are asked which item is the *best* (highest in terms of the property of interest) and which is the *worst* (lowest in terms of the property of interest). When working on 4-tuples, best–worst annotations are particularly efficient because each best and worst annotation will reveal the order of five of the six item pairs. For example, for a 4-tuple with items A, B, C, and D, if A is the best, and D is the worst, then $A > B$, $A > C$, $A > D$, $B > D$, and $C > D$. Real-valued scores of association between the items and the property of interest can be determined using simple arithmetic on the number of times an item was chosen best and number of times it was chosen worst (as described in Section 3.4.2) (Orme, 2009; Flynn and Marley, 2014).

It has been empirically shown that annotations for $2N$ 4-tuples is sufficient for obtaining reliable scores (where N is the number of items) (Louviere, 1991; Kiritchenko and Mohammad, 2016). Kiritchenko and Mohammad (2017) showed through empirical experiments that BWS produces more reliable and more discriminating scores than those obtained using rating scales. (See (Kiritchenko and Mohammad, 2016, 2017) for further details on BWS.)

Mohammad and Bravo-Marquez (2017) collected and annotated 7,100 English tweets posted in 2016. We will refer to the tweets alone as *Tweets-2016*, and the tweets and annotations together as the *Emotion Intensity Dataset* (or, *EmoInt Dataset*). This dataset was used in the 2017 WASSA Shared Task on Emotion Intensity.⁴

We build on that earlier work by first compiling a new set of English, Arabic, and Spanish tweets posted in 2017 and annotating the new tweets for emotion intensity in a similar manner. We will refer to this new set of tweets as *Tweets-2017*. Similar to the work by Mohammad and Bravo-Marquez (2017), we create four subsets annotated for intensity of fear, joy, sadness, and anger, respectively. However, unlike the earlier work, here a common dataset of tweets is annotated for all three negative emotions: fear, anger, and sadness. This allows one to study the relationship between the three basic negative emotions.

We also annotate tweets sampled from each of the four basic emotion subsets (of both *Tweets-2016* and *Tweets-2017*) for degree of valence. Annotations for arousal, dominance, and other basic emotions such as surprise and anticipation are left for future work.

In addition to knowing a fine-grained score indicating degree of intensity, it is also useful to qualitatively ground the information on whether the intensity is high, medium, low, etc. Thus, we manually identify ranges in intensity scores that correspond to these coarse classes. For each of the four emotions E , the 0 to 1 range is partitioned into the classes: *no E can be inferred*, *low E can be inferred*, *moderate E can be inferred*, and *high E can be inferred*. This data can be used for developing systems that predict the ordinal class of emotion intensity (*EI ordinal classification*, or *EI-oc*, systems). We partition the 0 to 1 interval of valence into: *very negative*, *moderately negative*, *slightly negative*, *neutral or mixed*, *slightly positive*, *moderately positive*, and *very positive mental state of the tweeter can be inferred*. This data can be used to develop systems that predict the ordinal class of valence (*valence ordinal classification*, or *V-oc*, systems).⁵

⁴ <http://saifmohammad.com/WebPages/EmoInt2017.html>

⁵Note that valence ordinal classification is the traditional sentiment analysis task most commonly explored in NLP literature. The classes may vary from just three (positive, negative, and neutral) to five, seven, or nine finer classes.

Dataset	Source of Tweets	Annotated In	
		2016	2017

	Tweets-2017	-	✓
EI-reg, EI-oc	Tweets-2016	✓	-
	Tweets-2017	-	✓
V-reg, V-oc	Tweets-2016	-	✓
	Tweets-2017	-	✓

Table 1: The annotations of English Tweets.

Finally, the full *Tweets-2016* and *Tweets-2017* datasets are annotated for the presence of eleven emotions: anger, anticipation, disgust, fear, joy, love, optimism, pessimism, sadness, surprise, and trust. This data can be used for developing *multi-label emotion classification*, or *E-c*, systems. Table 1 shows the two stages in which the annotations for English tweets were done. The Arabic and Spanish tweets were all only from 2017. Together, we will refer to the joint set of tweets from *Tweets-2016* and *Tweets-2017* along with all the emotion-related annotations described above as the *SemEval-2018 Affect in Tweets Dataset* (or *AIT Dataset* for short).

3 The Affect in Tweets Dataset

We now present how we created the Affect in Tweets Dataset. We present only the key details here; a detailed description of the English datasets and the analysis of various affect dimensions is available in Mohammad and Kiritchenko (2018).

3.1 Compiling English Tweets

We first compiled tweets to be included in the four EI-reg datasets corresponding to anger, fear, joy, and sadness. The EI-oc datasets include the same tweets as in EI-reg, that is, the Anger EI-oc dataset has the same tweets as in the Anger EI-reg dataset, the Fear EI-oc dataset has the same tweets as in the Fear EI-reg dataset, and so on. However, the labels for EI-oc tweets are ordinal classes instead of real-valued intensity scores. The V-reg dataset includes a subset of tweets from each of the four EI-reg emotion datasets. The V-oc dataset has the same tweets as in the V-reg dataset. The E-c dataset includes all the tweets from the four EI-reg datasets. The total number of instances in the E-c, EI-reg, EI-oc, V-reg, and V-oc datasets is shown in the last column of Table 3.

3.1.1 Basic Emotion Tweets

To create a dataset of tweets rich in a particular emotion, we used the following methodology.

For each emotion X , we selected 50 to 100 terms that were associated with that emotion at different intensity levels. For example, for the anger dataset, we used the terms: *angry, mad, frustrated, annoyed, peeved, irritated, miffed, fury, antagonism*, and so on. We will refer to these terms as the *query terms*. The query terms we selected included emotion words listed in the *Roget's Thesaurus*, nearest neighbors of these emotion words in a word-embeddings space, as well as commonly used emoji and emoticons. The full list of the query terms is available on the task website.

We polled the Twitter API, over the span of two months (June and July, 2017), for tweets that included the query terms. We randomly selected 1,400 tweets from the joy set for annotation of intensity of joy. For the three negative emotions, we first randomly selected 200 tweets each from their corresponding tweet collections. These 600 tweets were annotated for all three negative emotions so that we could study the relationships between fear and anger, between anger and sadness, and between sadness and fear. For each of the negative emotions, we also chose 800 additional tweets, from their corresponding tweet sets, that were annotated only for the corresponding emotion. Thus, the number of tweets annotated for each of the negative emotions was also 1,400 (the 600 included in all three negative emotions + 800 unique to the focus emotion). For each emotion, 100 tweets that had an emotion-word hashtag, emoticon, or emoji query term at the end (*trailing query term*) were randomly chosen. We removed the trailing query terms from these tweets. As a result, the dataset also included some tweets with no clear emotion-indicative terms.

Thus, the EI-reg dataset included 1,400 new tweets for each of the four emotions. These were annotated for intensity of emotion. Note that the EmoInt dataset already included 1,500 to 2,300 tweets per emotion annotated for intensity. Those tweets were not re-annotated. The EmoInt EI-reg tweets as well as the new EI-reg tweets were both annotated for ordinal classes of emotion (EI-oc) as described in Section 3.4.3

The new EI-reg tweets formed the EI-reg development (dev) and test sets in the AIT task; the number of instances in each is shown in the third and fourth columns of Table 3. The EmoInt tweets formed the training set.⁶

⁶Manual examination of the new EI-reg tweets later re-

3.1.2 Valence Tweets

The valence dataset included tweets from the new EI-reg set and the EmoInt set. The new EI-reg tweets included were all 600 tweets common to the three negative emotion tweet sets and 600 randomly chosen joy tweets. The EmoInt tweets included were 600 randomly chosen joy tweets and 200 each, randomly chosen tweets, for anger, fear, and sadness. To study valence in sarcastic tweets, we also included 200 tweets that had hashtags *#sarcastic, #sarcasm, #irony, or #ironic* (tweets that are likely to be sarcastic). Thus the V-reg set included 2,600 tweets in total. The V-oc set is comprised of the same tweets as in the V-reg set.

3.1.3 Multi-Label Emotion Tweets

We selected all of the 2016 and 2017 tweets in the four EI-reg datasets to form the E-c dataset, which is annotated for presence/absence of 11 emotions.

3.2 Compiling Arabic Tweets

We compiled the Arabic tweets in a similar manner to the English dataset. We obtained the the Arabic query terms as follows:

- We translated the English query terms for the four emotions to Arabic using Google Translate.
- All words associated with the four emotions in the NRC Emotion Lexicon were translated into Arabic. (We discarded incorrect translations.)
- We trained word embeddings on a tweet corpus collected using dialectal function words as queries. We used nearest neighbors of the emotion query terms in the word-embedding space as additional query terms.
- We included the same emoji used in English for anger, fear, joy and sadness. However, most of the fear emoji were not included, as they were rarely associated with fear in Arabic tweets.

In total, we used 550 Arabic query terms and emoji to poll the Twitter API to collect around 17 million tweets between March and July 2017. For each of the four emotions, we randomly selected 1,400 tweets to form the EI-reg datasets. The same tweets were used for building the EI-oc datasets. The sets of tweets for the negative emotions included 800 tweets unique to the focus emotion and 600 tweets common to the three negative emotions.

vealed that it included some near-duplicate tweets. We kept only one copy of such pairs. Thus the dev. and test set numbers add up to a little lower than 1,400.

The V-reg dataset was formed by including about 900 tweets from the three negative emotions (including the 600 tweets common to the three negative emotion datasets), and about 900 tweets for joy. The same tweets were used to form the V-oc dataset. The multi-label emotion classification dataset was created by taking all the tweets in the EI-reg datasets.

3.3 Compiling Spanish Tweets

The Spanish query terms were obtained as follows:

- The English query terms were translated into Spanish using Google Translate. The translations were manually examined by a Spanish native speaker, and incorrect translations were discarded.
- The resulting set was expanded using synonyms taken from a Spanish lexicographic resource, Wordreference⁷.
- We made sure that both masculine and feminine forms of the nouns and adjectives were included.
- We included the same emoji used in English for anger, sadness, and joy. The emoji for fear were not included, as tweets containing those emoji were rarely associated with fear.

We collected about 1.2 million tweets between July and September 2017. We annotated close to 2,000 tweets for each emotion. The sets of tweets for the negative emotions included $\sim 1,500$ tweets unique to the focus emotion and ~ 500 tweets common to the two remaining negative emotions. The same tweets were used for building the Spanish EI-oc dataset.

The V-reg dataset was formed by including about 1,100 tweets from the three negative emotions (including the 750 tweets common to the three negative emotion datasets), about 1,100 tweets for joy, and 268 tweets with sarcastic hashtags (*#sarcasmo*, *#ironia*). The same tweets were used to build the V-oc dataset. The multi-label emotion classification dataset was created by taking all the tweets in the EI-reg and V-reg datasets.

3.4 Annotating Tweets

We describe below how we annotated the English tweets. The same procedure was used for Arabic and Spanish annotations.

We annotated all of our data by crowdsourcing. The tweets and annotation questionnaires were uploaded on the crowdsourcing platform, Figure Eight (earlier called CrowdFlower).⁸ All the annotation tasks described in this paper were approved by the National Research Council Canada’s Institutional Review Board.

About 5% of the tweets in each task were annotated internally beforehand (by the authors of this paper). These tweets are referred to as gold tweets. The gold tweets were interspersed with other tweets. If a crowd-worker got a gold tweet question wrong, they were immediately notified of the error. If the worker’s accuracy on the gold tweet questions fell below 70%, they were refused further annotation, and all of their annotations were discarded. This served as a mechanism to avoid malicious annotations.

3.4.1 Multi-Label Emotion Annotation

We presented one tweet at a time to the annotators and asked which of the following options best described the emotional state of the tweeter:

- anger (also includes annoyance, rage)
- anticipation (also includes interest, vigilance)
- disgust (also includes disinterest, dislike, loathing)
- fear (also includes apprehension, anxiety, terror)
- joy (also includes serenity, ecstasy)
- love (also includes affection)
- optimism (also includes hopefulness, confidence)
- pessimism (also includes cynicism, no confidence)
- sadness (also includes pensiveness, grief)
- surprise (also includes distraction, amazement)
- trust (also includes acceptance, liking, admiration)
- neutral or no emotion

Example tweets were provided in advance with examples of suitable responses.

On the Figure Eight task settings, we specified that we needed annotations from seven people for each tweet. However, because of the way the gold tweets were set up, they were annotated by more than seven people. The median number of annotations was still seven. In total, 303 people annotated between 10 and 4,670 tweets each. A total of 174,356 responses were obtained.

Annotation Aggregation: One of the criticisms for several natural language annotation projects has been that they keep only the instances with high agreement, and discard instances that obtain low agreements. The high agreement instances

⁷<http://www.wordreference.com/sinonimos/>

⁸<https://www.figure-eight.com>

	anger	antic.	disg.	fear	joy	love	optim.	pessi.	sadn.	surp.	trust	neutral
<i>English</i>	36.1	13.9	36.6	16.8	39.3	12.3	31.3	11.6	29.4	5.2	5.0	2.7
<i>Arabic</i>	39.4	9.6	19.6	17.8	26.9	25.2	24.5	22.8	37.4	2.2	5.3	0.6
<i>Spanish</i>	32.2	11.7	14.7	10.5	30.5	7.9	10.2	16.7	23.0	4.6	4.6	4.7

Table 2: Percentage of tweets that were labeled with a given emotion (after aggregation of votes).

tend to be simple instantiations of the classes of interest, and are easier to model by automatic systems. However, when deployed in the real world, natural language systems have to recognize and process more complex and subtle instantiations of a natural language phenomenon. Thus, discarding all but the high agreement instances does not facilitate the development of systems that are able to handle the difficult instances appropriately.

Therefore, we chose a somewhat generous aggregation criterion: if more than 25% of the responses (two out of seven people) indicated that a certain emotion applies, then that label was chosen. We will refer to this aggregation as *Ag2*. If no emotion got at least 40% of the responses (three out of seven people) and more than 50% of the responses indicated that the tweet was neutral, then the tweet was marked as neutral. In the vast majority of the cases, a tweet was labeled either as neutral or with one or more of the eleven emotion labels. 107 English tweets, 14 Arabic tweets, and 88 Spanish tweets did not receive sufficient votes to be labeled a particular emotion or to be labeled neutral. These very-low-agreement tweets were set aside. We will refer to the remaining dataset as *E-c* (*Ag2*), or simply *E-c*, data.

Class Distribution: Table 2 shows the percentage of tweets that were labeled with a given emotion using *Ag2* aggregation. The numbers in these rows sum up to more than 100% because a tweet may be labeled with more than one emotion. Observe that joy, anger, disgust, sadness, and optimism get a high number of the votes. Trust and surprise are two of the lowest voted emotions.

3.4.2 Annotating Intensity with BWS

We followed the procedure described by Kiritchenko and Mohammad (2016) to obtain best-worst scaling (BWS) annotations.

Every 4-tuple was annotated by four independent annotators. The questionnaires were developed through internal discussions and pilot annotations. They are available on the SemEval-2018 AIT Task webpage.

Between 118 and 220 people residing in the United States annotated the 4-tuples for each of

the four emotions and valence. In total, around 27K responses for each of the four emotions and around 50K responses for valence were obtained.⁹

Annotation Aggregation: The intensity scores were calculated from the BWS responses using a simple counting procedure (Orme, 2009; Flynn and Marley, 2014): For each item, the score is the proportion of times the item was chosen as having the most intensity minus the percentage of times the item was chosen as having the least intensity.¹⁰ We linearly transformed the scores to lie in the 0 (lowest intensity) to 1 (highest intensity) range.

Distribution of Scores: Figure 1 shows the histogram of the V-reg tweets. The tweets are grouped into bins of scores 0–0.05, 0.05–0.1, and so on until 0.95–1. The colors for the bins correspond to their ordinal classes as determined from the manual annotation described in the next subsection. The histograms for the four emotions are shown in Figure 5 in the Appendix.

3.4.3 Identifying Ordinal Classes

For each of the EI-reg emotions, the authors of this paper independently examined the ordered list of tweets to identify suitable boundaries that partitioned the 0–1 range into four ordinal classes: *no emotion*, *low emotion*, *moderate emotion*, and *high emotion*. Similarly the V-reg tweets were examined and the 0–1 range was partitioned into seven classes: *very negative*, *moderately negative*, *slightly negative*, *neutral or mixed*, *slightly positive*, *moderately positive*, and *very positive mental state can be inferred*.¹¹

Annotation Aggregation: The authors discussed their individual annotations to obtain consensus on the class intervals. The V-oc and EI-oc datasets were thus labeled.

Class Distribution: The legend of Figure 1 shows the intervals of V-reg scores that make up the seven V-oc classes. The intervals of EI-reg scores that make up each of the four EI-oc classes are shown in Figure 5 in the Appendix.

⁹Gold tweets were annotated more than four times.

¹⁰Code for generating tuples from items as well as for generating scores from BWS annotations: <http://saifmohammad.com/WebPages/BestWorst.html>

¹¹Valence is a bi-polar scale; hence, more classes.

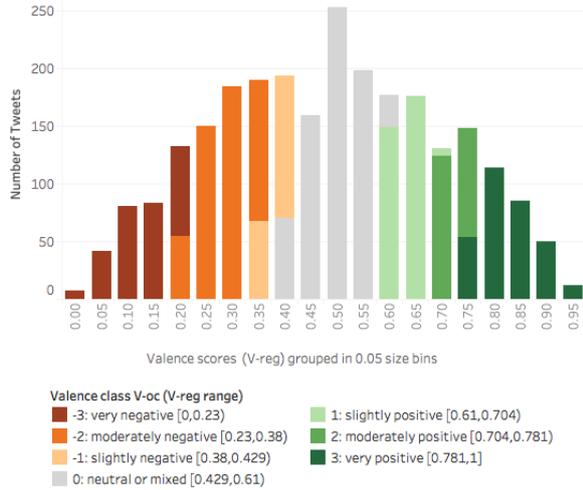

Figure 1: Valence score (V-reg), class (V-oc) distribution.

3.4.4 Annotating Arabic and Spanish Tweets

The annotations for Arabic and Spanish tweets followed the same process as the one described for English above. We manually translated the English questionnaire into Arabic and Spanish.

On Figure Eight, we used similar settings as for English. For Arabic, we set the country of annotators to fourteen Arab countries available in Crowdfunder as well as the United States of America.¹² For Spanish, we set the country of annotators to USA, Mexico, and Spain.

Annotation aggregation was done the same way for Arabic and Spanish, as for English. Table 2 shows the distributions for different emotions in the E-c annotations for Arabic and Spanish (in addition to English).

3.5 Training, Development, and Test Sets

Table 14 in Appendix summarizes key details of the current set of annotations done for the *SemEval-2018 Affect in Tweets (AIT) Dataset*. AIT was partitioned into training, development, and test sets for machine learning experiments as described in Table 3. All of the English tweets that came from Tweets-2016 were part of the training sets. All of the English tweets that came from Tweets-2017 were split into development and test sets.¹³ The Arabic and Spanish tweets are all from 2017 and were split into train, dev, and test sets.

¹² Algeria, Bahrain, Egypt, Jordan, Kuwait, Morocco, Oman, Palestine, Qatar, Saudi Arabia, Tunisia, UAE, Yemen.

¹³This split of Tweets-2017 was first done such that 20% of the tweets formed the dev. set and 80% formed the test set—independently for EI-reg, EI-oc, V-reg, V-oc, and E-c. Then we moved some tweets from the test sets to the dev. sets such that a tweet in any dev. set does not occur in any test set.

Dataset	Train	Dev	Test	Total
<i>English</i>				
E-c	6,838	886	3,259	10,983
EI-reg, EI-oc				
anger	1,701	388	1,002	3,091
fear	2,252	389	986	3,627
joy	1,616	290	1,105	3,011
sadness	1,533	397	975	2,905
V-reg, V-oc	1,181	449	937	2,567
<i>Arabic</i>				
E-c	2,278	585	1,518	4,381
EI-reg, EI-oc				
anger	877	150	373	1,400
fear	882	146	372	1,400
joy	728	224	448	1,400
sadness	889	141	370	1,400

anger	1,166	193	627	1,986
fear	1,166	202	618	1,986
joy	1,058	202	730	1,990
sadness	1,154	196	641	1,991
V-reg, V-oc	1,566	229	648	2,443

Table 3: The number of tweets in the SemEval-2018 Affect in Tweets Dataset.

4 Agreement and Reliability of Annotations

It is challenging to obtain consistent annotations for affect due to a number of reasons, including: the subtle ways in which people can express affect, fuzzy boundaries of affect categories, and differences in human experience that impact how they perceive emotion in text. In the subsections below we analyze the AIT dataset to determine the extent of agreement and the reliability of the annotations.

4.1 E-c Annotations

Table 4 shows the inter-rater agreement and Fleiss’ κ for the multi-label emotion annotations. The inter-rater agreement (IRA) is calculated as the percentage of times each pair of annotators agree. For the sake of comparison, we also show the scores obtained by randomly choosing whether a particular emotion applies or not. Observe that the scores obtained through the actual annotations are markedly higher than the scores obtained by random guessing.

4.2 EI-reg and V-reg Annotations

For real-valued score annotations, a commonly used measure of quality is reproducibility of the end result—if repeated independent manual annotations from multiple respondents result in similar

		IRA	Fleiss' κ
Random		41.67	0.00
<i>English</i>	avg. for all 12 classes	83.38	0.21
	avg. for 4 basic emotions	81.22	0.40
<i>Arabic</i>	avg. for all 12 classes	86.69	0.29
	avg. for 4 basic emotions	83.38	0.48
<i>Spanish</i>	avg. for all 12 classes	88.60	0.28
	avg. for 4 basic emotions	85.91	0.45

Table 4: Annotator agreement for the Multi-label Emotion Classification (E-c) Datasets.

Language	Affect Dimension	Spearman	Pearson
<i>English</i>	Emotion Intensity		
	anger	0.89	0.90
	fear	0.84	0.85
	joy	0.90	0.91
	sadness	0.82	0.83
	Valence	0.92	0.92
<i>Arabic</i>	Emotion Intensity		
	anger	0.88	0.89
	fear	0.85	0.87
	joy	0.88	0.89
	sadness	0.86	0.87
	Valence	0.94	0.94
<i>Spanish</i>	Emotion Intensity		
	anger	0.88	0.88
	fear	0.85	0.86
	joy	0.89	0.89
	sadness	0.86	0.86
	Valence	0.89	0.89

Table 5: Split-half reliabilities in the AIT Dataset.

intensity rankings (and scores), then one can be confident that the scores capture the true emotion intensities. To assess this reproducibility, we calculate average *split-half reliability (SHR)*, a commonly used approach to determine consistency (Kuder and Richardson, 1937; Cronbach, 1946; Mohammad and Bravo-Marquez, 2017). The intuition behind SHR is as follows. All annotations for an item (in our case, tuples) are randomly split into two halves. Two sets of scores are produced independently from the two halves. Then the correlation between the two sets of scores is calculated. The process is repeated 100 times, and the correlations are averaged. If the annotations are of good quality, then the average correlation between the two halves will be high.

Table 5 shows the split-half reliabilities for the AIT data. Observe that correlations lie between 0.82 and 0.92, indicating a high degree of reproducibility.¹⁴

¹⁴Past work has found the SHR for sentiment intensity annotations for words, with 6 to 8 annotations per tuple to be 0.95 to 0.98 (Mohammad, 2018b; Kiritchenko and Mohammad, 2016). In contrast, here SHR is calculated from whole sentences, which is a more complex annotation task and thus the SHR is expected to be lower than 0.95.

5 Evaluation for Automatic Predictions

5.1 For EI-reg, EI-oc, V-reg, and V-oc

The official competition metric for EI-reg, EI-oc, V-reg, and V-oc was the Pearson Correlation Coefficient with the Gold ratings/labels. For EI-reg and EI-oc, the correlation scores across all four emotions were averaged (macro-average) to determine the bottom-line competition metric. Apart from the official competition metric described above, some additional metrics were also calculated for each submission. These were intended to provide a different perspective on the results. The secondary metric used for the regression tasks was:

- Pearson correlation for a subset of the test set that includes only those tweets with intensity score greater or equal to 0.5.

The secondary metrics used for the ordinal classification tasks were:

- Pearson correlation for a subset of the test set that includes only those tweets with intensity classes low X, moderate X, or high X (where X is an emotion). We will refer to this set of tweets as the some-emotion subset.
- Weighted quadratic kappa on the full test set.
- Weighted quadratic kappa on the some-emotion subset of the test set.

5.2 For E-c

The official competition metric used for E-c was multi-label accuracy (or Jaccard index). Since this is a multi-label classification task, each tweet can have one or more gold emotion labels, and one or more predicted emotion labels. Multi-label accuracy is defined as the size of the intersection of the predicted and gold label sets divided by the size of their union. This measure is calculated for each tweet t , and then is averaged over all tweets T in the dataset:

$$Accuracy = \frac{1}{|T|} \sum_{t \in T} \frac{|G_t \cap P_t|}{|G_t \cup P_t|}$$

where G_t is the set of the gold labels for tweet t , P_t is the set of the predicted labels for tweet t , and T is the set of tweets. Apart from the official competition metric (multi-label accuracy), we also calculated micro-averaged F-score and macro-averaged F-score.¹⁵

¹⁵Formulae are provided on the task webpage.

Task	English	Arabic	Spanish	All
EI-reg	48	13	15	76
EI-oc	37	12	14	63
V-reg	37	13	13	63
V-oc	35	13	12	60
E-c	33	12	12	57
Total	190	63	66	319

Table 6: Number of teams in each task–language pair.

6 Systems

Seventy-five teams (about 200 team members) participated in the shared task, submitting to one or more of the five subtasks. The numbers of teams submitting predictions for each task–language pair are shown in Table 6. The English tasks were the most popular (33 to 48 teams for each task); however, the Arabic and Spanish tasks also got a fair amount of participation (about 13 teams for each task). Emotion intensity regression attracted the most teams.

Figure 2 shows how frequently various machine learning algorithms were used in the five tasks. Observe that SVM/SVR, LSTMs and Bi-LSTMs were some of the most widely used algorithms. Understandably, regression algorithms such as Linear Regression were more common in the regression tasks than in the classification tasks.

Figure 3 shows how frequently various features were used. Observe that word embeddings, affect lexicon features, and word n-grams were some of the most widely used features. Many teams also used sentence embeddings and affect-specific word embeddings. A number of teams also made use of distant supervision corpora (usually tweets with emoticons or hashtagged emotion words). Several teams made use of the AIT2018 Distant Supervision Corpus—a corpus of about 100M tweets containing emotion query words—that we provided. A small number of teams used training data from one task to supplement the training data for another task. (See row ‘AIT-2018 train-dev (other task)’.)

Figure 4 shows how frequently features from various affect lexicons were used. Observe that several of the NRC emotion and sentiment lexicons as well as AFINN and Bing Liu Lexicon were widely used (Mohammad and Turney, 2013; Mohammad, 2018b; Kiritchenko et al., 2014; Nielsen, 2011; Hu and Liu, 2004). Several teams used the AffectiveTweets package to obtain lexicon features (Mohammad and Bravo-Marquez, 2017).¹⁶

6.1 Results and Discussion

Tables 7 through 11 show the results obtained by the top three teams on EI-reg, EI-oc, V-reg, V-oc, and E-c, respectively. The tables also show: (a) the results obtained by the median rank team for each task–language pair, (b) the results obtained by a baseline SVM system using just word unigrams as features, and (c) the results obtained by a system that randomly guesses the prediction—the random baseline.¹⁷ Observe that the top teams obtained markedly higher results than the SVM unigrams baselines.

Most of the top-performing teams relied on both deep neural network representations of tweets (sentence embeddings) as well as features derived from existing sentiment and emotion lexicons. Since many of the teams used similar models when participating in different tasks, we present further details of the systems grouped by the language for which they submitted predictions.

¹⁷The results for each of the 75 participating teams are shown on the task website and also in the supplementary material file. (Not shown here due to space constraints.)

High-Ranking English Systems: The best performing system for regression (EI-reg, V-reg) and ordinal classification (EI-oc, V-oc) sub-tasks in English was *SeerNet*. The team proposed a unified architecture for regression and ordinal classification based on the fusion of heterogeneous features and the ensemble of multiple predictive models. The following models or resources were used for feature extraction:

- *DeepMoji* (Felbo et al., 2017): a neural network for predicting emoji for tweets trained from a very large distant supervision corpus. The last two layers of the network were used as features.
- *Skip thoughts*: an unsupervised neural network for encoding sentences (Kiros et al., 2015).
- *Sentiment neurons* (Radford et al., 2017): a byte-level recurrent language model for learning sentence representations.
- Features derived from affective lexicons.

These feature vectors were used for training XG Boost and Random Forest models (using both regression and classification variants), which were later stacked using ordinal logistic regression and ridge regression models for the corresponding ordinal classification and regression tasks.

Other teams also relied on both deep neural network representations of tweets and lexicon features to learn a model with either a traditional machine learning algorithm, such as SVM/SVR (*PlusEmo2Vec*, *TCS Research*) and Logistic Regression (*PlusEmo2Vec*), or a deep neural network (*NTUA-SLP*, *psyML*). The sentence embeddings were obtained by training a neural network on the provided training data, a distant supervision corpus (e.g., AIT2018 Distant Supervision Corpus that has tweets with emotion-related query terms), sentiment-labeled tweet corpora (e.g., Semeval-2017 Task4A dataset on sentiment analysis in Twitter), or by using pre-trained models.

Table 10: Task 4 valence ord. classifn. (V-oc): Results.

High-Ranking Arabic Systems: Top teams trained their systems using deep learning techniques, such as CNN, LSTM and Bi-LSTM (*AffecThor*, *EiTAKA*, *UNCC*). Traditional machine learning approaches, such as Logistic Regression, Ridge Regression, Random Forest and SVC/SVM, were also employed (*EMA*, *INGEOTEC*, *PARTNA*, *Tw-Star*). Many teams relied on Arabic pre-processing and normalization techniques in an attempt to decrease the sparsity due to morphological complexity in the Arabic language. *EMA* applied stemming and lemmatization using MADAMIRA (a morphological analysis and

disambiguation tool for Arabic), while *TwStar* and *PARTNA* used stemmer designed for handling tweets. In addition, top systems applied additional pre-processing, such as dropping punctuations, mentions, stop words, and hashtag symbols.

Many teams (e.g., *AffecThor*, *EiTAKA* and *EMA*) utilized Arabic sentiment lexicons (Mohammad et al., 2016; Badaro et al., 2014). Some teams (e.g., *EMA*) used Arabic translations of the NRC Emotion Lexicon (Mohammad and Turney, 2013). Pre-trained Arabic word embeddings (AraVec) generated from a large set of tweets were also used as additional input features by

EMA and *UNCC*. *AffecThor* collected 4.4 million Arabic tweets to train their own word embeddings. Traditional machine learning algorithms (Random Forest, SVR and Ridge regression) used by *EMA* obtained results rivaling those obtained by deep learning approaches.

High-Ranking Spanish Systems: Convolutional neural networks and recurrent neural networks with gated units such as LSTM and GRU were employed by the winning Spanish teams (*AffecThor*, *Amobee*, *ELIRF-UPV*, *UG18*). Word embeddings trained from Spanish tweets, such as the ones provided by Rothe et al. (2016), were used as the basis for training deep learning models. They were also employed as features for more traditional learning schemes such as SVMs (*UG18*). Spanish Affective Lexicons such as the *Spanish Emotion Lexicon* (SEL) (Sidorov et al., 2012) and *ML-SentiCon* (Cruz et al., 2014) were also used to build the feature space (*UWB*, *SINAI*). Translation was used in two different ways: 1) automatic translation of English affective lexicons into Spanish (*SINAI*), and 2): training set augmentation via automatic translation of English tweets (*Amobee*, *UG18*).

6.2 Summary

In the standard deep learning or representation learning approach, data representations (tweets in our case) are jointly trained for the task at hand via neural networks with convolution or recurrent layers (LeCun et al., 2015). The claim is that this can lead to more robust representations than relying on manually-engineered features. In contrast, here, most of the top-performing systems employed manually-engineered representations for tweets. These representations combine trained representations, models trained on distant supervision corpora, and unsupervised word and sentence embeddings, with manually-engineered features, such as features derived from affect lexicons. This shows that despite being rather powerful, representation learning can benefit from working in tandem with task-specific features. For emotion intensity tasks, lexicons such as the Affect Intensity Lexicon (Mohammad, 2018b) that provide intensity scores are particularly helpful. Similarly, tasks on valence, arousal, and dominance can benefit from lexicons such as ANEW (Bradley and Lang, 1999) and the newly created NRC Valence-Arousal-Dominance Lexicon (Mohammad, 2018a), which has entries for about 20,000 English terms.

Table 11: Task 5 emotion classification (E-c): Results.

7 Examining Gender and Race Bias in Sentiment Analysis Systems

Automatic systems can benefit society by promoting equity, diversity, and fairness. Nonetheless, as machine learning systems become more human-like in their predictions, they are inadvertently accentuating and perpetuating inappropriate human biases. Examples include, loan eligibility and crime recidivism prediction systems that negatively assess people belonging to a certain pin/zip code (which may disproportionately impact people of a certain race) (Chouldechova, 2017), and resumé sorting systems that believe that men are more qualified to be programmers than women (Bolukbasi et al., 2016). Similarly, sentiment and emotion analysis systems can also perpetuate and accentuate inappropriate human biases, e.g., systems that consider utterances from one race or gender to be less positive simply because of their race or gender, or customer support systems that prioritize a call from an angry male user over a call from the equally angry female user.

Discrimination-aware data mining focuses on measuring discrimination in data (Zliobaite, 2015; Pedreshi et al., 2008; Hajian and Domingo-Ferrer, 2013). In that spirit, we carried out an analysis of the systems’ outputs for biases towards certain races and genders. In particular, we wanted to test a hypothesis that a system should equally rate the intensity of the emotion expressed by two sentences that differ only in the gender/race of a person mentioned. Note that here the term *system*

refers to the combination of a machine learning architecture trained on a labeled dataset, and possibly using additional language resources. The bias can originate from any or several of these parts.

We used Equity Evaluation Corpus (EEC), a recently created dataset of 8,640 English sentences carefully chosen to tease out gender and race biases (Kiritchenko and Mohammad, 2018). We used the EEC as a supplementary test set in the EI-reg and V-reg English tasks. Specifically, we compare emotion and sentiment intensity scores that the systems predict on pairs of sentences in the EEC that differ only in one word corresponding to race or gender (e.g., ‘*This man made me feel angry*’ vs. ‘*This woman made me feel angry*’). Complete details on how the EEC was created, its constituent sentences, and the analysis of automatic systems for race and gender bias is available in Kiritchenko and Mohammad (2018); we summarize the key results below.

Despite the work we describe here and that proposed by others, it should be noted that mechanisms to detect bias can often be circumvented. Nonetheless, as developers of sentiment analysis systems, and NLP systems more broadly, we cannot absolve ourselves of the ethical implications of the systems we build. Thus, the Equity Evaluation Corpus is not meant to be a catch-all for all inappropriate biases, but rather just one of the several ways by which we can examine the fairness of sentiment analysis systems. The EEC corpus is freely available so that both developers and users can use it, and build on it.¹⁸

7.1 Methodology

The race and gender bias evaluation was carried out on the EI-reg and V-reg predictions of 219 automatic systems (by 50 teams) on the EEC sentences. The EEC sentences were created from simple templates such as ‘<noun phrase> feels devastated’, where <noun phrase> is replaced with one of the following:

- common African American (AA) female and male first names,
- common European American (EA) female and male first names,
- noun phrases referring to females and males, such as ‘*my daughter*’ and ‘*my son*’.

Notably, one can derive pairs of sentences from the EEC such that they differ only in one phrase cor-

responding to gender or race (e.g., ‘*My daughter feels devastated*’ and ‘*My son feels devastated*’). For the full lists of names, noun phrases, and sentence templates see (Kiritchenko and Mohammad, 2018). In total, 1,584 pairs of scores were compared for gender and 144 pairs of scores were compared for race.

For each submission, we performed the paired two sample t-test to determine whether the mean difference between the two sets of scores (across the two races and across the two genders) is significant. We set the significance level to 0.05. However, since we performed 438 assessments (219 submissions evaluated for biases in both gender and race), we applied Bonferroni correction. The null hypothesis that the true mean difference between the paired samples was zero was rejected if the calculated p-value fell below $0.05/438$.

7.2 Results

7.2.1 Gender Bias Results

Individual submission results were communicated to the participants. Here, we present the summary results across all the teams. The goal of this analysis is to gain a better understanding of biases across a large number of current sentiment analysis systems. Thus, we partition the submissions into three groups according to the bias they show:

- $F = M$: submissions that showed no statistically significant difference in intensity scores predicted for corresponding female and male noun phrase sentences,
- $F \uparrow - M \downarrow$: submissions that consistently gave higher scores for sentences with female noun phrases than for corresponding sentences with male noun phrases,
- $F \downarrow - M \uparrow$: submissions that consistently gave lower scores for sentences with female noun phrases than for corresponding sentences with male noun phrases,

Table 12 shows the number of submissions in each group. If all the systems are unbiased, then the number of submissions for the group $F = M$ would be the maximum, and the number of submissions in all other groups would be zero.

Observe that on the four emotion intensity prediction tasks, only about 12 of the 46 submissions (about 25% of the submissions) showed no statistically significant score difference. On the valence prediction task, only 5 of the 36 submissions (14% of the submissions) showed no statistically

Task	F = M	F \uparrow -M \downarrow	F \downarrow -M \uparrow	all
EI-reg				
anger	12	21	13	46
fear	11	12	23	46
joy	12	25	8	45
sadness	12	18	16	46
V-reg	5	22	9	36

Table 12: **Analysis of gender bias:** The number of submissions in each of the three bias groups.

significant score difference. Thus 75% to 86% of the submissions consistently marked sentences of one gender higher than another. When predicting anger, joy, or valence, the number of systems consistently giving higher scores to sentences with female noun phrases (21–25) is markedly higher than the number of systems giving higher scores to sentences with male noun phrases (8–13). (Recall that higher valence means more positive sentiment.)

In contrast, on the fear task, most submissions tended to assign higher scores to sentences with male noun phrases (23) as compared to the number of systems giving higher scores to sentences with female noun phrases (12). When predicting sadness, the number of submissions that mostly assigned higher scores to sentences with female noun phrases (18) is close to the number of submissions that mostly assigned higher scores to sentences with male noun phrases (16).

7.2.2 Race Bias Results

We did a similar analysis as for gender, for race. For each submission on each task, we calculated the difference between the average predicted score on the set of sentences with African American (AA) names and the average predicted score on the set of sentences with European American (EA) names. Then, we aggregated the results over all such sentence pairs in the EEC.

Table 13 shows the results. The table has the same form and structure as the gender result table. Observe that the number of submissions with no statistically significant score difference for sentences pertaining to the two races is about 5–11 (about 11% to 24%) for the four emotions and 3 (about 8%) for valence. These numbers are even lower than what was found for gender.

The majority of the systems assigned higher scores to sentences with African American names on the tasks of anger, fear, and sadness intensity prediction. On the joy and valence tasks, most submissions tended to assign higher scores to sen-

Task	AA = EA	AA \uparrow -EA \downarrow	AA \downarrow -EA \uparrow	All
EI-reg				
anger	11	28	7	46
fear	5	29	12	46
joy	8	7	30	45
sadness	6	35	5	46
V-reg	3	4	29	36

Table 13: **Analysis of race bias:** The number of submissions in each of the three bias groups.

tences with European American names.

We found the score differences across genders and across races to be somewhat small (< 0.03 in magnitude, which is 3% of the 0 to 1 score range). However, what impact a consistent bias, even with a magnitude $< 3\%$, might have in downstream applications merits further investigation.

8 Summary

We organized the SemEval-2018 Task 1: Affect in Tweets, which included five subtasks on inferring the affectual state of a person from their tweet. For each task, we provided training, development, and test datasets for English, Arabic, and Spanish tweets. This involved creating a new Affect in Tweets dataset of more than 22,000 tweets such that subsets are annotated for a number of emotion dimensions. For each emotion dimension, we annotated the data not just for coarse classes (such as anger or no anger) but also for fine-grained real-valued scores indicating the intensity of emotion. We used Best–Worst Scaling to obtain fine-grained real-valued intensity scores and showed that the annotations are reliable (split-half reliability scores > 0.8).

Seventy-five teams made 319 submissions to the fifteen task–language pairs. Most of the top-performing teams relied on both deep neural network representations of tweets (sentence embeddings) as well as features derived from existing sentiment and emotion lexicons. Apart from the usual evaluations for the quality of predictions, we also examined 219 EI-reg and V-reg English submissions for bias towards particular races and genders using the Equity Evaluation Corpus. We found that a majority of the systems consistently provided slightly higher scores for one race or gender. All of the data is made freely available.¹⁹

Appendix

Table 14 shows the summary details of the annotations done for the SemEval-2018 Affect in Tweets dataset. Figure 5 shows the histograms of the EI-reg tweets in the anger, joy, sadness, and fear datasets. The tweets are grouped into bins of scores 0–0.05, 0.05–0.1, and so on until 0.95–1. The colors for the bins correspond to their ordinal classes: no emotion, low emotion, moderate emotion, and high emotion. The ordinal classes were determined from the EI-oc manual annotations.

Supplementary Material: The supplementary pdf associated with this paper includes longer versions of tables included in this paper. Tables 1 to 15 in the supplementary pdf show result tables that include the scores of each of the 319 systems participating in the tasks. Table 16 in the supplementary pdf shows the annotator agreement for each of the twelve classes, for each of the three languages, in the Multi-label Emotion Classification (E-c) Dataset. We observe that the Fleiss’ κ scores are markedly higher for the frequently occurring four basic emotions (joy, sadness, fear, and anger), and lower for the less frequent emotions. (Frequencies for the emotions are shown in Table 2.) Also, agreement is low for the neutral class. This is not surprising because the boundary between neutral (or no emotion) and slight emotion is fuzzy. This means that often at least one or two annotators indicate that the person is feeling some joy or some sadness, even if most others indicate that the person is not feeling any emotion.

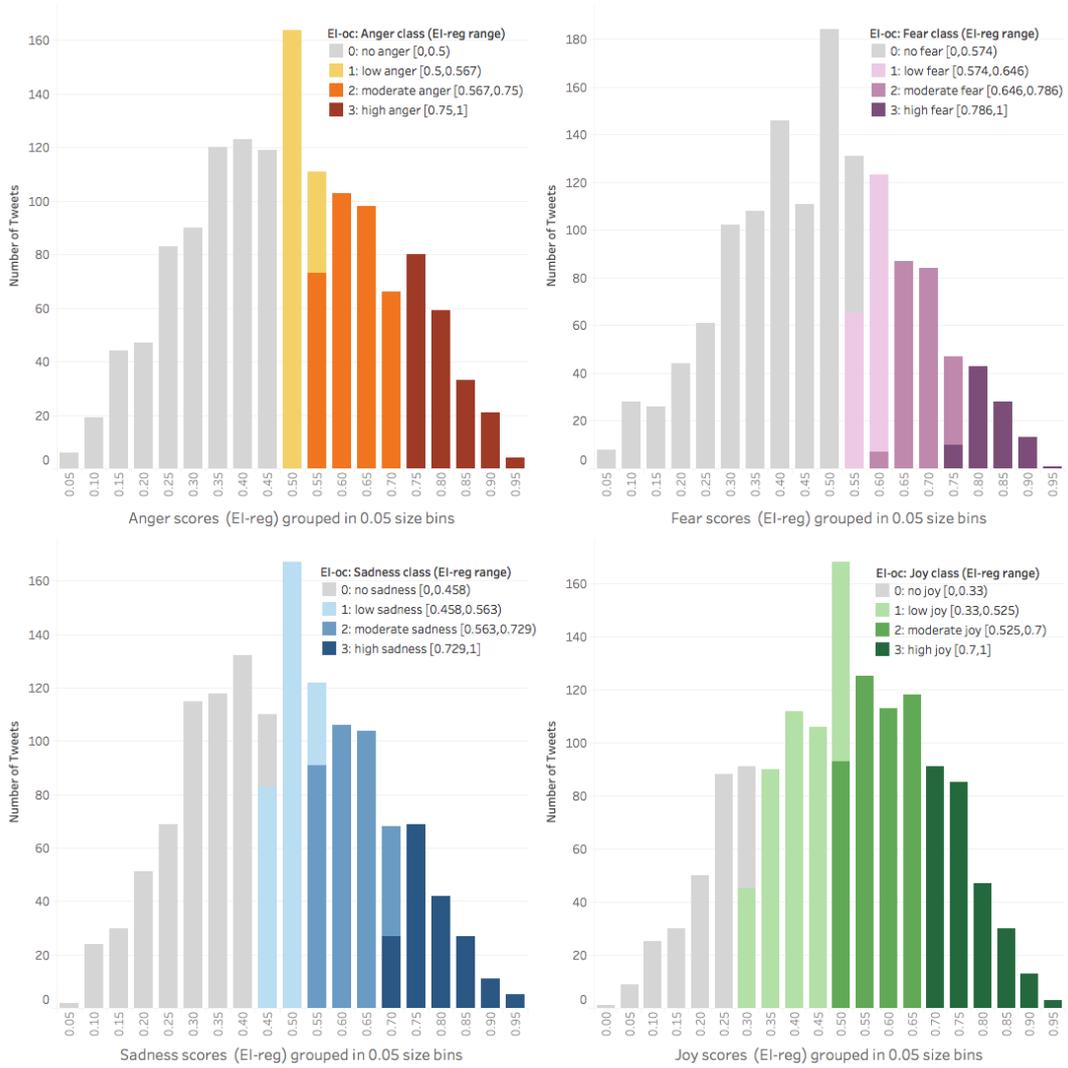

Figure 5: Emotion intensity score (EI-reg) and ordinal class (EI-oc) distributions for the four basic emotions in the SemEval-2018 AIT development and test sets combined. The distribution is similar for the training set (annotated in earlier work).

SeerNet at SemEval-2018 Task 1: Domain Adaptation for Affect in Tweets

Venkatesh Duppada, Royal Jain, Sushant Hiray

SeerNet Technologies, LLC

{venkatesh.duppada, royal.jain, sushant.hiray}@seernet.io

Abstract

The paper describes the best performing system for the SemEval-2018 Affect in Tweets (English) sub-tasks. The system focuses on the ordinal classification and regression sub-tasks for valence and emotion. For ordinal classification valence is classified into 7 different classes ranging from -3 to 3 whereas emotion is classified into 4 different classes 0 to 3 separately for each emotion namely anger, fear, joy and sadness. The regression sub-tasks estimate the intensity of valence and each emotion. The system performs domain adaptation of 4 different models and creates an ensemble to give the final prediction. The proposed system achieved 1st position out of 75 teams which participated in the fore-mentioned sub-tasks. We outperform the baseline model by margins ranging from 49.2% to 76.4%, thus, pushing the state-of-the-art significantly.

1 Introduction

Twitter is one of the most popular micro-blogging platforms that has attracted over 300M daily users¹ with over 500M² tweets sent every day. Tweet data has attracted NLP researchers because of the ease of access to large data-source of people expressing themselves online. Tweets are micro-texts comprising of emoticons, hashtags as well as location data, making them feature rich for performing various kinds of analysis. Tweets provide an interesting challenge as users tend to write grammatically incorrect and use informal and slang words.

In domain of natural language processing, emotion recognition is the task of associating words, phrases or documents with emotions from predefined using psychological models. The classification of emotions has mainly been researched from

¹<https://www.statista.com/statistics/282087/number-of-monthly-active-twitter-users/>

²<http://www.internetlivestats.com/twitter-statistics/>

two fundamental viewpoints. (Ekman, 1992) and (Plutchik, 2001) proposed that emotions are discrete with each emotion being a distinct entity. On the contrary, (Mehrabian, 1980) and (Russell, 1980) propose that emotions can be categorized into dimensional groupings.

Affect in Tweets (Mohammad et al., 2018) - shared task in SemEval-2018 focuses on extracting affect from tweets confirming to both variants of the emotion models, extracting valence (dimensional) and emotion (discrete). Previous version of the task (Mohammad and Bravo-Marquez, 2017) focused on estimating the emotion intensity in tweets. We participated in 4 sub-tasks of Affect in Tweets, all dealing with English tweets. The sub-tasks were: EI-oc: Ordinal classification of emotion intensity of 4 different emotions (anger, joy, sadness, fear), EI-reg: to determine the intensity of emotions (anger, joy, sadness, fear) into a real-valued scale of 0-1, V-oc: Ordinal classification of valence into one of 7 ordinal classes [-3, 3], V-reg: determine the intensity of valence on the scale of 0-1.

Prior work in extracting Valence, Arousal, Dominance (VAD) from text primarily relied on using and extending lexicons (Bestgen and Vincze, 2012) (Turney et al., 2011). Recent advancements in deep learning have been applied in detecting sentiments from tweets (Tang et al., 2014), (Liu et al., 2012), (Mohammad et al., 2013).

In this work, we use various state-of-the-art machine learning models and perform domain adaptation (Pan and Yang, 2010) from their source task to the target task. We use multi-view ensemble learning technique (Kumar and Minz, 2016) to produce the optimal feature-set partitioning for the classifier. Finally, results from multiple such classifiers are stacked together to create an ensemble (Polikar, 2012).

In this paper, we describe our approach and experiments to solve this problem. The rest of the paper is laid out as follows: Section 2 describes the system architecture, Section 3 reports results and inference from different experiments. Finally we conclude in Section 4 along with a discussion about future work.

2 System Description

2.1 Pipeline

Figure 1 details the System Architecture. We now describe how all the different modules are tied together. The input raw tweet is pre-processed as described in Section 2.2. The processed tweet is passed through all the feature extractors described in Section 2.3. At the end of this step, we extract 5 different feature vectors corresponding to each tweet. Each feature vector is passed through the model zoo where classifiers with different hyper parameters are tuned. The models are described in Section 2.4. For each vector, the results of top-2 performing models (based on cross-validation) are retained. At the end of this step, we’ve 10 different results corresponding to each tweet. All these results are ensembled together via stacking as described in Section 2.4.3. Finally, the output from the ensembler is the output returned by the system.

2.2 Pre-processing

The pre-processing step modifies the raw tweets to prepare for feature extraction. Tweets are pre-processed using `tweettokenize`³ tool. Twitter specific keywords are replaced with tokens, namely, USERNAME, PHONENUMBER, URLs, timestamps. All characters are converted to lowercase. A contiguous sequence of emojis is first split into individual emojis. We then replace an emoji with its description. The descriptions were scraped from EmojiPedia⁴.

2.3 Feature Extraction

As mentioned in Section 1, we perform transfer learning from various state-of-the-art deep learning techniques. We will go through the following sub-sections to understand these models in detail.

2.3.1 DeepMoji

DeepMoji (Felbo et al., 2017) performs distant supervision on a very large dataset (1246 million

tweets) comprising of noisy labels (emojis). DeepMoji was able to obtain state-of-the-art results in various downstream tasks using transfer learning. This makes it an ideal candidate for domain adaptation into related target tasks. We extract 2 different feature sets by extracting the embeddings from the softmax and the attention layer from the pre-trained DeepMoji model. The vector from softmax layer is of dimension 64 and the vector from attention layer is of dimension 2304.

2.3.2 Skip-Thought Vectors

Skip-Thought vectors (Kiros et al., 2015) is an off-the-shelf encoder that can produce highly generic sentence representations. Since tweets are restricted by character limit, skip-thought vectors can create a good semantic representation. This representation is then passed to the classifier. The representation is of dimension 4800.

2.3.3 Unsupervised Sentiment Neuron

(Radford et al., 2017) developed an unsupervised system which learned an excellent representation of sentiment. The original model was trained to generate amazon reviews, this makes the sentiment neuron an ideal candidate for transfer learning. The representation extracted from Sentiment Neuron is of size 4096.

2.3.4 EmoInt

Apart from all the pre-trained embeddings, we choose to also include various lexical features bundled through the EmoInt package⁵ (Duppada and Hiray, 2017) The lexical features include AFINN (Nielsen, 2011), NRC Affect Intensities (Mohammad, 2017), NRC-Word-Affect Emotion Lexicon (Mohammad and Turney, 2010), NRC Hashtag Sentiment Lexicon and Sentiment140 Lexicon (Mohammad et al., 2013). The final feature vector is the concatenation of all the individual features. This feature vector is of size (141, 1).

This gives us five different feature vector variants. All of these feature vectors are passed individually to the underlying models. The pipeline is explained in detail in Section 2.1

2.4 Machine Learning Models

We participated in 4 sub-tasks, namely, EI-oc, EI-reg, V-oc, V-reg. Two of the sub-tasks are ordinal classification and the remaining two are regressions. We describe our approach for building ML

³<https://github.com/jaredks/tweettokenize>

⁴<https://emojipedia.org/>

⁵<https://github.com/SEERNET/EmoInt>

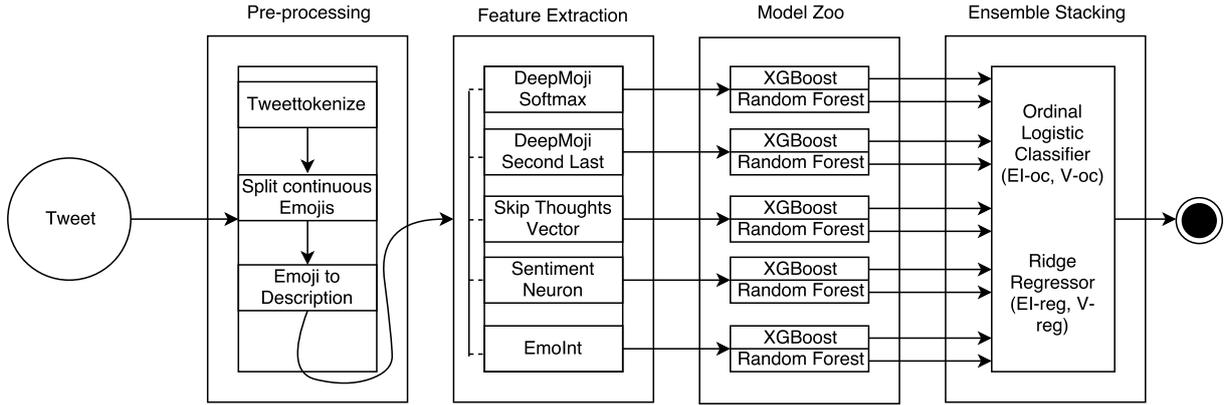

Figure 1: System Architecture.

models for both the variants in the upcoming sections.

2.4.1 Ordinal Classification

We participated in the emotion intensity ordinal classification where the task was to predict the intensity of emotions from the categories anger, fear, joy, and, sadness. Separate datasets were provided for each emotion class. The goal of the sub-task of valence ordinal classification was to classify the tweet into one of 7 ordinal classes $[-3, 3]$. We experimented with XG Boost Classifier, Random Forest Classifier of sklearn (Pedregosa et al., 2011).

2.4.2 Regression

For the regression tasks (E-reg, V-reg), the goal was to predict the intensity on a scale of 0-1. We experimented with XG Boost Regressor, Random Forest Regressor of sklearn (Pedregosa et al., 2011).

The hyper-parameters of each model were tuned separately for each sub-task. The top-2 best models corresponding to each feature vector type were chosen after performing 7-fold cross-validation.

2.4.3 Stacking

Once we get the results from all the classifiers/regressors for a given tweet, we use stacking ensemble technique to combine the results. In this case, we pass the results from the models to a meta classifier/regressor as input. The output of this meta model is treated as the final output of the system.

We observed that using ordinal regressors gave us better performance than using classifiers which treat each output class as disjoint. Ordinal Regression is a family of statistical learning meth-

Task	Baseline	2 nd best	Our Results
EI-reg	0.520	0.776	0.799
EI-oc	0.394	0.659	0.695
V-reg	0.585	0.861	0.873
V-oc	0.509	0.833	0.836

Table 1: Primary metrics across various sub-tasks.

ods where the output variable is discrete and ordered. We use the ordinal logistic classification with squared error (Rennie and Srebro, 2005) from the python library Mord.⁶ (Rennie and Srebro, 2005)

In case of regression sub-tasks we observed the best cross validation results with Ridge Regression. Hence, we chose Ridge Regression as the meta regressor.

3 Results and Analysis

3.1 Task Results

The metrics used for ranking various systems are discussed in this section.

3.1.1 Primary Metrics

Pearson correlation with gold labels was used as a primary metric for ranking the systems. For EI-reg and EI-oc tasks Pearson correlation is macro-averaged (MA Pearson) over the four emotion categories.

Table 1 describes the results based on primary metrics for various sub-tasks in English language. Our system achieved the best performance in each of the four sub-tasks. We have also included the results of the baseline and second best performing system for comparison. As we can observe,

⁶<https://github.com/fabianp/mord>

Task	Pearson (SE)	Kappa	Kappa (SE)
V-oc	0.884 (1)	0.831 (1)	0.873 (1)
EI-oc	0.547 (1)	0.669 (1)	0.503 (1)

Table 2: Secondary metrics for ordinal classification sub-tasks. System rank is mentioned in the brackets.

Task	Pearson (gold in 0.5-1)
V-reg	0.697 (1)
EI-reg	0.638 (1)

Table 3: Secondary metrics for regression sub-tasks. System rank is mentioned in brackets.

our system vastly outperforms the baseline and is a significant improvement over the second best system, especially, in the emotion sub-tasks.

3.1.2 Secondary Metrics

The competition also uses some secondary metrics to provide a different perspective on the results. Pearson correlation for a subset of the test set that includes only those tweets with intensity score greater or equal to 0.5 is used as the secondary metric for the regression tasks. For ordinal classification tasks following secondary metrics were used:

- Pearson correlation for a subset of the test set that includes only those tweets with intensity classes low X, moderate X, or high X (where X is an emotion). The organizers refer to this set of tweets as the some-emotion subset (SE).
- Weighted quadratic kappa on the full test set
- Weighted quadratic kappa on the some-emotion subset of the test set

The results for secondary metrics are listed in Table 2 and 3. We have also included the ranking in brackets along with the score. We see that our system achieves the top rank according to all the secondary metrics, thus, proving its robustness.

3.2 Feature Importance

The performance of the system is highly dependent on the discriminative ability of the tweet representation generated by the featurizers. We measure the predictive power for each of the featurizer used by calculating the pearson correlation of the system using only that featurizer. We describe the results for each sub task separately in tables 4-7.

Feature Set	Pearson
Deepmoji (softmax layer)	0.808
Deepmoji (attention layer)	0.843
EmoInt	0.823
Unsupervised sentiment Neuron	0.714
Skip-Thought Vectors	0.777
Combined	0.873

Table 4: Pearson Correlation for V-reg task. Best results are highlighted in bold.

Feature Set	Pearson
Deepmoji (softmax layer)	0.780
Deepmoji (attention layer)	0.813
EmoInt	0.785
Unsupervised sentiment Neuron	0.685
Skip-Thought Vectors	0.748
Combined	0.836

Table 5: Pearson Correlation for V-oc task. Best results are highlighted in bold.

Feature Set	Pearson
Deepmoji (softmax layer)	0.703
Deepmoji (attention layer)	0.756
EmoInt	0.694
Unsupervised sentiment Neuron	0.548
Skip-Thought Vectors	0.656
Combined	0.799

Table 6: Macro-Averaged Pearson Correlation for EI-reg task. Best results are highlighted in bold.

Feature Set	Pearson
Deepmoji softmax layer	0.611
Deepmoji attention layer	0.664
EmoInt	0.596
Unsupervised sentiment Neuron	0.445
Skip-Thought Vectors	0.557
Combined	0.695

Table 7: Macro-Averaged Pearson Correlation for EI-oc task. Best results are highlighted in bold.

We observe that deepmoji featurizer is the most powerful featurizer of all the ones that we’ve used. Also, we can see that stacking ensembles of models trained on the outputs of multiple featurizers gives a significant improvement in performance.

3.3 System Limitations

We analyze the data points where our model’s prediction is far from the ground truth. We observed some limitations of the system, such as, sometimes understanding a tweet’s requires contextual knowledge about the world. Such examples can be very confusing for the model. We use deepemoji pre-trained model which uses emojis as proxy for labels, however partly due to the nature of twitter conversations same emojis can be used for multiple emotions, for example, joy emojis can be sometimes used to express joy, sometimes for sarcasm or for insulting someone. One such example is ‘Your club is a laughing stock’. Such cases are sometimes incorrectly predicted by our system.

4 Future Work & Conclusion

The paper studies the effectiveness of various representations of tweets and proposes ways to combine them to obtain state-of-the-art results. We also show that stacking ensemble of various classifiers learnt using different representations can vastly improve the robustness of the system.

Further improvements can be made in the pre-processing stage. Instead of discarding various tokens such as punctuation’s, incorrectly spelled words, etc, we can utilize the information by learning their semantic representations. Also, we can improve the system performance by employing multi-task learning techniques as various emotions are not independent of each other and information about one emotion can aid in predicting the other. Furthermore, more robust techniques can be employed for distant supervision which are less prone to noisy labels to get better quality training data.

Abstract

This paper describes the results of the first shared task on Multilingual Emoji Prediction, organized as part of SemEval 2018. Given the text of a tweet, the task consists of predicting the most likely emoji to be used along such tweet. Two subtasks were proposed, one for English and one for Spanish, and participants were allowed to submit a system run to one or both subtasks. In total, 49 teams participated in the English subtask and 22 teams submitted a system run to the Spanish subtask. Evaluation was carried out *emoji-wise*, and the final ranking was based on macro F-Score. Data and further information about this task can be found at <https://competitions.codalab.org/competitions/17344>.

1 Introduction

Emojis are small ideograms depicting objects, people, and scenes (Cappallo et al., 2015). Emojis are one of the main components of a novel way of communication emerging from the advent of social media. They complement (usually) short text messages with a visual enhancement which is, as of now, a *de-facto* standard for online communication (Barbieri et al., 2017). Figure 1 shows an example of a social media message displaying an emoji.

Sometimes I think I wanna change the world... and I forget it just starts with changing me. ❤️

Figure 1: Message from Twitter including a single red heart emoji.

Emojis¹ can be considered somehow an evolution of character-based *emoticons* (Pavalanathan and Eisenstein, 2015), and currently they represent a widespread and pervasive global communication device largely adopted by almost any social media service and instant messaging platforms.

Any system targeting the task of modeling social media communication is expected to tackle the usage of emojis. In fact, their semantic load is sufficiently rich that oversimplifying them to *sentiment carriers* or *boosters* would be to neglect the semantic richness of these ideograms, which in addition to mood (😄) include in their vocabulary references to food (🍌), sports (⚽), scenery (🌈), etc². In general, however, effectively predicting the emoji associated with a piece of content may help to improve different NLP tasks (Novak et al., 2015), such as information retrieval, generation of emoji-enriched social media content, suggestion of emojis when writing text messages or sharing pictures online. Given that emojis may also mislead humans (Barbieri et al., 2017; Miller et al., 2017), the automated prediction of emojis may help to achieve better language understanding. As a consequence, by modeling the semantics of emojis, we can improve highly-subjective tasks like sentiment analysis, emotion recognition and irony detection (Felbo et al., 2017).

In this context, Barbieri et al. (2017) introduced the task of emoji prediction in Twitter by training several models based on bidirectional Long Short-Term Memory networks (LSTMs) (Graves, 2012), and showing they can outperform humans in solv-

¹<https://unicode.org/emoji/charts/full-emoji-list.html>

²<https://unicode.org/emoji/charts/emoji-ordering.html>

ing the same task. These promising results motivated us to propose the first shared task on Multilingual Emoji Prediction. Following the experimental setting proposed by Barbieri et al. (2017), the task consists of predicting most likely emoji associated of a given text-only Twitter message. Only tweets with a single emoji are included in the task datasets (trial, train and test sets), so that the challenge can be cast as a single label classification problem.

In this paper, we first motivate and describe the main elements of this shared task (Section 2 and 3). Then, we cover the dataset compilation, curation and release process (Section 4). In Section 5 we detail the evaluation metrics and describe the overall results obtained by participating systems. Finally, we wrap this task description paper up with the main conclusions drawn from the organization of this challenge, as well as outlining potential avenues for future work, in Section 6.

2 Related Work

Modeling the semantics of emojis, and their applications thereof, is a relatively novel research problem with direct applications in any social media task. By explicitly modeling emojis as self-containing semantic units, the goal is to alleviate the lack of an associated grammar. This context, which makes it difficult to encode a clear and univocal single meaning for each emoji, has given rise to work considering emojis as function words or even affective markers (Na’aman et al., 2017), potentially affecting the overall semantics of longer utterances like sentences (Monti et al., 2016; Donato and Paggio, 2017).

The polysemy of emoji has been explored user-wise (Miller et al., 2017), location-wise, specifically in countries (Barbieri et al., 2016b) and cities (Barbieri et al., 2016a), gender-wise, time-wise (Barbieri et al., 2018b; Chen et al., 2017), and even device-wise, due to the fact that emojis may have different pictorial characteristics (and therefore, different interpretations), depending on the device (e.g., Iphone, Android, Samsung, etc.) or *app* (Whatsapp, Twitter, Facebook, and so forth)³ (Tigwell and Flatla, 2016; Miller et al., 2016).

³The image that represents the same emoji can vary, e.g., for the emoji U+1F40F, the following are over different renderings by platform in Unicode v11 (up to April 2018): Apple 🐶, Google 🐶, Twitter 🐶, EmojiOne 🐶, Facebook 🐶, Samsung 🐶, Windows 🐶.

Today, modeling emoji semantics via vector representations is a well defined avenue of work. Contributions in this respect include models trained on Twitter data (Barbieri et al., 2016c), Twitter data together with the official unicode description (Eisner et al., 2016), or using text from a popular keyboard app Ai et al. (2017). In the latter contribution it is argued that emojis used in an affective context are more likely to become popular, and in general, the most important factor for an emoji to become popular is to have a clear meaning. In fact, the area of emoji vector evaluation has also experienced a significant growth as of recent. For instance, Wijeratne et al. (2017a) propose a platform for exploring emoji semantics. Further studies on evaluating emoji semantics may now be carried out by leveraging two recently introduced datasets with pairwise emoji similarity, with human annotations, namely EmoTwi50 (Barbieri et al., 2016c) and EmoSim508 (Wijeratne et al., 2017b). In the application avenue, emoji similarity has been studied for proposing efficient keyboard emoji organization, essentially for placing similar emojis close in the keyboard (Pohl et al., 2017).

An aspect related with emoji semantic modeling in which awareness is increasing dramatically is the inherent bias existing in these representations. For example, Barbieri and Camacho-Collados (2018) show that emoji modifiers can affect the semantics of emojis (they looked specifically into skin tones and gender). This recent line of research has also been explored in Robertson et al. (2018) who argue, for example, that users with darker-skinned profile photos employ skin modifiers more often than users with lighter-skinned profile photos, and that the vast majority of skin tone usage matches the color of a user’s profile photo.

The application of well defined emoji representations in extrinsic tasks is, an open area of research. A natural application, however, lies in the context of sentiment analysis. This has fostered research, for example, in creating sentiment lexicons for emojis (Novak et al., 2015; Kimura and Katsurai, 2017; Rodrigues et al., 2018), or in studying how emojis may be used to retrieve tweets with specific emotional content (Wood and Ruder, 2016). Moreover, Hu et al. (2017) study how emojis affect the sentiment of a text message, and show that not all emojis have the same impact. Finally, the fact that emojis carry sentiment

and emotion information is verified in the study by Felbo et al. (2017), where an emoji prediction classifier is used as pre-trained system, and then is fine-tuned for predicting sentiment, emotions and irony.

The last item to be covered in this review involves multimodality. Recently, emojis have been also studied from a prism where visual signals are incorporated, taking advantage of existing social media platforms like Instagram, with a strong focus on visual content. Recent contributions show that the usage of emojis depends on both textual and visual content, but seem to agree in that, in general, textual information is more relevant for the task of emoji prediction (Cappallo et al., 2015, 2018; Barbieri et al., 2018a).

3 Task Description

Given a text message including an emoji, the emoji prediction task consists of predicting that emoji by relying exclusively on the textual content of that message. In particular, in this task we focused on the one emoji occurring inside tweets, thus relying on Twitter data.

Last hike in our awesome camping weekend! 😊

Figure 2: Example of tweet with an emoji at the end, considered in the emoji prediction task.

The task is divided into two subtasks respectively dealing with the prediction of the emoji associated to English and Spanish tweets. The motivation for providing a multilingual setting stems from previous findings about the idiosyncrasy of use of emojis across languages (Barbieri et al., 2016b) (see Figure 3): one emoji may be used with completely different meanings depending not only on the language of the speaker, but also on regional dialects (Barbieri et al., 2016a).

For each subtask we selected the tweets that included one of the twenty emojis that occur most frequently in the Twitter data we collected (Table 1). Therefore, the task can be viewed as a multi-label classification problem with twenty labels.

Twitter datasets were shared among participants by providing a list of tweet IDs⁴ or directly the

⁴Participants were provided with a Java-based crawler (<https://github.com/fra82/twitter-crawler>) to ease the download of the textual

It's flipping hot out here! 🔥

Iniciamos el nuevo año con ilusión! 🔥

Figure 3: Example of distinct use of the fire emoji across languages: the first tweet (English) comments on the torrid weather, while the second one (Spanish) exploits the same emoji to wish an happy new year ('We start the new year with enthusiasm!').

English																			
1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20
❤️	😍	😂	💕	🔥	😏	👉	👉	👉	👉	👉	👉	👉	👉	👉	👉	👉	👉	👉	👉

Spanish																			
1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20
❤️	😍	😂	💕	😏	👉	👉	👉	👉	👉	👉	👉	👉	👉	👉	👉	👉	👉	👉	👉

Table 1: The 20 most frequent emojis of each language (due to a data processing issue we only considered 19 emojis in the Spanish task).

text of each tweet. The last approach was adopted to share the test sets (more details are provided in Section 4).

4 Task Data

The data for the task consists of a list of tweets associated with a given emoji (i.e. label). As explained in the previous section, the dataset includes tweets that contain one and only one emoji, of the 20 most frequent emojis. We split the data in trial⁵, training and test data. The quantity of tweets per set is displayed in Table 2.

The tweets were retrieved with the Twitter APIs and geolocalized in United States and Spain for subtasks 1 and 2, respectively. As for the trial and training data, the tweets were gathered from October 2015 to February 2017, whereas for the test data we decided to gather the tweets corresponding to the last months until the evaluation period started (from May 2017 to Jan 2018). This would prevent participants from gathering these tweets before-hand and also would enable us to test the emoji prediction task on a more realistic setting, as the test data is subsequent to the training data.

content of tweets from the ID list.

⁵Trial data was used as development by participants.

	Trial	Training	Test
English	50,000	500,000	50,000
Spanish	10,000	100,000	10,000

Table 2: Number of tweets for trial, training and test for each of the subtasks.

5 Evaluation

This section introduces the overall evaluation setting of this shared task. We first describe briefly the evaluation metrics used and then provide a succinct description of the baseline system.

5.1 Evaluation Metrics

As this was a single label classification problem, the classic *precision* (Prec.), *recall* (Recall), *f-score* (F1) and *accuracy* (Acc.) were used as official evaluation metrics. Note that because of the skewed distribution of the label set we opted for macro average over all labels.

5.2 Baseline

The baseline system for this task was a classifier based on FastText⁶ (Joulin et al., 2017). Given a set of N documents, the loss that the model attempts to minimize is the negative log-likelihood over the labels (in our case, the emojis):

$$loss = -\frac{1}{N} \sum_{n=1}^N e_n \log(\text{softmax}(BA_{x_n}))$$

where e_n is the emoji included in the n -th Twitter post, represented as hot vector, and used as label. Hyperparameters were set as default⁷.

5.3 Participant Systems

Due to the overwhelming number of participants, we cannot describe all systems.⁸ We do, however,

⁶github.com/facebookresearch/fastText

⁷<https://github.com/facebookresearch/fastText#full-documentation>

⁸This is the list of systems that ranked below the baseline in either of the subtasks: #TeamINF (Ribeiro and Silva, 2018), CENNLP (J R et al., 2018), DUTH (Effrosynidis et al., 2018), ECNU (Lu et al., 2018), EICA (Xie and Song, 2018), EPUTION (Zhou et al., 2018), LIS (Guibon et al., 2018), Manchester Metropolitan (Gerber and Shardlow, 2018), Peperomia (Chen et al., 2018), PickleTeam! (Groot et al., 2018), Shi (Shiyun et al., 2018), SyntNN (Zanzotto and Santilli, 2018), TAJJEB (Basile and Lino, 2018), The Dabblers (Alexa et al., 2018), THU_NGN (Wu et al., 2018), Tweety (Kopev et al., 2018), UMDSub (Wang and Pedersen, 2018), YNU-HPCC (Wang et al., 2018). Note that some participants did not submit a final paper but they are included in the results table.

briefly mention the main features of some significant systems ranked above the baseline in either of the subtasks.

- **Tübingen-Oslo** (Çöltekin and Rama, 2018). This supervised system consists of an SVM classifier with bag-of-n-grams features (both characters and words). *Tübingen-Oslo* is the top performing system in both tasks.
- **NTUA-SLP** (Baziotis et al., 2018). This system uses a Bi-LSTM with attention, and pre-trained word2vec vectors. They used external resources for associating each tweet with information on emotions, concreteness, familiarity, and others. They only participated in the English subtask but they classified second (according to the F1 score) with the highest recall.
- **EmoNLP** (Liu, 2018). This system is based on a Gradient Boosting Regression Tree Approach combined with a Bi-LSTM on character and word ngrams. It is complemented with several lexicons as well as learning sentiment specific word embeddings.
- **UMDuluth-CS8761** (Beaulieu and Asamoah Owusu, 2018) This supervised system combines an SVM with a bag-of-words approach for extracting salient features. This is one of the most competitive systems with the highest precision in English and the third best result in Spanish.
- **Hatching Chick** (Coster et al., 2018). This system builds an SVM classifier (with gradient descent optimization) on words and character ngrams. They obtained the second best result in the Spanish subtask, but their English system performed worse than the baseline.
- **TAJJEB** (Basile and Lino, 2018). This system made use of an SVM classifier over wide variety of features such as tf-idf, part-of-speech tags and bigrams. The system was competitive on both languages, outperforming the baseline on the Spanish dataset.
- **Duluth UROP** (Jin and Pedersen, 2018). This system consists of a soft voting ensemble approach combining different machine learning algorithms (Naïve Bayes, Lo-

gistic Regression, Random Forests, etc.). Infrequent classes are oversampled using the SMOTE algorithm. As for features, they use both unigrams and bigrams.

Table 4: Best F1 measure (among all the teams) for each emoji in English (20) and Spanish (19). We also report the relative frequency percentage of each emoji in the test set.

5.4 Results

Each system was evaluated according to its capacity to perform well across all emojis under consideration. As mentioned, and due to the skewed distribution of the label set, we evaluated each participating system according to Macro F-Score (F1).

The overall results are provided in Table 3, and already several interesting conclusions can be drawn from them. For instance, it is noteworthy the fact that the best systems for both subtasks are more than 10 points apart (English better), which suggests that a *one-size-fits-all* model may be suboptimal for this task, and that indeed the

particularities of each individual language should be taken into consideration for best performance. The most precise systems were *EmoNLP* and *Tübingen-Oslo*, whereas the highest Recall was obtained by *NTUA-SLP* and again *Tübingen-Oslo* (English and Spanish respectively, in both cases). Clearly, the *Tübingen-Oslo* system shows a fine balance between precision and recall, perhaps due to its little preprocessing, fine-tuning and reliance on external libraries. It seems reasonable to assume, thus, that combining word and ngram embeddings as features, with SVMs and NN classifiers, provides a robust and high performing architecture for emoji prediction, with the added value of being resource/knowledge agnostic.

5.5 Analysis

This evaluation is finally complemented with the overall emoji-wise performance across all systems (Table 4). The lexical notion of *near synonymy* seems to clearly apply to emojis as well, as we can clearly see a worse performance on those emojis which are pictorially similar (e.g., the photo camera with and without flash, or the expected confusion between least frequent hearts and the red heart, which accounts for over 20% of the whole label set in the test data).

Finally, emojis with several interpretations and less frequent seem to be much more difficult to predict (e.g., the face 😏 in the English and Spanish dataset, and 😄 in the Spanish dataset). Zhou et al. (2018) showed in their system description paper how exploiting user-specific features may provide significance performance boosts.⁹ This additional user-specific information may clearly help in these difficult cases which proved to be hard for all systems.

6 Conclusions

In this paper we have described the SemEval 2018 shared task in multilingual emoji prediction. The task, consisting in predicting the most likely emoji given the text of a tweet, was well received, with almost 50 system runs submitted to the English subtask and more than 20 to the Spanish subtask. One of the main conclusions that can be drawn is that the baseline we used (FastText) was highly competitive, with only 6 and 5 system runs performing better in English and Spanish.

⁹The use of user-specific data was not allowed by the main competition regulations and therefore none of the systems in the final ranking made use of it.

Table 3: Ranking of the participating systems by precision, recall, F1 and accuracy for the English track and the Spanish track. Those above the horizontal line ranked above the task baseline.

In terms of participating systems, and according to the post-participation survey the participants completed, we can see a high prevalence of neural approaches, with only 9 systems opting for more traditional linear models (6 SVMs, 3 Random Forests). Among the chosen neural architectures, LSTMs and CNNs are by far the preferred ones. It is noteworthy, however, the excellent performance of SVMs as used in the best performing system on both English and Spanish datasets.

This task has set the foundations for upcoming work on modeling emoji semantics, first, by providing a standardized testbed for emoji prediction in two languages, and second, by providing a comprehensive evaluation with a wide range of ideas, which we hope are of use for future research. Emojis, undoubtedly, are becoming increasingly important in understanding social media communication and in human-computer interaction, and thus we believe the problem of modeling emoji semantics can be further extended as follows. (1) Leveraging multimodal information (e.g., associated images (Barbieri et al., 2018a)); (2) incorporating more and more diverse languages (one step in this direction will be the re-run of this task for Italian at the Evalita 2018 evaluation campaign¹⁰); and (3) considering individual and communicative contexts for overall performance improvements.

Acknowledgments

We thank all the participants of the task. Francesco B. and Horacio S. acknowledge support from the TUNER project (TIN2015-65308-C5-5-R, MINECO/FEDER, UE) and the Maria de Maeztu Units of Excellence Programme (MDM-2015-0502). The work of V. Patti and V. Basile was partially funded by the IHatePrejudice project (S1618_L2_BOSC_01).

Abstract

This paper describes our participation in the SemEval-2018 task Multilingual Emoji Prediction. We participated in both English and Spanish subtasks, experimenting with support vector machines (SVMs) and recurrent neural networks. Our SVM classifier obtained the top rank in both subtasks with macro-averaged F1-measures of 35.99 % for English and 22.36 % for Spanish data sets. Similar to a few earlier attempts, the results with neural networks were not on par with linear SVMs.

1 Introduction

Emojis are graphical symbols that represent an idea or emotion. The use of emojis has become popular over the last decade, particularly in informal communication in the social media. Their popularity kindled a recent interest in investigating many aspects of emojis, including their interaction with natural language (e.g., Barbieri et al., 2016, 2017; Felbo et al., 2017; Kralj Novak et al., 2015). Although the emojis are presumably language-independent, their use typically goes together with linguistic text. In this context, the SemEval 2018 task 2, Multilingual Emoji Prediction (Barbieri et al., 2018), aims predicting the emoji from the surrounding micro-blogging (Twitter) text for English and Spanish.

The task at hand is to predict a label, an emoji, from a short text that it accompanies. This is essentially a text/document classification problem, and shares many aspects of other text classification problems such as topic classification, sentiment analysis, language identification and authorship attribution – just to name a few. Although each of these problems have some task-specific aspects, the same models can be used for all of them. In this study, we experiment with and compare two well-known methods: support vector machines

(SVMs) with bag of word/character n-gram features and recurrent neural networks (RNNs) with word and character sequences as input. The methods and implementations are similar to our earlier attempts in other text classification tasks (Çöltekin and Rama, 2016; Rama and Çöltekin, 2017; Çöltekin and Rama, 2017).¹ In the remainder of this paper, we describe our methods and experiments, present and discuss our results.

2 Experiments and Results

We participated in both subtasks using the same architectures. However, we trained and tuned the model parameters on each data set separately. The training set for the competition consisted of 500 000 tweets for English and 100 000 tweets for Spanish subtask. The data sets contained most frequent 20 emojis for English and 19 emojis for Spanish. Joining late to the party, our training set consisted of 485 151 English tweets, and 97 765 Spanish tweets, since about 3 % of the tweets were not available by the time we crawled them. As presented in Figure 1, the label distribution is similar and quite skewed for both languages. We included pre-processing steps of case normalization and discarding low-frequency features as part of our hyperparameter optimization. In all our experiments, we use only the data supplied by the organizers. We did not use any external sources (e.g., pre-trained word embeddings), nor did we perform any further linguistic processing (e.g., POS tagging, or parsing). The test size for English and Spanish is 50 000 and 10 000 respectively.

2.1 Support Vector Machines

The best results obtained in the shared task are based on multi-class (one-vs-rest) linear support

¹ The source code of our implementation is available at <https://github.com/coltekin/emoji2018>.

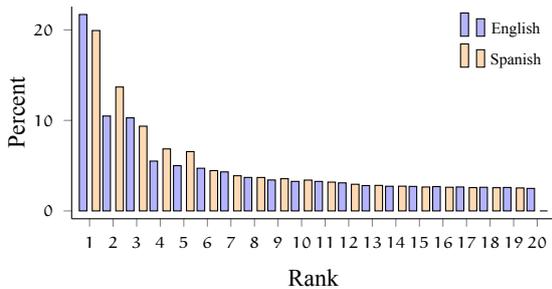

Figure 1: Label distribution in both data sets. Ratio of each label is plotted against its rank. Note that the emojis sharing the same rank are not necessarily identical in both languages.

vector machines (SVM). We use ‘bag of n-grams’ as features, combining both character n-grams and word n-grams of different sizes, weighted by sub-linear TF-IDF scaling applied globally to all n-grams (character and word n-grams with varying sizes). Although we also experimented with logistic regression and random forests using the same feature set, the results were consistently inferior to the SVMs. Therefore, we will not discuss the results of logistic regression and random forests. The models discussed in this section were implemented with scikit-learn package (Pedregosa et al., 2011) using liblinear back end (Fan et al., 2008).

We optimized the models for best macro F1-score on each language data set through a grid search using 5-fold cross validation. The hyperparameters considered during optimization were maximum character/word n-gram size, case normalization, minimum document frequency threshold for excluding low-frequency features, and SVM margin (or regularization) parameter ‘C’. Although there has been other parameter settings with competitive scores, we used maximum character n-grams size of 6, maximum word n-gram size of 4, minimum document frequency threshold of 2, SVM parameter C of 0.10, and we case normalized only word (not character) n-grams. Our submitted system achieved 36.55 precision, 36.22 recall and 35.99 F1-score on the English test set, and 23.49 precision, 22.80 recall and 22.36 F1-score on the Spanish test set. These figures were about 1% lower than the figures we obtained in 5-fold cross validation results on the training data.

Figure 2 presents the effects of character and word n-grams of different sizes. For all results presented in Figure 2, n-grams from size 1 up to the indicated number are included as features. Although both combining character and word n-grams, and

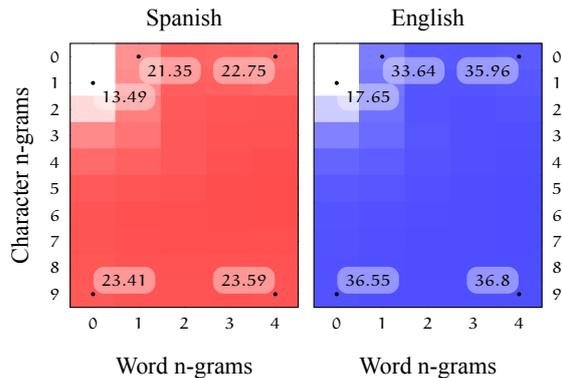

Figure 2: The effect of maximum character and word n-gram size combinations to F1-measure. Darker shades indicate higher F1-measure.

larger n-gram sizes increase the performance, the gains from higher n-gram values are rather small. The effects of other hyperparameters are smaller. In general, however, excluding features based on frequency seems to hurt the performance. Case normalization is useful if applied to word n-grams, but its effects are often negative if it is applied to both character and word n-grams. The optimum regularization parameter ‘C’ is stable over both languages and different training sizes.

2.2 Recurrent Neural Networks

Gaining popularity relatively recently, neural models are another common approach to text classification. Fully-connected networks are computationally impractical. However, convolutional networks (CNNs) and recurrent neural networks (RNNs) offer reasonably efficient computation, as well as better modeling of sequences. RNNs, particularly gated RNNs, have been used in many diverse natural language processing tasks successfully, and text classification is not an exception.

Our neural model includes two bidirectional RNN components: one taking a sequence of words as input and another taking a sequence of characters as input. The recurrent components of the network builds two representations for the text (one based on characters, the other based on words), the representations are concatenated and passed to a fully connected softmax layer that assigns an emoji to the document based on the RNN representations. Since the tweets are relatively short, we did not truncate the input documents. For both character and word inputs, we used embedding layers before the RNN layers. All neural network experiments were implemented with Tensorflow (Abadi et al., 2015) using Keras API (Chollet et al., 2015).

Although the history/context is not a parameter for recurrent networks, the architecture has many hyperparameters. We optimized the hyperparameters of the architecture through a random search for the embedding size of both characters and words, the hidden representation size of the RNN cells, the dropout parameter for each component of the network, frequency threshold for excluding features, RNN architecture, GRU (Cho et al., 2014) or LSTM (Hochreiter and Schmidhuber, 1997), and case normalization. For the RNN models, we used a random training-validation split (80%–20% for Spanish, and 90%–10% for English) during hyperparameter tuning. We used early stopping based on macro F1-measure, and picked the epoch with the best F1-measure for each hyperparameter setting. Besides these parameters – used for systematic random search – we also experimented with deeper architectures, both by stacking RNNs and by multiple fully-connected layers. Deeper networks, however, yielded worse results.

We obtained F1-scores of 33.02% for English data and 17.98% for the Spanish data on the (randomly split) development set. For both subtasks, we submitted results with the hyperparameter setting that worked best on the English data set (although it yielded a slightly lower F1-score than the best one obtained for Spanish). For both languages, the RNN results submitted used a model with embedding layers of size 32 (for characters) and 128 (for words). In the case of bidirectional GRU networks we used hidden units of sizes 32 and 128 for character and word input, respectively, minimum frequency threshold of 4 for characters and 1 for words, dropout parameter of 0.50 at the embedding layers and 0.10 at the RNN layers, and no case normalization.

2.3 Effect of training set size

The performance with different training set sizes is an important consideration in model choice. Furthermore, since the training set sizes for the two languages in present study are different, it is also be a plausible explanation for the fact that substantially lower performance of both models on the Spanish task. To shed light into these two issues, we present incremental results on (only) the English data set. In this experiment, we randomly set aside 10% of the English training data for testing, we split the remaining 90% into 10 splits, and train both systems by starting with one of splits, and incrementally adding another one in each iteration.

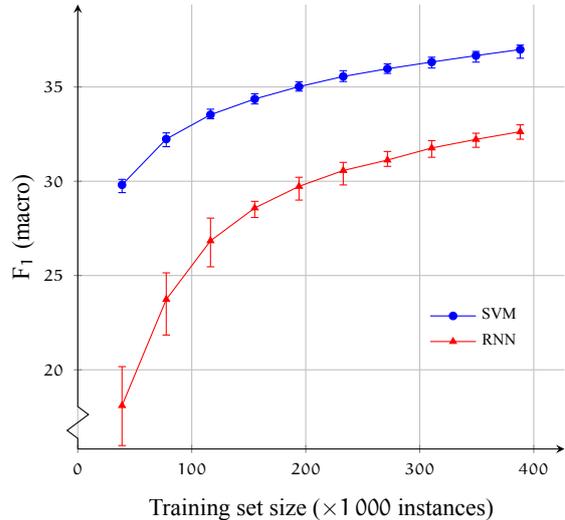

Figure 3: Learning curve for the SVM and RNN models on the English training set. The error bars indicate maximum and minimum values in 10 trials.

Figure 3 shows the F1-score against training set size, for both SVM and RNN models.

3 Discussion and conclusions

In this paper, we described our submitted systems at SemEval-2018 Task 2 on Multilingual Emoji Prediction. Besides providing details on our systems, this paper also intends to provide a comparison between two text classification methods: RNNs and linear SVMs. The comparison is motivated by the fact that, despite their popularity and argued superiority, we and others found linear models, particularly SVMs, yield better results than (deep) neural models in a series of other text classification tasks (e.g., Çöltekin and Rama, 2016; Rama and Çöltekin, 2017; Çöltekin and Rama, 2017; Medvedeva et al., 2017).

One plausible explanation is the fact that neural networks typically require more data to train. Indeed, the previous shared tasks cited above often provided modest-size training sets, mainly due to the cost of labeling. Emoji classification task has an advantage in this respect as the labeling is relatively cheap compared to many other text classification tasks. As a result, at least for English, the shared task included a rather large training set. However, our current findings also indicate that the linear SVMs still perform better than the RNN counterparts. Although the results presented in Figure 3 indicate that more data is, indeed, helpful for RNNs, the performance gap in favor of SVMs persists. Another interesting (but expected due to model complexity) observation in

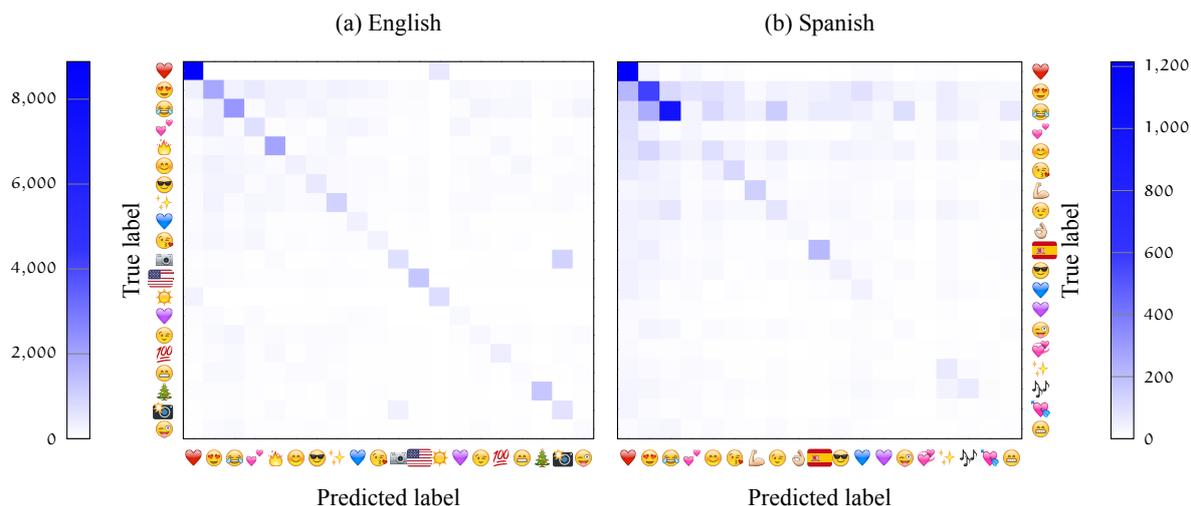

Figure 4: Confusion matrices for both data sets. The labels are sorted by frequency.

Figure 3 is that the RNNs also exhibit larger variation, especially with smaller data sizes.

Our findings seem to contradict with the majority of recent NLP literature, where RNNs are often claimed to be superior to linear models, and emoji classification is not an exception (e.g., Barbieri et al., 2017). Part of this impression comes from the fact that, in most studies, the linear baselines used in comparison are simple bag-of-words models. As words in a text are not independent, simple bag-of-words is deemed to fail. The simple addition of word n-gram features, however, circumvents this problem to a large extent, enabling the linear models to capture some local dependencies. RNNs, however, still have a potential advantage since they can, at least in theory, capture long-range dependencies as well. However, it seems either local dependencies are enough in many text classification tasks, or the data sets are (still) small for RNNs to generalize over useful long-range dependencies. Furthermore, character n-gram features are also useful, particularly for morphologically rich languages, as they also capture information present in sub-word units. Although including many overlapping character and word n-gram features result in large feature vectors, the sparse implementations of these models are computationally feasible and easy to tune – often more than corresponding deep neural network models.

A curious finding from our experiments is that despite the language-agnostic nature of our methods, both models yielded a rather large performance difference (13.63 % F1-measure on the test set) between English and Spanish. The possible explanation based on training set size is not sup-

ported by the experiments presented in Section 2.3. Figure 3 shows that, at about the training set size of Spanish data (100 000 instances), one can obtain about 32 % F1-score on the English data set, which is substantially higher than the best test and development set results we obtained using the full training data for Spanish (22.36 % and 23.59 % respectively). Hence, the difference is likely to be either due to differences between the languages, or due to some inherent confusability of the emojis in the Spanish data set. The confusion matrices in Figure 4 indicate higher majority class bias for Spanish. More experiments are needed for a better understanding of the differences.

3.1 Future directions

Past research has found that ensemble methods that combine multiple classifiers yield better performance compared to each individual classifier (Malmasi and Dras, 2015). Besides the differences in the learning algorithms, the models we compare in this work exploit rather different types of information. Hence, a combination of classifiers may result in better performance. Even though we did not experiment with ensemble methods in this work, the number of test instances that were predicted correctly by one of the models (but not by both) was 17.28 % and 19.95 % for English and the Spanish data respectively, indicating a promising upper bound for an ensemble approach.

Although we did not use any external resources in this task, another potential source of improvement is to use external information (e.g., embeddings or cluster labels) extracted from large unlabeled texts.

Abstract

This paper presents the first shared task on irony detection: given a tweet, automatic natural language processing systems should determine whether the tweet is ironic (Task A) and which type of irony (if any) is expressed (Task B). The ironic tweets were collected using irony-related hashtags (i.e. *#irony*, *#sarcasm*, *#not*) and were subsequently manually annotated to minimise the amount of noise in the corpus. Prior to distributing the data, hashtags that were used to collect the tweets were removed from the corpus. For both tasks, a training corpus of 3,834 tweets was provided, as well as a test set containing 784 tweets. Our shared tasks received submissions from 43 teams for the binary classification Task A and from 31 teams for the multiclass Task B. The highest classification scores obtained for both subtasks are respectively $F_1 = 0.71$ and $F_1 = 0.51$ and demonstrate that fine-grained irony classification is much more challenging than binary irony detection.

1 Introduction

The development of the social web has stimulated the use of figurative and creative language, including irony, in public (Ghosh et al., 2015). From a philosophical/psychological perspective, discerning the mechanisms that underlie ironic speech improves our understanding of human reasoning and communication, and more and more, this interest in understanding irony also emerges in the machine learning community (Wallace, 2015). Although an unanimous definition of irony is still lacking in the literature, it is often identified as a trope whose actual meaning differs from what is literally enunciated. Due to its nature, irony has important implications for natural language processing (NLP) tasks, which aim to understand and produce human language. In fact, automatic irony

detection has a large potential for various applications in the domain of text mining, especially those that require semantic analysis, such as author profiling, detecting online harassment, and, maybe the most well-known example, sentiment analysis.

Due to its importance in industry, sentiment analysis research is abundant and significant progress has been made in the field (e.g. in the context of SemEval (Rosenthal et al., 2017)). However, the SemEval-2014 shared task *Sentiment Analysis in Twitter* (Rosenthal et al., 2014) demonstrated the impact of irony on automatic sentiment classification by including a test set of ironic tweets. The results revealed that, while sentiment classification performance on regular tweets reached up to $F_1 = 0.71$, scores on the ironic tweets varied between $F_1 = 0.29$ and $F_1 = 0.57$. In fact, it has been demonstrated that several applications struggle to maintain high performance when applied to ironic text (e.g. Liu, 2012; Maynard and Greenwood, 2014; Ghosh and Veale, 2016). Like other types of figurative language, ironic text should not be interpreted in its literal sense; it requires a more complex understanding based on associations with the context or world knowledge. Examples 1 and 2 are sentences that regular sentiment analysis systems would probably classify as positive, whereas the intended sentiment is undeniably negative.

- (1) *I feel so blessed to get ocular migraines.*
- (2) *Go ahead drop me hate, I'm looking forward to it.*

For human readers, it is clear that the author of example 1 does not feel blessed at all, which can be inferred from the contrast between the positive sentiment expression “I feel so blessed”, and the negative connotation associated with getting ocular migraines. Although such connotative infor-

mation is easily understood by most people, it is difficult to access by machines. Example 2 illustrates implicit cyberbullying; instances that typically lack explicit profane words and where the offense is often made through irony. Similarly to example 1, a contrast can be perceived between a positive statement (“I’m looking forward to”) and a negative situation (i.e. experiencing hate). To be able to interpret the above examples correctly, machines need, similarly to humans, to be aware that irony is used, and that the intended sentiment is opposite to what is literally enunciated.

The irony detection task¹ we propose is formulated as follows: given a single post (i.e. a tweet), participants are challenged to automatically determine whether irony is used and which type of irony is expressed. We thus defined two subtasks:

- Task A describes a **binary irony classification task** to define, for a given tweet, whether irony is expressed.
- Task B describes a **multiclass irony classification task** to define whether it contains a specific type of irony (verbal irony by means of a polarity clash, situational irony, or another type of verbal irony, see further) or is not ironic. Concretely, participants should define which one out of four categories a tweet contains: ironic by clash, situational irony, other verbal irony or not ironic.

It is important to note that by a tweet, we understand the actual text it contains, without metadata (e.g. user id, time stamp, location). Although such metadata could help to recognise irony, the objective of this task is to learn, at message level, how irony is linguistically realised.

2 Automatic Irony Detection

As described by Joshi et al. (2017), recent approaches to irony can roughly be classified as either rule-based or (supervised and unsupervised) machine learning-based. While rule-based approaches mostly rely upon lexical information and require no training, machine learning invariably makes use of training data and exploits different types of information sources (or *features*), such as bags of words, syntactic patterns, sentiment information or semantic relatedness.

¹All practical information, data download links and the final results can be consulted via the CodaLab website of our task: <https://competitions.codalab.org/competitions/17468>.

Previous work on irony detection mostly applied supervised machine learning mainly exploiting lexical features. Other features often include punctuation mark/interjection counts (e.g. Davidov et al., 2010), sentiment lexicon scores (e.g. Bouazizi and Ohtsuki, 2016; Farías et al., 2016), emoji (e.g. González-Ibáñez et al., 2011), writing style, emotional scenarios, part of speech patterns (e.g. Reyes et al., 2013), and so on. Also beneficial for this task are combinations of different feature types (e.g. Van Hee et al., 2016b), author information (e.g. Bamman and Smith, 2015), features based on (semantic or factual) oppositions (e.g. Karoui et al., 2015; Gupta and Yang, 2017; Van Hee, 2017) and even eye-movement patterns of human readers (Mishra et al., 2016). While a wide range of features are and have been used extensively over the past years, deep learning techniques have recently gained increasing popularity for this task. Such systems often rely on semantic relatedness (i.e. through word and character embeddings (e.g. Amir et al., 2016; Ghosh and Veale, 2016)) deduced by the network and reduce feature engineering efforts.

Regardless of the methodology and algorithm used, irony detection often involves binary classification where irony is defined as instances that express the opposite of what is meant (e.g. Riloff et al., 2013; Joshi et al., 2017). Twitter has been a popular data genre for this task, as it is easily accessible and provides a rapid and convenient method to find (potentially) ironic messages by looking for hashtags like *#irony*, *#not* and *#sarcasm*. As a consequence, irony detection research often relies on automatically annotated (i.e. based on irony-related hashtags) corpora, which contain noise (Kunneman et al., 2015; Van Hee, 2017).

3 Task Description

We propose two subtasks A and B for the automatic detection of irony on Twitter, for which we provide more details below.

3.1 Task A: Binary Irony Classification

The first subtask is a two-class (or binary) classification task where submitted systems have to predict whether a tweet is ironic or not. The following examples respectively present an ironic and non-ironic tweet.

- (3) *I just love when you test my patience!!
#not.*

- (4) *Had no sleep and have got school now #not happy*

Note that the examples contain irony-related hashtags (e.g. #irony) that were removed from the corpus prior to distributing the data for the task.

3.2 Task B: Multiclass Irony Classification

The second subtask is a multiclass classification task where submitted systems have to predict one out of four labels describing i) verbal irony realised through a polarity contrast, ii) verbal irony without such a polarity contrast (i.e. other verbal irony), iii) descriptions of situational irony, and iv) non-irony. The following paragraphs present a description and a number of examples for each label.

Verbal irony by means of a polarity contrast

This category applies to instances containing an evaluative expression whose polarity (positive, negative) is inverted between the literal and the intended evaluation, as shown in examples 5 and 6:

- (5) *I love waking up with migraines #not 😞*
(6) *I really love this year's summer; weeks and weeks of awful weather*

In the above examples, the irony results from a polarity inversion between two evaluations. For instance, in example 6, the literal evaluation (“I really love this year’s summer”) is positive, while the intended one, which is implied by the context (“weeks and weeks of awful weather”), is negative.

Other verbal irony This category contains instances that show no polarity contrast between the literal and the intended evaluation, but are nevertheless ironic.

- (7) *@someuser Yeah keeping cricket clean, that's what he wants #Sarcasm*
(8) *Human brains disappear every day. Some of them have never even appeared. <http://t.co/Fb0Aq5Frqs> #brain #human-brain #Sarcasm*

Situational irony This class label is reserved for instances describing situational irony, or situations that fail to meet some expectations. As explained by Shelley (2001), firefighters who have a fire in their kitchen while they are out to answer a fire alarm would be a typically ironic situation. Some other examples of situational irony are the following:

- (9) *Most of us didn't focus in the #ADHD lecture. #irony*
(10) *Event technology session is having Internet problems. #irony #HSC2024*

Non-ironic This class contains instances that are clearly not ironic, or which lack context to be sure that they are ironic, as shown in the following examples:

- (11) *And then my sister should be home from college by time I get home from babysitting. And it's payday. THIS IS A GOOD FRIDAY*
(12) *Is Obamacare Slowing Health Care Spending? #NOT*

4 Corpus Construction and Annotation

A data set of 3,000 English tweets was constructed by searching Twitter for the hashtags #irony, #sarcasm and #not (hereafter referred to as the ‘hashtag corpus’), which could occur anywhere in the tweet that was finally included in the corpus. All tweets were collected between 01/12/2014 and 04/01/2015 and represent 2,676 unique users. To minimise the noise introduced by groundless irony hashtags, all tweets were manually labelled using a fine-grained annotation scheme for irony (Van Hee et al., 2016a). Prior to data annotation, the entire corpus was cleaned by removing retweets, duplicates and non-English tweets and replacing XML-escaped characters (e.g. & amp ;).

The corpus was entirely annotated by three students in linguistics and second-language speakers of English, with each student annotating one third of the whole corpus. All annotations were done using the brat rapid annotation tool (Stenetorp et al., 2012). To assess the reliability of the annotations, and whether the guidelines allowed to carry out the task consistently, an **inter-annotator agreement study** was set up in two rounds. Firstly, inter-rater agreement was calculated between the authors of the guidelines to test the guidelines for usability and to assess whether changes or additional clarifications were recommended prior annotating the entire corpus. For this purpose, a subset of 100 instances from the SemEval-2015 Task *Sentiment Analysis of Figurative Language in Twitter* (Ghosh et al., 2015) dataset were annotated. Based on the results, some clarifications and refinements were added to

the annotation scheme, which are thoroughly described in Van Hee (2017). Next, a second agreement study was carried out on a subset (i.e. 100 randomly chosen instances) of the corpus. As metric, we used **Fleiss’ Kappa** (Fleiss, 1971), a widespread statistical measure in the field of computational linguistics for assessing annotator agreement on categorical ratings (Carletta, 1996). The measure calculates the degree of agreement in classification over the agreement which would be expected by chance, i.e. when annotators would randomly assign class labels.

annotation	Kappa κ round 1	Kappa κ round 2
ironic / not ironic	0.65	0.72
ironic by clash / other / not ironic	0.55	0.72

Table 1: Inter-annotator agreement scores (Kappa) in two annotation rounds.

Table 1 presents the inter-rater scores for the binary irony distinction and for three-way irony classification (‘other’ includes both situational irony and other forms of verbal irony). We see that better inter-annotator agreement is obtained after the refinement of the annotation scheme, especially for the binary irony distinction. Given the difficulty of the task, a Kappa score of 0.72 for recognising irony can be interpreted as good reliability².

The distribution of the different irony types in the experimental corpus are presented in Table 2.

class label	# instances
Verbal irony by means of a polarity contrast	1,728
Other types of verbal irony	267
Situational irony	401
Non-ironic	604

Table 2: Distribution of the different irony categories in the corpus

Based on the annotations, 2,396 instances out of the 3,000 are ironic, while 604 are not. To balance the class distribution in our experimental corpus, 1,792 non-ironic tweets were added from a background corpus. The tweets in this corpus were collected from the same set of Twitter users as in the hashtag corpus, and within the same time span. It is important to note that these tweets do not contain irony-related hashtags (as opposed to the non-ironic tweets in the hashtag corpus), and were manually filtered from ironic tweets. Adding

²According to magnitude guidelines by Landis and Koch (1977).

these non-ironic tweets to the experimental corpus brought the total amount of data to 4,792 tweets (2,396 ironic + 2,396 non-ironic). For this shared task, the corpus was randomly split into a class-balanced training (80% or 3,833 instances) and test (20%, or 958 instances) set. In an additional cleaning step, we removed ambiguous tweets (i.e. where additional context was required to understand their ironic nature), from the test corpus, resulting in a test set containing 784 tweets (consisting of 40% ironic and 60% non-ironic tweets).

To train their systems, participants were not restricted to the provided training corpus. They were allowed to use additional training data that was collected and annotated at their own initiative. In the latter case, the submitted system was considered *unconstrained*, as opposed to *constrained* if only the distributed training data were used for training.

It is important to note that participating teams were allowed ten submissions at CodaLab, and that they could submit a constrained and unconstrained system for each subtask. However, only their last submission was considered for the official ranking (see Table 3).

5 Evaluation

For both subtasks, participating systems were evaluated using standard evaluation metrics, including accuracy, precision, recall and F_1 score, calculated as follows:

$$accuracy = \frac{true\ positives + true\ negatives}{total\ number\ of\ instances} \quad (1)$$

$$precision = \frac{true\ positives}{true\ positives + false\ positives} \quad (2)$$

$$recall = \frac{true\ positives}{true\ positives + false\ negatives} \quad (3)$$

$$F_1 = 2 \cdot \frac{precision \cdot recall}{precision + recall} \quad (4)$$

While accuracy provides insights into the system performance for all classes, the latter three measures were calculated for the positive class only (Task A) or were macro-averaged over four class labels (Task B). Macro-averaging of the F_1 score implies that all class labels have equal weight in the final score.

For both subtasks, two baselines were provided against which to compare the systems' performance. The first baseline randomly assigns irony labels and the second one is a linear SVM classifier with standard hyperparameter settings exploiting tf-idf word unigram features (implemented with scikit-learn (Pedregosa et al., 2011)). The second baseline system is made available to the task participants via GitHub³.

6 Systems and results for Task A

In total, 43 teams competed in Task A on binary irony classification. Table 3 presents each team's performance in terms of accuracy, precision, recall and F_1 score. In all tables, the systems are ranked by the official F_1 score (shown in the fifth column). Scores from teams that are marked with an asterisk should be interpreted carefully, as the number of predictions they submitted does not correspond to the number of test instances.

As can be observed from the table, the SVM unigram baseline clearly outperforms the random class baseline and generally performs well for the task. Below we discuss the top five best-performing teams for Task A, which all built a constrained (i.e. only the provided training data were used) system. The best system yielded an F_1 score of 0.705 and was developed by THU_NGN (Wu et al., 2018). Their architecture consists of densely connected LSTMs based on (pre-trained) word embeddings, sentiment features using the AffectiveTweet package (Mohammad and Bravo-Marquez, 2017) and syntactic features (e.g. PoS-tag features + sentence embedding features). Hypothesising that the presence of a certain irony hashtag correlates with the type of irony that is used, they constructed a multi-task model able to predict simultaneously 1) the missing irony hashtag, 2) whether a tweet is ironic or not and 3) which fine-grained type of irony is used in a tweet.

Also in the top five are the teams NTUA-SLP ($F_1= 0.672$), WLW ($F_1= 0.650$), NLPRL-IITBHU ($F_1= 0.648$) and NIHRIO ($F_1= 0.648$). NTUA-SLP (Baziotis et al., 2018) built an ensemble classifier of two deep learning models: a word- and character-based (bi-directional) LSTM to capture semantic and syntactic information in tweets, respectively. As features, the team used pre-trained character and word embeddings on a corpus of 550 million tweets. Their ensemble

classifier applied majority voting to combine the outcomes of the two models. WLW (Rohanian et al., 2018) developed an ensemble voting classifier with logistic regression (LR) and a support vector machine (SVM) as component models. They combined (through averaging) pre-trained word and emoji embeddings with handcrafted features, including sentiment contrasts between elements in a tweet (i.e. left vs. right sections, hashtags vs. text, emoji vs. text), sentiment intensity and word-based features like flooding and capitalisation). For Task B, they used a slightly altered (i.e. ensemble LR models and concatenated word embeddings instead of averaged) model. NLPRL-IITBHU (Rangwani et al., 2018) ranked fourth and used an XGBoost Classifier to tackle Task A. They combined pre-trained CNN activations using DeepMoji (Felbo et al., 2017) with ten types of handcrafted features. These were based on polarity contrast information, readability metrics, context incongruity, character flooding, punctuation counts, discourse markers/intensifiers/interjections/swear words counts, general token counts, WordNet similarity, polarity scores and URL counts. The fifth best system for Task A was built by NIHRIO (Vu et al., 2018) and consists of a neural-networks-based architecture (i.e. Multilayer Perceptron). The system exploited lexical (word- and character-level unigrams, bigrams and trigrams), syntactic (PoS-tags with tf-idf values), semantic features (word embeddings using GloVe (Pennington et al., 2014), LSI features and Brown cluster features (Brown et al., 1992)) and polarity features derived from the Hu and Liu Opinion Lexicon (Hu and Liu, 2004).

As such, all teams in the top five approached the task differently, by exploiting various algorithms and features, but all of them clearly outperformed the baselines. Like most other teams, they also showed a better performance in terms of recall compared to precision.

Table 3 displays the results of each team's official submission for Task A, i.e. no distinction is made between constrained and unconstrained systems. By contrast, Tables 4 and 5 present the rankings of the **best** (i.e. not necessarily the last, and hence official submission) constrained and unconstrained submissions for Task A.

As can be deduced from Table 4, when considering all constrained submissions from each team and ranking them based on performance, we see

Table 5: Best unconstrained systems for Task A.

In the top five unconstrained (i.e. using additional training data) systems for Task A are #NonDicevoSulSerio, INAOE-UPV, RM@IT, ValenTO and UTMN, with F₁ scores ranging between 0.622 and 0.527. #NonDicevoSulserio extended the training corpus with 3,500 tweets from existing irony corpora (e.g. Riloff et al. (2013); Barbieri and Saggion (2014); Ptáček et al. (2014) and built an SVM classifier exploiting structural features (e.g. hashtag count, text length), sentiment- (e.g. contrast between text and emoji sentiment), and emotion-based (i.e. emotion lexicon scores) features. INAOE-UPV combined pre-trained word embeddings from the Google News corpus with word-based features (e.g. *n*-grams). They also extended the official training data with benchmark corpora previously used in irony research and trained their system with a total of 165,000 instances. RM@IT approached the task using an ensemble classifier based on attention-based recurrent neural networks and the Fast-

Text (Joulin et al., 2017) library for learning word representations. They enriched the provided training corpus with, on the one hand, the data sets provided for SemEval-2015 Task 11 (Ghosh et al., 2015) and, on the other hand, the sarcasm corpus composed by Ptáček et al. (2014). Altogether, this generated a training corpus of approximately 110,000 tweets. ValenTO took advantage of irony corpora previously used in irony detection that were manually annotated or through crowdsourcing (e.g. Riloff et al., 2013; Ptáček et al., 2014). In addition, they extended their corpus with an unspecified number of self-collected irony tweets using the hashtags *#irony* and *#sarcasm*. Finally, UTMN developed an SVM classifier exploiting binary bag-of-words features. They enriched the training set with 1,000 humorous tweets from SemEval-2017 Task 6 (Potash et al., 2017) and another 1,000 tweets with positive polarity from SemEval-2016 Task 4 (Nakov et al., 2016), resulting in a training corpus of 5,834 tweets.

Interestingly, when comparing the best constrained with the best unconstrained system for Task A, we see a difference of 10 points in favour of the constrained system, which indicates that adding more training data does not necessarily improve the classification performance.

7 Systems and Results for Task B

While 43 teams competed in Task A, 31 teams submitted a system for Task B on multiclass irony classification. Table 6 presents the official ranking with each team’s performance in terms of accuracy, precision, recall and F_1 score. Similar to Task A, we discuss the top five systems in the overall ranking (Table 6) and then zoom in on the best performing constrained and unconstrained systems (Tables 7 and 8).

For Task B, the top five is nearly similar to the top five for Task A and includes the following teams: UCDCC (Ghosh, 2018), NTUA-SLP (Baziotis et al., 2018), THU_NGN (Wu et al., 2018), NLPRL-IITBHU (Rangwani et al., 2018) and NIHRIO (Vu et al., 2018). All of the teams tackled multiclass irony classification by applying (mostly) the same architecture as for Task A (see earlier). Inspired by siamese networks (Bromley et al., 1993) used in image classification, the UCDCC team developed a siamese architecture for irony detection in both subtasks. The neural network architecture makes use of Glove word

embeddings as features and creates two identical subnetworks that are each fed with different parts of a tweet. Under the premise that ironic statements are often characterised by a form of opposition or contrast, the architecture captures this incongruity between two parts in an ironic tweet.

Table 6: Official (CodaLab) results for Task B, ranked by F_1 score. The highest scores in each column are shown in bold and the baselines are indicated in purple.

NTUA-SLP, THU_NGN and NIHRIO used the same system for both subtasks. NLPRL-IITBHU also used the same architecture, but given the data skew for Task B, they used SMOTE (Chawla et al., 2002) as an oversampling technique to make sure each irony class was equally represented in the training corpus, which lead to an F_1 score increase of 5 points.

NLPRL-IITBHU built a Random Forest classifier making use of pre-trained DeepMoji embeddings, character embeddings (using Tweet2Vec) and sentiment lexicon features.

Table 8: Unconstrained systems for Task B. The highest scores in each column are shown in bold.

As can be deduced from Table 7, the top five constrained systems correspond to the five best-performing systems overall (Table 6). Only four unconstrained systems were submitted for Task B. Differently from their Task A submission, #NonDicevoSulSerio applied a cascaded approach for this task, i.e. the first algorithm served an ironic/non-ironic classification, followed by a system distinguishing between ironic by clash and other forms of irony. Lastly, a third classifier distinguished between situational and other verbal irony. To account for class imbalance in step two, the team added 869 tweets of the *situational* and *other verbal irony* categories. INAOE-UPV, INGEOTEC-IIMAS and IITG also added tweets to the original training corpus, but it is not entirely clear how many were added and how these extra tweets were annotated.

Similar to Task A, the unconstrained systems do not seem to benefit from additional data, as they do not outperform the constrained submissions for the task.

Table 9: Results for Task B, reporting the F₁ score for the class labels. The highest scores in each column are shown in bold.

A closer look at the best and worst-performing systems for each subtask reveals that Task A benefits from systems that exploit a variety of handcrafted features, especially sentiment-based (e.g. sentiment lexicon values, polarity contrast), but also bags of words, semantic cluster features and PoS-based features. Other promising features for the task are word embeddings trained on large Twitter corpora (e.g. 5M tweets). The classifiers and algorithms used are (bidirectional) LSTMs, Random Forest, Multilayer Perceptron, and an optimised (i.e. using feature selection) voting classifier combining Support Vector Machines with Logistic Regression. Neural network-based systems exploiting word embeddings derived from the training dataset or generated from Wikipedia corpora perform less well for the task.

Similarly, Task B seems to benefit from (ensemble) neural-network architectures exploiting large corpus-based word embeddings and sentiment features. Oversampling and adjusting class weights are used to overcome the class imbalance of labels 2 and 3 versus 1 and 0 and tend to improve the classification performance. Ensemble classifiers outperform multi-step approaches and combined binary classifiers for this task.

Task B challenged the participants to distinguish between different types of irony. The class distributions in the training and test corpus are natural (i.e. no additional data were added after the annotation process) and imbalanced. For the evaluation of the task, F_1 scores were macro-averaged; on the one hand, this gives each label equal weight in the evaluation, but on the other hand, it does not show each class contribution to the average score. Table 9 therefore presents the participating teams' performance on each of the subtypes of irony in Task B. As can be deduced from Table 9, all teams performed best on the *non ironic* and *ironic by clash* classes, while identifying *situational irony* and *other irony* seems to be much more challenging. Although the scores for these two classes are the lowest, we observe an important difference between *situational* and *other* verbal irony. This can probably be explained by the heterogeneous nature of the *other* category, which collects diverse realisations of verbal irony. A careful and manual annotation of this class, which is currently being conducted, should provide more detailed insights into this category of ironic tweets.

8 Conclusions

The systems that were submitted for both subtasks represent a variety of neural-network-based approaches (i.e. CNNs, RNNs and (bi-)LSTMs) exploiting word- and character embeddings as well as handcrafted features. Other popular classification algorithms include Support Vector Machines, Maximum Entropy, Random Forest, and Naïve Bayes. While most approaches were based on one algorithm, some participants experimented with ensemble learners (e.g. SVM + LR, CNN + bi-LSTM, stacked LSTMs), implemented a voting system or built a cascaded architecture (for Task B) that first distinguished ironic from non-ironic tweets and subsequently differentiated between the fine-grained irony categories.

Among the most frequently used features are

lexical features (e.g. n -grams, punctuation and hashtag counts, emoji presence) and sentiment- or emotion- lexicon features (e.g. based on SenticNet (Cambria et al., 2016), VADER (Hutto and Gilbert, 2014), aFinn (Nielsen, 2011)). Also important but to a lesser extent were syntactic (e.g. PoS-patterns) and semantic features, based on word, character and emoji embeddings or semantic clusters.

The best systems for Task A and Task B obtained an F_1 score of respectively 0.705 and 0.507 and clearly outperformed the baselines provided for this task. When looking at the scores per class label in Task B, we observe that high scores were obtained for the *non-ironic* and *ironic by clash* classes, and that *other irony* appears to be the most challenging irony type. Among all submissions, a wide variety of preprocessing tools, machine learning libraries and lexicons were explored.

As the provided datasets were relatively small, participants were allowed to include additional training data for both subtasks. Nevertheless, most submissions were constrained (i.e. only the provided training data were used): only nine unconstrained submissions were made for Task A, and four for Task B. When comparing constrained to unconstrained systems, it can be observed that adding more training data does not necessarily benefit the classification results. A possible explanation for this is that most unconstrained systems added training data from related irony research that were annotated differently (e.g. automatically) than the distributed corpus, which presumably limited the beneficial effect of increasing the training corpus size.

This paper provides some general insights into the main methodologies and bottlenecks for binary and multiclass irony classification. We observed that, overall, systems performed much better on Task A than Task B and the classification results for the subtypes of irony indicate that ironic by clash is most easily recognised (top $F_1 = 0.697$), while other types of verbal irony and situational irony are much harder (top F_1 scores are 0.114 and 0.376, respectively).

Abstract

Detecting irony is an important task to mine fine-grained information from social web messages. Therefore, the Semeval-2018 task 3 is aimed to detect the ironic tweets (subtask A) and their irony types (subtask B). In order to address this task, we propose a system based on a densely connected LSTM network with multi-task learning strategy. In our dense LSTM model, each layer will take all outputs from previous layers as input. The last LSTM layer will output the hidden representations of texts, and they will be used in three classification task. In addition, we incorporate several types of features to improve the model performance. Our model achieved an F-score of 70.54 (ranked 2/43) in the subtask A and 49.47 (ranked 3/29) in the subtask B. The experimental results validate the effectiveness of our system.

1 Introduction

Figurative languages such as irony are widely used in web messages such as tweets to convey different sentiment. Identifying the ironic texts can help to understand the social web better and has many applications such as sentiment analysis (Ghosh and Veale, 2016). Irony detecting techniques are important to improve the performance of sentiment analysis. For example, the tweet “*Monday mornings are my fave:)# not*” is an irony with negative sentiment, but it will be probably classified as a positive one by a standard sentiment analysis model (Van Hee et al., 2016b). Thus, capturing the ironic information in texts is useful to predict sentiment more accurately (Van Hee et al., 2016a).

However, determining whether a text is ironic is a challenging task since the differences between ironic and non-ironic texts are usually subtle. For example, the tweet “*Love this weather #not*” is ironic, but a similar tweet “*Hate this*

weather #not happy” is non-ironic. Different approaches are proposed to recognize the complex irony in texts. Existing methods to detect irony are mainly based on rules or machine learning techniques (Joshi et al., 2017). Rules based methods usually depend on lexicons to identify irony (Khattari et al., 2015; Maynard and Greenwood, 2014). However, these methods cannot utilize the contextual information from texts. Traditional machine learning based methods such as SVM (Desai and Dave, 2016) are also effective in this task, but they usually need manually feature engineering (Barbieri et al., 2014). Recently, deep learning techniques are successfully applied to this task. For example, Ghosh et al. (2016) propose to use a CNN-LSTM model to classify the ironic and non-ironic tweets. Their method can significantly improve the classification performance without heavy feature engineering. However, existing methods are aimed to detect irony in tweets with explicit irony related hashtags. For example, tweets with #irony or #sarcasm hashtags are very likely to be ironic. Therefore, models may focus on these hashtags rather than the contextual information.

To fill this gap, the SemEval-2018 task 3¹ aims to detect irony of tweets without explicit irony hashtags (Van Hee et al., 2018). The subtask A is aimed to determine whether a tweet is ironic. the subtask B is aimed to identify the irony types of tweets: Verbal irony by means of a polarity contrast, other verbal irony and situational irony. Several examples are as follows:

- **verbal irony by means of a polarity contrast:** I love waking up with migraines #not
- **other verbal irony:** @user Yeah keeping cricket clean, that’s what he wants #Sarcasm

¹<https://competitions.codalab.org/competitions/17468>

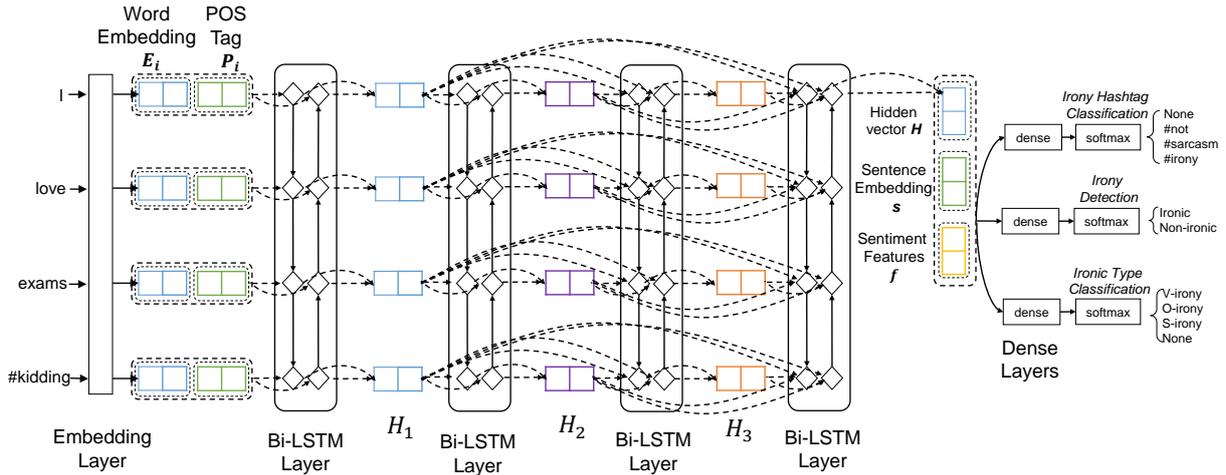

Figure 1: Architecture of our Dense-LSTM model. The V-irony, O-irony and S-irony denote the three different irony types respectively (Van Hee et al., 2018).

- **situational irony**: most of us didn't focus in the #ADHD lecture. #irony

In order to address this problem, we propose a system² based on a densely connected LSTM model (Wu et al., 2017) with multitask learning techniques. In our model, each LSTM layer will take all outputs of previous LSTM layers as input. Then different levels of contextual information can be learned at the same time. Our model is required to predict in three tasks simultaneously: 1) identifying the missing irony related hashtags; 2) classify ironic or non-ironic; 3) irony type classification. By using multitask learning strategy, the model can combine the information in the different tasks to improve the performance. The experimental results in both subtasks validate the effectiveness of our method.

2 Densely Connected LSTM with Multi-task Learning

The architecture of our densely connected LSTM model is shown in Figure 1. We denote this model as *Dense-LSTM*. The detailed information will be introduced in the following paragraphs.

In our model, the embedding layer is used to convert the input tweets into a sequence of dense vectors. The POS tag features P_i are one-hot encoded and concatenated with the word embedding vectors E_i . Usually the affective words and creative languages in tweets are important

irony clues. Since these words usually have specific POS tags, adding these features can help our model to capture the ironic information better. We use tweetokenize³ tool to tokenize and the Ark-Tweet-NLP⁴ tool to obtain the POS tags of tweets (Owoputi et al., 2013).

The first Bi-LSTM layer takes the sequential vectors as input. For the j_{th} Bi-LSTM layer, its output H_j will input all LSTM layers after it. As shown in Figure 1, the blue dashed lines represent such over-layer connections. All inputs of an LSTM layer will be concatenated together. Thus, the input of the j_{th} ($j > 1$) layer is $[H_1; \dots; H_{j-1}]$. It indicates that each layer can learn different levels of information at the same time. Since the irony information is complex, jointly using all levels of information is beneficial to predict irony more accurately. The last LSTM layer will output the hidden representation H of texts. It will be concatenated with the sentiment features and the sentence embedding features. The sentiment features can provide additional sentiment information to detect irony, such as the sentiment polarity assigned by lexicons. The sentiment features are generated via the AffectiveTweets⁵ package in weka provided by Mohammad et al. (Mohammad and Bravo-Marquez, 2017). We use the TweetToLexiconFeatureVector (Bravo-Marquez et al., 2014) and TweetToSen-

²https://github.com/wuch15/SemEval-2018-task3-THU_NGN.git

³<https://github.com/jaredks/tweetokenize>

⁴<http://www.cs.cmu.edu/ark/TweetNLP>

⁵<https://github.com/felipebravom/AffectiveTweets>

tiStrengthFeatureVector (Thelwall et al., 2012) filters in this package. The embedding of a sentence is obtained by taking the average of all words in this sentence using the 100-dim pre-trained embedding weights provided by Bravo et al. (Bravo-Marquez et al., 2016). By incorporating the vector representation of tweet sentence, the irony information can be easier to be captured.

Three dense layers with ReLU activation are used to predict for three different tasks including: determining the missing ironic hashtags (i.e. #not, #sarcasm, #irony or none of them) (*task1*); identifying ironic or non-ironic (*task2*); identifying the irony types (*task3*). Thus, the objective function of our model can be formulated as:

$$\mathcal{L} = \alpha_1 \mathcal{L}_1 + \alpha_2 \mathcal{L}_2 + \alpha_3 \mathcal{L}_3, \quad (1)$$

where \mathcal{L}_i and α_i denote the loss function and its weight of task i . \mathcal{L}_1 and \mathcal{L}_2 are categorical and binary cross-entropy respectively. In addition, the numbers of tweets with different irony types are very unbalanced. Motivated by the cost-sensitive entropy used by Santos et al. (2009), we formulate \mathcal{L}_3 as follows:

$$\mathcal{L}_3 = - \sum_{i=1}^N w_{y_i} y_i \log(\hat{y}_i), \quad (2)$$

where N is the number of tweets, y_i is the irony type of the i th tweet, \hat{y}_i is the prediction score, and w_{y_i} is the loss weight of irony type label y_i . w_{y_i} is defined as $\frac{\sum_{k=1}^C N_k}{N_{y_i}}$, where C is the number of irony types and N_j is the number of tweets with irony type label j . Thus, the infrequent irony types will gain relatively larger loss weights. By using this multi-task learning method, our model can incorporate different information such as the irony hashtags. In addition, classifying ironic/non-ironic and the irony types are similar tasks. Therefore, the performance of both tasks can be improved by combining the information of both tasks.

In order to improve the performance of our system, we use an ensemble strategy by averaging the classification results predicted by 10 models. Each model will be trained using a random dropout rate. Therefore in this way, the classification results will be voted by different models, which can improve the model performance.

3 Experiment

3.1 Dataset and Experimental Settings

The detailed statistics of the dataset⁶ in this task are shown in Table 1. V-irony, O-irony and S-irony represent the three types respectively: verbal irony by means of a polarity contrast, other types of verbal irony and situational irony (Van Hee et al., 2018). In subtask A, the performance of systems is evaluated by F-score for the positive class. In subtask B, the macro-averaged F-score over all classes is used as the metric.

Task	A		B			
	Ironic	Non-ironic	V-irony	O-irony	S-irony	Non-ironic
#train	1911	1923	1390	316	205	1923
#test	311	473	164	85	62	473

Table 1: The detailed statistics of the dataset.

We combine two pre-trained word embeddings: 1) the embeddings provided by Godin et al. (2015), which are trained on a corpus with 400 million tweets; 2) the embeddings provided by Barbieri et al. (2016), which are trained on 20 million tweets. The dimensions of them are 400 and 300 respectively. They are concatenated together as the embeddings of words.

In our network, the Dense-LSTM model has 4 LSTM layers with 200-dim hidden states. The hidden dimensions of dense layers are set to 300. The dropout rate of each layer is set to a random number between 0.2 to 0.4, and it will be set to a fixed value 0.3 in the comparative experiments without ensemble strategy. In subtask A, the loss weights α of the three task are set to 0.5, 1 and 0.5 respectively. In subtask B, they are 0.5, 0.5 and 1. We use RMSProp as the optimizer, and the batch size is set to 64. In addition, we use 10% training data for validation to select the hyperparameters above.

3.2 Performance Evaluation

We compare the performance of different methods including: 1) SVM, the benchmark system using SVM and BOW model; 2) CNN, using CNN with a global average pooling layer to obtain the hidden vector h , which is used to predict in the three tasks; 3) LSTM, using one Bi-LSTM layer in the network to get h ; 4) 2-layer LSTM, using 2 Bi-LSTM layers; 5) Dense-LSTM, using our

⁶<https://github.com/Cyvhee/SemEval2018-Task3/tree/master/datasets>

Dense-LSTM model; 6) Dense-LSTM+ens, using our Dense-LSTM model and ensemble strategy. In addition, we apply multi-task learning technique to all models except the benchmark system based on SVM. The results are shown in Table 1. The experimental results show that our Dense-LSTM model significantly outperforms the baselines. Since the layers in our Dense-LSTM can learn from all previous outputs, our model can combine different levels of contextual information to capture the high-level irony clues. In addition, our model can predict more accurately via ensemble. Since models with random dropout can extract different information, we can take advantage of all models by voting. The ensemble strategy can reduce the noise in the dataset and make our system more stable (Xia et al., 2011).

Model	Subtask A			Subtask B
	P	R	F	Macro-F
<i>Baseline</i>	54.78	62.70	58.47	32.69
<i>CNN</i>	59.32	61.41	60.35	45.30
<i>LSTM</i>	57.73	67.20	62.11	45.76
<i>2-layer LSTM</i>	60.34	68.49	64.16	47.16
<i>Dense-LSTM</i>	62.78	72.69	67.36	48.28
<i>Dense-LSTM+ens</i>	63.04	80.06	70.54	49.47

Table 2: The performance of different methods. P, R, F represent precision, recall and F-score respectively.

3.3 Effectiveness of Multi-task Learning

The performance of our Dense-LSTM model using different combinations of training tasks is shown in Table 3. Note that we don’t apply model ensemble here. Compared with the models trained in task2 or task3 only, the combination of both tasks can improve the performance. It may be because the two tasks have inherent relatedness and can share rich mutual information. Learning to predict the missing ironic hashtags (task1) can also improve the model performance. Since the ironic hashtags are often important ironic clues, identifying such clues can help our model to mine ironic information better.

3.4 Influence of Pre-trained Word Embedding

We compare the performance using different combinations of pre-trained embeddings in our model. The results are illustrated in Table 4. The results show that the pre-trained embeddings are important to capture irony information, and using the

Task Combination	Subtask A			Subtask B
	P	R	F	Macro-F
<i>task2</i>	60.05	71.06	65.10	-
<i>task3</i>	-	-	-	44.65
<i>task2+task3</i>	61.81	72.34	66.67	46.94
<i>task1+task2</i>	61.33	71.38	65.97	-
<i>task1+task3</i>	-	-	-	45.57
<i>task1+task2+task3</i>	62.78	72.69	67.36	48.28

Table 3: The performance in two subtasks using different combinations of training tasks.

combination of two different word embeddings can improve the model performance. It proves that this method can reduce the out-of-vocabulary words in the single embedding file and provide richer semantic information.

Feature	Subtask A			Subtask B
	P	R	F	Macro-F
<i>w/o pre-trained</i>	56.25	67.14	61.21	42.28
<i>+emb1</i>	60.96	69.95	65.14	47.69
<i>+emb2</i>	61.77	70.59	65.89	47.24
<i>+emb1 +emb2</i>	62.78	72.69	67.36	48.28

Table 4: Influence of pre-trained word embedding. The emb1 and emb2 denote the embeddings provided by Godin et al. (2015) and Barbieri et al. (2016) respectively.

3.5 Influence of Additional Features

The influence of different features on our model is shown in Table 5. According to this table, all features can improve the classification performance in both subtasks, and the combination of the three features can achieve better performance. The improvement brought by POS tags is most significant. Affective words are important irony clues and they are usually verbs, adjectives or hashtags. Thus, incorporating the POS tag features can help to identify these words and capture the ironic information better. The sentiment features also improve our model, which can be inferred from the results. The sentiment polarities of ironic tweets are usually negative, but these texts often contain positive sentiment words. Since our sentiment features are obtained by several different sentiment or emotion lexicons, they can be used to assign the sentiment scores of texts, which can provide rich information to detect irony. The sentence embedding can also slightly improve the performance. The sentence embedding contains information of each word in the sentence. Thus, it can help to capture the word information better, which is ben-

eficial to identify the overall sentiment of texts. The combination of all three types of features can take advantage of them and gain significant performance improvement. It validates the effectiveness of each type of features.

Feature	Subtask A			Subtask B
	P	R	F	Macro-F
None	59.84	70.42	64.70	45.56
+POS tags	61.04	72.03	66.08	46.61
+Sentiment Features	61.16	71.38	65.88	46.37
+Sentence Embedding	61.39	71.06	65.87	46.24
+All Features	62.78	72.69	67.36	48.28

Table 5: Influence of different features on our model.

4 Conclusion

Detecting irony in web texts is an important task to mine fine-grained sentiment information. In order to address this problem, we develop a system based on a densely connected LSTM model to participate in the SemEval-2018 Task 3. In our model, every LSTM layer will take all outputs of previous layers as inputs. Thus, the different levels of information can be learned at the same time. In addition, we propose to combine three different tasks to train our model jointly, which includes identifying the missing irony hashtags, determining ironic or non-ironic and classifying the irony types. These tasks have inherent relatedness thus the performance can be improved by sharing the mutual information. Our system achieved an F-score of 70.54 and 49.47 which ranked the 2nd and 3rd place in the two subtasks. The experimental results validates the effectiveness of our method.

Abstract

Character identification is a task of entity linking that finds the global entity of each personal mention in multiparty dialogue. For this task, the first two seasons of the popular TV show *Friends* are annotated, comprising a total of 448 dialogues, 15,709 mentions, and 401 entities. The personal mentions are detected from nominals referring to certain characters in the show, and the entities are collected from the list of all characters in those two seasons of the show. This task is challenging because it requires the identification of characters that are mentioned but may not be active during the conversation. Among 90+ participants, four of them submitted their system outputs and showed strengths in different aspects about the task. Thorough analyses of the distributed datasets, system outputs, and comparative studies are also provided. To facilitate the momentum, we create an open-source project for this task and publicly release a larger and cleaner dataset, hoping to support researchers for more enhanced modeling.

1 Introduction

Most of the earlier works in natural language processing (NLP) had focused on formal writing such as newswires, whereas many recent works have targeted at colloquial writing such as text messages or social media. Since the evolution of Web 2.0, the amount of user-generated contents involving colloquial writing has exceeded the one with formal writing. NLP tasks are relatively well-explored at this point for certain types of colloquial writing i.e., microblogs and reviews (Ritter et al., 2011; Kong et al., 2014; Ranganath et al., 2016; Shin et al., 2017). However, the genre of multiparty dialogue is still under-explored, even though digital contents in dialogue forms keep increasing at a faster rate than any other types of writing.¹ This inspires us

¹<https://medium.com/hijiffy/10-graphs-that-show-the-immense-power-of-messaging-apps-4a41385b24d6>

to create a new task called character identification that aims to link personal mentions (e.g., *she*, *mom*) to their global entities across multiple dialogues, where the entities indicate the specific characters referred by those mentions (e.g., *Judy*).

Due to the nature of multiparty dialogue where several speakers take turns to complete a context, character identification is a crucial step for adapting higher-end NLP tasks (e.g., summarization, question answering, machine translation) to this genre. It can also bring another level of sophistication to intelligent personal assistants or tutoring systems. This task is challenging because it needs to process through colloquialism that includes slangs, grammar mistakes, and/or rhetorical questions, as well as to handle cross-document resolution for the identification of entities that are mentioned but may not be actively participating during the conversation. Nonetheless, we believe that models produced by this task will remarkably enhance inference on dialogue contexts (e.g., business meetings, doctor-patient conversations) by providing finer-grained information about individual characters.

Section 2 illustrates the task of character identification and explains the key differences between it and other types of entity linking tasks. Section 3 describes the corpus, based on TV show transcripts, used for this task with annotation details. Section 4 gives brief overviews of the systems participated in this shared task. Section 5 explains the evaluation metrics and the results produced by those systems. Finally, Section 6 gives thorough analysis and comparative studies between these systems. This task was originally conducted at CodaLab.² The latest dataset and the system outputs can be found from our open source project, Emory NLP.³

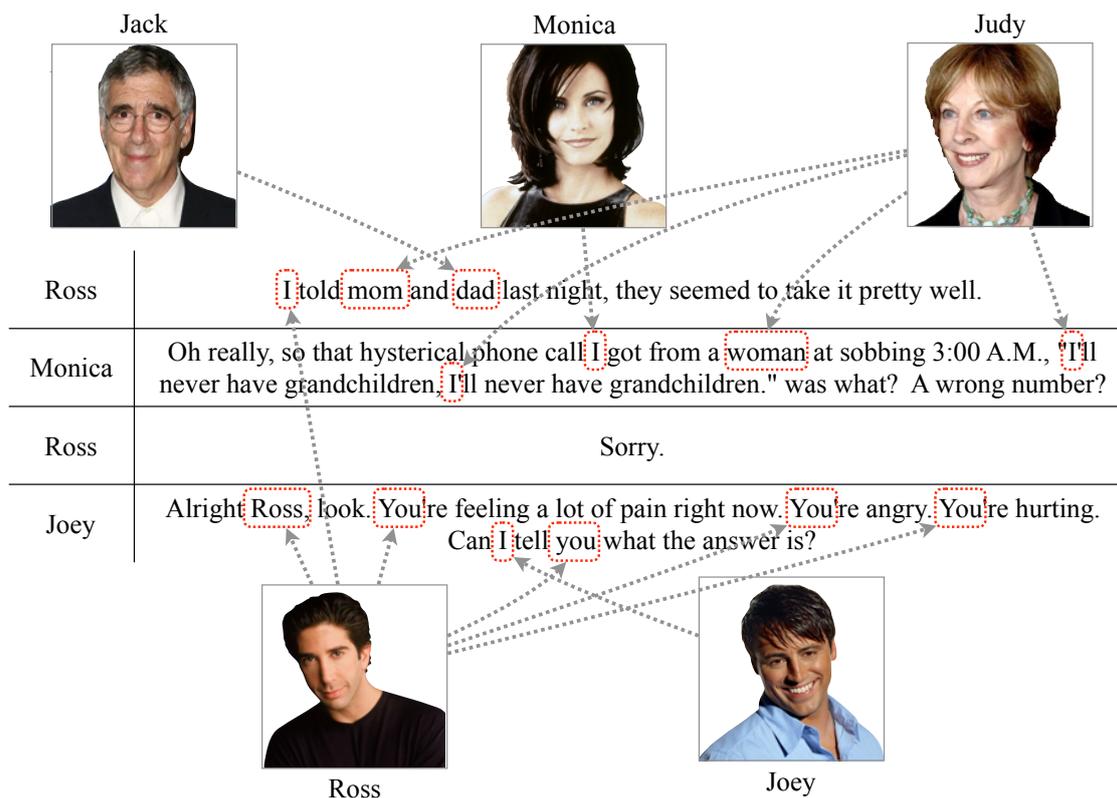

Figure 1: An example of character identification, excerpted from the Season 1 Episode 1 of *Friends*, where mentions are indicated in red boxes and entities are linked by arrows.

2 Task Description

Let a mention be a nominal that refers to a singular or a collective entity (e.g., *she*, *mom*, *Judy*), and an entity be the actual person that the mention refers to. Given a dialogue transcribed in text where all mentions are detected, the objective is to find the entity for each mention, who can be either active or passive in the dialogue. In Figure 1, entities such as *Ross*, *Monica*, and *Joey* are the active speakers of the dialogue, whereas *Jack* and *Judy* are not although they are passively mentioned as *mom* and *dad* in this context. Linking such mentions to their global entities demands inferred knowledge about the kinship from other dialogues, challenging cross-document resolution. Thus, character identification can be viewed as an entity linking task that aims for holistic understanding in multiparty dialogue.

Most of previous works on entity linking have focused on Wikification, which links named entity mentions to their relevant Wikipedia articles (Mihalcea and Csomai, 2007; Ratinov et al., 2011; Guo et al., 2013). Unlike Wikification where most entities come with structured information from knowledge bases (e.g., Infobox, Freebase, DBpedia), entities in character identification have no such precom-

puted information, which makes this task even more challenging. It is similar to coreference resolution in a sense that it groups mentions into entities, but distinguished because this task requires to identify each mention group as a known person. In Figure 1, coreference resolution would give a cluster of the four mentions, {*mom*, *woman*, *I*, *I*}; however, it would not identify that cluster to be the entity *Judy*, which in this case is not possible to identify without getting contexts from other dialogues.

3 Corpus

The character identification corpus was first created by collecting transcripts from the popular TV show, *Friends* (Chen and Choi, 2016). These transcripts were voluntarily provided by fans who made them publicly available.⁴ Dialogues in this corpus mimic daily conversations that are more natural and various in topics than other dialogue corpora (Janin et al., 2003; Danescu-Niculescu-Mizil and Lee, 2011; Hu et al., 2013; Kim et al., 2015; Lowe et al., 2015). Although they are scripted, the interpretation of these dialogues is no easier than unscripted

⁴<http://www.livesinabox.com/friends/scripts.shtml>

	Episodes	Scenes	Speakers	Utterances	Sentences	Tokens
Season 1	24	229	105	4,725	8,680	66,355
Season 2	23	219	101	4,501	7,380	65,675
Total	47	448	171	9,226	16,060	132,030

Table 1: Distributions from the subset of the character identification corpus used for this shared task.

dialogues; they not only involve as much disfluency and context switching as real dialogues do, but also include more humor, sarcasm, or metaphor. Thus, models evaluated on this corpus should give a general sense about the state of character identification on multiparty dialogue.

The original transcripts collected from the fan site were formatted in HTML; we converted them into JSON so that they could be easily processed. This structured data were then manually checked for potential errors. Table 1 shows the distributions from the subset of the character identification corpus used for this shared task. The provided dataset is divided into two seasons, each season is divided into episodes, each episode is divided into scenes, each scene contains utterances, where each utterance indicates a turn of speech.

3.1 Mention Annotation

For mention annotation, a heuristic-based mention detector was developed, which utilized dependency relations (Choi and McCallum, 2013), named entity tags (Choi, 2016), and personal noun gazetteers, then automatically detected mentions for the entire corpus. In this heuristic, a noun phrase was considered a personal mention if it was either:

1. A PERSON named entity, or
2. A pronoun or a possessive pronoun excluding the pronouns *it* and *they*, or
3. One of the personal noun gazetteers that are 603 common and singular personal nouns selected from Freebase and DBPedia.

Specific mentions such as *it* and *they* were excluded because they often referred to the ambiguous entity types, *collective*, *general*, and *other* (Section 3.2). For the quality assurance, about 10% of this pseudo annotation were randomly sampled and manually evaluated, showing a precision, a recall, and the F1-score of 97.58%, 94.34%, and 95.93%, respectively. Finally, the annotation was manually checked again while it was systematically corrected for routinely produced errors. Although mention detection was

the foundational step, including it as a part of this shared task could over-complicate the evaluation. Thus, gold mentions were provided for this year’s shared task such that participants could purely concentrate on the task of entity linking.

3.2 Entity Annotation

All mentions were double-annotated with their referent entities, and adjudicated upon disagreements. Annotation and adjudication tasks were conducted on Amazon Mechanical Turk. Each mention was annotated with either a primary character, that are *Ross*, *Chandler*, *Joey*, *Rachel*, *Monica*, and *Pheobe*, a secondary character (other frequently recurring characters across the show), or one of the following ambiguous types suggested by Chen et al. (2017):

- *Generic*: indicates actual characters in the show whose identities are unknown (e.g., That *waitress* is really cute, I am going to ask *her* out). Generic entities are annotated with their group names and optional numberings (e.g., Man 1, Woman 1).
- *Collective*: indicates the plural use of the pronoun *you*, which cannot be deterministically distinguished from the singular use.
- *General*: indicates mentions used in reference to a general case rather than an specific entity (e.g., The ideal *guy* you look for doesn’t exist).
- *Other*: indicates all the other kinds of entities.

For this year’s shared task, mentions annotated with the last three ambiguous types, *collective*, *general*, and *other*, were excluded from the dataset to reduce the high complexity of this task (Table 2).

	Primary	Secondary	Generic	Total
Season 1	5,160	2,526	178	7,864
Season 2	5,385	2,340	120	7,845
Total	10,545	4,866	298	15,709

Table 2: Distributions of the annotated entity types used for this shared task.

Speaker	Utterance
Joey	Yeah, right! ... <i>You</i> ₁ serious?
Rachel	Everything <i>you</i> ₂ need to know is in that first kiss.
Chandler	Yeah. For <i>us</i> ₃ , it's like the stand-up <i>comedian</i> ₄ <i>you</i> ₅ have to sit through before the main <i>dude</i> ₆ starts.
Ross	It's not that <i>we</i> ₇ don't like the <i>comedian</i> ₈ , it's that ... that's not why <i>we</i> ₉ bought the ticket.

{*You*₁} → *Rachel*, {*us*₃, *we*_{7,9}} → *Collective*, {*you*_{2,5}} → *General*, {*comedian*_{4,8}} → *Generic*, {*dude*₆} → *Other*

Table 3: Examples of the entity annotation described in Section 3.2.

	Episodes	Scenes	Entities	Mentions	Clusters _E	Clusters _S	Singleton _E	Singleton _S
Training	47	374	372	13,280	893	2,051	209	472
Evaluation	7	74	106	2,429	304	370	54	83
Total	47	448	401	15,709	1,197	2,421	263	555

Table 4: Distributions of the training and the evaluation sets in Section 3.3.

Table 3 shows examples of these ambiguous types. About 83% were assigned to the primary and secondary characters, 1.4% were assigned to *generic*, and the rest were assigned to the other ambiguous types, *collective*, *general*, and *other*. To evaluate the annotation quality, the annotation agreement scores as well as Cohen’s kappa scores were measured, showing 82.83% and 79.96%, respectively.

3.3 Data Split

The corpus was split into training and evaluation sets for this shared task (Table 4). No dedicated development set was provided; participants were encouraged to use sub-parts of the training set to create their own development sets or perform cross-validation for the optimization of statistical models. Two types of datasets are provided for both training and evaluation sets, one treating each episode as an individual dialogue and the other treating each scene as an independent dialogue.⁵

Processing a larger dialogue makes coreference resolution harder because it needs to link referential mentions that are farther apart; on the other hand, each cluster comprises a greater number of mentions which can help identifying the global entity of that cluster. The numbers of clusters grouped in each dataset are shown as Clusters_E and Clusters_S, implying episode-level and scene-level clusters, respectively. Our corpus includes singleton mentions, which take about 22% of all mentions.

3.4 Data Format

To help participants adapting their existing coreference resolution systems to this task, the original dataset in JSON was converted into the CoNLL’12

shared task format (Pradhan et al., 2012), where each column is delimited by white spaces and represents the following:

1. Season and episode ID.
2. Document ID.
3. Token ID.
4. Word form.
5. Part-of-speech tag (auto-generated).
6. Phrase structure tag (auto-generated).
7. Lemma (auto-generated).
8. Predicate sense (not provided).
9. Word sense (not provided).
10. Speaker.
11. Named entity tag (auto-generated).
12. Entity ID.

The part-of-speech tags, lemmas, and named entity tags were automatically generated by NLP4J,⁶ and the phrase structure tags were produced by the Stanford parser.⁷ Table 5 shows the example of the first utterance in Figure 1 in the CoNLL’12 format.

4 System Description

This section describes the top-2 scoring systems of this shared task. The AMORE-UPF is a group of researchers from the Universitat Pompeu Fabra in Spain (Section 4.1). The KNU CI is a group of researchers from Kangwon National University in South Korea (Section 4.2).

Table 5: Example of the first utterance in Figure 1 annotated in the CoNLL’12 format.

4.1 AMORE-UPF System

The AMORE-UPF system approaches this task as a multi-class classification. It uses a bidirectional Long Short-Term Memory (LSTM) that processes the input dialogue and resolves mentions, by means of a comparison between the LSTM’s hidden state, for each mention, to vectors in an entity library. In this model, learned representations of each entity are stored in the entity library, that is a matrix where each row represents an entity and whose values are learned during training (Figure 2).

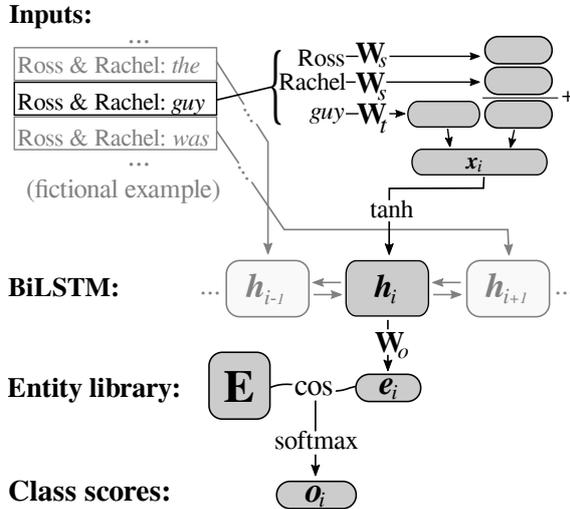

Figure 2: The overview of AMORE-UPF system.

4.2 KNU-CI System

The KNU-CI system tackles this task as a sequence-labeling problem. It uses an attention-based recurrent neural network (RNN) encoder-decoder model. The input dialogue of character identification consists of several conversations, resulting a long sequence of text. The RNN encoder-decoder model

suffers from poor performance when the length of the input sequence is long. To overcome this issue, this system applies an attention, position encoding, and the self-matching network to the original RNN encoder-decoder model. As a result, the best performance is achieved by the attention-based RNN depicted in Figure 3.

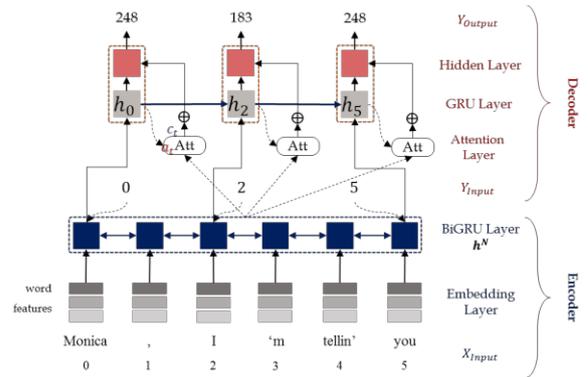

Figure 3: The overview of KNU-CI system.

5 Evaluation

Following Chen et al. (2017), the labeling accuracy (Acc) and the macro-average F1 score (F1) are used for the evaluation (C : the total number of characters, $F1_i$: the F1-score for the i 'th character):

$$Acc = \frac{\# \text{ of corrected identified mentions}}{\# \text{ of all mentions}}$$

$$F1 = \frac{1}{C} \sum_{i=1}^C F1_i$$

Table 6 shows the overall scores from all submitted systems. Two types of evaluation are performed for this task. The first one is based on seven characters where six of them compose the primary characters

(Section 3.2) and every other character is grouped as one entity called `Others` (`Main + Others`). The other is based on 78 characters comprising all characters appeared in the dataset, except for the ones appear either in the training or the evaluation set but not both, which is grouped to the `Others` (`ALL`).

System	Main + Others		ALL	
	Acc	F1	Acc	F1
AMORE-UPF	77.23	79.36	74.72	41.05
KNU-CI	85.10	86.00	69.49	16.98
Kampfpudding	73.36	73.51	59.45	37.37
Zuma-AR	46.85	44.68	33.06	16.09

Table 6: Overall scores from the submitted systems.

Table 7 shows the F1 scores for the primary characters and `Others`, illustrating detailed evaluation for `Main + Others`. Table 8 gives detailed evaluation for `ALL`, showing the F1-scores for the top-12 most frequently appeared secondary characters and `Others` that appear only in the training or the evaluation set but not both. The 18 characters in these two tables comprise about 85% of all mentions.

6 Analysis

Based on the evaluation results, several interesting observations can be made for how different system architectures affect model performance on this task. The analysis in this section primarily focuses on the top-2 scoring systems, AMORE-UPF and KNU-CI, as their results vastly outperform the other two and the authors of those systems provide more detailed descriptions to the organizers.

6.1 Overall Performance

It is worth pointing out the significance of the two evaluation metrics proposed in Section 5 in terms of the model performance. The labeling accuracy indicates the raw predicative power of the model. This metric is biased towards more frequently appearing characters such as the primary characters, a total of which compose 70+% of the evaluation set. Thus, it is possible to achieve a relatively high labeling accuracy score without handling referents for the secondary characters well. On the contrary, the macro-average F1 score neutralizes the imbalance between frequently and not so frequently appearing characters. It reveals the model performance on a per-entity basis, which tends to favor transient and extra characters more because every character is treated equally in this metric.

For the overall performance, KNU-CI outperforms for `Main + Others` with the labeling accuracy of 85.10% and the macro-average F1 score of 86.00%, whereas AMORE-UPF outperforms for `ALL` with the labeling accuracy of 74.72% and the macro-average F1 of 41.05% (Table 6). All systems produce better results for `Main + Others` than `ALL`, which is expected due to the fewer number of entities to classify (7 vs 78). It is possible that KNU-CI’s attention model is highly optimized for the identification of the primary characters, whereas AMORE-UPF’s LSTM model distributes weights for the secondary characters more evenly, but more detailed analysis needs to be made to see the comparative strengths between these two systems.

6.2 Main + Other Identification

Table 7 depicts the strength of the KNU-CI system for the primary characters in comparisons to the others, which is attributed to its unique sequence labeling architecture and the attention mechanism. Their encoder-decoder architecture helps consolidating sequential information of the input dialogue along with the mentions. The hidden units in RNNs enable the network to aggregate character-related information and to disambiguate timeline shifts across utterances. The encoder takes the input dialogue and provides the decoder with context-rich features. Coupled with the attention mechanism, this model focuses on the primary characters; thus, it results better performance on `Main + Others`. However, this architecture is not as well-adaptive as the number of characters increases for the identification, which can be observed from the system’s low macro-average F1 score for `All`.

6.3 All Character Identification

Table 8 describes the strength of the AMORE-UPF system for the secondary characters using the bidirectional LSTM model, leading it to outperform all the others for `All`. Although both AMORE-UPF and KNU-CI utilize variations of RNNs as their underlying architectures, the performance downfall is not as prominent for AMORE-UPF as the number of characters increases, thanks to its entity library. The entity library is consumed and updated as necessary given the mention embeddings. It is used to regularize training each individual character, which helps avoiding the bias towards frequently appearing characters. As the result, AMORE-UPF yields better performance for `All` while accomplishing reasonable results for `Main + Others` as well.

Character	Ross	Rachel	Chandler	Joey	Phoebe	Monica	Others
Evaluation	18.98	13.96	9.80	9.51	9.02	8.97	29.77
Training	13.93	12.37	11.43	9.43	8.79	10.61	33.44

7 Conclusion

In this shared task, we propose a novel entity linking task called character identification that aims to find the global entities for all personal mentions, representing individual characters in the contexts of multiparty dialogue. Among 90+ participants signed up for this task at CodaLab, only four submitted their system outputs, which is unfortunate. However, the top-2 scoring systems depict unique strengths, allowing us to make a good analysis for this task. It would be interesting to see if the sequence labeling architecture from KNU-CI coupled with the entity library from AMORE-UPF could produce an even higher performing model for both the **Main + Other** and **All** evaluation.

To facilitate the momentum, we create an open-source project that will continuously support this task.⁸ It is worth mentioning that *Character Identification* is a part of a bigger project called *Character Mining* that strives for machine comprehension on dialog.⁹ Currently, this project provides more and cleaner annotation for character identification than the corpus described in Section 3, hoping to engage more researchers to this task.

Abstract

This paper describes our winning contribution to SemEval 2018 Task 4: *Character Identification on Multiparty Dialogues*. It is a simple, standard model with one key innovation, an *entity library*. Our results show that this innovation greatly facilitates the identification of infrequent characters. Because of the generic nature of our model, this finding is potentially relevant to any task that requires effective learning from sparse or unbalanced data.

1 Introduction

SemEval 2018 Task 4 is an **entity linking** task on multiparty dialogue.¹ It consists in predicting the referents of nominals that refer to a person, such as *she*, *mom*, *Judy* – henceforth *mentions*. The set of possible referents is given beforehand, as well as the set of mentions to resolve. The dataset used in this task is based on Chen and Choi (2016) and Chen et al. (2017), and consists of dialogue from the TV show *Friends* in textual form.

Our main interest is whether deep learning models for tasks like entity linking can benefit from having an explicit **entity library**, i.e., a component of the neural network that stores entity representations learned during training. To that end, we add such a component to an otherwise relatively basic model – a bidirectional LSTM (long short-term memory; Hochreiter and Schmidhuber 1997), the standard neural network model for sequential data like language. Training and evaluating this

model on the task shows that the entity library is beneficial in the case of infrequent entities.²

2 Related Work

Previous entity linking tasks concentrate on linking mentions to Wikipedia pages (Bunescu and Paşca 2006; Mihalcea and Csomai 2007 and much subsequent work; for a recent approach see Francis-Landau et al. 2016). By contrast, in the present task (based on Chen and Choi 2016; Chen et al. 2017) only a list of entities is given, without any associated encyclopedic entries. This makes the task more similar to the way in which a human audience might watch the TV show, in that they are initially unfamiliar with the characters. What also sets the present task apart from most previous tasks is its focus on multiparty dialogue (as opposed to, typically, newswire articles).

A task that is closely related to entity linking is *coreference resolution*, i.e., the task of clustering mentions that refer to the same entity (e.g., the CoNLL shared task of Pradhan et al. 2011). Since mention clusters essentially correspond to entities (an insight central to the approaches to coreference in Haghghi and Klein 2010; Clark and Manning 2016), the present task can be regarded as a type of coreference resolution, but one where the set of referents to choose from is given beforehand.

Since our main aim is to test the benefits of having an entity library, in other respects our model is kept more basic than existing work both on entity linking and on coreference reso-

*denotes equal contribution.

²Source code for our model and for the training procedure is published on <https://github.com/amore-upf/semEval2018-task4>.

lution (e.g., the aforementioned approaches, as well as Wiseman et al. 2016; Lee et al. 2017, Francis-Landau et al. 2016). For instance, we avoid feature engineering, focusing instead on the model’s ability to learn meaningful entity representations from the dialogue itself. Moreover, we deviate from the common strategy to entity linking of incorporating a specialized coreference resolution module (e.g., Chen et al. 2017).

3 Model Description

We approach the task of character identification as one of multi-class classification. Our model is depicted in Figure 1, with inputs in the top left and outputs at the bottom. In a nutshell, our model is a bidirectional LSTM (long short-term memory, Hochreiter and Schmidhuber 1997) that processes the dialogue text and resolves mentions, through a comparison between the LSTM’s hidden state (for each mention) to vectors in a learned entity library.

The model is given chunks of dialogue, which it processes token by token. The i^{th} token \mathbf{t}_i and its speakers S_i (typically a singleton set) are represented as one-hot vectors, embedded via two distinct embedding matrices (\mathbf{W}_t and \mathbf{W}_s , respectively) and finally concatenated to form a vector \mathbf{x}_i (Eq. 1; see also Figure 1). In case S_i contains multiple speakers, their embeddings are summed.

$$\mathbf{x}_i = \mathbf{W}_t \mathbf{t}_i \parallel \sum_{s \in S_i} \mathbf{W}_s \mathbf{s} \quad (1)$$

We apply an activation function f ($= \tanh$). The hidden state $\vec{\mathbf{h}}_i$ of a *unidirectional* LSTM for the i^{th} input is recursively defined as a combination of that input with the LSTM’s previous hidden state $\vec{\mathbf{h}}_{i-1}$. For a *bidirectional* LSTM, the hidden state \mathbf{h}_i is a concatenation of the hidden states $\vec{\mathbf{h}}_i$ and $\overleftarrow{\mathbf{h}}_i$ of two unidirectional LSTMs which process the data in opposite directions (Eq. 2; see also Figure 1). In principle, this enables a bidirectional LSTM to represent the entire dialogue with a focus on the current input, including for instance its relevant dependencies on the context.

$$\mathbf{h}_i = \text{BiLSTM}(f(\mathbf{x}_i), \vec{\mathbf{h}}_{i-1}, \overleftarrow{\mathbf{h}}_{i+1}) \quad (2)$$

In the model, learned representations of each entity are stored in the *entity library* $\mathbf{E} \in \mathbb{R}^{N \times k}$ (see Figure 1): \mathbf{E} is a matrix which represents each of N entities through a k -dimensional vector, and whose values are updated (only) during training.

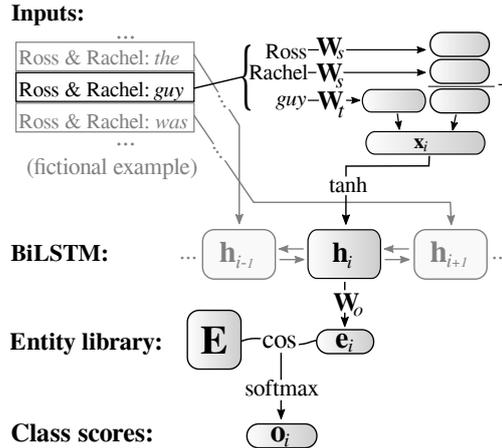

Figure 1: The AMORE-UPF model (bias not depicted).

For every token \mathbf{t}_i that is tagged as a mention,³ we map the corresponding hidden state \mathbf{h}_i to a vector $\mathbf{e}_i \in \mathbb{R}^{1 \times k}$. This extracted representation is used to retrieve the (candidate) referent of the mention from the entity library: The similarity of \mathbf{e}_i to each entity representation stored in \mathbf{E} is computed using cosine, and softmax is then applied to the resulting similarity profile to obtain a probability distribution $\mathbf{o}_i \in [0, 1]^{1 \times N}$ over entities (‘class scores’ in Figure 1):

$$\mathbf{o}_i = \text{softmax}(\text{cosine}(\mathbf{E}, \underbrace{(\mathbf{W}_o \mathbf{h}_i + \mathbf{b})}_{\mathbf{e}_i})) \quad (3)$$

At testing time, the model’s prediction \hat{c}_i for the i^{th} token is the entity with highest probability:

$$\hat{c}_i = \text{argmax}(\mathbf{o}_i) \quad (4)$$

We train the model with backpropagation, using negative log-likelihood as loss function. Besides the BiLSTM parameters, we optimize \mathbf{W}_t , \mathbf{W}_s , \mathbf{W}_o , \mathbf{E} and \mathbf{b} . We refer to this model as **AMORE-UPF**, our team name in the SemEval competition. Note that, in order for this architecture to be successful, \mathbf{e}_i needs to be as similar as possible to the entity vector of the entity to which mention t_i refers. Indeed, the mapping \mathbf{W}_o should effectively specialize in “extracting” entity representations from the hidden state because of the way its output \mathbf{e}_i is used in the model—to do entity retrieval. Our entity retrieval mechanism is inspired by the attention mechanism of Bahdanau et al. (2016), that has been used in previous work to interact with an external memory (Sukhbaatar et al., 2015; Boleda et al., 2017).

³For multi-word mentions this is done only for the last token in the mention.

JOEY TRIBBIANI (183): "... see <u>Ross</u> , because <u>I</u> think you love <u>her</u> ." 335 183 335 306

Figure 2: Example of the data provided for the SemEval 2018 Task 4. It shows the speaker (first line) of the utterance (second line) and the ids of the entities to which the target mentions (underlined) refer (last line).

To assess the contribution of the entity library, we compare our model to a similar architecture which does not include it (**NoEntLib**). This model directly applies softmax to a linear mapping of the hidden state (Eq. 5, replacing Eq. 3 above).

$$\mathbf{o}_i = \text{softmax}(\mathbf{W}_o \mathbf{h}_i + \mathbf{b}) \quad (5)$$

4 Experimental Setup

Data We use the training and test data provided for SemEval 2018 Task 4, which span the first two seasons of the TV show *Friends*, divided into scenes (train: 374 scenes from 47 episodes; test: 74 scenes from 40 episodes).⁴ In total, the training and test data contain 13,280 and 2,429 nominal mentions (e.g., *Ross*, *I*; Figure 2), respectively, which are annotated with the ID of the entity to which they refer (e.g., 335, 183). The utterances are further annotated with the name of the speaker (e.g., JOEY TRIBBIANI). Overall there are 372 entities in the training data (test data: 106). Our models do not use any of the provided automatic linguistic annotations, such as PoS or named entity tags.

We additionally used the publicly available 300-dimensional word vectors that were pre-trained on a Google News corpus with the word2vec Skip-gram model (Mikolov et al., 2013).⁵

Parameter settings Using 5-fold cross-validation on the training data, we performed a random search over the hyperparameters and chose those which yielded the best mean F1-score. Specifically, our submitted model is trained in batch mode using the Adam optimizer (Kingma and Ba, 2014) with a learning rate of 0.0005. Each batch covers 24 scenes, which are given to the model in chunks of 757 tokens. The token embeddings (\mathbf{W}_t) are initialized with the word2vec vectors. Dropout rates of 0.008 and 0.0013 are applied on the input \mathbf{x}_i and hidden layer \mathbf{h}_i of the LSTM, respectively. The size of \mathbf{h}_i is set to

⁴The organizers also provided data divided by episodes rather than scenes, which we didn’t use.

⁵The word vectors are available at <https://code.google.com/archive/p/word2vec/>.

Models	all entities		main entities	
	F ₁	Acc	F ₁	Acc
AMORE-UPF	41.1**	74.7**	79.4	77.2
NoEntLib	26.4	71.6	79.5	77.5

Table 1: Results obtained for the submitted AMORE-UPF model and a variant of it that does not use an entity library (NoEntLib). Best results are in boldface. Differences with respect to the 2nd row marked by ‘**’ are significant at the 0.001 probability level (see text).

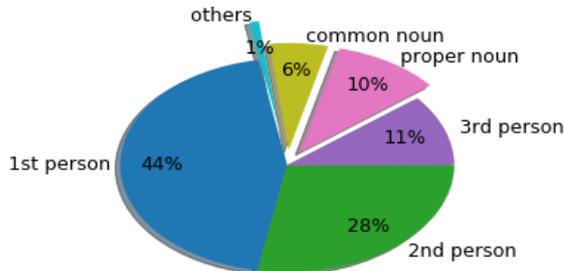

Figure 3: Distribution of all 2,429 target mentions in the test data in terms of their part-of-speech.

459 units, the embeddings of the entity library \mathbf{E} and speakers \mathbf{W}_s are set to $k = 134$ dimensions.

Other configurations, including randomly initialized token embeddings, weight sharing between \mathbf{E} and \mathbf{W}_s , self-attention (Bahdanau et al., 2016) on the input layer, a uni-directional LSTM, and rectifier or linear activation function f on the input embeddings did not improve performance.

For the final submission of the answers for the test data, we created an ensemble model by averaging the output (Eq. 3) of the five models trained on the different folds.

5 Results

Two evaluation conditions were defined by the organizers – *all entities* and *main entities* – with macro-average F₁-score and label accuracy as the official metrics, and macro-average F₁-score in the *all entities* condition applied to the leaderboard. The *all entities* evaluation has 67 classes: 66 for entities that are mentioned at least 3 times in the test set and one grouping all others. The *main entities* evaluation has 7 classes, 6 for the main characters and one for all the others. Among all four participating systems in this SemEval task our model achieved the highest score on the *all entities* evaluation, and second-highest on the *main entities* evaluation.

Table 1 gives our results in the two evaluations, comparing the models described in Section 4. While both models perform on a par on main

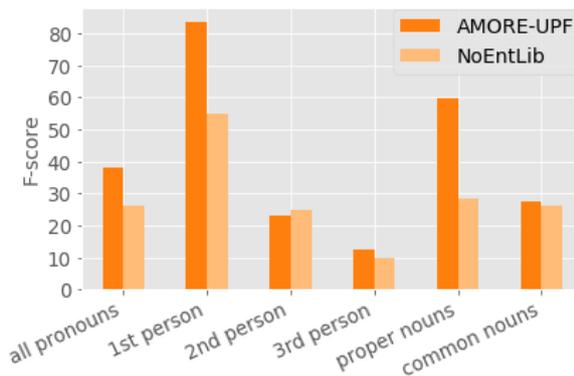

Figure 4: F₁-score of the models on *all entities* depending on the part-of-speech of the target mentions.

entities, AMORE-UPF outperforms NoEntLib by a substantial margin when all characters are to be predicted (+15 points in F₁-score, +3 points in accuracy; Table 1).⁶ The difference between the models with/without an entity library are statistically significant based on approximate randomization tests (Noreen, 1989), with the significance level $p < 0.001$. This shows that the use of an entity library can be beneficial for the linking of rarely mentioned characters.

Figure 3 shows that most of the target mentions in the test data fall into one of five grammatical categories. The dataset contains mostly pronouns (83%), with a very high percentage of first person pronouns (44%). Figures 4 and 5 present the accuracy and F₁-score which the two models described above obtain on *all entities* for different categories of mentions. The entity library is beneficial when the mention is a first person pronoun or a proper noun (with an increase of 30 points in F₁-score for both categories; Figure 4), and closer inspection revealed that this effect was larger for rare entities.

6 Discussion

The AMORE-UPF model consists of a bidirectional LSTM linked to an entity library. Compared to an LSTM without entity library, NoEntLib, the AMORE-UPF model performs particularly well on rare entities, which explains its top score in the *all entities* condition of SemEval 2018 Task 4. This finding is encouraging, since rare entities are especially challenging for the usual approaches in NLP, due to the scarcity of information about them.

We offer the following explanation for this beneficial effect of the entity library, as a hypothesis for

⁶The mean difference between the single models (trained on a single fold) and the ensemble AMORE-UPF is between -1.3 points (accuracy main entities, std = 1.3) and -4.2 points (F₁-score all entities, std = 1.3).

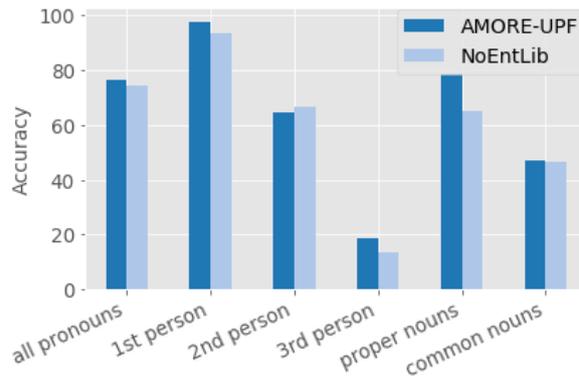

Figure 5: Accuracy of the models on *all entities* depending on the part-of-speech of the target mentions.

future work. Having an entity library requires the LSTM of our model to output some representation of the mentioned entity, as opposed to outputting class scores more or less directly as in the variant NoEntLib. Outputting a meaningful entity representation is particularly easy in the case of first person pronouns and nominal mentions (where the effect of the entity library appears to reside; Figure 4): the LSTM can learn to simply forward the speaker embedding unchanged in the case of pronoun *I*, and the token embedding in the case of nominal mentions. This strategy does not discriminate between frequent and rare entities; it works for both alike. We leave further analyses required to test this potential explanation for future work.

Future work may also reveal to what extent the induced entity representations may be useful in others, to what extent they encode entities' attributes and relations (cf. Gupta et al. 2015), and to what extent a module like our entity library can be employed elsewhere, in natural language processing and beyond.

SemEval-2018 Task 5: Counting Events and Participants in the Long Tail

Marten Postma, Filip Ilievski, Piek Vossen

Vrije Universiteit Amsterdam

The Netherlands

{m.c.postma, f.ilievski, piek.vossen}@vu.nl

Abstract

This paper discusses SemEval-2018 Task 5: a referential quantification task of counting events and participants in local, long-tail news documents with high ambiguity. The complexity of this task challenges systems to establish the meaning, reference and identity across documents. The task consists of three subtasks and spans across three domains. We detail the design of this referential quantification task, describe the participating systems, and present additional analysis to gain deeper insight into their performance.

1 Introduction

We present a “referential quantification” task that requires systems to establish the meaning, reference and identity of events¹ and participants in news articles. By “referential quantification”, we mean questions concerning the number of incidents of an event type (e.g. *How many killing incidents happened in 2016 in Columbus, MS?*) or participants in roles (e.g. *How many people were killed in 2016 in Columbus, MS?*), as opposed to factoid questions for specific properties of individual events and entities (e.g. *When was 2pac murdered?*). The questions are given with certain constraints on the location, time, participants, and event types, which requires understanding of the meaning of words mentioning these properties (e.g. Word Sense Disambiguation), but also adequately establishing the identity (e.g. reference and coreference) across mentions. The task thus represents both an intrinsic and application-based evaluation, as systems are forced to resolve ambiguity of meaning and reference, as well as variation in reference in order to answer the questions.

¹By event, we denote a specific instance of an event, e.g. a killing incident happening at a specific location, time, and involving certain participants.

Figure 1 shows an overview of our quantification task. We provide the participants with a set of questions and their corresponding news documents.² Systems are asked to distill event- and participant-based knowledge from the documents to answer the question. Systems submit both a numeric answer (3 events in Figure 1), and the corresponding events with their mentions found in the provided texts (e.g., the leftmost incident in Figure 1 is referred to by the coreferring mentions “killed” and “assault” found in two separate documents). Systems are evaluated on both the numeric answers as well as on the sets of coreferring mentions. Mentions are represented by tokens and offsets provided by the organizers.

The incidents and their corresponding news articles are obtained from structured databases, which greatly reduces the need for annotation and mainly requires validation instead. Given this data and using a metric-driven strategy, we created a task that further maximizes ambiguity and variation of the data in relation to the questions. This ambiguity and variation includes a substantial amount of low-frequent, local events and entities, reflecting a large variety of long-tail phenomena. As such, the task is not only highly ambiguous but can also not be tackled by relying on the most frequent and popular (head) interpretations.

We see the following contributions of our task:

1. To the best of our knowledge, we propose the first task that is deliberately designed to address large ambiguity of meaning and reference over a high number of infrequent instances.
2. We introduce a methodology for creating large event-based tasks while avoiding a lot of annotation, since we base the task on structured data. The remaining annotation concerns targeted mentions given the structured data rather than full doc-

²Question parsing is unnecessary, as questions are provided in a structured format.

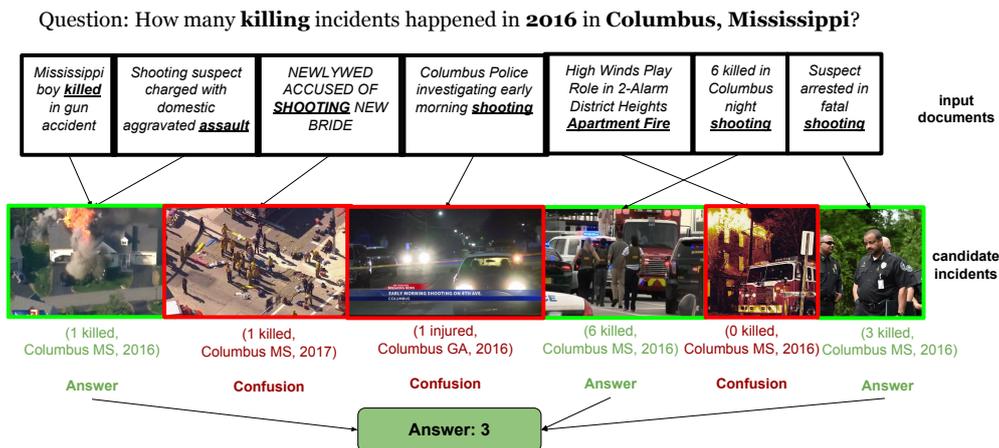

Figure 1: Task overview. Systems are provided with a question and a set of input documents. Their goal is then to find the documents that fit the question constraints and reason over them to provide an answer.

uments with open-ended interpretations.

3. We made all of our code to create the task available,³ which may stimulate others to create more tasks and datasets that tackle long-tail phenomena for other aspects of language processing, either within or outside of the SemEval competition.

4. This task provides insights into the strengths and weaknesses of semantic processing systems with respect to various long-tail phenomena. We expect that systems need to innovate by adjusting (deep) learning techniques to capture the referential complexity and knowledge sparseness, or by explicitly modeling aspects of events and entities to establish identity and reference.

2 Motivation & Target Communities

Expressions can have many different meanings and possibly an infinite number of references. At the same time, variation in language is also large, as we can make reference to the same things in many ways. This makes the tasks of Word Sense Disambiguation, Entity Linking, and Event and Nominal Coreference extremely hard. It also makes it very difficult to create a task that represents the problem at its full scale. Any sample of text will reduce the problem to a small set of meanings and references, but also to meanings that are popular at that time excluding many unpopular ones from the distributional long tail. Given this Zipfian distribution, a task that is challenging with respect to ambiguity, reference, and variation, and that is representative for the long tail as well, needs to fit certain constraints.

³<https://github.com/cttl/LongTailQATask>

Our task directly relates to the following communities in semantic processing: 1. disambiguation and reference; 2. reading comprehension and question answering.

2.1 Disambiguation & Reference

Semantic NLP tasks are often limited in terms of the range of concepts and meanings that are covered. This is a necessary consequence of the annotation effort that is needed to create such tasks. Likewise, in Ilievski et al. (2016), we observed that most well-known datasets for semantic tasks have an extremely low ambiguity and variation. Even in datasets that tried to increase the ambiguity and temporal diversity for the disambiguation and reference tasks, we still measured a notable bias with respect to ambiguity, variance, dominance, and time. Overall, tasks and their datasets show a strong semantic overfitting to the head of the distribution (the most popular part of the world) and are not representative for the diversity of the long tail.

Our task differs from existing ones in that: 1. we deliberately created a task with a high number of event instances per event, many of which with similar properties, leading to high confusability 2. we present an application-based task which requires to perform on a combination of intrinsic tasks such as reference, disambiguation, and spatial-temporal reasoning, that are usually tested separately in existing tasks.

2.2 Reading Comprehension & Question Answering

In several recent tasks, systems are asked to answer entity-based questions, typically by point-

ing to the correct segment or coreference chain in text, or by composing an answer by abstracting over multiple paragraphs/text pieces. These tasks are based on Wikipedia (SQuAD (Rajpurkar et al., 2016), WikiQA (Yang et al., 2015), QASent (Wang et al., 2007), WIKIREADING (Hewlett et al., 2016)) or on annotated individual documents (MARCO (Nguyen et al., 2016), CNN and DailyMail datasets (Hermann et al., 2015)).

Weston et al. (2015) outlined 20 skill sets, such as causality, resolving time and location, and reasoning over world knowledge, that are needed to build an intelligent QA system. These have been partially captured by the datasets MCTest (Richardson et al., 2013) and QuizBowl (Iyyer et al., 2014)), as well as the SemEval task on *Answer Selection in Community Question Answering* (Nakov et al., 2015, 2016).⁴

However, all these datasets avoid representing real-world referential ambiguity to its full extent by mainly asking questions that require knowledge about popular Wikipedia entities and/or text understanding of a single document.⁵ Unlike existing work, our task deliberately addresses the referential ambiguity of the world beyond Wikipedia, by asking questions about long-tail events described in multiple documents. By doing so, we require deep processing of text and establishing identity and reference across single documents.

3 Task Requirements

Our quantification task consists of questions like *How many killing incidents happened in 2016 in Columbus, MS?* on a dataset that maximizes confusability of meaning, reference and identity. To guide the creation of such task, we defined five requirements that apply to the data for a single event type, e.g. *killing* (Postma et al., 2016).

Each event type should contain:

R1 Multiple event instances per event type, e.g. *the killing of Joe Doe* and *the killing of Joe Roe*.

R2 Multiple event mentions per event instance within the same document.

R3 Multiple documents with varying creation times that describe the same event.

R4 Event confusability by combining one or multiple confusion factors:

⁴The 2017 run can be found at <http://alt.qcri.org/semeval2017/task3/>.

⁵e.g. the Quiz Bowl dataset deliberately focuses on domains with much training data and frequent answers, thus avoiding the long tail problem in reference.

a) ambiguity of event mentions, e.g. *John Doe fires a gun*, and *John Doe fires a worker*.

b) variance of event mentions, e.g. *John Doe kills Joe Roe*, and *John Doe murders Joe Roe*.

c) time, e.g. *killing A that happened in January 2013*, and *killing B in October 2016*.

d) participants, e.g. *killing A committed by John Doe*, and *killing B committed by Joe Roe*.

e) location, e.g. *killing A that happened in Columbus, MS*, and *killing B in Houston, TX*.

R5 Representation of non-dominant events and entities, i.e. instances that receive little media coverage. Hence, the entities would not be restricted to celebrities and the events are not widely discussed such as general elections.

4 Data & Resources

In this Section, we present our data sources and an example document. We also discuss considerations of licensing and availability.

4.1 Structured data

The majority of the source texts in this task are sampled from structured databases that contain supportive news sources about gun violence incidents. While these texts already contain enough confusability with respect to the aspects defined in Section 3, we add confusion through leveraging structured data from two other domains: fire incidents and business.

As a direct consequence of using these databases and our exploitation strategy, we are able to satisfy all requirements we set in Section 3. These databases contain many event instances per event type (R1), multiple event mentions in the same document per event instance (R2), cover a wide spread of publishing times per event instance (R3), represent non-dominant events and entities (R5), and contain rich annotation of event properties that allows us to create high confusability (R4, see Section 5.3 for our methodology).

For a large portion of the information in the structured databases, we manually validated that this information could be found in the supportive news sources, and excluded the documents for which this was not the case. For the remaining documents, we performed automatic tests to filter out low-quality entries.

4.1.1 Gun Violence

The gun violence data is collected from the standard reports provided by the *Gun Violence Archive*

(GVA) website.⁶ Each incident contains information about: 1. its **location** 2. its **time** 3. how many people were **killed** 4. how many people were **injured** 5. its **participants**. Participant information includes: (a) the **role**, i.e. victim or suspect (b) the **name** (c) the **age** 6. the **news articles** describing this incident. Table 1 provides a more detailed overview of the information available in the GVA.

Event Property	Granularity	Example value
Location	Address	Central Avenue
	City	Waynesboro
	State	Mississippi
Incident time	Day	14-3-2017
	Month	3-2017
	Year	2017
Participant	First name	John
	Last name	Smith
	Full name	John Smith

Table 1: Overview of the GVA incident properties of location, time, and participant.

To prevent systems from cheating (by using the structured data directly), the set of incidents and news articles is extended with news articles from the Signal-1M Dataset (Corney et al., 2016) and from the Web, that also stem from the gun violence domain, but are not found in the GVA.

4.1.2 Other domains

For the fire incidents domain, we make use of the *FireRescue1* reports,⁷ which describe the following information about 417 incidents: 1. their **location** as a surface form 2. their **reporting time** 3. one **free text summary** describing the incidents. 4. **no** information about **participants**. Based on this information, we manually annotated the incident time and mapped the location to its representation in Wikipedia.

We further carefully selected a small amount of news articles from the business domain from The Signal-1M Dataset. Since these documents were not semantically annotated with respect to event information, we manually annotated this data with the same kind of information as the other databases: incident location, time, and information on the affected participants.

⁶<http://gunviolencearchive.org/reports/>

⁷<https://www.firerescue1.com/incident-reports/>

4.2 Example document

For each document, we provide its **title**, **content (tokenized)**, and **creation time**, e.g.:

Title: *\$70K reward in deadly shooting near N. Philadelphia school*

Content: *A \$70,000 reward is being offered for information in a quadruple shooting near a Roman Catholic school ...*

DCT: *2017-4-5*

4.3 Licensing & Availability

The news documents in our task are published on a very diverse set of (commercial) websites. Due to this diversity, there is no easy mechanism to check their licenses individually. Instead, we overcome potential licensing issues by distributing the data under the Fair Use policy.^{8 9}

During the SemEval-2018 period, but also afterwards, systems can easily test their submissions via our competition on Codalab.¹⁰

5 Task Design

For every incident in the task, we have fine-grained structured data with respect to its event type, location, time, and participants, and unstructured data in the form of the news sources that report on it. In this Section, we explain how we exploited this data in order to create the task. We present our three subtasks and the question template after which we outline the question creation. Finally, we explain how we divided the data into trial and test sets and provide some statistics about the data. For detailed information about the task, e.g. about the question and answer representation, we refer to the CodaLab website of the task.

5.1 Subtasks

The task contains two event-based subtasks and one entity-based subtask.

Subtask 1 (S1): Find the single event that answers the question e.g. *Which killing incident happened in Wilmington, CA in June 2014?* The main challenge is not to determine how many incidents satisfy the question, but to identify the documents that describe the single answer incident.

Subtask 2 (S2): Find all events (if any) that answer the question. This subtask differs from

⁸Fair use policy in USA: <https://goo.gl/hXiEKL>

⁹Fair use policy in EU: <https://goo.gl/s8V5Zs>

¹⁰<https://competitions.codalab.org/competitions/17285>

S1 in that the system now also has to determine the number of answer incidents, which makes this subtask harder. To make it more realistic, we also include questions with zero as an answer.

Subtask 3 (S3): Find all participant-role relations that answer the question e.g. *How many people were killed in Wilmington, CA with the last name Smith?* The goal is to determine the number of entities that satisfy the question. The system not only needs to identify the relevant incidents, but also to reason over the participant roles.

5.2 Question Template

Questions in each subtask consist of an event type and two event properties.

Event type We consider four event types in this task described through their representation in WordNet (Fellbaum, 1998) and FrameNet (F. Baker et al., 1998). Each question is constrained by exactly one event type.

event type	description	meanings
kill	at least one person is killed	wn30:kill.n.02 wn30:kill.v.01 fn17:Killing
injure	at least one person is injured	wn30:injure.v.01 wn30:injured.a.01 fn17:Cause_harm fn17:Experience-_bodily_harm
fire_burning	the event of something burning	wn30:fire.n.01 fn17:Fire_burning
job_firing	terminated employment	wn30:displace.v.03 fn17:Firing

Table 2: Description of the event types. The meanings column lists meanings that best describe the event type. It contains both FrameNet 1.7 frames (prefixed by *fn17*) and WordNet 3.0 synsets (prefixed by *wn30*).

Event properties For each event property in our task (time, location, participants), we distinguish between three levels of granularity (see Table 1). In addition, we make a distinction between the surface form and the meaning of an event property value. For example, the surface form *Wilmington* can denote several meanings: the Wilmington cities in the states of California, North Carolina, and Delaware. When composing questions, for time and location we take the semantic (meaning) level, while for participants we use the surface form of their names. This is because the vast majority of the participants in our task are long tail instances which have no semantic representation

in a structured knowledge base.

5.3 Question Creation

Our question creation strategy consists of three consecutive phases: question composition, generation of answer and confusion sets, and question scoring. These steps are common for both the event-based subtasks (S1 and S2) and the entity-based subtask S3.

1. Question composition We compose questions based on the template described in Section 5.2. This entails: 1. choice of a subtask 2. choice of an event type, e.g. *kill* 3. choice of two event properties (e.g. *time and location*) with their corresponding granularities (e.g. *month and city*) and concrete values (e.g. *June 2014 and Wilmington, CA*). This step generates a vast amount of potential questions (hundreds of thousands) in a data-driven way, i.e. we select the event type and properties per question purely based on the combinations we find in our data. Example questions are:

Which kill event happened in June 2014 in Wilmington, CA? (subtask S1)

How many kill events happened in June 2014 in Wilmington, CA? (subtask S2)

How many people were killed in June 2014 in Wilmington, CA? (subtask S3)

2. Answer and confusion sets generation For each generated question, we define a set of answer and confusion incidents with their corresponding documents. **Answer** incidents are the ones which entirely fit the question parameters, e.g. *all kill incidents that occur in June 2014 and in the city of Wilmington, CA*. **Confusion** incidents fit some, but not all, values of the question parameters, i.e. they differ with respect to an event type or property (e.g. *all fire incidents in June 2014 in Wilmington, CA*; or *all killings in June 2014, but not in Wilmington, CA*; or *all killings in Wilmington, CA, but not in June 2014*).

3. Question scoring The generated questions with their corresponding answers and confusion are next scored with respect to several metrics that measure their complexity. The per-question scores allow us to detect and remove the “easy” ones, and keep those that: 1. have a high number of answer incidents (only applicable to S2 and S3) 2. have a high number of confusion incidents 3. have a high average number of answer and confusion documents, i.e. news sources describing the answer and the confusion incidents correspondingly 4. have a

high temporal spread with respect to the publishing dates reporting on each incident from the answer and confusion incidents 5. have a high ambiguity with respect to the surface forms of an event property value in a granularity level (e.g. we would favor *Wilmington*, since it is a city in at least three US states in our task data).

5.4 Data Partitioning

We divided the overall task data into two partitions: **trial** and **test** data. In practice, we separated these two data partitions by reserving one year of news documents (2017) from our task for the trial data, while using all the other data as test data.

The trial data stems from the gun violence domain, whereas the test data also contains data from the fire incidents and business domain. A subset of the trial and test data has been annotated for event coreference. Table 3 presents the most important statistics of the trial and test data.

	S	#Qs	Avg answer	Avg # answer docs
trial	1	424	1.00	1.68
	2	469	4.22	7.68
	3	585	5.48	5.47
test	1	1032	1.00	1.60
	2	997	3.79	6.64
	3	2456	3.66	3.74

Table 3: General statistics about trial and test data. For each subtask (*S*), we show the number of questions (*#Qs*), the average answer (*Avg answer*), and the average number of answer documents (*Avg # answer docs*).

We made an effort to make the trial data representative for the test data with respect to the main aspects of our task: its referential complexity, high confusability, and long-tail instances. Despite the fact that the trial data contains less questions than the test data, Table 3 shows that it is similar to the test data with respect to the core properties, meaning that the trial data can be used as training data.

6 Evaluation

This Section describes the evaluation criteria in this task and the baselines we compare against.

6.1 Criteria

Evaluation is performed on three levels: incident-level, document-level, and mention-level.

The incident-level evaluation compares the numeric answer provided by the system to the gold

answer for each of the questions. The comparison is done twofold: by exact matching and by Root Mean Square Error (RMSE) for difference scoring. The scores per subtask are then averaged over all questions to compute a single incident-level evaluation score.

The document-level evaluation compares the set of answer documents between the system and the gold standard, resulting in a value for the customary metrics of Precision, Recall, and F1 per question. The scores per subtask are then averaged over all questions to compute a single document-level evaluation score.

The mention-level evaluation is a cross-document event coreference evaluation. Mention-level evaluation is only done for questions with the event types *killing* or *injuring*. We apply the customary metrics to score the event coreference: BCUB (Bagga and Baldwin, 1998), BLANC (Recasens and Hovy, 2011), entity-based CEAF (CEAF_E) and mention-based CEAF (CEAF_M) (Luo, 2005), and MUC (Vilain et al., 1995). The final F1-score is the average of the F1-scores of the individual metrics. The set of mentions to annotate should conform to the schema defined in the task annotation guidelines.¹¹

6.2 Baselines

To stimulate participation in general and to stimulate approaches beyond surface form or majority class strategies, we implemented one baseline to infer incidents per subtask and one baseline for mention annotation.¹²

Incident inference baseline This baseline uses surface forms based on the question components to find the answer documents. We only consider documents that contain the label of the event type or at least one of its WordNet synonyms. The labels of locations and participants are queried directly in the document (e.g. if the location requested is the *US state of Texas*, then we only consider documents that contain the surface form *Texas*, and similarly for participants such as *John*). The temporal constraint is handled differently: we only consider documents whose publishing date falls within the time requested in the question.

For subtask 1, this baseline assumes that all documents that fit the created constraints are referring

¹¹Link to the guidelines: <https://goo.gl/8JpwCE>.

¹²The code of the baselines can be found here: <https://goo.gl/MwSqBj>.

to the same incident. If there is no such document, then the baseline does not answer the question (because S1 always has at least one supporting document). For subtask 2, we assume that none of the documents are coreferential. Hence, if 10 documents match the constraints, we infer that there are also 10 corresponding incidents. No baseline was implemented for subtask 3.

Mention annotation baseline We annotate mentions of events of type *killing* and *injuring*, when these surface forms or their synonyms in WordNet are found as tokens in a document. We assume that all mentions of the same event type within a document are coreferential, whereas all mentions found in different documents are not.

7 Participants

In this Section, we describe the systems that took part in SemEval-2018 task 5. We refer to the individual system papers for further information.

NewsReader (Vossen, 2018) consists of three steps: 1. the event mentions in the input documents are represented as Event-Centric Knowledge Graphs (ECKGs). 2. the ECKGs of all documents are compared to each other to decide which documents refer to the same incident, resulting in an incident-document index. 3. the constraints of each question (its event type, time, participant names, and location) are matched with the stored ECKGs, resulting in a number of incidents and source documents for each question.

NAI-SEA (Liu and Li, 2018) consists of three components: 1. extraction of basic information on time, location, and participants with regular expressions, named entity recognition, and term matching; 2. event classification with an SVM classifier; 3. document similarity by applying a classifier to detect similar documents. In terms of resources, NAI-SEA combines the training data with data on American cities, counties, and states.

Team **FEUP** (Abreu and Oliveira, 2018) developed an experimental system to extract entities from news articles for the sake of Question & Answering. For this main task, the team proposed a supervised learning approach to enable the recognition of two different types of entities: Locations (e.g. *Birmingham*) and Participants (e.g. *John List*). They have also studied the use of distance-based algorithms (using Levenshtein distance and Q-grams) for the detection of documents' closeness based on entities extracted.

Team **ID-DE** (Mirza et al., 2018) created KOI (Knowledge of Incidents), a system that builds a knowledge graph of incidents, given news articles as input. The required steps include: 1. Document preprocessing using various semantic NLP tasks such as Word Sense Disambiguation, Named-Entity Recognition, Temporal expression recognition, and Semantic Role Labeling. 2. Incident extraction and document clustering based on the output of step 1. 3. Ontology construction to capture the knowledge model from incidents and documents which makes it possible to run SPARQL queries on the ontology to answer the questions.

8 Results

R	Team	s2_inc_acc norm	s2_inc_acc (% of Qs answered)	s2_inc_rmse
1	FEUP	26.38	26.38 (100.0%)	6.13
2	*NewsReader	21.87	21.87 (100.0%)	43.96
3	Baseline	18.25	18.25 (100.0%)	8.50
4	NAI-SEA	17.35	17.35 (100.0%)	20.59
5	ID-DE	13.74	20.36 (67.5%)	6.15

Table 4: For subtask 2, we report the normalized incident-level accuracy (*s2_inc_acc norm*), the accuracy on the answered questions only (*s2_inc_acc*), and the RMSE value (*s2_inc_rmse*). Systems are ordered by their rank (R).

R	Team	s3_inc_acc norm	s3_inc_acc (% of Qs answered)	s3_inc_rmse
1	FEUP	30.42	30.42 (100.0%)	478.71
2	*NewsReader	21.05	21.05 (100.0%)	296.45
3	NAI-SEA	20.20	20.2 (100.0%)	13.45
4	ID-DE	12.87	19.32 (66.61%)	7.87

Table 5: For subtask 3, we report the normalized incident-level accuracy (*s3_inc_acc norm*), the accuracy on the answered questions only (*s3_inc_acc*), and the RMSE value (*s3_inc_rmse*). Systems are ordered by their rank (R).

Before we report the system results, we introduce a few clarifications regarding the result tables:

1. For the incident- and document-level evaluation, we report both the performance with respect to the subset of questions answered and a **normalized score**, which indicates the performance on all questions of a subtask. If a submission provides answers for all questions, the normalized score will be the same as the non-normalized score.
2. Contrary to the other metrics, a lower **RMSE** value indicates better system performance. In addition, the RMSE scores have not been normalized since it is not reasonable to set a default value for non-answered questions.

3. **The mention-level evaluation** was the same across all three subtasks. For this reason, results are only reported once (see Section 8.3).

4. The teams whose member **co-organized SemEval-2018 task 5** are marked explicitly with an asterisk in the results.

8.1 Incident-level evaluation

The incident-level evaluation assesses whether the system provided the right numeric answer to a question. The results of this evaluation are given in the Tables 4 and 5, for the subtasks 2 and 3 correspondingly.¹³ On both subtasks, the order of the participating systems is identical, team *FEUP* having the highest score.

These tables also show the RMSE values, which measure the proximity between the system and the gold answer, punishing cases where the absolute difference between them is large. While for subtask 2 the system with the lowest error rate corresponds to the system with the highest accuracy, this is different for subtask 3. *NAI-SEA*, ranked third in terms of accuracy, has the lowest RMSE. This means that although their answers were not exactly correct, they were on average much closer to the correct answer than those of the other systems. This is more notable in subtask 3 since here the range of answers is larger than in subtask 2 (the maximum answer in subtask 3 is 171).

We performed additional analysis to compare the performance of systems per subtype and per numeric answer class. Table 6 shows that the system *FEUP* is not only superior in terms of incident-level accuracy overall, but this is also mirrored for most of the event types, especially those corresponding to the gun violence domain. On the other hand, Figure 2 shows the accuracy distribution of each system per answer class. Notably, for most systems the accuracy is highest for the questions with answer 0 or 1, and gradually declines for higher answers, forming a Zipfian-like distribution. The exception here is the team *ID-DE*, whose accuracy is almost uniformly spread across the various answer classes.

8.2 Document-level evaluation

The intent behind document-level evaluation is to assess the ability of systems to distinguish between answer and non-answer documents. The tables 9, 10, and 11 present the F1-scores for the

¹³Incident-level evaluation was not performed for subtask 1, because per definition, its answer is always 1.

subtasks 1, 2, and 3, respectively. Curiously, the system ranking is very different and almost opposite compared to the incident-level rankings, with the system *NAI-SEA* being the one with the highest F1-score. This can be explained by the multifaceted nature of this task, in which different systems may optimize for different goals.

Next, we investigated the F1-scores of systems per event property pair. As shown in Table 7, the best-performing system consistently has the highest performance over all pairs of event properties.

R	Team	s1_doc.f1 norm	s1_doc.f1 (% of Qs answered)
1	NAI-SEA	78.33	78.33 (100.0%)
2	ID-DE	36.67	82.99 (44.19%)
3	FEUP	24.65	24.65 (100.0%)
4	*NewsReader	23.82	46.2 (51.55%)
5	Baseline	11.09	67.33 (16.47%)

Table 9: For subtask 1, we report the normalized document-level F1 (*s1_doc.f1 norm*) and the accuracy on the answered questions only (*s1_doc.f1*). Systems are ordered by their rank (*R*).

R	Team	s2_doc.f1 norm	s2_doc.f1 (% of Qs answered)
1	NAI-SEA	50.52	50.52 (100.0%)
2	ID-DE	37.24	55.16 (67.5%)
3	*NewsReader	36.91	36.91 (100.0%)
4	FEUP	30.51	30.51 (100.0%)
5	Baseline	26.38	26.38 (100.0%)

Table 10: For subtask 2, we report the normalized document-level F1 (*s2_doc.f1 norm*) and the accuracy on the answered questions only (*s2_doc.f1*). Systems are ordered by their rank (*R*).

R	Team	s3_doc.f1 norm	s3_doc.f1 (% of Qs answered)
1	NAI-SEA	63.59	63.59 (100.0%)
2	ID-DE	46.33	69.56 (66.61%)
3	*NewsReader	26.84	26.84 (100.0%)
4	FEUP	26.79	26.79 (100.0%)

Table 11: For subtask 3, we report the normalized document-level F1 (*s3_doc.f1 norm*) and the accuracy on the answered questions only (*s3_doc.f1*). Systems are ordered by their rank (*R*).

8.3 Mention-level evaluation

Table 8 shows the event coreference results for the participating systems: *ID-DE* and *NewsReader*, as well as our baseline. The columns present the F1-score for the metrics BCUB, BLANC, CEAF_E, CEAF_M, and MUC. The final column indicates

Event type	Subtask	#Qs	FEUP	ID-DE	NAI-SEA	*NewsReader	Baseline
fire_burning	S2	79	40.51	-	31.65	39.24	49.37
	S3	0	-	-	-	-	-
injuring	S2	543	21.92	$\hat{13.44}$	14.36	21.73	17.68
	S3	1502	30.49	$\hat{8.39}$	16.78	23.17	-
job_firing	S2	4	0.0	-	25.0	25.0	50.0
	S3	26	30.77	-	26.92	15.38	-
killing	S2	371	30.19	$\hat{17.25}$	18.6	18.33	12.13
	S3	928	30.28	$\hat{20.47}$	25.54	17.78	-

Table 6: For subtask 2 (S2) and subtask 3 (S3), we report the incident-level accuracy and the number of questions (#Qs) per event type. The best result per event type for a subtask is marked in bold. “ $\hat{\cdot}$ ” indicates that the accuracy is normalized for the number of answered questions, in cases where a system answered a subset of all questions.

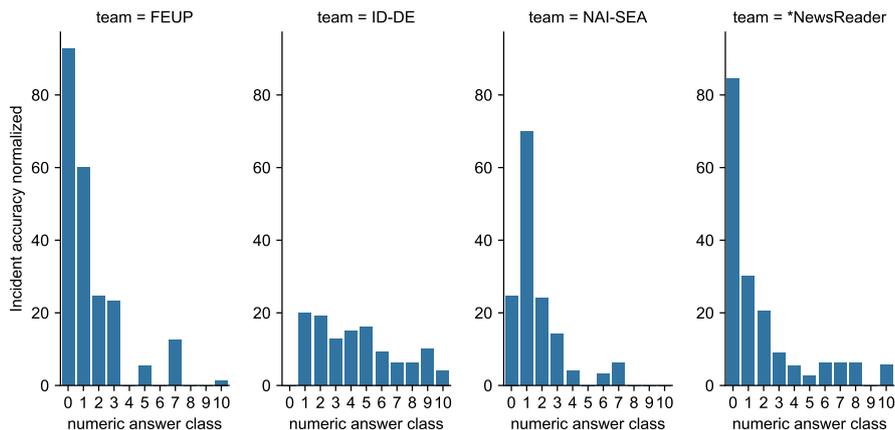

Figure 2: Incident-level accuracy of all systems per numeric answer class for subtask 2. The class 10 represents all answers of 10 or higher.

Event properties	Subtask	#Qs	FEUP	ID-DE	NAI-SEA	*NewsReader	Baseline
location&time	S1	594	23.06	$\hat{26.64}$	82.91	$\hat{26.22}$	$\hat{8.71}$
	S2	680	30.95	$\hat{41.81}$	49.99	39.22	28.61
	S3	1335	26.4	$\hat{41.55}$	63.27	36.15	-
participant&location	S1	140	13.48	$\hat{43.86}$	70.22	$\hat{11.83}$	$\hat{9.76}$
	S2	49	14.66	$\hat{21.26}$	50.41	13.53	10.02
	S3	301	14.2	$\hat{44.28}$	62.38	6.65	-
participant&time	S1	298	33.06	$\hat{53.28}$	73.01	$\hat{24.65}$	$\hat{16.47}$
	S2	268	32.27	$\hat{28.55}$	51.87	35.34	23.71
	S3	820	32.06	$\hat{54.88}$	64.56	19.09	-

Table 7: Document-level F1-score and number of questions (#Qs) for each subtask (S1, S2, and S3) and event property pair as given in the task questions. The best result per property pair for a subtask is marked in bold. “ $\hat{\cdot}$ ” indicates that the F1-score is normalized for the number of answered questions, in cases where a system answered a subset of all questions.

R	Team	BCUB	BLANC	CEAF_E	CEAF_M	MUC	AVG
1	ID-DE	44.61%	31.59%	37.45%	47.23%	53.12%	42.8%
2	*NewsReader	37.28%	28.11%	42.15%	46.16%	46.29%	40.0%
3	Baseline	6.14%	0.89%	13.3%	8.45%	3.59%	6.47%

Table 8: Results for mention-level evaluation, scored with the customary event coreference metrics: BCUB (Bagga and Baldwin, 1998), BLANC (Recasens and Hovy, 2011), entity-based CEAF (CEAF.E) and mention-based CEAF (CEAF.M) (Luo, 2005), and MUC (Vilain et al., 1995). The individual scores are averaged in a single number (AVG), which is used to rank (R) the systems.

the mean F1-score over these five metrics, which is used to rank the participants. The Table shows that the system *ID-DE* has a slightly better event

coreference score on average over all metrics than the second-ranked system, *NewsReader*.

9 Conclusions

In this paper we have introduced SemEval-2018 Task 5, a referential quantification task of counting events and participants in local news articles with high ambiguity. The complexity of this task challenges systems to establish the meaning, reference, and identity across documents. SemEval-2018 Task 5 consists of two subtasks of counting events, and one subtask of counting event participants in their corresponding roles. We evaluated system performance with a set of metrics, on three levels: incident-, document-, and mention-level.

We described the approaches and presented the results of four participating systems, as well as two baseline algorithms. All four teams submitted a result for all three subtasks, and two teams participated in the mention-level evaluation. We observed that the ranking of systems differs dramatically per evaluation level. Given the multifaceted nature of this task, it is not surprising that different systems optimized for different goals. Although the systems are able to retrieve many of the answer documents, the highest accuracy of counting events or participants is 30%. This suggests that further research is necessary in order to develop complete and robust models that can natively deal with the challenge of counting referential units within sparse and ambiguous textual data.

Out-of-competition participation is enabled by the Codalab platform, where this task was hosted.

Abstract

We present KOI (Knowledge of Incidents), a system that given news articles as input, builds a knowledge graph (KOI-KG) of incidental events. KOI-KG can then be used to efficiently answer questions such as “How many killing incidents happened in 2017 that involve Sean?” The required steps in building the KG include: (i) document preprocessing involving word sense disambiguation, named-entity recognition, temporal expression recognition and normalization, and semantic role labeling; (ii) incidental event extraction and coreference resolution via document clustering; and (iii) KG construction and population.

1 Introduction

SemEval-2018¹ Task 5: *Counting Events and Participants in the Long Tail* (Postma et al., 2018) addresses the problem of *referential quantification* that requires a system to answer numerical questions about events such as (i) “How many killing incidents happened in June 2016 in San Antonio, Texas?” or (ii) “How many people were killed in June 2016 in San Antonio, Texas?”

Subtasks S1 and S2 For questions of type (i), which are asked by the first two subtasks, participating systems must be able to identify the type (e.g., *killing*, *injuring*), time, location and participants of each event occurring in a given news article, and establish within- and cross-document event coreference links. Subtask S1 focuses on evaluating systems’ performances on identifying *answer incidents*, i.e., events whose properties fit the constraints of the questions, by making sure that there is only *one* answer incident per question.

Subtask S3 In order to answer questions of type (ii), participating systems are also required to identify participant roles in each identified answer incident (e.g., *victim*, *subject-suspect*), and use such information along with victim-related numerals (“*three people were killed*”) mentioned in the corresponding *answer documents*, i.e., documents that report on the answer incident, to determine the total number of victims.

Datasets The organizers released two datasets: (i) *test data*, stemming from three domains of gun violence, fire disasters and business, and (ii) *trial data*, covering only the gun violence domain. Each dataset contains (i) an input document (in CoNLL format) that comprises news articles, and (ii) a set of questions (in JSON format) to evaluate the participating systems.²

This paper describes the KOI (Knowledge of Incidents) system submitted to SemEval-2018 Task 5, which constructs and populates a knowledge graph of incidental events mentioned in news articles, to be used to retrieve answer incidents and answer documents given numerical questions about events. We propose a fully unsupervised approach to identify events and their properties in news texts, and to resolve within- and cross-document event coreference, which will be detailed in the following section.

2 System Description

2.1 Document Preprocessing

Given an input document in CoNLL format (one token per line), for each news article, we first split the sentences following the annotation of: (i) whether a token is part of the article title or content; (ii) sentence identifier; and (iii) whether a to-

* Both share the same amount of work.

¹<http://alt.qcri.org/semeval2018/>

²<https://competitions.codalab.org/competitions/17285>

ken is a newline character. We then ran several tools on the tokenized sentences to obtain the following NLP annotations.

Word sense disambiguation (WSD) We ran Babelfy³ (Moro et al., 2014) to get disambiguated *concepts* (excluding stop-words), which can be multi-word expressions, e.g., *gunshot wound*. Each concept is linked to a sense in BabelNet⁴ (Navigli and Ponzetto, 2012), which subsequently is also linked to a WordNet sense and a DBpedia entity (if any).

Named-entity recognition (NER) We relied on spaCy⁵ for a statistical entity recognition, specifically for identifying persons and geopolitical entities (countries, cities, and states).

Time expression recognition and normalization We used HeidelTime⁶ (Strötgen and Gertz, 2013) for recognizing textual spans that indicate time, e.g., *this Monday*, and normalizing the time expressions according to a given document creation time, e.g., *2018-03-05*.

Semantic role labeling (SRL) Senna⁷ (Collobert et al., 2011) was used to run semantic parsing on the input text, for identifying sentence-level events (i.e., predicates) and their participants.

2.2 Event Extraction and Coreference Resolution

Identifying document-level events Sentence-level events, i.e., *predicates* recognized by the SRL tool, were considered as the candidates for the document-level events. Note that predicates containing other predicates as the patient argument, e.g., *'says'* with arguments *'police'* as its agent and *'one man was shot to death'* as its patient, were not considered as candidate events.

Given a predicate, we simultaneously determined whether it is part of document-level events and also identified its type, based on the occurrence of *BabelNet concepts* that are related to four event types of interest stated in the task guidelines: *killing*, *injuring*, *fire burning* and *job firing*. A predicate is automatically labeled as a sentence-level event with one of the four types if such re-

lated concepts occur either in the predicate itself or in one of its arguments. For example, a predicate *'shot'*, with arguments *'one man'* as its patient and *'to death'* as its manner, will be considered as a *killing* event because of the occurrence of *'death'* concept.⁸

Concept relatedness was computed via path-based WordNet similarity (Hirst et al., 1998) of a given BabelNet concept, which is linked to a WordNet sense, with a predefined set of related WordNet senses for each event type (e.g., *wn30:killing.n.02* and *wn30:kill.v.01* for the killing event), setting 5.0 as the threshold. Related concepts were also annotated with the corresponding event types, to be used for the mention-level event coreference evaluation.

We then assumed all identified sentence-level events in a news article belonging to the same event type to be automatically regarded as *one* document-level event, meaning that each article may contain at most four document-level events (i.e., at most one event per event type).

Identifying document-level event participants

Given a predicate as an identified event, its participants were simply extracted from the occurrence of named entities of type *person*, according to both Senna and spaCy, in the agent and patient arguments of the predicate. Furthermore, we determined the role of each participant as *victim*, *perpetrator* or *other*, based on its mention in the predicate. For example, if *'Randall'* is mentioned as the agent argument of the predicate *'shot'*, then he is a perpetrator. Note that a participant can have multiple roles, as is the case for a person who kills himself.

Taking into account all participants of a set of identified events (per event type) in a news article, we extracted document-level event participants by resolving name coreference. For instance, *'Randall'*, *'Randall R. Coffland'*, and *'Randall Coffland'* all refer to the same person.

Identifying document-level number of victims

For each identified predicate in a given document, we extracted the first existing *numeral* in the patient argument of the predicate, e.g., *one* in *'one man'*. The normalized value of the numeral was then taken as the number of victims, as long as the predicate is not suspect-related predicates such

⁵<https://spacy.io/>

⁶<https://github.com/HeidelTime/heideltime>

⁷<https://ronan.collobert.com/senna/>

⁸We assume that a predicate that is labeled as a *killing* event cannot be labeled as an *injuring* event even though an *injuring*-related concept such as *'shot'* occurs.

as *suspected* or *charged*. The number of victims of document-level events is simply the maximum value of identified number of victims per predicate.

Identifying document-level event locations To retrieve candidate event locations given a document, we relied on disambiguated DBpedia entities as a result of Babelify annotation. We utilized SPARQL queries over the *DBpedia SPARQL endpoint*⁹ to identify whether a DBpedia entity is a *city* or a *state*, and whether it is *part of* or *located in* a city or a state. Specifically, an entity is considered to be a city whenever it is of type `dbo:City` or its equivalent types (e.g., `schema:City`). Similarly, it is considered to be a state whenever it is either of type `yago:WikicatStatesOfTheUnitedStates`, has a senator (via the property `dbp:senators`), or has `dbc:States_of_the_United_States` as a subject.

Assuming that document-level events identified in a given news article happen at *one* certain location, we simply ranked the candidate event locations, i.e., pairs of city and state, based on their frequencies, and took the one with the highest frequency.

Identifying document-level event times Given a document D , suppose we have dct as the document creation time and T as a list of normalized time expressions returned by HeidelTime, whose types are either `date` or `time`. We considered a time expression $t_i \in T$ as one of candidate event times $T' \subseteq T$, if $dct - t_i$ is a non-negative integer less than n days.¹⁰ We hypothesize that the event reported in a news article may have happened several days before the news is published.

Assuming that document-level events identified in a given news article happen at *one* certain time, we determine which one is the document-level event time from the set of candidates T' by applying two heuristics: A time expression $t_j \in T'$ is considered as the event time, if (i) t_j is mentioned in sentences containing event-related concepts, and (ii) t_j is the earliest time expression in the candidate set.

Cross-document event coreference resolution We approached cross-document event coreference by clustering similar document-level events that

⁹<https://dbpedia.org/sparql>

¹⁰Based on our empirical observations on the trial data we found $n = 7$ to be the best parameter.

Resource Type	Properties
<i>IncidentEvent</i>	<i>eventType, eventDate, location, participant, numOfVictims</i>
<i>Document</i>	<i>docDate, docID, event</i>
<i>Participant</i>	<i>fullname, firstname, lastname, role</i>
<i>Location</i>	<i>city, state</i>
<i>Date</i>	<i>value, day, month, year</i>

Table 1: KOI-KG ontology

are of the same type, via their *provenance*, i.e., news articles where they were mentioned. From each news article we derived TF-IDF-based vectors of (i) BabelNet senses and (ii) spaCy’s persons and geopolitical entities, which are then used to compute cosine similarities among the articles.

Two news articles will be clustered together if (i) the computed similarity is above a certain threshold, which was optimized using the trial data, and (ii) the event time distance of document-level events found in the articles does not exceed a certain threshold, i.e., 3 days. All document-level events belonging to the same document cluster are assumed to be coreferring events and to have properties resulting from the aggregation of locations, times and participants of contributing events, with the exception of number of victims where the maximum value was taken instead.

2.3 Constructing, Populating and Querying the Knowledge Graph

We first built an *OWL ontology*¹¹ to capture the knowledge model of incidental events and documents. We rely on reification (Noy and Rector, 2006) for modeling entities, that is, incident events, documents, locations, participants and dates are all resources of their own. Each resource is described through its corresponding properties, as shown in Table 1.

An incident event can be of type *injuring*, *killing*, *fire_burning*, and *job_firing*. Documents are linked to incident events through the property *event*, and different documents may refer to the same corresponding incident event. We borrow URIs from DBpedia for values of the properties *city* and *state*. Participant roles can be either *victim*, *perpetrator* or *other*. A date has a unified literal value of the format “yyyy-mm-dd”, as well as separated values for the day, month, and year.

To build the KOI knowledge graph (KOI-KG)

¹¹Available at <https://koi.cs.ui.ac.id/ns>

```

SELECT ?event ?document
WHERE {
  ?event koi:eventType koi:killing .
  ?event koi:eventDate [
    koi:year "2017" ] .
  ?event koi:participant [
    koi:firstname "Sean" ] .
  ?document koi:event ?event .
}

```

Figure 1: A SPARQL query over KOI-KG for “Which killing events happened in 2017 that involve persons with Sean as first name?”

we relied on Apache Jena,¹² a Java-based Semantic Web framework. The output of the previously explained event extraction and coreference resolution steps was imported into the Jena TDB triple store as RDF triples. This facilitates SPARQL querying, which can be done using the Jena ARQ module. The whole dump of KOI-KG is available for download at <https://koi.cs.ui.ac.id/incidents>.

Given a question in JSON format, we applied mapping rules to transform it into a SPARQL query, which was then used to retrieve corresponding *answer incidents* and *answer documents*. Constraints of questions such as event type, participant, date, and location were mapped into SPARQL join conditions (that is, triple patterns). Figure 1 shows a SPARQL representation for the question “Which killing events happened in 2017 that involve persons with Sean as first name?”. The prefix *koi* is for the KOI ontology namespace (<https://koi.cs.ui.ac.id/ns#>). In the SPARQL query, the join conditions are over the event type *killing*, the date ‘2017’ (as year) and the participant ‘Sean’ (as firstname).

For Subtask S2, we extended the SPARQL query with counting feature to retrieve the total number of unique events. Analogously, for Subtask S3, we retrieve number of victims by counting event participants having *victim* as their roles, and by getting the value of the *numOfVictims* property (if any). The value of the *numOfVictims* property was preferred as the final value for an incident if it exists, otherwise, KOI relied on counting event participants.

We also provide a SPARQL query interface for KOI-KG at <https://koi.cs.ui.ac.id/dataset.html?tab=query&ds=/incidents>.

¹²<http://jena.apache.org/>

3 Results and Discussion

Evaluation results Participating systems were evaluated according to three evaluation schemes: (i) *mention-level evaluation*, for resolving cross-document coreference of event mentions, (ii) *document-level evaluation* (*doc-f1*), for identifying events and their properties given a document, and (iii) *incident-level evaluation*, for combining event extraction and within-/cross-document event coreference resolution to answer numerical questions in terms of exact matching (*inc-acc*) and Root Mean Square Error (*inc-rmse*). Furthermore, the percentage of questions in each subtask that can be answered by the systems (*%ans*) also contributes to the final ranking.

Regarding the *mention-level evaluation*, KOI achieves an average F1-score of 42.8% (36.3 percentage point increase over the baseline) from several established metrics for evaluating coreference resolution systems. For *document-level* and *incident-level evaluation* schemes, we report in Table 2 the performance of three different system runs of KOI:

- v1 Submitted version of KOI during the *evaluation period*.
- v2 Similar as v1, however, instead of giving no answers when we found no matching *answer incidents*, KOI simply returns *zero* as the numerical answer with an empty list of *answer documents*.
- v3 Submitted version of KOI during the *post-evaluation period*, which incorporates improvement on document-level event time identification leading to enhanced cross-document event coreference.¹³

Compared to the baseline provided by the task organizers, the performance of KOI is considerably better, specifically of KOI v3 for subtask S2 with *doc-f1* and *inc-acc* around twice as much as of the baseline. Hereafter, our quantitative and qualitative analyses are based on KOI v3, and mentions of the KOI system refer to this system run.

Subtask S1 We detail in Table 3, the performance of KOI on retrieving relevant *answer documents* given questions with event constraints,

¹³Submission v1 and v2 did not consider heuristic (i) that we have discussed in Section 2.2.

system run	subtask S1		subtask S2				subtask S3			
	%ans	doc-f1	%ans	doc-f1	inc-acc	inc-rmse	%ans	doc-f1	inc-acc	inc-rmse
<i>baseline</i>	16.5	67.3	100.0	26.4	18.3	8.5	-	-	-	-
KOI v1*	44.2	83.0	67.5	55.2	20.4	6.2	66.6	69.6	19.3	7.9
KOI v2	44.2	83.0	100.0	51.2	25.6	5.2	100.0	49.1	24.8	7.1
KOI v3	55.1	85.7	100.0	54.8	27.4	5.3	100.0	50.9	23.0	7.7

Table 2: KOI performance results at SemEval-2018 Task 5 (in percentages) for three subtasks, *baseline* was provided by the task organizers, *) denotes the system run that we submitted during the evaluation period.

	micro-averaged			macro-averaged		
	p	r	f1	p	r	f1

time	86.0	42.4	56.8	51.7	46.3	47.4

Table 3: KOI performance results for subtask S1, on *answer document* retrieval (p for precision, r for recall and f1 for F1-score).

in terms of *micro-averaged* and *macro-averaged* scores. Note that the official `doc-f1` scores reported in Table 2 correspond to macro-averaged F1-scores.

We first analyzed the system performance only on *answered questions*, i.e., for which KOI returns the relevant answer documents (55.1% of all questions), yielding 79.8% and 85.7% micro-averaged and macro-averaged F1-scores, respectively.

In order to have a fair comparison with systems that are able to answer *all questions*, we also report the performance of KOI that returns empty sets of answer documents for unanswered questions. In this evaluation scheme, the macro-averaged precision is significantly lower than the micro-averaged one (51.7% vs 86.6%), because systems are heavily penalized for not retrieving relevant answer documents per question, i.e., given zero precision score, which brings the average over all questions down. Meanwhile, the micro-averaged precision measures the systems’ ability in returning relevant documents for all questions regardless of whether the questions were answered or not. KOI focuses on yielding high quality answer documents, which is reflected by high micro-averaged precision of above 80% in general. The following result analy-

	subtask S2		subtask S3	
	inc-acc	inc-rmse	inc-acc	inc-rmse
overall	27.4	5.3	23.0	7.7
zero	96.3	0.2	55.2	6.8
non-zero	18.9	5.6	11.9	8.0

Table 4: KOI performance results for subtasks S2 and S3, on answering numerical questions, i.e., number of incidents and number of victims.

ses are based on the *all questions* scheme.

By analyzing the document retrieval per event type, we found that KOI can identify *fire_burning* events in documents quite well, yielding the highest recall among all event types, but the contrary for *job_firing* events. With respect to event constraints, answering questions with *location* constraint results in the worst performance, meaning that our method is still lacking in identifying and/or disambiguating event locations from news documents. Specifically, questions with *city* constraint are more difficult to answer compared to the ones with *state* constraint (49.6% vs 61.5% micro-averaged F1-scores, respectively).

Subtask S2 The key differences between Subtask S1 and S2 are: (i) questions with *zero* as an answer are included, and (ii) there can be more than one *answer incidents* per question, hence, systems must be able to cluster *answer documents* into the correct number of clusters, i.e., incidents.

As shown in Table 4, KOI is able to answer questions with *zero* as the true answer with 96.3% accuracy. Meanwhile, for questions with non-zero number of incidents as the answers, KOI gives numerical answers with 18.9% accuracy, resulting in overall accuracy (`inc-acc`) of 27.4% and RMSE (`inc-rmse`) of 5.3.

We also analyzed questions (with non-zero answer incidents) for which KOI yields perfect sets of answer documents with 100% F1-score, i.e., 7.7% of all questions. For 61.8% of such answered questions, KOI returns the perfect number of inci-

2016-06-19

Man playing with gun while riding in a car fatally shoots, kills driver

A man was fatally shot early Sunday morning after the passenger in the car he was driving accidentally discharged the gun, according to the San Antonio Police Department. The shooting occurred about 3 a.m. when group of four men were driving out of the Iron Horse Apartments at 8800 Village Square on the Northeast Side. The passenger in the front seat was playing with a gun and allegedly shot himself in the hand, according to officers at the scene. The bullet went through his hand and struck the driver in the abdomen. The men then drove to Northeast Baptist Hospital, which was nearby, but the driver was pronounced dead at the hospital, according to investigators. Police believe the driver and passenger to be related and are still investigating the incident. The other two men in the vehicle were detained. No charges have been filed.

2016-06-19

41-year - old man killed in overnight shooting

SAN ANTONIO - A 41-year-old man is dead after a shooting police say may have been accidental. The victim died after another man drove him to Northeast Baptist Hospital for treatment of that gunshot wound. Police say they got a call at around 2:45 a.m. for the shooting in the 8800 block of Village Drive. The man told them he and the victim were in a pickup when he fired the shot, but police say it's not known why the men were in the truck. Investigators say the man told them he fired the shot accidentally and struck the victim. Police say the shooter took the victim to the emergency room at Northeast Baptist, where hospital personnel pronounced him dead. Police are questioning the man who did the shooting.

Table 5: An identified ‘killing’ event by KOI for “Which killing incidents happened in June 2016 in San Antonio, Texas?” with two supporting documents.

dents. For the rest, KOI tends to overestimate the number of incidents, i.e., for 30.9% of the cases, KOI fails to establish cross-document event coreference links with the current document clustering method.

Subtask S3 We also show in Table 4, the KOI performance on answering numerical questions about number of victims. KOI is able to answer correctly 55.2% of questions with zero answers, and 11.9% of the ones with non-zero answers.

Analyzing the questions with zero as the true answer, for which KOI is able to answer correctly, in 41.1% of the cases KOI is able to identify the non-existence of victims when the set of answer documents is not empty. In 40.0% of the cases, the correctly predicted zero answers are actually by chance, i.e., because KOI fails to identify relevant answer documents.

Meanwhile, for questions with gold numerical answers greater than zero, KOI returns wrong answers in 88.1% of the cases. Among these answers, 66.9% of the answers are lower than the true number of victims, and 33.1% are higher. This means that KOI tends to underestimate the number of victims with 6.6 RMSE.

For 22.5% of all questions, KOI is able to identify the perfect sets of answer documents with 100% F1-score. Among these questions, 34.3% were answered correctly with the exact number of victims, for which: 52.7% of correct answers result from solely counting participants (as victims), 35.3% were inferred only from numeral mentions, and the rest of 12.0% were answered by combining both victim counting and numeral mentions.

Qualitative Analysis Recalling the example questions mentioned in the beginning of Section 1, for the first question, KOI is able to perfectly identify 2 killing incidents with 5 supporting documents pertaining to the event-time and -location constraints. One of the identified answer incidents with two supporting documents is shown in Table 5, which shows how well the system is able to establish cross-document event coreference, given overlapping concepts and entities. However, in answering the second question, KOI returns one less number of victims since it cannot identify the killed victim in the answer incident shown in Table 5, due to the lack of numeral mentions and named event participants as victims.

4 Conclusion

We have introduced a system called KOI (Knowledge of Incidents), that is able to build a knowledge graph (KG) of incidental events by extracting relevant event information from news articles. The resulting KG can then be used to efficiently answer numerical questions about events such as “How many people were killed in June 2016 in San Antonio, Texas?” We have submitted KOI as a participating system at SemEval-2018 Task 5, which achieved competitive results. A live demo of our system is available at <https://koi.cs.ui.ac.id/>. Future directions of this work include the incorporation of supervised (or semi-supervised) approaches for specific steps of KOI such as the extraction of numeral information (Mirza et al., 2017), as well as the investigation of applying our approach to other domains such as disease outbreaks and natural disasters.

Abstract

This paper presents the outcomes of the Parsing Time Normalization shared task held within SemEval-2018. The aim of the task is to parse time expressions into the compositional semantic graphs of the Semantically Compositional Annotation of Time Expressions (SCATE) schema, which allows the representation of a wider variety of time expressions than previous approaches. Two tracks were included, one to evaluate the parsing of individual components of the produced graphs, in a classic information extraction way, and another one to evaluate the quality of the time intervals resulting from the interpretation of those graphs. Though 40 participants registered for the task, only one team submitted output, achieving 0.55 F1 in Track 1 (parsing) and 0.70 F1 in Track 2 (intervals).

1 Introduction

The task of extracting and normalizing time expressions (e.g., finding phrases like *two days ago* and converting them to a standardized form like 2017-07-17) is a fundamental component of any time-aware language processing system. TempEval 2010 and 2013 (Verhagen et al., 2010; UzZaman et al., 2013) included a restricted version of a time normalization task as part of their shared tasks. However, the annotation scheme used in these tasks (TimeML; (ISO, 2012)) has some significant limitations: it assumes times can be described as a prefix of YYYY-MM-DDTHH:MM:SS (so it can't represent, e.g., *the past three summers*), it is unable to represent times that are relative to events (e.g., *three weeks postoperative*), and it fails to reflect the compositional nature of time expressions (e.g., that *following* represents a similar temporal operation in *the following day* and *the following year*). This latter issue especially has discouraged machine learning approaches to time

normalization; the most accurate systems for normalizing times are still based on sets of complex, manually-constructed rules (Bethard, 2013; Lee et al., 2014; Strötgen and Gertz, 2015).

The Parsing Time Normalizations shared task is a new approach to time normalization based on the Semantically Compositional Annotation of Time Expressions (SCATE) schema (Bethard and Parker, 2016), in which times are annotated as compositional time entities. Such entities are more expressive, being able to represent many more time expressions, and are more machine-learnable, as they can naturally be viewed as a semantic parsing task. The top of Figure 1 shows an example. Each annotation in the example corresponds to a formally defined time entity. For instance, the annotation on top of *since* corresponds to a BETWEEN entity that identifies an interval starting at the most recent March 6 and ending at the document creation time. The bottom of Figure 1 shows how those time entities can be composed to identify appropriate intervals on the timeline. Here, the BETWEEN entity finds the interval on the timeline that is between the intervals of its two arguments: the LAST and the DOC-TIME. Formally, this BETWEEN operator is defined as:

$$\begin{aligned} \text{BETWEEN}([t_1, t_2]: \text{INTERVAL}, \\ [t_3, t_4]: \text{INTERVAL}): \text{INTERVAL} \\ = [t_2, t_3] \end{aligned}$$

In the proposed task, systems need only to identify time entities in text and link them correctly to signal how they are to be composed (i.e., systems would only need to produce annotation structures like those at the top of Figure 1). The timeline intervals implied by such system output are inferred through a time entity interpreter provided to the participants by the workshop organizers.

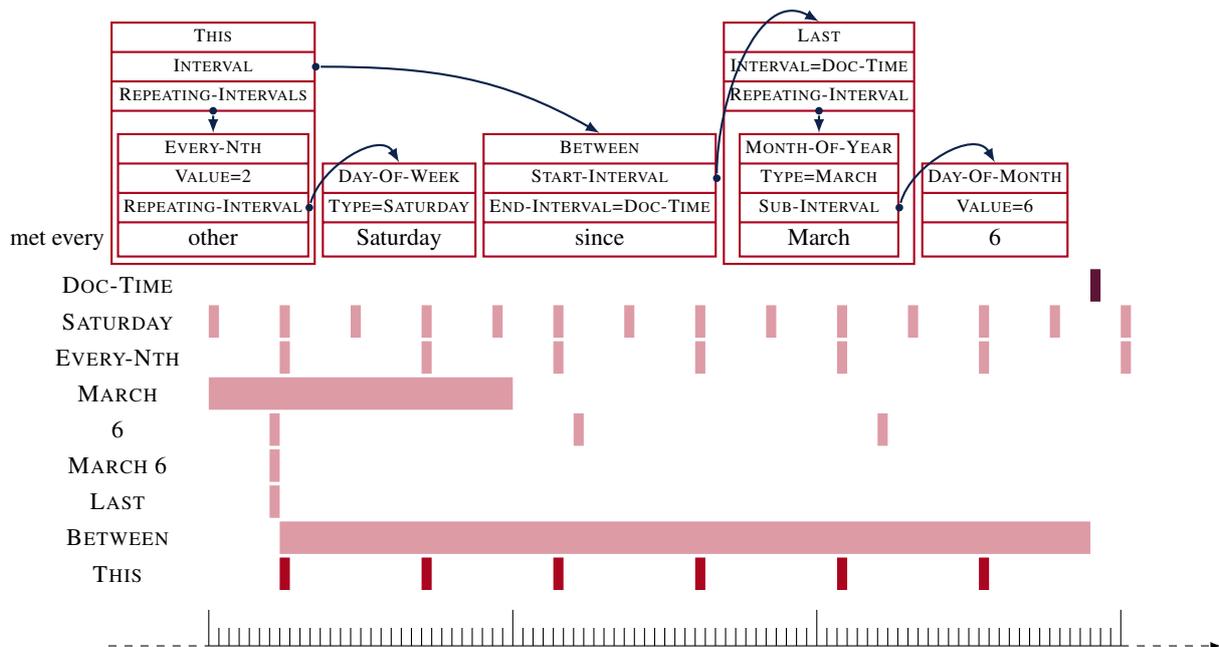

Figure 1: Example of semantically compositional time annotations and their interpretation.

The remainder of this paper is organized as follows. We describe the task goal and proposed tracks in Section 2. Section 3 contains the description of the data annotation schema and the statistics of our dataset. In Section 4, we explain the two evaluation metrics used in the task and in Section 5 the models used as baselines. We present the participant systems in Section 6 and the results obtained in Section 7. Finally, we discuss some conclusions learned in Section 8.

2 Tasks

The ultimate goal of the shared task is to interpret time expressions, identifying appropriate intervals that can be placed on a timeline. Given a document, a system must identify the **time entities** by detecting the spans of characters and labeling them with the proper SCATE type. Examples of time entities and their corresponding types in Figure 1 would be (6, DAY-OF-MONTH), (Saturday, DAY-OF-WEEK), (March, MONTH-OF-YEAR) or (since, BETWEEN). Besides the time entities explicitly expressed in the text, implicit occurrences must also be identified, like the THIS and LAST time entities in Figure 1 that do not have any explicit triggers in the text.

Once time entities have been identified, they should be linked together using the relations described in the SCATE schema. Following with the example in Figure 1, the time entity 6 should be linked as a SUB-INTERVAL of March, Saturday

should be a REPEATING-INTERVAL of the time entity *other*, and so on. Finally, all the time entities must be completed with some additional properties needed for their interpretation. For example, the time entity *other* should have a VALUE of 2, the END-INTERVAL of *since* is the Document Creation Time, etc. Once again, the properties required by each time entity type are defined by the SCATE schema.¹

Every resulting graph, composed of a set of linked time entities, represents a **time expression** that can be semantically interpreted. For this purpose, we provide a Scala library² that reads the graphs in Anafora XML format (Chen and Styler, 2013) and converts them into intervals on the timeline.

An example of interpreting the time entities corresponding to the expression *every Saturday since March 6* relative to an anchor time of April 21, 2017 is given in Figure 2. In this example, the values *today* and *result* store the entities that represent the time expressions April 21, 2017 and *every Saturday since March 6* respectively. The Scala command on the right side interprets the latter and produces the corresponding time intervals.

The task includes two evaluation methods, one for the parsing step, i.e. time entity identification

Figure 2: Interpretation of *every Saturday since March 6*.

and linking, and one to score the resulting time intervals. For the later, we only consider time expressions that yield a finite set of bounded intervals, for example, *last Monday*. Time expressions that refer to an infinite set of intervals, like *every month*, are not considered in the interval-based part of the evaluation.

Participants only need to produce Anafora outputs with parsed time entities; the interpretation is carried out by the evaluation system. The evaluation system is also able to obtain the intervals from timestamps in TimeML format. Thus, systems can be evaluated by both methods or just by the interval-based one, depending on the output format.

In summary, the tasks offers two tracks:

Track 1: Parse text to time entities. Systems must identify time entities in text and link them correctly to signal how they have to be composed. The output must be given in Anafora format. In this track, all time entities and relations of every time expression are evaluated.

Track 2: Produce time intervals. Systems can participate through Track 1 or by providing TimeML annotations. In both cases, the intervals are inferred by our interpreter. In this track, only bounded time intervals are scored.

3 Data

The Parsing Time Normalization corpus³ covers two different domains: newswire and clinical notes. For the former, we have annotated a subset of Tempeval-2013 corpus (UzZaman et al., 2013), which contains a collection of news articles from

³<https://github.com/bethard/anafora-annotations/releases>

different sources, such as Wall Street Journal, New York Times, Cable News Network, Voices of America, etc. For the clinical domain, we have annotated a subset of the THYME corpus used in the Clinical TempEvals (Bethard et al., 2015, 2016, 2017), which includes a set of de-identified clinical notes and pathology reports from cancer patients at the Mayo Clinic.

The Newswire annotation was performed by linguistic students at the University of Alabama at Birmingham, and by linguistics students at the University of Arizona, funded as part of a university-sponsored undergraduate research opportunity. The clinical portion of the corpus was annotated by linguistics students at the University of Colorado, funded as part of the United States National Institutes of Health (NIH) award R01LM010090.

Documents have been annotated by two annotators and adjudicated by a third, and despite the complexity of the annotation scheme, high levels of inter-annotator agreement have been achieved: 0.917 F_1 on annotation spans and types, and 0.821 F_1 on the complete task of spans, types, and links. (We use F_1 since the κ coefficient (Cohen, 1960) converges to F_1 in cases where the number of non-annotations is much larger than the number of annotations (Hripcsak and Rothschild, 2005).)

Annotated data is stored in Anafora XML format (Chen and Styler, 2013), where, for example, the annotations from Figure 1 look like Figure 3. A more detailed explanation of the annotation guidelines can be found in Bethard and Parker (2016). Libraries for parsing this format are available to

</data>

```

Figure 3: Snippet of the Anafora XML for Figure 1.

participants in both Python⁴ and Scala⁵.

Table 1 shows the statistics of the resulting annotation. The Newswire portion of the corpus contains 98 documents with 2,428 time entities annotated. These entities compose a total of 968 time expressions of which 564 correspond to bounded intervals. The Clinical portions of the corpus includes 408 documents. The annotation covers 27,362 time entities that compose 8,163 time expressions. From these, 4,204 yield bounded intervals.

4 Evaluation Metrics

We propose two types of scoring metrics for this task, one for the evaluation of each track. The first follows a more traditional information extraction evaluation: measure the precision and recall of finding and linking the various time entities. Specifically, we define:

$$P(S, H) = \frac{|S \cap H|}{|S|}$$

$$R(S, H) = \frac{|S \cap H|}{|H|}$$

$$F_1(S, H) = \frac{2 \cdot P(S, H) \cdot R(S, H)}{P(S, H) + R(S, H)}$$

where S is the set of items predicted by the system and H is the set of items produced by the humans. For these calculations, each item is an annotation,

⁴<https://github.com/bethard/anaforatools>

⁵<https://github.com/bethard/timenorm>

and one annotation is considered as equal to another if it has the same character span (offsets), type, and properties (with the definition applying recursively for properties that point to other annotations).

The second scoring method evaluates the accuracy of systems with respect to the timeline in a more direct way. First, annotations, in either TimeML or SCATE format, are converted into time intervals. TimeML TIMEX3 (time expression) annotations are translated into intervals following ISO 8601 semantics of their VALUE attribute. For example, 2010-02-25 is converted to the interval [2010-02-25T00:00:00, 2018-02-26T00:00:00), that is, the 24-hour period starting at the first second of the day on 2010-02-25 and ending just before the first second of the day on 2010-02-26. SCATE annotations are converted to intervals according to the formal semantics of each entity, using the Scala library provided by Bethard and Parker (2016). For example, Next(Year(2010), SimplePeriod(YEARS, 4)), is converted to [2011-01-01T00:00, 2015-01-01T00:00), i.e., the 4 years following 2010. Note that there may be more than one interval associated with a single annotation, as in the *every Saturday since March 6* example in Figure 2. Once all annotations have been converted into intervals along the timeline, we can calculate the overlap between the intervals of different annotations.

Given two sets of intervals, we define the interval precision, P_{int} , as the total length of the intervals in common between the two sets, divided by the total length of the intervals in the first set. Interval recall, R_{int} is defined as the total length of the intervals in common between the two sets,

	Newswire			Clinical		
	Train	Dev	Test	Train	Dev	Test
Documents	64	14	20	232	35	141
SCATE entities	1,628	402	398	14,936	2,896	9,530
SCATE time exp.	636	146	186	4,469	879	2,815
SCATE bounded	391	80	93	2,303	430	1,471

Table 1: Number of documents and SCATE annotations for both sections of the corpus following the SCATE schema.

divided by the total length of the intervals in the second set. Formally:

$$I_S \cap I_H = \{i \cap j : i \in I_S \wedge j \in I_H\}$$

$$P_{\text{int}}(I_S, I_H) = \frac{\sum_{i \in \text{COMPACT}(I_S \cap I_H)} |i|}{\sum_{i \in I_S} |i|}$$

$$R_{\text{int}}(I_S, I_H) = \frac{\sum_{i \in \text{COMPACT}(I_S \cap I_H)} |i|}{\sum_{i \in \cup I_H} |i|}$$

where I_S and I_H are sets of intervals, $i \cap j$ is the possibly empty interval in common between the intervals i and j , $|i|$ is the length of the interval i , and COMPACT takes a set of intervals and merges any overlapping intervals.

Given two sets of annotations (e.g., one each from two time normalization systems), we define the overall precision, P , as the average of interval precisions where each annotation from the first set is paired with all annotations that textually overlap it in the second set. Overall recall is defined as the average of interval recalls where each annotation from the second set is paired with all annotations that textually overlap it in the first set. Formally:

$$\text{OI}_a(B) = \bigcup_{b \in B: \text{OVERLAPS}(a,b)} \text{INTERVALS}(b)$$

$$P(S, H) = \frac{1}{|S|} \sum_{s \in S} P_{\text{int}}(\text{INTERVALS}(s), \text{OI}_s(H))$$

$$R(S, H) = \frac{1}{|H|} \sum_{h \in H} R_{\text{int}}(\text{INTERVALS}(h), \text{OI}_h(S))$$

where S and H are sets of annotations, $\text{INTERVALS}(x)$ gives the time intervals associated with the annotation x , and $\text{OVERLAPS}(a, b)$ decides whether the annotations a and b share at least one character of text in common.

Note that as defined, P and R can be applied only to time expressions that yield a finite set of bounded intervals.

5 Baseline systems

Two systems were used as baselines to compare the participating systems against.

Character-based model (Laparra et al., 2018) is a novel supervised approach for time normalization that follows the SCATE schema. This model decomposes the normalization of time expressions into two modules:

time entity identification detects the spans of characters that belong to each time expression and labels them with their corresponding time entity type. This step is performed by character-based recurrent neural network with two stacked bidirectional Gated Recurrent Units.

time entity composition links relevant time entities together while respecting the entity type constraints imposed by the SCATE schema. This component is a rule-based algorithm that iterates over the time entities that are found by the previous step, linking them and filling in the required properties. The version used for the shared task includes some improvements to the sentence segmentation and Month-Of-Year normalization of Laparra et al. (2018).

These two tasks are run sequentially using the output of the former as input to the latter. Once identification and composition steps are completed, the final product, i.e. the semantic composition of the time entities, can be fed to the SCATE interpreter to produce time intervals.

HEIDELTIME (Strötgen and Gertz, 2015)⁶ is rule-based temporal tagger with multilingual support that includes English, German, Dutch, Vietnamese, Arabic, Spanish, Italian, French, Chinese and Russian. Heidelberg identifies temporal expressions based on language specific patterns and

⁶<https://code.google.com/p/heideltime/>

normalizes them according to TIMEX annotations (Sundheim, 1996). As the output of HeidelTime follows TimeML format, we use this system as a baseline only for Track 2.

6 Participating systems

Although 40 people registered to the the evaluation task, only 1 team submitted results. The team participated in Track 1 and, consequently, in Track 2. The team also submitted improved results just after the end of the evaluation phase. This improvement was obtained by solving a few bugs in the original system, and with no access to the test data, so we have included the fixed version in this paper as an additional run.

CHRONO (Olex et al., 2018) is a primarily rule-based system that performs time normalization by running the following three steps:

- 1) Temporal tokens are identified and flagged using regex expressions to identify formatted dates/times, and by parsing out specific temporal words and numeric tokens.
- 2) Temporal phrases are identified by searching for consecutive numeric/temporal tokens according to certain constraints.
- 3) Temporal phrases are parsed and normalized into the SCATE schema via detailed rule-based parsing, including the utilization of part-of-speech tags, to identify each component of an expression and link sub-intervals appropriately.

A machine learning approach is taken to disambiguate PERIODS and CALENDAR-INTERVALS after the rule-base parsing has determined it is one or the other (e.g. if it sees the word *week* it will pass it to the ML module for assignment to a PERIODS or CALENDAR-INTERVALS). The ML feature vector is a boolean vector composed of the target token’s temporal status (1=temporal, 0=not temporal), the temporal context (1=at least one temporal token within a window of ± 5 , 0=no temporal tokens within window), the numeric context (1=a numeric token exists immediately before of after the target, 0=no numeric tokens in context), and the lexical context of all words within a 5-word window of the target (1=word is present, 0=word is not present). The group explored different supervised models like naive Bayes, decision trees, support vector machines, and neural networks. They found

Domain	Model	F_1	P	R
Newswire	Character	0.51	0.57	0.46
Newswire	Chrono	0.44	0.46	0.42
Newswire	Chrono*	0.55	0.61	0.50
Clinical	Character	0.57	0.52	0.63

Table 2: Official results in Track 1 (parsing) for the Newswire and Clinical domains.

that the best results were obtained by the neural network.

CHRONO* improves the previous version by solving three bugs in the model. First, the parsing method for various types of temporal components were supposed to be executed in a specific order. However, some of them were swapped and not analyzed in the expected order. Second, the system was supposed to assume there is only one year, one month, and one day mentioned per temporal phrase. This worked for the month and day, however, it was failing with 4-digit years. Finally, for most parsing methods the system loops through each token in the temporal phrase but it skipped the loop when identifying full numeric expressions, like "1953" or "08091998". Thus, phrases like "Last 1953" were not being counted as having any numeric values in them.

7 Evaluation Results

The official results are presented in Table 2 and Table 4. For each track we present the precision (P), recall (R) and F_1 score obtained by the metrics presented in Section 4. The only participant of the task submitted output just for the Newswire domain, thus, we only report the performance of this system in this domain. The results of the Character-based baseline have been obtained training the model with the training set of the corresponding domain (Newswire or Clinical) and a set of randomly generated dates, as explained in Laparra et al. (2018).

In Track 1 (Table 2) the original version of CHRONO do not reach the Character-based baseline, 0.44 F_1 vs 0.51 F_1 . However, the fixed version of the system (CHRONO*) outperforms the baseline in terms of F_1 (0.55) as well as in terms of P (0.61) and R (0.50).

Table 3 shows a more detailed comparison between the Character-based baseline and CHRONO*. These figures represent the performances of both models for each SCATE temporal type. This includes the identification of the time entity, its prop-

SCATE-type	#	Char	Chrono*
AMPM-Of-Day	1	0.000	0.667

Clinical	Character	0.72	0.70	0.75

Table 4: Official results in Track 2 (intervals) for the Newswire and Clinical domains.

erties and links. In general, CHRONO* performs better or similar for all the types. It is remarkable that, while the outcomes for the THIS and NEXT operators are much better, CHRONO* fails to extract properly the LAST operator.

In Track 2 (Table 4) the best system is the Character-based baseline with 0.76 F_1 , followed by HEIDELTIME with 0.74 F_1 . None of the versions of CHRONO performs better than the baselines, although the fixed version (CHRONO*) gets enhanced results, 0.65 F_1 vs 0.70 F_1 , following the improvement obtained in Track 1. It is re-

markable that HEIDELTIME and CHRONO*, essentially rule-based systems, obtain better R than the Character-based baseline, that relies strongly on a supervised model. Specifically, HEIDELTIME obtains the best R (0.77), but CHRONO* also outperforms the Character-based baseline in terms of R , 0.75 vs 0.71. However, the Character-based baseline obtains a much higher P (0.83) than the 0.71 of HEIDELTIME and the 0.65 of CHRONO*.

As explained in Section 4, the metric for Track 1 evaluates the individual temporal components extracted by the systems, either time entities or links between time entity pairs. On the other hand, the intervals scored by the metric for Track 2 are produced by interpreting the whole graph. Moreover, not all the time expressions yield a finite set of bounded intervals, as can be seen in Table 1. Consequently, better performances in Track 1 do not necessarily yield better results in Track 2. In particular, although CHRONO* is better than the Character-based baseline in Track 1 it produces an excessive number of time expressions yielding bounded intervals (108), which affects the P in Track 2. In contrast, the Character-based baseline is more conservative and accurate in this respect (85).

Although we didn't receive any submission for the Clinical domain, in order to set a reference for future research, we present in Table 2 and Table 4 the performances of the baseline systems in this domain.

8 Conclusion

The Parsing Time Normalization task is the first effort to extend time normalization to richer and more complex time expressions. We have provided a complete annotation for two different domains, newswire and clinical notes, and introduced two different metrics for evaluation. In particular, the interval based evaluation for Track 2 is a novelty for these kind of tasks. The performance of the systems shows that there is still room for improvement, especially for Track 1.

Although, CHRONOS included a small supervised component in its architecture, we were expecting a higher number of machine learning based approaches. However, CHRONOS shows that rule-based models can obtain competitive results. Sadly, the scarcity of participating systems does not allow us to form a further judgment.

No submissions were received for the clinical

domain, despite a wider and more complete dataset for this domain. This was almost certainly the result of a change in management at the Mayo Clinic that put on hold the data use agreement process (which is required for access to the clinical data) for several months during the practice phase. Thus, though many people showed interest in the task (more than 40 people registered) and Mayo reported several data use agreement applications, this problem de-motivated the participation.

The CodaLab competition for the Parsing Time Normalizations shared task⁷ will continue to accept submissions in its Post-Evaluation phase indefinitely, so as more researchers make it through the data use agreement process, we expect we will see future participation in this task.

Abstract

Temporal information extraction is a challenging task. Here we describe Chrono, a hybrid rule-based and machine learning system that identifies temporal expressions in text and normalizes them into the SCATE schema. After minor parsing logic adjustments, Chrono has emerged as the top performing system for SemEval 2018 Task 6: Parsing Time Normalizations.

1 Introduction

Understanding and processing temporal information is vital for navigating life. The human mind processes subtle temporal expressions instantly and effortlessly; however, it is difficult for computers to do the same. Identifying, processing, and utilizing this information requires knowledge and understanding of syntax, semantics, and context to link temporal information to related events and order them on a time-line. SemEval 2018 Task 6 (Laparra et al., 2018) aims to normalize fine-grained temporal information and relationships into the Semantically Compositional Annotations for Temporal Expressions (SCATE) schema developed by (Bethard and Parker, 2016). This scheme aims to improve upon the current TIMEX3/TimeML (Pustejovsky et al., 2003) standard by representing a wide variety of temporal expressions, allowing for events to act as anchors, and using mathematical operations over a time-line to define the semantics of each annotation. To address this challenge, we developed Chrono¹, a hybrid rule-based and machine learning (ML) Python package that normalizes temporal expressions into the SCATE schema.

¹<https://github.com/AmyOlex/Chrono>

2 The Chrono System

Our approach to building this hybrid system includes four processing phases: 1) text pre-processing, 2) flagging numeric and temporal tokens, 3) temporal expression identification, and 4) SCATE normalization.

1) Text Pre-processing: Python’s Natural Language Toolkit (NLTK) WhitespaceTokenizer and part-of-speech (POS) tagger (Bird and Loper, 2004) process raw text files to identify individual tokens, token spans, and POS tags. Punctuation is not handled at this phase as it is important for identifying correct spans.

2) Flagging Numeric and Temporal Tokens: All numeric tokens are flagged regardless of context. Subsequent phases utilize contextual information to determine if a numeric token is part of a temporal expression. Depending on the task, a rule may remove all or some punctuation, and/or convert tokens to lowercase prior to parsing. In the following, RP and LC denote **Removing all Punctuation** and converting to **LowerCase**, respectively.

Numeric Flagging: Tokens are flagged as numeric if either 1) the token has a POS tag of “CD” (Cardinal Number), or 2) the text can be converted to a numeric expression. Textual representations of numeric expressions are converted to numerics with the Word2Number² Python module. A custom method recognizes ordinals from “first” to “thirty-first” and converts them into the associated numerics 1 to 31, respectively. LC normalization is done prior to parsing textual numerics.

Temporal Flagging: Temporal tokens are flagged through rule-based parsing using lists of key words and regular expressions. This phase is more liberal in its identification of a temporal token than the SCATE normalization phase, so

²<https://github.com/akshaynagpal/w2n>

it identifies a broader range of potential temporal tokens that are refined in future steps. Tokens may be numeric and temporal simultaneously. Numeric tokens with the characters ‘\$’, ‘#’, or ‘%’ are NOT marked as temporal. The following types of tokens are flagged as temporal:

- Formatted date patterns using ‘/’ or ‘-’: mm/dd/yyyy, mm/dd/yy, yyyy/mm/dd, or yy/mm/dd
- Formatted time patterns matching hh:mm:ss
- Sequence of 4 to 8 consecutive digits matching range criteria for 24-hour times or for a year, month, and/or day (e.g. 1998 or 08241998).
- Spelled out month or abbreviation, e.g. “Mar.” or “March”, are flagged after RP except periods as they are required to retrieve correct spans.
- Days of the week, e.g. “Sat.” or “Saturday”, are parsed similar to months.
- Temporal words indicating periods of time, e.g. “yesterday” or “decade”, are flagged after RP and LC.
- Mentions of AM and PM in any format are flagged after RP except periods.
- The parts of a week, e.g. “weekend” and “weekends”, are flagged after RP and LC.
- Seasons of the year are flagged after RP and LC.
- Various parts of a day, e.g. “noon” or “morning”, are flagged after RP and LC.
- Time zones are flagged after RP.
- Other temporal words, e.g. “this”, “now”, “nearly”, and others, are flagged after RP and LC.

3) Temporal Expression Identification: A temporal expression is represented by a *temporal phrase*, which we define as two or more consecutive temporal/numeric tokens on the same line, or an isolated temporal token, with some exceptions. If a numeric token contains a ‘\$’, ‘#’, or ‘%’, or the text ‘million’, ‘billion’, or ‘trillion’ it is not included in a temporal phrase as these generally refer to non-temporal values. Additionally, isolated numeric tokens are not considered a temporal phrase.

4) SCATE Normalization: Chrono parses each temporal phrase into zero or more SCATE entities, links sub-intervals, and disambiguates the SCATE entities “Period” and “Calendar-Interval” via a machine learning module. Chrono imple-

ments 32 types of entities with 5 parent types that have been described by (Bethard and Parker, 2016). Parsing strategies differ depending on the composition of a temporal phrase being parsed. Each temporal phrase is interrogated by all of the following parsing strategies.

Formatted Dates and Times: Formatted dates/times are parsed using regular expressions. To identify which format the date/time is in, Chrono looks for a 2-digit or 4-digit year first, then uses that position for orientation to identify the remaining elements. If a formatted date/time is identified, then the appropriate sub-intervals are linked during element parsing. 4-digit years take precedence over 2-digit years.

Numeric Dates and Times: Header and metadata for Newswire articles frequently have numeric dates listed with no punctuation (e.g. “19980218” codes for “Feb, 18 1998”), and isolated 4-digit year mentions are frequent. After formatted dates and times are parsed, any phrase containing a numeric token is interrogated for a potential date or year mention. If a numeric token is 4-digits it is tested for a year between 1500 and 2050, 6-digit tokens are parsed for 2-digit year/month/day, and 8-digit strings are parsed for a 4-digit year and 2-digit month/day. All elements must be in the proper range, otherwise the token is skipped. Appropriate sub-intervals are linked during element parsing.

24-hour Time: 24-hour times are identified by either the format *hhmmzzz*, where *zzz* is the time zone, or a 4-digit number that has not been classified as a year. Hour digits must be less than 24 and minutes less than 60. Sub-intervals are linked at this time if existing. Time zones are handled separately and are linked back to the hour entity during the final sub-interval linking step.

Temporal Token Search: The majority of textual temporal entities are identified by looking for specific tokens. Token categories include days of the week, months, parts of a day/week, time zones, and other temporal operators such as “early”, “this”, “before”, etc. Prior to looking for these tokens, text is normalized by RP and LC. Exceptions to RP include searching for day/month abbreviations, such as “Sat.” or “Aug.”. In these cases periods are not removed because they are part of the SCATE span. Another exception to RP and LC is identifying mentions of AM or PM where periods are kept and text is not converted to lowercase

in order to capture variations like “PM” or “p.m.”. Non-temporal mentions of the months or seasons of the year “may”, “march”, “spring”, and “fall” are disambiguated using POS tags, where tokens that refer to a temporal entity generally have a POS tag of “NN” or “NP”. Sub-intervals are not linked during token searches.

Text Year: Another special case of parsing temporal tokens are textual representations of years such as “nineteen ninety-seven”. The Word2Number Python module was modified to recognize these phrases. Previously, it would add 19 and 97 together instead of returning 1997.

Periods and Calendar-Intervals: The same temporal token can refer to either a SCATE “Period” or “Calendar-Interval”. For example, in the phrases “in a week” vs “next week” the token “week” is classified differently. Due to language intricacies it is difficult to define a rule-based system to disambiguate these entities as the classification is contingent on the topic being discussed where phrasing around the entity can be different for each instance. Thus, Period/Calendar-Interval tokens are initially identified by a token search using a defined list of terms, then the identified term and its span are passed to a ML algorithm for classification.

Machine Learning Classification: Four ML algorithms are available in Chrono to differentiate between “Period” and “Calendar-Interval” entities using contextual information. Chrono implements Naive Bayes (NB), Neural Network (NN), Decision Tree (DT), and Support Vector Machine (SVM). Binary feature vectors for all implementations have the following features:

- temporal_self: If the target is flagged as temporal, this feature is set to “1”.
- temporal_context: If there is at least one temporal word within a 5-word window up- or down-stream of the target this feature is set to “1”.
- numeric: If there is a numeric expression either directly before or after (a 1-word window) the target, this feature is set to “1”.
- context: All words within a 5-word window are identified as features and set to “1” if that word is present. Prior to identifying these features all words are normalized with RP and LC. The 5-word window includes crossing sentence boundaries before and after the target word.

We use NLTK with default parameters to implement NB and DT, NN is a simple feed-forward network with three hidden layers implemented using Python’s Keras package³ with epochs set to 5 and batch set to 10, and SVM is implemented using SciKitLearn (Pedregosa et al., 2011) with C set to 0.05 and max iterations set to 3.

Ordinals: Ordinals such as “first” or “3rd” are classified as an “NthFromStart” entity in the SCATE schema. These mentions are identified by normalizing with RP and LC before searching for the ordinal tokens representing the numbers 1-31.

Sub-Interval Linking: After all SCATE entities are identified, all temporal phrases are re-parsed to identify sub-intervals within each phrase. For example, entities in the phrase “August 1998” are parsed by two different methods leaving the sub-interval link vacant. During sub-interval linking, the year “1998” has the “August” entity added as a sub-interval. Sub-interval linking reviews entities from the smallest to the largest, adding missing sub-intervals as needed. This method assumes each temporal phrase contains zero or one of each type of SCATE entity.

Next/Last Parsing: Determining whether an entity is referring to a date in the future, “Next”, or past, “Last”, depends on context and the document time (doc-time). Next/Last parsing is done after all other parsing, and checks two cases: 1) if a temporal phrase contains a year, no additional annotation is made, and 2) if specific modifier words are present (e.g. “next” or “last”) immediately preceding a temporal expression, the modifier is annotated with a sub-interval referencing the following temporal entity. If neither of these cases hold, the year is set as the doc-time year, and the month and day are compared to the full doc-time to determine if it occurs before or after. Note the year assumption is not always valid and more complex, content-based parsing may be required to achieve higher precision. Finally, if a day of the week (e.g. “Saturday”) is mentioned, Chrono finds the first preceding verb in the sentence, and if it is past tense the temporal entity is annotated as “Last”, otherwise it is annotated as “Next”.

3 Results

Training and evaluation of Chrono utilizes the Newswire corpus, consisting of 81 documents, provided by the task organizers. Average preci-

³<https://github.com/keras-team/keras>

sion, recall, and F1-measure of 5-fold cross validation for Track 1 (parsing) are reported in Table 1 (annotations for “Event” and “Modifier” are ignored). Scores for “100% Correct Entity” consider the entity location and all properties (like sub-intervals), and scores for “Correct Span” only consider the entity location.

On average, all ML algorithms perform similarly for the “100% Correct Entity”. All versions also obtain a higher F1 score when only considering correct spans versus getting all entity properties correct. This indicates that Chrono correctly identifies the majority of temporal entities, but has trouble parsing some of the properties.

ChronoNN processed the final evaluation dataset, which consisted of 20 previously unseen Newswire articles, and received a F1 of .44. The evaluation dataset contained five articles from BBC that were not represented in the training dataset. Chrono’s low performance indicates that it may be over-fit to the the training dataset. This is one downfall of rule-based systems, where new rules need to be developed for each new type of temporal representation. Upon further review we found the submitted version of Chrono had three minor parsing flaws that resulted in unintentional false positives.

1) *Formatted dates* such as “2013-02-22” were being parsed twice. The first parse specifically looked for a 4-digit year and identified all correct entities, then the second parse looked for a formatted date with a 2-digit year, but didn’t check to see if a year had already been found, so returned a 2-digit year with the value “22”. This was easily fixed by having the 2-digit year parser check for a 4-digit year flag before proceeding (month and day flags were already implemented).

2) *24-hour time priority* was incorrectly placed above 4-digit year. This resulted in any isolated 4-digit year being parsed as a 24-hour time expression rather than a year as originally intended. A simple flip of parsing order resolved this issue.

3) *Numeric temporal expressions*, such as an isolated 4-digit year, were being parsed as a whole phrase rather than breaking out each token within the phrase. For example, the year in the phrase “Last 1953” was not being identified because it was not in a phrase all by itself. To fix this the parsing function was edited to loop through each token in a phrase (a method that was already implemented in most other parsers and was just over-

100% Correct Entity			
	P	R	F1

looked here).

ChronoNN received a Post-Evaluation F1 of .55 for Track 1 after implementing these fixes, which sets ChronoNN as the top performing system for SemEval 2018 Task 6, Track 1.

4 Conclusions and Future Work

Chrono is currently the top performing system for Track 1 of Task 6, but there are still many areas that can be improved. Notably, we plan to implement “Event” and “Between” parsing, as well as refine current strategies as new temporal expressions are identified. Utilizing sentence tokenization instead of relying on new lines could improve phrase identification; however, this did not appear to be a major source of error in parsing the Newswire dataset. Additionally, usability can be improved by moving all parsing rules to separate, customizable files. We also plan to expand ML use to additional disambiguation tasks, and implement an ensemble system utilizing all four ML methods. We aim to extract the temporal phrase parser into a stand-alone system and compare it’s performance directly to existing programs like SUTime (Chang and Manning, 2012) and HeidelTime (Strtgen and Gertz, 2010) as it has done a decent job of identifying temporal entities in this challenge. Finally, we will evaluate Chrono’s performance on the THYME dataset (Styler IV et al., 2014) using the post-evaluation submission system.

NEUROSENT-PDI at SemEval-2018 Task 1: Leveraging a Multi-Domain Sentiment Model for Inferring Polarity in Micro-blog Text

Mauro Dragoni

Fondazione Bruno Kessler

Via Sommarive 18

Povo, Trento, Italy

dragoni@fbk.eu

Abstract

This paper describes the NeuroSent system that participated in SemEval 2018 Task 1. Our system takes a supervised approach that builds on neural networks and word embeddings. Word embeddings were built by starting from a repository of user generated reviews. Thus, they are specific for sentiment analysis tasks. Then, tweets are converted in the corresponding vector representation and given as input to the neural network with the aim of learning the different semantics contained in each emotion taken into account by the SemEval task. The output layer has been adapted based on the characteristics of each subtask. Preliminary results obtained on the provided training set are encouraging for pursuing the investigation into this direction.

1 Introduction

Sentiment Analysis is a natural language processing (NLP) task (Dragoni et al., 2015) which aims at classifying documents according to the opinion expressed about a given subject (Federici and Dragoni, 2016a,b). Many works available in the literature address the sentiment analysis problem without distinguishing domain specific information of documents when sentiment models are built. The necessity of investigating this problem from a multi-domain perspective is led by the different influence that a term might have in different contexts. The idea of adapting terms polarity to different domains emerged only in the last decade (Blitzer et al., 2007; Dragoni and Petrucci, 2017). Multi-domain sentiment analysis approaches discussed in the literature focus on building models for transferring information between pairs of domains (Dragoni, 2015; Petrucci and Dragoni, 2015). While on the one hand such approaches allow to propagate specific domain information to others, their drawback is the neces-

sity of building new transfer models every time a new domain has to be analyzed. Thus, such approaches do not have a great generalization capability of analyzing texts, because transfer models are limited to the N domains used for building the models.

The NeuroSent tool applied in SemEval 2018 Task 1 (Mohammad et al., 2018) leverages on the following pillars: (i) the use of word embeddings for representing each word contained in raw sentences; (ii) the word embeddings are generated from an opinion-based corpus instead of a general purpose one (like news or Wikipedia); (iii) the design of a deep learning technique exploiting the generated word embeddings for training the sentiment model; and (iv) the use of multiple output layers for combining domain overlap scores with domain-specific polarity predictions.

The last point enables the exploitation of linguistic overlaps between domains, which can be considered one of the pivotal assets of our approach. This way, the overall polarity of a document is computed by aggregating, for each domain, the domain-specific polarity value multiplied by a belonging degree representing the overlap between the embedded representation of the whole document and the domain itself. Within the SemEval 2018 Task 1 challenge, we consider with the term *domain* one of the emotions that have been considered into the provided datasets.

2 Related Work

Sentiment analysis from the multi-task and multi-domain perspective is a research field which started to be explored only in the last decade. According to the nomenclature widely used in the literature (see (Blitzer et al., 2007; Dragoni and Petrucci, 2017)), we call *domain* a set of documents about similar topics, e.g. a set of reviews

about similar products like mobile phones, books, movies, etc.. The massive availability of multi-domain corpora in which similar opinions are expressed about different topics opened the scenario for new challenges. Researchers tried to train models capable to acquire knowledge from a specific domain and then to exploit such a knowledge for working on documents belonging to different ones. This strategy was called domain adaptation. The use of domain adaptation techniques demonstrated that opinion classification is highly sensitive to the domain from which the training data is extracted. The reason is that when using the same words, and even the same language constructs, we may obtain different opinions, depending on the domain. The classic scenario occurs when the same word has positive connotations in one domain and negative connotations in another one, as we showed within the examples presented in Section 1.

Several approaches related to multi-domain sentiment analysis have been proposed. Roughly speaking, all of these approaches rely on one of the following ideas: (i) the transfer of learned classifiers across different domains (Blitzer et al., 2007; Pan et al., 2010; Bollegala et al., August 2013; Xia et al., May-June 2013), and (ii) the use of propagation of labels through graph structures (Ponomareva and Thelwall, 2013; Tsai et al., March 2013; Dragoni et al., April 2015; Dragoni, 2015, 2017; Petrucci and Dragoni, 2017, 2016, 2015; Dragoni et al., 2014; Dragoni and Petrucci, 2018).

While on the one hand such approaches demonstrated their effectiveness in working in a multi-domain environment, on the other hand they suffered by the limitation of being influenced by the linguistic overlap between domains. Indeed, such an overlap leads learning algorithms to infer similar polarity values to domains that are similar from the linguistic perspective.

The adoption of evolutionary algorithms within the sentiment analysis research field is quite recent. First studies focused on the use of evolutionary solutions for modeling financial indicators by starting from investors sentiments (Yamada and Ueda, 2005; Chen and Chang, 2005; Huang et al., 2012; Yang et al., 2017; Simoes et al., 2017). Here, the evolutionary component was used for learning the trend of financial indicators with respect to the sentiment information extracted from opinions provided by the investors. With respect

to these papers, we propose an approach adopting evolutionary computation to a more fine-grained level where the evolution component affects also the polarities of opinion concepts.

Studies considering the use of evolutionary algorithms for optimizing the polarity values of opinion concepts have been proposed only recently (Ferreira et al., 2015; Onan et al., 2016, 2017). However, these works focused on learning candidate refinements of opinion concepts polarity without considering the context dimension associated with them. A variant of this problem is the use of polarity adaptation strategy in the field of social media and microblogs (Alahmadi and Zeng, 2015; Wang et al., 2014; Keshavarz and Abadeh, 2017; Hu et al., 2016; Fu et al., 2016; Gong et al., 2016).

With respect to state of the art, this work represents the first exploration of evolutionary algorithms for multi-domain sentiment analysis with the aim of learning multiple dictionaries of opinion concepts. Moreover, we differ from the literature by do not considering the propagation of polarity information across domain (i.e., we keep them completely separated) in order to avoid transfer learning drawbacks.

3 System Implementation

NeuroSent has been entirely developed in Java with the support of the Deeplearning4j library¹ and it is composed by following two main phases:

- Generation of Word vectors (Section 3.1): raw text, appropriately tokenized using the Stanford CoreNLP Toolkit, is provided as input to a 2-layers neural network implementing the skip-gram approach with the aim of generating word vectors.
- Learning of Sentiment Model (Section 3.2): word vectors are used for training a recurrent neural network with an output layer customized based on the addressed subtask. The customizations have been explained in Section 4.

In the following subsections, we describe in more detail each phase by providing also the settings used for managing our data.

3.1 Generation of Word Vectors

The generation of the word vectors has been performed by applying the skip-gram algorithm on

¹<https://deeplearning4j.org/>

the raw natural language text extracted from the smaller version of the SNAP dataset (McAuley and Leskovec, 2013). The rationale behind the choice of this dataset focuses on three reasons:

- the dataset contains only opinion-based documents. This way, we are able to build word embeddings describing only opinion-based contexts.
- the dataset is multi-domain. Information contained into the generated word embeddings comes from specific domains, thus it is possible to evaluate how the proposed approach is general by testing the performance of the created model on test sets containing documents coming from the domains used for building the model or from other domains.
- the dataset is smaller with respect to other corpora used in the literature for building other word embeddings that are currently freely available, like the Google News ones.² Indeed, as introduced in Section 1, one of our goal is to demonstrate how we can leverage the use of dedicated resources for generating word embeddings, instead of corpora's size, for improving the effectiveness of classification systems.

The aspect of considering only opinion-based information for generating word embeddings is one of the peculiarity of our system. While embeddings currently available are created from big corpora of general purpose texts (like news archives or Wikipedia pages), ours are generated by using a smaller corpus containing documents strongly related to the problem that the model will be thought for. On the one hand, this aspect may be considered a limitation of the proposed solution due to the requirement of training a new model in case of problem change. However, on the other hand, the usage of dedicated resources would lead to the construction of more effective models.

Word embeddings have been generated by the Word2Vec implementation integrated into the Deeplearning4j library. The algorithm has been set up with the following parameters: the size of the vector to 64, the size of the window used as input of the skip-gram algorithm to 5, and the minimum word frequency was set to 1. The reason for

²<https://github.com/mmihaltz/word2vec-GoogleNews-vectors>

which we kept the minimum word frequency set to 1 is to avoid the loss of rare but important words that can occur in domain specific documents.

3.2 Learning of The Sentiment Model

The sentiment model is built by starting from the word embeddings generated during the previous phase.

The first step consists in converting each textual sentence contained within the dataset into the corresponding numerical matrix \mathbf{S} where we have in each row the word vector representing a single word of the sentence, and in each column an embedding feature. Given a sentence s , we extract all tokens t_i , with $i \in [0, n]$, and we replace each t_i with the corresponding embedding \mathbf{w} . During the conversion of each word in its corresponding embedding, if such embedding is not found, the word is discarded. At the end of this step, each sentence contained in the training set is converted in a matrix $\mathbf{S} = [\mathbf{w}^{(1)}, \dots, \mathbf{w}^{(n)}]$.

Before giving all matrices as input to the neural network, we need to include both padding and masking vectors in order to train our model correctly. Padding and masking allows us to support different training situations depending on the number of the input vectors and on the number of predictions that the network has to provide at each time step. In our scenario, we work in a many-to-one situation where our neural network has to provide one prediction (sentence polarity and domain overlap) as result of the analysis of many input vectors (word embeddings).

Padding vectors are required because we have to deal with the different length of sentences. Indeed, the neural network needs to know the number of time steps that the input layer has to import. This problem is solved by including, if necessary, into each matrix \mathbf{S}_k , with $k \in [0, z]$ and z the number of sentences contained in the training set, null word vectors that are used for filling empty word's slots. These null vectors are accompanied by a further vector telling to the neural network if data contained in a specific positions has to be considered as an informative embedding or not.

A final note concerns the back propagation of the error. Training recurrent neural networks can be quite computationally demanding in cases when each training instance is composed by many time steps. A possible optimization is the use of truncated back propagation through time (BPTT)

that was developed for reducing the computational complexity of each parameter update in a recurrent neural network. On the one hand, this strategy allows to reduce the time needed for training our model. However, on the other hand, there is the risk of not flowing backward the gradients for the full unrolled network. This prevents the full update of all network parameters. For this reason, even if we work with recurrent neural networks, we decided to do not implement a BPTT approach but to use the default backpropagation implemented into the DL4J library.

Concerning information about network structure, the input layer was composed by 64 neurons (i.e. embedding vector size), the hidden RNN layer was composed by 128 nodes, and the output layers with a different number of nodes based on the addressed subtask. The network has been trained by using the Stochastic Gradient Descent with 1000 epochs and a learning rate of 0.002.

4 The Tasks

The SemEval 2018 Task 1 is composed by a set of five subtasks aiming to attract systems able to automatically determine the intensity of emotions and the intensity of sentiment of tweets' authors. Then, organizers included also a multi-label emotion classification task for tweets. For each task, there were provide separate training and test datasets for four languages: English, Arabic, and Spanish. The proposed system implements a strategy only for the English language. Below, we provide a summary of the five subtasks including how we configured the output layer of our neural network.

Subtask #1: EI-reg Given a tweet and an emotion E , the system has to determine the intensity of E that best represents the mental state of the tweet's author by providing a real-valued score between 0 and 1. Here, four emotions are considered: anger, fear, joy, and sadness. Separated datasets have been provided for training the system. The output layer of our neural network is composed by a single neuron implementing the SIGMOID activation function.

Subtask #2: EI-oc Given a tweet and an emotion E , the system has to classify the tweet into one of four ordinal classes of intensity of E that best represents the mental state of the tweet's author. Also here, four emotions are considered:

anger, fear, joy, and sadness. Separated datasets have been provided for training the system. The output layer of our neural network is composed by four neurons and the SOFTMAX strategy has been implemented for selecting the most candidate emotion intensity class.

Subtask #3: V-reg Given a tweet, the system has to determine the valence of a sentiment that best represents the mental state of tweet's author by providing a real-valued score between 0 and 1. The output layer of our neural network is composed by a single neuron implementing the SIGMOID activation function.

Subtask #4: V-oc Given a tweet, the system has to classify it into one of seven ordinal classes (from -3 to 3) corresponding to various levels of positive and negative sentiment intensity. The output layer of our neural network is composed by seven neurons and the SOFTMAX strategy has been implemented for selecting the most candidate emotion intensity class.

Subtask #5: E-c Given a tweet, the system has to classify it as a *neutral*, or *no emotion* or as one, or more, of eleven given emotions that best represent the mental state of the tweet's author. The eleven emotions are: anger, anticipation, disgust, fear, joy, love, optimism, pessimism, sadness, surprise, and trust. The output layer of our neural network is composed by eleven neurons implementing the SIGMOID activation function. This way, each emotion has been managed separately.

The NeuroSent system has been applied to all five subtasks. In Section 5, we report the preliminary results obtained by NeuroSent on the training set compared with a set of baselines.

5 In-Vitro Evaluation

The NeuroSent approach have been preliminarily evaluated by adopting the Dranziera protocol (Dragoni et al., 2016).

The validation procedure leverages on a five-fold cross evaluation setting in order to validate the robustness of the proposed solution. The approach has been compared with four baselines: Support Vector Machine (SVM) (Chang and Lin, 2011), Naive Bayes (NB) and Maximum Entropy (ME) (McCallum, 2002), and Convolutional Neural Network (Chaturvedi et al., 2016).

In Table 1, we provide for subtasks two, four, and five the average Pearson correlation obtained

Approach	Task #1.1	Task #1.2	Task #1.3	Task #1.4	Task #1.5
Support Vector Machine	0.3189	0.4890	0.3698	0.5145	0.3498
Naive-Bayes	0.2944	0.4956	0.3544	0.5387	0.4167
Maximum Entropy	0.2765	0.5073	0.3025	0.5777	0.4178
CNN Architecture	0.2433	0.6037	0.2466	0.5895	0.5487
NeuroSent	0.2187	0.6687	0.2079	0.6241	0.5814

Table 1: Results obtained on the training set by NeuroSent and by the four baselines.

on the five folds in which the training set has been split. While, for subtasks one and three, we provide the average mean square error.

The obtained results demonstrated the suitability of NeuroSent with respect to the adopted baselines. We may also observe how solutions based on neural networks obtained a significant improvement with respect to the others for the Tasks #1.2 and #1.4.

Then, for Tasks #1.2, #1.4, and #1.5, we performed a detailed error analysis concerning the performance of NeuroSent. In general, we observed how our strategy tends to provide false negative predictions. An in depth analysis of some incorrect predictions highlighted that the embedded representations of some positive opinion words are very close to the space region of negative opinion words. Even if we may state that the confidence about positive predictions is very high, this scenario leads to have a predominant negative classification for borderline instances.

On the one hand, a possible action for improving the effectiveness our strategy is to increase the granularity of the embeddings (i.e. augmenting the size of the embedding vectors) in order to increase the distance between the positive and negative polarities space regions. On the other hand, by increasing the size of embedding vectors, the computational time for building, or updating, the model and for evaluating a single instance increases as well. Part of the future work, will be the analysis of more efficient neural network architectures able to manage augmented embedding vectors without negatively affecting the efficiency of the platform.

6 Conclusion

In this paper, we described the NeuroSent system presented at SemEval 2018 Task 1. Our system makes use of artificial neural networks to classify tweets by polarity or for detecting emotion levels. The results obtained on the training set

demonstrated that the adopted solution is promising and worthy of investigation. Therefore, future work will focus on improving the system by exploring the integration of sentiment knowledge bases (Dragoni et al., 2015) in order to move toward a more cognitive approach.

FOI DSS at SemEval-2018 Task 1: Combining LSTM States, Embeddings, and Lexical Features for Affect Analysis

Maja Karasalo Mattias Nilsson Magnus Rosell Ulrika Wickenberg Bolin

FOI - Swedish Defence Research Agency

{majkar, matnil, magros, ulrwic}@foi.se

Abstract

This paper describes the system used and results obtained for team FOI DSS at SemEval-2018 Task 1: Affect In Tweets. The team participated in all English language subtasks, with a method utilizing transfer learning from LSTM nets trained on large sentiment datasets combined with embeddings and lexical features. For four out of five subtasks, the system performed in the range of 92-95% of the winning systems, in terms of the competition metrics. Analysis of the results suggests that improved pre-processing and addition of more lexical features may further elevate performance.

1 Introduction

In the field of automatic emotion detection, many contributions consider the issue of detecting presence of emotions (Liu, 2012). The task of detecting intensity of emotion in a given text is less studied, but is relevant to many applications in fields such as e.g., brand management, public health, politics, and disaster handling (Mohammad, 2016). When developing prediction systems, access to suitably annotated data is critical. Most annotated emotion and affect datasets are categorical, but examples of sets annotated with intensity or degree of emotional content include EmoBank (Buechel and Hahn, 2017a,b), AFINN (Nielsen, 2011), the Pietro Facebook post set (Preoŕiuc-Pietro et al., 2016), and the Warriner-Kuperman set (Warriner et al., 2013). For tweets, the Tweet Emotion Intensity Dataset (Mohammad and Bravo-Marquez, 2017) has recently been published, with more than 7000 tweets annotated with emotion category and intensity.

This paper describes methods used and results achieved with the FOI DSS contribution to the five subtasks for English tweets of SemEval 2018 Task 1: Affect in Tweets (Mohammad et al., 2018).

The paper is organized as follows. A description of Task 1 is provided in Section 2. Section 3 discusses the provided datasets. Section 4 describes the methods and system used to produce predictions of scores and labels for all subtasks. In Sections 5 and 6 results are presented and analyzed, and suggestions for improvements are outlined. Finally, concluding remarks are found in Section 7.

2 Task formulation

Task 1 consisted of five subtasks, all regarding estimation of the mental state of a tweeter, based on the tweeted text. Valence¹ intensity, as well as emotion, and emotion intensity classification, were covered. The subtasks are summarized below:

1. **Emotion intensity regression (EI-reg):** For a given tweet and emotion², determine the intensity of the emotion as a score $\in [0, 1]$.
2. **Emotion intensity, ordinal classification (EI-oc):** For a given tweet and emotion², classify the tweet into one of four ordinal classes of intensity.
3. **Valence regression (V-reg):** For a given tweet, determine the intensity of valence as a score $\in [0, 1]$.
4. **Valence, ordinal classification (V-oc):** For a given tweet, classify it into one of seven ordinal classes corresponding to levels of positive and negative intensity.
5. **Multi-label emotion classification (E-c):** For a given tweet and eleven emotions³, classify the tweet as neutral, or expressing one or more of the emotions.

¹The intrinsic attractiveness (positive valence) or averseness (negative valence) of an event, object, or situation (Frijda, 1986).

²anger, joy, fear or sadness.

³anger, anticipation, disgust, fear, joy, love, optimism, pessimism, sadness, surprise and trust.

Subtask	Train	Val.	Test
EI anger	1701	388	1002
EI fear	2252	389	986
EI joy	1616	290	1105
EI sadness	1533	397	975
V	1181	449	937
E-c	6838	886	3259

Table 1: Number of tweets in the datasets for different subtasks. The sets for EI-reg and EI-oc were identical, as was also the case for V-reg and V-oc.

3 Data

The dataset made available for Task 1 was the AIT Dataset (Mohammad and Kiritchenko, 2018). For each subtask, labeled datasets for training and validation were released for the prediction system development phase. Intensity scores were roughly normally distributed, and ordinal classes were defined as intervals for the scores. Unlabeled test data was later released for the evaluation phase. Table 1 gives a brief overview of the data. Details on the data and annotation can be found in (Mohammad et al., 2018) and (Mohammad and Kiritchenko, 2018).

In addition to the test data, an unlabeled "mystery" set of 16937 short texts was provided for the regression subtasks. The task organizers asked that participants in these subtasks use their existing systems to produce predictions for the mystery set as well, and the results were used to perform a bias analysis. This is further discussed in Section 5.4.

4 Method

Initially, the team focused on Subtask 4 (V-reg). Several different approaches were explored, and evaluated using the official competition metric, the Pearson Correlation Coefficient (PCC) with gold ratings. The combination of methods found to have the best performance on the V-reg task was chosen. The approach is described in Sections 4.1 - 4.3. Contributions to Subtasks 1, 2, 3 and 5 were constructed by altering the final stage model to fit each task, and tuning the hyperparameters for best performance.

4.1 Pre-processing

We performed some rudimentary pre-processing of the tweets prior to feature extraction. Following the findings reported in (Zhao, 2015) we ex-

panded negations such as "can't" and "n't" etc., into "cannot" and "not". The hashtag character # was also removed and we replaced user names and links with "usr" and "http://url", respectively. We finally mapped unicoded emoticons into their associated emoticon text description⁴.

4.2 Feature Extraction

The small amount of labeled data prevented us from automatically discovering optimal features for the different tasks. Instead, we utilized transfer learning techniques (i.e., reusing a model trained on a different but related task where more data is available) and classical natural language processing features. Three different methods were used to extract features from the tweet sets; two using variants of Long Short-Term Memory (LSTM) nets obtained by training on large sentiment datasets and extracting the internal model states, and one utilizing the Weka Affective Tweets package. The feature vectors from each of the methods described below were then concatenated to form one 5265 dimensional feature vector for each tweet.

4.2.1 Sentiment Neuron

In (Radford et al., 2017), the authors consider the problem of predicting the next character in a text given the preceding characters. More specifically, they predict next byte (each UTF-8 encoded character constitutes one to four bytes) from the previous bytes using a single layer multiplicative LSTM (Krause et al., 2016) with 4096 states. The model was trained using 82 million Amazon product reviews amounting to 38 billion bytes of training data. The authors show state-of-the-art (or close to state-of-the-art) sentiment classification performance on four different datasets when training a logistic regression classifier with the model's states as feature vector. Because of the reported strong predictive quality of the model's state we used that as one of the feature vectors for our method. We used the authors code for feature extraction available on github⁵.

4.2.2 Bidirectional-LSTM

Tweets can often be quite different from typical text seen in novels, news, or product reviews.

⁴<https://apps.timwhitlock.info/emoji/tables/unicode#block-6a-additional-emoticons>

⁵<https://github.com/openai/generating-reviews-discovering-sentiment>

The short messages commonly contain intentional misspelling to express affects (e.g., happpppyy), hashtags (e.g., #love), and emoticons (e.g., :-)). One option to capture the specific characteristics of tweets would be to fine-tune the sentiment neuron model described in the previous section using twitter data. We did not explore this direction in this work. Instead, in an attempt to directly capture affects, we trained (from scratch) a bidirectional LSTM on a sentiment labeled (two classes; positive and negative sentiment) twitter dataset⁶. The dataset contains 1.5 million tweets and we used 90% for training and 10% for validation. We used a bidirectional LSTM with 512 states in each direction (1024 in total). The input characters were first mapped to integers and subsequently fed to the embedding front-end (where an integer to a dense 64 dimensional embedding is learned) of the bidirectional LSTM. A dropout of 50% was used during the training for the sentiment prediction. The model achieves approximately 85% classification accuracy on the validation set. Similar to the sentiment neuron’s multiplicative LSTM we use the bidirectional LSTM’s state as a feature vector.

4.2.3 Weka Affective Tweets filters

A combination of tweet-level filters from the Weka Affective Tweets package (Mohammad and Bravo-Marquez, 2017) was used as the third part of the feature extraction method. These filters produce embeddings and lexical features, e.g. counts of positive and negative sentiment words, from systems such as the NRC-Canada System⁷.

To evaluate contributions from different filters, the final stage model (Section 4.3) was run using their resulting feature vectors for the V-reg dataset as input. For combinations of filters, the resulting feature vectors were concatenated and run through the final stage model. Details of this evaluation can be found in Section 5.1

4.3 Final stage

For each of the different subtasks we trained a fully connected neural network with two hidden layers mapping the input feature vector (i.e., the concatenation of the feature vectors described in Sections 4.2.1 - 4.2.3) to the target value, class, or

⁶<http://thinknook.com/twitter-sentiment-analysis-training-corpus-dataset-2012-09-22/>

⁷<http://saifmohammad.com/WebPages/NRC-Canada-Sentiment.htm>

classes. The activation function for the two hidden layers was *tanh* and the activation functions for the output layer were set to linear, softmax, and sigmoid for the V-reg/EI-reg, V-oc/EI-oc, and E-c subtasks, respectively.

The Adam optimizer (Kingma and Ba, 2015) was used for the classification subtasks with categorical cross-entropy loss for the V-oc/EI-oc subtasks and binary cross-entropy loss for the E-c subtask. For the regression subtasks of V-reg and EI-reg we used mean squared error as loss function and the ADADELTA optimizer (Zeiler, 2012). However, the performance difference between Adam and ADADELTA was minor in our regression subtasks.

We used L2-regularization on the parameters of the hidden layers. For each subtask, the hyper-parameters (i.e., the penalty and the layer sizes) of the neural network were found by a grid search evaluating the PCC (or the Jaccard similarity score for E-c subtask) on the validation data.

The hyper-parameter search range was [0.001, 0.05] for the penalty and [5, 80] for the two layer sizes. Many configurations with quite different hyper-parameter values resulted in very similar scores. E.g., for the V-reg subtask the configurations⁸ (0.03,10,15), (0.03,15,40), and (0.0096,70,35) all resulted in PCCs in the range 0.841-0.846.

5 Results

In this section we present a performance analysis of the set of features used, as well as results on the different subtasks.

5.1 Feature evaluation

To assess the quality of the feature vectors described in Section 4.2 we computed the PCC on the V-reg subtask using the validation data. For each set of features listed in Table 2 we performed a hyper-parameter search to find the parameters of the final stage model maximizing the PCC (cf. Section 4.3).

As seen in Table 2 the features provided by the Weka Affective Tweets package have the strongest individual predictive power. From the Weka filters, the feature combination chosen to be included in the combined method was $W_E + W_{SS} + W_L$, which produced the highest PCC during evaluation.

⁸configuration = (penalty, layer 1 size, layer 2 size)

Features	PCC
Weka	
TweetToEmbeddings (W_E) ⁹	0.665
TweetToEmbeddings 400 (W_{E400}) ¹⁰	0.702
TweetToSentiStrength (W_{SS})	0.675
TweetToLexicon (W_L)	0.790
TweetToInputLexicon (W_{IL})	0.687
$W_E + W_{SS} + W_L$	0.800
$W_E + W_{SS} + W_L + W_{IL}$	0.797
$W_{E400} + W_{SS} + W_L$	0.795
Sentiment Neuron (SN)	0.767
Bi-LSTM	0.738
SN + Bi-LSTM	0.818
Bi-LSTM + $W_E + W_{SS} + W_L$	0.820
SN + $W_E + W_{SS} + W_L$	0.838
SN + Bi-LSTM + $W_E + W_{SS} + W_L$	0.846

Table 2: **V-reg validation set:** PCC of valence intensity score predictions with gold scores for the different feature vector combinations.

Although the sentiment neuron is not trained on Twitter specific data it still shows good performance. The bidirectional LSTM has the weakest performance but still has a positive impact on the final score.

5.2 Results on validation and test data

The official competition metric was PCC for Subtasks 1-4, but as Subtask 5 was a multi-label classification task, the metric used was multi label accuracy, or Jaccard similarity score. The PCC/Jaccard similarity score for validation and test data for the FOI DSS system is presented in Table 3. For the regression tasks, the system’s performance on the test data is close to the validation data results. For the classification tasks, the gap between validation and test scores is somewhat larger, indicating that the model may be biased for the validation data.

The team’s ranking in different subtasks varied from 6 (out of 46 and 35 teams, respectively) for EI-reg and V-oc, to 11 of 37 for EI-oc. For Subtasks 1,3,4, and 5 the scores of our system was in the range of 92-95 % of the winning result on each subtask. The weakest performance was observed on Subtask 2 (EI-oc), with a PCC corresponding

⁹The TweetToEmbeddingsFeatureVector filter using embeddings trained from the small default corpus, yielding a 100-dimensional feature vector. <https://affectivetweets.cms.waikato.ac.nz>.

¹⁰The TweetToEmbeddingsFeatureVector filter using embeddings trained from the 10 million tweets of the Edinburgh corpus (Petrović et al., 2010), yielding a 400-dimensional feature vector.

Subtask	Validation	Test	Baseline (Test)
EI-reg	0.739	0.737	0.520
EI-oc	0.636	0.590	0.394
V-reg	0.846	0.831	0.585
V-oc	0.818	0.777	0.509
E-c	0.554	0.544	0.442

to 84 % of winning PCC. Figure 1 shows results of the FOI DSS system compared to mean, median and max competition results for test data on all English subtasks.

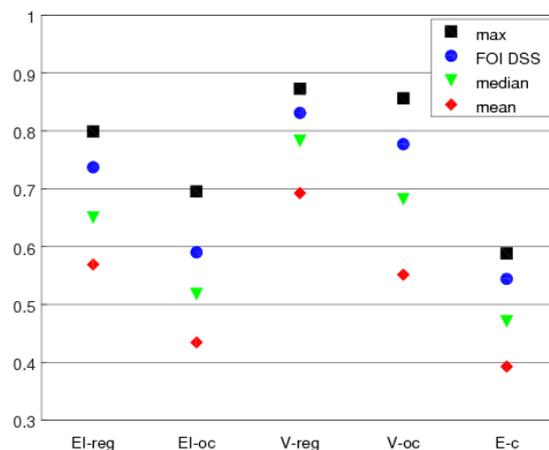

Figure 1: PCC/Jaccard similarity score of test data score and label predictions with gold scores and labels for all English subtasks. FOI DSS results compared to mean, median and max results for all participating teams.

5.3 Error analysis on the V-reg subtask

As already mentioned, our method achieved a PCC of 0.831 for the V-reg subtask on the test data. Figure 2 shows the corresponding scatter plot of the estimated and gold valence. To get some insight into potential future improvements of our system it is of interest to do analysis of tweets having poor valence estimates.

Some of the tweets from the validation and test datasets with large absolute error between the estimated and gold valence are listed in Table 4. For the first validation set tweet our method predicted a fairly low valence whereas the gold score is fairly high. A possible explanation could be that our system has problems with the constructions

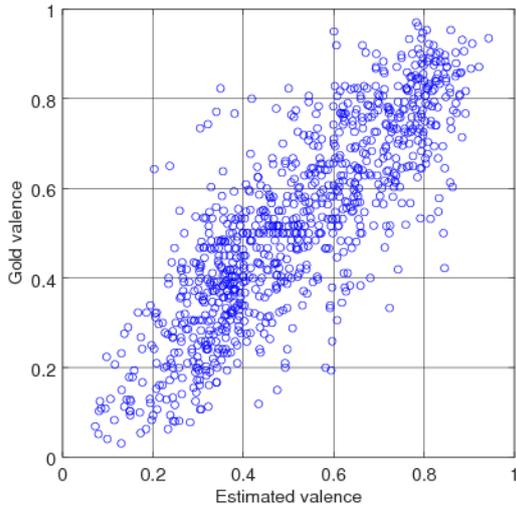

Figure 2: Scatter plot showing the estimated versus gold valence for the V-reg test dataset.

and concatenations such as B4, Thankful4all, and ImWakingUpHappyNot. Especially not properly splitting the last concatenation leaves the end of the tweet "dreading the day" which should result in a low valence.

The emoticon of the second validation tweet, `\xF0\x9F\x98\xA4`, is interesting. It depicts a face with steam coming out of the nostrils, which clearly signals anger, but the mapping⁴ we used describes it (wrongly according to us) as "face with look of triumph". In the third tweet we failed to map the emoticon `\xF0\x9F\xA4\xA3` to words. The emoticon shows some sort of laughing creature.

The top two test set tweets in Table 4 had the largest prediction errors for this set. They were both predicted to have a lower valence than the gold score. Interestingly, they both contain the hashtag #blessed and include constructions using the word *not*, where, if the negation is missed, the sentiment of the tweet would change from positive to negative. Possibly, our method has trouble correctly interpreting the negation and also has failed to award enough importance to the positive sentiment word *blessed*. Since our pre-processing involved removing hashtag character #, added intensity expressed this way will not be captured.

Finally, the third test set tweet had a high predicted valence but a low gold score. This text contains both negative words and phrases such as *nervous* and *I could puke*, but also expresses laughter. It would seem our method has deemed the latter a marker of high valence, while a human reader

would probably interpret it as a nervous laughter, thus low valence, considering the context provided by the tweet as a whole.

5.4 Mystery dataset and bias analysis

An analysis for inappropriate gender and race bias in scoring and classifications was performed by the task organizers for the "mystery" dataset (Section 3). For most teams, the bias was small (below 3%) but statistically significant, in part likely due to biases in the AIT dataset. For the FOI DSS system, the biases were below average for EI-joy, EI-sadness and valence, and 1% or less for all datasets except gender bias for EI-fear (2.3%). Biases in the datasets used to train our LSTM models as well as in the lexicons used to extract lexical features may have contributed to biases in scoring and classification.

6 Discussion

Designing high performance regression and classification algorithms using only a small amount of labeled data is always a challenge. The variability in tweets is enormous, and thus, there is a major risk of over-fitting when designing and tuning the algorithms on the the very limited labeled datasets provided for the competition. We used transfer learning and classical NLP features to alleviate the problem. We believe further improvements can be made by reducing the noise of the dataset, features, and final prediction. In the following, we discuss some of these ideas.

6.1 Pre-processing extensions

The error analysis in Section 5.3 indicates that the performance of our method could be improved by extending and refining the pre-processing. Splitting concatenations into separate words and addressing some common abbreviations would be one extension. Adjusting the emoticon lookup tables would be another.

6.2 Weka filter combinations: robustness

The combination of Weka Affective Tweets filters used in the FOI DSS system, $W_E + W_{SS} + W_L$, achieved the highest PCC during evaluation (Section 5.1). However, as results for neural networks are hard to reproduce, it should be examined what combinations of filters on average perform better. Initial findings from two such evaluations conducted after the end of the competition are reported in this section:

Dataset	Tweet	Pred.	Gold
Validation	B4 I couldnt get out of bed or look in mirror Thankful4all the support I have recieved here ImWakingUpHappyNot dreading theday	0.303	0.734
	3 and a half hour more \xF0\x9F\x98\xA4 #EXO	0.603	0.250
	@TheEllenShow I follow you bc your TV show keeps me laughing \xF0\x9F\xA4\xA3. When you #startle your guest sitting on that couch...booo...	0.461	0.783
Test	i'll have my own apartment and not have to sneak alcohol into my dorm room or worry about being loud #blessed	0.349	0.823
	mum got out of a rilly bad car crash completely not injured and i found a rilly sentimental piece of jewellery i thought i'd lost #blessed	0.203	0.643
	I'm so nervous I could puke + my body temp is rising ha ha ha ha ha	0.845	0.422

Table 4: Tweets with large prediction errors for the valence validation and test sets.

1. W_{E400} : When used on their own, the W_{E400} filter, which utilizes a much larger corpus¹⁰, outperforms W_E (Table 2). Therefore it is of interest to compare performance of the two filters combined with W_{SS} and W_L .
2. W_{IL} : Using its default lexicon¹¹, W_{IL} produces 4-dimensional feature vectors. We wanted to investigate whether contributions from W_{IL} on average increases performance.

The different vector combinations were input to the final stage model (Section 4.3) for 486 different hyper-parameter configurations, and the resulting PCC scores were compared. For 59% of the configurations, $W_E + W_{SS} + W_L$ still performed better than $W_{E400} + W_{SS} + W_L$. It would therefore seem that the loss of features captured by the larger W_{E400} vector is compensated for when combining the smaller W_E vector with $W_{SS} + W_L$.

However, $W_E + W_{SS} + W_L + W_{IL}$ outperformed $W_E + W_{SS} + W_L$ for 67% of the configurations. We may therefore conclude that including the W_{IL} filter would result in an overall more robust system.

6.3 Final stage: robustness

The purpose of the validation data is to measure generalization of the method. However, given the small dataset size there is as well an imminent risk of over-fitting against the validation data when searching for the optimal hyper-parameters. The latter might be the reason for the performance gaps between validation and test PCCs for the EI-oc and V-oc subtasks in particular. Also, even when using the same hyper-parameter settings, the

performance (in terms of PCC/Jaccard similarity score) of the final stage varies depending on the random initialization of the network parameters. Constructing an ensemble estimate, using multiple final stage models for each subtask, could perhaps be beneficial for the performance on the test set.

7 Conclusions

This paper presents the method and results for the FOI DSS contribution to SemEval-2018 Task 1. A major challenge with this task was the small amount of available labeled data. We utilized techniques such as transfer learning as well as classical NLP features. Our system used features from Weka Affective Tweets combined with two LSTM-state vectors. Fully connected neural networks with two hidden layers were used to map the features into the target outputs for each of the subtasks. For subtasks EI-reg, V-reg, V-oc, and E-c the PCC/Jaccard similarity score of our system was in the range of 92-95 % of the winning result. The weakest performance was observed on subtask EI-oc. Initial error- and robustness analysis indicates that performance might be enhanced by improved pre-processing of the tweets, and by including more lexical features. The difference between our results on validation and test data was larger for the emotion intensity classification subtasks than for the regression and emotion classification subtasks, which would be interesting to investigate further.

Acknowledgments

We would like to thank Magnus Sahlgren for valuable input on the algorithmic design.

NLPZZX at SemEval-2018 Task 1: Using Ensemble Method for Emotion and Sentiment Intensity Determination

Zhengxin Zhang, Qimin Zhou, Hao Wu

School of Information Science and Engineering, Yunnan University

Chenggong Campus, Kunming, P.R. China

{zzyynu, zqmyynu}@gmail.com, haowu@ynu.edu.cn

Abstract

In this paper, we put forward a system that competed at SemEval-2018 Task 1: “Affect in Tweets”. Our system uses a simple yet effective ensemble method which combines several neural network components. We participate in two subtasks for English tweets: EI-reg and V-reg. For two subtasks, different combinations of neural components are examined. For EI-reg, our system achieves an accuracy of 0.727 in Pearson Correlation Coefficient (all instances) and an accuracy of 0.555 in Pearson Correlation Coefficient (0.5-1). For V-reg, the achieved accuracy scores are respectively 0.835 and 0.670.

1 Introduction

Sentiment analysis is a research area in the field of natural language processing. It aims to detect the sentiment expressed by the author of some form of textual data and many deep learning approaches have been successfully exploited (Cambria, 2016). The goal of SemEval-2018 Task 1 “Affect in Tweets” is to automatically determine the intensity of emotions and intensity of sentiment of the tweeters from their tweets (Mohammad et al., 2018). All tweets fall into three languages: *English*, *Arabic* and *Spanish*. We participate in two subtasks for English tweets: EI-reg and V-reg. For EI-reg, all English tweets are separated into four emotions, anger, fear, joy and sadness. Every emotion has train, dev and test datasets. This subtask determines the intensity which is a real-valued score between 0 and 1 of emotion that represents the mental state of the tweeter. The instances with higher scores correspond to a greater degree of emotion than instances with lower scores. For V-reg, all English tweets are divided into three datasets: train, dev and test datasets. It determines the intensity of

sentiment or valence that best represents the mental state of the tweeter a real-valued score between 0 and 1. The instances with higher scores correspond to a greater degree of positive sentiment than instances with lower scores. Both the two subtasks are regression tasks.

For these two subtasks, we have adopted separate ensemble method with existing neural network components (Brueckner and Schuler, 2014; Kim, 2014; Li and Qian, 2016; Yang et al., 2017) (see Figure 1). We use BiLSTM-CNN component, BiLSTM-Attention component and Deep BiLSTM-Attention component with different embeddings for simple ensemble. In these subtasks, our final model is just an average of scores provided by what we select from these single neural network components. Every emotion or valence employs different ensemble method, so there are several distinct ensemble methods in the two subtasks. Experimental results show that our proposed ensemble methods are simple yet effective.

The remainder of the paper is structured as follows. We provide details of the proposed ensemble method in Section 2. We present the experimental result of proposed methods in Section 3. Finally, a conclusion is drawn in section 4.

2 Methodology

We propose an simple ensemble method of different neural network components. We mainly introduce the implementation details of these components, including raw tweets preprocessing, lexicon features and embedding resources we use in these components, the architecture of these components and the best parameters of different single components. The parameters that can maximize the Pearson Correlation Coefficient between the predicted values and real values are chosen to be the best parameters.

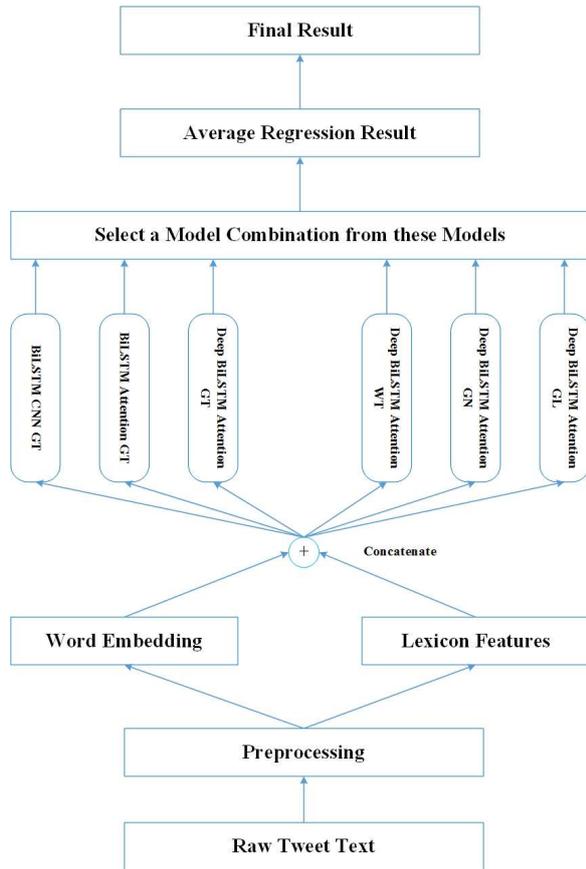

Figure 1: The architecture of our system.

2.1 Data Preprocessing

In general, tweet are not always syntactically well-structured and the language used does not always strictly adhere to grammatical rules (Barbosa and Feng, 2010). So we need to preprocess raw tweets before feature extraction. Firstly, we perform a few preprocessing steps, such as remove # and retain the word itself, remove stop words with nltk.corpus. Then the tweets are transformed into lowercase. Finally, we utilize TweetTokenizer¹ to process the tweets.

2.2 Feature Extraction

Each tweet is represented as a concatenation of two different feature vectors, one is lexicon features and another is word embedding. In our system, each tweet is divided into words, every word is represented as a $d + m$ dimension vector and thus each tweet is represented as $l(d + m)$ matrix, where d is the dimension of word embedding and m is the dimension of lexicon features. Suppose each tweet has the same length, so l is the length

¹<http://www.nltk.org/>

of tweet. We utilize a variety of resources for feature extraction as follows:

1. AFINN: Calculating positive and negative sentiment scores from the lexicon (Nielsen, 2011).
2. NRC Affect Intensity Lexicon: The NRC Affect Intensity Lexicon is a list of English words and their associations with four basic emotions (anger, fear, sadness, joy) (Mohammad, 2017).
3. NRC Emotion Lexicon: The NRC Emotion Lexicon is a list of English words and their associations with eight basic emotions (anger, fear, anticipation, trust, surprise, sadness, joy, and disgust) and two sentiments (negative and positive) (Mohammad and Turney, 2010).
4. NRC Hashtag Emotion Lexicon: Association of words with eight emotions (anger, fear, anticipation, trust, surprise, sadness, joy, and disgust) generated automatically from tweets with emotion-word hashtags (Mohammad, 2012).
5. NRC Emoticon Lexicon: Association of words with positive (negative) sentiment generated automatically from tweets with emoticons (Kiritchenko et al., 2014; Mohammad et al., 2013; Zhu et al., 2014).
6. NRC Emoticon Affirmative Context Lexicon and NRC Emoticon Negated Context Lexicon: Association of words with positive (negative) sentiment in affirmative or negated contexts generated automatically from tweets with emoticons (Kiritchenko et al., 2014; Mohammad et al., 2013; Zhu et al., 2014).
7. NRC Hashtag Affirmative Context Sentiment Lexicon and NRC Hashtag Negated Context Sentiment Lexicon: Association of words with positive (negative) sentiment in affirmative or negated contexts generated automatically from tweets with sentiment-word hashtags (Kiritchenko et al., 2014; Mohammad et al., 2013; Zhu et al., 2014).
8. NRC Hashtag Sentiment Lexicon: Association of words with positive (negative) sentiment generated automatically from tweets

with sentiment-word hashtags (Kiritchenko et al., 2014; Mohammad et al., 2013; Zhu et al., 2014).

9. **Emoji**: This is a manual classification of the dictionary, in which each emoji has a corresponding polarity value.
10. **Sentiwordnet**: Sentiwordnet is a lexical resource explicitly devised for supporting sentiment classification and opinion mining applications (Baccianella et al., 2010), through the wordnet entry in the emotional classification, and marked each entry belongs to the positive and negative categories weight size.

2.3 Neural Networks

2.3.1 Embeddings

The final model combines three neural network components as *BiLSTM-CNN*, *BiLSTM-Attention*, and *Deep BiLSTM-Attention*. Towards BiLSTM-CNN and BiLSTM-Attention, we use *glove.twitter.27B.200d* which contains pre-trained word vectors with Glove algorithm (Pennington et al., 2014). For Deep BiLSTM-Attention, different pre-trained word vectors are used, such as *word2vec-twitter-model*, *GoogleNews-vectors-negative300*, *glove.twitter.27B.200d* and *glove.840B.300d*.

1. *word2vec-twitter-model*²: *word2vec* model (Mikolov et al., 2013) is a NLP tool launched by Google in 2013. It features the quantification of all words so that words can be quantified to measure the relationship between them. *word2vec-twitter-model* is trained on tweets and the embedding dimension used in our system is 400.
2. *GoogleNews-vectors-negative300*³: *GoogleNews* vectors is trained on Google News corpus. It resembles *word2vec-twitter-model* and the embedding dimension is 300.
3. *glove.840B.300d*⁴: *Glove* is an unsupervised learning algorithm for obtaining vector representations for words. Training is conducted on aggregated co-occurrences of words from

²<http://www.spark.tc/building-a-word2vec-model-with-twitter-data/>

³<https://github.com/mmihaltz/word2vec-GoogleNews-vectors>

⁴<https://nlp.stanford.edu/projects/glove/>

a global corpus, and the resulting representations showcase interesting linear substructures of the word vector space. The embedding dimension used in our system is 300.

4. *glove.twitter.27B.200d*⁴: This word embedding is trained on 2 billion tweets from twitter. It is similar to *glove.840B.300d*, but the embedding dimension is 200.

2.3.2 Bidirectional LSTM with CNN

The BiLSTM with CNN first transform tweets into text matrices, the BiLSTM is applied to these matrices to build new text matrices, CNN is applied to the output of the BiLSTM to obtain text vectors for the prediction of emotional intensity. The BiLSTM with CNN achieves a rather good result on the task of emotional analysis (He et al., 2017). so we choose it for our task.

Model Architecture: Embedding vectors are fed into a BiLSTM network followed by a CNN layer. The CNN layer consists of one dimensional convolutional layer and pooling layer where the number of filters is 256, the window size of the filter is 3, and the *activation function* is Relu. The input and output shape of convolutional layer are both 3D tensor. The output of the CNN layer is flattened after max-pooling operation. After the Flatten layer, two dense layers are stacked and the *activation functions* are respectively configured as Relu and Sigmoid. Also dropout (Srivastava et al., 2014) is utilized to avoid potential overfitting, it is used between two dense layers. The reason why we select Relu is to prevent the vanishing gradient problem and accelerate the calculation. Since the task is a regression problem, we put a dense projection with sigmoid activation to obtain an intensity value between 0 and 1.

Model Training: The network parameters are learned by minimizing the *mean squared error* (MSE) between the real and predicted values of emotion intensity or valence intensity. We optimize this loss function via *Adam* that is an algorithm for first-order gradient-based optimization of stochastic objective functions, based on adaptive estimates of lower-order moments (Kingma and Ba, 2014). Batch size and training *epochs* may be different for different emotions and valence. To avoid overfitting issues, we use dropout in this model. Finally, we apply these three parameters for system tuning. In addition, we try various optimization algorithms with the same param-

EI-reg	Anger			Fear			Joy			Sadness		
	BS	Epochs	Dp	BS	Epochs	Dp	BS	Epochs	Dp	BS	Epochs	Dp
BiLSTM CNN+GT	16	6	0.5	32	2	0.5	8	4	0.5	32	5	0.5
BiLSTM Attention+GT	32	3	0.5	32	3	0.5	8	7	0.5	32	4	0.5
Deep BiLSTM Attention	32	2	0.3	8	7	0.3	16	9	0.1	16	5	0.6

Table 1: The best parameters of EI-reg.

V-reg	Valence		
	BS	Epochs	Dp
BiLSTM CNN+GT	8	5	0.5
BiLSTM Attention+GT	8	10	0.6
Deep BiLSTM Attention+WT	16	8	0.5
Deep BiLSTM Attention+GN	32	10	0.5
Deep BiLSTM Attention+GL	8	5	0.2
Deep BiLSTM Attention+GT	16	8	0.2

Table 2: The best parameters of V-reg.

eters, such as *SGD*, *RMSprop*, *Adagrad*, *Adam* and *Adamax*, and find that Adam works best. So we fix the optimization algorithm with Adam (Kingma and Ba, 2014) and tune the parameters, the best configurations for EI-reg and V-reg are respectively given in Tables 2.3.1 and 2.3.1, where *BS* is batch size, *Dp* is dropout.

2.3.3 Bidirectional LSTM with Attention

Bidirectional LSTM with Attention achieves a good result on the SemEval-2017 Task 4 ‘‘Sentiment Analysis in Twitter’’ (Baziotis et al., 2017), so we exploit *Bidirectional LSTM with Attention model* and *Deep Bidirectional LSTM with Attention model* for our tasks.

Model Architecture: For Bidirectional LSTM with attention model, embedding vectors are fed into a BiLSTM network followed by an attention layer (Yang et al., 2017). Not all words contribute equally to the expression of sentiment in a tweet, so we use an attention layer to find the importance of each word in tweet. After the attention layer, it is consistent with Bidirectional LSTM with CNN model. The difference between the Bidirectional LSTM with attention model and its deep version is that, we use two BiLSTM layers followed by an attention layer in the deep version.

Model Training: We use the same method to learn the network parameters. In EI-reg, we use the same batch size, training *epochs* and dropout to train the Deep BiLSTM Attention model with different pre-training word embeddings in every emotion, but in V-reg, batch size, training *epochs* and dropout are different in Deep BiLSTM Attention model with different pre-training word embeddings. In these models, we also use dropout.

The best parameters of EI-reg for these models are given in Table 2.3.1 and V-reg’s best parameters are given in Table 2.3.1.

2.4 Ensemble Methods

Currently, ensembling is a widely used strategy which combines multiple single components to improve overall performance, there are many ensemble methods that have been proposed, such as, Voting, Blending, Bagging, Boosting, etc ⁵. In this system, due to time constraint, we choose a simple average of the scores provided by different components, as each single component can predict emotional intensity or valence intensity. It can be defined as

$$Prediction_{intensity} = \sum_{i=1}^n \frac{model_i}{n} \quad (1)$$

where n is the number of neural components. $Model_i$ represents the prediction results of i -th component. Suppose three components are exploited to predict the intensity of anger, and three prediction values of a same tweet 0.76, 0.72 and 0.7 are suggested, then the final result of this tweet will be $(0.76 + 0.72 + 0.74)/3 = 0.74$.

3 Experiments

Dataset	train	dev	test	sum
anger	1,701	388	17,939	20,028
fear	2,252	389	17,923	20,564
joy	1,616	290	18,042	19,948
sadness	1,533	397	17,912	19,842
valence	1,181	449	17,874	19,504

Table 3: Statistics of the datasets.

For experiments, we use five datasets from two different subtasks, These datasets, ‘‘EI-reg-En-anger (anger)’’, ‘‘EI-reg-En-joy (joy)’’, ‘‘EI-reg-En-fear (fear)’’, ‘‘EI-reg-En-sadness (sadness)’’ and ‘‘2018-Valence-reg-En (valence)’’ are downloaded from SemEval-2018 Task 1 ‘‘Affect in Tweets’’ ⁶. As for the EI-reg task dataset format, each tweet

⁶<https://competitions.codalab.org/competitions/17751>

EI-reg	Average		Anger		Fear		Joy		Sadness	
	All	0.5-1								
Baseline	0.520	0.396	0.526	0.455	0.525	0.302	0.575	0.476	0.453	0.350
BiLSTM CNN+GT	-	-	-	-	0.691	0.508	0.701	0.512	0.694	0.507
BiLSTM Attention+GT	-	-	0.701	0.583	0.715	0.506	0.711	0.513	0.720	0.557
Deep BiLSTM Attention+WT	-	-	0.697	0.582	0.709	0.507	0.728	0.503	0.704	0.541
Deep BiLSTM Attention+GN	-	-	0.681	0.557	-	-	-	-	0.698	0.535
Deep BiLSTM Attention+GL	-	-	-	-	-	-	-	-	-	-
Deep BiLSTM Attention+GT	-	-	-	-	-	-	-	-	0.717	0.551
Ensemble	0.727	0.555	0.716	0.607	0.726	0.519	0.736	0.529	0.729	0.565

Table 4: Performance comparisons of models in different emotions, where the best values are marked in **bold**.

consists of the id, the tweet, the emotion of the tweet, the emotion intensity and for the V-reg task, each tweet consists of the id, the tweet, the sentiment of the tweet and the sentiment intensity. All datasets have been divided into train set, dev set and test set. Test set’s gold labels are given only after the evaluation period. Statistics of the datasets are shown in Table 3.

To measure the performance of selected methods, two submetrics of Pearson Correlation Coefficient (PCC) are used. PCC (all instances) is Pearson correlation for a subset of test data that includes all tweets. The value varies between -1 and 1. PCC (0.5-1) is the Pearson correlation for a subset of test data that includes only those tweets with intensity score greater or equal to 0.5. For both metrics, a larger value indicate a better prediction accuracy.

For each dataset, we use dev set to select our ensemble methods. Firstly we run these six components on all dev datasets. Then, combine these results of different components, different combinations of components lead to different results on dev set. Finally, we select the combination with a higher score for testing.

Our system is implemented on Keras with a Tensorflow backend ⁷. We present the result of PCC (all instances) and PCC (0.5-1) for each emotion and valence on the test data, shown in Tables 3 and 3. For simplicity, we denote *WT*, *GN*, *GL* and *GT* for the word vectors of *word2vec-twitter-model*, *GoogleNews-vectors-negative300*, *glove.840B.300d* and *glove.twitter.27B.200d*. We compare the results of our single components, official baseline and our ensemble system. Every emotion and valence adopts different ensemble methods, the symbol ‘-’ means that the component is not used in the ensemble method in this emotion or valence. For example, we only use *BiLSTM Attention+GT*, *Deep BiLSTM Attention+WT*

⁷<https://keras.io/>

V-reg	Valence	
	All	0.5-1
Baseline	0.585	0.449
BiLSTM CNN+GT	-	-
BiLSTM Attention+GT	-	-
Deep BiLSTM Attention+WT	0.825	0.665
Deep BiLSTM Attention+GN	0.820	0.640
Deep BiLSTM Attention+GL	0.822	0.648
Deep BiLSTM Attention+GT	0.825	0.659
Ensemble	0.835	0.670

Table 5: Performance comparisons of models in valence, where the best values are marked in **bold**.

and *Deep BiLSTM Attention+GN* these three components for ensemble on anger dataset. The reason why we don’t use all the six components for ensemble is that ensemble does not always have a good effect, a same component can have different effects on different datasets, either good or bad. The official result for EI-reg, our average PCC reaches 0.727 in all instances and 0.555 in 0.5-1 (both ranked 10 out of 48 participants). For V-reg, the result is 0.835 in all instances (ranked 7 out of 38) and 0.670 in 0.5-1 (ranked 6 out of 38). The average result of baseline for EI-reg is 0.520 and 0.396, for V-reg, the result is 0.585 and 0.449. These results demonstrate that the ensemble approach achieves important improvement in performance across all the emotions and valence, and gains the best performance for Anger.

4 Conclusions and Future Works

We have proposed a simple yet effective ensemble method which integrates various neural components to perform the sentiment or emotion analysis for the tweet. Experimental results reflect that our method is effective in the prediction tasks of emotional intensity and sentimental intensity. Some other useful findings can be drawn from the experimental results: a) The model of integration for each emotion is different; b) As for lexicon features and word embedding, it is important for emotion or sentiment analysis; c) ensemble is not al-

ways valid. Also, we have tried data augmentation considering insufficient training data, however the effect is not a good.

As for future works, although our ensemble method has achieved good results, we would want to examine the multi-task deep learning approach on these tasks, by which it would predict the different emotional intensity at the same time, and improve the generalization effect of the prediction model.

Abstract

This paper presents an emotion classification system for English tweets, submitted for the SemEval shared task on Affect in Tweets, sub-task 5: Detecting Emotions. The system combines lexicon, n-gram, style, syntactic and semantic features. For this multi-class multi-label problem, we created a classifier chain. This is an ensemble of eleven binary classifiers, one for each possible emotion category, where each model gets the predictions of the preceding models as additional features. The predicted labels are combined to get a multi-label representation of the predictions. Our system was ranked eleventh among thirty five participating teams, with a Jaccard accuracy of 52.0% and macro- and micro-average F1-scores of 49.3% and 64.0%, respectively.

1 Introduction

Most research in the domain of sentiment analysis focuses on the automatic prediction of polarity or valence in text, but also the detection of emotions has attracted growing interest in the last couple of years (Mohammad and Bravo-Marquez, 2017). Although emotion detection is a rather new research focus in NLP, the study of emotions has a long history in fields like psychology and neuroimaging. Many different frameworks exist, but the specific emotion approach, in which emotions are classified as specific discrete categories, predominates. In a lot of those approaches, some emotions are considered more basic than others, with Ekman’s theory of six basic emotions (*joy, sadness, anger, fear, disgust, and surprise*) (Ekman, 1992) as the most well-known. Another popular theory is Plutchik’s wheel of emotions (Plutchik, 1980), in which *joy, sadness, anger, fear, disgust, surprise, trust, and anticipation* are considered most basic.

Emotion analysis in NLP makes use of the frameworks developed by psychologists, mostly

by employing categorical models of (basic) emotions. In traditional emotion classification tasks, a ‘document’ or sentence is classified under one or more emotion classes (or classified as neutral/no class when no emotions are present). Such emotion classification systems have been developed and tested on different kinds of data, including fairy tales (Alm et al., 2005), newspaper headlines (Strapparava and Mihalcea, 2007), chat messages (e.g. Holzman and Pottenger, 2003; Brooks et al., 2013), and tweets (e.g. Mohammad, 2012; Wang et al., 2012). The big advantage of using tweet datasets is the relative ease with which twitter data can be collected and the possibility of using hashtags as emotion labels (distant supervision approach).

For this paper, we used the data that was collected for the SemEval shared task on Affect in Tweets (Mohammad et al., 2018), a collection of tweets annotated for eleven emotions: *anger, anticipation, disgust, fear, joy, love, optimism, pessimism, sadness, surprise, and trust* (Mohammad and Kiritchenko, 2018). We participated in Sub-task 5: Detecting Emotions (English emotion classification).

The remainder of this paper is structured as follows: in Section 2 we describe how we first analyzed the data in order to get more insight in the task. Section 3 discusses how the data was pre-processed and which information sources were extracted. Next, in Section 4 the actual experimental setup and results are discussed and we end this paper with a conclusion in Section 5.

2 Data analysis

We first analyzed the training data provided by the task organizers, which consisted of 6838 tweets. We found that *disgust, anger* and *joy* were present in the largest numbers (present in about 35 to 40%

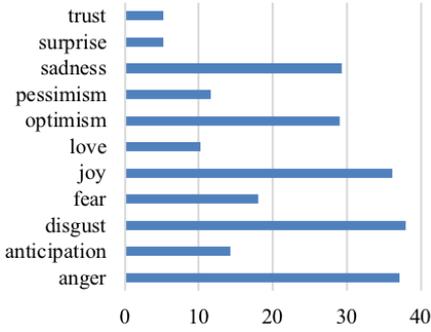

Figure 1: Proportion of training tweets in which the specified emotion is present (%).

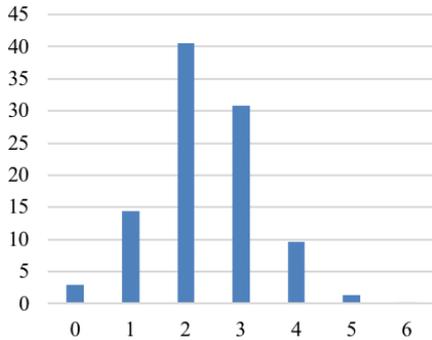

Figure 2: Proportion of training tweets in which a specific amount of emotion classes is present (%).

of the tweets), while *surprise* and *trust* only occur in around 5% of the tweets (Figure 1). Only three percent of the tweets was annotated as neutral.

As can be derived from Figure 2, most tweets contained two or three emotions (together 70%), and in only about 1% of the tweets five or more (max six) emotions were present. We also calculated the correlations and found ten emotion pairs that were moderately or highly correlated ($\|phi\| \geq 0.30$ for moderate correlation, $\|phi\| \geq 0.50$ for high correlation, according to Cohen’s conventions on effect size (Cohen, 1988)). The correlated pairs are shown in Table 1 and suggest that the classification performance can be boosted when correlations between emotion categories are implemented in the model.

In order to get more insight into the data, we re-annotated a subset of 500 tweets from the training set. In Table 2, inter-annotator agreement (IAA) scores per emotion class between the gold labels and our annotations are presented. Except for *anger* and *joy* these scores are rather low. Overall, we assigned less emotion classes to a tweet than the official annotators. We often disagreed with the gold labels and had the feeling that the anno-

Pair	phi
anger - joy	-0.44
anger - optim.	-0.37
disg. - optim.	-0.41
joy - disg.	-0.46
joy - sadn.	-0.33
surpr. - pessim.	-0.40

Pair	phi
anger - disg.	0.68
joy - love	0.40
joy - optim.	0.52
sadn. - pessim.	0.30

Table 1: Phi coefficients for moderate or high negative (left) and positive (right) correlations between emotion pairs.

Emotion	Kappa	Emotion	Kappa
Anger	0.678	Optimism	0.436
Anticipation	0.259	Pessimism	0.124
Disgust	0.132	Sadness	0.537
Fear	0.399	Surprise	0.276
Joy	0.717	Trust	0.367
Love	0.470		

Table 2: IAA (Kappa) per emotion class based on 500 re-annotated instances.

tators of the official labels focused too much on lexical clues instead of keeping the context and the perspective of the writer of the tweet in mind. This leads us to presume that the threshold to assign an emotion label to a tweet when two out of seven annotators agreed (Mohammad and Kiritchenko, 2018) might have been a bit too generous.

We further noticed that some tweets appeared twice in the data set, but not completely identically: we suspect that one of them was the original tweet with emotion hashtag and the other one with the hashtag removed. An example:

- (1) a. *Whatever you decide to do make sure it makes you #happy.*
- b. *Whatever you decide to do make sure it makes you .*

Since labels differed depending on the presence or absence of the emotion hashtag, we decided to keep both variants in our training set.

3 Preprocessing & Feature Extraction

3.1 Preprocessing

While we did not remove the ‘almost identical’ tweets from the data set, there were also some tweets in the training set that were completely identical but had been assigned other emotion labels. For those tweets, we took the majority class for each binary emotion category, and removed all other instances. This reduced our training set from 6838 to 6782 tweets. No duplicates were present in the development set, so the amount of

886 tweets was preserved. In the updated training set, as well as in the development and test set, all user names were replaced with the generic @ID.

All tweets were processed with Weka (Witten et al., 2016) using the Affective Tweets package (Mohammad and Bravo-Marquez, 2017), in order to extract lexicon and word embedding features. We used the default preprocessing settings for each filter. For the other features, we performed word and sentence tokenization (using NLTK), stemming (using spaCy), lowercasing, and POS-tagging (simple and detailed, corresponding to spaCy’s POS and Tag function).

3.2 Feature extraction

For our supervised classification system, we employed features that measure different aspects of the tweet. These can be subsumed under five different categories: lexicon features (see Table 3 for an overview), n-gram features (binary, n equal to 3, 4 and 5 for characters and n equal to 1 or 2 for tokens), and various style, syntactic and semantic features (see Table 4).

Regarding the latter category, both features from traditional and distributional semantics were integrated. We first took the synset depth (distance to root) of all content words (calculated with WordNet (Miller, 1995)) and averaged the scores to get a mean synset depth for the tweet. Furthermore, we included two types of features from distributional semantics, namely word embeddings and word clusters. The word embeddings were extracted with Weka Affective Tweets, using pre-trained embeddings from 10 million tweets taken from the Edinburgh Twitter Corpus (Petrovic et al., 2010). For the word clusters, we downloaded a subset of around 1.5M tweets from the SemEval 2018 AIT DISC corpus (Mohammad et al., 2018). We first created word embeddings with word2vec using both skipgram and continuous bow and afterwards applied k-means clustering on the resulting word vectors. We experimented with various cluster sizes (800 of size 100, 1000 of size 100 and 800 of size 300). These clusters were implemented as binary features.

4 Experiments & Results

4.1 Baseline & Binary Experiments

We trained different models on the training set and tested them on the development set, using scikit-learn (Pedregosa et al., 2011). For the baseline ex-

Table 4: Style, syntactic and semantic features.

periments, we used an SVM classifier with linear kernel (LinearSVC) and used the lexicon features from the Weka Affective Tweets package. The results for each binary classifier are shown in Table 5 (second column). Combining the predictions of these eleven binary classifiers resulted in a jaccard accuracy of 42.7%.

Before optimizing the separate classifiers, we took a more detailed look at the lexicon features and the clusters to assess whether it is beneficial to use only a part of the lexicons (e.g. only the emotion lexicons) or whether it is better to use all lexicons (even polarity lexicons). We found that the combination of all lexicons (including the valence-arousal-dominance lexicon of Warinner et al. (2013)) gave the highest performance. As regards the clusters, we tried all cluster types on each emotion category and picked the cluster that gave the highest performance on that particular category.

For every emotion category, we tested different classifiers on different combinations of features. The classifiers we used, were SVM, SGD (linear SVM with stochastic gradient descent learning), Logistic Regression, and Random Forest. Table 5 shows the F1-scores (in bold) on the positive class for the best performing classifiers and feature combinations, which are significantly higher than the baseline results. We joined the predictions of these optimized binary classifiers, and achieved a jaccard accuracy of 47.7%.

Emotion	BL	Optimized		
	F1	Classifier	Features	F1
Anger	<i>0.67</i>	SGD	all features except clusters	0.73
Anticip.	<i>0.00</i>	SGD	all features	0.30
Disgust	<i>0.56</i>	Log. R.	lexicons, embeddings, clusters	0.67
Fear	<i>0.62</i>	Log. R.	lexicons, embeddings, n-grams, clusters	0.69
Joy	<i>0.75</i>	Log. R.	lexicons, embeddings, n-grams, puncts, pos n-grams, pos frequencies, clusters	0.80
Love	<i>0.29</i>	Log. R.	all features	0.55
Optim.	<i>0.59</i>	SGD	all features	0.68
Pessim.	<i>0.04</i>	SGD	lexicons, embeddings, clusters	0.20
Sadness	<i>0.52</i>	Log. R.	all features	0.59
Surprise	<i>0.00</i>	SGD	all features except clusters	0.35
Trust	<i>0.00</i>	SGD	lexicons	0.12

Table 5: F1-scores on the positive class for the binary classifiers in the baseline (BL) setup (italics) and with the optimal classifier and feature sets (in bold)

4.2 Classifier Chain

Because the emotion categories are highly correlated (see Section 2), we envisaged to implement these relations in the model by using a classifier chain. We combined the best performing classifier per emotion category in a chain that passes predicted labels on to the next classifiers. We ordered the classifiers by performance on the positive class F1-score on the baseline (the emotion that is easiest to predict first, the emotion that is the most difficult to predict last). On the development set, this classifier chain approach led to a jaccard accuracy of 52.37%, which is significantly higher than the score without classifier chain (47.7%, see Section 4.1).

In our final model, the training and development data were joined, resulting in a combined training set of 7668 tweets. During the evaluation period, we achieved 52.0% jaccard accuracy, 64.0% micro-avg F1-score and 49.3% macro-avg F1-score on the held-out test set (see Table 6).

4.3 Discussion

As can be derived from Table 7 the number of false positives is rather low for all emotion classes (be-

Evaluation	jaccard	micro F1	macro F1
dev set	0.524	0.644	0.478
held-out test set	0.520	0.640	0.493

Table 7: Confusion matrices for the results on the held out test set. P = predicted labels; G = gold labels.

low 20% for most emotions). The model had most trouble with recognizing positive instances of *surprise*, *pessimism*, and *trust*, but also *love* and *anticipation* were more challenging. For these categories, the false negative rate was thus very high. We assume that these bad results are mostly due to a lack of sufficient training data for these categories.

We evaluated all features by computing the ANOVA F-values, and extracted the hundred most predictive features for each emotion category. For all emotions, the top 100 features consisted exclusively of lexical information. In none of the emotion categories, style or syntactic features occurred in this top 100. However, features regarding labels of preceding classifiers belonged to the most predictive features for all emotions except for *optimism* and *surprise*.

5 Conclusion

Our emotion classification system for English tweets achieved 52.0% jaccard accuracy on the held-out test set. We started from binary classifiers which we optimized for each emotion category separately, and combined them in a classifier chain. We proved that passing on labels from previously predicted emotions categories improves the performance significantly. For future work, it would be interesting to investigate the model’s performance on other datasets than twitter data.

Abstract

Emotion classification is a new task that combines several disciplines including Artificial Intelligence and Psychology, although Natural Language Processing is perhaps the most challenging area. In this paper, we describe our participation in SemEval-2018 Task1: Affect in Tweets. In particular, we have participated in EI-oc, EI-reg and E-c subtasks for English and Spanish languages.

1. Introduction

Emotions are playing a significant role in the effective communication of people. In fact, sometimes, emotional intelligence is more important than cognitive intelligence for successful interaction (Pantic et al., 2005). Therefore, affective computing is a key element to the advancement of Artificial Intelligence. The basic task of affective computing is emotion recognition. This task consists of identifying a set of emotions in a document.

The identification of emotions in texts has multiple benefits in different areas, such as psychology to detect some psychological disorder like depression (Cherry et al., 2012), e-learning to improve student motivation (Suero Montero and Suhonen, 2014) or business intelligence to know the preferences of consumers (Cambria, 2016).

Currently, more and more people express their emotions on social media, such as Twitter or Facebook. Therefore, the role of emotion in social media is becoming more important for the researchers in affective computing.

In this paper, we present the different systems we developed as part of our participation in SemEval-2018 Task 1: Affect in Tweets (Mohammad et al., 2018). We have participated in EI-oc, EI-reg and

E-c subtasks for English and Spanish. Below, we briefly describe these subtasks:

- **EI-oc** is an emotion intensity ordinal classification task. Given a tweet and an emotion E, it consists of classifying the tweet into one of four ordinal classes of intensity of E that best represents the mental state of the tweeter. Separate datasets are provided for anger, fear, joy, and sadness emotions.
- **EI-reg** is an emotion intensity regression task. Given a tweet and an emotion E, it consists of determining the intensity of E that best represents the mental state of the tweeter. The intensity of E is a real-valued score between 0 (least emotion) and 1 (most emotion). Separate datasets are provided for anger, fear, joy, and sadness emotions.
- **E-c** is an emotion multi-classification task. Given a tweet, it consists of classifying it as 'neutral' or 'no emotion' or as one, or more, of eleven given emotions (anger, anticipation, disgust, fear, joy, love, optimism, pessimism, sadness, surprise, trust) that best represent the mental state of the tweeter.

The rest of the paper is organized as follows. In Section 2 we explain the data used in our methods. Section 3 describes the resources used by our systems. Section 4 presents the details of the proposed systems. Section 5 displays the results and analyses them. We conclude in Section 6 with remarks on future work.

2. Data

To run our experiments, we used the datasets provided by the task organizers (Mohammad et al., 2018) as follows. During pre-evaluation period,

we trained our models on the *train* set, and evaluated our different approaches on the *dev* set. During evaluation period, we trained our models on the *train* and *dev* sets, and tested the model on the *test* set. Table 1 shows the number of tweets for each language and subtask dataset.

Subtask-language	train	dev	test	Total
EI-oc-es	4544	793	2616	7953
EI-oc-en	7102	1465	4070	12637
EI-reg-es	4544	793	2616	7953
EI-reg-en	7102	1464	71816	80382
E-c-es	7561	679	2854	11064
E-c-en	6838	886	3259	10983

Table 1: Number of tweets for each language and subtask dataset

3. Resources

For the development of the task, we used different lexicons that we explain in detail below.

- **Wordnet-Affect (WNA)** (Strapparava et al., 2004). This resource is an extension of WordNet Domains. WNA provides a set of English emotional words organized in a tree. The leaf nodes represent specific emotions that are grouped into general categories (parent nodes). For example, *anger*, *hate* and *dislike* belong to the overall emotion *general-dislike*. However, the emotions of WNA are not the same as the emotions of the SemEval subtasks. For this reason, each overall emotion of WNA has been mapped with SemEval subtasks emotions (see Appendix A, Table 8 and Table 9).

In order to use this resource in Spanish, we have employed the lexical disambiguator Babelfy (Moro et al., 2014) to obtain the corresponding *BabelNet synset id* of a term. Next, we have used the BabelNet API (Navigli and Ponzetto, 2012) to obtain a correspondence between the *BabelNet synset id* and the *WordNet synset id*. WNA includes a subset of appropriate synsets of WordNet 1.6 to represent affective concepts. However, the *WordNet synsets id* obtained with BabelNet API corresponds to the 3.0 version of WordNet. Therefore, we have obtained the equivalent synset to the 3.0 version in the 1.6 version. With this, using the synset of the 1.6 version

of WordNet, we can map directly the associated emotion and confident value from WNA.

- **Spanish Emotion Lexicon (SEL)** (Sidorov et al., 2012). It includes 2,036 Spanish words that are associated with the measure of Probability Factor of Affective use (PFA) with respect to at least one basic emotion: joy, anger, fear, sadness, surprise, and disgust. The higher the value of the PFA, the more probable the association of the word with the emotion is.
- **NRC Affect Intensity Lexicon** (Mohammad, 2017). It has almost 6,000 entries in English. Each of them has an intensity score associated to one of the following basic emotions: anger, fear, sadness and joy. The scores range from 0 to 1, where 1 indicates that the word has a high association to the emotion and 0 that the word has a low association to the emotion. However, this resource is not in Spanish. For this reason, we have adapted it to Spanish in the following way. We have translated English terms to Spanish and we have selected the maximum value of intensity if the translation of some terms is the same.
- **NRC Word-Emotion Association Lexicon (EmoLex)** (Mohammad and Turney, 2010). This lexicon has a list of English words associated to one or more of the following emotions: anger, fear, anticipation, trust, surprise, sadness, joy. Moreover, the lexicon is also available for more than one hundred languages (including Spanish). All these versions have been generated by translating the English terms using Google Translate.

4. System description

In this section we describe the systems developed for the subtasks EI-oc, EI-reg and E-c.

In first place, we preprocessed the corpus of tweets provided for each subtask and language (English and Spanish). We applied the following preprocessing steps: the documents were tokenized using NLTK TweetTokenizer¹, stemming was performed using NLTK Snowball stemmer², stopwords

¹<http://www.nltk.org/api/nltk.tokenize.html>

²http://www.nltk.org/_modules/nltk/

were removed (only for English), and all letters were converted to lower-case.

In relation to the resources, we have tested several combinations. However, for the final SemEval systems we have used the best systems obtained during the development phase. For EI-oc and EI-reg subtasks in Spanish, we used SEL, NRC Affect Intensity and WNA lexicons adapted to the emotions of these subtasks. On the other hand, for English, we used NRC Affect Intensity and WNA lexicons adapted to the emotions of the EI-oc and EI-reg subtasks. Regarding to subtask E-c, for Spanish, we used SEL, EmoLex Spanish version and WNA lexicons adapted to the emotions of this subtask. However, for English, we used Emolex and WNA lexicon adapted to the emotions of the E-c subtask.

Next, it is described the methodology used for each subtask:

- **Subtask EI-oc.** To perform the classification, we checked the presence of lexicon terms in the tweet and then we added the intensity value of these words grouping them by the emotional category (*anger, fear, sadness* and *joy*). The result is a vector of four values for each lexicon. Moreover, each tweet is represented as a vector of unigrams using the TF-IDF weighting scheme. The union of the lexicon vectors and the TF-IDF representation of the tweet are used as features for the classification using the SVM algorithm. We selected the SVM formulation, known as C-SVC, the value of the C parameter was 1.0 and the kernel chosen was the linear.
- **Subtask EI-reg.** In this case, we checked the presence of lexicon terms in the tweet and then we computed the sum, the average and the maximum of the intensity value of the words of the tweet grouping them by the emotional category (*anger, fear, sadness* and *joy*). The result is a vector of twelve values for each lexicon. The union of the lexicon vectors and the TF-IDF representation of the tweet are used as features for the classification using the SVM algorithm with the same configuration as that used in subtask EI-oc.
- **Subtask E-c.** In this subtask, we identified the presence of lexicon terms in the tweet and we assigned 1 as confidence value (CV).

Then, we summed the CV of the words whose emotion is the same obtaining a vector of emotions for each lexicon. The union of these vectors and the TF-IDF representation of the tweet are used as features for the classification using the Random Forest algorithm with 25 as number of trees.

5. Analysis of results

The official competition metric to evaluate the systems in EI-reg and EI-oc subtasks is the Pearson Correlation Coefficient (PCC) between semantic similarity scores of machine assigned and human judgments. In the case of the E-c subtask, systems are evaluated by calculating multi-label accuracy. Since this is a multi-label classification task, each tweet can have one or more gold emotion labels, and one or more predicted emotion labels. Multi-label accuracy is defined as the size of the intersection of the predicted and gold label sets divided by the size of their union. This measure is calculated for each tweet, and then is averaged over all the tweets in the dataset.

The results of our participation in the three subtasks and those of the teams that are in the first and the last position can be seen in Tables 2, 3, 4, 5, 6 and 7. It should be noted that the results of Spanish subtasks are lower than those obtained for English. Another important issue is that the participation in Spanish subtasks is lower than the participation in English subtasks. These facts are due to most of the works and resources for textual emotion mining are in English (Yadollahi et al., 2017).

In relation to our results, in most subtasks we obtained the lowest correlation on *anger* emotion and the best correlation on *joy* emotion. On the contrary, in WASSA-2017 Shared Task on Emotion Intensity (Mohammad and Bravo-Marquez, 2017), most of the systems performed better on *anger* emotion and worse on *fear* and *sadness* emotions. In this competition, it was found that despite using deep learning techniques, training data, and large amounts of unlabeled data, the best systems included features from affect lexicons. Given that, we plan to analyze the recall of the lexicons used in our experiments and to explore new lexicons in order to improve the classification.

On the other hand, it should be noted that we achieved higher ranking positions for Spanish sub-

tasks. In particular, our best participation has been in the E-c subtask. An important difference found between the classification in both languages was that taking stopwords into consideration contributes to the emotion classification for Spanish while the opposite occurs for English. Therefore, we will further study this issue in order to incorporate an specific treatment to those stopwords that can modify the meaning of a sentence, such as negators, intensifiers and diminishers.

6. Conclusions

In this paper, we have presented the systems developed for our participation in 3 subtasks (EI-oc, EI-reg, E-c) of SemEval-2018 Task 1: Affect in Tweets. We have addressed these subtasks in two of the three available languages, English and Spanish. Overall, we have obtained better results in Spanish subtasks than in English subtasks. In future works, we plan to continue working on emotion recognition in Spanish because we have observed that the participation in this language is very low, although it is the second most spoken language. Our next study will focus on exploring more affect lexicons because in WASSA-2017 Shared Task on Emotion Intensity (Mohammad and Bravo-Marquez, 2017), it was demonstrated that using features from affect lexicons is beneficial for this task. Moreover, we will study the use of stopwords in Spanish because in the development phase it was observed that stopwords contribute to the emotion classification.

Abstract

This paper describes our system created for the SemEval-2018 Task 1: Affect in Tweets (AIT-2018). We participated in both the regression and the ordinal classification subtasks for emotion intensity detection in English, Arabic, and Spanish.

For the regression subtask we use the AffectiveTweets system with added features using various word embeddings, lexicons, and LDA. For the ordinal classification we additionally use our Brainy system with features using parse tree, POS tags, and morphological features. The most beneficial features apart from word and character n -grams include word embeddings, POS count and morphological features.

1 Introduction

The task of Detecting Emotion Intensity assigns the intensity to a tweet with given emotion. The emotions include anger, fear, joy, and sadness. The intensity is either on a scale of zero to one for the regression subtask, or one of four classes (0: no, 1: low, 2: moderate, 3: high) for the classification subtask. The task was prepared in three languages: English, Arabic, and Spanish. For each language there are four training and test sets of data – one for each emotion. The data creation is described in (Mohammad and Kiritchenko, 2018) and detailed description of the task is in (Mohammad et al., 2018).

We participated in the emotion intensity regression task (**EI-reg**) and in the emotion intensity ordinal classification task (**EI-oc**) in English, Arabic and Spanish.

2 System Description

We used two separate systems for ordinal classification – AffectiveTweets (Section 3) and Brainy

(Section 4). For the regression task we just use the AffectiveTweets system. We train a separate model for each emotion. The Brainy system performed better in our pre-evaluation experiments on the development data for all emotions in Spanish and for fear and joy emotions in Arabic.

3 AffectiveTweets System

3.1 Tweets Preprocessing

Tweets often contain slang expressions, misspelled words, emoticons or abbreviations and it's needed to make some preprocessing steps before extracting features. First, every tweet was tokenized using *TweetNLP*¹(Gimpel et al., 2011). Then the AffectiveTweets² (Mohammad and Bravo-Marquez, 2017) package for Weka machine learning workbench (Hall et al., 2009) was used for feature extraction. The following steps were applied on tokens for every language in both tasks:

1. Tokens were converted to lowercase
2. URL links were replaced with *http://www.url.com* token
3. Twitter usernames (tokens starting with @) were replaced with *@user* token
4. Tokens containing sequences of letters occurring more than two times in a row were replaced with two occurrences of them (e.g. *huuuungry* is reduced to *hungry*, *loooooove* to *loove*)
5. Common sequences of words and emojis were divided by space (e.g. token *,nice:D:D'* was divided into two tokens *,nice'* and *,:D:D'*)

¹<http://www.cs.cmu.edu/~ark/TweetNLP/>

²<https://affectivetweets.cms.waikato.ac.nz/>

These steps lead to reduction of feature space as shown in (Go et al., 2009). We also used some individual preprocessing for Arabic language. After the above described steps every token was also processed via *Stanford Word Segmenter*³(Monroe et al., 2014). When using word embeddings, we transformed Arabic words from regular UTF-8 Arabic to a more ambiguous form⁴. This was done only for word embedding features.

3.2 Features

Our AffectiveTweets system used combinations of features that are described in this section. The submitted combination of features is shown in Table 1.

- **Word n-grams (WN_i^n):** word n -grams⁵ from i to n (for $i = 1, n = 2$, *unigrams* and *bigrams* were used).
- **Character n-grams (ChN_i^n):** character n -grams⁵ from i to n (for $i = 2, n = 3$ character *bigrams* and *trigrams* were used).
- **Word Embeddings (WE):** an average of the word embeddings of all the words in a tweet.
- **Affective Lexicons (L):** we used AffectiveTweets package to extract features from affective lexicons. In every language we also used SentiStrength (**L-se**) lexicon-based method (Thelwall et al., 2012).
- **LDA – Latent Dirichlet Allocation (D_n):** topic distribution of tweet, that is obtained from our pre-trained model, n indicates number of topics in model (for $n = 5$, feature vector with dimension 5 will be produced and each component of the vector refers to one topic). We used LDA features only in AffectiveTweets system.

3.2.1 English Word Embeddings:

- **Ultradense Word Embeddings (WE-ue):** Rothe et al. (2016) created embeddings in the Twitter domain.
- **Baseline Word Embeddings (WE-b):** Mohammad and Bravo-Marquez (2017) created embeddings from the Edinburgh Twitter Corpus (Petrović et al., 2010).

³<https://nlp.stanford.edu/software/segmenter.shtml>

⁴Some characters were replaced, for more details see (Soliman et al., 2017).

⁵Value of each feature is set to its frequency in the tweet

3.2.2 Spanish Word Embeddings:

- **Ultradense Word Embeddings (WE-us):** Rothe et al. (2016) created embeddings from web domain.
- **FastText Word Embeddings (WE-ft):** Bojanowski et al. (2016) trained embeddings on Wikipedia.

3.2.3 Arabic Word Embeddings:

- **Zahran et al. (2015) Word Embeddings (var-SG, var-GloVe, and var-CBOW)**
- **Soliman et al. (2017) Word Embeddings (tw-SG, tw-CBOW, web-SG, web-CBOW, wiki-SG, and wiki-CBOW)**

Mentioned Arabic word embeddings were created with Global Vectors (GloVe) (Pennington et al., 2014) and Word2Vec toolkit (Mikolov et al., 2013) using skip-gram (SG) model and continuous bag-of-words (CBOW) model. These Arabic word embeddings were trained on different data domains – Twitter (tw), web pages (web), Wikipedia (wiki), and their combination (var) for more details see the cited papers.

3.2.4 English lexicons (L-en):

- We used all affective lexicons from the AffectiveTweets package.

3.2.5 Spanish lexicons (L-es):

- Translated NRC Word-Emotion Association Lexicon (Mohammad and Turney, 2013)
- Emotion Lexicon (Sidorov et al., 2012)
- Polarity lexicon (Urizar and Roncal, 2013)
- Expanded Word-Emotion Association Lexicon (Bravo-Marquez et al., 2016) (we translated this lexicon to Spanish)
- iSOL (Molina-González et al., 2013)
- ML-SentiCon (Cruz et al., 2014)
- Ultradense lexicon (Rothe et al., 2016)
- LYSA Twitter lexicon (Vilares et al., 2014)

3.2.6 Arabic lexicons (L-ar):

- Translated NRC Word-Emotion Association Lexicon
- Translation of Bing Liu’s Lexicon
- Arabic Emoticon Lexicon
- Arabic Hashtag Lexicon

Table 1: Used features in the AffectiveTweets system

- Arabic Hashtag Lexicon (dialectal)
- Translated NRC Hashtag Sentiment Lexicon
- SemEval-2016 Arabic Twitter Lexicon

Lexicons are described in (Mohammad and Turney, 2013; Mohammad et al., 2016a; Salameh et al., 2015; Mohammad et al., 2016b).

3.3 Model Training

In our AffectiveTweets system we used an L_2 -regularized L_2 -loss SVM regression and classification model with the regularization parameter C set to 1, implemented in LIBLINEAR Library (Fan et al., 2008)⁶.

3.4 LDA Training

To use topics created with LDA (Latent Dirichlet Allocation) (Blei et al., 2003) as features, we trained our own models for every language. Tweets used to train the Arabic and Spanish models were taken from SemEval-2018 AIT DISC corpus (Mohammad et al., 2018) and tweets for English model were taken from Sentiment140⁷ training data (Go et al., 2009). We trained our LDA models with LDA implementation from MALLET⁸(McCallum, 2002).

We used the same preprocessing for LDA as for regular feature extraction. Additionally we removed stopwords and following special characters [, . ! -]. Tokens from Spanish tweets were stemmed with *Snowball*⁹ stemming algorithm.

4 Brainy System

We use Maximum Entropy classifier from Brainy machine learning library (Konkol, 2014) and UD-

Pipe (Straka et al., 2016) for preprocessing and doesn't use any lexicons, just word embeddings. The system is based on (Hercig et al., 2016).

4.1 Preprocessing

The same preprocessing has been done for all datasets. We use UDPipe (Straka et al., 2016) with Spanish Universal Dependencies 1.2 models and Arabic Universal Dependencies 2.0 models for POS tagging and lemmatization. Tokenization has been done by TweetNLP tokenizer (Owoputi et al., 2013). We further replace all user mentions with the token "@USER" and all links with the token "\$LINK".

4.2 Features

The Brainy system used the following features. The exact combination of features for each emotion and the change in performance caused by its removal is shown in Table 9.

- **Character n-grams (ChN_n):** Separate binary feature for each character n -gram in the utterance text. We do it separately for different orders $n \in \{1, 2, 3, 4, 5\}$ and remove n-grams with frequency t .
- **Bag of Words (BoW):** We used bag-of-words representation of a tweet, i.e. separate binary feature representing the occurrence of a word in the tweet.
- **Bag of Morphological features (BoM):** for all verbs in the tweet. The morphological features¹⁰ include abbreviation, aspect, definiteness, degree of comparison, evidentiality, mood, polarity, politeness, possessive, pronominal type, tense, verb form, and voice.

⁶<https://www.csie.ntu.edu.tw/~cjlin/liblinear/>

⁸<http://mallet.cs.umass.edu/>

⁹<http://snowballstem.org/>

¹⁰<http://universaldependencies.org/u/feat/index.html>

- **Bag of POS (BoPOS):** We used bag-of-words representation of a tweet, i.e. separate binary feature representing the occurrence of a POS tag in the tweet.
- **Bag of Parse Tree Tags (BoT):** We used bag-of-words representation of a tweet, i.e. separate binary feature representing the occurrence of a parse tree tag in the tweet. We remove tags with a frequency ≤ 2 .
- **Emoticons (E):** We used a list of positive and negative emoticons (Montejo-Ráez et al., 2012). The feature captures the presence of an emoticon within the text.
- **First Words (FW):** Bag of first five words with at least 2 occurrences.
- **Last Words (LW):** Bag of last five words with at least 2 occurrences.
- **Last BoM (LBoM):** Bag of last five morphological features (see BoM) with at least 2 occurrences.
- **FastText (FT):** An average of the FastText (Bojanowski et al., 2016) word embeddings of all the words in a tweet.
- **N-gram Shape (NSh):** The occurrence of word shape n-gram in the tweet. Word shape assigns words into one of 24 classes¹¹ similar to the function specified in (Bikel et al., 1997). We consider unigrams, bigrams, and trigrams with frequency ≤ 2 .
- **POS Count Bins (POS-B):** We map the frequency of POS tags in a tweet into a one-hot vector with length three and use this vector as binary features for the classifier. The frequency belongs to one of three equal-frequency bins¹². Each bin corresponds to a position in the vector. We remove POS tags with frequency $t \leq 5$.
- **TF-IDF:** Term frequency – inverse document frequency of a word computed from the training data for words with at least 5 occurrences and at most 50 occurrences.

¹¹We use `edu.stanford.nlp.process.WordShapeClassifier` with the `WORDSHAPECHRIS1` setting available in Stanford CoreNLP library (Manning et al., 2014).

¹²The frequencies from the training data are split into three equal-size bins according to 33% quantiles.

- **Text Length Bins (TL-B):** We map the tweet length into a one-hot vector with length three and use this vector as binary features for the classifier. The length of a tweet belongs to one of three equal-frequency bins¹². Each bin corresponds to a position in the vector.
- **Verb Bag of Words (V-BoW):** Bag of words for parent, siblings, and children of the verb from the sentence parse tree.

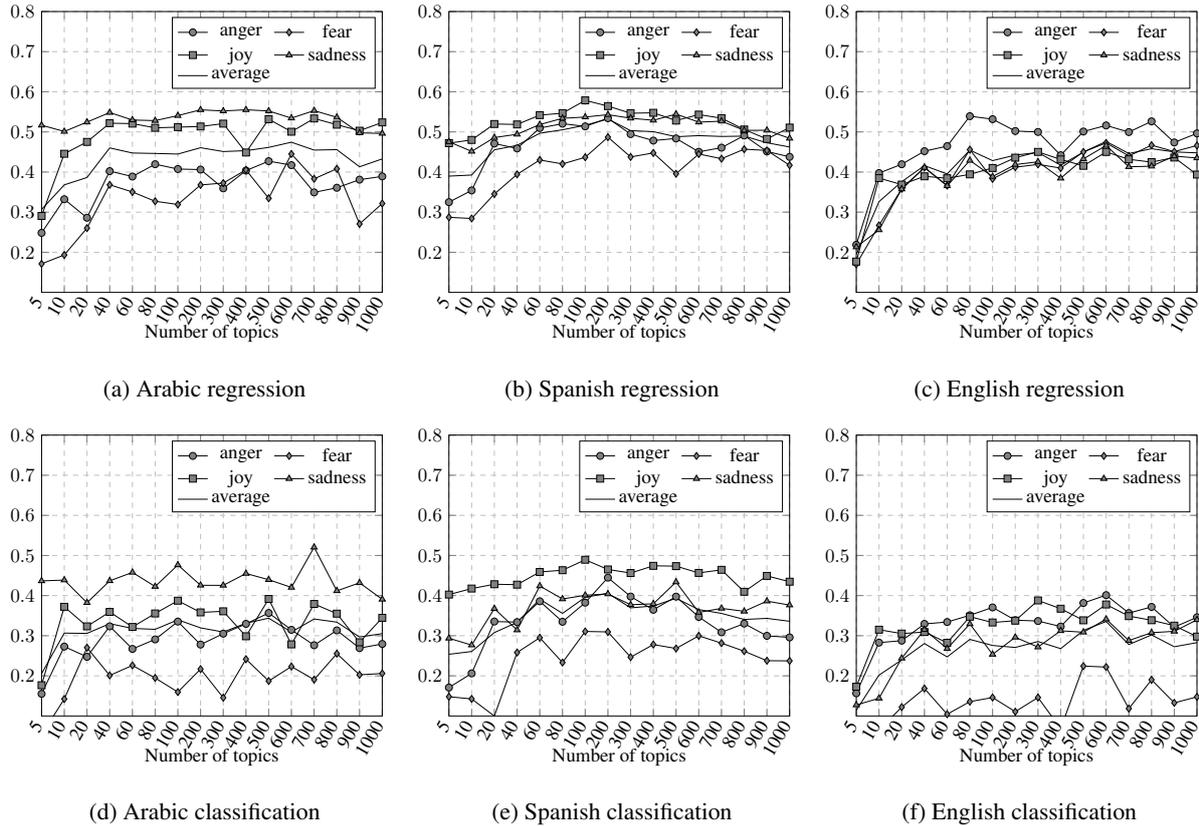

Figure 1: LDA performance based on number of topics, the y-axis denotes Pearson correlation

5 Experiments

All presented experiments are evaluated on the test data for the given task.

We performed ablation experiments to see which features are the most beneficial (see Table 9, 8, and 10). Numbers represent the performance change when the given feature is removed¹³.

Word embeddings features have a great impact on system performance, so we compared several word embeddings for every language (Table 2, 3, and 4). For English was best **WE-ue** word embeddings, but for submission we used **WE-b** word embeddings, because it worked better on dev data. In Spanish tweets the **WE-us** word embeddings outperformed the **WE-ft** word embeddings in regression and **WE-us** was better for classification in anger and on average of all emotions. For classification in Arabic was **var-CBOW** best on every emotion except anger and for regression **var-SG** worked best on average and on fear.

We also experimented with only LDA features to find out how the numbers of topics in LDA model affect the performance (see Figure 1). We star-

ted with models containing 5 topics and continued up to 1000 (step was non-equidistantly increased). Our experiments suggest that the best setting is around 200-300 topics. We selected the number of topics based on the performance on the development data.

6 Results

Our results in the emotion intensity regression subtask are in Table 5 and our results in the emotion intensity ordinal classification subtask are in Table 6 and Table 7. The system settings and features for each language and emotion were selected based on our pre-evaluation experiments with evaluation on the development data.

7 Conclusion

We competed in the emotion intensity regression and ordinal classification tasks in English, Arabic and Spanish.

Our ranks are 27th out of 48 for English, 5th out of 14 for Arabic, and 5th out of 16 for Spanish for the regression task and 21st out of 39 for English, 5th out of 14 for Arabic, and 5th out of 16 for Spanish for the ordinal classification task.

¹³The lowest number denotes the most beneficial feature

Abstract

In this paper, we propose an attention-based classifier that predicts multiple emotions of a given sentence. Our model imitates human’s two-step procedure of sentence understanding and it can effectively represent and classify sentences. With emoji-to-meaning preprocessing and extra lexicon utilization, we further improve the model performance. We train and evaluate our model with data provided by SemEval-2018 task 1-5, each sentence of which has several labels among 11 given emotions. Our model achieves 5th/1st rank in English/Spanish respectively.

1 Introduction

Since the revolution in deep neural networks, especially with the help of Long short-term memory (Hochreiter and Schmidhuber, 1997), it has been easy for machines to imitate human’s linguistic activities, such as sentence classification (Kim, 2014), language model (Sundermeyer et al., 2010), machine translation (Bahdanau et al., 2015).

Emotion classification is a subpart of sentence classification that predicts the emotion of the given sentence by understanding the meaning of it. Multi-label emotion classification requires more powerful ability to comprehend the sentence in variety of aspects. For example, given a sentence ‘For real? Look what I got for my birthday present!!’, it is easy for human to figure out that the sentence not only expressing ‘joy’ but also ‘surprise’. However, machines may require more task-specific structure to solve the same problem.

Attention mechanisms are one of the most spotlighted trends in deep learning and recently made their way into NLP. Applied to systems with neural networks, it functions as visual attention mechanisms found in humans (Denil et al., 2012) and the most effective region of features will be highlighted over time, making the system better exploit

the features related to the training objective. (Bahdanau et al., 2015) is one of the most significant footprints of attention mechanism in NLP and they applied attention mechanisms to machine translation for the first time. The model generates target word under the influence of related source words. Furthermore, Vaswani et al. (2017) proposed a brand new architecture for neural machine translation. The model utilizes attention mechanisms not only as the submodule but also as the main structure, improving time complexity and performance.

Inspired by (Vaswani et al., 2017), we come up with attention-based multi-label sentence classifier that can effectively represent and classify sentences. Our system is composed of a self-attention module and multiple CNNs enabling it to imitate human’s two-step procedure of analyzing sentences: comprehend and classify. Furthermore, our emoji-to-meaning preprocessing and extra lexicon utilization improve model performance on given dataset. We evaluated our system on the dataset of (Mohammad et al., 2018), where it ranked 5th/1st rank in English/Spanish respectively.

2 Model

Our system is mainly composed of two parts: self-attention module and multiple independent CNNs as depicted in Figure 1. This structure is actually imitating how human perform the same task. In general, human firstly read a sentence and try to comprehend the meaning, which corresponds to self-attention in our system. Then human categorize the sentence to each emotion separately but not all at once, and that is the reason why our system use 11 independent CNNs. In addition to main structure, we added the description of preprocessing in the model description because it makes up a large proportion in NLP tasks, especially when

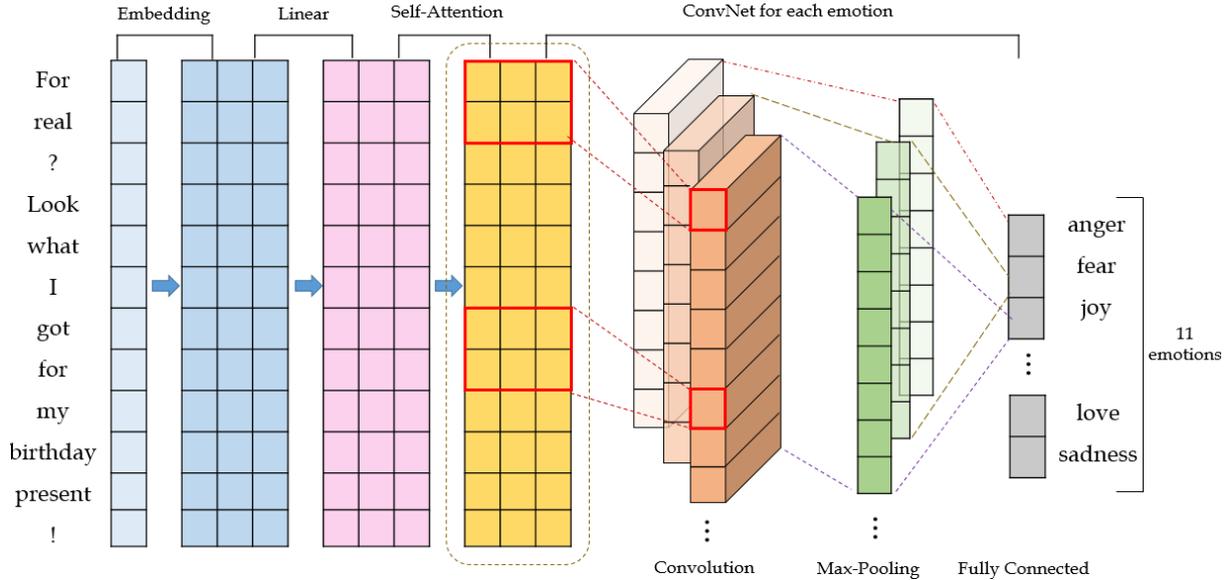

Figure 1: Overall architecture of the model. Preprocessed data goes through embedding layer, self-attention layer, Convolution layer and pooling layer step by step.

the dataset is small. Details are described in the following paragraph step by step.

Preprocessing: For raw data, we applied 3 steps of preprocessing:

- (i) Our system mainly deals with limited numbers of tweet data, which is very noisy. In this case, preprocessing of data has crucial impact on model performance. Emoji may be referred to as a typical property of tweets and we found that considerable number of tweets contain emojis. Each emoji has a meaning of their own, and we converted every emoji in the data to phrase/word that represents its meaning. We call this procedure as **emoji-to-meaning** preprocessing. Some tweets have too many repetition of certain emoji that may make the sentence over-biased to certain emotions. Against expectations, removing overlapped emojis reduced performance.
- (ii) Lower-case and tokenize data with **TweetTokenizer** in (Bird and Loper, 2002).
- (iii) Remove all of the mentions and '#' symbols in the beginning of all topics. Unlike mentions, topics may include emotional words and hence we don't remove the topic itself.

Embedding: It is especially helpful to use pre-trained word embeddings when dealing with a small dataset. Among those well-known word embeddings such as Word2Vec(Mikolov et al., 2013),

GloVe(Pennington et al., 2014) and fastText(Piotr et al., 2016), we adopt 300-dimension GloVe vectors for English ,which is trained on Common Crawl data of 840 billion tokens and 300-dimension fastText vectors for Spanish, which is trained on Wikipedia.

Self-attention: Vaswani et al. (2017) proposed a non-recurrent machine translation architecture called Transformer that is based on dot-product attention module. Usually, attention mechanisms are used as a submodule of deep learning models, calculating the importance weight of each position given a sequence. In our system, we adopt the self-attention mechanisms in (Vaswani et al., 2017) to represent sentences. The detailed structure of self-attention is shown in Figure 2. Dot-product of every embedded vector and weight matrix $W \in \mathbb{R}^{d_e \times 3d_e}$ is split through dimension as Q, K, V of the same size, where d_e is the dimensionality of embedded vectors. Then attended vector is computed as in (3).

$$E = [emb(x_1), emb(x_2), \dots, emb(x_n)] \quad (1)$$

$$[Q, K, V] = [eW \text{ for } e \text{ in } E] \quad (2)$$

$$Attn(Q, K, V) = softmax\left(\frac{QK^T}{\sqrt{d_e}}\right)V \quad (3)$$

Multi-head attention allows the model to benefit from ensemble effect only with the same amount

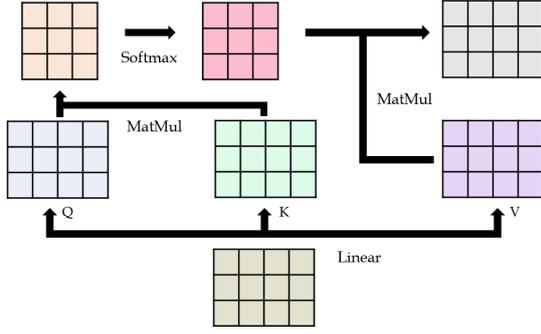

Figure 2: Inner architecture of self-attention module

of parameter.

$$Multihead(Q, K, V) = Concat(head_1, \dots, head_h) \quad (4)$$

where $head_i = Attn(Q_i, K_i, V_i)$

$$Q = [Q_1, \dots, Q_h], Q_i \in \mathbb{R}^{n \times \frac{d_e}{h}}$$

$$K = [K_1, \dots, K_h], K_i \in \mathbb{R}^{n \times \frac{d_e}{h}}$$

$$V = [V_1, \dots, V_h], V_i \in \mathbb{R}^{n \times \frac{d_e}{h}}$$

For each self-attention layer, there are additional position-wise feed-forward networks right after the attention submodule.

$$FFN(x) = max(0, xW_1 + b_1)W_2 + b_2 \quad (5)$$

$$\text{where } W_1 \in \mathbb{R}^{d_e \times d_f}, W_2 \in \mathbb{R}^{d_f \times d_e} \quad (6)$$

In addition to these two sub-layers, there is a residual connection around each sub-layer, followed by layer normalization. Also, we can stack self-attention layers by substituting the embedding vectors in (1) with the output of the last self-attention layer.

Convolution & Pooling: Followed by self-attention layer are 11 independent 1-layer Convolution layers with max-pooling layers. Kim (2014) has proved that CNNs have lots of potential in sentence processing task and we adopt the CNNs in the same way.

Output & Loss: Each output of CNNs go through a fully-connected layer to generate a logit. Sigmoid activation is applied to calculate the probability of each emotion, and we use the sum of each class' cross-entropy as the final loss function.

3 Experiments & Results

3.1 Data

For the SemEval 2018 shared task, Mohammad et al.(2018) has provided tweet data with multiple

labels among 11 pre-set emotions: 'angry', 'anticipation', 'disgust', 'fear', 'joy', 'love', 'optimism', 'pessimism', 'sadness', 'surprise' and 'trust'. We only use English and Spanish data among three different languages. The dataset consists of 6838/887/3259 tweets in English, 3561/679/2854 tweets in Spanish for train/validation/test data respectively.

3.2 Setup

We implemented a model with 3-layer self-attention and 1-layer CNN. With the restriction of fixed-size GloVe vector, we found that 300-dimension hidden state is excessive for such a small dataset that we added a position-wise linear layer between the embedding layer and self-attention layers to make $d_e = 30$. We employed $h = 2$ for multi-head attention and set $d_f = 64$. Two regularization techniques are applied to our system: Dropout with $P_{drop} = 0.1$ for self-attention, and L2 regularization for all weight matrix but not bias. We added 0.001 times regularization loss to original loss function. We optimized the loss with Gradient Descent using Adam optimization algorithm with additional learning rate decay.

3.3 Model variants

We conduct experiments with following variants of our model.

- **AC:** Self-attention + CNNs, which is our basic system.
- **AC - attn:** Basic system without self-attention module.
- **AC + nrc1:** We mainly used NRC Emotion lexicon(Mohammad and Turney, 2013) to make word-level label of each sentence, counting the occurrence of each emotion in the sentence. Each of the word-level label is concatenated to the output vector of each pooling layer.
- **AC + nrc2:** At evaluation/test step, binarize the word-level label and add 0.4 times the label value to the logit.
- **AC + synth:** Inspired by (Sennrich et al., 2016), we made synthetic data using unlabeled SemEval-2018 AIT DISC data¹ with

¹<https://www.dropbox.com/s/2phcvj300lcdnpl/SemEval2018-AIT-DISC.zip?dl=0>

pre-trained model, and fine-tuned the model with synthetic data.

3.4 Experimental results

We conduct several experiments to prove the effectiveness of our model, each to verify the benefit from: (1) tweets specific preprocessing (2) self-attention representation (3) emotional lexicon utilization. Experimental results are **mainly compared with English data**.

3.4.1 Impact of emoji-to-meaning

We firstly verify the efficiency of emoji-to-meaning preprocessing. Table 1 shows the accuracies of the same model with different preprocessing. We found that emoji-to-meaning preprocessing can improve the model accuracy by 1%. When a emoji is converted to its meaning, it can be represented as a combination of emotional words allowing it to not only reduce redundant vocabulary but also further emphasize the influence of certain emotions.

Model	Accuracy(valid)	Accuracy(test)
AC (w/o)	54.86%	54.91%
AC	55.94%	55.90%

Table 1: Experimental results with and without emoji-to-meaning preprocessing.

3.4.2 Impact of self-attention

To examine the effectiveness of self-attention representation, we simply get rid of self-attention layers. Table 2 shows that by removing the self-attention layers, both the validation/test accuracy dropped over 4%. This may be attributed to the ability of self-attention: It helps the model to better learn the long-range dependency of sentences. Learning long-range dependencies is a key challenge in NLP tasks and self-attention module can shorten the length of paths forward and backward signals have to traverse in the network as described in (Vaswani et al., 2017).

Model	Accuracy(valid)	Accuracy(test)
AC - attn	51.04%	51.60%
AC	55.94%	55.90%

Table 2: Comparison between our basic system and basic system without self-attention module.

3.4.3 Impact of extra resources

Lack of data has crucial impact on model generalization. Generalization techniques such as dropout or L2 regularization can relieve over-fitting problem to a certain extent; however, it can't totally substitute the effect of rich data. So we apply some heuristic methods to exploit extra resources as described in 3.3. Table 2 shows that model can slightly benefit from extra lexicon if used properly. However, adding synthetic data which is made from pre-trained model didn't help a lot, and in some cases even reduce the accuracy of the test result. Actually, Sennrich et al.(2016) emphasized that they used the monolingual sentences as the target sentences, informing that the target-side information, which corresponds to label in our task, is not synthetic. However, we made synthetic labels with a pre-trained model and it may only cause over-fitting problem to the original training data.

Model	Accuracy(valid)	Accuracy(test)
AC	55.94%	55.90%
AC + nrc1	56.13%	56.02%
AC + nrc2	57.16%	56.40%
AC + synth	55.88%	55.90%
Ensemble	59.76%	57.40%

Table 3: Experimental results with extra resources and an ensemble result

3.4.4 Ensemble

Our best results are obtained with an ensemble of 9 parameter sets of AC + nrc2 model that differ in their random initializations. The ensemble model achieved validation/test accuracy of 59.76%/57.40% in English data and 50.00%/46.90% in Spanish data respectively.

4 Conclusion

In this paper, we proposed an attention-based sentence classifier that can classify a sentence into multiple emotions. Experimental results demonstrated that our system has effective structure for sentence understanding. Our system shallowly follows human's procedure of classifying sentences into multiple labels. However, some emotions may have some relatedness while our model treats them independently. In our future work, we would like to further take those latent relation among emotions into account.

Abstract

This paper describes our participation in Affective Tweets task for emotional intensity and sentiment intensity subtasks for English, Spanish, and Arabic languages. We used two approaches, μ TC and EvoMSA. The first one is a generic text categorization and regression system; and the second one is a two-stage architecture for Sentiment Analysis. Both approaches are multilingual and domain independent.

1 Introduction

Sentiment Analysis is a research area where does a computational analysis of people's feelings or beliefs expressed in texts such as emotions, opinions, attitudes, appraisals, etc. (Liu and Zhang, 2012). People communicate not only the emotion or sentiment they are feeling, but also the intensity, that is, the degree of emotion or sentiment. In this context, SemEval is one of the forums that conducts evaluations on semantics at different levels, for instance, it proposes tasks such as sentiment analysis, the intensity of emotion or sentiment (affective tweets) (Mohammad et al., 2018), irony detection, among others (SemEval, 2017).

In this work, we present the results of our participation in Affective Tweets task for four of the five subtasks in English, Spanish, and Arabic languages and for all emotions available: anger, fear, joy, and sadness.

The subtasks are A) emotion intensity regression (EI-REG): given a tweet and an emotion, determine the intensity of the emotion that best represents the mental state of the tweeter, a real-value score between 0 and 1.

B) Emotion intensity ordinal classification

(EI-OC): given a tweet and an emotion E, classify the tweet into one of four ordinal classes of intensity of emotion: anger, fear, joy, and sadness, that best represents the mental state of the tweeter.

C) A sentiment intensity regression task (V-REG): given a tweet, determine the intensity of sentiment, a real-valued score between 0 (most negative) and 1 (most positive).

D) A sentiment analysis, ordinal classification (V-OC): given a tweet, classify it into one of seven ordinal classes, corresponding to several levels of positive and negative sentiment intensity.

In this context, one crucial step is the procedure used to transform the data (i.e., tweets) into the inputs (vectors) of the supervised learning techniques used. Typically, Natural Language Processing (NLP) approaches for data representation use n-grams of words, linguistic information such as dependency relations, syntactic information, lexical units (e.g., lemmas, stems), affective lexicons, error correction, etc. However, selecting the best configuration of those characteristics could be a cumbersome task, many times disregarded in favor of some *well-known* competitive setups. (Tellez et al., 2017b) studies the dependency between the performance and the proper selection of the text model. This selection can be seen as a combinatorial optimization problem where the objective is to maximize the performance metric of the classifier being used; this approach is implemented by μ TC, (Tellez et al., 2018). Due to its combinatorial nature, and the kind of parameters that compose the configuration space, the resulting classifiers are multilingual and domain independent. Therefore, with a tight dependency on the training set, it is mandatory to provide additional information about the particular task to avoid overfitting. In this sense, the use of multiple knowledge sources is essential, and combining them simply and effectively is the idea be-

*corresponding author: sabino.miranda@infotec.mx

hind EvoMSA. EvoMSA (§2.2) is a stacking system based on genetic programming, and particularly on the use of semantic genetic operators, that focus on sentiment analysis. The core of our contribution is to use both μ TC and EvoMSA to learn from different annotated collections and then use that diverse knowledge to tackle the SemEval 2018 Task 1 challenge.

Looking at systems that obtained the best results in previous SemEval editions, it can be concluded that it is necessary to include more datasets, see for instance BB_twttr system (Cliche, 2017) for Sentiment Analysis in the Twitter task, which uses more datasets besides the one given in the competition. Here, it was decided to follow a similar approach by including an additional human-annotated dataset publicly available for English, Spanish, and Arabic to build robust models.

2 System Description

As commented, we use two systems to evaluate the Affective Tweets task: μ TC and EvoMSA. On the one hand, μ TC is used mainly to evaluate two tasks for the Arabic language because in our experiments it obtained the best performance in almost all subtask in this language both for regression and classification tasks. On the other hand, EvoMSA is used to evaluate English and Spanish languages, and ordinal sentiment classification (valence) task for Arabic. In the following paragraphs, we describe these approaches.

2.1 μ TC

μ TC¹ is a minimalistic and wide system able to tackle text classification and regression tasks independent of domain and language a detail. For complete details of the model see (Tellez et al., 2018). Essentially, μ TC creates text classifiers (or a text regressors) searching for the best models in a given configuration space. A configuration consists of instructions to enable several preprocessing functions, a combination of tokenizers among the power set of several possible ones (character q-grams, n-word grams, skip-grams, etc.), and a weighting scheme (application of frequency filters and the use of TF, TFIDE, or several distributional schemes). μ TC seeks the best configurations optimizing a score which is evaluated through a classifier or a regressor; currently, it uses SVM for both tasks. In Table 1, we can see details of text

transformations used in our solution for detecting *Anger* emotion for Arabic. This set of text transformations was selected among millions of possible configurations through the combinatorial optimization process implemented in μ TC. In ordinal classification tasks the model is found out based on the training dataset provided for each emotion, if this is the case.

2.2 EvoMSA

EvoMSA² is a Sentiment Analysis System based on B4MSA and EvoDAG. It is an architecture of two phases to solve classification or regression tasks, see Figure 1. EvoMSA improves the performance of a global classifier combining the predictions of a set of classifiers with different models on the same text to be classified. Roughly speaking, in the first stage, a set of B4MSA classifiers (see Sec. 2.2.1) are trained with two kind of datasets; datasets provided by SemEval, and large datasets annotated by humans for sentiment analysis for English and Spanish languages (Mozetič et al., 2016), called HA datasets. In the case of HA datasets, it is split into balanced small datasets that feed each B4MSA classifier which produces three real output values, one for each sentiment (negative, neutral and positive). In the case of SemEval datasets, for instance, for EI-OC, the classifier produces one of four ordinal classes of intensity of emotion (0, 1, 2, 3). It creates a decision functions space with mixtures of values coming from different views of knowledge. Finally, EvoDAG’s inputs are the concatenation of all the decision functions predicted by each B4MSA system, and EvoDAG produces a final value or prediction. The following subsections describe the internal parts of EvoMSA. The precise configuration of our benchmarked system is described in Sec. 4.

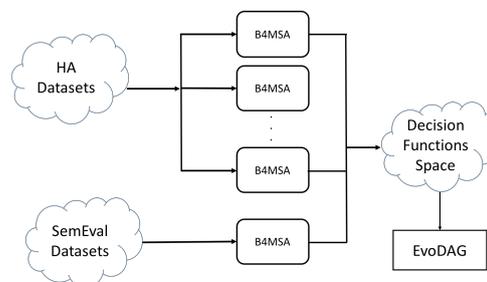

Figure 1: EvoMSA Architecture

¹<https://github.com/INGEOTEC/microTC>

²<https://github.com/INGEOTEC/EvoMSA>

2.2.1 B4MSA

B4MSA³ is related to μ TC, but this framework is mainly focused for multilingual sentiment analysis. For complete details of the model see (Tellez et al., 2017a,b).

The core idea behind B4MSA is similar to that of μ TC, i.e., it tackles the sentiment analysis problem as a model selection problem, yet using a different view of the underlying combinatorial problem. Also, contrarily to μ TC, B4MSA takes advantage of several domain-specific particularities like emojis and emoticons and makes explicit handling of negation statements expressed in texts. Nonetheless, EvoMSA avoids the sophisticated use of B4MSA fixing the model for each language in favor of performing an optimization process at the level of the decision functions of several models. Table 1 shows text transformation parameters used in our system for English and Spanish languages.

2.2.2 EvoDAG

EvoDAG⁴ (Graff et al., 2016, 2017) is a Genetic Programming system specifically tailored to tackle classification and regression problems on very high dimensional vector spaces and large datasets. In particular, EvoDAG uses the principles of Darwinian evolution to create models represented as a directed acyclic graph (DAG). An EvoDAG model has three distinct node's types; the inputs nodes, that as expected received the independent variables, the output node that corresponds to the label, and the inner nodes are the different numerical functions such as: sum, product, sin, cos, max, and min, among others. Due to lack of space, we refer the reader to (Graff et al., 2016) where EvoDAG is broadly described. In fact, in this research, we followed the steps explained there. In order to give an idea of the type of models being evolved, Figure 2 depicts a model evolved for the Arabic polarity classification at global message task. As can be seen, the model is represented using a DAG where direction of the edges indicates the dependency, e.g., cos depends on X_3 , i.e., cosine function is applied to X_3 . As commented above, there are three types of nodes; the inputs nodes are colored in red, the inner nodes are blue (the intensity is related to the distance to the height, the darker the closer), and the green node is the output node. As men-

tioned previously, EvoDAG uses as inputs the decision functions of B4MSA, then the first three inputs (i.e., X_0 , X_1 , and X_2) correspond to the decision functions values of the negative, neutral, and positive polarity of B4MSA model trained with SemEval Arabic dataset, and the later two (i.e., X_3 and X_4) correspond to the decision function values of two B4MSA systems each one trained with other dataset for two classes. It is important to mention that EvoDAG does not have information regarding whether input X_i comes from a particular polarity decision function, consequently from EvoDAG point of view all inputs are equivalent.

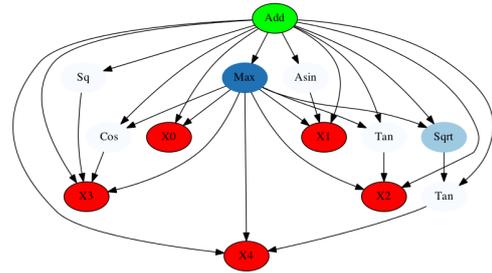

Figure 2: An evolved model for the Arabic task.

3 Experimental Settings

As we mentioned, to determine the best configuration of parameters for text modeling, μ TC and B4MSA integrate a hyper-parameter optimization phase that ensures the performance of the classifier based on the training data. The text modeling parameters for B4MSA were set for all process as we show in Table 1 for English and Spanish language for classification and regression tasks. In the case of the Arabic language, the parameters were calculated by the optimization phase; an example is showed in Table 1. A text transformation feature could be binary (yes/no) or ternary (group/delete/none) option. Tokenizers denote how texts must be split after applying the process of each text transformation to texts. Tokenizers generate text chunks in a range of lengths, all tokens generated are part of the text representation. Both, B4MSA and μ TC, allow selecting tokenizers based on n -words, q -grams, and skip-grams, in any combination. We call n -words to the well-known word n -grams; in particular, we allow to use any combination of unigrams, bigrams, and trigrams. Also, the configuration space allows selecting any combination of character q -grams (or just q -grams) for $q = 1$ to 9. Finally, we allow to

³<https://github.com/INGEOTEC/b4msa>

⁴<https://github.com/mgraffg/EvoDAG>

use (2, 1) and (3, 1) skip-grams (two words separated by one word, and three words separated by a gap).

Table 1 shows the final configurations for English and Spanish and an example for one emotion for Arabic. For example, *numbers* are deleted in Arabic, but it is grouped in English and Spanish. In the case of English, it is split in unigrams, bigrams, character q -grams of sizes 2, 3, and 4.

Text transformation	English	Spanish	Arabic
remove diacritics	yes	yes	yes
remove duplicates	yes	yes	yes
remove punctuation	yes	yes	yes
emoticons	group	group	group
lowercase	yes	yes	false
numbers	group	group	delete
urls	group	group	group
users	group	group	none
hashtags	none	none	none
entities	none	none	none
Term weighting			
TF-IDF	yes	yes	no
Entropy	no	no	yes
Tokenizers			
n-words	{1, 2}	{1, 2}	{1, 2}
q-grams	{2, 3, 4}	{2, 3, 4}	{2, 3, 7, 9}
skip-grams	—	—	—

Table 1: Example of set of configurations for text modeling

3.1 Datasets

SemEval provides datasets to train systems for each subtask. For instance, for emotion Anger in English, subtask emotion intensity ordinal classification, OC, the training data is distributed for four classes (class 0 = 445, class 1 = 322, class 2 = 507, class 3 = 427). The Arabic datasets for each emotion have around 800 samples each one, for English the sizes are between 1500 and 2200 samples, and for Spanish are between 1000 and 1150 samples, for more details of the data distribution and how the datasets were built we refer the reader to (Mohammad et al., 2018; Mohammad and Kiritchenko, 2018). In addition of SemEval data, we use extra datasets annotated by humans around 73 thousand tweets for English, 223 thousand for Spanish (Mozetič et al., 2016), and two thousand for Arabic (NRC, 2017). Table 2 shows the distribution of classes for datasets. Those datasets are mainly used for sentiment analysis; however, we use this extra information to improve the final decision in the approach we implemented (EvoMSA).

HA-DataSet	Positive	Neutral	Negative	Total
English	21,166	33,620	18,454	73,240
Spanish	107,252	89,782	26,272	223,306
Arabic	448	202	1,350	2,000

Table 2: Statistics of Human-Annotated training data. We used the labeled English and Spanish data from (Mozetič et al., 2016), and the Arabic data from (NRC, 2017).

4 Results

We present the results of our approaches in Table 3 and Table 4. All experiments were tested on the development dataset provided by SemEval. In the case of OC tasks, we use the macro-F1 score to measure the performance, and in the case of Reg tasks, we use the Pearson correlation coefficient. Table 3 shows the results of emotional intensity for ordinal classification (OC) and regression tasks (Reg) grouped by each emotion and language. Table 4 shows the results of sentiment analysis, ordinal classification task (V-OC) and sentiment intensity regression task (V-Reg) group by each emotion and language. We present three system configurations in Table 3 and Table 4. EvoMSA configuration uses only the training datasets provided by SemEval, and it is used as regressor or classification system. In addition of SemEval data, EvoMSA-HA uses extra information comes from sentiment analysis domain, and this information improves the performance as we can see. And μ TC uses only the training data provided by the contest as the knowledge base to calculate the final class or real value. As we can see in Table 3, the best performance obtained are grouped by EvoMSA-HA configuration for both OC and Reg tasks for English and Spanish languages. For the Arabic language, μ TC is quite good with OC and Reg task. According to the results we obtained, we decided to use for the evaluation phase the following configuration: EvoMSA-HA is used for OC, Reg, V-OC, and V-Reg tasks for English and Spanish; also for OC (Fear and Joy) and V-OC tasks for Arabic; and μ TC is used for Arabic in OC (Anger and Sadness), Reg, and V-Reg tasks. In the table, the performance of our configuration systems, on gold standard, is labeled by subscripts; they stand for the rank in the general evaluation. For example, for Spanish in OC task, we were ranked for Anger emotion in position 4; Fear, position 2; Joy, position 3; and Sadness, position 2.

Configuration	Anger	Fear	Joy	Sadness

5 Conclusions

In this paper was presented our solution for Affective Tweets task combining two approaches EvoMSA and μ TC. Both systems are designed to be multilingual and language and domain independent as much as possible. For the training step, we use extra human annotated datasets out of any specific emotion, but related to sentiment-analysis information; our solution performs well in Spanish and Arabic languages; however, there is room for further improvements in performance for tasks in English language using another sort of knowledge such as semantic information (word embeddings) into EvoMSA architecture.

firstname.lastname@epita.fr

Abstract

In this paper we present our system for detecting valence task. The major issue was to apply a state-of-the-art system despite the small dataset provided : the system would quickly overfit. The main idea of our proposal is to use transfer learning, which allows to avoid learning from scratch. Indeed, we start to train a first model to predict if a tweet is positive, negative or neutral. For this we use an external dataset which is larger and similar to the target dataset. Then, the pre-trained model is re-used as the starting point to train a new model that classifies a tweet into one of the seven various levels of sentiment intensity.

Our system, trained using transfer learning, achieves 0.776 and 0.763 respectively for Pearson correlation coefficient and weighted quadratic kappa metrics on the subtask evaluation dataset.

1 Introduction

The goal of detecting valence task is to classify a given tweet into one of seven classes, corresponding to various levels of positive and negative sentiment intensity, that best represents the mental state of the tweeter. This can be seen as a multiclass classification problem, in which each tweet must be classified in one of the following classes : very negative (-3), moderately negative (-2), slightly negative (-1), neutral/mixed (0), slightly positive (1), moderately positive (2) and very positive (3) (Mohammad et al., 2018).

Several companies have been interested in customer opinion for a given product or service. Sentiment analysis is one approach to automatically detect their emotions from comments posted in social networks.

With the recent advances in deep learning, the ability to analyse sentiments has considerably improved. Indeed, many experiments have used state-of-the-art systems to achieve high perfor-

mance. For example, (Baziotis et al., 2017) use Bi-directional Long Short-Term Memory (B-LSTM) with attention mechanisms while (Deriu et al., 2016) use Convolutional Neural Networks (CNN). Both systems obtained the best performance at the the 2016 and 2017 SemEval 4-A task respectively.

The amount of data is argued to be the main condition to train a reliable deep neural network. However, the dataset provided to build our system is limited. To address this issue, two solutions can be considered. The first solution consists in extending our dataset by either manually labeling new data, which can be very time consuming, or by using over-sampling approaches. The second solution consists in applying a transfer learning, which allows to avoid learning the model from scratch.

In this paper, we apply a transfer learning approach, from a model trained on a similar task : we propose to pre-train a model to predict if a tweet is positive, negative or neutral. Precisely, we apply a B-LSTM on an external dataset. Then, the pre-trained model is re-used to classify a tweet according to the seven-point scale of positive and negative sentiment intensity.

The rest of the paper is organized as follows. Section 2 presents a brief definition of transfer learning. The description of our proposed system is presented in Section 3. The experimental setup and results are described in Section 4. Finally, a conclusion is given with a discussion of future works in Section 5.

2 Transfer Learning

Transfer Learning (TL) consists in transferring the knowledge learned on one task to a second related task. In other words, the TL is about training a base network and then copy its first n layers to the first n layers of a target network (Yosinski et al., 2014). Usually the first n layers of a pre-

trained model (or source model) are frozen when training the new model. This means that weights are not changed during training on the new task. TL should not be confused with fine-tuning where the back-propagation error affects the entire neural network (including the first n layers).

For a limited number of training examples, TL allows to provide more precise predictions than the traditional supervised learning approaches. Moreover, TL significantly speeds up the learning process as training does not start from scratch. For example, (Cirean et al., 2012) use a CNN trained to recognize the Latin handwritten characters for the detection of Chinese characters. In natural language processing, TL has improved the performance of several systems from various domains such as : sentiment classification (Glorot et al., 2011), automatic translation (Zoph et al., 2016), speech recognition and document classification (Wang and Zheng, 2015).

3 Proposed System

In this section, we present the four main steps of our approach : (1) **Text processing** to filter the noise from the raw text data, (2) **Feature extraction** to represent words in tweets as vectors of length 426 by concatenating several features, (3) **Pre-training model** to predict the tweet polarity (positive, negative or neutral) based on external data and (4) **Learning** a new model where the pre-trained model is adapted to our task by removing the last layer and adding a fully-connected layer followed by an output layer.

3.1 Text processing

Tweets are processed using *ekphrasis*¹ tool which allows to perform the following tasks : tokenization, word normalization, word segmentation (for splitting hashtags) and spell correction (*i.e* replace a misspelled word with the most probable candidate word). All words are lowercase. E-mails, URLs and user handles are normalized. A detailed description of this tool is given in (Baziotis et al., 2017).

3.2 Feature extraction

Each word in each tweet is represented by a vector of 426 dimensions which are obtained by the concatenation of the following features :

1. <https://github.com/cbaziotis/ekphrasis>

- *AFINN* and *Emoji Valence*² are two lists of english words and emojis rated for valence scoring range from -5 (very negative) to $+5$ (very positive) (Nielsen, 2011).
- *Depeche Mood* is a lexicon of $37k$ words associated with emotion scores (afraid, amused, angry, annoyed, sad, happy, inspired and don't care) (Staiano and Guerini, 2014).
- *Emoji Sentiment Lexicon* is a lexicon of the 969 most frequent emojis. The emojis sentiment is computed from the sentiment (positive, negative or neutral) of tweets in which they occur. Each emoji is associated with a unicode, number of occurrences, position in the tweet $[0, 1]$ (0 : start of the tweet, 1 : end of the tweet), probabilities of negativity, neutrality, and positivity of the emoji (Novak et al., 2015).
- *Linguistic Inquiry and Word Count* is a dictionary containing 5,690 stems associated with 64 categories, from linguistic dimensions to psychological processes (Tausczik and Pennebaker, 2010).
- *NRC Word-Emotion Association*, *Hashtag Emotion/Sentiment* and *Affect Intensity Lexicons* are lists of english words and their associations with eight emotions (anger, fear, anticipation, trust, surprise, sadness, joy, and disgust) and two sentiments (positive, negative), each with specificities detailed in (Mohammad and Turney, 2013), (Mohammad and Kiritchenko, 2015) and (Mohammad, 2017). The intensity score for both emotions and sentiments takes a value between 0 and 1.
- *Opinion Lexicon English* contains around $7k$ positive and negative sentiment words for the english language (Hu and Liu, 2004).
- *Sentiment140* is a list of words and their associations with positive and negative sentiment (Mohammad et al., 2013).
- *Words embeddings* are dense vectors of real numbers capturing the semantic meanings of words. We use datastories embeddings (Baziotis et al., 2017) which were trained on 330M english twitter messages posted from 12/2012 to 07/2016. The embeddings used in this work are 300 dimensional.

2. <https://github.com/words/emoji-emotion>

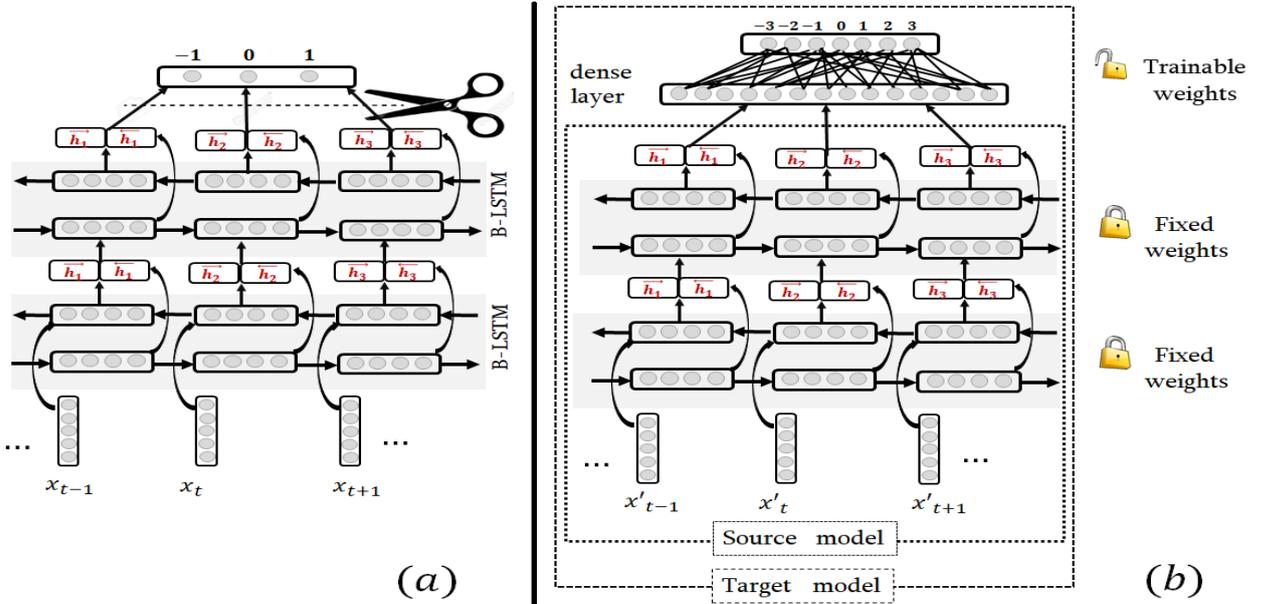

Figure 1 – Our transfer learning approach for sentiment analysis. (a) Pre-trained model learned with B-LSTM network with 2 layers of 150 neurons each to predict if a tweet is positive, negative or neutral. (b) The first layers of pre-trained model are locked and re-purposed to predict various levels of positive and negative sentiment intensity.

3.3 Pre-training model

The objective is to build a model which allows to predict the tweeter’s attitude (positive, negative or neutral). Bidirectional Long Short-Term Memory networks (B-LSTM) (Schuster and Paliwal, 1997) have become a standard for sentiment analysis (Baziotis et al., 2017) (Mousa and Schuller, 2017) (Moore and Rayson, 2017). B-LSTM consists in two LSTMs in different directions running in parallel : the first forward network reads the input sequence from left to right and the second backward network reads the sequence from right to left. Each LSTM yields a hidden representation : \vec{h} (left to right vector) and \overleftarrow{h} (right-to-left vector) which are then combined to compute the output sequence. For our problem, capturing the context of words from both directions allows to better understand the tweet semantic. We here use a B-LSTM network with 2 layers of 150 neurons each. The architecture is shown in Figure 1 (a).

For training, we use the external dataset³ composed of 50333 tweets (7840 negatives, 19903 positives and 22590 neutrals).

3. https://github.com/cbaziotis/datastories-semeval2017-task4/tree/master/dataset/Subtask_A/downloaded.

3.4 Learning model

Let us note that our final objective is to train a model to classify a tweet into seven classes (very negative, moderately negative, slightly negative, neutral, slightly positive, moderately positive and very positive). To train the model, we use the dataset provided for the target task (Mohammad and Kiritchenko, 2018). The training and development dataset contain respectively 1180 and 448 tweets. Since the dataset is small, fine-tuning may result in overfitting. Therefore, we propose to freeze the network layers except the final dense layer that is associated with the three classes sentiment analysis, which is removed after pre-training. Then, we add a fully-connected layer of 150 neurons followed by an output layer of 7 neurons, as illustrated on Figure 1 (b).

4 Results and Analysis

The official⁴ evaluation metric is *Pearson Correlation Coefficient* (P). Submitted systems are also evaluated with the weighted quadratic kappa (W). However, the pre-trained model was evaluated using classification accuracy. We implemented our system using Keras tool with the Tensorflow backend.

4. https://github.com/felipebravom/SemEval_2018_Task_1_Eval

4.1 Pre-trained model evaluation

As proposed in (Baziotis et al., 2017), we used B-LSTM with the following parameters : size of LSTM layers is 150 (300 for B-LSTM), 2 layers of B-LSTM, with a dropout of 0.3 and 0.5 for embedding and LSTM layers respectively. Other hyper-parameters used are : Gaussian noise with σ of 0.3, and L_2 regularization of 0.0001. We trained the B-LSTM over 18 epochs with a learning rate of 0.01 and batch size of 128 sequences.

We trained our model with external data (more details in section 3.3) but for the evaluation we adapted the training and development sets provided for the target task. The various levels of positive sentiments (*i.e* slightly, moderately and very positive) were regrouped in the same class. The same goes for the various levels of negative sentiments. Our model achieves 69.4% of accuracy.

4.2 Model evaluation

We adapted the pre-trained model described above by removing the last fully-connected layer, and added a dense layer of 150 neurons followed by an output layer of 7 neurons. As a reminder, the pre-trained layers are frozen. We used the training and development sets to train our system, and evaluated by predicting the valence on the evaluation set. We trained our model over 8 epochs with a learning rate of 0.01 and batch size of 50 sequences. Our model achieves 0.776 and 0.763 respectively on P and W .

4.3 Other experiments

Finally, we conducted a set of experiments to validate our system and approach. We evaluated more commonly used systems, with and without transfer learning. These new systems are built by :

- using similar number of layers, parameters and hyper-parameters.
- replacing B-LSTM layers by LSTM, CNN and dense layers.
- for the DNN, computing predictions using the mean of each word-vector of tweets, since it can not use sequences as input.
- for the CNN, using multiple convolutional filters of sizes 3, 4 and 5.
- for the combinations of systems, averaging the output probabilities.

The results are presented on Table 1.

We can observe that TL approach achieves better scores, and that B-LSTM is leading the score

Approach	Systems	Pearson
Without TL	DNN	0.683
	CNN	0.702
	LSTM	0.721
	B-LSTM	0.735
	CNN + LSTM	0.742
With TL	CNN	0.741
	B-LSTM	0.776
	CNN + B-LSTM	0.755

Table 1 – Pearson scores on test set with different systems and combinations.

on both approaches as a single system. Moreover, combining systems enhances greatly the prediction without TL, but decreases the score with TL : the combination of independent systems compensates a small lack of data, but becomes useless with enough training.

5 Conclusion

In this paper, we propose to use a transfer learning approach for sentiment analysis (SemEval2018 task 1). Using B-LSTM networks, we pre-trained a model to predict the tweet polarity (positive, negative or neutral) based on an external dataset of 50k tweets. To avoid the overfitting, layers (except the last one) of the pre-trained model were frozen. A dense layer was then added followed by a seven neurones output layer. Finally, the new network was trained on the small target dataset. The system achieves a score of 0.776 on Pearson Correlation Coefficient.

Improvements could be made concerning the features, and by using attention mechanisms. However, the future work will focus on multiple transfers, to increase the amount of data used in the process. We will perform transfers from two classes (positive and negative) to three classes (adding neutral), then five classes and finally seven classes. Numerous datasets⁵ are currently available to deploy such a system.

Acknowledgments

We thank Dr. Yassine Nair Benrekia for interesting scientific discussions.

KDE-AFFECT at SemEval-2018 Task 1: Estimation of Affects in Tweet by Using Convolutional Neural Network for n -gram

Shinnosuke Himeno and Masaki Aono

Department of Computer Science and Engineering

Toyohashi University of Technology

himeno@kde.cs.tut.ac.jp, aono@tut.jp

Abstract

This paper describes our approach to SemEval-2018 Task1: Estimation of Affects in Tweet for 1a and 2a. Our team KDE-AFFECT employs several methods including one-dimensional Convolutional Neural Network for n -grams, together with word embedding and other preprocessing such as vocabulary unification and Emoji conversions into four emotional words.

1 Introduction

With the rapid spread of SNS services (e.g. Twitter, Facebook, Instagram), massive user opinions have accumulated on the Internet. Among such opinions, it has been observed that not a few SNS contents naturally entail the affects (including joy, anger, sadness, fear) within themselves. Hence, the need to accurately detect the affects is increasing year by year.

In SemEval-2018 Task 1: Estimation of Affects in Tweet, we have attempted to extend our horizon from positive, neutral, and negative polarity estimations in former SemEval sentiment analysis in tweet having been held till 2017, to multiple emotions (joy, anger, sadness, and fear) in terms of regression (Task-1 1a) and classification (Task-1 2a). In doing so, we have adopted a standard one-dimensional Convolutional Neural Network (CNN), which is believed to be effective for text polarity estimation, where the kernel window size for 1D convolution is analogous to the concept of word n -gram. In addition, as most people have noticed, a tweet has potentially many Emojis to express emotions. In the following, we first briefly survey related work on tweet sentiment analysis including emotion estimation. Then, we describe our system, followed by showing the results returned from the organizer, and finally concluding our paper.

2 Related Work

Sentiment analysis of tweets has been studied by many researchers from the standpoint of classifying a tweet into either positive or negative polarity, and classifying it into multiple emotions (Giachanou and Crestani, 2016; Silva et al., 2016). A supervised approach to polarity classification of a tweet was proposed by Go et al. (2009). They employed Naive Bayes, Maximum Entropy, Support Vector Machine, and several other machine learning methods for their supervised learning. Bravo-Marque et al. (2013) presented an approach using multiple emotion dictionaries, while Saif et al. (2016) employed co-occurrence information of words. Severyn et al. (2015) introduced a deep learning approach. Lu et al. (2013) proposed a deep learning method suited for short texts. In SemEval, since 2014, sentiment analysis tasks using Twitter have been officially conducted, where a variety of methods have been tested (Hagen et al., 2015; Giorgis et al., 2016; Deriu et al., 2016; Rouvier and Favre, 2016; Xu et al., 2016). In SemEval2017 Rosenthal et al. (2017), Cliche et al. (2017) and Hamdan et al. (2017) presented methods for combining multiple Convolutional Neural Networks (CNNs) and multiple Long Short-Term Memories (LSTMs). Mohammad (2017) published an open dictionary of emotion scores for each word. Mohammad et al. published a dataset for estimating emotion intensities (Mohammad and Bravo-Marquez, 2017).

3 Methodology

In this section, we focus on our methods and ideas employed in this task. The fundamental idea of our method is based on the observation that “ n -grams” seem to have vital effects to represent the emotion of a tweet, where “ n -gram” denotes n consecutive words (instead of n consecutive char-

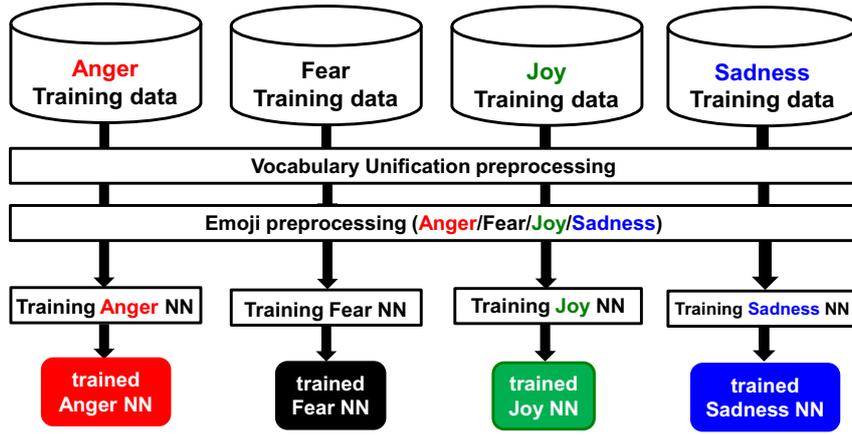

Figure 1: Overall Training Flow of KDE-AFFECT

acters). For instance, if the tweet sentence is “At last I made it.”, 2-gram includes (At, last) and (made, it). Similarly, 3-gram includes (At, last, I) and (I, made, it).

We have adopted the method based on the n -gram convolution proposed by Kim (2014). Here, we prepare a matrix corresponding to a sentence representing an n -gram convolution in which this filtering process is carried out by the unit of an n -gram.

The overview of our system is as follows: First we apply preprocessing with “vocabulary unification” including lower case conversion, URL unification, two or more consecutive character squeezing, and hashtag elimination. Second, we apply Emoji conversion into four emotional words, which will be elaborated later. From Emoji conversion, we train the model independently for each emotion. Finally, we predict the emotion score for an unknown tweet by using the trained model. The overall system flow is shown in Figure 1.

3.1 Preprocessing with Vocabulary Unification

This step is applied to all emotions. It consists of the following processing:

- lower case conversion
- conversion of every instance of a URL string in a tweet to “<URL>”
- collapse of two or more consecutive letters into two
- elimination of hash sign (#)

It should be noted that by a url string we mean a regular expression starting with either “http”, “https”, “ftp”, or “www”. Any url string is converted to <URL>. For example, “I want to be

happy on <http://t.co/S6moxr1U>” is converted to “I want to be happy on <URL>”.

3.2 Preprocessing for Emoji

From our observation of real tweets, approximately more than 20% of them have some kind of Emojis. Emotions are naturally represented by many different Emojis. Hence, we introduce the conversion of possible emotions represented by an Emoji into each emotional word. Please note that Emoji preprocessing is applied to all Emoji data, regardless of emotions. For instance, each anger Emoji might appear not only in an Anger dataset, but in Fear, Joy, and Sadness datasets as well. This is why we have decided to apply the Emoji conversion despite the differences of emotions. In the following, we present Emoji for each emotion, where Emoji has been taken from a Full Emoji Web site¹. The selection of Emoji has been made by using the labels (such as “face-positive”) annotated to the above Web sites.

3.2.1 Anger Emoji

The Anger Emojis we selected are shown in Figure 2. All of them are replaced by “anger”.

Figure 2: Anger Emoji

3.2.2 Fear Emoji

The Fear Emojis we selected are shown in Fig. 3. All of them are replaced by “fear”.

¹<https://unicode.org/emoji/charts/full-emoji-list.html>

Figure 3: Fear Emoji

3.2.3 Joy Emoji

The Joy Emojis we selected are shown in Fig. 4. All of them are replaced by "joy".

Figure 4: Joy Emoji

3.2.4 Sadness Emoji

The Sadness Emojis we selected are shown in Fig. 5. All of them are replaced by "sadness".

Figure 5: Sadness Emoji

3.3 Convolutional Neural Network for n -gram

Once preprocessing is done, we have a kind of rectified tweet, represented by a matrix. Figure 6 illustrates a word-by-word matrix representation of a rectified tweet. Here we take a matrix of 80 by 300, where 80 is the maximum number of words per tweet, and 300 corresponds to our embedding vector size. If a tweet has less than 80 words, zero padding is performed to fill the input matrix.

3.3.1 Embedding

In Embedding, each tweet is converted to a matrix. Specifically, we first divide a tweet into words using a whitespace, thereby treating a special character (one of “.h, “,h, “!h, and “?h) as a separate word. Second, we transform each word into its distributed representation of 300 dimensions using Word2Vec (Mikolov et al., 2013a,b). The training of Word2Vec itself is done by using approximately 470 million tweets after the processing de-

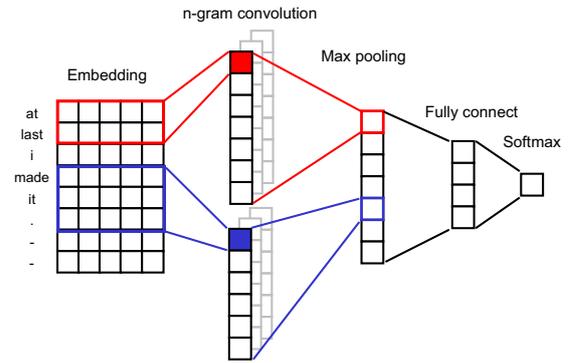

Figure 6: Our n -gram Convolution-based Approach

scribed in 3.1. We finally obtain the embedding by padding zero values to a fixed size of a 80 by 300 dimensional matrix.

3.3.2 n -gram Convolution Layer

In an n -gram convolutional layer, we perform convolution, and generate a length $m - n + 1$ vector, where m denotes the maximum word length (here 80). This is straightforward, since both ends are trimmed during the n -gram convolution stage shown in Figure 6. For instance, if 3-gram is concerned, the length in our implementation will be $80-3+1 = 78$. Note that we have multiple n -gram convolutional layers for each emotion. “Joy” neural network architecture, for example, has 2-gram, 3-gram, 4-gram, and 5-gram convolutional layers, which will be discussed later in Table 3.

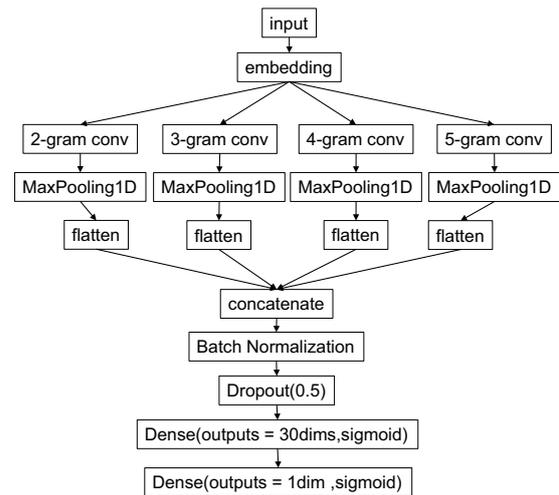

Figure 7: KDE-AFFECT system’s DNN architecture

3.3.3 Max Pooling Layer

In a Max Pooling layer, from each n -gram convolutional layer, the maximum value is computed,

Intensity range	Intensity amount
[0.0, 0.35)	0 (no E)
[0.35, 0.5)	1 (low amount of E)
[0.5, 0.65)	2 (moderate amount of E)
[0.65, 1.0]	3 (high amount of E)

Table 1: Inferred Intensity Level

and a vector of the length equal to the number of filters is generated. In our system, the output of four multiple n -gram convolutional layers are flattened and concatenated in the subsequent layers. The output dimension is the number of filters multiplied by the number of n -gram convolutional layers.

3.3.4 Fully-connected Layers

In our system, we have two fully-connected layers, where the first hidden fully-connected layer accepts the input from the concatenation layer connected from multiple max pooling layers. Empirically, we set 30 outputs for the first fully-connected layer. The second layer outputs either the estimated intensity value of an emotion (Task 1a) or the estimated intensity level (Task 2a). The way to estimate the intensity level (Task 2a) is elaborated in the next section.

3.4 Estimating Intensity Level (Task 2a)

For Task 2a, we need to estimate the intensity level. Specifically, participants are required to classify the emotional intensities into four levels; high amount, moderate amount, low amount, and nothing. Our strategy for the amount of emotional intensity amount level is simple, which is based on the inferred intensity range as shown in Table 1. In Table 1, the left column denotes the range of emotional amount that we have defined for this task. For example, [0.0, 0.35) means that the left boundary 0.0 is inclusive, while the right boundary 0.35 is exclusive in the range of the amount of emotion.

4 Experiments

Here we describe the experimental environment and our evaluation results.

4.1 dataset

All participants are given SemEval 2018: Task 1 Affect in Tweets (AIT) (Mohammad et al., 2018) dataset. The details are shown in Table 2.

	Anger	Fear	Joy	Sadness
Training	1701	2252	1616	1532
Dev.	388	389	290	397
Test (1a)	17940	17924	18043	17913
Test (2a)	1002	986	1105	975

Table 2: SemEval 2018: Task 1 dataset (1a and 2a)

4.2 Evaluation Measure

Here, the evaluation measure for a model is correlation coefficient r . Given variables x and y , where x corresponds to a predicted emotion value and y to a true emotion value, and their associated sample variances S_x , S_y , and the covariance S_{xy} are represented by the following equation:

$$r = \frac{S_{xy}}{S_x S_y}$$

4.3 Experiment Environment

For our deep learning program for the task, we used the following list of hyper-parameters:

loss function: Root Mean Square Error (RMSE)

filter number: $200 \times n$

epochs: 30

dropout rate: 0.5

optimizer: Adam

batch size: 64

The framework we use is Keras with backend Tensorflow. In our Ubuntu server, it took approximately 1 second for each epoch.

4.4 Preliminary Experiments for n -gram Convolutions

For each emotion, our system attempts to find an empirical optimal combination of n -gram convolutions. Table 3 summarizes the results of preliminary experiments for this purpose. Here, $r(A)$ denotes the correlation coefficient for Anger. Similarly, $r(F)$ for Fear, $r(J)$ for Joy, and $r(S)$ for Sadness. From the table, we decided as follows: For Anger, we chose [1,2,3,4,5,6] (meaning we took the combination of 1-gram, 2-gram, 3-gram, 4-gram, 5-gram, and 6-gram convolutions). For Fear, we chose [2,3,4,5,6]. For Joy and Sadness, we chose [2,3,4,5].

4.5 Experimental Result (Task 1a)

According to the Official Leaderboard for Task 1a, our team KDE-AFFECT turned out to be 30-th. If

n	$r(A)$	$r(F)$	$r(J)$	$r(S)$
[1, 2, 3, 4, 5, 6]	0.5529	0.5919	0.5771	0.6349
[2, 3, 4, 5, 6]	0.5518	0.5994	0.5464	0.6173
[1, 2, 3, 4, 5]	0.5381	0.5948	0.5730	0.6078

CrystalFeel ^{18th}	0.530	0.576	0.466	0.540	0.538
Baseline ^{26th}	0.394	0.382	0.355	0.496	0.370

Table 5: Our result with selected other teams for Task 2a

we use similar notations as in Table 3, and pick up the top-3 ranked teams, as well as randomly chosen teams CrystalFeel (14-th place), ELipRF-UPV (15-th place), iit_delhi (29-th), DeepMiner (31-th), and the baseline (37-th), the result looks like Table 4.

4.6 Experimental Result (Task 2a)

According to the Official Leaderboard for Task 2a, our team KDE-AFFECT turned out to be 17-th. If we use similar notations as in Table 3, and pick up top-3 ranked teams, as well as randomly chosen teams UNCC (9-th place), ECNU (16-th place), CrystalFeel (14-th place), and the baseline (26-th), the result looks like Table 5.

5 Conclusion

This paper describes the approach we took for SemEval-2018 Task 1: Affect in Tweets (subtasks

1a and 2a). We have chosen a combination of different n -gram convolutions with preprocessing including vocabulary unification and Emoji conversion.

RNN for Affects at SemEval-2018 Task 1: Formulating Affect Identification as a Binary Classification Problem

SAS Inst.

ethfcan@gmail.com

Abstract

Written communication lacks the multimodal features such as posture, gesture and gaze that make it easy to model affective states. Especially in social media such as Twitter, due to the space constraints, the sources of information that can be mined are even more limited due to character limitations. These limitations constitute a challenge for understanding short social media posts.

In this paper, we present an approach that utilizes multiple binary classifiers that represent different affective categories to model Twitter posts (e.g., tweets). We train domain-independent recurrent neural network models without any outside information such as affect lexicons. We then use these domain-independent binary ranking models to evaluate the applicability of such deep learning models on the affect identification task. This approach allows different model architectures and parameter settings for each affect category instead of building one single multi-label classifier. The contributions of this paper are two-folds: we show that modeling tweets with a small training set is possible with the use of RNNs and we also prove that formulating affect identification as a binary classification task is highly effective.

1 Introduction

Social media platforms allow users to share information, communicate with other users, learn about new products, and get latest news. The importance of social media data is getting larger every day as social media usage grows every year (Dugan, 2015). Twitter is one such social media platform where users can write short posts as well as share links. Twitter is also used for getting news (Center, 2017).

A large body of research has been conducted using Twitter data including analyzing user inten-

tions (Java et al., 2007), determining influence of users (Romero et al., 2011), predicting retweet counts (Can et al., 2013), classifying sentiments of tweets (Jansen et al., 2009; Agarwal et al., 2011; Neethu and Rajasree, 2013; Kontopoulos et al., 2013; Pak and Paroubek, 2010). All of these studies have one goal in common: understanding/modeling information diffuse in Twitter.

One aspect of modeling social media posts is focusing on emotional states of users. There has been plenty of efforts on determining affective states (Schwarz and Clore, 1983) and their effects to human behavior for different domains from education (Sidney et al., 2005) to health care (Lisetti et al., 2003). For Twitter, this problem is even more challenging as the information source is limited to the number of characters allowed in a single post and multimodal features (e.g., posture, gesture, and eye gaze) are not available.

In this paper, we formulate affect identification task as a binary classification problem and investigate the applicability and effectiveness of domain-independent deep learning models as well as features. Our dataset includes eleven affect categories (i.e., anger, anticipation, disgust, fear, joy, love, optimism, pessimism, sadness, surprise, and trust) for each tweet. The presence of one affect category in a tweet does not stop another category to be present (e.g., joy and optimism can both be present in a tweet). We represent each affect category as one class and build binary classifiers for each class. Recurrent neural networks are trained for each affect category and no domain-dependent features such as affect lexicons are used. Our goal is to evaluate a generic model for different affective states.

Binary models have been successfully applied to several applications including action recognition in videos (Can and Manmatha, 2013), prediction of whether or not a tweet will be

Figure 1: Most frequently used emojis and their counts for each affect category.

retweeted (Hong et al., 2011), and topic classification (Joachims, 1998). In this paper, we describe our approach for affect recognition of English tweets (Task E-c: Detecting Emotions), a subcategory of Task 1 in the SemEval 2018 challenge (Mohammad et al., 2018).

2 Corpus

In this paper, we use English tweets that have been annotated by affect categories (Mohammad et al., 2018). The dataset contains emojis, hashtags, and the textual content of tweets; however, it does not have user ids. The training, validation, and test splits are done by the task organizers. Figure 1 shows top three mostly used emojis in each class and their frequencies for the training set.

2.1 Breakdown of Emojis to Classes

Due to the importance of visual cues in predicting affective states, we pay attention to a form of visual cues: emojis. Here we present some of our findings based on different affect categories.

- *Trust*: emojis are not frequently used. Not easy to determine through emojis.
- *Sadness*: The sobbing face emoji is expectedly the most common one but interestingly laughing with joy emoji is the second most common. Weary face emoji is also very common in sadness: 56.16% of all weary face emojis are used in this class.

- *Anger* and *disgust* share the same property: the most common emoji is the laughing with joy emoji and the second most common is sobbing face emoji. The fact that a joy emoji being the most commonly used in these affective classes is quite interesting and can indicate irony. The third most common emoji in these two classes are also the same: rage emoji.
- An emoji that can be intuitively associated with love (heart eyes) actually occurs more in *joy* tweets than *love* tweets.
- An unexpected finding is on fire emoji where *joy* and *optimism* classes have a large portion of all fire emojis in the training set (46.7% and 36.7% respectively).
- The affective class that uses most emojis is *joy*.

3 Methodology

Since each tweet in the data contains eleven affect categories (i.e., anger, anticipation, disgust, fear, joy, love, optimism, pessimism, sadness, surprise, and trust), we created eleven datasets with the same tweets but with different class information. For example, the first dataset has one values (i.e., positive) for tweets that show anger and zero (i.e., negative) for those that do not have anger. Other datasets are created in the same way for the remaining affects classes. By building one model for each affect category, we formulated affect identification problem as a binary classification task. Then in testing time, we obtained predictions from every specific model and fused the results to obtain a unique result for each tweet.

3.1 Training Binary Classification Models

The advantage of using binary classification models for each affect category is that each model can be trained by itself, enabling different model architectures and parameters. For example, while one category may benefit from a deeper model, the other affect category can obtain the best results with a shallower model. In this way, the models do not have to be the same for each affect class.

3.2 Model Architecture

We built separate RNN models for each affect category, resulting with eleven classifiers. For the classifiers, we used three GRU layers, two of

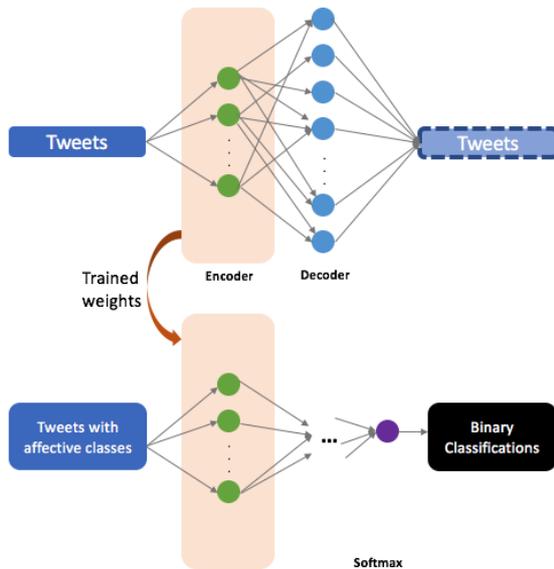

Figure 2: Using the unlabeled tweets for training an auto-encoder and using the trained weights for the affect classification process.

which are bi-directional. To be able to build a more generalized model, a dropout of 0.2 is used in each layer. Each bidirectional layer contains 100 neurons and the final encoding layer has 50 neurons.

3.3 Training Auto-Encoder

Because the dataset is not very big, we wanted the classifiers to learn as much information as possible without overfitting it. Therefore, we built an auto-encoder from the tweets' content (e.g., unlabeled tweets, no affect categories). The goal of the auto-encoder is to get weights that can be used in the classifiers. As shown in Figure 2, we used the trained weights from the auto-encoder to start building binary classifiers. To convert a text-generating auto-encoder into a classifier, we added a softmax layer.

3.4 Features

For modeling affect categories in tweets, we use only the words and emojis. No domain-dependent features, or features that are aware of task in hand (e.g., affect lexicons) are used as our goal is to determine how well a generic RNN model can perform for affect recognition task.

3.4.1 Emojis

To represent emojis as embeddings, we used the pre-trained embeddings from the emoji2vec package (Eisner et al., 2016).

3.4.2 Word Embeddings

For this study, an embedding length of 200 is used. We utilized pre-trained global vectors trained on tweets (Pennington et al., 2014)

3.4.3 Hashtags

Hashtags have a lot of semantic information about the tweets. However, most of that information is neglected if the hashtags cannot be found in the words embeddings. Therefore, we followed a greedy approach for dividing hashtags into their corresponding words.

Once the # is removed, we take the content of the hashtag and search if the content is present in the vocabulary as its entirety. If vocabulary has the hashtag content, we use it. If not, more processing is done. Starting from the beginning of the word we keep a pointer, searching for a valid word that from $index=0$ to $index=pointer$. Once $0, j$ indices represent a substring that is a valid word, we continue the recursive search for the rest of the content (i.e., $j+1$ to the end of the string). The words that are found are added to the list of words that represent the hashtag. Then we use those words and represent them as embeddings.

Because this approach is greedily finding the shortest possible words contained within the hashtag, it is not guaranteed to represent the correct semantics all the time. For example, the #feelsadforyou is correctly divided to ['feel', 'sad', 'for', 'you'], however, #toniteinashville ('tonite in asheville') becomes ['tonite', 'in', 'as', 'he', 'ville'], which is not correct. Achieving perfect semantics would require human labeling, therefore, we used the greedy approach and have observed that utilizing hash tag contents significantly improves the effectiveness of the models.

3.5 Results on Validation Set

The accuracies of binary classification models for each affect category are presented in Figure 3. We compare the models' performances with majority baselines where the percentage of the class value that occurs most is taken as the majority baseline for each class.

4 Results

In this section, we report the results for the test set as well as discussion on the results.

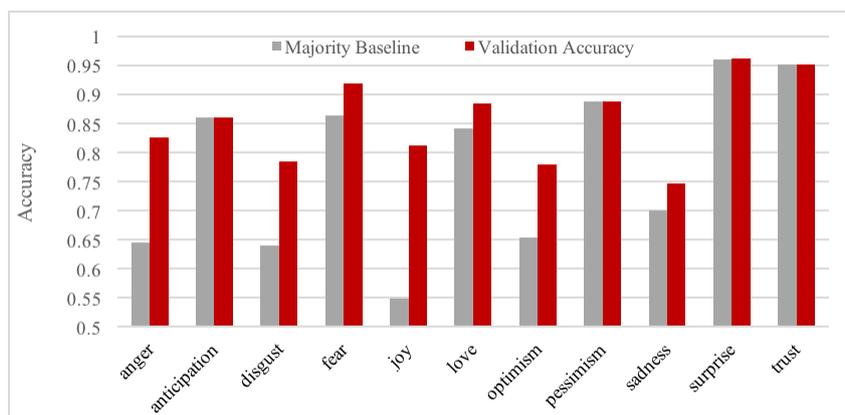

Figure 3: Accuracies per affect category. Majority baseline of each class is compared to the performance of the RNN classifier for that class.

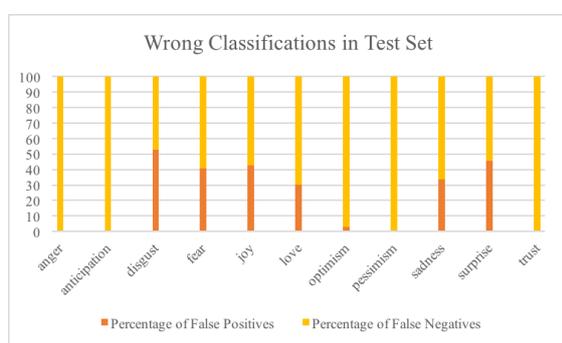

Figure 4: The distribution of false positives and false negatives for observations that are classified incorrectly in the test set.

4.1 Experimental Results

For all of our experiments, we used SAS Deep Learning Toolkit. We utilized an environment with 4 workers, with 24 threads in each worker, and mini-batch size per thread on each worker was 6. Adam optimizer is used in all experiments.

Using the test set, the proposed model achieved a 0.398 accuracy, 0.539 micro-avg F1, and 0.358 macro-avg F1. A random baseline achieves 0.185 accuracy, 0.307 micro-avg F1, and 0.285 macro-avg F1. Compared to the random baseline, the generic RNN model is quite successful at identifying affect categories.

4.2 Discussion

Some of the affect categories have very few positive examples, therefore it is very difficult for classifiers to learn nuances of those affects. For example, surprise and trust categories have 96.05% and 95.15% majority baselines respectively. In other words, only 4-5% of all training set observations have these affect categories as true.

As can be seen in Figure 4, when the number of positive observations are limited, the classifiers tend to make more false negatives. For affect categories that have a major class value that is dominant, we experimented with sampling as well where the number of positive and negative examples were equal. However, that made the dataset significantly smaller, further making it difficult for the RNN models to learn distinctions. Rather than using smaller datasets or including external data, we prefer to employ binary models. One of the main advantages of using binary models over multi-label models is to better deal with the uneven distribution of positive examples across classes.

5 Conclusion

Affect identification without visual cues is a challenging task, making the text as the only source of information that can be used for machine learning models. This problem gets more challenging as the text data gets limited by the number of characters in Twitter.

This paper presented a simple yet effective approach for classifying affect categories of Tweets. The main motivation of this paper was to evaluate how well a domain-independent RNN model can perform for classifying affects. Therefore, no domain-dependent source of information such as affective lexicons or pre-trained affect features are used. We built binary classification models per each affect category. The results showed that RNNs are powerful enough to outperform the baselines significantly, even without prior knowledge about the domain and with a relatively small dataset.

Abstract

In this paper, we describe our contribution in SemEval-2018 contest. We tackled task 1 “Affect in Tweets”, subtask E-c “Detecting Emotions (multi-label classification)”. A multi-label classification system Tw-StAR was developed to recognize the emotions embedded in Arabic, English and Spanish tweets. To handle the multi-label classification problem via traditional classifiers, we employed the binary relevance transformation strategy while a TF-IDF scheme was used to generate the tweets’ features. We investigated using single and combinations of several preprocessing tasks to further improve the performance. The results showed that specific combinations of preprocessing tasks could significantly improve the evaluation measures. This has been later emphasized by the official results as our system ranked 3rd for both Arabic and Spanish datasets and 14th for the English dataset.

1 Introduction

Social media platforms and micro-blogging systems such as Twitter have recently witnessed a high rate of accessibility (Duggan et al., 2015). Tweets usually combine multiple emotions expressed by the appraisal or criticism of a specific issue. Sentiment analysis represents a coarse-grained opinion classification as it detects either the subjectivity (objective/subjective) or the polarity orientation (positive, negative or neutral) (Pirani et al., 2017).

For opinionated texts which are usually rich of several emotions, a fine-grained analysis is needed. Through such analysis, specific emotions can be recognized within a tweet which is crucial for many applications. For instance, recognizing anger emotions in the tweets representing the customers’ opinions about a specific service in a hotel would definitely help to take the proper response to keep the customers satisfied (Li et al., 2016).

Existing MLC systems are conducted either by problem transformation approaches or algorithm adaptation ones. Each of which combines several methods and has different merits. While problem transformation methods are simpler and easier to implement, algorithm adaptation methods have a more accurate performance but with a high computational cost (Zhang and Zhou, 2014). Therefore, to develop a multi-label classifier that combines the simplicity of the problem transformation methods along with accurate performance remains an interesting issue to investigate.

Since preprocessing tasks have been found of positive impact on sentiment analysis of different languages (Haddi et al., 2013; Yıldırım et al., 2015; El-Beltagy et al., 2017), we hypothesize that the application of single or combinations of various preprocessing techniques on tweets before feeding them to the multi-label emotion classifier, can improve the classification performance without the need to complex methods that consider the dependencies between labels.

Here, we describe the participation of our team “Tw-StAR” (Twitter-Sentiment analysis team for ARabic) in Task 1, subtask E-c, in Arabic, English and Spanish tweets (Mohammad et al., 2018). This task requires classifying the emotions embedded in tweets into one or more of 11 emotion labels.

To accomplish this mission, we have subjected tweets to single or combinations of the following preprocessing techniques: stopwords removal, stemming, lemmatization and common emoji recognition and tagging. Manipulated tweets were then fed into a multi-label classifier built via one of the problem transformation approaches called Binary Relevance (BR) and trained with TF-IDF features using the Support Vector Machines (SVM) algorithm. Experimental study indicated the positive impact of stopwords removal, emoji tagging and lemmatization on the classification per-

formance. This was emphasized later through the contest’s official results as Tw-StAR performed well in multi-label emotion classification of the three tackled languages where it was ranked third, for Arabic and Spanish and 14th for English.

2 Multi-Label Classification Approaches

Unlike single-label classification (binary or multi-class) which classifies an instance into one of two or more labels, each instance in MLC can be associated with a set of labels at the same time (Zhang and Zhou, 2014). MLC problems have been targeted either by algorithm adaptation or problem transformation methods.

2.1 Algorithm Adaptation Methods

Adapt traditional classification algorithms used in binary and multi-class classification to perform MLC such that multi-label outputs are obtained. Using these methods, several machine learning (ML) algorithms such as k-nearest neighbors (KNN), decision trees (DT) and neural networks were extended to address MLC (Tsoumakas et al., 2009).

2.2 Problem Transformation Methods

Rather than modifying the classification algorithm, these methods alter the MLC problem itself by converting it into one or multiple single-label classification problems that could be handled by traditional single-label classifiers (Tsoumakas et al., 2009). The most popular strategies used to conduct such transformation are:

- Label Powerset (LP): transforms an MLC problem to a multi-class classification problem where the classes represent all the possible combinations of the given training labels. After transformation, each input instance is associated with a unique single class containing a potential combination of labels. Hence, LP strategy explicitly models label correlations which leads to more accurate classification however, it usually suffers from sparsity and overfitting issues (Alali, 2016).
- Binary Relevance (BR): decomposes the MLC problem into several single-label binary classification sub-problems; each of which corresponds to one label. Thus, for each sub-problem responsible of a specific label, a separate binary classifier is trained on

the original dataset with the objective of determining the relevance of its particular label for a given instance. The predicted labels by all binary classifiers for a certain instance are then merged into one vector resulting in the multi-label class of this instance (Cherman et al., 2011). As BR is implemented in parallel and scales linearly, it forms a low cost solution to MLC problems (Read et al., 2011; Luaces et al., 2012). Several ML algorithms were used with BR approach such as KNN, DT and SVM. According to (Madjarov et al., 2012), SVM-based methods suit small datasets and perform better than DTs especially for domains with large number of features as in text classification since they exploit the information from all the features, while DTs use only a (small) subset of features and may miss some crucial information.

3 Tw-StAR Framework

To recognize the emotions embedded in the Arabic, English and Spanish datasets (Mohammad et al., 2018), Tw-StAR was applied on tweets contained in the provided datasets using the following pipeline:

3.1 Preprocessing

- Initial Preprocessing: for all datasets, a common initial preprocessing step that includes removing the non-sentimental content such as URLs, usernames, dates, digits, hashtags symbols, and punctuation was performed.
- Stopwords Removal (Stop): Stopwords are function words with high frequency of presence in texts; they usually do not carry significant semantic meaning by themselves. Therefore, it is preferable to ignore them while analyzing a textual content. In this task, Arabic was targeted by a list of 1,661 stopwords provided by the NLP group at King Abdulaziz University¹. For English, we used a list of 1,012 words resulted from combining the list published with the Terrier package² and the list of snowball³. In Spanish, a list of 731 words from snowball⁴ was used.

¹<https://github.com/abahanshal/arabic-stop-words-list1>

²<https://bitbucket.org/kganes2/text-mining-resources/>

³<http://snowball.tartarus.org/algorithms/english/stop.txt>

⁴<http://snowball.tartarus.org/algorithms/spanish/stop.txt>

- Stemming (Stem): concerns about reducing the variants of a word to their shared basic form (stem) or root. Therefore, it enables decreasing the vocabulary and increasing the recall (Darwish and Magdy, 2014). In the current study, we used ISRI stemmer (Taghva et al., 2005) for Arabic, Porter2 (Porter, 1980) for English and Snowball for Spanish⁵. ISRI stemmer does not use a root dictionary and provide a normalized form for words whose root are not found. This is done through normalizing the hamza, removing diacritics representing vowels, remove connector و if it precedes a word beginning with و, etc. The English stemmer returns the root of a word by removing suffixes related to plural, tenses, adverbs, etc. Finally, the Snowball stemmer used for Spanish translates the rules of stemming algorithms expressed in natural way to an equivalent program.
- Lemmatization (Lem): removes inflectional endings only and returns the base or dictionary form of a word. Farasa (Abdelali et al., 2016) lemmatizer was employed for Arabic while Treetagger (Schmid, 1995) was used for both English and Spanish. Farasa uses SVMrank to rank possible ways to segment words to prefixes, stems, and suffixes. On the other hand, TreeTagger⁶ forms a language-independent tool for annotating text with part-of-speech and lemma information included.
- Common Emoji Recognition (Emo): we fixed a list of nine categories of the most common emoji detected in the tweets through UTF-8 encoding. Each emoji is replaced with a tag that implies the emoji’s emotion. The tags included: AngryEmoj, HappyEmoj, FearEmoj, LoveEmoj, SadEmoj, SurpriseEmoj, DisgustedEmoj, OptimistEmoj and PessimismEmoj. Thus, a tweet such: “*I hung up on my manager last night ☹*” will be replaced by: “*I hung up on my manager last night SadEmoj*”.

3.2 Feature Extraction

Vector space model (VSM) was used to generate the features vectors. Each tweet was represented using a vector containing all corpus words denoted

by their number of occurrences in this tweet referred to as term frequency (tf). A larger value of a term frequency indicates its prominence in a given tweet, however, if this term appears in too many tweets it will be less informative such as stop words (Maas et al., 2011). Therefore, to enhance the classification and reduce the dimensionality, we focused on the most discriminative terms through applying Term Frequency-Inverse Document Frequency (TF-IDF) weighting scheme. This scheme increases the weight of a term proportionally to the number of times a term appears in the document, but is often offset by the frequency of the term in the corpus, which means how many documents it appears in (Taha and Tiun, 2016).

3.3 Emotions Classification

Having the data transformed using the BR method and the TF-IDF features generated, tweets were fed into a multi-label SVM classifier with the linear kernel. This classifier adopts one-Vs-All strategy such that each label has its own binary classifier. Consequently, a number of binary SVM classifiers equals to the number of emotion labels were trained in parallel to recognize the emotions embedded in a tweet.

4 Results and Discussion

The proposed model Tw-StAR was applied on Arabic, English and Spanish multi-labeled tweet datasets; their statistics are listed in Table 1.

Using One-Vs-All SVM classifier from Scikit-learn⁷, Tw-StAR was trained to recognize the following emotions: anger, anticipation, disgust, fear, joy, love, optimism, pessimism, sadness, surprise, trust in addition to “noEmotion” label that denotes tweets that have none of the previous emotions. Within the presented framework, the preprocessing tasks listed in Section 3 were examined separately and combined. This enabled defining the preprocessing technique/combination for which the MLC performance of each language is better improved.

Tables 2, 3 and 4 list the results obtained for each language when applying several single/combinations of preprocessing tasks where accuracy, macro average f-measure and micro average f-measure are referred to as (Acc.), (Mac-F) and (Mic-F) respectively.

⁶<http://www.cis.uni-muenchen.de/schmid/tools/TreeTagger/>

⁷<http://scikit-learn.org>

Language	Train	Dev	Test
Arabic	2,278	585	1,518
English	6,838	886	3,259
Spanish	3,559	679	2,854

Table 1: Statistics of the used datasets.

Preprocessing	Acc.	Mic-F	Mac-F
Stop	0.38	0.509	0.367
Stem	0.431	0.559	0.424
Emo	0.414	0.543	0.39
Stem+Stop	0.434	0.564	0.435
Emo+Lem+Stop	0.434	0.561	0.415
Emo+ Stem+Stop	0.449	0.58	0.444

Table 2: Preprocessing impact on Arabic MLC.

Preprocessing	Acc.	Mic-F	Mac-F
Stop	0.446	0.577	0.429
Stem	0.449	0.58	0.443
Emo	0.459	0.588	0.434
Stem+Stop	0.462	0.593	0.458
Emo+Lem+Stop	0.48	0.606	0.461
Emo+ Stem+Stop	0.475	0.602	0.466

Table 3: Preprocessing impact on English MLC.

Table 2 clearly suggests that for the Arabic tweets, stemming using ISRI stemmer improved the accuracy by 5.1% percentage points compared to that scored by stopwords removal was applied. Moreover, combining stemming with stopwords removal could further improve the micro F-measure as it increased from 55.9% to 56.4%. This is due to the fact that ISRI can handle wider range of Arabic vocabulary as it returns a normalized form of words having no stem rather than retaining them unchanged (Kreaa et al., 2014).

Unlike Arabic dataset, Table 3 and Table 4 show that stemming had a different behavior when it was applied on both English and Spanish tweets. Compared to the accuracy achieved by stopwords removal, stemming has slightly increased the accuracy by 0.3% and 0.8% in English and Spanish datasets respectively. This could be related to the insufficiency of the stemming algorithms employed by both porter2 and snowball stemmers to handle informal English and Spanish tweets. Lemmatization by Treetagger, however, was a better choice to handle English and Spanish terms as it forms a language-independent lemmatizer with

Preprocessing	Acc.	Mic-F	Mac-F
Stop	0.39	0.482	0.381
Stem	0.398	0.484	0.368
Emo	0.402	0.501	0.384
Stem+Stop	0.409	0.492	0.379
Emo+Lem+Stop	0.431	0.523	0.413
Emo+ Stem+Stop	0.428	0.518	0.401

Table 4: Preprocessing impact on Spanish MLC.

L.	Team(R.)	Acc.	Mic	Mac
A.	EMA(1)	0.489	0.618	0.461
	Tw-StAR(3)	0.465	0.597	0.446

	Tw-StAR(14)	0.481	0.607	0.452
S.	MILAB-SNU(1)	0.469	0.558	0.407
	Tw-StAR(3)	0.438	0.520	0.392

Table 5: Tw-StAR official ranking.

implicitly POS tagger included. Thus, combining emoji tagging with lemmatization and stopwords removal could achieve the best performances with a micro average F-measure of 60.6% and 52.3% for English and Spanish respectively.

Since the provided tweets were rich of emoji, emoji tagging could effectively contribute in improving the performance in all datasets especially when it was combined with the other best-performed tasks such as stem+stop in Arabic and lem+stop in both English and Spanish. This led to the best performances as the achieved micro F-measure was 58%, 60.2% and 52% in Arabic, English and Spanish datasets respectively. Hence, these preprocessing combinations were adopted for the official submission. Table 5 lists the official results of Tw-StAR against the systems ranked first for each language where (L.), (A.), (E.), (S.), (R.) (Mic) and (Mac) refer to language, Arabic, English, Spanish, rank, micro and macro f-measure respectively.

5 Conclusion and Future Work

Here we emphasized the key role of preprocessing in emotion MLC. Stemming, lemmatization and emoji tagging were found the most effective tasks for emotion MLC. For the future work, the obtained performances would be further improved if negation detection was included to infer the negative emotions. Moreover, other ML methods could be examined with BR and deep neural models.

Abstract

The paper describes our approach for SemEval-2018 Task 1: Affect Detection in Tweets. We perform experiments with manually compiled sentiment lexicons and word embeddings. We test their performance on twitter affect detection task to determine which features produce the most informative representation of a sentence. We demonstrate that general-purpose word embeddings produces more informative sentence representation than lexicon features. However, combining lexicon features with embeddings yields higher performance than embeddings alone.

1 Introduction

The paper describes our approach for SemEval-2018 Task 1: Affect Detection in Tweets (Mohammad et al., 2018).

The research question we address in this paper is what are the best features for tweet affect detection. Our solution uses two types of features: *lexicon features* obtained from manually compiled emotion lexicons, and *word embeddings* built unsupervisedly from large corpora. We use well established lexicons, namely DepecheMood and Vader Sentiment, and most popular Word embeddings, namely GloVe and Google News. We systematically compare all features on two subtasks and demonstrate that even though lexicon features produce unsatisfactory results in isolation, they significantly improve an algorithm performance when combined with more general embeddings.

In addition, we demonstrate that special treatment of Twitter hash-tags also improves the algorithm performance.

2 Tasks and Data

The paper addresses three subtasks:

Task	Train	Dev	Test
EI-reg			
all emotions	7102	1464	71816
<i>anger</i>	1701	388	17939
<i>fear</i>	2252	389	17923
<i>joy</i>	1616	290	18042
<i>sadness</i>	1533	397	17912
V-reg	1181	449	17874
E-c	6838	886	3259

Table 1: Training, development and test set split for three subtasks

- **EI-reg**—an emotion intensity regression task: Given a tweet and an emotion E , determine the intensity of E that best represents the mental state of the tweeter—a real-valued score between 0 (no E at all) and 1 (the highest magnitude of E); separate datasets are provided for fear, sadness, anger, and joy.
- **V-reg**—a sentiment intensity regression task: Given a tweet, determine the intensity of sentiment or valence (V) that best represents the mental state of the tweeter—a real-valued score between 0 (most negative) and 1 (most positive).
- **E-c**—an emotion classification task: Given a tweet, classify it as 'neutral or no emotion' or as one, or more, of eleven given emotions that best represent the mental state of the tweeter: trust, sadness, disgust, fear, optimism, love, joy, pessimism, anticipation, surprise, and anger.

We use English data for all three subtasks. The train, development and test set sizes are shown in Table 1. More details on the data can be found in the task organizers' paper (Mohammad and Kiritchenko, 2018).

3 Approach

3.1 Baseline

As a baseline we use the Text-Processing API¹. The API uses a Naive Bayes model trained using movie reviews and NLTK. The model returns probabilities for negative, positive and neutral labels. Negative and positive probabilities sum to 1 while neutral probability stands alone.

3.2 Lexicon Features

3.2.1 DepecheMood

DepecheMood (Staiano and Guerini, 2014) is an emotion lexicon collected using crowdsourcing. The respondents annotated news articles with eight predefined emotions: afraid, amused, angry, annoyed, dont_care, happy, inspired, sad. Document annotations were then used in a dimensionality reduction algorithm to obtain word emotional scores. The lexicon contains approximately 37 thousand entry. Each entry consists of a word and eight values between 0 and 1, one value for each emotion.

3.2.2 Vader

Vader (Valence Aware Dictionary and sEntiment Reasoner) is a rule-based sentiment analysis tool and a lexicon specifically attuned to sentiments expressed in social media, such as Twitter (Hutto and Gilbert, 2014). The lexicon consists of more than 7000 term, which were compelled from other lexicons and then manually annotated. Git repository² of Vader Sentiment toolkit provides function *polarity_scores* which takes as an input a text and returns 4-dimensional feature vector, which contains negative, positive, neutral and compound scores.

3.3 Embeddings

3.3.1 GloVe

GloVe (Pennington et al., 2014) is an unsupervised algorithm that constructs embeddings from large corpora. The GloVe project³ provides a number of models trained on various collections. We use the following two models:

1. Common Crawl: 300-dimensional vectors trained on huge Internet corpus of 840 billion tokens and 2.2 million distinct words.

¹<http://text-processing.com/api/sentiment/>

²<https://github.com/cjhutto/vaderSentiment>

³<https://nlp.stanford.edu/projects/glove/>

2. Twitter Crawl: 200-dimensional vectors trained on 2 billion tweets with 27 billion tokens and 1.2 million distinct words.

3.3.2 Google News

We use word2vecs (Mikolov et al., 2013) embedding trained on Google News collection⁴, which have become almost standard embeddings since they are most frequently used in various research tasks. These embeddings are 300-dimensional vectors built using Google News dataset of 100 billion tokens and 3 million distinct words and phrases.

3.4 Method

We use various combinations of baseline, lexicon and embedding features, described above. Text-processing API and Vader return text-level features. For other sources a tweet representation is built by averaging the word vectors. Concatenation is used to combine features obtained from various sources.

We run several preliminary experiments with V-reg task to compare several algorithms, namely Gradient Boosting Regressor and Random Forest. We use sklearn implementations⁵. Gradient Boosting Regressor yields the best performance for all feature combinations (Table 2). In our official submission we apply Gradient Boosting Regressor for tasks EI-reg and V-reg, and Gradient Boosting Classifier for task E-c.

Hash-tags are special types of tokens in Twitter used to specify a topic or a context for a given message. They frequently contain emotional words. Here are several examples from the dataset:

- @leesyatt you are a cruel, cruel man. #therewillbeblood #revenge.
- can't believe Achilles killed me! #angry.
- Worst juror ever? Michelle. You were Nicole's biggest threat. #bitter #bb18.
- All hell is breaking loose in Charlotte. #CharlotteProtest #anger #looting.
- straight people are canoodling on the quad and I'm #offended .

Thus, we try two different setting: first, processing hash-tags similar to all other words in the text;

Lexicons + Embeddings + Baseline	64.09	66.95	63.80	65.73	72.35	65.93

Table 2: Experimental results for on development set for two subtasks. Pearson correlation. Gradient Boosting Regressor is used for the EI-reg subtask. Gradient Boosting Regressor (Boost) and Random Forest (RF) is used for V-reg. # means that hash-tags are used separately as additional features.

second processing hash-tags separately to preserve authors’ encoding of their emotions. The second strategy consistently yields better results as can be seen from Table 2.

4 Discussion

Comparisons of feature sets and algorithms are presented in Table 2. As can be seen from the table, results are consistent: emeddings yield higher performance than lexicon features for all tasks. DepechMode, even though it has five times more entries than Vader, seems to be less suitable for tweet emotion prediction and yields performance much lower than the baseline. Moreover, using both lexicons in combination not always improves performance and in some cases works even worse than Vader alone.

There is no significant difference between different embeddings. Various embeddings achieve better performance depending on the task, though the best results obtained by using all three in combination.

It can also be seen from Table 2 that separate treatment of hash tags improves model performance. For example, for joy detection task the

difference is about 10%, which means that joy is frequently expressed explicitly in hash tags.

The best results for all tasks obtained by using all feature sets in combination (with the only exception of *angry* intensity detection subtask). This makes an improvement in 5.5% for *anger* detection subtask, 4% for *fear*, 7.5% for *joy*, 5.4% for *sadness*, and about 2% for sentiment intensity detection subtask. This means that even though lexicons cannot be used by themselves to detect emotions, they provide important features that cannot be extracted from embeddings. We hypothesize that the main reason for that is low *coverage*, meaning that many tweets have few lexicon features or no such features at all.

The coverage of the task corpora by various feature sets is presented in Table 3. It can be seen from the table that embeddings have much higher coverage than DepecheMood lexicon. Another interesting observation is that *GloVe Twitter* does not have a higher coverage than *GloVe Common Crawl* though *GloVe Twitter* has higher coverage of hash-tags.

Feature set	Task									
	EI-reg								V-reg	
	anger		fear		joy		sadness		<	#
<	#	<	#	<	#	<	#			
<i>DepecheMood</i>	53.4		52.5		53.6		54.74		53.1	
<i>GloVe Common Crawl</i>	86.0	6.2	85.1	6.2	85.2	4.9	87.4	4.8	85.3	4.5
<i>GloVe Twitter</i>	80.1	6.5	80.1	6.5	82.0	5.2	82.7	5.1	81.7	4.7
<i>Google News</i>	74.6	5.7	74.6	5.8	75.1	4.5	76.9	4.5	75.5	4.2

<i>Baseline</i>	3
<i>Lexicon features</i>	
DepecheMood	8
Vader	4
<i>Embeddings</i>	
GloVe Common Crawl	300
Glove Twitter	200
Google News	300

Table 4: Feature sets and their dimensionality.

5 Results

The best model, used in our officially submitted solution, exploits all six feature sets plus separate embedding vectors for hash-tags. The list of feature sets and their dimensionality is presented in Table 4.

The official results for EI-reg and V-reg tasks are presented in Table 5. We report results for all instances and for instance with highest emotion intensity. The numerical values are similar to what we obtained on the development set. The official results for E-c classification task are presented in Table 6.

6 Conclusion

In this paper we presented our approach for SemEval Affect Detection in Tweets Task. We compare manually collected lexical features with embeddings automatically extracted from huge corpora. We demonstrated that even though lexicons are less suitable for affect detection in tweets due to low coverage they can improve model performance when lexical features are used together with more general embeddings.

In addition, we demonstrated that hash tags are important features for tweet affection detection, since they frequently include emotional words.

	All instances	Gold in 0.5-1
EI-reg		
Anger	65.4 / 82.7	52.6 / 70.8
Fear	67.2 / 77.9	49.7 / 60.8
Joy	64.8 / 79.2	42.0 / 56.8
Sadness	63.5 / 79.8	51.7 / 66.6
Macro-avg	65.3 / 79.9	49.0 / 63.8
V-reg		
	78.2 / 87.3	62.1 / 69.7

Table 5: Official results for EI-reg (emotion intensity regression) and V-reg (valence intensity regression). Scores are given in the format X / Y, where X is our result, and Y is the best official result on the task. Pearson correlation.

Accuracy	micro-avg F1	macro-avg F1
47.7 / 58.8	61.0 / 70.1	41.6 / 52.8

Table 6: Official results for E-c (emotion classification) task. Scores are given in the format X / Y, where X is our result, and Y is the best official result on the task.

In this paper we used rather simplistic methods to combine various features, i.e., vector concatenation. In the future we plan to try another approach: to build a separate classifier for each feature set and then use a meta classifier on top of their results.

Abstract

The „Affect in Tweets” task is centered on emotions categorization and evaluation matrix using multi-language tweets (English and Spanish). In this research, SemEval Affect dataset was preprocessed, categorized, and evaluated accordingly (precision, recall, and accuracy). The system described in this paper is based on the implementation of supervised machine learning (Naive Bayes, KNN and SVM), deep learning (NN Tensor Flow model), and decision trees algorithms.

1 Introduction

Emotion Analysis is still a challenging task in NLP (*Natural Language Processing*); the researchers try to recognize not only emotions “generally speaking” but also their intensity. Because the level of subjectivity is particularly high in this matter, prediction of emotions, mainly in text, demands for continuous research and improvement strategies. SemEval competition has already a tradition in developing tasks to address this subject. This year proposed an even more challenging task: emotion intensity prediction in tweets.

Within this context, this present study aims to develop a system that can not only detect emotions but also their intensities, namely emotion intensity regression and emotion

intensity ordinal classification tasks for fear, joy, sadness and anger. Better results are finally provided thanks to the combination between neural network and proper decision tree algorithms.

From the four tasks, namely: EI-reg, EI-oc, VAD-reg, and VAD-oc, the system focuses on the first two of them, for both English and Spanish datasets, according to their relation with the emotion concept.

While tweets annotation, emotion intensity regression and emotion intensity ordinal classification is an active field of emotion analysis, we believe that a supervised machine learning (Naive Bayes, KNN and SVM), deep learning approach (NN Tensor Flow model), and decision trees would increase the effectiveness of this system.

2 State of the Art

Some of the most used technologies which led to considerable results and step forwards in the domain of sentiment analysis are mainly represented by machine learning algorithms which already have led to impressive results can be thoroughly analyzed in several studies such as: the work of Bac Huy Nguyen (2015); latent semantic analysis (LSA) by Andrew *et al.* (2014), support vector machines in the work of Rohini S. Rahate and Emmanuel M, (2013), grammatical dependency relations, Support Vector Regression (SVR), and Neural Networks.

An important work has been done by the tool IZU-NLP at EmoInt-2017 (Yuanye He et al., 2017), meant to determine numerical values that would represent the emotion intensity in a tweet. There are researchers who prefer to combine several methods in order to achieve better results. For instance, in the paper of Sreekanth Maunendra and Sankar Desarkar (2017) there were implemented three regression methods: (1) content-based features (ex. hashtags, emoticons); (2) training based on word and character n-grams; and finally (3) lexicons, word embeddings, word n-grams and character n-grams all together.

Best-Worst Scaling (BWS) was highly valued in the work of Saif M. Mohammad and Felipe Bravo-Marquez (2017) when producing the first datasets of tweets annotated for sentiment intensities (anger, fear, joy, and sadness).

Some existing tools and resources that enlarged the perspective and built the basis of sentiment analysis are: Emo-Int2017, NRC Emotion lexicon, Best-Worst Scaling resources; VADER-Sentiment-Analysis, SentiWordNet (Andrea Esuli *et al.*, 2010), NLTK Sentiment Analyze, and Affective Tweets. All these works prove the interest of researchers on this subject and the fast evolution of this specific domain in time.

In the context of the Semeval Competition, we developed a system for emotion intensity and ordinal classification of the subtasks already stated above.

3 Dataset and method

3.1 Data set

The SemEval affect dataset used in this work contains an annotated set multi-language tweets (English and Spanish).

For each emotion (anger, fear, sadness, joy) we had 3 sets of data (for train, developing and test).

The English data set was revised by Hardik Meisheri Dec 5, 2017 consisting of ~100 million English tweet ids and for Spanish the data set released on Dec 5, 2017 containing ~1.2 million Spanish tweet ids.

3.2 Method

This research is oriented towards the first two tasks of SemEval so it will contain two

components, one for Task EI-reg and the other one for Task EI-oc. The first step was to preprocess the development data set in multiple stages as follows: basic cleaning (Ids, useless stopwords, emoticons), tokenization and parsing to make data less repetitive. Then we apply the NN Tensor Flow model, the basic one, offered by Python with 600 neurons and with a layer of 1 to 1000.

The neural network was trained separately for each language using the same configuration. Once we obtained the results, we applied a Decision Tree Algorithm in order to refine them. For all subtasks we use Neural Network Tensor Flow (NNTF): Analyzing Tweet's Sentiment with Character-Level LSTMs NN Tensor Flow - python implemented neuronal network with the same parameters for the EI-oc subtask, we improved our results by implementing also the classifiers from pattern.vector. The algorithms are based on three big approaches - they implement the Naive Bayes, KNN and SVM classifiers respectively. Even though machine learning and neural networks gave decent result, the difficulty in controlling the actual reasoning implied the necessity of adding a refining algorithm that would improve final results. An algorithm that would meet this condition is the Decision Tree Classification, a Weka J48 implementation that was improved by adding an algorithm used to generate same decision trees: check for base classification (this classification should be done by the first method described in this paper - NN Tensor Flow); for each score/class; find the normalized score; best_score will be the highest normalized score, this will be the root; create a decision node that splits on best_score; search on the sublists obtained by splitting on best_score; add those nodes as child of node.

For development and training we used the results from the first method for both English and French.

4 Results and Observations

In both sets of results we will notice that the best results were obtained in the single positive feeling dataset - the one for joy. For EI-reg, the lowest result was registered for anger (accuracy), while the highest was the recall for joy. For EI-oc the best result is in the precision of joy, the lowest result being again in accuracy, but this time for sadness.

The implementation of the Decision Tree Algorithm leads to growth and uniformization of the results in the EI-reg subtask, while it

identifying manually certain patterns and indices about intensity and/or their classification.

NNTF + Classification Algorithm								
EI-reg					EI-oc			
	Anger	Fear	Sadness	Joy	Anger	Fear	Sadness	Joy

Table 2. Results obtained after implementing the Decision Tree Algorithm (a-accuracy, r-recall, p-precision)

Algorithm helps the improvement of intensity detection.

5 Conclusions

Within our project, we succeeded to obtain relevant results as participants in Semeval-Task 1 Affect in Tweets, by implementing machine learning and decision tree algorithms.

A constant concern relates to the modalities of sentiment summarization and visualization. When the results of sentiment analysis tasks need to be presented to an end user, a corresponding level of uncertainty should be taken into account (uncertain results shown as certain may lead to incorrect conclusions). Of course it is clear that we may increase it by

positive emotion.) Much and interesting work is to be done as we speak about such a subjective part and manifestation of human mind - emotions.

Abstract

We propose a novel attentive hybrid GRU-based network (SAHGN), which we used at SemEval-2018 Task 1: Affect in Tweets. Our network has two main characteristics, 1) has the ability to internally optimize its feature representation using attention mechanisms, and 2) provides a hybrid representation using a character-level Convolutional Neural Network (CNN), as well as a self-attentive word-level encoder. The key advantage of our model is its ability to signify the relevant and important information that enables self-optimization. Results are reported on the valence intensity regression task.

1 Introduction

Affect analysis is one of the main topics of natural language processing (NLP). It involves many sub-tasks such as sentiment and valence analyses expressed in text. We focus on the task of determining valence intensity.

Hand-crafted features and/or sentiment lexicons are commonly used for affect analysis (Mohammad, Kiritchenko, & Zhu, 2013; Taboada, Brooke, Tofiloski, Voll, & Stede, 2011) with classifiers such as random forest and support vector machines (SVM).

Affect in tweets (AIT) is a challenging task as it requires handling an informal writing style, which typically has many grammar mistakes, slangs, and misspellings.

In this paper, we present a self-attentive hybrid GRU-based network (SAHGN) that competed at SemEval-2018 Task 1 (Mohammad, Bravo-Marquez, Salameh, & Kiritchenko, 2018; Mohammad & Kiritchenko, 2018).

Our contributions can be summarized as below.

- **The implementation of a social media text processor:** A library to help process social media text such as short-forms, emoticons, emojis, misspellings, hash tags, and slangs, as well as tokenization, word normalization, and sentence encoding.
- **The implementation of a self-attentive deep learning system:** This system can predict valence and intensity with limited corpora and vocabulary, and yet can have acceptable performance.

2 High-Level Description of Our System

Our goal is to provide a system that can predict valence and intensity for short text. Figure 1 shows a high-level description of our solution, which consists of two main components, social media text processor (Section 3) and self-attentive hybrid GRU-based network (Section 4.2).

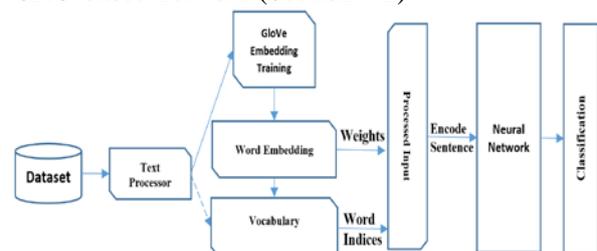

Figure 1: System architecture.

3 Social Media Text Processor

The social media text processor aims to provide a reliable and fast tokenization. It involves the following preprocessing steps:

- Use a named entity recognizer (NER) (Finkel, Grenager, & Manning, 2005) to identify entities such as persons, names, and places, and then replace them accordingly.
- Build a vocabulary using an NGram tokenizer.

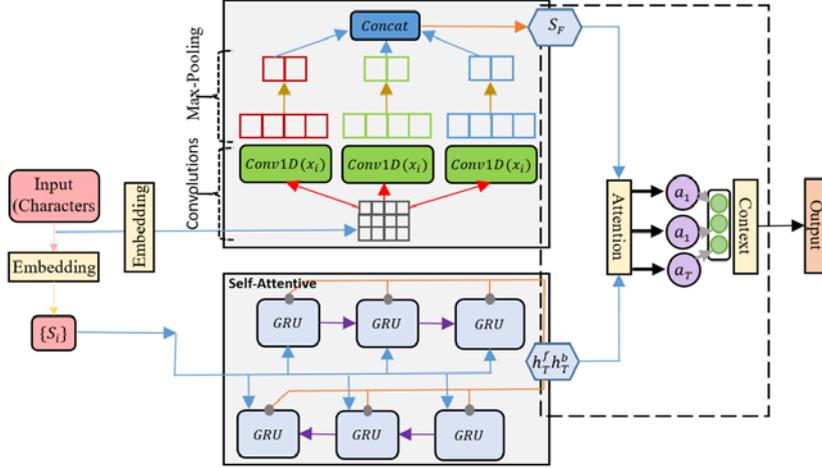

Figure 2: The architecture of Self-Attentive Hybrid GRU-Based Network.

- Tokenize sentences into a set of tokens, and then use them to encode text into a sequence of indices (Table 1), which are fed into the network.
- Clean text from accents, punctuations, and non-Latin characters.
- Identify emoticons and emojis, and then replace them with meaningful text; e.g., replace the happy face emoticon :) with <happy>.
- Recognize hashtags, URLs, and then briefly describe them; e.g. replace #depressed by <hashtag_start>depressed<hashtag_end>.
- Identify user reference mentions, and then replace them with a person entity; e.g. <person>.

Text	@name I am feeling under the weather after I met with Carl :(#sick \u0001F600
Pro-cessed	<SOS> <reference> I am feeling under the weather after I met with <person> <crying> <hashtag_start> sick <hashtag_end> <grinning_face> <EOS>

Table 1: Example of processed text.

4 Model Description

The overall architecture of our SAHGN model is shown in Figure 2. The main components include 1) a word sequence encoder, 2) a bidirectional GRU-based layer that applies a self-attentive mechanism on the word level, 3) a character-level CNN feature extractor, and 4) an attention with context-aware mechanism.

4.1 Word Sequence Encoder

A network input is described as a sequence (S) of tokens (such as words), where $S = [s_1, s_2, \dots, s_t]$

and t denotes the timestep. S_i is a one-hot input (i) vector of a fixed length (T) of tokens. A sequence that exceeds this length is truncated.

Word encoding. We use a W word vocabulary to encode a sequence. W has fixed terms to determine the start and end of the sequence, as well as the out of vocabulary (OOV) words. We handle the variable length through padding for short sequences and truncating for long sequences.

Embedding layer. We apply a pretrained GloVe word embedding (Pennington, Socher, & Manning, 2014) on S_i . GloVe projects these words into a low-dimensional vector representation (x_i), where $x_i \in R^W$ and W is the word weight embedding matrix. W is used to initialize the word embedding layer.

We used the official training and development corpora to train the GloVe word embedding with a dimension of 100. The vocabulary size of this model is 8145 words, which is small and poses a major challenge to training, as well as to performance.

4.2 Self-attentive GRU-based Mechanism

Recurrent neural network (RNN) is commonly used for NLP problems (Yin, Kann, Yu, & Schütze, 2017; Young, Hazarika, Poria, & Cambria, 2017), as it enables remembering values over arbitrary time durations. RNN processes every element of an input embedding (x_i) sequentially, such that $h_t = \tanh(W_{x_i} + W_{h_{t-1}})$. W is the weight matrix between an input and hidden states, while h_t is the hidden state of the recurrent connection at timestep (t). The design of the RNN enables variable length processing while preserving the sequence order.

However, RNN has many limitations with long sequences, in particular the exponentially growing or decaying gradients. A common way to resolve these issues is by using gating mechanisms, such as LSTM and GRU (Gers, Schmidhuber, & Cummins, 2000; Hochreiter & Schmidhuber, 1997). We use GRU as it is faster to converge, in addition to being memory efficient.

Bidirectional GRU layer. In our model, we use bidirectional GRU layers. GRU receives a sequence of tokens as inputs, and then projects word information $H = (h_1, h_2, \dots, h_T)$, where h_t denotes the hidden state of GRU at a timestep (t). It captures the temporal and abstract information of sequences in a forward (h^f) or reverse (h^b) manner. After that, we concatenate forward and backward representations; e.g. $h_t = h_t^f || h_t^b$.

Attention mechanism. Words do not have equal valence weights in sentences. Towards that, we use an attention mechanism to signify the relatively important words.

Attention is used to compute the compatibility between a given source (x_i) and query (q). It uses an alignment function $f(x_i, q)$ to measure the level of dependency of q to x_i . This function produces an attention weight $a = f(x_i, q)_{i=1}^T$. Then, a softmax function is applied to produce a probability distribution $p(z|x, q)$ for each word (t) of an input (x). Hence, a bigger weight of x_i indicates a higher importance than other words.

The attention alignment approaches have the same implementation, but they mainly differ on how they compute weights. This can be either in an additive manner $f(x_i, q) = \tanh(W^T B(W_{x_i} + W_q))$ (Bahdanau, Cho, & Bengio, 2014), or a multiplicative manner $f(x_i, q) = \tanh((W_{x_i} \cdot W_q))$ (Vaswani et al., 2017). In our model training, we use an additive attention mechanism, as it helped improve the prediction performance.

Self-Attention mechanism. In our model training, we have a small number of corpora, which are not sufficient to train an efficient word embedding or alleviate well-known problems such as polysemy. In an effort to overcome such limitations, we use a self-attention mechanism. This approach measures the dependency of different tokens in the same input embedding (x_i). It mainly computes attention for each word by replacing q and x_i with a set of token pairs (x_i, x_j).

4.3 Character-level CNN

The CNN encoding layer (Figure 3) takes an input of a sequence (S) of characters, where $S = [s_1, s_2, \dots, s_t]$ such that t denotes the timestep. S_i is a one-hot input (i) vector of a fixed length (T) of characters.

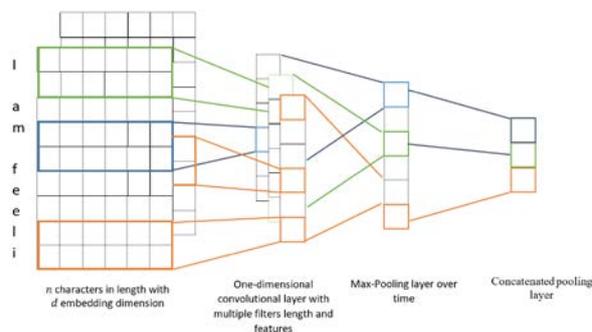

Figure 3: Character-level CNN.

CNN usually uses temporal convolutions (timestep-based) rather than spatial convolutions with text analysis.

We mainly use convolutions to extract low-level character information such as misspellings, slangs, and so on.

Character encoding. We define a charset of the size 95, including the upper and lower cases of the English alphabet, special characters, padding, and the start and end of a given input sequence. We need this charset to build a vocabulary, which is used to encode a character sequence. Similarly to the word embedding, we handle the variable length through padding and truncating (Section 4.1).

Character embedding layer. We build a character embedding of 32 dimensions. We use a uniform distribution scheme of a range (-0.5 to +0.5) to initialize its weight matrix.

We apply 3 convolutions of 100 features, as well as different filter lengths 2, 3, and 4. Each one-dimensional operation is used, where $C_i^n = Conv1d(S_i)$, and n is the filter length. After that, a max-pooling layer is applied on the feature map to extract abstract information, $\widehat{C}_i^n = \max(C_i^n)$. Then, we concatenate these feature representations into one output.

As opposed to recurrent layers (Section 4.2), convolutional operations with max-pooling are helpful to extract word features without paying attention to their sequence order (Kalchbrenner, Grefenstette, & Blunsom, 2014). These features are combined with recurrent features to improve the performance of our model.

4.4 Attention with Context

Output vectors received from previous steps are concatenated, and then fed into an attention with context.

We use a context-aware attention mechanism (Yang et al., 2016) to compute a fixed representation ($r = \sum_{i=1}^T a_i h_i$) of a sequence as the weighted sum of all tokens in that sequence. This representation is used as a classification feature vector to be fed to the final fully-connected sigmoid layer. This layer outputs a continuous value representing the valence of a given sentence.

4.5 Training

In our training, we use mini batch stochastic gradient of the size 32, to minimize the mean-squared error using back-propagation. We use Adam optimizer with a learning rate of 0.001 (Kingma & Ba, 2014). For training, we use 80% of the training set and 20% for validation. We test and report our results on both development and test sets.

Regularization. We use dropout to randomly drop neurons off the network, which helps preventing co-adaptation of neurons (Srivastava, Hinton, Krizhevsky, Sutskever, & Salakhutdinov, 2014). Dropout is also applied on the recurrent connection of our GRU-based layers. Additionally, we apply a weight decay approach through setting an L2 regularization penalty (Cortes, Mohri, & Rostamizadeh, 2012).

Hyperparameters. The size of the embedding layer is 200, and of the GRU layers is 150, which becomes 300 for bidirectional GRU. We apply a dropout of 0.4, and a dropout of 0.2 on the recurrent connections. Finally, an L2 regularization of 0.00001 is applied at the loss function.

5 Results

We report our results using the Pearson correlation between the prediction and gold rating sets on the test set (all instances). The other one (gold in 0.5-1 shown in Table 2) differs in including tweets only with intensity greater than or equal to 0.5.

Our model performed well on the development set scoring 0.869, while on the testing set, the performance degraded to 0.752. This degradation could be related to the size of the corpus we used to train our word embedding. We also trained only on 80% of the training set.

Dataset	Valence task	
	Pearson correlation (all instances)	Pearson correlation (gold in 0.5-1)
Development	0.869	0.692
Testing	0.752	0.559

Table 2: Results of valence intensity regression (English).

6 Conclusion

In this paper, we presented a self-attentive hybrid GRU-based network for predicting valence intensity for short text.

We used a hybrid approach combining low-character-level features with self-attentive word embedding. Our network uses two different attention mechanisms to signify the relevant and important words, and hence optimize feature representation.

With limited corpora and vocabulary of the size 8152, our model still managed to achieve an optimized feature representation, which achieved excellent results on the development set. However, our model failed to maintain the same performance on the testing set.

For future work, we will explore the performance of our model with larger corpora against the testing set. It would also be interesting to see if the model performs well on other long-text NLP tasks such as topic classification.

Abstract

Traditional sentiment analysis approaches mainly focus on classifying the sentiment polarities or emotion categories of texts. However, they can't exploit the sentiment intensity information. Therefore, the SemEval-2018 Task 1 is aimed to automatically determine the intensity of emotions or sentiment of tweets to mine fine-grained sentiment information. In order to address this task, we propose a system based on an attention CNN-LSTM model. In our model, LSTM is used to extract the long-term contextual information from texts. We apply attention techniques to selecting this information. A CNN layer with different kernel sizes is used to extract local features. The dense layers take the pooled CNN feature maps and predict the intensity scores. Our system achieves an average Pearson correlation score of 0.722 (ranked 12/48) in the emotion intensity regression task, and 0.810 in the valence regression task (ranked 15/38). It indicates that our system can be further extended.

1 Introduction

Detecting the intensity of sentiment is an important task for fine-grained sentiment analysis (Kiritchenko et al., 2016; Mohammad and Bravo-Marquez, 2017). Intensity refers to the degree or amount of an emotion or degree of sentiment. For example, we can express our emotion by “very happy” or “a little angry”. The intensity can be analysis in multiple categories (i.e. low, moderate and high) or real-valued. Identifying the intensity information of sentiment has potential to applications such as electronic business, social computing and public health (Wilson, 2008).

Twitter is a social platform which contains rich textual content. There have been many approaches to twitter sentiment analysis (Khan et al., 2015; Severyn and Moschitti, 2015; Philander et al.,

2016). However, twitter sentiment analysis is challenging because tweets usually contain non-standard languages, including emoticons, emojis, creatively spelled words, and hash tags (Mohammad and Bravo-Marquez, 2017). In order to improve the collective techniques on tweet sentiment intensity analysis, the SemEval-2018 Task 1 is aimed to identify the categorical and real-valued intensity of emotions or sentiment for English, Arabic, and Spanish (Mohammad et al., 2018).

Existing approaches to analysis the intensity of emotions or sentiment are mainly based on lexicons and supervised learning. Lexicon-based methods usually rely on lexicons to assign the intensity scores of affective words in texts (Mohammad and Bravo-Marquez, 2017). However, these method can't utilize the contextual information from texts. Supervised methods are mainly based on SVR (Madisetty and Desarkar, 2017), linear regression (John and Vechtomova, 2017) and neural networks (Goel et al., 2017; Köper et al., 2017). Usually neural network-based methods outperform SVR and linear regression-based methods significantly. Motivated by the successful applications of neural models in this task, we propose a system using a CNN-LSTM model with attention mechanism. Firstly, a tweet will be converted into a sequence of dense vectors by an embedding layer. Next, we use a Bi-LSTM layer to extract contextual information from them. The sequential features will be selected by an attention layer. Then we apply a CNN with different kernel sizes to extracting different local information. Thus, our model can exploit both local and long-term information by combining CNN and LSTM. Finally, two dense layers are used to predict the intensity scores. The system performance quantified by an average Pearson correlation score is 0.722 in the emotion intensity regression task (EI-reg) and 0.810 in the valence regression task (V-

reg). Our model outperforms several baseline neural networks, which proves that our model can identify the intensity of emotions and sentiment effectively.

2 Related Work

Sentiment analysis in social media such as Twitter is an important task for opinion mining (Severyn and Moschitti, 2015). Traditional Twitter sentiment analysis methods mainly focus on identifying the polarities (Da Silva et al., 2014; dos Santos and Gatti, 2014) or emotion categories (Dini and Bittar, 2016) of tweets. However, it’s a difficult task to analysis the noisy tweets. They usually contain various nonstandard languages including emoticons, emojis, creatively spelled words and hash tags. In addition, these languages usually contain rich sentiment information. In order to capture such information, several lexicon-based methods are proposed. Nielsen et al. (2011) proposed to use a dictionary to incorporate emoticon information into tweet analysis models. Mohammad et al. proposed to use hash tags to identify emotion categories of tweets (2015). These lexicon-based methods are free from manual annotation, but they rely on the emotion lexicons and can’t mine high-level contextual information from tweets. Supervised methods such as neural networks are also applied to tweet sentiment analysis. For example, Dos et al. (2014) propose to classify tweets using a deep convolutional neural network. Approaches based on deep neural networks need sufficient samples to train, but they usually outperforms lexicon-based methods in these tasks.

However, these approaches usually ignore the intensity of emotions and sentiment, which provides important information for fine-grained sentiment analysis. Therefore, in order to capture such information, Mohammad et al. proposed to identify the emotion and sentiment intensity (valence) of texts (2016). Different approaches have been proposed to detect the tweet emotion intensity in the EmoInt-2017 shared task (Mohammad and Bravo-Marquez, 2017). For example, Madisetty et al. (2017) proposed an ensemble model based on SVR. Goel et al. (2017) and Koper et al. (2017) applied CNN-LSTM architecture to this task. These systems reached the top ranks in the EmoInt shared task.

Motivated by the successful application of CNN-LSTM model (Zhou et al., 2015; Chen et al.,

2016) and the attention mechanism for text classification (Yin et al., 2015), we propose a system using attention-based CNN-LSTM model to address this task. In our model, we first use LSTM to extract sequential information, and select features via attention layer. Then we combine CNN with different kernel sizes to learn local information. Finally the dense layers are used to predict the intensity scores. In addition, several features are incorporated into our model. The evaluation results show that our system outperform several baseline neural networks and can be further extended.

3 Attention CNN-LSTM Model

Our network architecture is shown in Figure 1. We will explain the detailed information of our system in the following subsections.

3.1 Network Architecture

As shown in Figure 1, an embedding layer is used to provide word embedding and one-hot encoded part-of-speech (POS) tags of the input tweets. The Bi-LSTM layer takes the concatenated word embedding and POS tags as input, and output each hidden states. Let h_i be the output hidden state at time step i . Then its attention weight α_i can be formulated as follows:

$$\begin{aligned} m_i &= \tanh(h_i), \\ \hat{\alpha}_i &= w_i m_i + b_i, \\ \alpha_i &= \frac{\exp(\hat{\alpha}_i)}{\sum_j \exp(\hat{\alpha}_j)}, \end{aligned} \quad (1)$$

where $w_i m_i + b_i$ denote a linear transformation of m_i . Therefore, the output representation r_i is given by:

$$r_i = \alpha_i h_i. \quad (2)$$

Based on such text representation, the sequence of features will be assigned with different attention weights. Thus, important information such as affective words can be identified more easily. The convolutional layer takes the text representation r_i as input. We use CNN with four different kernel sizes to learn local information with different contextual length. Based on this architecture, our model can combine both long-term and local information, which can help to identify sentiment information better. The output CNN feature maps are concatenated together, and will be squeezed by a global max pooling layer. They are concatenated with the lexicon features. We use two dense layers

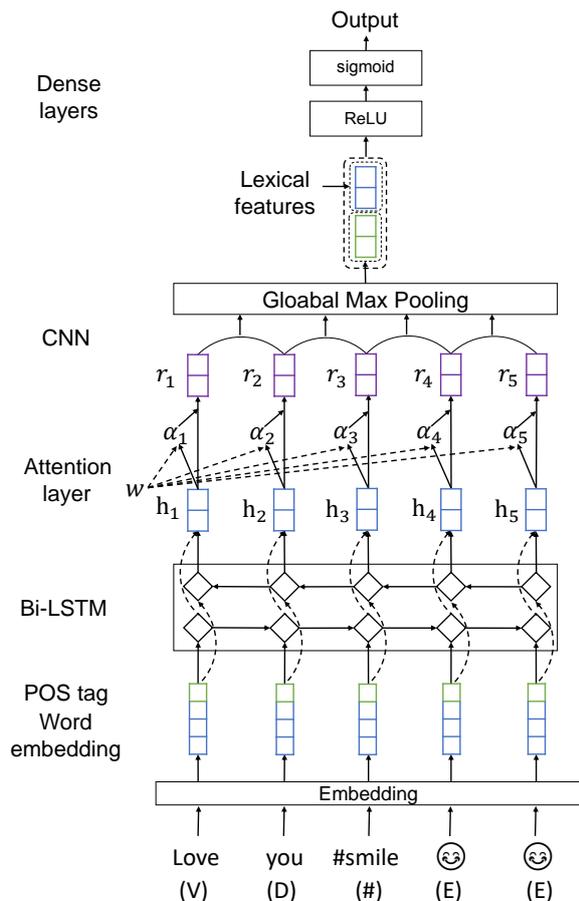

Figure 1: The architecture of our attention CNN-LSTM model.

with ReLU and sigmoid activation respectively to predict the final intensity score. In order to mitigate overfitting, we apply dropout technique at each layer to regularize our model.

3.2 Word Embedding

We use Word2Vec (Mikolov et al., 2013) as the vector representation of the words in tweets. We combine two kinds of word embeddings: The first embeddings are provided by Godin et al. (2015). They are trained on a corpus with 400 million tweets. The second embeddings are provided by Barbier et al. (2016). They are trained on 20 million geolocalized tweets. The dimensions of two embeddings are 400 and 300 respectively. We fine-tune the word embeddings during the network training.

3.3 Additional Features

We incorporate POS tags and lexicon features into our model. POS tags usually contain rich semantic information. For example, sentiment intensity can be expressed by adjectives like “very” and “slight”. POS tags can help the neural model to identify such words. We use the Ark-Tweet-NLP¹ tool to obtain the POS tags of tweets (Owoputi et al., 2013). The POS tag feature of each word is concatenated with the word embedding.

Usually affective words in tweets such as specific hashtags express sentiment explicitly. Therefore, incorporating lexicon information can help our model to predict intensity more accurately. We use the AffectiveTweets² (Mohammad and Bravo-Marquez, 2017) package in Weka³ to obtain the lexicon features of tweets. We use the TweetToLexiconFeatureVector (Bravo-Marquez et al., 2014), TweetToSentiStrengthFeatureVector (Thelwall et al., 2012) and TweetToInputLexiconFeatureVector filters in AffectiveTweets. In our experiment, the lexicon features are 49-dim. These lexicon features are concatenated with the pooled CNN feature maps.

3.4 Model Ensemble

We use an ensemble strategy to improve the model performance. Our model is trained for 10 times by using randomly selected dropout rate. Then the final predictions on the test set are given by the average of all model predictions. In this way, the random error of our system can be reduced.

4 Experiment

4.1 Preprocess

In order to process the noisy tweet texts, we use tweetokenize⁴ for tokenizing, and use Ark-Tweet-NLP tool for POS tagging. In addition, we refine the texts and POS tags using several rules: 1) all URLs will be replaced with the word “URL”, and their POS tags will be set to “URL”; 2) all @users will be replaced with “USERNAME”, and their POS tags will be set to @; 3) POS tags of hashtags are set to “#”; 4) POS tags of emojis and emoticons are set to “E”.

4.2 Experiment Settings

The details of English datasets⁵ we use is shown in Table 1. The intensity in both task is annotated between 0 and 1. In the EI-reg task, the Pearson correlation scores across all four emotions will be averaged as the final score. In the V-reg task, the correlation score for valence is used as the competition metric.

Task	EI-reg				V-reg
	anger	fear	joy	sadness	valence
#train	1,701	2,252	1,616	1,533	1,174
#dev	388	389	290	397	449
#test	1,002	986	1,105	975	937

Table 1: Detailed statistics of the English datasets in our experiment

In our network, the dimension of word embeddings is $400 + 300$. The hidden states of Bi-LSTM are 2×300 -dim. The kernel sizes of CNN are 3, 5, 7 and 9 respectively. The number of feature maps are 4×200 . The dimension of the first dense layer is set to 200. The padding length of tweets is set to 50. The dropout rate is a random number between 0.1 and 0.3. The loss function we use is MAE, and the batch size is set to 8. We combine the training and development sets in our experiment. We use 90% for training and reserve 10% for cross validation. In our official submissions, we use the full training and development sets to train models.

4.3 Evaluation Results

We compare the performance of our model and several baselines. The models to be compared include: 1) CNN, using CNN and dense layers. 2) LSTM, using LSTM and dense layers. 3) CNN+LSTM, combining CNN with LSTM to predict. 4) CNN+LSTM+att, adding attention mechanism to CNN-LSTM model. 5) CNN+LSTM+att+ensemble, using ensemble strategy in the attention-based CNN-LSTM model. The results in the EI-reg and V-reg tasks are shown in Table 2. In comparison, we also present the cross validation results. Our system reaches average Pearson correlation score of 0.722 in the EI-reg task and 0.810 in the V-reg task. The results indicate that our CNN-LSTM model outperforms the CNN and LSTM baselines. It proves that CNN-LSTM model can combine

⁵<http://www.saifmohammad.com/WebDocs/AIT-2018/AIT2018-DATA>

the long-term information and local information in texts. The attention mechanism can also improve the model performance. Since the attention layer can select important information, our model can focus on important words in texts (e.g. affective words) to predict the intensity of emotions and sentiment more accurately. Although our system still needs to be improved compared with the top systems, our model outperforms the common baseline models, which validates the effectiveness of our model.

4.4 Influence of Pre-trained Word Embedding

We compare the performance using different pre-trained embeddings in the EI-reg task. The results are shown in Table 3. The results show that the pre-trained embeddings are important, and combining different word embedding can improve the model performance. It may be because the combination of embedding can cover more out-of-vocabulary words and provide rich semantic information.

4.5 Influence of Additional Features

The influence of the POS tag features and lexicon features is shown in Table 4. The results show that POS tags can improve the model performance significantly. Affective words, emojis and hashtags usually contain rich sentiment information. POS tags can be used to identify such words. Therefore, incorporating the POS information into our neural model can help to identify these words in tweets better. The lexicon features can also improve our model. The lexicon features are obtained by the sentiment words in tweets. Thus, incorporating these features into neural networks can improve the performance of our system.

4.6 Analysis of Inappropriate Biases

In the EI-reg and V-reg tasks, an automatically generated mystery set is used for testing the inappropriate biases in NLP systems, such as gender and race (i.e. African American and European American names). For example, the pairs of sentences “She is happy.” and “He is happy.”; “Jamel feels angry.” and “Harry feels angry.” should be assigned with the same intensity by an unbiased NLP system. The score differences are calculated for such sentence pairs. The average score difference, the p-value, and whether the score differences are statistically significant are shown in Ta-

Model	EI-reg										V-reg

Table 4: Influence of POS tags and lexicon features.

ble 5. Although the average differences are small, but they are statistical significant in most tasks. Our system is based on word embedding, and we fine-tune the weights during the network training. Thus, our system will be influenced by the distribution of training data, which may lead to these biases.

Task	Gender			Race		
	Avg-D	p	Sig	Avg-D	p-value	Sig
<i>Anger</i>	-0.002	0.00003	✓	0.002	0.01553	×
<i>Fear</i>	-0.023	0	✓	0.023	0	✓
<i>Joy</i>	0.02	0	✓	-0.04	0	✓
<i>Sadness</i>	-0.001	0.09654	×	0.011	0	✓
<i>Valence</i>	0.001	0.00382	×	-0.021	0	✓

Table 5: The average differences, p-value and statistical significance of predictions on the mystery set in each task. We denote them as Avg-D, p and Sig respectively.

4.7 Visualization of Attention Mechanism

Attention mechanism can encourage the neural model to focus on important words in texts. In order to prove its effectiveness of the attention layer, we present several examples in Table 6. The green color represents low attention, while red color represents high attention. We can see that the affec-

tive words (e.g. Happy) and hashtags (e.g. #funny) have high attention weights. It indicates that our attention-based model can capture important sentiment information to predict the intensity of tweets better.

5 Conclusion

Identifying the intensity of emotions or sentiment is important for fine-grained sentiment analysis. Thus, the Semeval-2018 task 1 is aimed to analyze the affective intensity of tweets. In this paper, we introduce the system participating in this task. We apply an attention-based CNN-LSTM model to predict the intensity scores of emotions and sentiment. We also use additional features to improve the performance of our system. Our system ranked 12/48 and 15/38 in the EI-reg and V-reg subtasks respectively. It indicates that our system can be further extended.

Acknowledgments

Abstract

This paper describes our system that has been used in Task1 Affect in Tweets. We combine two different approaches. The first one called N-Stream ConvNets, which is a deep learning approach where the second one is XGboost regressor based on a set of embedding and lexicons based features. Our system was evaluated on the testing sets of the tasks outperforming all other approaches for the Arabic version of valence intensity regression task and valence ordinal classification task.

1 Introduction

Sentiment Analysis is the task of automatically identifying the valence or polarity of a piece of text. This piece of text can be a user review, a document, an SMS message, a tweet, etc. According to (Mohammad, 2016), the term sentiment analysis also refers to determining the attitude towards a particular target or topic. The attitude can be the polarity (positive or negative), or an emotional or effectual attitude such as joy, anger, sadness and so on.

Most of the researchers in sentiment analysis have focused on developing systems to determine the polarity of a given text. This involves designing classifiers based on a set of examples with a manually annotated sentiment polarity. Although developing systems that automatically determine the intensity (i.e. the degree or the amount) of emotions that are communicated in a text has a wide range of applications in commerce, public health, social welfare, etc., most of the work has focused on categorical classification (whether a given piece of text communicates anger, joy, sadness, etc.). This can be attributed to the lack of suitable annotated data (Mohammad and Bravo-Márquez, 2017).

In task1: *Affect in Tweets*, the organizers provide an array of tasks where systems have to au-

tomatically determine the intensity of emotions (anger, fear, joy, and sadness) and the intensity of the sentiment (aka valence) of the tweeters from their tweets. They provide annotated datasets for each task with English, Arabic, and Spanish tweets (Mohammad et al., 2018). We define the tasks below:

EI-reg (an emotion intensity regression task): Given a tweet and an emotion E , determine the intensity of E that best represents the mental state of the tweeter with a real-valued score between 0 (least E) and 1 (most E).

EI-oc (an emotion intensity ordinal classification task): Given a tweet and an emotion E , classify the tweet into one of four ordinal classes of intensity of E that best represents the mental state of the tweeter.

V-reg (a sentiment intensity regression task): Given a tweet, determine the intensity of sentiment or valence V that best represents the mental state of the tweeter with a real-valued score between 0 (most negative) and 1 (most positive).

V-oc (a sentiment analysis, ordinal classification, task): Given a tweet, classify it into one of seven ordinal classes, corresponding to various levels of positive and negative sentiment intensity, that best represents the mental state of the tweeter.

We proposed one system to solve the intensity regression tasks (i.e. EI-reg and V-reg) and use it as a feature extractor to train Decision Trees to solve the ordinal classification tasks (i.e. EI-oc and V-oc). We developed two versions of the proposed system for the English and the Arabic language tweets.

Our system is an ensemble of two different approaches. The first one, called N-Channels ConvNet, is a deep learning approach where the second one is an XGboost regressor based on a set of embedding and lexicons-based features.

The rest of the paper is organized as follows:

Section 2 presents the tools and the resources that are used. Section 3 describes the proposed system. In Section 4 we report the experimental results, whereas in Section 5 the conclusions and the future work are presented.

2 Resources

This section explains the tools and the resources that have been used in our system.

2.1 Sentiment Lexicons

We used the following lexicons for the English version of our system:

AFINN (Nielsen, 2011), General Inquirer (Stone et al., 1968), Bing-Liu opinion lexicon (HL) (Hu and Liu, 2004), MPQA (Choi and Wiebe, 2014), NRC hashtag sentiment lexicon (Mohammad et al., 2013), NRC emotion lexicon (EmoLex), NRC affect intensity lexicon, NRC hashtag emotion lexicon and Vader lexicon. More details about each lexicon, such as how it was created, the polarity score for each term, and the statistical distribution of the lexicon, can be found in (Jabreel and Moreno, 2016).

For the Arabic version we used the following lexicons:

Arabic Hashtag lexicon, Dialectal Arabic Hashtag lexicon, Arabic Bing Liu lexicon, Arabic Sentiment140 lexicon and Arabic translation of the NRC emotion lexicon. The first two were created manually, whereas the rest were translated to Arabic from the English version using Google Translator. (Mohammad et al., 2016).

2.2 Embeddings

Word embeddings are an approach for distributional semantics which represents words as vectors of real numbers. Such representation has useful clustering properties, since the words that are semantically and syntactically related are represented by similar vectors (Mikolov et al., 2013). For example, the words "coffee" and "tea" will be very close in the created space.

We used two publicly available pre-trained embedding models in the English version of our system. The first one was used in (Rouvier and Favre, 2016). It was trained using word2vec (skipgram model) on an unannotated corpus of 20 million English tweets containing at least one emoticon. The second one was provided by (Baziotis et al., 2017). It was trained on a big dataset of 330M

English Twitter messages, gathered from 12/2012 to 07/2016 and a vocabulary size of 660K words using Glove algorithm.

Additionally, we have trained two embedding models on 60M English tweets (30M contain positive emoticons, 30M negative ones). The first one was trained by applying word2vec skipgram of window size 5 and filtering words that occur less than 4 times. The dimensionality of the vector was set to 300. The second one was trained using fastText (Bojanowski et al., 2016). The dimensionality of the vector was set to 300.

Similarly, we used two publicly available pre-trained embedding models in the Arabic version of our system and trained two. The first one is the model Arabic-SKIP-G300, provided by (Zahran et al., 2015). Arabic-SKIP-G300 was trained on a large corpus of Arabic text collected from different sources such as Arabic Wikipedia, Arabic Gigaword Corpus, Ksucorpus, King Saud University Corpus, Microsoft crawled Arabic Corpus, etc. It contains 300-dimensional vectors for 6M words and phrases. The second one is Twitter-SG-AraVec (Soliman et al., 2017), which was trained using word2vec skipgram algorithm on 66M Arabic tweets and 1B tokens. The dimensionality of the vector was set to 300.

Our embedding models were trained on the distant supervision corpus (about 16M Arabic tweets) provided by the organizers. We were able to find about 12M tweets. Again, similar to our English embeddings, we trained the two Arabic embedding models.

3 System Description

This section explains the proposed system, whose architecture is shown in Figure 1. First, we pre-process the tweets (Subsection 3.1). Afterwards, we pass them to the N-Channels ConvNet and the XGboost regressors (Subsections 3.2 and 3.3). Finally we ensemble the output of the two systems to get the final result as described in subsection 3.4. The proposed system is also used as feature extractor to train an ordinal Decision Tree classifier, as described in subsection 3.5.

3.1 Preprocessing

Some standard pre-processing methods were applied on the tweets:

- *Normalization*: Each tweet in English was converted to the lowercase. URLs and user-

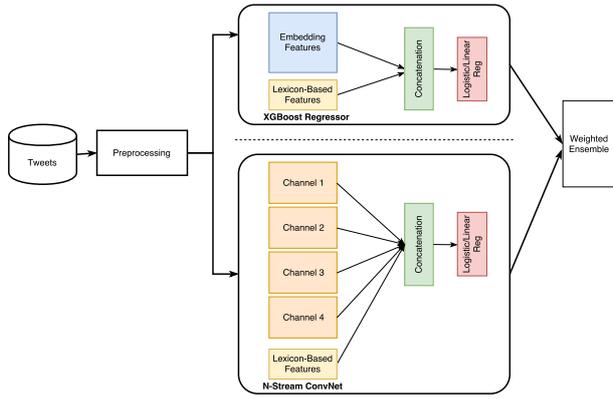

Figure 1: System Architecture.

names were omitted. Non-Arabic letters were removed from each tweet in the Arabic-language sets. Words with repeated letters (i.e. elongated) are corrected.

- *Tokenization*: All English-language tweets were tokenized using Ark Tweet NLP (Gimpel et al., 2011), while all Arabic-language tweets were tokenized using Stanford Tokenizer (Green and Manning, 2010).

3.2 N-Channels ConvNet

Convolutional Neural Networks (ConvNets) have achieved remarkable results in computer vision and speech recognition tasks in recent years. The next subsection explains the architecture of our proposed ConvNet.

3.2.1 Architecture

The N-Channels ConvNet model architecture, shown in the bottom box in figure 1, is inspired by Inception-Net (Szegedy et al., 2016) and the CNN proposed by (Kim, 2014). It is composed of multiple channels followed by a logistic regressor. Figure 2 shows the channel architecture. The input to each channel is a sequence of words w_1, w_2, \dots, w_n where n is the number of words. We pass the input through an embedding layer to map each word w_i into a real-valued vector. Each channel has its own embedding layer which is initialized by a specific pre-trained embedding model. We use five channels with the four pre-trained embedding models described in subsection 2.2 and a character based one. The result from the embedding layer is a matrix $n \times d_c$ where d_c is the vector dimension. This matrix is passed to a projection or pre-activation layer. The projection layer is nothing but a fully-connected or dense layer whereas the

pre-activation layer can be any non-linear function such as rectified linear unit (ReLU). Afterward, we feed the projected matrix to three Conv1D. Each one has a different kernel (1, 2, and 3) and 200 filters. To get more details about the architecture of this Conv1D please check (Kim, 2014). We pass the output of each Conv1D through a global max-pooling layer which produces a vector with dimensionality of 200. Finally, the three vectors are concatenated. This yields a vector with dimensionality of 600 that represents the tweet (i.e. the input sequence of words).

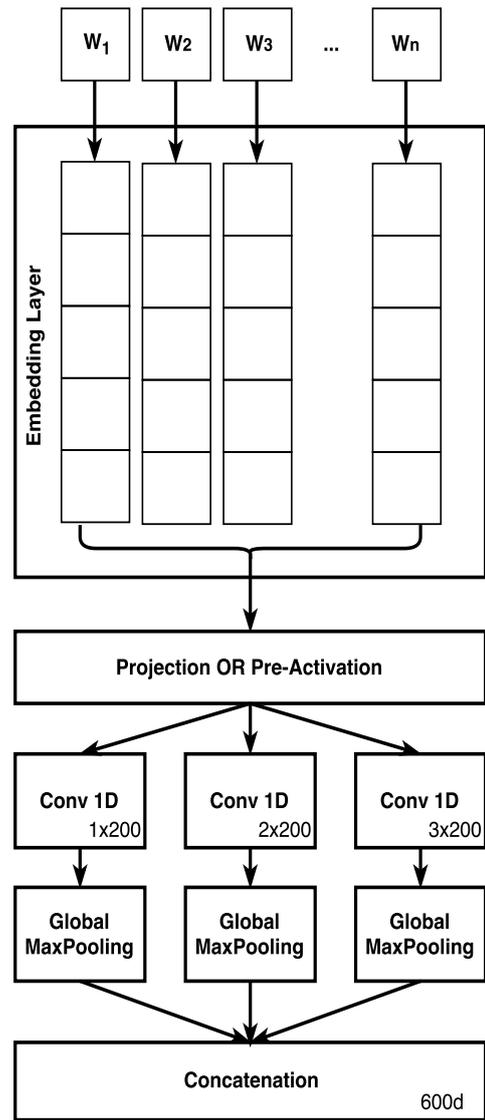

Figure 2: Channel Architecture.

Finally, the outputs of all channels are concatenated with a lexicon-based vector (see next section) and fed to a single sigmoid neuron which gives the intensity of the emotion/valence.

3.2.2 Training

The proposed model was trained by minimizing the mean squared error between the real and predicted intensities. The optimization was done by applying back-propagation through layers via minibatch gradient descent. The training parameters were the following: batch size of 32, 100 epochs and Adam optimization method with learning rate of 0.001, $\beta_1 = 0.9$ and $\beta_2 = 0.999$ and $\epsilon = 10^{-9}$. To prevent the over-fitting, we used dropout and early stopping methods.

3.3 XGBoost Regressor

XGBoost (Chen and Guestrin, 2016) has become a widely used and really popular tool among Data Scientists in industry, as it shows great performance on large-scale problems. It is a highly flexible and versatile tool that can work through most regression, classification and ranking problems as well as user-built objective functions.

We trained an XGBoost regressor to give the intensity of the emotion/valence based on the two types of features explained in the next subsection.

3.3.1 Features

Each tweet is represented with a vector by concatenating the following two feature vectors:

Lexicon Features: For each lexicon, we used the sum of the scores provided by the lexicon for each word in the tweet. Let L denote the set of lexicons and $f_i^l(w)$ the score of the word w based on the feature i in the lexicon l (note that some lexicons have only one feature like the sentiment score and some of them have multiple features like anger emotion score, positive score, etc). Then, the set of features that represent a given tweet T and a lexicon $l \in L$ can be obtained as follows:

$$V_{T,l} = \forall_{f_i^l \in F_l} \sum_{w \in T} f_i^l(w) \quad (1)$$

Here, F_l denotes the set of features in lexicon l .

Embedding Features: We used the *sum* pooling function to obtain the tweet representation in the embedding space. More formally, let us consider an embedding matrix $E \in \mathbb{R}^{d \times |V|}$ and a tweet $T = w_1, w_2, \dots, w_n$, where d is the dimension size, $|V|$ is the length of the vocabulary (i.e. the number of words in the embedding model), w_i is i -th the word in the tweet and n is the number of words. First, each word w_i is substituted by the corresponding vector v_i^j in the matrix E where j

is the index of the word w_i in the vocabulary. This step ends with the matrix $W \in \mathbb{R}^{d \times n}$. The vector $V_{T,E}$ that represents the tweet T is computed by aggregating the matrix W . This aggregation is done by taking the summation over its columns. The sum pooling function is an element-wise function, and it converts texts with various lengths into a fixed-length vector allowing to capture the information throughout the entire text.

3.3.2 Training

The XGBoost regressor has some parameters that need to be tuned. Table 1 shows the values of each parameter we chose for the different emotions. All those values were chosen using the grid-search on the development sets.

	P	# Est.	S	M	O
Eng.	Anger	300	0.75	5	Logistic
	Fear	300	0.75	5	Linear
	Sadness	300	0.75	5	Logistic
	Joy	300	0.75	7	Linear
	Valence	300	0.75	5	Linear

3.4 Ensemble

We combined the results of the two systems described above with the intention of improving the performance and increasing the generalizability of the final system. We used the weighted average method to achieve that. Let r_1 and r_2 respectively denote the output of the XGBoost regressor and the N-Channels ConvNet system. The final output r was obtained as follows:

$$r = \alpha * r_1 + (1 - \alpha) * r_2; \quad \alpha \in [0, 1] \quad (2)$$

Table 2 shows the value of α for each individual model. All these values were obtained by grid search on the development set.

3.5 Decision Tree for Ordinal Classification Tasks

To solve the problem of ordinal classification we simply used the proposed model as feature extrac-

tor and trained a Decision Tree. The idea is to use the emotion/intensity as input feature and use rules generated from the Decision Tree to get the appropriate class. Figure 3 shows as an example the Decision Tree classifier of the *fear* emotion.

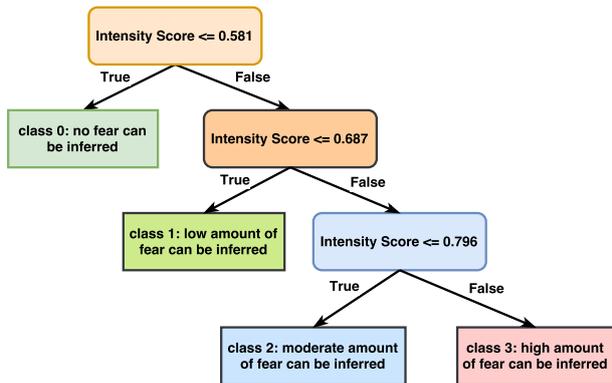

Figure 3: An example of a decision tree classifier.

4 Results

We trained and validated our models on the training and validation sets provided by the organizers. More details about the data and the evaluation metrics can be found in (Mohammad et al., 2018; Mohammad and Kiritchenko, 2018).

Tables 3 and 4 show the results of the emotion and valence intensity regression tasks of our two systems and their combination (the ensemble model). It also shows the baseline results. The evaluation metrics are the Pearson correlation for all samples and for a subset of the test set that includes only those tweets with intensity score greater or equal to 0.5. The values in the tables show the superiority of the N-Channels ConvNet over the XGBoost regressor. For instance, the results of the English version of the emotion

intensity task show that the N-Channels ConvNet outperforms the XGBoost regressor by 5.9% with respect to macro-avg measure. The performance of N-Channels Convnet is very close to the ensemble model. The improvement is only 1.2%. The improvement in the final system of the Arabic version is very small (0.3%). The results of the Pearson correlation of samples whose intensity score is greater or equal to 0.5 show that our system can be used as a classifier. This conclusion is confirmed by the results of the ordinal classification tasks, shown in Tables 5 and 6.

As we described in subsection 3.5, our approach to design a system to solve the ordinal classification tasks was to use the intensity score as input feature to train a Decision Tree. During the inference phase we used our system to produce the intensity score for the new (unseen) samples (i.e. use it as feature extractor). Thus, the performance in this phase heavily relies on the performance of the proposed system. This is clearly shown in the results reported in tables 5 and 6. For example, our system gives very good results in the valence intensity regression task for both the English and Arabic versions (the Pearson correlation is 0.828 for both). This affects positively the performance of our system for the valence ordinal classification tasks (the Pearson correlation is about 0.80 for both).

5 Conclusion

We have presented an ensemble model of two different approaches. The first one, called N-Channels ConvNet, is a deep learning approach whereas the second one is an XGBoost regressor based on a set of embedding and lexicons-based features. The ensemble technique helped to improve the performance of the final model in all subtasks. We have realized that The N-Channels ConvNet gives a performance very close to the ensemble model. This observation confirms the fact that deep learning models, and especially ConvNets, have achieved remarkable results in many fields such as computer vision, speech recognition and natural language processing. Distant Supervision is an approach of transfer learning which aims to train a model on a large amount of semi-labeled data and use it as a pre-trained model for training another model on a small amount of fully-labeled data. This approach has been shown to be very efficient. Thus, the authors are considering

Abstract

In this paper we present our contribution to SemEval-2018, a classifier for classifying multi-label emotions of Arabic and English tweets. We attempted “Affect in Tweets”, specifically Task E-c: Detecting Emotions (multi-label classification). Our method is based on preprocessing the tweets and creating word vectors combined with a self correction step to remove noise. We also make use of emotion specific thresholds. The final submission was selected upon the best performance achieved, selected when using a range of thresholds. Our system was evaluated on the Arabic and English datasets provided for the task by the competition organisers, where it ranked 2nd for the Arabic dataset (out of 14 entries) and 12th for the English dataset (out of 35 entries).

1 Introduction

Social network platforms such as Facebook, LinkedIn and Twitter are now at the hub of everything we do. Twitter is one of the most popular social network platforms; as recently as 2013 an incredible 21% of the global internet population used Twitter actively on a monthly basis ([globalwebindex](#), accessed 05/2016). Twitter is used by celebrities, movie stars, politicians, sports stars and everyday people. Every day, millions of users share their opinions about themselves, news, sports, movies and many many other topics. This makes platforms like Twitter rich sources of data for public opinion mining and sentiment analysis ([Pak and Paroubek, 2010](#)). However, although these corpora are rich, they are somewhat noisy because tweets can be informal, misspelt and contain slang, emoticons ([Albogamy and Ramsay, 2015](#)) and made-up words. Furthermore, Arabic tweets have the added complication of dialects in which the same words or expressions can have different connotations.

Multi-label classification of tweets is a classification problem where tweets are assigned to two or more classes. It is considered more complex than traditional classification tasks because the classifier has to predict several classes.

There has been much work in the areas of sentiment detection ([Rosenthal et al., 2017](#)), emotion intensity ([Mohammad and Bravo-Marquez, 2017](#)) and emotion categorisation ([Hasan et al., 2014](#)). Sentiment analysis aims to classify tweets into positive, negative, and neutral categories, emotion intensity is determining the intensity or degree of an emotion felt by the speaker and emotion categorisation is the classification of tweets based on their emotions. The most commonly used classification techniques are Naive Bayes and Support Vector Machines (SVM). Some researchers report that SVMs ([Barbosa and Feng, 2010](#)) perform better while others support Naive Bayes ([Pak and Paroubek, 2010](#)). Furthermore, sophisticated techniques such as deep neural networks have also been proposed but such techniques are rarely used by non-experts of machine learning in practice ([Sarker and Gonzalez, 2017](#)) and they also take a long time to train.

We propose a simple and effective method to classify tweets that performs reasonably well. Our system does not make use of any lexicons or stop word lists and is quick to train.

2 Methods

The SemEval Task E-c requires the classification of tweets into either a neutral emotion or one of eleven emotions ([Mohammad et al., 2018](#)). Datasets for tweets are made available in three languages; Arabic, English and Spanish. We focus firstly on Arabic and then English because this links well with our existing work. Datasets from previous SemEval tasks are also available if

required. We use the SemEval-2018 development and training data for training our system, with no external resources such as sentiment dictionaries or other corpora. We use the training set to compute scores for each of the classes in conjunction with a self correction stage and a multi-threshold stage to obtain an optimal set of scores. Apart from the preprocessing steps, notably stemming, we use exactly the same machinery for the two languages. We now briefly discuss our approach.

Preprocessing. Tweets are preprocessed by lowercasing (English tweets only), identifying and replacing emojis with emojis identifiers, tokenising and then stemming. We developed two tokenisers; one that is NLTK based and does not preserve hashtags, emoticons, punctuation and other content and one that is “tweet-friendly” because it preserves these items. Emojis cause us technical problems due to their surrogate-pair nature so we replace emojis with emoji identifiers (e.g. _45_). We also separate out contiguous emojis because we want, for example, the individual emojis in a group of repeating unhappy face emojis to be recognised, and processed, as being the same emoji as a single unhappy face emoji. We remove usernames because we believe they are noise since, by and large, they will not reappear in the test set, are not helpful to us and if not removed will compromise our ability to detect useful information. Arabic tweets are stemmed using a stemmer developed specifically for Arabic tweets by Albogamy and Ramsay (Albogamy and Ramsay, 2016). English tweets are stemmed by taking the shortest result from Morphy (Fellbaum, 1998) when tokens are stemmed as nouns, verbs, adjectives and adverbs. Although there are surprisingly few examples of these, we believe that multi-word hashtags, joined by underscore or a dash, also contain useful information so we leave the hashtag as is but also take a copy of the hashtag and split it into its constituent words. This is so that where possible we improve the quality of information in the tweet. Stop word lists are not used at any stage. We debated using stop words vs insignificant words and, as in our previous work (Ahmad and Ramsay, 2016), we prefer to let our algorithms exclude these words. We do however remove less common words on the grounds that if they do not appear very often then we are unlikely to learn anything from them. The

English training dataset contains approximately 6300 distinct words after preprocessing, we find that taking the top 2500 of these gives us the most common words and the best results.

Our approach is not to collect scores for individual emotions, instead we collect scores relative to the other emotions. Constructing scores in this manner allows us to observe that words such as “blessed” are much more significant for emotions such as “joy”, “love” and “optimism” than they are for “anger” and “anticipation”. Words that are insignificant will have small scores, words that are significant will have large scores and by using a varying threshold we can determine a best set.

Base set. Every tweet in the training dataset is tokenised and we count how many tweets each token in the tweet occurs in. We also remove singletons and calculate an IDF for each token. We iterate through the tokens for each tweet to create a base set of scores and obtain a count of how many times each token occurs in each of the 11 emotions as well as a count of the total number of tokens in each emotion. In a later stage we iterate over a range of thresholds, this base set is the starting point in each and is modified by the various processes as described below.

Conditional probabilities. We now use this base set to create a set of emotion probabilities for each token. One, common, way of using probabilities is in conjunction with Bayes Theorem. However, this does not seem to work very well for this task hence we perform the following steps. We calculate the probability of each token appearing in each emotion using $P(T|E)$. We do this only on the top 2500 most important tokens in the dataset, i.e. those with the highest IDF scores. We normalise these probabilities by dividing each value by the sum of all the probabilities for this token for all emotions. We get an average value for these values and subtract this from each of the scores to calculate the distance from the mean. This is, essentially, a local IDF step to ensure that if a token is equally common for all emotions then we do not allow it to contribute to any of them, and if it is below the overall average for a emotion we want it to be allowed to vote against it.

We want to assign extra weight to tokens that have very skewed distributions, hence we multiply each score by the standard deviation. This empha-

sises the contribution of such tokens to the emotion and allows us to remove unhelpful tokens. In this way we create a set of emotion scores for each token for every emotion.

Self-correction. We want to remove tokens that we have incorrectly assigned to emotions. We classify each tweet to determine which emotions it demonstrates and we identify the tokens that led us to these conclusions. A tweet is classified for each emotion by adding the scores for each token for each emotion. These scores are normalised and compared to a threshold t . If the value is less than t we deduce the tweet did not demonstrate the emotion, otherwise it did demonstrate the emotion. We are unsure what a good threshold is so we use a range of values for t from 0 to 1 (in steps of 0.1) to create score sets. We calculate the Jaccard for each of these and use the best one of these for classification. This approach is based on Brills (Brill, 1995) suggestion that one should attempt to learn from ones own mistakes.

As each tweet is classified we compare our prediction to the gold standard. For the ones that we predict correctly we increment a counter for each token against the correctly classified emotion. Similarly, for the ones where we failed to classify the tweet correctly we decrement the counter for each token against the incorrectly classified emotion. When all tweets have been classified we examine these counters. For each token, if we have an overall negative score for an emotion we deduce that the token is unhelpful in classifying tweets for that emotion and we downplay its significance in further calculations. Using this technique we are able to remove tokens such as “terrifying” from contributing to emotions such as “love”. We have tried repeating this process multiple times, but we find that beyond one iteration the improvement is insignificant. A possible explanation for this may be because the actual numbers of tokens that are removed are quite small; 1% for Arabic and 5% for English.

Per-emotion thresholds. The raw data for each emotion is different and, hence, we find that a single fixed threshold across all emotions produces poor results. We therefore try a range of thresholds from 0 to 1 in increments of 0.1 to classify tweets, using the same mechanism described above, but this time on an emotion-by-emotion

basis to generate an individual threshold for each emotion.

SemEval results. We classify the training data using our sets of scores and per-emotion thresholds. We identify the set with the best Jaccard score and use it to classify the test data to generate our eventual submission file.

2.1 Other Strategies

Increased training data. We believe that having more training data might improve our classifier. One of the obvious places to get more data is from the datasets for some of the other tasks, specifically EI-reg and EI-oc. A key problem with this data is that both of these tasks only supply datasets for anger, fear, joy and sadness. The EI-reg dataset is marked up with a per-tweet intensity value between 0-1 that represents the mental state of the tweeter. The EI-oc dataset tweets are marked up with one of four ordinal classes (0,1,2,3). To expand our training dataset we extract tweets with values of 0.5 and above from the EI-reg datasets and tweets with a value of 3 from the EI-oc dataset. The best Jaccard score we obtain with this expanded dataset is 0.417 (English). When we extract tweets with values of 0.9 or above from the EI-reg dataset we improve the quality of tweets, at the cost of decreasing the number of tweets extracted, and this slightly improves our Jaccard to 0.429.

Similarly, the competition organisers also make available a corpus of 100 million English tweet IDs. We download 10,000 of these filtered on words that we believe are representative of the emotions we are looking for e.g. “angry”, “elated”, “trusting”. A serious weakness with this technique, however, is that the accuracy of this data is compromised, we therefore classify this data using our classifier. We then combine this data with the standard English dataset and classify it again. We do not want this data to be more relevant than the real data, so we weight down the scores from this data. The best Jaccard score we obtain with this expanded dataset is 0.430.

Latent semantic analysis (LSA). Latent Semantic Analysis (LSA) is a theory and method for extracting and representing the contextual-usage meaning of words by statistical computations applied to a large corpus of text (Landauer and

Tweet tokeniser	Split hashtags	Stem	Tune	Multi-threshold	Jaccard (AR)	Jaccard (EN)
					0.324	0.340
✓					0.318	0.340
✓	✓				0.333	0.349
✓	✓	✓			0.342	0.401
✓	✓	✓	✓		0.370	0.431
✓	✓	✓	✓	✓	0.452	0.455

Table 1: Results.

Dumais, 1997). Essentially, to improve our classifier we need to improve the quality of our tweets. We use LSA to find words in tweets that are similar to other words, e.g. “car” and “automobile”. We do not have the computing power to do this on a per-tweet basis so we do this on a per-emotion basis. The concepts we find, however, are not very reliable, e.g. “blessed” and “happiness”. We expand our tweets with these words but find that this does not improve our scores. A possible explanation for this might be because of the relatively small numbers of tweets in the datasets.

Duplicate tweets. We note that there are tweets in the English dataset that are semantically similar, e.g. “*You offend me, @Tansorma*” and “*@SunandBeachBum ‘you people’ infuriate me!*”. It may be possible to use *clustering* (Sarker and Gonzalez, 2017) to relate tweets like these as a means to removing duplicates. We further note that there are many cases of tweets that differ only by hashtags or emojis, e.g. “*@britishairways term 5 security queues at arrivals*” and “*@britishairways term 5 security queues at arrivals #shocking*”. A further study could assess the impact of using Minimum Edit Distance (Wagner and Fischer, 1974) on this later data to improve the quality of the dataset.

Emoticon weighting. Emoticons have proved crucial in the automated emotion classification of informal texts (Novak et al., 2015). To increase their significance we double their raw count values. We find that this increases the accuracy of our classifier by 0.44% for both Arabic and English.

Word frequencies. We try to use the word frequency as an extra weight to further dampen the contribution of words that are low frequency

because low frequency words do not contribute very much. However, because we have earlier taken only the 2500 commonest words we find that this does not improve our scores.

2.2 Computing Resources

The system was written in Python on a MacBook Pro, 2.7 GHz Intel Core i5, 8 GB RAM. The training and classification phase takes approximately 15 minutes.

3 Results, Comments and Conclusion

We described a self-correcting, multi-threshold, classifier to solve the problem of multi-label classification of tweets.

We find that due to the nature of the data it is difficult to accurately distinguish between emotions such as “joy” and “love” because many of the words that score highly for “joy” also score highly for “love”, e.g. “rejoice”, “birthday” and “cheerful”. Consequently when a tweet is labelled as “love” it is highly likely that it will also be labelled as “joy”. We find similar issues with “anger” and “disgust”, although not to the same extent, because words like “shit” and “hate” score highly for both emotions. Overall, we believe that we score much higher on emotions such as “anger”, “joy”, “love” and “disgust”, than on “trust” “anticipation”, “optimism” and “pessimism”.

Our results, given in Table 1, show that although processes such as lowercasing, tokenising and stemming do contribute, the tuning stage and the introduction of multiple thresholds yield the biggest improvements. This is because removing words which are implicit in the classifier making wrong decisions and allowing each emotion to have its own threshold are obviously sensible things to do.

One unanticipated finding was that our tweet-friendly tokeniser has an adverse effect decreasing the Jaccard score when it is used. A possible ex-

planation for this is that the simple tokeniser removes # and @ symbols, thus modifying hashtags such as “#sleep” into “sleep” and allowing them to combine with the word “sleep” in other tweets. On the other hand the tweet-friendly tokeniser preserves the “#sleep” hashtag and it therefore cannot combine with the word “sleep”. We want the best of both worlds so we preserve our hashtag but also take a copy and split it into its constituent words.

Contrary to expectations, the performance improvement gained from using our Arabic stemmer is disappointingly low at just 2.67%. We believed that our Arabic stemmer would have a bigger impact than demonstrated because the stemmer is aimed at, and specifically developed for, Arabic tweets. In fact our simplistic Morphy English stemmer produced a better improvement of 14.8% for English than our carefully tuned Arabic stemmer did for Arabic.

The scores we achieved put us 2nd for the Arabic dataset and 12th for the English dataset despite the fact that we use no external resources, we simply train on the basis of the SemEval data. We will be carrying out further experiments to see whether adding external resources would give us further improvement.

Abstract

This paper describes the performing system for SemEval-2018 Task 1 subtask 3 - Given a tweet, determine the intensity of sentiment or valence (V) that best represents the mental state of the tweeter—a real-valued score between 0 (most negative) and 1 (most positive). The proposed system gets features in tweets from the existing emotional dictionary and represents the word using word embedding, then utilizes the joint representations as the inputs of the bidirectional long short-term memory (BiLSTM) to learn and get the regression result. To boost performance we ensemble several BiLSTMs together. We ranked 6th in subtask 3 among all teams. Our approach achieves the Pearson(All instances) score 0.836 and Pearson(gold in 0.5-1) score 0.667, we outperform the baseline model of this task by 25.1% and 21.8% of Pearson(All instances) and Pearson(gold in 0.5-1) scores respectively.

1 Introduction

Sentiment analysis (SA) is a field of knowledge which deals with the analysis of people's opinions, sentiments, evaluations, appraisals, attitudes and emotions towards particular entities (Liu, 2012). EmoInt (Mohammad and Bravo-Marquez, 2017) is a shared task hosted by WASSA 2017, aiming to predict the emotion intensity in tweets. SemEval 2018 Task 1 subtask 3 (Mohammad et al, 2018) is similar to EmoInt, however the goal of subtask 3 is to detect valenc-

e or sentiment intensity, in which scores are floating point values between 0 and 1, representing low and high intensities of the emotion being expressed, respectively. Obviously we don't know in advance whether twitter's emotional intensity is positive or negative, but in EmoInt task we can determine whether twitter emotions are positive or negative based on one of four datasets: anger, fearness, joy, sadness. This is still a challenging task and remains active areas of research. These setbacks are: extensive usage of hashtags, slang, abbreviations, and emoticons. And tweets are usually typed on mobile devices like mobile phone, laptop or iPad which can result in a substantial amount of typos.

Existing methods for modeling emotion intensity rely vastly on manually constructed lexicons, which contain information about intensity weights for each available word (Mohammad and Bravo-Marquez, 2017a; Neviarouskaya et al., 2007). The intensity for the whole tweet can be deduced by combining individual scores of words, which is easy and ignores the word order compositionality of the language. Building such lexicons is a labour-intensive procedure. We can learn from these models the skills of combining feature extraction and classification or regression stages given a sufficient amount of training data.

Some deep learning methods are used to process the same question. Deep neural architectures for emotion intensity prediction in tweets (Goel et al., 2017) and character- and word-level recurrent neural models for tweet emotion intensity detection (Lakomkin et al., 2017).

In our work, we firstly clean tweets, then build lexical features and find optimal combinations of features to produce a final vector representation of a tweet, next train a neural network regression model and finally get the tweet’s intensity scores. In addition, we adjust our models’ parameters and through the ensemble models to get the best performing results.

2 Data cleaning

We use the dataset provided by the official organizers to train our system, there are 1181 labeled training tweets, 449 labeled dev tweets. Test set are unlabeled 17874 tweets and the gold labels were given only after the evaluation period. Before training model or predicting test set we firstly clean the tweets, this is imperative. We utilize the following pre-processing steps.

- (1) **Hashtags** are crucial markers for determining sentiment. The “#” symbol is removed and the word itself is retained. Eg, a hashtag like “#the_best_one”, finally we get “the best one”.
- (2) **Username mentions**, we replace it with “username”.
- (3) **Shortening**, we transform word “don’t”, “I’ve”, “I’ll” et al into “do” “n’t”, “ve”, “ll”.
- (4) **Punctuations**, only “!” and “?” are retained, others like “;” “>” “)” “,” “-” are deleted.
- (5) **Numerical symbols**, considering that the data in the dataset is relatively standardized and there are few numbers, so we remove the all digitals and only keep English words.
- (6) Extra spaces are removed and all words become lowercase letters.

3 Feature Extraction

In order to completely extract features from tweets, we consider two characteristics which are annotated lexicons and pre-trained word embedding.

3.1 Annotated Lexicon

For extracting lexicon features, we follow the procedure as per the baseline system provided in the WASSA Emotion Intensity Task. The knowledge sources that have been used are: MPQA subjective lexicon (Wilson et al., 2005), Bing Liu lexicon (Ding et al., 2008), AFINN (Nielsen, 2011), Sentiment140 (Kiritchenko et al., 2014),

NRC Hashtag Sentiment Lexicon (Mohammad and Kiritchenko, 2015), NRC Hashtag Emotion Association Lexicon (Mohammad et al., 2013), NRC Word-Emotion Association Lexicon(, 2013), NRC-10 Expanded Lexicon (Bravo Marquez et al., 2016) and the SentiWordNet (Esuli and Sebastiani, 2007). Two more features are calculated on the basis of emoticons (obtained from AFINN (Nielsen, 2011)) and negations present in the text. We use several of the above lexicons as following:

- **Emoji Valence (EV)**: This is a hand classified lexicon of Unicode emojis, rated on a scale of -5 (negative) to 5 (positive).
- **SentiWordNet (SWN)**: Calculates positive and negative sentiment score using SentiWordNet, which is an opinion mining resource available through NLTK.
- **Depeche Mood (DM) (Staiano and Guerini, 2014)**: This is a lexicon comprised of about 37,000 unigrams annotated with real-valued scores for the emotional states *afraid, amused, angry, annoyed, don’t care, happy, inspired* and *sad*.
- **Emoticon Sentiment Lexicon**: Note that this is a sentiment lexicon drawn from emoticons, and is not an emotionlexicon.
- **NRC-Emoticon-AffLexNegLex-v1.0**: Each line of this lexicon represents a real-valued sentiment score: $score = PMI(w, pos) - PMI(w, neg)$, where PMI stands for Pointwise Mutual Information between a term w and the positive/negative class.
- **NRC-Hashtag-Sentiment-Lexicon-v1.0 (Mohammad and Turney, 2013)**: The lexicon is an association of words with positive (negative) sentiment generated automatically from tweets with sentiment-word hashtags.
- **NRC-Hashtag-Sentiment-AffLexNegLex-1.0**: The same lexicon as Sentiment 140, but here tweets with only emotional hashtags are considered during training.

3.2 Word Embedding

The text can be converted into word embedding, which represents each word of the text with a d dimensional vector (Mikolov et al., 2013). Considering that we have to deal with tweets, we use GloVe word embedding

trained on 2 billion tweets from twitter (Pennington et al., 2014), vectors of 100, 200 and 300 dimensions are provided as part of the pre-trained model. For this work, we use the 300 dimensional vectors of 42B tokens. We also considered GoogleNews- vectors-negative300 in our experiments but the effects was not as good as the GloVe word embedding.

4 Model Training

Based on the application of features extractions and word embedding, we can represent each word in a tweet as a high dimensional space vector, and the dimension of the vector is $d + l$. d represents the dimension of GloVe word embedding 300 and l stands for the length of the additional lexical dictionary. After representing the tweets, we need to train models. Since the task requires the computation of a real valued emotion intensity score for the tweets in the test set, we explore several regression methods. Our system is implemented in Keras and we finally choose the best single BiLSTM model, which contains two layers of BiLSTM following the embedding layer and, we add a dropout layer. Some parameters of our model are: dropout probability 0.25 and 0.5 respectively; units of the BiLSTM layers are 512 and 256 respectively; units of the full connection layer is 256. The complete model structure is shown below Figure 1:

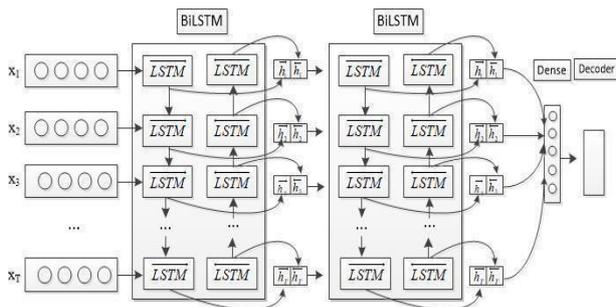

Figure 1: A two layer bidirectional LSTM model.

5 System tuning

When training model on Keras so there only some parameters need to change, we tune the parameters such as the choice of loss function, dropout probability, dimension of the BiLSTM layer. As for feature combination we use all the annotated lexicons mentioned in section 3.1 so

as to control the variables and we don't consider the impact of different dictionary combinations on the results, which may be discussed in the future work. Note that all of our tuning processes are done on the development set, each time we finished a model we record the results. Ensembling of some models is universal used method to improve the performance of the overall system by combining predictions of several classifiers. Our system ensembles ten exactly the same BiLSTMs models and average the results, it turns out that the ensemble result is better than that of a single model. That is to say when we ensemble the model, the weight of each single BiLSTM is the same.

6 Experiment and results

All our experiments have been developed using Keras deep learning library with Theano backend, and with CUDA enabled. And all our experiments are performed on a computer with Intel Core(TM) i3 @3.4GHz 16GB of RAM and GeForce GTX 1060 GPU. After testing many neural network models, we finally find the best results on LSTM and BiLSTM models. Table 1 shows the results of a single layer LSTM changing the loss function and word embedding, we can learn that MAE loss function can get the best result with Glove word embedding, in general the performance on Glove word embedding is better than word2vec embedding. Table 2 shows the results of a single BiLSTM changing the loss function and integrating ten models under different loss functions and different word embedding we can learn that MAPE loss function can get the best result with Glove word embedding, in general the performance on Glove word embedding is better than word2vec embedding. Table 3 is the result of double layers BiLSTM changing the loss function and integrating ten models under different loss functions and different word embedding we can learn that MAPE loss function can get the best result with Glove word embedding, in general the performance on Glove word embedding is better than word2vec embedding.

The system in this subtask are evaluated using the Pearson correlation coefficient, which computes a bivariate linear coefficient, and the

secondary evaluation metrics, which is Pearson correlation for a subset of the test set that includes only those tweets with intensity score greater or equal to 0.5. We present the results of the system submitted to the competition leaderboard in Table 4. The score of our system is 0.836 (Pearson) and 0.667 (Pearson gold in 0.5-1). Note that the model we used on the test set is the best model on the development set, i.e., in Table 3 the third line.

Table 4: Performance on test dataset. Final results in about test set on leaderboard and our system ranks 6th overall.

7 Conclusions

In this paper, we propose a deep learning framework to predict the emotion intensity in tweets. The proposed system is based on two layers BiLSTM and the last layer of model using a linear regression so that we can get the intensity score, which is a consecutive emotional value. Before training model we implement features extraction and represent the tweets by word embedding. Both single model and ensemble model are described in detail with a view of making our experiments replicable. The optimal parameters are mentioned along with our method of bringing the approaches together. Our submitted system beats the baseline system by about 25.1% on the test set. Our source code is in here <https://github.com/ynuwm/SemEval-2018>

Abstract

In this paper we describe our submission to SemEval-2018 Task 1: *Affects in Tweets*. The model which we present is an ensemble of various neural architectures and gradient boosted trees, and employs three different types of vectorial tweet representations. Furthermore, our system is language-independent and ranked first in 5 out of the 12 subtasks in which we participated, while achieving competitive results in the remaining ones. Comparatively remarkable performance is observed on both the Arabic and Spanish languages.

1 Introduction

The *Affects in Tweets* shared task (Mohammad et al., 2018) is the second iteration of a task which offers a new approach to Sentiment Analysis - one that concerns itself with emotion and sentiment *intensity*, rather than simple categorical classification. The shared task is divided into a set of subtasks, where the aim is to predict the emotion intensity of a predetermined emotion (fear, anger, sadness, joy) or sentiment (valence) intensity of a given set of tweets. Such predictions are either formulated as a regression problem where the output is a continuous-valued score in the interval $(0, 1)$, or as ordinal classification into a given number of classes representing intensity. Additionally, each one of the subtasks targets a particular language: English, Arabic or Spanish.

In total, we participated in 12 different subtasks and our system achieved the best performance on the test set out of all participants in 5 out of those, ranked second in 3 others, and performed compet-

itively in the rest. Moreover, our system can arguably be considered the best overall performing system for both Arabic and Spanish¹. It should be noted, however, that the shared task includes traditional emotion classification subtasks in which we did not participate.

The system described in this paper builds upon a survey of some of the best performing systems from previous related shared tasks (Mohammad and Bravo-Marquez, 2017; Rosenthal et al., 2017). In particular, we draw inspiration from the systems described in (John and Vechtomova, 2017), which makes use of gradient boosted trees for regression; (Goel et al., 2017), which employs an ensemble of various neural models; and (Baziotis et al., 2017), which features Long Short Term Memory (LSTM) networks with an attention mechanism. Our work contributes to the aforementioned approaches by further developing a variety of neural architectures, using transfer learning via pre-trained sentence encoders, testing methods of ensembling neural and non-neural models, and gauging the performance and stability of a regressor across languages.

The rest of this paper describes the pipeline of the system used for our submission, which is an ensemble of neural and non-neural models.

2 Data and features

The provided training and development data is comprised of tweets, an emotion or sentiment, and labels describing the intensity of the emotion or

¹<https://competitions.codalab.org/competitions/17751#results>

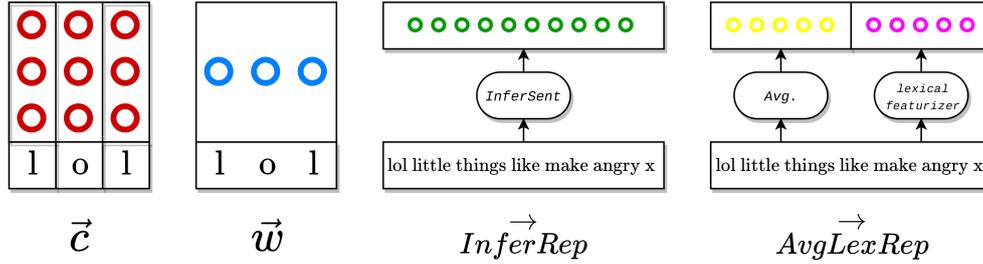

Figure 1: Graphical visualization of various feature vectors used in our ensemble model. These are from left to right: character embedding, word embedding, $InferRep$ and $AvgLexRep$ representations.

sentiment. We refer readers interested in an exhaustive description of the data to (Mohammad et al., 2018; Mohammad and Kiritchenko, 2018). In this work, we convert each tweet into a combination of three types of vector representations: character and word-level vectors for Arabic and Spanish; and character, word, and sentence-level vectors for English. This section describes the procedure that allows us to obtain these varied representations, which are later employed by our classification and regression models.

2.1 Preprocessing

The syntactic and orthographic form of tweets often differs substantially from text belonging to other domains (John and Vechtomova, 2017). As such, pre-processing procedures are as important as the architecture of any given model.

In pre-processing our data, we first replace all same-character sequences of length 3 or more with only 2 occurrences. We also replace all user mentions with a unique common token, as well as all control characters with whitespaces. Emojis are surrounded with spaces, enforcing that any two emojis are not consecutive characters. Finally, all text is lowercased. In the case of Spanish text, we further remove the characters $¿$ and $¡$, and replace accented characters with their unaccented versions, as well as \tilde{n} with n . In the case of Arabic text, we remove quotation marks as well.

Following the cleaning process, we tokenize the resulting text by applying the `tokenize` tool (Krieger and Ahn, 2010), as provided in the CMU Tweet NLP software (Owoputi et al., 2013), which is, by design, able to cope with the noise that appears in social media. Once the tokenization is completed, we filter all stopwords².

²We employ the stopwords lists available from <https://www.ranks.nl/stopwords>

2.2 Lexicons

Lexicons are one of the resources which we employ in order to compute features. In short, a lexicon is a collection of words that are associated with a value for an arbitrary number of affective categories. In our case, given a tweet, we produce several features per lexicon which are the result of aggregating individual matching word values in each category, adding the numerical values and counting those which are nominal. We provide an overview of the lexicons used per language below, with the number of features contributed by each individual lexicon in parenthesis. In the case of English, the following lexicons and extracted values jointly produce a feature vector of dimension 43:

- MPQA lexicon (2): Number of positive and negative words (Wilson et al., 2005).
- Bing Liu lexicon (2): Number of positive and negative words (Hu and Liu, 2004).
- Emoticons (2): Positive and negative aggregated scores for emoticons (Nielsen, 2011).
- Sentiment140 lexicon (2): Positive and negative aggregated scores (Kiritchenko et al., 2014).
- NRC Word-Emotion Association Lexicon (10): Number of words matching each category (Mohammad and Turney, 2013).
- NRC Hashtag Sentiment lexicon (2): Positive and negative aggregated scores (Kiritchenko et al., 2014).
- NRC Hashtag Emotion Association Lexicon (8): Aggregated scores for each category (Mohammad and Kiritchenko, 2015).

- NRC-10-Expanded lexicon (10): Aggregated scores for each category (Bravo-Marquez et al., 2016).
- SentiWordnet (2): Positive and negative aggregated scores (Baccianella et al., 2010).
- AFINN lexicon (2): Positive and negative aggregated scores (Nielsen, 2011).
- Negations (1): Number of negative words (Mohammad and Bravo-Marquez, 2017).
- Spanish Sentiment lexicon (2): Number of positive and negative words (Perez Rosas et al., 2012).
- ML Senticon (1): Aggregated score for polarity (Cruz et al., 2014).
- Sentwords (3): Aggregated score for each category in an automatically translated version of the lexicon described in (Beth Wariner et al., 2013).

Note that the lexicons are not directly used on tweet data, but rather that lexical features are extracted after applying the same data cleaning and tokenization process which we described for the training data to each one of the lexicons listed.

In the case of Arabic we also employ the same first 6 lexicons which we listed for English, but with the content words automatically translated (Salameh et al., 2015). However, we extract 4 scores from the MPQA lexicon (on the affective categories *positive*, *negative*, *neutral* and *both*), an a single combined score from the Bing Liu and Emoticons lexicons. Furthermore, we employ 3 lexicons generated by distant supervision techniques on Arabic tweets as follows (Mohammad et al., 2016), in order to obtain a feature vector of dimension 26:

- Arabic Emoticon Lexicon (2): Number of positive and negative words.
- Arabic Hashtag Lexicon (2): Number of positive and negative words.
- Arabic dialectal Hashtag Lexicon (2): Number of positive and negative words.

Finally, the following lexicons are used in Spanish to produce a feature vector of dimension 14. In contrast to the Arabic language, the majority of the lexicons here listed are manually annotated or semi-automatically generated from Spanish data:

- Emoticons (1): Combination of positive and negative aggregated scores for emoticons (Nielsen, 2011).
- El Huyar dictionary (2): Positive and negative aggregated scores (Saralegi and San Vicente, 2013).
- ISOL lexicon (2): Number of positive and negative words (Martínez-Cámara et al., 2014).
- SDAL lexicon (3): Aggregated scores for each category (Dell’ Amerlina Ríos and Gravano, 2013).

2.3 Word embeddings

Word embeddings are another popular choice for feature extraction. We employ pre-trained word embeddings for English and train our own embeddings on separated Arabic and Spanish tweet data that we manually collected. All sets of embeddings comprise 400 dimensions and are detailed below for each language:

- English: Word2vec skip-gram embeddings, trained on the Edinburgh Twitter Corpus (Petrović et al., 2010).
- Arabic: Word2vec skip-gram embeddings, trained on 4.38 million tweets³.
- Spanish: Word2vec skip-gram embeddings, trained on 3.02 million tweets⁴.

2.4 Manually-crafted representations

In the Arabic and Spanish subtasks, some model components in our ensemble use a combination of the two types of representations described so far (lexical features and word embeddings) as an input feature vector. To obtain this, we average the embeddings corresponding to each word in a given tweet up to a maximum of 25 words, and append the computed lexical features to the result. These features are extracted using the filters provided in the Affective Tweets package (Mohammad and Bravo-Marquez, 2017) available for WEKA (Hall et al., 2009). In this paper, we will refer to this combined representation as *AvgLexRep*.

³Available for download from akulmizev.com/embeddings/ar_tweets.csv.

⁴Available for download from akulmizev.com/embeddings/es_tweets.csv.

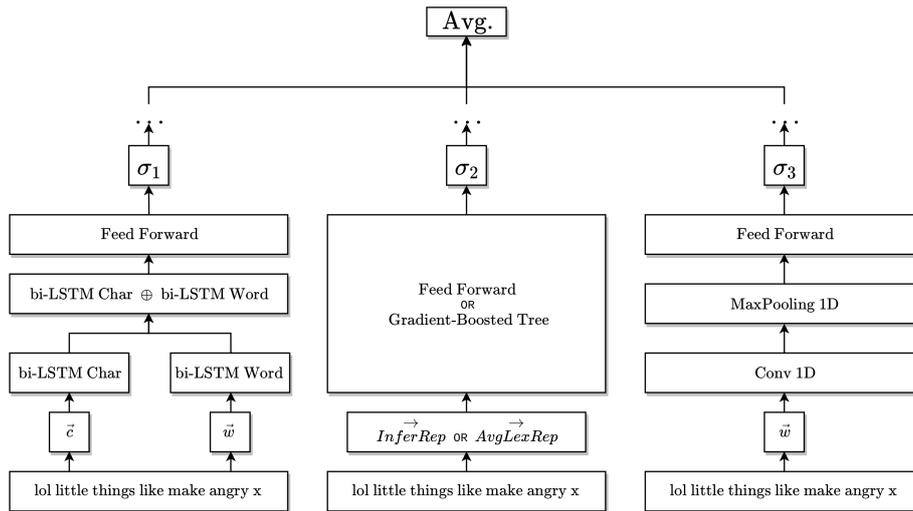

Figure 2: Diagram of our system which describes how the different models used are ensembled. The outputs of each component in the ensemble are averaged into a single score.

2.5 Learned representations

Engineering a representation of the data (such as the one described in Section 2.4) that can support effective machine learning is a complex task, requiring human ingenuity and domain-specific knowledge. Representation learning techniques (Bengio et al., 2003) enable machine learning algorithms to automatically extract and organize discriminative features, thereby mapping raw data into forms that make it easier to extract useful information. Some model components in our ensemble employ this kind of representation, which we obtain using 2 different methods:

- Encoding a tweet using (Conneau et al., 2017)’s BiLSTM-max pooling encoder, which is pre-trained on a natural language inference dataset⁵ and produces representations that perform well on a wide variety of NLP tasks. This approach in particular employs GloVe word embeddings (Pennington et al., 2014) as input and produces a vector containing 4096 dimensions, to which we will refer with the name $InferRep$. However, note that we only produce this feature vector for the English language subtasks.
- Encoding a tweet using one or a combination of three neural architectures which use skip-gram word embeddings (Mikolov et al., 2013) as input and are trained on the shared

task’s training data for regression subtasks. These correspond to the CNN, Bi-LSTM and CHAR-LSTM models described in Section 3. Representations produced by the CHAR-LSTM model are of dimension 612⁶, and the ones obtained via the Bi-LSTM model are of dimension 512. Representations produced by the CNN model have different dimensionality depending on the number and size of filters used. We will collectively refer to such representations with the name $RegRep$.

3 System architecture

While $RegRep$ is produced as part of end-to-end trainable regression and classification models, $AvgLexRep$ and $InferRep$ are generated independently. Thus, $AvgLexRep$ and $InferRep$ are fed separately into these models after being generated. The pipeline of our ensemble is represented schematically in Figure 2.

3.1 Neural models

We implement three varieties of neural network architectures which are commonly used in text classification tasks using Keras (Chollet et al., 2015) with a TensorFlow backend. In all of them, our objective function is Mean Squared Error (MSE) and dropout (Srivastava et al., 2014) is used for regularization at various levels. These architectures are listed below:

⁵Stanford Natural Language Inference dataset (Bowman et al., 2015). This is only available for English.

⁶512 dimensions correspond to word final hidden states and 100 dimensions to character hidden states.

- Convolutional Neural Network (CNN) with max pooling.
- Bidirectional Long-Short Term Memory (Bi-LSTM) with attention.
- Combined character and word features bi-LSTMs (CHAR-LSTM).

3.2 Regression

For *AvgLexRep* and *InferRep*, which are not part of an end-to-end trainable model, we perform regression using either a feed-forward Deep Neural Network (DNN) or Gradient Boosted Trees (GBT)⁷. The depth of the feed-forward network is determined constructively, starting with one layer and adding layers which are half the size of the previous one until performance on cross-validation stops improving.

3.3 Model selection for regression

We perform model selection using 5-fold cross-validation on the training data from the shared task. In each subtask that involves regression, the possible models are ranked according to their individual performance and ensembled through simple averaging. The ensemble itself is built constructively based on the ordering defined by the ranking, starting from a single component and adding components in order whenever the average performance on cross-validation improves.

Ensembling has long been shown to be an effective method of variance reduction for complex models (Perrone, 1993), and we indeed find in our experiments that averaging predictions leads to results better than those of any individual model⁸.

Furthermore, we also find predictions obtained via simple averaging to be more accurate (on cross-validation) compared to those obtained via feeding the outputs from all model components into a sigmoid layer. Although such a finding might appear counter-intuitive, it can perhaps be explained through the fact that the training dataset is relatively small, and therefore ensembling via a non-linear function of the outputs can potentially lead to overfitting.

⁷We use the GBT implementation provided in scikit-learn (Pedregosa et al., 2011).

⁸We refer the reader to (Hashem and Schmeiser, 1993) for an explanation of why this is the case.

3.4 Ordinal classification

Our system for each ordinal classification subtask makes use of the ensemble model which we build for the corresponding regression subtask in the same language, and model selection is performed using the same procedure described in Section 3.3. However, instead of averaging the predictions, the best model’s predictions are concatenated and fed as features to an ordinal meta-classifier (Antoniuk et al., 2013).

3.5 Hyperparameter tuning

Hyper-parameter optimization is carried out using 5-fold cross-validation. At first, a reasonable range is determined manually, and then grid-search is performed within that range. For Gradient Boosted Trees, the hyper-parameters optimized are maximum tree depth, number of estimators, and maximum leaf nodes. For neural models, the parameters optimized are batch size, number of epochs, size of the layers or filters, and whether or not dropout is used at different levels. Dropout is by default always set at 0.2. Furthermore, we use a fixed random seed to enable replicability.

4 Evaluation

System	Anger		Sadness		Joy		Fear	
	CV	Test	CV	Test	CV	Test	CV	Test
DNN (Infer.)	0.707	0.703	0.755	0.654	0.713	0.667	0.742	0.701
GBT (Infer.)	0.716	0.707	0.739	0.677	0.708	0.688	0.748	0.697
CHAR-LSTM	0.698	0.682	0.716	0.626	0.722	0.700	0.727	0.663
CNN	0.642	0.636	0.521	0.4316	0.637	0.628	0.615	0.459
Ensemble	0.756	0.749	0.770	0.699	0.758	0.740	0.773	0.726

Table 1: Comparison of Pearson correlation cross-validation (CV) and official results (Test) scores in the Emotion Intensity regression (EI-reg) English subtasks. Results are given for both the ensemble and its individual models.

Table 1 displays the scores (both 5-fold cross-validation and test scores) of the individual models and the ensemble model for the Emotion Intensity English regression subtasks. The ensemble model in this case is always for the best three models. Table 2 shows the results obtained using 5-fold cross-validation on the combined training and development data and the official test set results for each subtask. All scores are reported as the Pearson correlation coefficient between our system’s predictions and the provided gold-labels (i.e. human judgments).

Task	Emotion	English		Arabic		Spanish	
		CV	Test	CV	Test	CV	Test
El-reg	Anger	0.756	0.749	0.620	0.647	0.731	0.676
	Joy	0.758	0.740	0.690	0.756	0.712	0.753
	Fear	0.773	0.726	0.619	0.642	0.720	0.776
	Sadness	0.770	0.669	0.717	0.694	0.728	0.746
	Macro-avg.	0.764	0.728	0.662	0.685	0.723	0.738
V-reg	Valence	0.800	0.829	0.820	0.816	0.775	0.795
El-oc	Anger	0.670	0.620	0.620	0.551	0.635	0.606
	Joy	0.701	0.686	0.610	0.631	0.668	0.667
	Fear	0.635	0.528	0.565	0.551	0.658	0.706
	Sadness	0.738	0.622	0.682	0.618	0.655	0.677
	Macro-avg.	0.691	0.616	0.619	0.587	0.654	0.664
V-oc	Valence	0.770	0.776	0.778	0.752	0.749	0.756

Table 2: Pearson correlation using cross-validation (CV) on the training data and official results of the shared task (Test) obtained with our system, for each one of the Emotion Intensity (EI), Valence (V), regression (reg) and ordinal classification (oc) subtasks.

5 Analysis

It can be observed in Table 2 that the test and cross-validation scores are similar, meaning that cross-validation provided an accurate estimate of the generalization error and that our system’s overfitting of the different combined training and development sets is minimal. In fact, for the English valence subtasks, the Arabic Emotion Intensity regression subtask and all Spanish subtasks except the ones involving anger as the target emotion, the test scores are higher or equal than the cross-validation scores. This indicates both that our system generalizes appropriately and that the test sets are not substantially different than the training sets.

Overall performance is higher for English, likely due to the availability of better quality lexicons and word embeddings. Nonetheless, it is interesting to note that on average, cross-validation provided an optimistic estimate of the generalization error for English and a pessimistic one for Spanish and Arabic.

Furthermore, as shown in Table 1 for various English regression subtasks, it is clear that the ensemble outperforms all individual models on both cross-validation and the test set. This points towards the success of our ensembling method in reducing the variance of individual models. We omit similar results for other subtasks because the trend displayed by those is comparable.

Finally, it is interesting to note that the mod-

els using $InferRep$ (DNN and GBT), which rely on tweet representations produced through transfer learning from Natural Language Inference, outperformed the models using the task-specific $RegRep$ (CNN, Bi-LSTM and CHAR-LSTM) for all emotions except Sadness.

6 Conclusion and future work

In this paper we have described *AffecThor*, the system which we submitted to the SemEval-2018 *Affects in Tweets* shared task. *AffecThor* uses three different types of learned and manually-crafted representations and is an ensemble of neural and non-neural models. It is the best performing system on 5 out of 12 subtasks, and the second best performing in 3 others. Furthermore, it is arguably the best overall performer for Spanish and Arabic.

Our work explored two methods of ensembling regressors: simple averaging and using a non-linearity (sigmoid) layer on top of the different sub-models as part of an end-to-end trainable neural model, and found that simple averaging is more robust. However, we believe that ensembling using a linear combination (weighted-averaging) where the weights are learned could lead to better results, as is shown in (Perrone, 1993; Hashem and Schmeiser, 1993).

Finally, the availability of fine-grained labeled data across emotions and languages opens up the possibility of investigating multi-task and multi-lingual learning objectives. In the future, we would like to extend this work in that direction.

Amobee at SemEval-2018 Task 1: GRU Neural Network with a CNN Attention Mechanism for Sentiment Classification

Alon Rozental*, Daniel Fleischer*

Amobee, Tel Aviv, Israel

alon.rozentel@amobee.com

daniel.fleischer@amobee.com

Abstract

This paper describes the participation of Amobee in the shared sentiment analysis task at SemEval 2018. We participated in all the English sub-tasks and the Spanish valence tasks. Our system consists of three parts: training task-specific word embeddings, training a model consisting of gated-recurrent-units (GRU) with a convolution neural network (CNN) attention mechanism and training stacking-based ensembles for each of the sub-tasks. Our algorithm reached 3rd and 1st places in the valence ordinal classification sub-tasks in English and Spanish, respectively.

1 Introduction

Sentiment analysis is a collection of methods and algorithms used to infer and measure affection expressed by a writer. The main motivation is enabling computers to better understand human language, particularly sentiment carried by the speaker. Among the popular sources of textual data for NLP is Twitter, a social network service where users communicate by posting short messages, no longer than 280 characters long—called tweets. Tweets can carry sentimental information when talking about events, public figures, brands or products. Unique linguistic features, such as the use of slang, emojis, misspelling and sarcasm, make Twitter a challenging source for NLP research, attracting the interest of both academia and the industry.

Semeval is a yearly event in which international teams of researchers work on tasks in a competition format where they tackle open research questions in the field of semantic analysis. We participated in Semeval 2018 task 1, which focuses on sentiment and emotions evaluation in tweets. There were three main problems: identifying the

presence of a given emotion in a tweet (sub-tasks EI-reg, EI-oc), identifying the general sentiment (valence) in a tweet (sub-tasks V-reg, V-oc) and identifying which emotions are expressed in a tweet (sub-task E-c). For a complete description of Semeval 2018 task 1, see the official task description (Mohammad et al., 2018).

We developed an architecture based on gated-recurrent-units (GRU, Cho et al. (2014)). We used a bi-directional GRU layer, together with a convolutional neural network (CNN) attention-mechanism, where its input is the hidden states of the GRU layer; lastly there were two fully connected layers. We will refer to this architecture as the Amobee sentiment classifier (ASC). We used ASC to train word embeddings to incorporate sentiment information and to classify sentiment using annotated tweets. We participated in all the English sub-tasks and in the valence Spanish sub-tasks, achieving competitive results.

The paper is organized as follows: section 2 describes our data sources, section 3 describes the data pre-processing pipeline. A description of the main architecture is in section 4. Section 5 describes the word embeddings generation; section 6 describes the extraction of features. In section 7 we describe the performance of our models; finally, in section 8 we review and summarize the results.

2 Data Sources

We used four sources of data:

1. Twitter Firehose: we randomly sampled 200 million tweets using the Twitter Firehose service. They were used for training word embeddings and for distant supervision learning.
2. Semeval 2017 task 4 datasets of tweets, annotated according to their general sentiment

*These authors contributed equally to this work.

on 3 and 5 level scales; used to train the ASC model.

3. Annotated tweets from an external source¹, annotated on a 3-level scale; used to train the ASC model.
4. Official Semeval 2018 task 1 datasets: used to train task specific models.

Datasets of Semeval 2017 and the external source were combined with compression²; the resulting dataset contained 88,623 tweets with the following distribution: positive: 30097 sentences (34%), neutral: 35818 (40%), negative: 22708 (26%). Description of the official Semeval 2018 task 1 datasets can be found in [Mohammad et al. \(2018\)](#); [Mohammad and Kiritchenko \(2018\)](#).

3 Preprocessing

We started by defining a cleaning pipeline that produces two cleaned version of an original text; we refer to them as “simple” and “complex” versions. Both versions share the same initial cleaning steps:

1. Word tokenization using the [CoreNLP](#) library ([Manning et al., 2014](#)).
2. Parts of speech (POS) tagging using the [Tweet NLP](#) tagger, trained on Twitter data ([Owoputi et al., 2013](#)).
3. Grouping similar emojis and replacing them with representative keywords.
4. Regex: replacing URLs with a special keyword, removing duplications, breaking `#CamelCasingHashtags` into individual words.

The complex version contains these additional steps:

1. Word lemmatization, using CoreNLP.
2. Named entity recognition (NER) using CoreNLP and replacing the entities with representative keywords, e.g. `_date_`, `_number_`, `_brand_`, etc.
3. Synonym replacement, based on a manually-created dictionary.
4. Word replacement using a Wikipedia dictionary, created by crawling and extracting lists of places, brands and names.

¹ <https://github.com/monkeylearn/sentiment-analysis-benchmark>

² Transformed 5 labels to 3: $\{-2, -1\} \rightarrow \{-1\}$, $\{1, 2\} \rightarrow \{1\}$, $\{0\} \rightarrow \{0\}$.

As an example, table 1 shows a fictitious tweet and the results after the simple and complex cleaning stages.

4 ASC Architecture

Our main contribution is an RNN network, based on GRU units with a CNN-based attention mechanism; we will refer to it as the Amobee sentiment classifier (ASC). It is comprised of four identical sub-models, which differ by the input data each of them receives. Sub-model inputs are composed of word embeddings and embeddings of the POS tags—see section 5 for a description of our embedding procedure. The words were embedded in a 200 or 150 dimensional vector spaces and the POS tags were embedded in a 8 dimensional vector space. We pruned the tweets to have 40 words, padding shorter sentences with a zero vector. The embeddings form the input layer.

Next we describe the sub-model architecture; the embeddings were fed to a bi-directional GRU layer of dimension 200. Inspired by the attention mechanism introduced in [Bahdanau et al. \(2014\)](#), we extracted the hidden states of the GRU layer; each state corresponds to a decoded word in the GRU as it reads each tweet word by word. The hidden states were arranged in a matrix of dimension 40×400 for each tweet (bi-directionality of the GRU layer contributes a factor of 2). We fed the hidden states to a CNN layer, instead of a weighted sum as in the original paper. We used 6 filter sizes [1, 2, 3, 4, 5, 6], with 100 filters for each size. After a max-pooling layer we concatenated all outputs, creating a 600 dimensional vector. Next was a fully connected layer of size 30 with tanh activation, and finally a fully connected layer of size 3 with a softmax activation function.

We defined 4 such sub-models with embedding inputs of the following settings: w2v-200, w2v-150, ft-200, ft-150 (ft=FastText, w2v=Word2Vec, see discussion in the next section). We combined the four sub-models by extracting their hidden $d = 30$ layer and concatenating them. Next we added a fully connected $d = 25$ layer with tanh activation and a final fully connected layer of size 3. See figure 1 for an illustration of the entire architecture. We used the AdaGrad optimizer ([Duchi et al., 2011](#)) and a cross-entropy loss function. We used the [Keras](#) library ([Chollet et al., 2015](#)) and the [TensorFlow](#) framework ([Abadi et al., 2016](#)).

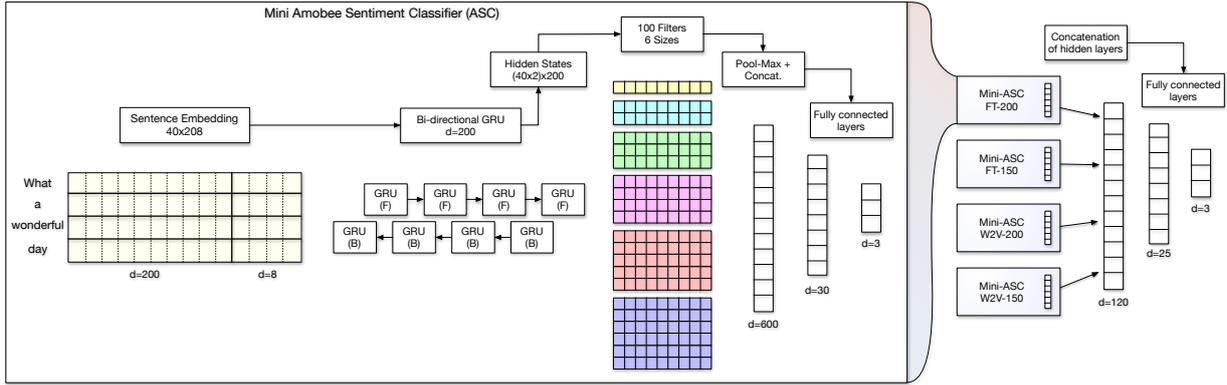

Figure 1: Architecture of the ASC network. Each of the four sub-models on the right has the same structure as depicted in the central region.

Complex Cleaning	twitter-entity be right happy-smily ! fly in .date_ pleasant to fly

Table 1: An example of a tweet processing, producing two cleaned versions.

5 Embeddings Training

Word embedding is a family of techniques in which words are encoded as real-valued vectors of lower dimensionality. These word representations have been used successfully in sentiment analysis tasks in recent years. Among the popular algorithms are Word2Vec (Mikolov et al., 2013) and FastText (Bojanowski et al., 2016).

Word embeddings are useful representations of words and can uncover hidden relationships. However, one disadvantage they have is the typical lack of sentiment information. For example, the word vector “good” can be very close to the word vector “bad” in some trained, off-the-shelf word embeddings. Our goal was to train word embeddings based on Twitter data and then re-learn them so they will contain emotion-specific sentiment.

We started with our 200 million tweets dataset; we cleaned them using the pre-processing pipeline (described in section 3) and then trained generic embeddings using the Gensim package (Řehůřek and Sojka, 2010); we created four embeddings for the words and two embeddings for the POS tags: for each sentence we created a list of corresponding POS tags (there are 25 tags offered by the tagger we used); treating the tags as words, we trained $d = 8$ embeddings using the word2vec algorithm on the simple and complex cleaned datasets. The embeddings parameters are specified in table 2.

Following Tang et al. (2014); Cliche (2017),

who explored training word embeddings for sentiment classification, we employed a similar approach. We created distant supervision datasets, first, by manually compiling 4 lists of representative words for each emotion: anger, fear, joy and sadness; then, we built two datasets for each emotion: the first containing tweets with the representative words and the second does not. Each list contained about 40 words and each dataset contained roughly 2 million tweets. We used the ASC sub-model architecture (section 4) to train as following: training for one epoch with embeddings set to be untrainable (fixed). Then train for 6 epochs where the embeddings can change.

Overall we trained 16 word embeddings—4 embedding configurations for each emotion. In addition, we decided to use the trained models’ final hidden layer ($d = 15$) as a feature vector in the task-specific architectures; our motivation was using them as emotion and intensity classifiers via transfer learning.

	Algorithm	Dimension	Dataset
Words	Word2Vec	200	Simple
	Word2Vec	150	Complex
	FastText	200	Simple
	FastText	150	Complex
Tags	Word2Vec	200	Simple
	Word2Vec	150	Complex

Table 2: Parameters for the word and POS tag embeddings.

6 Features Description

In addition to our ASC models, we extracted semantic and syntactic features, based on domain knowledge:

- Number of magnifier and diminisher words, e.g. “incredibly”, “hardly” in each tweet.
- Logarithm of length of sentences.
- Existence of elongated words, e.g. “wowww”.
- Fully capitalized words.
- The symbols #, @ appearing in the sentence.
- Predictions of external packages: [Vader](#) (part of the NLTK library, [Hutto and Gilbert, 2014](#)) and [TextBlob](#) ([Loria et al., 2014](#)).

Additionally, we compiled a list of 338 emojis and words in 16 categories of emotion, annotated with scores from the set $\{0.5, 1, 1.5, 2\}$. For each sentence, we summed up the scores in each category, up to a maximum value of 5, generating 16 features. The categories are: anger, disappointed, fear, hopeful, joy, lonely, love, negative, neutral, positive, sadness and surprise. Finally, we used the NRC Affect Intensity lexicon ([Mohammad, 2017](#)) containing 5814 entries; each entry is a word with a score between 0 and 1 for a given emotion out of the following: anger, fear, joy and sadness. We used the lexicon to produce 4 emotion features from hashtags in the tweets; each feature contained the largest score of all the hashtags in the tweet. For a summary of all features used, see table 6 in the appendix.

7 Experiments

Our general workflow for the tasks is as follows: for each sub-task, we started by cleaning the datasets, obtaining two cleaned versions. We ran a pipeline that produced all the features we designed: the ASC predictions and the features described in section 6. We removed sparse features (less than 8 samples). Next, we defined a shallow neural network with a soft-voting ensemble. We chose the best features and meta-parameters—such as learning rate, batch size and number of epochs—based on the dev dataset. Finally, we generated predictions for the regression tasks. For the classification tasks, we used a grid search method on the regression predictions

Task	Metric	Score	Ranking
V-oc-Spanish	Pearson	0.765	1/14
V-reg-Spanish		0.770	2/14
V-oc		0.813	3/37
EI-oc Average		0.646	4/39
V-reg		0.843	5/38
E-c	Jaccard	0.566	6/35
EI-reg Average	Pearson	0.721	13/48

Table 3: Summary of results.

to optimize the loss. Most model trainings were conducted on a local machine equipped with a Nvidia GTX 1080 Ti GPU. Our official results are summarized in table 3.

7.1 Valence Prediction

In the valence sub-tasks, we identified how intense a general sentiment (valence) is; the score is either in a continuous scale between 0 and 1 or classified into 7 ordinal classes $\{-3, -2, -1, 0, 1, 2, 3\}$, and is evaluated using the Pearson correlation coefficient.

We started with the regression task and defined the following model: first, we normalized the features to have zero mean and $SD = 1$. Then, we inserted 300 instances of fully connected layers of size 3, with a softmax activation and no bias term. For each copy, we applied the function $f(x) = (x_0 - x_2) / 2 + 0.5$ where x_0, x_2 are the 1st and 3rd component of each hidden layer. Our aim was transforming the label predictions of the ASCs (trained on 3-label based sentiment annotation) into a regression score such that high certainty in either label (negative, neutral or positive) would produce scores close to 0, 0.5 or 1, respectively. Finally, we calculated the mean of all 300 prediction to get the final node; this is also known as a soft-voting ensemble. We used the Adam optimizer ([Kingma and Ba, 2014](#)) with default values, mean-square-error loss function, batch size of 400 and 65 epochs of training. For an illustration of the network, see figure 2. We experimented with the dev dataset, testing different subsets of the features. Finally we produced predictions for the regression sub-task V-reg.

We analyzed the relative contribution of each feature by measuring variable importance using [Pratt \(1987\)](#) approach. We calculated scores d_i for each feature using the following formula: $d_i = \hat{\beta}_i \hat{\rho}_i / R^2$ where $\hat{\beta}_i$ denotes the sample estimation

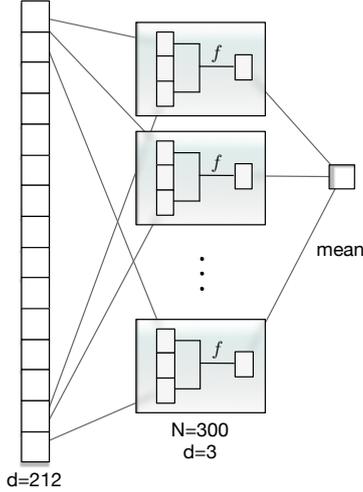

Figure 2: Architecture of the final classifier in the valence sub-tasks, where $f = (x_0 - x_2)/2 + 0.5$ and the input dimension is 212 for the V-reg sub-task.

of the feature, $\hat{\rho}_i$ is the simple correlation between the labels and the i th feature and R^2 is the coefficient of determination (see Thomas et al. 1998). We present the relative contribution of each feature in figure 3 and the top 10 features in table 4. We can see that the ASC models, both general and emotion-specific, contributed about 72% of the total contribution made by all features, in this sub-task.

For the ordinal classification task, we used the predictions of the regression task on the sentences, which were the same in both tasks. Using a grid search method, we partitioned the regression scores into 7 categories such that the Pearson correlation coefficient was maximized. We submitted the classes predictions as sub-task V-oc. Our final scores were 0.843, 0.813 in the regression and classification sub-tasks, respectively.

Name	Dim.	%
ASC_anger	25	31.38%
ASC	25	18.92%
ASC_fear	25	10.63%
ASC_joy	25	8.13%
W2V_200_sadness	15	7.10%
W2V_200_fear	15	3.82%
ASC_sadness	25	3.46%
W2V_200_joy	15	1.74%
Blob	1	1.64%
Joy	1	1.60%

Table 4: Relative contribution of features in the valence regression sub-task.

EI-reg	Anger	Fear	Joy	Sadness
Features	204	274	150	181
Learning rate	10^{-4}	10^{-5}	10^{-5}	$3 \cdot 10^{-5}$
Epochs	330	700	700	1000

Table 5: Summary of training parameters for the emotion intensity regression tasks.

7.2 Emotion Intensity

In the emotion intensity sub-tasks, we identified how intense a given emotion is in the given tweets. The four emotions were: anger, fear, joy and sadness; the score is either in a scale between 0 and 1 or classified into 4 ordinal classes $\{0, 1, 2, 3\}$. Performance was evaluated using the Pearson correlation coefficient. Our approach was similar to the valence tasks; first we generated features, then we used the same architecture as in the valence sub-tasks, depicted in figure 2. However, in these sub-tasks we used the emotion-specific embeddings for each emotion sub-task. We generated regression predictions and submitted them as the EI-reg sub-tasks; finally we carried a grid search for the best partition, maximizing the Pearson correlation and submitted the classes predictions as sub-tasks EI-oc. For a summary of the training parameters used in the regression sub-tasks, see table 5.

Our system performed as following: in the regression tasks, the scores were: 0.748, 0.670, 0.748, 0.721 for the anger, fear, joy and sadness, respectively, with a macro-average of 0.721. In the classification tasks, the scores were: 0.667, 0.536, 0.705, 0.673 for the anger, fear, joy and sadness, respectively, with a macro-average of 0.646.

7.3 Multi-label Classification

In the multi-label classification sub-task, we had to label tweets with respect to 11 emotions: anger, anticipation, disgust, fear, joy, love, optimism, pessimism, sadness, surprise and trust. The score was evaluated using the Jaccard similarity coefficient. We started with the same cleaning and feature-generation pipelines as before, creating an input layer of size 217. We added a fully connected layer of size 100 with tanh activation. Next there were 300 instances of fully connected layers of size 11 with sigmoid activation function. We calculated the mean of all $d = 11$ vectors, producing the final $d = 11$ vector. For an illustration, see figure 4 for an illustration. We used

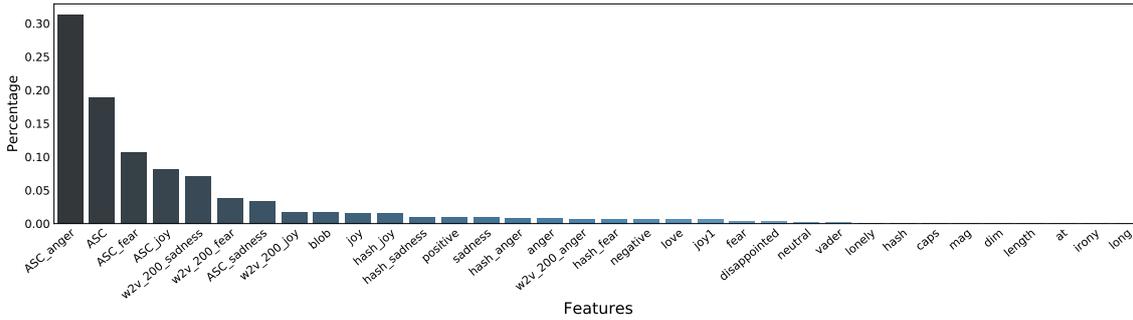

Figure 3: Relative contribution of features in the valence regression sub-task.

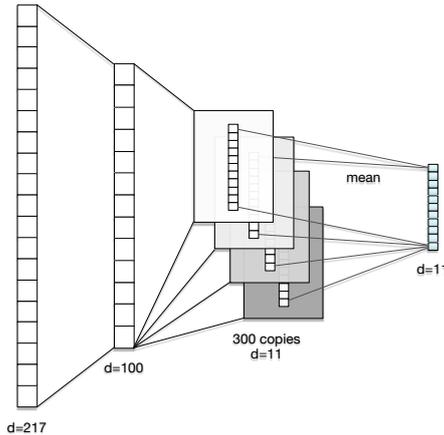

Figure 4: Architecture of the multi-label sub-task E-c.

the following loss function, based on Tanimoto distance: $L(y, \tilde{y}) = 1 - \frac{y \cdot \tilde{y}}{\|y + \tilde{y}\|_1 - y \cdot \tilde{y} + \epsilon}$, where $\|\cdot\|_1$ is an L^1 norm and $\epsilon = 10^{-7}$ is used for numerical stability. We trained with a batch size of 10, for 40 epochs with Adam optimization with default parameters. Our final score was 0.566.

7.4 Spanish Valence Tasks

We participated in the Spanish valence tasks to examine the current state of neural machine translation (NMT) algorithms. We used the [Google Cloud Translation API](#) to translate the Spanish training, development and test datasets for the two valence tasks from Spanish to English. We then treated the tasks the same way as the English valence tasks, using the same cleaning and feature extraction pipelines and the same architecture described in section 7.1 to generate regression and classification predictions. We reached 1st and 2nd places in the classification and regression sub-tasks, with scores of 0.765, 0.770, respectively.

8 Review and Conclusions

In this paper we described the system developed to participate in the Semeval 2018 task 1 workshop. We reached 3rd place in the valence ordinal classification sub-task and 5th place in the valence regression sub-task. In the Spanish valence tasks, we reached 1st and 2nd places in the classification and regression sub-tasks, respectively. In the emotions intensity sub-tasks we reached 4th and 13th places in the classification and regression sub-tasks, respectively.

Summarizing the methods used: training of word embeddings based on a Twitter corpus (200M tweets), developing and using Amobee sentiment classifier (ASC) architecture—a bi-directional GRU layer with a CNN-based attention mechanism and an additional hidden layer—used to adjust the embeddings to include emotional context, and finally a shallow feed-forward NN with a stack-based ensemble of final hidden layers from all previous classifiers we trained. This form of transfer learning proved to be important, as the hidden layers features achieved a significant contribution to minimizing the loss.

Overall, we had better performance in the valence tasks, both in English and Spanish. We posit this is due to the fact our annotated supervised training dataset (non task-specific) was based on Semeval 2017 task 4, which focused on valence classification. In addition, the annotations in Semeval 2017 were label-based, lending themselves more easily to the ordinal classification tasks. In the Spanish tasks, we used external translation (Google API) and achieved good results without the use of Spanish-specific features.

Acknowledgment

We thank Zohar Kelrich for assisting in translating the Spanish datasets to English.

Abstract

This paper describes our system implementation for subtask V-oc of SemEval-2018 Task 1: affect in tweets. We use multi-task learning method to learn shared representation, then learn the features for each task. There are five classification models in the proposed multi-task learning approach. These classification models are trained sequentially to learn different features for different classification tasks. In addition to the data released for SemEval-2018, we use datasets from previous SemEvals during system construction. Our Pearson correlation score is 0.638 on the official SemEval-2018 Task 1 test set.

1 Introduction

In recent years, people began to study how to create computational systems that process and understand the human languages. Today, people share their thoughts on social networks of the Internet, e.g. Facebook, Line, Twitter and so on. Thus, if the messages in the textual contents of social networks can be extracted and summarized automatically via algorithms, it is possible to learn what people are interested in or are concerned with, and use such information to predict future market trends.

Here we continue our previous works on the task 4 of SemEval-2017: Sentiment Analysis in Twitter (Rosenthal et al., 2017). SemEval-2017 subtask 4A is similar to task 1 of SemEval-2018: Affect in Tweets (Mohammad et al., 2018). They are challenging tasks as the messages on Twitter, called tweets, are short and informal. Furthermore, in addition to noisy or incomplete texts, the emotional content of a tweet can be ambiguous and subjective.

Affect in Tweets is an expanded version of WASSA-2017 shared task (Mohammad and Bravo-Marquez, 2017). The best system in

WASSA-2017 is an ensemble of three sets of approaches, including feed-forward neural network, multi-task deep learning and sequence modeling using CNNs and LSTMs (Goel et al., 2017). They attempt to use the idea of multi-task learning to explore the notion of generalized or shared learning across different emotions. In this paper, we extend the idea with different label methods.

The rest of this paper is organized as follows. In Section 2, we introduce our system. In Section 3, we describe the details of training and experimental settings. In Section 4, we present the evaluation results along with our comments.

2 System Description

2.1 Baseline System

Using RNN has become a very common technique for various NLP tasks. There are many units for RNN-based model like simple RNN, gated recurrent units (GRU) (Chung et al., 2014), and long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997). For the baseline, we use LSTM as unit for its long-range dependency.

Figure 1 shows the architecture of our baseline system. Our baseline system contains an input layer, an embedding layer, Bi-LSTM layers and an output layer. At the input layer, the words of tweet are pre-processed, and they are treated as a sequence of words w_1, w_2, \dots, w_n . Each word is represented by a one-hot vector, and the size of input layer is equal to the size of word list.

At the embedding layer, each word is converted to a word vector. We use pre-trained word vector which are stored in a matrix. Words are mapped to word vectors by the word embedding matrix. A word not in the word embedding matrix is represented by a zero vector.

A Bi-LSTM layer contains h units. We use bidirectional (Schuster and Paliwal, 1997) structure

to gather two-way contextual information at each point. The hidden states from the first word to the penultimate word in a tweet are connected to the hidden states of the next word. The state values in both directions are combined with sum. Only the last Bi-LSTM states of the last word are connected to the output layer. Finally, the network output is converted to probability by a soft-max function.

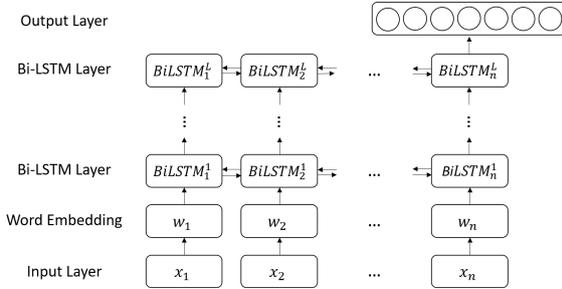

Figure 1: LSTM-RNN architecture.

2.2 Multi-task Learning

Multi-task learning has been used with success in applications of machine learning, from natural language processing (Collobert and Weston, 2008) and speech recognition (Deng et al., 2013). By sharing representations with related tasks, a model tends to generalize better on the original task (Ruder, 2017). In this work, different labels for the same data are exploited in multi-task learning.

Figure 2 shows our multi-task learning framework. The overall system is divided into five models. The Three-class model is trained first, and its trained parameters are used to initialize the parameters in other models. Then we train the Negative, Neutral, Positive class models, and their trained parameters are used to initialize the parameters of the Seven class model. The final output is obtained from the Seven class model.

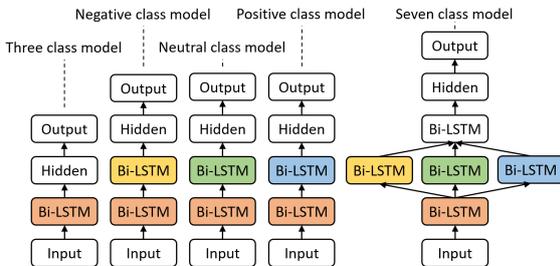

Figure 2: Multi-task learning of sentiment classification.

Three class model In Three class model, the tweets are converted to the word vector and used as the input to Bi-LSTM layer. The output layer has three units for three classes $\{-1, 0, 1\}$.

Negative class model The Negative class model has one more Bi-LSTM layer than Three class model. The output layer has four units for four classes $\{-3, -2, -1, other\}$.

Neutral class model The Neutral class model has the same architecture as the Negative class model. The output layer has two units for two classes $\{0, other\}$.

Positive class model The Positive class model has the same architecture as the Negative class model. The output layer has four units for four classes $\{other, 1, 2, 3\}$.

Seven class model The Seven class model combines the Bi-LSTM layers of the Negative class, Neutral class, and Positive class models. Further, it has one additional Bi-LSTM layer. The output layer has seven units for seven classes $\{-3, -2, -1, 0, 1, 2, 3\}$. Note that attention mechanism (Luong et al., 2015; Wang et al., 2016) is incorporated in this model.

3 Training

3.1 Data

We use the dataset provided for the SemEval-2018 shared task (Mohammad et al., 2018), which includes a new dataset and the datasets provided for SemEval-2017 (Rosenthal et al., 2017). Table 1 summarizes the statistics of these datasets.

3.2 Different Labeling

The SemEval-2017 dataset consists of three-class data, which is different from the new SemEval-2018 dataset. In order to exploit SemEval-2017 dataset, we modify the data labels. In the baseline system, we change the label to $\pm 1, \pm 2, \text{ or } \pm 3$. Adding a lot of data lead to imbalance problem, so we apply two methods of data balance. Method 1 is that adding data to positive and negative classes randomly such that they have same size respectively. Method 2 is that adding data to all classes randomly such that they have 3,000 tweets. Table 1 shows the numbers of data points after these different labeling methods.

dataset	labels	Negative			Neutral	Positive			total
		-3	-2	-1	0	1	2	3	
train-18	-	129	249	78	341	167	92	125	1,181
train-17	-	8,581			18,186	15,219			41,986
train-all	to ± 1	129	249	8,659	18,527	15,386	92	125	43,167
train-all	to ± 2	129	8,830	78	18,527	167	15,311	125	43,167
train-all	to ± 3	8,710	249	78	18,527	167	92	15,344	43,167
train-all	bal-method 1	3,013	3,012	3,012	18,527	5,201	5,201	5,201	43,167
train-all	bal-method 2	3,000	3,000	3,000	3,000	3,000	3,000	3,000	21,000
dev-18	-	69	95	34	105	58	35	53	449

Table 1: Statistics of our different labeling methods and datasets. train-18 and dev-18 are from SemEval-2018 Task 1. train-17 is from SemEval-2017 task 4. train-all means the merger of the train-18 and train-17 datasets.

3.3 Pre-processing

We begin with basic pre-processing methods (Yang et al., 2017), e.g. splitting a tweet into word, replacing URLs and USERS with normalization patterns <URL> and <USER>, and converting uppercase letters to lowercase letters. As tweets are informal and complex, the basic pre-processing is too simple to convey enough important information.

Tweets often have emoticons and hashtags, which could be instrumental to sentiment analysis. Thus, we use text processing tool¹ (Baziotis et al., 2017) to improve text normalization, including sentiment-aware tokenization, spell correction, word normalization, word segmentation (for splitting hashtags). and word annotation.

3.4 Early Stopping

The early stopping method is used to prevent overfitting when the loss of a development set ceases to decrease for a few epochs. We randomly take 20% of SemEval-2018 train data as the development set for early stopping and the remaining 80% data as the train set.

3.5 Settings

The maximum length for any tweet in the used datasets is $n = 99$. The embedding is based on a publicly available set of word vectors learned from 400 million tweets for the ACL WNUT 2015 shared task (Baldwin et al., 2015).

The baseline system uses 4 hidden Bi-LSTM layers, with 300 neurons in each layer. Dropout method with probability 0.3 is used to prevent the model from overfitting (Srivastava et al., 2014).

¹github.com/cbaziotis/ekphrasis

In the multi-task learning approach, the numbers of neurons in the Bi-LSTM and hidden layers are [200, 200], [200, 150, 200], [200, 150, 100], [200, 150, 200], [200, [150, 150, 150], 200, 200] for the 5 different class models, respectively.

4 Results

4.1 Baseline System

First, we compare the experiments of different labeling in baseline system to decide how to use the train-17 dataset. In baseline system, we use the basic pre-processing for text normalization. The results are shown in Table 2. The calculation of Pearson correlation coefficient (Pcc.) requires calculating the mean value of the data, which is often close to zero. From the results, labeling to more distant from zero get the higher Pcc. Therefore, we use labeling to ± 3 method in the multi-task learning system.

train set	labels	Pcc.	Acc.
train-18	-	0.515	0.298
train-all	to ± 1	0.572	0.261
train-all	to ± 2	0.629	0.323
train-all	to ± 3	0.649	0.347
train-all	bal-method 1	0.548	0.303
train-all	bal-method 2	0.553	0.347

Table 2: Results of different labeling. Pcc. means the pearson correlation coefficient (all classes). Acc. means the accuracy.

4.2 Multi-task Learning System

Table 3 shows the results of multi-task learning. With basic pre-processing for text normalization, the multi-task learning system is better than the

model	training set	Pcc.	Pcc.(s-m)	Kappa	Kappa(s-m)	Acc.
baseline	train-18	0.515	0.567	0.499	0.534	0.298
baseline	train-all	0.649	0.712	0.628	0.700	0.347
multi-task	train-18	0.603	0.660	0.579	0.623	0.312
multi-task	train-all	0.689	0.760	0.671	0.753	0.350
multi-task*	train-18	0.622	0.667	0.616	0.653	0.361
multi-task*	train-all	0.691	0.770	0.665	0.757	0.323
multi-task*	train-all	0.638	0.698	0.606	0.643	-

Table 3: Results of multi-task learning. Final row is the official SemEval-2018 test set result and others are development set results. Here * means using the ekphrasis tool for pre-processing and s-m means some-emotion.

baseline system. When the basic pre-processing method is replaced by using ekphrasis tool, the performance is further improved. Finally, we submit the results from our best system for the unseen test set to SemEval-2018, getting 0.638 for Pcc. eventually. We note this is significantly lower than 0.691 on the development data.

5 Conclusion

The proposed method improves performance on SemEval-2018 over baseline systems without multi-task learning. External dataset can significantly improve the Pcc. performance, but not the Acc. performance. The possible reason is that all the labels of external dataset are marked as ± 3 , resulting in data imbalance problem. In the future, we will use skewness-robust weights to solve this problem and use more resources to improve the system as sentiment lexicons.

Abstract

In this paper we describe our systems submitted to Semeval 2018 Task 1 “Affect in Tweet” (Mohammad et al., 2018). We participated in all subtasks of English tweets, including emotion intensity classification and quantification, valence intensity classification and quantification. In our systems, we extracted four types of features, including linguistic, sentiment lexicon, emotion lexicon and domain-specific features, then fed them to different regressors, finally combined the models to create an ensemble for the better performance. Officially released results showed that our system can be further extended.

1 Introduction

The Semeval 2018 Task 1 aims to automatically determine the intensity of emotions of the tweeters from their tweets, including five subtasks. That is, given a tweet and one of the four emotions (*anger*, *fear*, *joy*, *sadness*), the subtask 1 and 2 are to determine the intensity and classify the tweet into one of the four ordinal classes of intensity of the emotion respectively. Similarly, the subtask 3 and 4 determine the intensity and classify the tweet into one of seven ordinal classes of intensity of valance. Subtask 5 is a multi-label emotion classification task which classifies the tweets as neutral or no emotion or as one, or more, of eleven given emotions (*anger*, *anticipation*, *disgust*, *fear*, *joy*, *love*, *optimism*, *pessimism*, *sadness*, *surprise*, *trust*) that best represent the mental state of the tweeter. For each task, training and test datasets are divided into **English**, **Arabic**, and **Spanish** tweets. We participated in all subtasks of English tweets.

Traditional sentiment classification is a coarse-grained task in sentiment analysis which focuses on sentiment polarity classification of the whole sentence (*i.e.*, positive, negative, neutral, mixed).

Semeval 2018 Task 1 subtask 5 takes basic human emotion proposed by Ekman (Ekman, 1999) into consideration, including *Anger*, *Anticipation*, *Disgust*, *Fear*, *Joy*, *Sadness*, *Surprise*, and *Trust*.

The difference between these subtasks lies in the emotion granularity and classification or quantification, so in our work, the similar method is adopted for five subtasks. We extracted a rich set of elaborately designed features. In addition to linguistic features, sentiment lexicon features and emotion lexicon features, we also extracted some domain specific features. Also, we conducted a series of experiments on different machine learning algorithms and ensemble methods to obtain the better performing for each subtask. For subtask 5, we adopted multiple binary classification and constructed a model for each emotion.

2 System Description

We first performed data preprocessing, then extracted several types of features from tweets and constructed supervised models for this task.

2.1 Data Preprocessing

Firstly, all words are converted to lower case, URLs are replaced by “*url*”, abbreviations, slang and elongated words are transformed to their normal format. Then, emojis are replaced by corresponding emojis names by “Emoji Library”¹. Finally, we use *Stanford CoreNLP tools* (Manning et al., 2014) for tokenization, POS tagging, named entity recognizing (NER) and parsing.

2.2 Feature Engineering

We extracted a set of features to construct supervised models for five subtasks, that is linguistic

¹<https://github.com/fvancesco/emoji/>

features, sentiment lexicon features, emotion lexicon features and domain-specific features.

2.2.1 Linguistic Features

- **Lemma unigram** Considering there is similar emotion intensity expressed by “anger” and “angers”, we choose word lemma unigram features from tweets rather than word unigram features.
- **Negation** Negation in a sentence often affects its sentiment orientation, and conveys its intensity of the sentiment. For example, a sentence with several negation words is more inclined to negative sentiment polarity. Following previous work (Zhang et al., 2015), we manually collected 29 negations² and designed two binary features. One is to indicate whether there is any negation in the tweet and the other is to record whether this tweet contains more than one negation.
- **NER** Given a tweet “@JackHoward the Christmas episode genuinely had me in tears of laughter”, it has useful information like person name and festival which may convey tweeter’s happiness. So we extracted 12 types of named entities (DURATION, SET, NUMBER, LOCATION, PERSON, ORGANIZATION, PERCENT, MISC, ORDINAL, TIME, DATE, MONEY) from the sentence and represented each type of named entity as a binary feature to check whether it appears in the sentence.

2.2.2 Sentiment Lexicon Features

Many tasks related to sentiment or emotion analysis depend upon affect, opinion, sentiment, sense and emotion lexicons. So we employ eight sentiment lexicons to capture the sentiment information of the given sentence. The eight sentiment lexicons are as follows: *Bing Liu lexicon*³, *General Inquirer lexicon*⁴, *IMDB*⁵, *MPQA*⁶, *NRC Emotion Sentiment Lexicon*⁷, *AFINN*⁸, *NRC Hashtag*

²<https://github.com/haierlord/resource>

³<http://www.cs.uic.edu/liub/FBS/sentiment-analysis.html#lexicon>

⁴<http://www.wjh.harvard.edu/inquirer/homecat.htm>

⁵<http://www.aclweb.org/anthology/S13-2067>

⁶<http://mpqa.cs.pitt.edu/>

⁷<http://www.saifmohammad.com/WebPages/lexicons.html>

⁸http://www2.imm.dtu.dk/pubdb/views/publication_details.php?id=6010

*Sentiment Lexicon*⁹, and *NRC Sentiment140 Lexicon*¹⁰.

There is not a unified form among the eight lexicons. For example, Bing Liu lexicon use two values for each word to represent its sentiment scores which one for positive sentiment and the other for negative sentiment. In order to unify the form, we transformed the two scores into a one-dimensional value by subtracting negative emotion scores from positive emotion scores. Given a tweet, we calculated the following six scores:

- the ratio of positive words to all words.
- the ratio of negative words to all words.
- the maximum sentiment scores.
- the minimum sentiment scores.
- the sum of sentiment scores.
- the sentiment score of the last word in tweet.

2.2.3 Emotion Lexicon Features

Considering subtask 1, 2, 5 are related to emotion intensity prediction, subtask 3, 4 are related valence intensity prediction, three emotion lexicons and one valence lexicon are adopted. That is NRC Hashtag Sentiment Lexicon (Mohammad and Kiritchenko, 2015), NRC Affect Intensity Lexicon (Mohammad, 2017), NRC Word-Emotion Association Lexicon (Bravo-Marquez et al., 2017) and ANEW-1999 Lexicon (Bradley and Lang, 1999). Given a tweet, we calculate three scores for each lexicon to construct emotion lexicon features: the maximum scores, the sum of scores, the number of words exist in lexicons.

2.2.4 Domain-specific Features

- **Punctuation** People often use exclamation mark(!) and question mark(?) to express surprise or emphasis. Therefore, we extract the following 6 features:
 - whether the tweet contains an exclamation mark.
 - whether the tweet contains more than one exclamation mark.
 - whether the tweet has a question mark.

⁹<http://www.umiacs.umd.edu/saif/WebDocs/NRC-Hashtag-Sentiment-Lexicon-v0.1.zip>

¹⁰<http://help.sentiment140.com/for-students/>

- whether the tweet contains more than one question mark.
 - whether the tweet contains both exclamation marks and question marks.
 - whether the last token of this tweet is an exclamation or question mark.
- **Bag-of-Hashtags** Hashtags reflect emotion orientation of tweets directly, so we constructed a vocabulary of hashtags appearing in the training set and development set, then adopted the bag-of-hashtags method for each tweet.
 - **Emoticon** We collected 67 emoticons from Internet¹¹, including 34 positive emoticons and 33 negative emoticons, then designed the following 4 binary features:
 - to record whether the positive and negative emoticons are present in the tweet, respectively (1 for yes, 0 for no).
 - to record whether the last token is a positive or a negative emoticon.

- **Intensity Words** Some words appeared more frequently in tweets with higher intensity, some words has higher score in emotion lexicons, these words may contain information that express strong emotion intensity. So we extracted this type words in two ways:
 - Pick up words whose emotion score is greater than threshold from emotion lexicons.
 - Calculate the probability of each word appearing at different intensity for subtask 2 and 4, then pick up words whose probability greater than threshold(*i.e.*, 0.5).

Finally, for each word in intensity words list, we use a binary feature to check whether it appears in the given tweet.

2.3 Learning Algorithms

We explore six algorithms as follows: Logistic Regression (LR) and Support Vector Regression (SVR) implemented in *Liblinear*¹², Bagging Regressor (BR), AdaBoost Regressor (ABR) and

¹¹<https://github.com/haierlord/resource/blob/master/Emoticon.txt>

¹²<https://www.csie.ntu.edu.tw/~cjlin/liblinear/>

Gradient Boosting Regressor (GBR) implemented in *scikit-learn tools*¹³ and XGBoost Regressor (XGB)¹⁴. All these algorithms are used with default parameters.

3 Experiments

3.1 Dataset

The statistics of the English datasets provided by Semeval 2018 Task 1 are shown in Table 1 and 2. How the English data created is described in (Mohammad and Kiritchenko, 2018).

Datasets		anger	fear	joy	sadness
train		1,701	2,252	1,616	1,533
dev		388	689	290	397
test	subtask 1	17,939	17,923	18,042	17,912
	subtask 2	1,002	986	1,105	975

Table 1: The statistics of data sets for subtask 1 and 2.

Subtask	train	dev	test
3	1,181	449	17,874
4	1,181	449	937
5	6,838	886	3,259

Table 2: The statistics of data sets for subtask 3, 4, 5.

3.2 Evaluation Metric

To evaluate the performance of different systems, the official evaluation measure *Pearson Correlation Coefficient* with the Gold ratings/labels is adopted for the first four subtasks. The correlation scores across all four emotions will be averaged (macro-average) to determine the final system performance.

As for the last subtask, systems are evaluated by calculating multi-label accuracy namely *Jaccard index*, the formula are follow:

$$Accuracy = \frac{1}{|T|} \sum_{t \in T} \frac{|G_t \cap P_t|}{|G_t \cup P_t|}$$

where G_t is the set of the gold labels for tweet t , P_t is the set of the predicted labels for tweet t , and T is the set of tweets.

3.3 Experiments on Training and Test Data

Firstly, we performed a series of experiments in order to explore the effectiveness of each feature type. Table 3 lists the performance contributed by

¹³<http://scikit-learn.org/stable/>

¹⁴<https://github.com/dmlc/xgboost>

Features	macro-avg	anger	fear	joy	sadness
Linguistic	0.393	0.398	0.402	0.485	0.286
+.SentiLexi	0.594(+20.1%)	0.606	0.532	0.634	0.603
+.EmoLexi	0.635(+4.1%)	0.689	0.632	0.612	0.606
+.domain	0.657(+2.2%)	0.691	0.658	0.642	0.638

Table 3: Performance of different features on development set for subtask 1. “+” means to add current features to the previous feature set. The numbers in the brackets are the performance increments compared with the previous results.

Algorithm	macro-avg	anger	fear	joy	sadness
BR	0.602	0.609	0.618	0.584	0.597
XGBOOST	0.628	0.663	0.656	0.576	0.618
ABR	0.635	0.664	0.666	0.573	0.637
SVR	0.657	0.691	0.658	0.642	0.638
GBR	0.667	0.694	0.675	0.630	0.668
XGBOOST+ABR+SVR+GBR	0.680	0.715	0.689	0.647	0.670

Table 4: Performance of different learning algorithm on development set for subtask 1.

Subtask	System	macro-avg	anger	fear	joy	sadness
1	rank 1	0.799 (1)	0.827 (1)	0.779 (1)	0.792 (1)	0.798 (1)
	our system	0.695(14)	0.713(15)	0.677(18)	0.693(16)	0.697(14)
	baseline	0.520(36)	0.526(33)	0.525(34)	0.575(33)	0.453(36)
2	rank 1	0.695 (1)	0.706 (1)	0.637 (1)	0.720 (2)	0.717 (1)
	our system	0.531(16)	0.565(13)	0.441(21)	0.581(15)	0.536(20)
	baseline	0.394(26)	0.382(27)	0.355(26)	0.469(26)	0.370(29)

Table 5: Performance of our system, top-ranked system and baseline on test set for subtask 1, 2. SVM and unigrams are adopted in baseline. The numbers in the brackets are the official rankings.

System	Subtask3	Subtask4	Subtask5
rank 1	0.873 (1)	0.836 (1)	0.588 (1)
our system	0.813(14)	0.686(17)	0.501(11)
baseline	0.585(28)	0.509(24)	0.442(19)

Table 6: Performance of our system, top-ranked system and baseline on test set for subtask 3, 4, 5. SVM and unigrams are adopted in baseline. The numbers in the brackets are the official rankings.

different features on development set with Support Vector Regression algorithm for subtask 1. We find that:

(1) All feature types make contribution to the performance of emotion intensity prediction and their combination achieves the best performance.

(2) Linguistic features act as baseline and have shown poor performance for emotion intensity prediction. However, we find the system performance drops once we remove the Linguistic features.

(3) Sentiment lexicon features make a considerable contribution to the performance, which indicates that sentiment lexicon features are beneficial not only in traditional sentiment polarity analysis tasks, but also in emotion intensity prediction tasks.

(4) Beside, we find that the system performance only drops by 0.2% if we remove intensity words features. This indicates that these intensity words fail to distinguish emotion intensity. The reason may be that their function have overlap with sentiment and emotion lexicon features.

Also, we explored the performance of different learning algorithms. Table 4 shows the results of different algorithms for subtask 1 based on all features described before. From table 4, we find that GBR outperforms other single algorithm, and the ensemble model are superior to the models using single algorithm. The ensemble model use the four algorithms to build the ensemble regression models, which averages the output scores of al-

l regression algorithm.

Therefore, the system configurations for test data are: using all features for five subtasks, ensemble model for subtask 1 and 3, Logistic Regression for subtask 2, 4 and 5.

Based on the system configurations described above, we train separate model for each subtask and evaluate them against the test set in SemEval 2018 Task 1. Table 5 and Table 6 shows the results with ranks on test set for subtask 1 to 5. Compared with the top ranked systems, there is much room for improvement in our work. First, the biggest issue is that we only used hand-craft features but ignoring deep learning method. Second, we find that our system achieves greater performance on test set compared with the development set, the possible reason might be the different data distribution held between them.

4 Conclusion

In this paper, we extracted several traditional NLP, sentiment lexicon, emotion lexicon and domain specific features from tweets, adopted supervised machine learning algorithms to perform emotion intensity prediction. The system performance ranks above average. In future work, we consider to use deep learning method to model sentence with the aid of sentiment word vectors.

Abstract

While significant progress has been achieved for **Opinion Mining in Arabic (OMA)**, very limited efforts have been put towards the task of Emotion mining in Arabic. In fact, businesses are interested in learning a fine-grained representation of how users are feeling towards their products or services. In this work, we describe the methods used by the team **Emotion Mining in Arabic (EMA)**, as part of the SemEval-2018 Task 1 for Affect Mining for Arabic tweets. EMA participated in all 5 subtasks. For the five tasks, several preprocessing steps were evaluated and eventually the best system included diacritics removal, elongation adjustment, replacement of emojis by the corresponding Arabic word, character normalization and light stemming. Moreover, several features were evaluated along with different classification and regression techniques. For the 5 subtasks, word embeddings feature turned out to perform best along with Ensemble technique. EMA achieved the 1st place in subtask 5, and 3rd place in subtasks 1 and 3.

1 Introduction

Emotion recognition has captured the interest of researchers for many years. Different models have been used to detect people's emotions such as human computer interaction (HCI) (Hibbeln et al., 2017; Patwardhan and Knapp, 2017; Constantine et al., 2016) and their facial expressions (Trad et al., 2012; Wegrzyn et al., 2017). Recently, with Web 2.0, the size of textual data charged with opinions and emotions on the web has tremendously increased. Thus, researchers have been looking at automatically performing sentiment and emotion analysis from textual data. In fact, learning emotions of users is critical for different applications such as shaping marketing strategies (Bougie et al., 2003), providing

customers with better personalized recommendations for advertisements and products (Mohammad and Yang, 2011), improving recommendation of typical recommender systems (Badaro et al., 2013, 2014c,d), tracking emotions of users towards politicians, movies, music, products, etc. (Pang et al., 2008), or accurately predicting stock market prices (Bollen et al., 2011).

Some efforts have already been placed in developing emotion classification models from text (Shaheen et al., 2014; Houjeij et al., 2012; Abdul-Mageed and Ungar, 2017). Since sentiment lexicons helped in improving the accuracy of sentiment classification models (Liu and Zhang, 2012; Taboada et al., 2011), several researchers are working on developing emotion lexicons for different languages such as English, French, Chinese (Mohammad, 2017; Bandhakavi et al., 2017; Yang et al., 2007; Poria et al., 2012; Das et al., 2012; Mohammad et al., 2013; Abdaoui et al., 2017; Staiano and Guerini, 2014; Badaro et al., 2018a). There were also couple of attempts for developing Arabic emotion lexicons (Mohammad and Turney, 2013; Mohammad et al., 2013; El Gohary et al., 2013; Badaro et al., 2018b).

Building on our previous work on opinion mining which involved development of sentiment lexicons (ArSenL (Badaro et al., 2014a)), opinion mining models (Baly et al., 2014; Al Sallab et al., 2015; Al-Sallab et al., 2017; Baly et al., 2017b) and applications (Badaro et al., 2014b, 2015), and building on our analysis and characterization for Twitter Data (Baly et al., 2017a,c), we participate in SemEval 2018 Task 1 (Mohammad et al., 2018): Affect in Arabic Tweets. In fact, analyzing sentiment and emotions from dialectal Arabic such as text data from Twitter is of great importance given the tremendous increase of Arabic speaking users

on Twitter.¹

In this paper, we describe our approaches to SemEval 2018 Task 1 (Mohammad et al., 2018): Affect in Arabic Tweets, along with the achieved results for each of the subtasks where we employed preprocessing steps, features and classification models based on our prior work on sentiment analysis. In section 2, we present a brief overview of related work to emotion classification for English and Arabic. In section 3, we describe the five subtasks that are part of Affect in Tweet task. In section 4, we present our proposed approach and finally, we conclude in section 5.

2 Related Work

There have been extensive efforts for extracting emotions from different modalities including HCI (Constantine et al., 2016; Hibbeln et al., 2017; Patwardhan and Knapp, 2017), facial expressions (Trad et al., 2012; Wegrzyn et al., 2017) and speech (Houjeij et al., 2012). The related work for text emotion classification can be categorized into approaches for Emotion classification in English, that are leading the advances, versus research progress in Emotion in Arabic texts.

Emotion detection task from text is usually defined as a categorical classification task, where given a text, the classifier needs to predict the emotion label corresponding to the input text. Two typical categorical representations for emotions exist: Ekman representation (Ekman, 1992) which includes anger, happiness, surprise, disgust, sadness and fear and Plutchik model (Plutchik, 1980, 1994) which includes Ekman’s six emotions in addition to two labels: trust and anticipation.

2.1 English Emotion Analysis

In general, there are three different approaches for emotion classification: keyword-based detection, learning-based detection, and hybrid detection (Avetisyan et al., 2016).

Keyword-based techniques, also known as lexicon-based, depend on identifying emotional keywords in the input sentence (Strapparava et al., 2004; Mohammad and Turney, 2010, 2013). These models rely on the existence of large scale emotion lexicons and their accuracy is correlated with the accuracy of the emotion lexicon that is being utilized. On the other hand, they do not require

the existence of training data.

Learning-based approaches or feature-based approaches depend on the existence of annotated training data that are processed in order to extract several features such as syntactic, stylistic and semantic features (Ho and Cao, 2012; Bandhakavi et al., 2017). Additionally, in hybrid methods, emotions are detected by using a combination of emotional keywords and learning patterns collected from training datasets.

Due to the notable lack of resources related to emotion (annotated data and lexicons), progress on automatic affect intensity is still lagging. Mohammad and Bravo-Marquez (2017) created not only the first datasets of tweets annotated with emotion intensities, but also developed an emotion regression system with benchmark results. Abdul-Mageed and Ungar (2017) developed a large scale English dataset with fine grained emotion labels and trained deep learning models on top of it achieving an average accuracy of 87.58%.

2.2 Arabic Emotion Analysis

Emotion recognition for Arabic text has been gaining more attention recently. El Gohary et al. (2013) applied a knowledge-based approach to achieve 65% accuracy on the six basic Ekman emotions. Rabie and Sturm (2014) extracted a sample Arabic emotion lexicon and demonstrated how it enhanced the emotion detection results. Sayed et al. (2016) utilized Conditional Random Fields (CRF) and AdaBoost classifiers for classifying emotions of tweets and expression levels in which CRF achieved the best results. Alsharif et al. (2013) used Naive Bayes and SVM to classify Arabic poems into four emotion classes.

While some attempts were performed for Emotion recognition from Arabic text, there is still a lot of area for improvement as for example, developing large scale emotion lexicon for more accurate emotion recognition model, developing highly accurate emotion mining models for MSA as well as dialectal Arabic whether through the use of feature based approaches or deep learning.

3 SemEval 2018 Task 1: Affect in Arabic Tweets

We describe in this section the subtasks of SemEval 2018 task 1.

¹<https://weedoo.tech/twitter-arab-world-statistics-feb-2017/>

3.1 Subtasks' Descriptions

SemEval 2018 Task 1 Affect in Tweets (Mohammad et al., 2018) included five subtasks each with annotated dataset for English, Arabic and Spanish. The tasks were as follows:

1. EI-reg (Emotion Intensity Regression Task):

Given a tweet and an emotion E (anger, fear, joy or sadness), determine the intensity of E that best represents the emotion intensity of the tweeter by predicting a real-valued score between 0 (least E) and 1 (most E).

2. EI-oc (Emotion Intensity Ordinal Classification):

Given a tweet and an emotion E, classify the tweet into one of four ordinal classes of intensity of E, from 0 (low amount) to 3 (high amount), that best represents the mental state of the tweeter.

3. V-reg (a sentiment intensity regression task):

Given a tweet, determine the valence (V) that best represents the mental state of the tweeter by predicting a real-valued score between 0 (most negative) and 1 (most positive).

4. V-oc (a sentiment analysis, ordinal classification, task):

Given a tweet, classify it into one of seven ordinal classes, from -3 (very negative) to +3 (very positive), corresponding to various levels of positive and negative sentiment intensity, that best represents the sentiment of the tweeter.

5. E-c (an emotion classification task):

Given a tweet, classify it as *neutral (no emotion)* or as one, or more, of eleven given emotions that best represent the tweeter.

3.2 Datasets

For each of the 5 tasks, 3 sets of datasets were released, each set corresponding to a language (English, Arabic and Spanish). For each language, 3 datasets were released (training, development and test). For subtasks 1 and 2 Arabic, each emotion of the four emotions had a training set of around 800 tweets on average and a development set of around 200 tweets. Subtasks 3 and 4 Arabic had a dataset consisting of 932 tweets for training and 138 tweets for development. For subtask 5 Arabic, 2278 tweets were used for training and 585 tweets for development.

4 Explored Models for Competition

We present a description of EMA system covering preprocessing steps, features used, machine learn-

ing models employed and results achieved. An overview of the system is show in Figure 1.

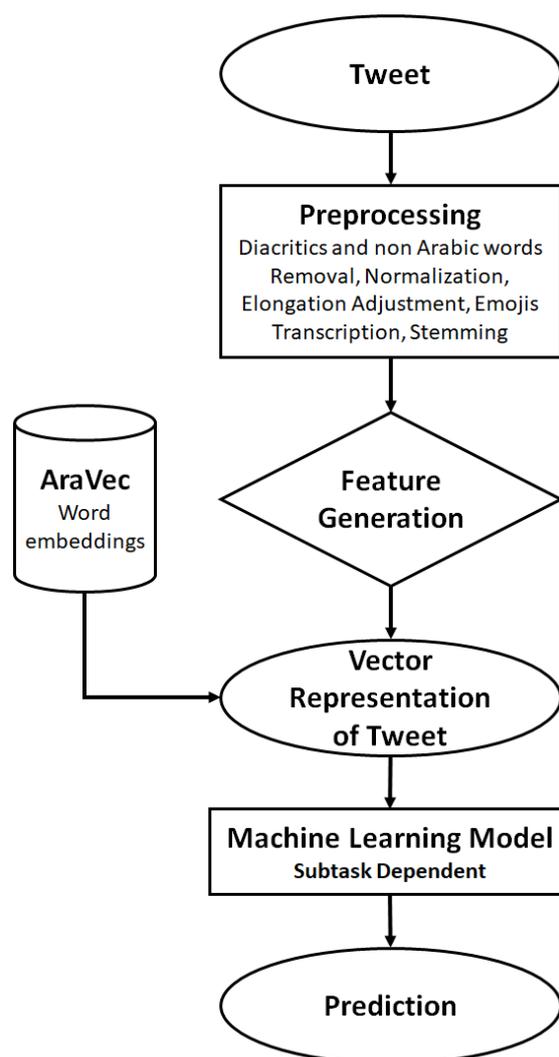

Figure 1: Overview of EMA System.

4.1 Preprocessing

The provided datasets contained raw tweets that included different properties used in Twitter such as hashtags, user mentions, urls, images, Arabizi and emojis. Thus, preprocessing steps were needed to enhance the analysis of the tweet. We experimented with different preprocessing configurations that led to mixed results. For example, using stems instead of lemmas proved to be better. One justification is that tweets are mostly in dialectal Arabic while most Arabic morphological analyzers are trained on MSA data. We present next the steps that led to the best performance.

We first applied the normalization rules followed by Shoukry and Rafea (2012): Diacritics were removed, the “hamza” on characters was

normalized in addition to normalizing some word ending characters such as the “t marbouta” and “ya’ maqsoura”. We then removed elongations as well as non Arabic letters. We manually created a lexicon containing the most frequent emojis in tweets and transcribed each emoji to its corresponding Arabic word. The lexicon consisted of 100 emojis. The tweets were finally stemmed using A Robust Arabic Light Stemmer (ARLSTEM) (Abainia et al., 2017).

4.2 Features

We have tried different features separately including unigrams, bigrams, trigrams, scores from emotion lexicon, ArSEL (Badaro et al., 2018b), sentiment lexicon, ArSenL ((Badaro et al., 2014a) and word embeddings from AraVec (Soliman et al., 2017) and FastText by Facebook (Bojanowski et al., 2016). AraVec was trained on three different datasets (Wikipedia, Text data from Web and Twitter) while FastText was trained on Wikipedia. Using word embeddings from AraVec outperformed significantly all other features including word embeddings trained on Wikipedia provided by Facebook. This is likely due to the fact that AraVec is a large scale dataset (around 205,000 words) trained on the same data domain (twitter), and includes several Arabic dialects. Word embeddings overcome the problem of sparsity present with n-grams and also reduce semantic complexity by providing similar representations to words that can appear in the same context. Each word was represented by a vector of real numbers of dimension 300. The sentence embeddings were computed by taking the average of its word embeddings. If a word did not have a vector representation, we tried using its stem’s representation. If neither the word nor its stem had a vector representation in AraVec, the average of the embeddings of closest words was utilized. By closest words, we mean words that had the smallest minimum edit distance (Levenshtein distance) with the target term. Eventually, each tweet was represented by a vector consisting of 300 real valued numbers. The same feature is used for all subtasks. For feature extraction, we used Python with NLTK, gensim and Numpy libraries.

4.3 Classification and Regression Models

Overall, we tried different learning models including Ridge regression, support vector machines, random forests, ensemble methods and deep neu-

ral networks such as convolutional neural networks with long short term memory layer. Deep neural networks performed poorly compared to other models. One possible explanation was that the training data size was very small and deep neural networks perform best when trained on a large scale data to ensure a well representation of the data (Beleites et al., 2013).

For regression subtasks 1 and 3, we tried different machine learning models including Ridge, Elastic Net, Decision Trees, random forest, xgboost and support vector regressor with (rbf kernel). The best was an Ensemble of Ridge regression (RR), Support Vector Regressor (SVR), and Random Forests (RF). In fact, the 3 models performed reasonably well on their own. For classification subtasks 2 and 4, we also tried different classification models including Ridge, Elastic Net, Decision Trees, Random Forest, Support Vector Classifier (SVC) with linear and non linear kernels and convolutional neural nets. For subtask 2, SVC performed best. As for subtask 4, an ensemble of SVC and Ridge Classifier performed best. Ridge Classifier allows defining a linear mapping without allowing weights to be large thanks to regularization effect for generalization while SVM tries to find the best classification margins. Adding ElasticNet did not help much since L1 and L2 errors were already covered by optimized using the ensemble of Ridge and SVM. Moreover, Zhou et al. (2015) shows that ElasticNet can be reduced to SVM. Random Forest with its large number of estimators had a better generalization than regular decision trees. Combining all these models in an ensemble model ensured a better generalization and accuracy on the test data.

For subtask 5, we tested SVC (with both penalties L1 and L2), RC, RF and Ensemble. SVC with L1 performed best. While Pearson correlation measure was used for evaluating subtasks 1 to 4, Accuracy was used to evaluate subtask 5.

For all subtasks, we utilized the training data for training the different models and the development set was treated as unseen data in order to make sure that comparison across the different models is fair. The best model was selected based on its performance on the development set. Our focus was on feature extraction and preprocessing, so most feature-based models performed well. One main problem faced in all problems was sparsity, since most tweets were in Dialectical Arabic.

4.4 Experimental Results

All experiments were conducted using Python with scikit-learn and Keras libraries. A grid search mechanism was utilized to optimize the hyperparameters of the different learning models used and whose performances are reported in below tables: alpha parameter for Ridge, penalty C, kernel and gamma for Support Vectors, and, number trees, maximum tree depth and number of features per tree for Random Forests. Rows 2 to 5 in tables 1 and 2 show the results (Pearson Score) of the different regression techniques used for subtasks 1 and 3 respectively on the corresponding development sets for each of the four emotions (Joy, Sadness, Fear and Anger). Average performance is also reported in the last column. The last two rows in table 1 show the result on the test set of our Ensemble model on average and per each emotion and the performance of the best team for subtask1 respectively. The last two rows in table 2 show the performance of Ridge Regression on the test set and the performance of the best team respectively. In both subtasks, EMA ranked 3rd among participants. By examining the results of the different participants in subtask 1, we can observe that the proposed systems perform best for the Joy emotion. Tables 3 and 4 show the hyperparameters for each technique employed. For Random Forest, the number of estimators was set to 1000.

In Tables 5 and 6, we show the results of subtasks 2 and 4 respectively. SVC was the best performing model on the development set in subtask 2 and Ensemble methods performed best in subtask 4. The last column in table 5 shows the performance of SVC on the test set on average and per each of the four emotions. The last row in table 6 represents the Pearson score achieved by the Ensemble of RC and SVC on the test set. EMA was ranked 8th and 5th in subtasks 2 and 4 respectively. Tables 7 and 8 show the best hyperparameters of the classification models used.

Regression Model	Joy	Sadness	Fear	Anger	Avg
RR	0.610	0.635	0.481	0.566	0.573

5 Conclusion and Future Work

In this paper, we presented EMA (Emotion Mining in Arabic) at SemEval 2018 Task 1 Affect in Tweets to perform Arabic Emotion and Sentiment mining. Several methods were tested for deciding on features, regression and classification techniques. Word embeddings provided the best feature while the choice of the predictor was task dependent. EMA ranked 1st in subtask 5 and 3rd in subtasks 1 and 3. As future work, we suggest finding the best combination of the different features that were employed in separate models. Other future work includes dealing with sparsity caused by dialectal Arabic.

Abstract

In this paper we present deep-learning models that submitted to the SemEval-2018 Task 1 competition: “Affect in Tweets”. We participated in all subtasks for English tweets. We propose a Bi-LSTM architecture equipped with a multi-layer self attention mechanism. The attention mechanism improves the model performance and allows us to identify salient words in tweets, as well as gain insight into the models making them more interpretable. Our model utilizes a set of word2vec word embeddings trained on a large collection of 550 million Twitter messages, augmented by a set of word affective features. Due to the limited amount of task-specific training data, we opted for a transfer learning approach by pretraining the Bi-LSTMs on the dataset of Semeval 2017, Task 4A. The proposed approach ranked 1st in Subtask E “Multi-Label Emotion Classification”, 2nd in Subtask A “Emotion Intensity Regression” and achieved competitive results in other subtasks.

1 Introduction

Social media content has dominated online communication, enriching and changing language with new syntactic and semantic constructs that allow users to express facts, opinions and emotions in short amount of text. The analysis of such content has received great attention in NLP research due to the wide availability of data and the interesting language novelties. Specifically the study of affective content in Twitter has resulted in a variety of novel applications, such as tracking product perception (Chamlertwat et al., 2012), public opinion detection about political tendencies (Pla

Figure 1: Attention heat-map visualization. The color intensity corresponds to the weight given to each word by the self-attention mechanism.

and Hurtado, 2014; Tumasjan et al., 2010), stock market monitoring (Si et al., 2013; Bollen et al., 2011b) etc. The wide usage of figurative language, such as emojis and special language forms like abbreviations, hashtags, slang and other social media markers, which do not align with the conventional language structure, make natural language processing in Twitter even more challenging.

In the past, sentiment analysis was tackled by extracting hand-crafted features or features from sentiment lexicons (Nielsen, 2011; Mohammad and Turney, 2010, 2013; Go et al., 2009) that were fed to classifiers such as Naive Bayes or Support Vector Machines (SVM) (Bollen et al., 2011a; Mohammad et al., 2013; Kiritchenko et al., 2014). The downside of such approaches is that they require extensive feature engineering from experts and thus they cannot keep up with rapid language evolution (Mudinas et al., 2012), especially in social media/micro-blogging context. However,

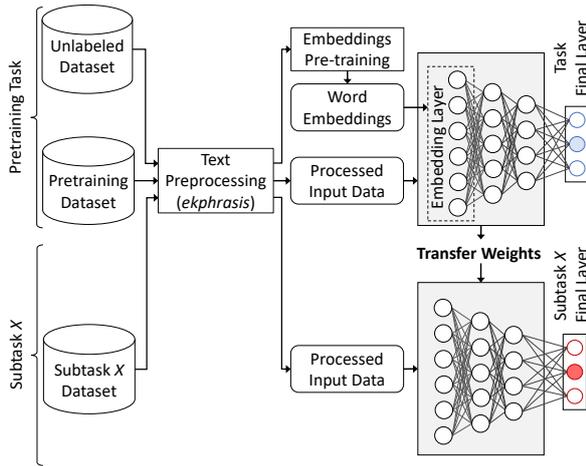

Figure 2: High-level overview of our approach

recent advances in artificial neural networks for text classification have shown to outperform conventional approaches (Deriu et al., 2016; Rouvier and Favre, 2016; Rosenthal et al., 2017a). This can be attributed to their ability to learn features directly from data and also utilize hand-crafted features where needed. Most of aforementioned works focus on sentiment analysis, but similar approaches have been applied to emotion detection (Canales and Martínez-Barco, 2014) leading to similar conclusions. SemEval 2018 Task 1: “Affect in Tweets” (Mohammad et al., 2018) focuses on exploring emotional content of tweets for both classification and regression tasks concerning the four basic emotions (joy, sadness, anger, fear) and the presence of more fine-grained emotions such as disgust or optimism.

In this paper, we present a deep-learning system that competed in SemEval 2018 Task 1: “Affect in Tweets”. We explore a transfer learning approach to compensate for limited training data that uses the sentiment analysis dataset of Semeval Task 4A (Rosenthal et al., 2017b) for pretraining a model and then further fine-tune it on data for each subtask. Our model operates at the word-level and uses a Bidirectional LSTM equipped with a deep self-attention mechanism (Pavlopoulos et al., 2017). Moreover, to help interpret the inner workings of our model, we provide visualizations of tweets with annotations of the salient tokens as predicted by the attention layer.

2 Overview

Figure 2 provides a high-level overview of our approach, which consists of three main steps:

(1) the *word embeddings pretraining*, where we train word2vec and affective word embeddings on our unlabeled Twitter dataset, (2) the *transfer learning* step, where we pretrain a deep-learning model on a sentiment analysis task, (3) the *fine-tuning* step, where we fine-tune the pretrained model on each subtask.

Task definitions. Given a tweet we are asked to:

Subtask EI-reg: determine the intensity of a certain emotion (*joy, fear, sadness, anger*), as a real-valued number between in the $[0, 1]$ interval.

Subtask EI-oc: classify its intensity towards a certain emotion (*joy, fear, sadness, anger*) across a 4-point scale.

Subtask V-oc: classify its valence intensity (i.e sentiment intensity) across a 7-point scale $[-3, 3]$.

Subtask V-reg: determine its valence intensity as a real-valued number between in the $[0, 1]$ interval.

Subtask E-c: determine the existence of none, one or more out of eleven emotions: *anger, anticipation, disgust, fear, joy, love, optimism, pessimism, sadness, surprise, trust*.

2.1 Data

Unlabeled Dataset. We collected a big dataset of 550 million English tweets, from April 2014 to June 2017. This dataset is used for (1) calculating word statistics needed in our text preprocessing pipeline (Section 2.3) and (2) training word2vec and affective word embeddings (Section 2.2).

Pretraining Dataset. For transfer learning, we utilized the dataset of Semeval-2017 Task4A. The dataset consists of 61,854 tweets with $\{positive, neutral, negative\}$ sentiment (valence) annotations. To our knowledge, this is the largest Twitter dataset with affective annotations.

2.2 Word Embeddings

Word embeddings are dense vector representations of words (Collobert and Weston, 2008; Mikolov et al., 2013), capturing their semantic and syntactic information. To this end, we train *word2vec* word embeddings, to which we add 10 affective dimensions. We use our pretrained embeddings, to initialize the first layer (embedding layer) of our neural networks.

Word2vec Embeddings. We leverage our unlabeled dataset to train Twitter-specific word embeddings. We use the *word2vec* (Mikolov et al., 2013) algorithm, with the skip-gram model, negative sampling of 5 and minimum word count of 20,

utilizing Gensim’s (Řehůřek and Sojka, 2010) implementation. The resulting vocabulary contains 800,000 words.

Affective Embeddings. Starting from small manually annotated lexica, continuous norms (within the $[-1, 1]$ interval) for new words are estimated using semantic similarity and a linear model along ten affect-related dimensions, namely: valence, dominance, arousal, pleasantness, anger, sadness, fear, disgust, concreteness, familiarity. The method of generating word level norms is detailed in (Malandrakis et al., 2013) and relies on the assumption that given a similarity metric between two words, one may derive the similarity between their affective ratings. This approach uses a set of N words with known affective ratings (seed words), as a starting point. Concretely, we calculate the affective rating of a word w as follows:

$$\hat{v}(w) = \alpha_0 + \sum_{i=1}^N \alpha_i v(t_i) S(t_i, w), \quad (1)$$

where $t_1 \dots t_N$ are the seed words, $v(t_i)$ is the affective rating for seed word t_i , α_i is a trainable weight corresponding to seed t_i and $S(\cdot)$ stands for the semantic similarity metric between t_i and w . The seed words t_i are selected separately for each dimension, from the words available in the original manual annotations (see 2.2). The $S(\cdot)$ metric is estimated as shown in (Palogiannidi et al., 2015) using word-level contextual feature vectors and adopting a scheme based on mutual information for feature weighting.

Manually annotated norms. To generate affective norms, we need to start from some manual annotations, so we use ten dimensions from four sources. From the Affective Norms for English Words (Bradley and Lang, 1999) we use norms for valence, arousal and dominance. From the MRC Psycholinguistic database (Coltheart, 1981), we use norms for concreteness and familiarity. From the Paivio norms (Clark and Paivio, 2004) we use norms for pleasantness. Finally from (Stevenson et al., 2007) we use norms for anger, sadness, fear and disgust.

2.3 Preprocessing¹

We utilized the *ekphrasis*² (Baziotis et al., 2017) tool as a tweet preprocessor. The preprocessing steps included in *ekphrasis* are: Twitter-specific tokenization, spell correction, word normalization, word segmentation (for splitting hashtags) and word annotation.

Tokenization. Tokenization is the first fundamental preprocessing step and since it is the basis for the other steps, it immediately affects the quality of the features learned by the network. Tokenization on Twitter is challenging, since there is large variation in the vocabulary and the expressions which are used. There are certain expressions which are better kept as one token (e.g. anti-american) and others that should be split into separate tokens. *Ekphrasis* recognizes Twitter markup, emoticons, emojis, dates (e.g. 07/11/2011, April 23rd), times (e.g. 4:30pm, 11:00 am), currencies (e.g. \$10, 25mil, 50€), acronyms, censored words (e.g. s**t), words with emphasis (e.g. *very*) and more using an extensive list of regular expressions.

Normalization. After tokenization, we apply a series of modifications on the extracted tokens, such as spell correction, word normalization and segmentation. Specifically for word normalization we use lowercase words, normalize URLs, emails, numbers, dates, times and user handles (@user). This helps reducing the vocabulary size without losing information. For spell correction (Jurafsky and James, 2000) and word segmentation (Segaran and Hammerbacher, 2009) we use the Viterbi algorithm. The prior probabilities are obtained from word statistics from the unlabeled dataset.

The benefits of the aforementioned procedure are the reduction of the vocabulary size, without removing any words, and the preservation of information that is usually lost during tokenization. Table 1 shows an example text snippet and the resulting preprocessed tokens.

¹Significant portions of the systems submitted to SemEval 2018 in Tasks 1, 2 and 3, by the NTUA-SLP team are shared, specifically the preprocessing and portions of the DNN architecture. Their description is repeated here for completeness.

2.4 Neural Transfer Learning for NLP

Transfer learning aims to make use of the knowledge from a source domain, to improve the performance of a model in a different, but related, target domain. It has been applied with great success in computer vision (CV) (Razavian et al., 2014; Long et al., 2014). Deep neural networks in CV are rarely trained from scratch and instead are initialized with pretrained models. Notable examples include face recognition (Taigman et al., 2014) and visual QA (Agrawal et al., 2017), where image features trained on ImageNet (Deng et al., 2009) and word embeddings estimated on large corpora via unsupervised training are combined. Although model transfer has seen widespread success in computer vision, transfer learning beyond pretrained word vectors is less pervasive in NLP.

In our system, we explore the approach of pretraining a network in a sentiment analysis task in Twitter and use it to initialize the weights of the models of each subtask. We chose the dataset of Semeval 2017 Task4A (SA2017) (Rosenthal et al., 2017b), which is a semantically similar dataset to the emotion datasets of this task. By pretraining on a dataset in a similar domain, it is more likely that the source and target dataset will have similar distributions.

To build our pretrained model, we initialize the weights of the embedding layer with the word2vec Twitter embeddings and train a bidirectional LSTM (BiLSTM) with a deep self-attention mechanism (Pavlopoulos et al., 2017) on SA2017, similar to (Baziotis et al., 2017). Afterwards, we utilize the encoding part of the network, which is the BiLSTM and the attention layer, throwing away the last layer. This pretrained model is used for all subtasks, with the addition of a subtask-specific final layer for classification/regression.

2.5 Recurrent Neural Networks

We model the Twitter messages using Recurrent Neural Networks (RNN). RNNs process their inputs sequentially, performing the same operation, $h_t = f_W(x_t, h_{t-1})$, on every element in a sequence, where h_t is the hidden state t the time step, and W the network weights. We can see that the hidden state at each time step depends on the previous hidden states, thus the order of elements (words) is important. This process also enables RNNs to handle inputs of variable length.

RNNs are difficult to train (Pascanu et al.,

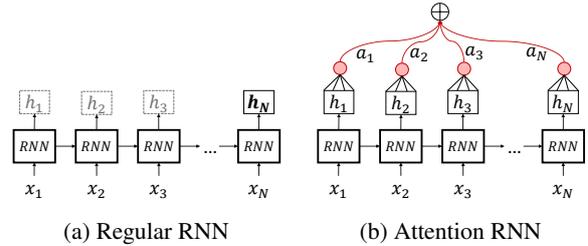

Figure 3: Comparison between regular RNN and attentive RNN.

2013), because gradients may grow or decay exponentially over long sequences (Bengio et al., 1994; Hochreiter et al., 2001). A way to overcome these problems is to use more sophisticated variants of regular RNNs, like Long Short-Term Memory (LSTM) networks (Hochreiter and Schmidhuber, 1997) or Gated Recurrent Units (GRU) (Cho et al., 2014), introducing a gating mechanism to ensure proper gradient flow through the network.

2.6 Self-Attention Mechanism

RNNs update their hidden state h_i as they process a sequence and the final hidden state holds a summary of the information in the sequence. In order to amplify the contribution of important words in the final representation, a self-attention mechanism (Bahdanau et al., 2014) is used as shown in Fig. 3. By employing an attention mechanism, the representation of the input sequence r is no longer limited to just the final state h_N , but rather it is a combination of all the hidden states h_i . This is done by computing the sequence representation, as the convex combination of all h_i . The weights a_i are learned by the network and their magnitude signifies the importance of each h_i in the final representation. Formally:

$$r = \sum_{i=1}^N a_i h_i \quad \text{where} \quad \sum_{i=1}^N a_i = 1, \quad a_i > 0$$

3 Model Description

Next, we present in detail the submitted models. For all subtasks, we adopted a transfer learning approach, by pretraining a BiLSTM network with a deep attention mechanism on SA2017 dataset. Afterwards, we replaced the last layer of the pretrained model with a task-specific layer and finetuned the whole network for each subtask.

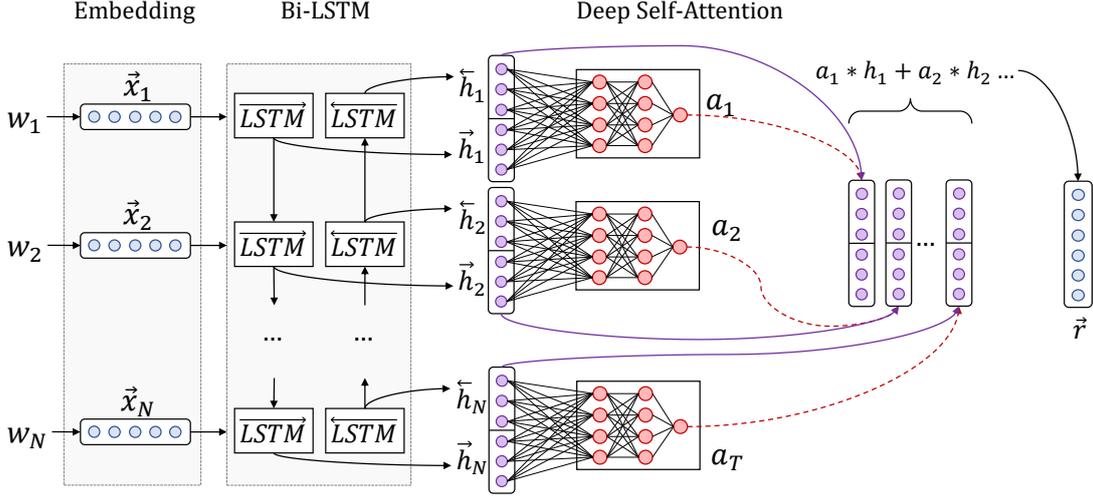

Figure 4: The proposed model, composed of a 2-layer BiLSTM with a deep self-attention mechanism.

3.1 Transfer Learning Model (TF)

Our transfer learning model is based on the sentiment analysis model in (Baziotis et al., 2017). It consists of a 2-layer bidirectional LSTM (BiLSTM) with a deep self-attention mechanism.

Embedding Layer. The input to the network is a Twitter message, treated as a sequence of words. We use an embedding layer to project the words w_1, w_2, \dots, w_N to a low-dimensional vector space R^W , where W is the size of the embedding layer and N the number of words in a tweet. We initialize the weights of the embedding layer with our pre-trained word embeddings (Section 2.2).

BiLSTM Layer. An LSTM takes as input a sequence of word embeddings and produces word annotations h_1, h_2, \dots, h_N , where h_i is the hidden state of the LSTM at time-step i , summarizing all the information of the sentence up to w_i . We use bidirectional LSTMs (BiLSTM) in order to get word annotations that summarize the information from both directions. A BiLSTM consists of 2 LSTMs, a forward LSTM \vec{f} that parses the sentence from w_1 to w_N and a backward LSTM \overleftarrow{f} that parses the sentence from w_N to w_1 . We obtain the final annotation for each word h_i , by concatenating the annotations from both directions,

$$h_i = \vec{h}_i \parallel \overleftarrow{h}_i, \quad h_i \in R^{2L} \quad (2)$$

where \parallel denotes the concatenation operation and L the size of each LSTM.

Attention Layer. To amplify the contribution of the most informative words, we augment our BiLSTM with a self-attention mechanism. We use a

deep self-attention mechanism (Pavlopoulos et al., 2017), to obtain a more accurate estimation of the importance of each word. The attention weight in the simple self-attention mechanism, is replaced with a multilayer perceptron (MLP), composed of l layers with a non-linear activation function (\tanh). The MLP learns the attention function g . The attention weights a_i are then computed as a probability distribution over the hidden states h_i . The final representation r is the convex combination of h_i with weights a_i .

$$e_i = g(h_i) \quad (3)$$

$$a_i = \frac{\exp(e_i)}{\sum_{t=1}^N \exp(e_t)} \quad (4)$$

$$r = \sum_{i=1}^N a_i h_i, \quad r \in R^{2L} \quad (5)$$

Output Layer. We use vector r as the feature representation, which we feed to a final task-specific layer. For the regression tasks, we use a fully-connected layer with one neuron and a sigmoid activation function. For the ordinal classification tasks, we use a fully-connected layer, followed by a *softmax* operation, which outputs a probability distribution over the classes. Finally, for the multi-label classification task, we use a fully-connected layer with 11 neurons (number of labels) and a sigmoid activation function, performing binary classification for each label.

3.2 Fine-Tuning

After training a network on the pretraining dataset (SA2017), we fine-tune it on each subtask, by re-

placing its final layer with a task-specific layer. We experimented with two fine-tuning schemes. The first approach is to fine-tune the whole network, that is, both the pretrained encoder (BiLSTM) and the task-specific layer. The second approach is to use the pretrained model only for weight initialization, freeze its weights during training and just fine-tune the final layer. Based on the experimental results, the first approach obtains significantly better results in all tasks.

3.3 Regularization

In both models, we add Gaussian noise to the embedding layer, which can be interpreted as a random data augmentation technique, that makes models more robust to overfitting. In addition to that, we use dropout (Srivastava et al., 2014) and we stop training after the validation loss has stopped decreasing (early-stopping).

Furthermore, we do not fine-tune the embedding layers. Words occurring in the training set, are projected in the embedding space and the classifier correlates certain regions of the embedding space to certain emotions. However, words included only in the test set, remain at their initial position which may no longer reflect their “true” emotion, leading to mis-classifications.

4 Experiments and Results

4.1 Experimental Setup

Training We use Adam algorithm (Kingma and Ba, 2014) for optimizing our networks, with minibatches of size 32 and we clip the norm of the gradients (Pascanu et al., 2013) at 1, as an extra safety measure against exploding gradients. For developing our models we used PyTorch (Paszke et al., 2017) and Scikit-learn (Pedregosa et al., 2011).

Class Weights. In subtasks *EI-oc* and *V-oc*, some classes have more training examples than others, introducing bias in our models. To deal with this problem, we apply class weights to the loss function, penalizing more the misclassification of under-represented classes. These weights are computed as the inverse frequencies of the classes in the training set.

Hyper-parameters. In order to tune the hyperparameter of our model, we adopt a Bayesian optimization (Bergstra et al., 2013) approach, performing a more time-efficient search in the high dimensional space of all the possible values, compared to grid or random search. We set size of the

embedding layer to 310 (300 *word2vec* + 10 affective dimensions), which we regularize by adding Gaussian noise with $\sigma = 0.2$ and dropout of 0.1. The sentence encoder is composed of 2 BiLSTM layers, each of size 250 (per direction) with a 2-layer self-attention mechanism. Finally, we apply dropout of 0.3 to the encoded representation.

4.2 Experiments

In Table 2, we compare the proposed transfer learning models against 3 strong baselines. Pearson correlation is the metric used for the first four subtasks, whereas Jaccard index is used for the *E-c* multi-label classification subtask. The first baseline is a unigram Bag-of-Words (BOW) model with TF-IDF weighting. The second baseline is a Neural Bag-of-Words (N-BOW) model, where we retrieve the *word2vec* embeddings of the words in a tweet and compute the tweet representation as the average (centroid) of the constituent *word2vec* embeddings. Finally, the third baseline is similar to the second one, but with the addition of 10-dimensional affective embeddings that model affect-related dimensions (valence, dominance, arousal, etc). Both BOW and N-BOW features are then fed to a linear SVM classifier, with tuned $C = 0.6$. In order to assess the impact of transfer learning, we evaluate the performance of each model in 3 different settings: (1) random weight initialization (LSTM-RD), (2) transfer learning with frozen weights (LSTM-TL-FR), (3) transfer learning with fine-tuning (LSTM-TL-FT). The results of our neural models in Table 2 are computed by averaging the results of 10 runs to account for model variability.

Baselines. Our first observation is that N-BOW baselines significantly outperform BOW in subtasks *EI-reg*, *EI-oc*, *V-reg* and *V-oc*, in which we have to predict the intensity of an emotion, or the tweet’s valence. However, BOW achieves slightly better performance in subtask *E-c*, in which we have to recognize the emotions expressed in each tweet. This can be attributed to the fact that BOW models perform well in tasks where the occurrence of certain words is sufficient, to accurately determine the classification result. This suggests that in subtask *E-c*, certain words are highly indicative of some emotions. Word embeddings, though, that encode the correlation of each word with different dimensions, enable NBOW to better predict the intensity of various emotions. Further-

	EI-reg (pearson)				EI-oc (pearson)				V-Reg	V-oc	E-c
	anger	fear	joy	sadness	anger	fear	joy	sadness	(pearson)	(pearson)	(jaccard)
BOW	0.5249	0.5227	0.5716	0.4721	0.3996	0.3491	0.4456	0.3835	0.5963	0.4954	0.4572
NBOW	0.6539	0.6318	0.6355	0.6305	0.5573	0.3796	0.5044	0.5009	0.7501	0.6527	0.4541
NBOW+A*	0.656	0.6359	0.6384	0.6341	0.5367	0.3906	0.4803	0.5005	0.7457	0.6578	0.4478
LSTM-RD	0.7568	0.7357	0.7313	0.7479	0.6387	0.5874	0.6226	0.6343	0.8462	0.7722	0.5788
LSTM-TL-FR	0.7347	0.6509	0.7321	0.7269	0.5999	0.4666	0.6264	0.6030	0.8275	0.7331	0.5243
LSTM-TL-FT	0.7717	0.7273	0.7638	0.7665	0.6329	0.5702	0.6351	0.6400	0.8390	0.7652	0.5788

Table 2: Results of our experiments across all subtasks on the official evaluation metrics. For subtasks *EI-reg*, *EI-oc*, *V-reg*, *V-oc*, the evaluation metric is Pearson correlation. For subtask *E-c*, the evaluation metric is multi-label accuracy (Jaccard index). BOW stands for Bag-of-Words baseline, N-BOW stands for Neural Bag-of-Words baseline and N-BOW+A indicates the inclusion of the affective word features. As for the neural models, RD stands for random initialization, TL for Transfer Learning, FR for Frozen pretrained layers (without fine-tuning) and FT for Fine-Tuning. For our deep-learning models, the results are computed by averaging 10 runs to account for the variability in training performance.

	Ave.diff. Overall	Ave.diff.	p-value
Anger	0.001	0	0.02223
Fear	-0.003	-0.003	0
Joy	0.004	0.010	0
Sadness	0.002	-0.002	0
Valence	0.005	0.005	0

Table 3: Analysis for inappropriate biases

more, regarding the affective embeddings, we can directly observe their impact by the performance gain over the NBOW baseline.

Transfer Learning. We observe that our neural models achieved better performance than all baselines by a large margin. Moreover, we can see that our transfer learning model yielded higher performance over the non-transfer model in most of the Emotion Intensity (EI) subtasks. In the Emotion multi-label classification subtask (E-c), transfer learning did not outperform the random initialization model. This can be attributed to the fact that our source dataset (SA17) was not diverse enough to boost the model performance when classifying the tweets into none, one or more of a set of 11 emotions. As for fine-tuning or freezing the pretrained layers, the overall results show that enabling the model to fine-tune always results in significant gains. This is consistent with our intuition that allowing the weights of the model to adapt to the target dataset, thus encoding task-specific information, results in performance gains. Regarding the emotion of *joy*, we observe that in EI-reg and EI-oc subtasks, LSTM-RD matches the performance of LSTM-TL-FR. We interpret this result as an indication of the semantic similarity between the source and the target task.

Mystery dataset. The submitted models were also evaluated against a mystery dataset, in order to investigate if there is statistically significant social bias in them. This is a very important experiment, especially when automated machine learning algorithms are interacting with social media content and users in the wild. The mystery dataset consists of pairs of sentences that differ only in the social context (e.g. gender or race). Submitted models are expected to predict the same affective values for both sentences in the pair. The evaluation metric is the average difference in prediction scores per class, along with the p-value score indicating if the difference is statistically significant. Results are summarized in Table 3.

4.3 Attention visualizations

Fig. 10 shows a heat-map of the attention weights on top of 8 example tweets (2 tweets per emotion). The color intensity corresponds to the weight given to each word by the self-attention mechanism and signifies the importance of this word for the final prediction. We can see that the salient words correspond to the predicted emotion (e.g. “irritated” for anger, “mourn” for sadness etc.). An interesting observation is that when emojis are present they are almost always selected as important, which indicates their function as weak annotations. Also note that the attention mechanism can hint to dependencies between words even if they far in a sentence, like the “why” and “mad” in the sadness example.

4.4 Competition Results

Our official ranking was 2/48 in subtask 1A (EI-reg), 5/39 in subtask 2A (EI-oc), 4/38 in subtask

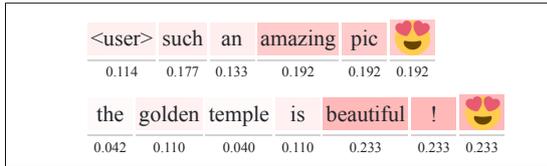

Figure 5: Examples of intensity of *joy*

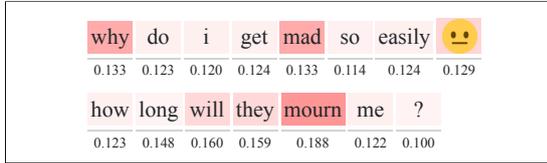

Figure 6: Examples of intensity of *sadness*

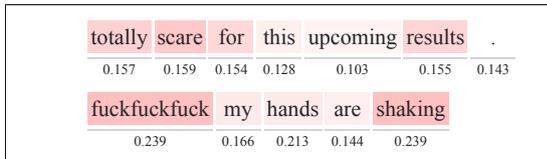

Figure 7: Examples of intensity of *fear*

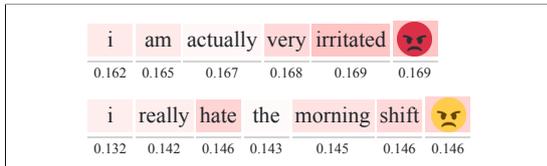

Figure 8: Examples of intensity of *anger*

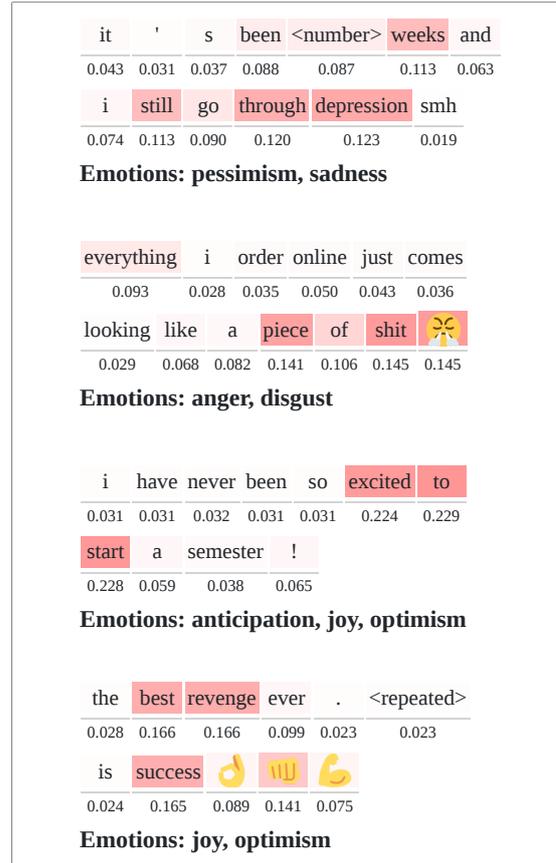

Figure 9: Examples of emotion recognition

Figure 10: Attention heat-map visualization. The color intensity of each word corresponds to its weight (importance), given by the self-attention mechanism (Section 2.6).

3A (V-reg), 8/37 (tie with 6 and 7 place) in subtask 4A (V-oc) and 1/35 in subtask 5A (E-c). All of our models achieved competitive results. We used the same transfer learning approach in all subtasks (LSTM-TL-FT), utilizing the same pre-trained model.

5 Conclusion

In this paper we present a deep-learning system for short text emotion intensity, valence estimation for both regression and classification and multi-class emotion classification. We used Bidirectional LSTMs, with a deep attention mechanism and took advantage of transfer learning in order to address the problem of limited training data.

Our models achieved excellent results in single and multi-label classification tasks, but mixed results in emotion and valence intensity tasks. Future work can follow two directions. Firstly, we aim to revisit the task with different transfer learning approaches, such as (Felbo et al., 2017; Howard and Ruder, 2018; Hashimoto et al., 2016).

Secondly, we would like to introduce character-level information in our models, based on (Wieting et al., 2016; Labeau and Allauzen, 2017), in order to overcome the problem of out-of-vocabulary (OOV) words and learn syntactic and stylistic features (Peters et al., 2018), which are highly indicative of emotions and their intensity.

Finally, we make both our pretrained word embeddings and the source code of our models available to the community³, in order to make our results easily reproducible and facilitate further experimentation in the field.

CrystalFeel at SemEval-2018 Task 1: Understanding and Detecting Emotion Intensity using Affective Lexicons

Raj Kumar Gupta and Yinping Yang*

Institute of High Performance Computing (IHPC)

Agency for Science, Technology and Research (A*STAR), Singapore

{*gupta-rk, yangyp*}@ihpc.a-star.edu.sg

Abstract

While sentiment and emotion analysis has received a considerable amount of research attention, the notion of understanding and detecting the intensity of emotions is relatively less explored. This paper describes a system developed for predicting emotion intensity in tweets. Given a Twitter message, CrystalFeel uses features derived from parts-of-speech, n-grams, word embedding, and multiple affective lexicons including Opinion Lexicon, SentiStrength, AFFIN, NRC Emotion & Hash Emotion, and our in-house developed EI Lexicons to predict the degree of the intensity associated with fear, anger, sadness, and joy in the tweet. We found that including the affective lexicons-based features allowed the system to obtain strong prediction performance, while revealing interesting emotion word-level and message-level associations. On gold test data, CrystalFeel obtained Pearson correlations of .717 on average emotion intensity and of .816 on sentiment intensity.

1 Introduction

While humans experience emotions every day, the degree of one's emotions varies from one experience to another. To date, a vast majority of NLP and computational linguistics research deals with ground truth data constructed through the assignment of discrete labels to text messages by annotators. Conventionally, sentiment analysis seeks to determine the valence (positive, negative or neutral) of the feelings and opinions that annotators can recognize in a text message (Hu and Liu, 2004; Pang and Lee, 2008; Socher et al., 2013). Emotion classification, a closely related task, typically seeks to predict the presence or absence of an emotion, i.e., if there is joy or no joy, anger or no

anger, fear or no fear, in a particular message (Alm et al., 2005; Aman and Szpakowicz, 2007; Wen and Wan, 2014). The detection of emotion intensity along a continuous scale is a relatively less explored task.

One of the key reasons for the lack of work on detecting emotion intensity is plausibly attributable to the difficulty in measuring the very concept of emotion intensity. As highlighted in prior research, the question “how intense was your emotional experience on a scale of 1 to 10?” cannot generate reliable responses even for the same emotion type (Frijda et al., 1992). For example, asking people to respond to “how intense was your fear towards getting rejected” and “how intense was your fear towards receiving a medical test result” would lead to inconsistent answers across the same annotators at different times, as well as across different annotators. Because of the lack of a clear reference point, it is nearly impossible to construct ground truth datasets with adequate reliability.

To address the measurement issue, Mohammad and Bravo-Marquez (2017) used a best-worst scaling (BWS) method to create a tweet emotion intensity dataset. Annotators were asked to rank the best and worst examples of the intensity of emotions among n text examples (called n -tube, where $n > 2$ and typically $n = 4$). This reduces the reference point ambiguity issue faced by annotators with regards to which baseline they would have used to rate a text along a single scale. Upon having a target tweet annotated with 24 ranking judgements, the emotion intensity score for the tweet was computed as a real-valued score in the range of 0 to 1 (based on linear transformed value of the difference between the percentage of the number of times the tweet ranked the highest and the times ranked the lowest among all ranking judgements). In total, the dataset consists of 7,097 an-

	Emotion intensity score in range of [0, 0.5]	Emotion intensity score in range of (0.5, 1.0]
Anger	No words Sir... Thank you for the concern.. [0.197]	Everything I order online just comes looking like a piece of shit [0.864]
Fear	They are building a shell command on a server, combining that with user input, and then executing that in a shell on the client. #shudder [0.482]	Let's hope the ct scan gives us some answers on this lump today #nervous [0.818]
Joy	'You're here to feed me. I won't die of starvation,' he said, slightly smiling. I frowned. Panira. Kainis. [0.177]	Omgsh Alexis is sooooo freaking funny on #BachelorInParadise That pizza segment! Plus I love her and Jazzy's friendship! [0.813]
Sadness	I will not fall to the dark side [0.208]	That moment when you look back and realise you've been a #selfish #horrible #judgemental person. #FeelingAshamed [0.909]

Table 1: Examples of tweets with their emotion intensity scores from the task dataset.

notated tweets across four emotions of anger, fear, joy and sadness, which formed the training dataset for the present SemEval-2018 Task 1 dataset (Mohammad et al., 2018). Table 1 provides a few examples from the dataset.

The ability to detect the degree or intensity of emotions is beneficial to many AI applications. For example, a virtual service assistant would be able to employ more appropriate response strategy when a high-intensity anger or frustration is sensed from its customer, as compared to respond monotonically in normal dialogues. Customer relationship management systems can be more targeted by engaging customers who express high degrees of joy or excitement with their products and services. Homecare robots, empowered with the ability to recognize high-intensity grief or distress, would be less likely to miss the opportunity to alert professional human care givers.

In this paper, we discuss our approach to address this emotion intensity detection task, with a focus on the use of and experiments with affective lexicons. In the following sections, we introduce our in-house developed Emotion Intensity lexicons, and compare the performance of feature sets derived from various affective lexicons as well as parts-of-speech, n-grams and word embedding with SVM-based classifier.

2 Emotion Intensity and Affective Lexicons

In its simplest form, emotion intensity refers to the degree or amount of an emotion (Mohammad and Bravo-Marquez, 2017). A basic feature of emotion intensity would be the use of quantifier words. For example, one may indicate that he or she is a *bit* annoyed, *very* pissed off, or *extremely* angry. On the other hand, one may also say that he or she feels *angry*, *livid*, or *furious*. Without quantifier

words, emotion words in itself are salient features indicating the intensity of emotions.

In 2016, we started in-house efforts to develop a multidimensional affective lexicon that computationally captures and distinguishes different psychological and linguistic meanings associated with each emotion-related word. Our initial version of Emotion Intensity (EI) Lexicon is a collection of 3,204 emotion-related English words, common emoticons and Internet slangs labelled in strength and intensity dimensions (as used in Gupta and Yang 2017). In the beginning, the rationale underlying our work centered on the fact that human emotions can be characterized using two fundamental dimensions: the dimension of evaluation *strength* in that an expression would have different levels of pleasantness or unpleasantness (Osgood et al., 1957), and the dimension of *intensity* (Shaver et al., 1987) which concerns about—and what Osgood et al. (1957) originally called as—motivational “potency” and physical “activity”¹. By developing a lexicon that distinguishes strength and intensity, anger-based expressions (high in potency), for example, can be differentiated from equally unpleasant, sadness-based expressions (low in potency).

In EI, each lexicon item is coded with strength and intensity scores in the range of [-3, -2, -1, 0, 1, 2, 3]. For example, items such as “excited”, “astonished” and “thrill” are coded as “3” (high-intensity, positive); items such as “thank”, “cooperative”, “concern”, “:)” and “:d” are coded as “1” (low-intensity, positive); items such as “sorry”, “agh” and “:/” are coded as “-2” (medium-intensity, negative); items such as “hate”, “resented”, “D:” are coded as “-3” (high-intensity, negative); words such as “great”, “haze”,

¹For illustration, the feeling of depression is very negative in evaluation strength, but it may not be highly intense.

“fulfill”, “sick” and “sleepy” are coded as “0” as they are related to emotions by reflecting external, bodily, physical or cognitive conditions, but are not “genuine” emotions (Ortony et al., 1987; Clore et al., 1987).

In Gupta and Yang (2017), we explored the use of the Emotion Intensity (EI) Lexicon and found it helpful in enhancing sarcasm detection and sentiment analysis. Encouraged by its effectiveness, we continue to develop and use the lexicon by adding more psychologically meaningful affective dimensions. We consider three more dimensions: the “basic” emotion categories (Shaver et al., 1987; Ekman, 1973) including fear, anger, sadness, joy, love and surprise, *fine-grained emotion categories* (as summarized in Robinson 2009) including finer emotions such as joy-contentment, joy-cheerfulness, joy-excitement, and *psychological conditions* including affective condition, cognitive condition, physical & bodily state and external condition (Clore et al., 1987). In addition, we also add a *levels of polarity* dimension to reflect if a word is more uni-polarized (e.g., “angry” and “careless” are *definitely* negative) or more bi-polarized (e.g., “surprised” and “sympathetic” may imply both positive and negative feelings). These new considerations contribute to forming the Enhanced Emotion Intensity (E2I) Lexicon. The following table (Table 2) presents the properties of our lexicon in the context of five affective lexicons which were shown to be useful in prior sentiment and emotion analysis research.

3 CrystalFeel System

Focusing on features design and experiments, we employed SVM as the main classifier for the CrystalFeel system. In terms of features, we considered two broad categories: affective lexicon based features, and non-affective lexicon based features.

⁸The construction of the full Enhanced Emotion Intensity Lexicon is under development of a research manuscript. The lexicon will be released to the research community.

3.1 Affective Lexicons-Based Feature Sets

Following the discussion in Section 2, seven sets of affective lexicons based features were extracted for the experiments:

- OL (6 features): counts of positive (+ive) & negative (−ive) words (2 features), order of +ive & −ive words (1 feature), count of both +ive & −ive words (1 feature), start positions of first occurrence of +ive & −ive words (2 features)
- SS (16 features): counts of +ive & −ive words (2), order of +ive & −ive words (1), count of both +ive & −ive words (1), start positions of first occurrence of +ive & −ive words (2), count of words of different strengths of -5 to 4 (10)
- AFFIN (17 features): counts of +ive & −ive words (2), order of +ive & −ive words (1), count of both +ive & −ive words (1), start positions of first occurrence of +ive & −ive words (2), count of words of different strengths of -5 to 5 (11)
- NRC-EmoLex (14 features): counts of +ive & −ive words (2), order of +ive & −ive words (1), count of both +ive & −ive words (1), start positions of first occurrence of +ive & −ive words (2), count of words belonging to 8 emotions (8)
- NRC-Hash-Emo (14 features): counts of +ive & −ive words (2), order of +ive & −ive words (1), count of both +ive & −ive words (1), start positions of first occurrence of +ive & −ive words (2), total intensity of words belonging to 8 emotions (8)
- EI (24 features): counts of +ive & −ive words (2), order of +ive & −ive words (1), count of both +ive & −ive words (1), start positions of first occurrence of +ive & negative words (2), counts of words holding three strengths of 1 to 3 (3), count of words holding three intensities of 1 to 3 (3), counts of positive & negative words holding three strengths of 1 to 3 (6), counts of positive & negative words holding three intensities of 1 to 3 (6)
- E2I (115 features, including 24 EI features): counts of +ive & −ive words (2), order of +ive & −ive words (1), count of both +ive

		Lexicon Size	Lexical/Words Coverage	Affective Dimension Size	Affective Dimension Coverage	Construction Method
1.	Opinion Lexicon (OL) ² (Hu and Liu, 2004)	6,789	standard English, informal English	1	sentiment/valence	Automatic
2.	AFINN ³ (Nielsen, 2011)	2,477	standard English, informal English	2	sentiment/valence, strength	Manual (Expert Annotation)
3.	SentiStrength (SS) ⁴ (Thelwall et al., 2012)	2,503	standard English, informal English, emoticons, idioms	2	sentiment/valence, strength	Manual (Expert Annotation)
4.	NRC Word-Emotion Association Lexicon (NRC-Emo-Lex) ⁵ (Mohammad and Turney, 2010, 2013)	14,182	standard English	2	sentiment/valence, emotion category (8 emotions)	Manual (Crowd-sourced Annotation)
5.	NRC Hashtag Emotion Association Lexicon (NRC-Hash-Emo) ⁶ (Mohammad, 2012; Mohammad and Kiritchenko, 2015)	16,862	informal English	2	emotion category (8 emotions), association (real-valued numeric score)	Automatic
6.	Emotion Intensity (EI) Lexicon ⁷ (Gupta and Yang, 2017)	3,204	standard English, informal English, emoticons	3	sentiment/valence, strength, intensity	Manual (Expert Annotation)
7.	Enhanced Emotion Intensity (E2I) Lexicon ⁸	3,446	standard English, informal English, emoticons, idioms	7	sentiment/valence, strength, intensity, emotion category (6 basic emotions), fine-grained emotion category (31 fine emotions), psychological condition (4 conditions), polarity condition (4 conditions)	Manual (Expert Annotation)

Table 2: Affective lexicons used in our emotion intensity analysis experiments.

& -ive words (1), start positions of first occurrence of +ive & -ive words (2), counts of words holding three strengths of 1 to 3 (3), count of words holding three intensities of 1 to 3 (3), counts of words belonging to 6 emotions and unspecific words (7), counts of words belonging to 31 emotions and unspecific words (32), counts of words belonging to 4 psychological conditions (4), counts of words belonging to 4 polarity conditions (4), pairwise intersection features across all the dimensions (56)

3.2 N-grams, POS, Word Counts, and Word Embedding Feature Sets

In addition to affective lexicons, we extracted 25-dimensional Tweet part-of-speech (POS) features (Owoputi et al., 2013) for each tweet. Furthermore, as emotion intensity is likely to be associated with the total tweet length and use of capital letters, we added the word counts (WC) features set including counting of total words and counting of uppercase letters. We extracted n-

grams in the same way as in our earlier work (Gupta and Yang, 2017). Lastly, we used FastText (Joulin et al., 2016) to convert the tweets into a 100-dimensional feature vectors. To train FastText model, we downloaded close to 8 million tweets using Twitter Streaming API. In summary:

- POS (25 features): Counts of proper nouns, verbs, conjunctions, adjectives, hashtags, emoticons, urls, punctuations etc. computed using TweetPOS tagger
- WC (2 features): Counts of uppercase letters, text length
- N-grams (12,650 features): uni-grams & bi-grams
- Word Embedding (100 features): word embedding features computed using FastText

3.3 Feature Experiments

Based on the setup, we use the official SemEval-2018 Task 1 training and development datasets to

	Pearson correlations (r)				
	Anger	Fear	Joy	Sadness	Avg.
Individual Affective Lexicons Feature Sets					
OL	0.364	0.426	0.538	0.383	0.428

Word Embedding	0.611	0.557	0.585	0.580	0.583
All Features Sets					
All Features	0.702	0.689	0.666	0.689	0.686

Table 3: Results of feature experiments trained and tested on SemEval-2018 training and development data (highest results in each features sets group are bolded).

train and test the performance of various individual and combined feature conditions. The results are presented in Table 3.

Among individual lexicon based feature sets, features derived from E2I alone led to highest macro-averaged Pearson correlations ($r = 0.456$). (Note that r ranges from -1 to 1 where -1 means perfect reverse correlation and 1 means perfect correlation; a random algorithm gives close to 0 .) The performances of NRC-Hash-Emo and OL came closely as second ($r = 0.445$) and third ($r = 0.428$). Interestingly, on specific emotions, E2I’s advantage ($r = 0.531$) on the prediction of sadness is significantly greater than the second highest prediction of sadness from AFFIN derived features ($r = 0.440$). NRC-Hash-Emo led to highest results for anger ($r = 0.453$) and fear ($r = 0.492$), and OL features led to the highest value for joy ($r = 0.538$).

For the combined affective lexicon features settings, we observed that there was a tendency for each feature set to result in additional advantage (e.g., combining OL + SS features with OL or SS features alone) on the macro-averaged scores, suggesting the complementarity across these lexicons. Combining all the lexicons resulted in a large improvement (avg. $r = 0.605$).

Among non-affective lexicons based features sets, word embedding features obtained the best result ($r = 0.583$). Except for predicting fear,

in which n-grams performed better ($r = 0.608$), word embedding’s advantage also held for predicting anger ($r = 0.611$), joy ($r = 0.585$) and sadness ($r = 0.580$).

Finally, we combined all the lexicon-based features (with small variations⁹ from the individual experiment conditions) and non-lexicon based features. This “all-features” condition resulted in the highest performance for avg. Pearson correlation ($r = 0.684$) and individual correlations for all four emotions. The all-features setting was used for the CrystalFeel system for gold test data.

3.4 Word-level and Message-level Analysis

So to what extent are emotion words from affective lexicons indicative of emotion intensity in tweets at the message level? To explore this question, we ran correlation analysis by calculating bivariate Pearson correlation coefficients between each feature derived from the affective lexicons and the emotion intensity ground truth labels. Figure 1 shows the results.

The analysis indicated several interesting patterns related to the usefulness of lexicon dimensions. First, the sentiment/valence dimension of affective lexicons were generally useful, as the counts of +ive and -ive words (regardless the source of the lexicons) showed up in top ten fea-

⁹The variations are not including two features of start positions of first occurrence of +ive & -ive words (2) for NRC-EmoLex and NRC-Hash-Emo.

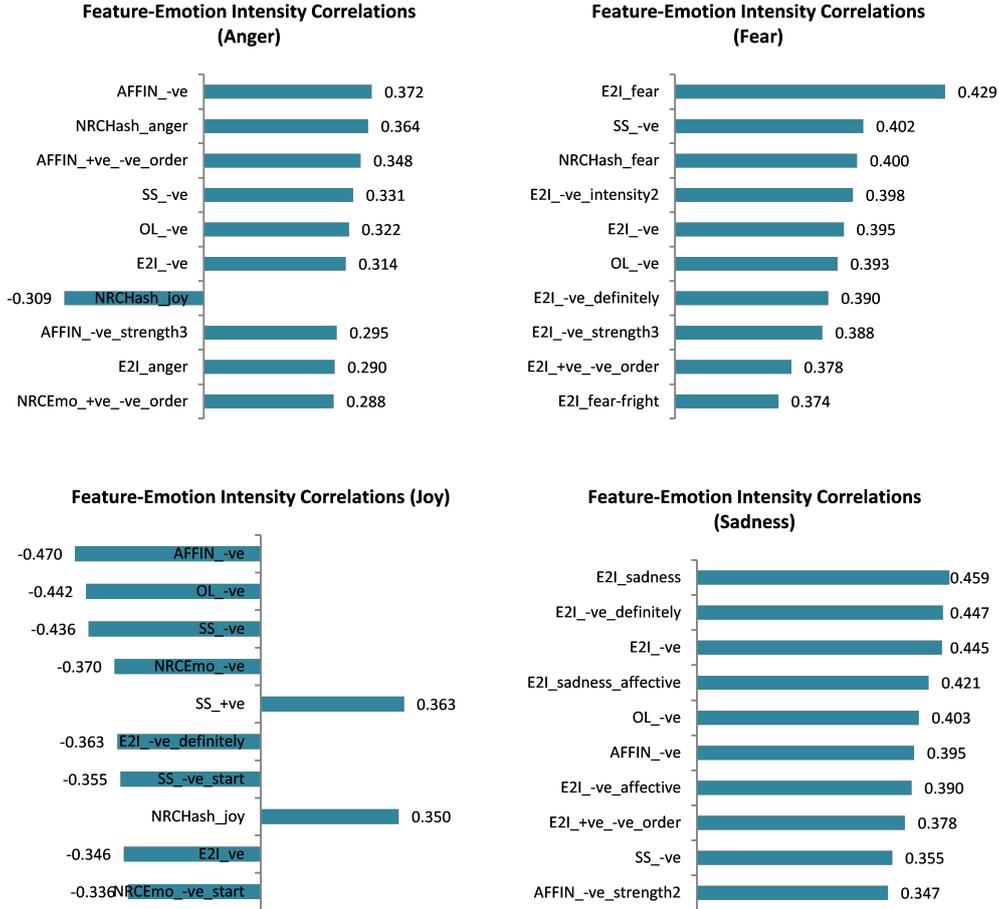

Figure 1: Top ten features with highest bivariate feature-emotion intensity correlations across the four emotion datasets.

	Pearson correlations (r)				
	Anger	Fear	Joy	Sadness	Avg.
Random_Baseline	-0.008	-0.018	-0.058	0.024	-0.008
SVM_Unigrams_Baseline	0.520	0.526	0.575	0.525	0.520
CrystalFeel	0.740	0.700	0.708	0.720	0.717

Table 4: Evaluation Results on subtask 1 emotion intensity regression (EI-reg).

	Pearson correlations (r)				
	Anger	Fear	Joy	Sadness	Avg.
Random_Baseline	-0.008	-0.018	0.024	-0.058	-0.008
SVM_Unigrams_Baseline	0.520	0.526	0.525	0.575	0.520
CrystalFeel	0.576	0.466	0.540	0.538	0.530

Table 5: Evaluation Results on subtask 2 emotion intensity ordinal classification (EI-oc).

tures for all four emotions. Second, features derived from the advanced dimensions of the affective lexicons appeared across the emotions too, suggesting the meaningfulness of lexicons distinguishing finer dimensions of psycholinguistic properties of words. Specifically, for example, on strength dimension, count of negative words with strength 3 from AFFIN lexicon (AFFIN_ive_strength3) is positively correlated with anger intensity in tweets ($r = 0.295$). On emotion

category dimension, counts of anger words from NRC-Hash-Emo (NRCHash_anger) and from E2I (E2I_anger) are positively associated with anger intensity in tweets. Third, more fine-grained dimensions from E2I are shown as top individual features correlated with anger and sadness intensities and in particular with sadness intensity. For example, count of fear-fright words from E2I (E2I_fear-fright) is highly correlated with fear intensity ($r = 0.374$) and count of sadness words

as genuine emotions (E2I_sadness_affective) is highly correlated with sadness intensity ($r = 0.421$).

Furthermore, the results revealed interesting word-level and message-level feature associations across the four emotions. While the top features for intensities of anger, fear and sadness in tweets (9 or 10 out of 10 top features) are *positive* associations with the presence and higher amount of negative or emotion-specific words, the top features for intensity of joy (7 out of 10 top features) are *negative* associations with the absence and lower amount of negative words. It deserves future research to further investigate these patterns and to cross examine these patterns in other datasets.

CrystalFeel	0.468	0.601	0.522

Table 8: Evaluation Results on subtask 5 multi-label emotion classification (E-c).

4 Results

We evaluated the CrystalFeel system using gold test datasets provided by SemEval-2018 Task 1 (Mohammad et al., 2018). Besides testing the main task of emotion intensity, since it is our primary interest, we have also participated in all other subtasks. In all subtasks, CrystalFeel system outperformed the baseline set by the task organizer. Tables 4-8 summarize the final results.

5 Conclusion

This paper describes CrystalFeel system which is capable of predicting the intensity of emotions associated with a Twitter message. The results of the feature experiments supported the usefulness of our in-house developed EI & E2I lexicons as a new manually constructed lexicon on a relatively small number of lexicon items. In addition, the lexicon also aided us to understand the different patterns of associations between emotion-specific words and emotion-specific intensities at the tweets/messages level. Based on the current analysis, it appeared that our approach possesses a special advantage in understanding and predicting sadness-specific intensity present in tweets. For the use of classifiers, we focused on using SVM as our machine learning classifier in the present study. We plan to investigate the use of deep learning methods in future work.

Abstract

This paper describes our system that has been submitted to SemEval-2018 Task 1: Affect in Tweets (AIT) to solve five subtasks. We focus on modeling both sentence and word level representations of emotion inside texts through large distantly labeled corpora with emojis and hashtags. We transfer the emotional knowledge by exploiting neural network models as feature extractors and use these representations for traditional machine learning models such as support vector regression (SVR) and logistic regression to solve the competition tasks. Our system is placed among the Top3 for all subtasks we participated.

1 Introduction

Finding a good representation of texts is very challenging since texts are sequences of words which are represented in a discrete space of the vocabulary. For this reason, many past works have investigated in finding the mapping of words (Mikolov et al., 2013; Pennington et al., 2014) or sentences (Kiros et al., 2015) to continuous spaces, so that each text can be represented by a fixed-size, real-valued N-dimensional vector. This vector representation then can be applied to machine learning models to solve problems like classification and regression. A good representation should contain essential information inside each text and be a useful input for statistical models.

Emotions in texts further deepen the complexity of modeling natural language since they not only depend on the semantics of a language but also are inherently subjective and ambiguous. Despite the difficulty, accounting for emotion is important in achieving true natural language understanding, especially in areas involving human-computer interactions such as dialogue systems (Fung, 2015).

Humans can naturally capture and express different emotions in texts, so machines should also

be able to infer them. Many works (Tang et al., 2014; Felbo et al., 2017; Thelwall, 2017) explored modeling sentiment or emotion in texts in various directions. This work is highly related to these efforts.

Semeval-2018 Task 1: Affect in Tweets (AIT-2018) encourages more efforts in this area with the task of sentiment analysis, which is one of the most practical applications of modeling emotional text representations. We have participated in five subtasks regarding English tweets: emotion intensity regression, emotion intensity ordinal classification, valence (sentiment) regression, valence ordinal classification, and emotion classification (More details on the tasks in Mohammad et al. (2018)).

Although these five tasks take different formats, the most important objective is finding a good representation of the tweets regarding emotions. However, the given competition training datasets are too small to achieve our goal (Table 3). Therefore, we explore utilizing larger datasets that are distantly supervised by emojis and hashtags to learn a robust representation and transfer the knowledge of each dataset to the competition datasets to solve the tasks. We aim to minimize the use of lexicons and linguistic features by replacing them with continuous vector representations.

2 Emoji sentence representations

Thanks to the endless stream of social media such as Twitter and Facebook, researchers nowadays are lucky enough to have access to almost an unlimited number of texts generated every day. Nevertheless, annotating these texts with explicit emotion or sentiment human labels is very expensive and difficult. For this reason, many works naturally focused on finding direct or indirect evidence of emotion inside each text, such as hash-

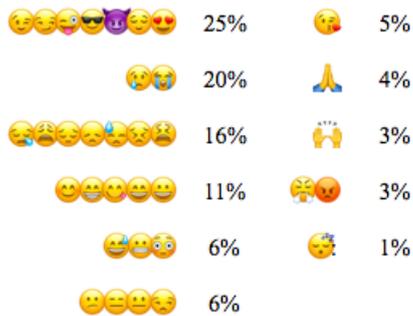

Figure 1: 11 clusters of emojis used as categorical labels and their distributions in the training set. Because some emojis appear much less frequently than others, we group the 34 emojis into 11 clusters according to the distance on the correlation matrix of the hierarchical clustering from Felbo et al. (2017) and use them as categorical labels

tags and emoticons (Suttles and Ide, 2013; Wang et al., 2012), and found them useful to distantly label an emotion of each text. Furthermore, the recent popular culture of using emojis (Wood and Ruder, 2016) inside social media posts and messages provides us even richer evidence of different emotions, and they have been proven to be very effective in learning rich representations for various affect-related tasks (Felbo et al., 2017).

2.1 Methodology & Emoji Dataset

In this paper, we compare two models using two different emoji dataset to transform the competition data into robust sentence representations.

First model is the pre-trained DeepMoji model (Felbo et al., 2017), which is trained through emoji predictions on a dataset of 1.2 billion tweets with 64 common emoji labels. We use the pretrained deep learning network, which consists of Bidirectional Long Short Term Memory (Bi-LSTM) with attention, except the last softmax layer, as a feature extractor of the original competition datasets. As a result, each sample is transformed into a 2304-dimensional vector from the model.

The second model is our proposed emoji cluster model. We crawled 8.1 million tweets with each of which has 34 different facial and hand emojis, assuming these kinds of emojis are more relevant to emotions. Since some emojis appear much less frequently than others, we cluster the 34 emojis into 11 clusters (Figure 1) according to the distance on the correlation matrix of the hierarchical clustering from Felbo et al. (2017). Sam-

ples with emojis in the same cluster are assigned the same categorical label for prediction. Samples with multiple emojis are duplicated in the training set, whereas in the dev and test set we only use samples with one emoji to avoid confusion. We then train a one-layer Bi-LSTM classifier with 512 hidden units to predict the emoji cluster of each sample. We take part of the dataset to construct a balanced dev set with 15,000 samples per class (total 165,000) for hyperparameter tuning and early stopping. We use 200 dimension Glove vectors pre-trained on a much larger Twitter corpus to initialize the embedding layer.

The motivation for exploring two different models is that, firstly, we want to replicate the effectiveness of using emoji for representing emotions from the previous work (Felbo et al., 2017) with a smaller dataset and a simpler model. Note that the dataset size of the emoji cluster model is less than 1% of that of the first model, whereas DeepMoji uses more than 1 billion training samples. Moreover, the first model implements a two-layer Bi-LSTM with self-attention, which has much more parameters than the second model’s simple one-layer Bi-LSTM does. Secondly, we want to verify that ensembling both emoji representations trained from different datasets to boost our performance. We will present the result of the comparisons and the ensembles in Section 5.2.

One thing i dislike is ladders man
I hate inconsistency The paper is irritating me As of right now i hate dre
im sick of crying im tired of trying
why body pain why uuugh i really have nothing to do right now i dont wanna go back to mex
looking forward to holiday
well today am on lake garda enjoying the life perfect time to read book im feeling great enjoying my holiday

Table 1: Test samples from the Emoji Cluster model and their top-3 nearest sentences according to the learned representations. It shows that emotionally similar sentences are clustered together

2.2 Evaluation

As a result, the model can achieve 29.8% top-1 accuracy and 61.0% top-3 accuracy on the emoji cluster prediction task. Since the objective of this model is not to predict the cluster label but to find a good sentence representation, we visual-

ize the test set samples to discover that samples with similar semantics and emotions are grouped together (Table 1). Finally, similar to the first model, we use this model as a feature extractor on the competition datasets. Each text sample in the competition datasets is transformed into a 512-dimensional vector through the model except the last class predicting softmax layer.

In conclusion, we trained two deep learning models with two different emoji datasets to extract emoji representations of the competition datasets. They are transformed into high dimensional, real-valued, and continuous vectors, which can be used as features for the classification and regression tasks.

From now on, we will call the vectors from the first model, *DeepMoji representations*, and those from the second, *Emoji Cluster representations*.

3 Emotional word vectors (EVEC)

We also explore word-level representations, along with emoji sentence representations. Although sentence-level representations already build up from word representations (in particular we use pretrained Glove vectors (Pennington et al., 2014)), they may not be enough to attend to the valence that each word contains. Previous works (Tang et al., 2014) examine the significance of using sentiment-specific word embedding for related tasks. For this reason, we train emotional word vectors that not only cluster together direct emotion words such as anger and joy, but also capture emotions inside indirect emotion words, such as anger inside headache and joy inside beach. We learn these vectors by training a Convolutional Neural Network (CNN) from another separate Twitter corpus distantly labeled with hashtags.

3.1 Methodology

Our intuition to learn effective emotion word vectors is that given a document labeled with emotion there exists one or more emotionally significant words inside. Nevertheless, we do not know which ones are more important. We assume that a deep learning model, which learns the representations of the data with different level of abstractions (LeCun et al., 2015) will be able to capture those words and encode the information in its word embedding layer while classifying the documents label.

For the model structure, we use CNN since it

is proven to be effective in text classification tasks by looking at the documents n-gram features and its gradient can be directly back-propagated to the word embedding, whereas Recurrent Neural Network (RNN) models are updated sequentially. We use a similar structure used by (Kim, 2014), which includes a max-pooling layer to force the network to find the most relevant feature for predicting the emotion class correctly.

After the CNN network learns how to classify the documents into different emotion categories, we extract emotional word vectors from the network's embedding layer and use them as same as how other word embeddings, such as word2vec (Mikolov et al., 2013) or Glove, are used, treating them as features for other classification or regression models.

3.2 Hashtag Dataset

To accumulate a large corpus of emotion-labeled texts, we use a distant supervision method by using hashtags of tweets to automatically annotate emotions. Such method has proven to provide relevant emotion labels by previous works (Wang et al., 2012). Their source of the emotion words came from emotion words list made from Shaver et al. (1987), where the authors organize emotions into a hierarchy in which the first layer contains six basic emotions and each emotion has a list of emotion words. Wang et al. (2012) again expanded the list by including their lexical variants and also introduced some filtering heuristics, such as only using tweets with emotional hashtags at the end of tweets to make the distant supervision more relevant to human annotation. We combine their dataset, another public dataset ¹, which used the same method, and our own extracted tweets between January and October 2017 using the Twitter Firehose API.

For the emotion labels, we focus on four emotion categories: joy, sadness, anger, and fear, since the competition tasks are only limited to those categories. In total, our hashtag dataset consists of 1.9 million tweets (Table 2).

3.3 Evaluation

For every sample in the SemEval competition dataset, we extract all emotional word vectors of the words in the sentence and simply average them

¹<http://hci.epfl.ch/sharing-emotion-lexicons-and-data#emo-hash-data>

Emotion Label	%	Samples
Joy	36.5%	It's been such a great week #happy
Sadness	33.8%	I think I miss my boyfriend #lonely
Anger	23.5%	Ignoring me isn't going to make our problems go away. #annoyed
Fear	6%	What to wear for this job orientation.. #nervous

Table 2: Description of the Twitter hashtag corpus. Hashtags at the end were removed from the document and used as labels. It is hard to construct a well-balanced dataset for all four classes since Twitter users tend to use more hashtags related to happy and sad emotions.

into one vector. For words out of vocabulary of the hashtag corpus, we add zero vectors with the same dimension. As a result, every sentence is transformed into a 300-dimension vector to be used as features for the competition tasks. We expect these emotional word vectors can replace sentiment or emotion lexicons, since they are continuous representations learned from a large corpus, which can be more robust and rich in information about emotions inside words.

4 System Description

4.1 Features

These are the three features that are used as input for our system to solve SemEval-2018 Task 1.

Emoji Sentence Representations: Two models will be compared - *DeepMoji representations* (2304 dimensions) and *Emoji cluster representations* (512 dimensions). See Section 2.

Emotional Word Vectors (EVEC): Average of emotional word vectors learned from hashtag corpus (300 dimensions). See Section 3.

Tweet-specific features: We employ Tweet-specific features to capture information that two previous representations cannot. Inspired from the previous SemEval papers (Zhou et al., 2016; Balikas and Amini, 2016), we choose five features, (1) number of words in uppercase, (2) number of positive and negative emoticons, (3) Sum of emoji valence score ², (4) number of elongated words, and (5) number of exclamation & question marks. Note that we do not use any linguistic features or sentiment/emotion lexicons for our system.

4.2 Preprocessing

Tweets in the competition datasets are tokenized after all non-alphanumeric characters are removed, except for extracting tweet-specific features. Some words, especially for hashtags, are merged together (e.g. #iloveyou), so unknown

words in the vocabulary is put into a wordsegment library ³ to preserve the right segment (e.g. i, love, you). Then, the tokens are transformed into emoji sentence representations (2304 or 512 dimensions) and emotional word vectors (300 dimensions), according to the vocabulary of the emoji and hashtag dataset. These datasets respectively have 262,975 and 48,929 words in their vocabularies.

4.3 Regression and Ordinal Classification

Due to the fact that the datasets of regression tasks (EI-reg & V-reg) and ordinal classification tasks (EI-oc & V-oc) have the same sample sentences, we assume that regression labels are more informative than the ordinals, since they tell us the rank among the samples within the same ordinal class. Therefore, we first train a regression model and then use it to predict ordinals, rather than training a separate classifier. We later prove that this trick yields a better result in ordinal classification.

For regression, since our features are extracted from deep learning models, we find Support Vector Regression (SVR) and Kernel-Ridge Regression methods, which are effective for nonlinear features, perform better than linear methods. We tune the hyper-parameters with the given development (dev) set and later merge both train and dev set to train the final model with the best hyper-parameter found. Also, we try ensembles by averaging the final regression predictions of different methods or feature combinations to boost performance. The best groups of models are selected by the development set results of many combinations.

Another important finding is that the mapping between the regression labels and ordinal labels are very different among emotion categories. For example in Figure 2, Class 0 for fear is distributed in [0,0.6], whereas class 0 for joy is distributed in [0, 0.4]. Therefore, we try to find the mapping from the regression values (continuous) to ordinal

²<https://github.com/words/emoji-emotion>

³<http://www.grantjenks.com/docs/wordsegment/>

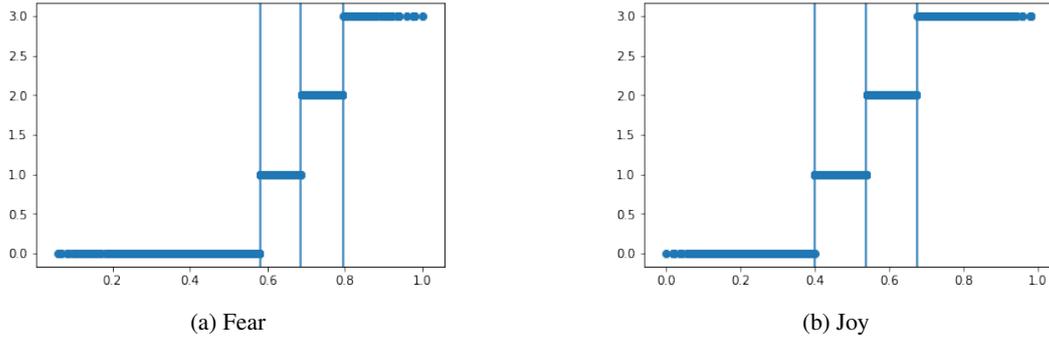

Figure 2: Distribution of regression labels (x-axis) and ordinal labels (y-axis) on the training dataset of Task 1a & 2a. Class 0 for fear is distributed in $[0,0.6]$, whereas class 0 for joy is distributed in $[0, 0.4]$. Vertical lines are boundaries between ordinal classes, which are used for scope mapping method

values (discrete) from the training dataset. We experiment with three different mapping:

1. *naive mapping*: divides $[0,1]$ into same size segments according to the number of ordinals
2. *scope mapping*: finds the boundary of each segment in the training dataset (vertical lines on Figure 2)
3. *polynomial mapping*: fits a polynomial regression function from the training data and finds the closest ordinal label.

4.4 Multi-label Classification

This task of multi-label classification is different from previous tasks in that the model needs to predict the binary label for each of the 11 classes given a tweet. The task is difficult in terms of three aspects. Firstly, some of the classes have opposite emotions (such as optimism and pessimism) but may have been labeled both as true. Secondly, it is not trivial to distinguish similar emotions such as joy, love, and optimism, which will include a lot of noise in the labels and make it hard to perform classification during training. Lastly, most of the tweets are labeled with no more than 3 categories out of 11 classes, which make the labels very sparse and imbalanced (Table 4).

We propose to train two models to tackle this problem: regularized linear regression and logistic regression classifier chain (Read et al., 2009). Both models aim to exploit labels' correlation to perform multi-label classification.

4.4.1 Regularized linear regression model

We formulate the multi-label classification problem as a linear regression with label distance as

the regularization term. We denote the features for i -th tweet as $x_i \in R^N$ where N is the number of features and the number of categories as C . Our prediction is $y'_i = W * x_i$ where $W \in R^{M*C}$ is the weight of the linear regression model. We take the following formula as loss function to minimize. The loss consists of two parts. First part aims to minimize the mean square loss between our prediction y'_i and ground truth label y_i . The second part is the regularization term to capture relationship among different emotion labels. To model the correlations among emotions, we implicitly treat each emotion category as a vertice in an undirected graph g and use Laplacian matrix of g for regularization (Grone et al., 1990; Shahid et al., 2016).

$$loss = \frac{1}{M} \sum_i^M (y' - y)^2 + \lambda y_i'^T L y_i'$$

$$L = D - A$$

where M is the number of samples, $L \in R^{C*C}$ is the Laplacian matrix, $A \in R^{C*C}$ is the Euclidean matrix, $D \in R^{C*C}$ is the Degree matrix. To derive L , we first compute the co-occurrence matrix $O \in R^{C*C}$ among the emotion labels and take each row/column $O_i \in R^C$ as the representation of each emotion. Then we compute the distance matrix A by taking the Euclidean distance of different labels. That is $A_{ij} = (O_i - O_j)^2$. Here, A can be regarded as the adjacency matrix of the graph g . Afterwards, we calculate the degree matrix D by summing up each row/column and making it a diagonal matrix.

Subtasks	1a&2a	3a&4a	5a
Train	7,102	1,181	6,838
Dev	1,464	449	886
Test	4,068	937	3,259

Table 3: Statistics of the competition dataset for all 5 subtasks

# of labels	0	1	2	3	4	5	6
%	2.9	14.3	40.6	30.9	9.6	1.4	0.2

Table 4: Number of multi-labels. Most samples have from 1-3 labels, but can have no labels or up to 6 labels. (subtask 5a)

4.4.2 Logistic regression classifier chain

Classifier chain is another method to capture the correlation of emotion labels. It treats the multi-label problem as a sequence of binary classification problem while taking the prediction of the previous classifier as extra input. For example, when training the i -th emotion category, we take both the features of input tweet and also the 1st, 2nd, \dots , $(i-1)$ -th prediction as the input of our logistic regression classifier to predict the i -th emotion label of input tweet. We further ensemble 10 logistic regression chains by shuffling the sequence of 11 emotion labels to achieve better generalization ability.

5 Experiments & Results

Most of our system experiments were implemented by using PyTorch (Paszke et al., 2017) and Scikit-learn (Pedregosa et al., 2011).

5.1 Competition dataset

SemEval-2018 Affect in Tweets (AIT) is created by human annotators through crowd-sourcing methods (Mohammad and Kiritchenko, 2018). Total three datasets are given: emotion intensity (with four emotion categories; Subtask 1a & 2a), sentiment intensity (subtask 3a & 4a), and multi-label emotion classification (subtask 5a).

For emotion and sentiment intensity datasets, each tweet sample has both an *ordinal label* (coarse; $\{0,1,2,3\}$ for emotion, $\{-3,-2,-1,0,1,2,3\}$ for sentiment) and real-value *regression label* (fine-grained; $[0,1]$). For multi-label emotion classification dataset, each can have none or up to six number of multi-labels (Table 4).

We used the given development set to tune the hyper-parameters and select models. For the fi-

nal submission, we merged the train & development set together to retrain the model with the best hyper-parameter found (Table 3).

5.2 Regression: Subtask 1a & 3a

Table 5 shows the test set results on regression tasks, Subtask 1a&3a. We experimented with different features that we introduced before to analyze the effectiveness of each representation. For emoji sentence representations, *emoji cluster* worked better on sadness and sentiment, whereas *DeepMoji* outperformed in anger, fear, and joy. We presumed such difference was due to the different emoji types of the two datasets used to train each model. *Emoji cluster* only used 11 classes of emojis that were clustered together, but *DeepMoji* used 64 emoji classes. It may be possible clustering of emoji classes made it easy for regression models to predict the intensities in certain emotion categories, whereas some emotion categories needed more detailed representations.

The emotional word vectors overall did help enhance the performance of the regression model for all emotion categories. This shows that emotional word vectors can serve as additional word-level information which are helpful for solving this task.

Tweet-specific features boosted the performance, notably for sentiment, since features like capital letters, emojis, elongated words, and the number of exclamation marks, could help to figure out the subtle difference of the emotion intensities.

One thing to note is that our system’s rank in the fear category (7th) is relatively lower than other emotion categories. We found out from the previous literature (Wood and Ruder, 2016) that fear emojis were the most ambiguous, having the least correlation with human-annotated emotion labels among the six emotion categories. On the other hand, joy emojis were the most highly correlated. This may explain our best performance in the joy category and worst performance in the fear category. Future systems using emojis as a dataset may need to take this shortcoming into account.

5.3 Ordinal Classification: Subtask 2a& 4a

As mentioned in Sec 4.3, we used our best regression model to also predict ordinal labels. Since each emotion category has a different distribution of regression labels and ordinal labels, we experimented three different mappings, *naive mapping*, *scope mapping*, and *polynomial mapping*. Using

Features	Regression Method	Pearson correlation (all instances)				
		1a (EI-reg)				3a (V-reg)
		Anger	Fear	Joy	Sadness	Valence
Emoji Cluster	SVR	.733	.632	.679	.693	.811
Emoji Cluster	KernelRidge	.735	.638	.675	.692	.809

DeepMoji + EVEC + feat.	KernelRidge	.790	.716	.734	.739	.826
Best Ensemble		<u>.811(2)</u>	<u>.728(7)</u>	<u>.773(2)</u>	<u>.753(5)</u>	<u>.860(3)</u>

Table 5: Test set results on Subtask 1a & 3a. For 1a, separate regression models were trained for each emotion category. The number next to the best result (bold & underlined) indicates our ranking of the competition. Underlined ones show the models that were selected for ensemble according to the dev set.

Task		Pearson (all instances)		
		Naive	Scope	Poly
2a (EI-oc)	Anger	.654	.664	.704(2)
	Fear	.498	.562	.570(*)
	Joy	.632	.720(1)	.712
	Sadness	.645	.697(*)	.692
4a (V-oc)	Valence	.813	.816	.833(2)

Table 6: Test set results on Subtask 2a & 4a. The predictions of the best regression models are mapped into ordinal predictions. The number next to the best result (bold & underlined) indicates our ranking of the competition. (*) indicates better results that we acquired after our final submission

the training set, we found the ideal mapping function to match the regression predictions and the ordinal predictions.

Test set results (Table 6) on ordinal classification show that our mapping methods are indeed much more effective. For anger, fear, and sentiment categories, polynomial mapping performed the best, whereas scope mapping outperformed for joy and sadness categories. With our method, we achieved higher ranks in ordinal classification tasks (2a & 4a), placed both in 2nd. Figure 3 shows how a cubic function is fitted to find the mapping between regression labels and ordinal labels.

Additionally, we report some results better than the final submission. The change is due to a new model selection strategy. For the final submission, we searched for the optimal pair of regression model & mapping method by looking at the

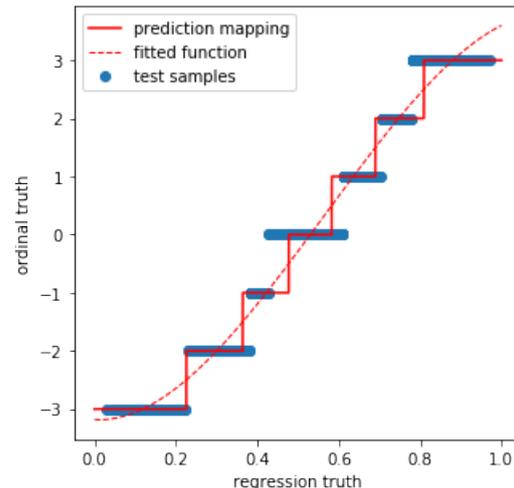

Figure 3: Plot of test labels and the mapping function derived from the training set. A polynomial function is fitted to map the regression predictions into ordinal predictions

ordinal classification results on the development set. However, it turned out that always using the best ensemble prediction and then searching for the optimal mapping method with respect to the development set was better.

5.4 Multi-label Classification: Subtask 5a

We found the best hyper-parameters by evaluating on our development set. We initialized the weight matrix W with a normal distribution of standard deviation of 0.1. We used gradient descent to optimize this function and set the learning rate to 1.0.

Features	CC	RLR
Emoji Cluster	.528	.545
DeepMoji	.532	.552
Emoji Cluster + EVEC	.545	.558
DeepMoji + EVEC	.544	.558
Emoji Cluster + EVEC + f	.546	.558
DeepMoji + EVEC + f	<u>.550</u>	<u>.562</u>
Best ensemble	.576(3)	

Table 7: Test set results on Subtask 5a. The competition metric is Jaccard index.

	Gender		Race	
	Ours	Avg	Ours	Avg
Anger	<u>0.5%</u>	0.1%	<u>1%</u>	0.4%
Fear	<u>-0.9%</u>	-0.3%	<u>3.3%</u>	0.5%
Joy	<u>-1.2%</u>	0.4%	<u>-0.9%</u>	-0.7%
Sadness	<u>0%</u>	0.2%	<u>1.3%</u>	0.8%
Valence	<u>-0.6%</u>	0.5%	<u>-1%</u>	-0.6%

Table 8: Average differences of the system’s bias. Gender difference is from female to male, and race differences is from African American names to European American names (sign of the percentage indicates the direction). “Ours“ indicate the bias of our system, and “Avg“ is the average of the biases of all systems from the competition.

The optimal λ we found was -0.0001.

We found that regularized linear regression model was always better than classifier chain model. The ensemble of classifier chain and regularized linear regression of both features combination (underlined elements in Table 7) achieved best performance than any single model (Table 7).

5.5 Analysis of system’s gender/racial biases

In this year’s competition, the organizers gave out a mystery test set that was included in the regression tasks (subtask 1a & 3a). At the end of the evaluation period, they announced that these were set of pair sentences that differ only in the subject’s or object’s gender or racial names (See the task paper [Mohammad et al. \(2018\)](#) for details). It turned out that our system also included some biases like most other systems did, but fairly small, less than 1.5% for gender bias and 3.5% for racial bias (Table 8). We believe that this is an interesting experiment and look forward to discussing more about the issue during the workshop.

6 Conclusion

In this paper, we explored a couple of different methods to find good representations of emo-

Subtask	System	Score(rank)
1a EI-reg	SeerNet	.799(1)

Table 9: Official final scoreboard on all 5 subtasks that we participated. Scores for Subtask 1-4 are macro-average of the Pearson scores of 4 emotion categories and 5 is Jaccard index. About 35 participants are in each task.

tions inside tweets for solving 5 subtasks of predicting emotion/sentiment intensity and emotion labels. We used external datasets, which were much larger than the competition dataset but distantly labeled with emojis and #hashtags, to exploit the transferred knowledge to build a more robust machine learning system to solve the task. We avoided using traditional NLP features like linguistic features and emotion/sentiment lexicons by substituting them with continuous vector representations learned from huge corpora.

We performed experiments to show that emoji sentence representations and emotional word vectors trained from neural networks can be used with tweet-specific features as input for other traditional regression models, such as SVR and Kernel Regression, to solve the task of regression and ordinal classification. We proved the effectiveness of finding the mapping of the relationship between regression and ordinal labels from the training set to perform ordinal classification. Moreover, we tried using classifier chain and regularized logistic regression to deal with multi-label classification.

As a final official result (Table 9), our system ranked among the top three in every subtask of the competition we participated. For future work, we want to work further on employing these emotion representations on other tasks, such as text generation, while we gather more data and improve the model to train the representations.

Abstract

This paper describes the system we built as the YNU-HPCC team in the SemEval-2018 competition. As participants of Task 1, named Affect in Tweets, we implemented the sentiment system for all five subtasks in English and Spanish. All subtasks involved predicting emotion or sentiment intensity (regression and ordinal classification) and determining emotions (multi-label classification). Our system mainly applied the bidirectional long-short term memory (BiLSTM) model with an attention mechanism. We used BiLSTM in order to extract word information from both directions. The attention mechanism was used to find the contribution of each word to improving the scores. Furthermore, based on the BiLSTM with an attention mechanism, a few deep-learning algorithms were employed for different subtasks. For regression and ordinal classification tasks, we used domain adaptation and ensemble learning methods to leverage the base model, while a single base model was used for the multi-label task. Our system achieved very competitive results on the official leaderboard.

1 Introduction

Sentiment analysis is an area of natural language processing (NLP), which aims to systematically identify and study affective state, and to quantify subjective sentiment expressed in texts. Tweets in Twitter always constitute a challenging task among NLP problems because of the colorful writing styles used.

In previous work on sentiment analysis tasks, researchers usually used a variety of hand-crafted features and sentiment lexicons to generate the solution system by combining traditional methods such as naive Bayes, support vector machines (SVMs) (Mohammad et al., 2013), and decision trees (Blake, 2007). Recently, many ensemble

learning models based on these traditional methods (Giorgis et al., 2016) have attracted the interest of researcher and have shown good results. These approaches require long-term studies to gather information from massive or unstructured datasets, and often result in redundant or missing features. In contrast, the novel deep learning method (Socher et al., 2013) has immediately and shown exceptionally good results in NLP.

In this paper, we primarily present a deep learning system for the SemEval-2018 shared Task 1: Affect in Tweets. We employ the bidirectional long short-term memory with an attention mechanism (BiLSTM_{ATT}) as a base model. For the regression and ordinal classification tasks, we used fine-tuning methods on the base model, combined with multi-tasking and AdaBoost algorithm. We use a simple BiLSTM with an attention mechanism for the multi-label task. Our contributions are as follows:

- We propose a base model combining the BiLSTM with an attention mechanism for the sentiment analysis problem.
- Using the base model, a domain adaptation method of fine-tuning combined with multi-tasking is used for associated tasks.
- An ensemble learning method using the AdaBoost algorithm implemented on the base model is of great use for performing the task with unevenly distributed data.

The remainder of this paper is organized as follows. In Section 2, we describe an overview of our system. The details of the model are presented in Section 3. Finally, comparative results of the experiments are discussed, and a conclusion is drawn in Sections 4 and 5, respectively.

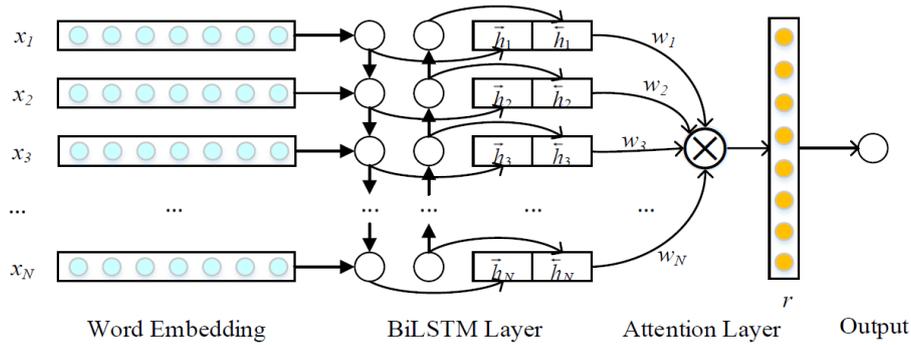

Figure 1: Architecture of the BiLSTM with Attention Mechanism.

2 Overview

This section shows an overview of our system or experiments, which consists of three steps: (1) the data processing step, in which we use some text processing tools for preparing the data as input to the deep learning models, (2) the training step, where we build and train our models, and then predict and (3) evaluate our test results.

Task description. In all five subtasks, we take participant in all subtasks for English and Spanish (Mohammad et al., 2018). Subtasks EI-reg and V-reg, which require the system to detect emotion and sentiment intensity (a real-value score between 0 and 1) from given tweets, are both treated as regression problems. The difference between them is that subtask EI-reg has four different emotion sub-datasets (anger, fear, joy and sadness). In subtasks EI-oc and V-oc, we are given the message and scores, which are ordinal values from four-level and seven-level scales corresponding to positive or negative emotion and sentiment intensity, respectively. Subtask E-c is a multi-label task that requires the system to identify the tweets as "no emotion" or as one, or more, of eleven given emotions.

2.1 Data processing

We built our text processing tools in order to utilize more information from the original text. The objectives of the tools are word-splitting, word annotation, processing of unknown word, and so on.

Text pre-processing. It is difficult to feed original tweets directly into a deep learning model. Imported from the NLTK API¹, the twitter-tokenizer shows great usefulness in fast word segmentation. The tokenizer is able to identify all the words,

¹<http://www.nltk.org/>.

most of the emoticons and emojis, and omits all useless punctuation. The English (or Spanish) dataset primarily contains English (or Spanish) text. Therefore, all non-English (or non-Spanish) letters are treated as unknown words. Moreover, we converted all words to lower case and normalized the construction of user (@user), URLs (<http://ie.com>), and numbers and hashtags (#hashtag).

Pre-trained word embedding. Word embedding techniques aim to use continuous low-dimension vectors representing the features of the words (Mikolov et al., 2013), captured in context. For English tasks, a pre-trained word vector with a dimension of 300, which combined word embedding from training with the GloVe algorithm (Pennington et al., 2014) with the emoji embedding (Barbieri et al., 2016), which included most of the emoticons and emojis, was used to map the tweets. For the Spanish task, we used only the word embedding training by Barbieri et al. (2016). Unknown words were added to the vocabulary, and their vectors were randomly generated from a uniform distribution of $U(-0.25, 0.25)$. The pre-trained word embeddings were used for initializing the word embedding layer (the input layer) of our deep learning models.

2.2 Deep Learning models

Recently, most advanced work in NLP employs deep learning methods.

Convolutional Neural Networks (CNNs). Although CNNs were first applied for computer vision, they also show great importance for NLP problems (Zhang and Wallace, 2015). CNNs are able to quickly extract local n -gram features, and are easy to train. However, CNNs have difficulty

capturing long-distance dependencies.

Recurrent Neural Networks (RNNs). Another effective neural network is the RNN, which captures dynamic information in serial data by periodically connecting hidden layer nodes. RNNs can store a state of context or even a story, learn and express relevant information in any long context window, unlike CNN’s fixed-input formation. An RNN is able to overcome the problem of long-distance dependency. However, it is difficult to train because gradients may explode or vanish over long sequences (Hochreiter, 1998). One way to address this problem is by employing a variant of the regular RNN, the LSTM (Graves, 2012). LSTMs have a more complex internal structure with cells replacing RNN nodes, which allows LSTMs to remember information for either a long or short time.

Attention Mechanism. Between sequences, an attention mechanism shows a considerable improvement by changing the contribution of each word to the analysis of the whole text (Rocktschel et al., 2015; Raffel and Ellis, 2015). Before the RNN model summarizes the hidden states for the output, an attention mechanism amplifies the results by aggregating the hidden states and weighting their relative importance.

Domain Adaptation. Domain adaptation enhances learning in target domains by transferring learning from source domains that may have a distribution different from the target domain. Domain adaptation not only addresses the difference between source and target domains, but also pays attention to the relevance of both domains. The method provides an elegant way to access the full resources of similar tasks for target tasks (Mou et al., 2016).

Ensemble Learning. Ensemble learning is a supervised learning algorithm that ensembles two or more weak learners to amplify system performance (Maclin and Opitz, 1999). The AdaBoost algorithm (Li et al., 2008) is one of the ensemble learning algorithms that repeats training and adjusts the weights of all weak learners continuously to take into consideration the previous iteration error prediction samples. Therefore, the AdaBoost algorithm focuses more attention on a small proportion of special samples in a dataset for better scores.

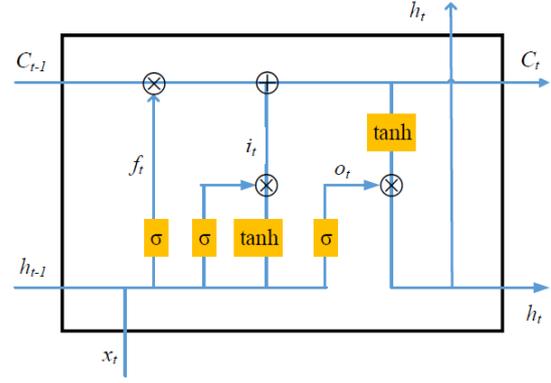

Figure 2: Architecture of cell in LSTM.

3 Model Description

We proposed the base BiLSTM model with an attention mechanism for subtask E-c (3.1). Two additional models (3.2 and 3.3) based on the BiLSTM with an attention mechanism are used for other subtasks.

4 BiLSTM with Attention Mechanism (BiLSTM_{ATT})

Figure 1 shows the architecture of BiLSTM with an attention mechanism, which has four different layers as follows.

Embedding Layer. After the pre-processing of text, tweets are transformed into a sequence of words, $X = (x_1, x_2, \dots, x_N)$, $X \in R^{N \times d}$, where N is the number of a tweet, and d denotes the dimension of a word vector. The word tokens are then directly fed into the model embedding layer, which was initialized by the pre-trained word embeddings.

BiLSTM Layer. LSTM replaces the nodes of a regular RNN model with special structures (cells). The architecture of the LSTM is shown in Figure 2. It calculates the hidden state h_t at time t using the following equations:

- Gates

$$\begin{aligned} f_t &= \sigma(W_f \cdot [h_{t-1}, x_t] + b_f) \\ i_t &= \sigma(W_i \cdot [h_{t-1}, x_t] + b_i) \\ o_t &= \sigma(W_o \cdot [h_{t-1}, x_t] + b_o) \end{aligned} \quad (1)$$

- Transformation

$$\tilde{C}_t = \tanh(W_c \cdot [h_{t-1}, x_t] + b_c) \quad (2)$$

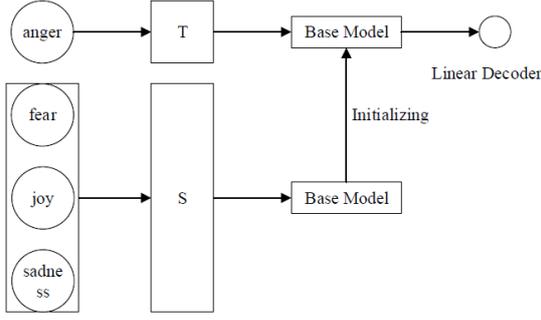

Figure 3: The Model of EIM. Here anger sub-dataset is the target domain and other three sub-datasets regarded as source domain.

- State update

$$\begin{aligned} C_t &= f_t * C_{t-1} + i_t * \tilde{C}_t \\ h_t &= o_t * \tanh(C_t) \end{aligned} \quad (3)$$

where σ denotes the sigmoid function, x_t is the t -th word vector, C_t , f_t , i_t and o_t are all gate vectors of the cell, and W and b are cell parameters.

We use bidirectional LSTM so as to obtain word features $H = (h_1, h_2, \dots, h_n)$ concatenated from both directions. A forward LSTM processes the tweet from x_1 to x_n , while a backward LSTM processes from x_n to x_1 . For word x_t , a forward LSTM obtains a word feature as \vec{h}_t and a backward LSTM obtains the feature as \overleftarrow{h}_t . Then, h is calculated as follows:

$$h_i = \vec{h}_i \oplus \overleftarrow{h}_i, h_i \in R^{2L} \quad (4)$$

Where \oplus denotes the function of concatenation and L is the size of the one-directional LSTM.

Attention Layer. We add an attention layer for finding the contribution of each word to the whole sequence. The attention mechanism assigns a weight w_i to each word feature h_i with a focus on results. The hidden states are finally calculated to produce a hidden sentence feature vector r by a weighted sum function. Formally:

$$\begin{aligned} e_i &= \tanh(W_h h_i + b_h), e_i \in [-1, 1] \\ w_i &= \frac{\exp(e_i)}{\sum_{t=1}^N \exp(e_t)}, \sum_{i=1}^N w_i = 1 \\ r &= \sum_{i=1}^N w_i h_i, r \in R^{2L} \end{aligned} \quad (5)$$

where W_h and b_h are the weight and bias from the attention layer.

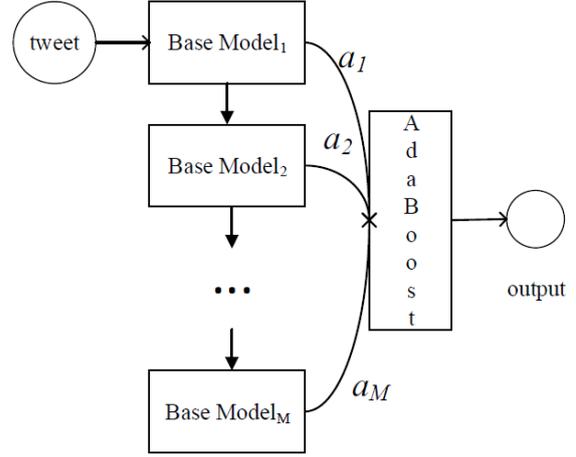

Figure 4: The Model of SIM

Output Layer. The representation r is a sentence feature vector, which we put into a fully-connected layer that outputs the results for the whole sentence. Different tasks require different forms of the output. This base model is dedicated to sub-task E-c, with eleven fully-connected sigmoid layers as the output layer.

4.1 Emotion Intensity Model (EIM)

Figure 3 shows an overview of the EIM, the model we used for task EI-reg and EI-oc with more than one sub-dataset. To train one emotion dataset as a target task (T), the other three emotion datasets were treated as source tasks (S). Our approach was to first train the base model on S , and then to directly initialize the base model on T using the tuned parameters. The parameters were then fine-tuned for predicting the results of S . The output layer of the EIM uses the linear decoder for regression. For ordinal classification task EI-oc, real-value scores from the EIM are translated into four-point classes with thresholds according to the training sets for EI-reg and EI-oc.

4.2 Sentiment Intensity Model (SIM)

Figure 4 shows the architecture of the SIM. Based on the base model, we use the AdaBoost algorithm ensemble the M weak learners to a stronger learner for subtask V-reg and V-oc. Initially, each sample has the same weight. After each iteration, the algorithm weights the samples with poor predictions by the previous learner, and the weighted samples are again used to train the next learner. Finally, we use the calculated weight a_i of each

Model	subtask EI-reg				subtask V-reg
	p				p
	anger	fear	joy	sadness	
CNN	0.428	0.498	0.501	0.631	0.700

Table 1: Comparable results of experiments for subtask EI-reg and V-reg.

learner for the weighted sum of scores. The output layer of the SIM is the same as the one in the task EI-reg. The results of task V-oc are obtained from the real-value scores of the SIM with thresholds according to the training sets for V-reg and V-oc.

4.3 Training and Hyper-parameters

We train the model for task E-c using the categorical cross-entropy loss function, and for other tasks using mean squared error. For all tasks, we use the Adam (Kingma and Ba, 2014) optimizer to train models, and the Relu activation function for fast calculation. An early stopping (Prechelt, 1998) strategy is used to prevent over-fitting. All models use stochastic gradient descent with mini-batches of size 32.

Hyper-parameters. The dimension of word embeddings (d) is 300; the number of each LSTM (L) is 100; the dropout ratio is 0.25 at all layers for all models. Finally, we set 30 learners from the base model to train the SIM by ensemble learning.

5 Experiment

Corpus. The datasets we used were all provided by the competition, with no other external corpus. Except for subtasks EI-reg and EI-oc, which had four sub-datasets, subtasks had only one dataset each for English and Spanish. We thank Mohammad and Kiritchenko (Mohammad et al., 2013) for contributions to the data.

Evaluation Measure. For regression and ordinal tasks (including task EI-reg, EI-oc, V-reg, and V-oc), the official competition metric was the value (p) of the Pearson Correction Coefficient. Moreover, tasks EI-oc and V-oc have a second metric, the quadratic weighted kappa (k). For the multi-label task (task E-c), apart from the official competition metric (multi-label accuracy, a), a micro-averaged F-score ($f1^{micro}$) and a macro-averaged

F-score ($f1^{macro}$) were also calculated for our submissions.

Results. On the competition leaderboard, our system placed 22/48 (9/24) for English (Spanish) in task EI-reg, 12/39 (8/16) in task EI-oc, 27/38 (7/14) in task V-reg, 14/31 (6/14) in task V-oc and 7/35 (6/14) in task E-c.

Experiments and Analysis. We trained our models on the training set and evaluated the prediction with the golden scores of the development set. In order to illustrate the good performance of our methods, we compare the results with baseline models of CNN, LSTM, CNN-LSTM (Zhang et al., 2017) and a regular BiLSTM. From the results shown in Table 1, we can see that our approach achieved a significant result. A regular LSTM tends to ignore future contextual information while processing sequences in a time series. The BiLSTM is able to use both past and future contexts by processing the text from both directions. Not all words make the same contribution to sentiment analysis in the text. The attention mechanism is able to shuffle the word annotation weights according to their importance to the meaning of sentence. We can see that the attention based BiLSTM obtained higher scores than the BiLSTM without the attention mechanism. Moreover, the SIM and the EIM showed their best performance on subtasks V-reg and EI-reg, respectively. SIM employed the AdaBoost algorithm so as to integrate 30 the models of BiLSTM_{ATT}. The SIM was able to adapt to the training error rate of each learner, so that the whole system was improved effectively. The EIM fine-tuned the parameters for the multi-task approach, which made full use of associated sub-datasets of the task EI-reg. Before training the target dataset, the special parameter initialization gave the target model additional knowledge from the other source datasets. In addition, for the same training tweets that were used in task EI-reg (or V-reg) and EI-oc (or V-oc), we defined the thresh-

old for translating from real-value score to ordinal classes by referring to the training labels across the training dataset.

6 Conclusion

In this paper, we described our deep learning models for the sentiment analysis task SemEval-2018 shared Task 1: Affect in Tweets. We used the BiLSTM with an attention mechanism as a base model and built the SIM and EIM for all subtasks. The final system for submission achieved good results. We would like to further explore text sentiment analysis, and employ more interesting methods for NLP problems.

Abstract

The present study describes our submission to SemEval 2018 Task 1: Affect in Tweets. Our Spanish-only approach aimed to demonstrate that it is beneficial to automatically generate additional training data by (i) translating training data from other languages and (ii) applying a semi-supervised learning method. We find strong support for both approaches, with those models outperforming our regular models in all subtasks. However, creating a stepwise ensemble of different models as opposed to simply averaging did not result in an increase in performance. We placed second (EI-Reg), second (EI-Oc), fourth (V-Reg) and fifth (V-Oc) in the four Spanish subtasks we participated in.

1 Introduction

Understanding the emotions expressed in a text or message is of high relevance nowadays. Companies are interested in this to get an understanding of the sentiment of their current customers regarding their products and the sentiment of their potential customers to attract new ones. Moreover, changes in a product or a company may also affect the sentiment of a customer. However, the intensity of an emotion is crucial in determining the urgency and importance of that sentiment. If someone is only slightly happy about a product, is a customer willing to buy it again? Conversely, if someone is very angry about customer service, his or her complaint might be given priority over somewhat milder complaints.

Mohammad et al. (2018) present four tasks¹ in which systems have to automatically determine the intensity of emotions (EI) or the intensity of the sentiment (Valence) of tweets in the languages English, Arabic, and Spanish. The goal is to either predict a continuous regression (reg) value or

¹We did not participate in subtask 5 (E-c).

to do ordinal classification (oc) based on a number of predefined categories. The EI tasks have separate training sets for four different emotions: anger, fear, joy and sadness. Due to the large number of subtasks and the fact that this language does not have many resources readily available, we only focus on the Spanish subtasks. Our work makes the following contributions:

- We show that automatically translating English lexicons and English training data boosts performance;
- We show that employing semi-supervised learning is beneficial;
- We show that the stepwise creation of an ensemble model is not necessarily better method than simply averaging predictions.

Our submissions ranked second (EI-Reg), second (EI-Oc), fourth (V-Reg) and fifth (V-Oc), demonstrating that the proposed method is accurate in automatically determining the intensity of emotions and sentiment of Spanish tweets. This paper will first focus on the datasets, the data generation procedure, and the techniques and tools used. Then we present the results in detail, after which we perform a small error analysis on the largest mistakes our model made. We conclude with some possible ideas for future work.

2 Method

2.1 Data

For each task, the training data that was made available by the organizers is used, which is a selection of tweets with for each tweet a label describing the intensity of the emotion or sentiment (Mohammad and Kiritchenko, 2018). Links and usernames were replaced by the general tokens URL and @username, after which the tweets

Task	NRC-HSL	S-140	SenStr	AFINN	EMOTICONS	Bing Liu	MPQA	NRC-10-exp	NRC-HEAL	NEGATION

<i>V-Reg</i>	✗	✗	✗	✗	✗	✓	✓	✓	✗	✗
<i>V-Oc</i>	✗	✗	✗	✗	✗	✗	✓	✗	✗	✗

Table 1: Lexicons included in our final ensemble. NRC-10 and SentiWordNet are left out of the table because they never improved the score for a task.

were tokenized by using TweetTokenizer. All text was lowercased. In a post-processing step, it was ensured that each emoji is tokenized as a single token.

2.2 Word Embeddings

To be able to train word embeddings, Spanish tweets were scraped between November 8, 2017 and January 12, 2018. We chose to create our own embeddings instead of using pre-trained embeddings, because this way the embeddings would resemble the provided data set: both are based on Twitter data. Added to this set was the Affect in Tweets Distant Supervision Corpus (DISC) made available by the organizers (Mohammad et al., 2018) and a set of 4.1 million tweets from 2015, obtained from Toral et al. (2015). After removing duplicate tweets and tweets with fewer than ten tokens, this resulted in a set of 58.7 million tweets, containing 1.1 billion tokens. The tweets were preprocessed using the method described in Section 2.1. The word embeddings were created using word2vec in the gensim library (Řehůřek and Sojka, 2010), using CBOW, a window size of 40 and a minimum count of 5.² The feature vectors for each tweet were then created by using the AffectiveTweets WEKA package (Mohammad and Bravo-Marquez, 2017).

2.3 Translating Lexicons

Most lexical resources for sentiment analysis are in English. To still be able to benefit from these sources, the lexicons in the AffectiveTweets package were translated to Spanish, using the machine translation platform Apertium (Forcada et al., 2011).

All lexicons from the AffectiveTweets package were translated, except for SentiStrength. Instead

²Embeddings available at www.let.rug.nl/rikvannoord/embeddings/spanish/

of translating this lexicon, the English version was replaced by the Spanish variant made available by Bravo-Marquez et al. (2013).

For each subtask, the optimal combination of lexicons was determined. This was done by first calculating the benefits of adding each lexicon individually, after which only beneficial lexicons were added until the score did not increase anymore (e.g. after adding the best four lexicons the fifth one did not help anymore, so only four were added). The tests were performed using a default SVM model, with the set of word embeddings described in the previous section. Each subtask thus uses a different set of lexicons (see Table 1 for an overview of the lexicons used in our final ensemble). For each subtask, this resulted in a (modest) increase on the development set, between 0.01 and 0.05.

2.4 Translating Data

The training set provided by Mohammad et al. (2018) is not very large, so it was interesting to find a way to augment the training set. A possible method is to simply translate the datasets into other languages, leaving the labels intact. Since the present study focuses on Spanish tweets, all tweets from the English datasets were translated into Spanish. This new set of “Spanish” data was then added to our original training set. Again, the machine translation platform Apertium (Forcada et al., 2011) was used for the translation of the datasets.

2.5 Algorithms Used

Three types of models were used in our system, a feed-forward neural network, an LSTM network and an SVM regressor. The neural nets were inspired by the work of Prayas (Goel et al., 2017) in the previous shared task. Different regression algorithms (e.g. AdaBoost, XGBoost) were also

tried due to the success of SeerNet (Duppada and Hiray, 2017), but our study was not able to reproduce their results for Spanish.

For both the LSTM network and the feed-forward network, a parameter search was done for the number of layers, the number of nodes and dropout used. This was done for each subtask, i.e. different tasks can have a different number of layers. All models were implemented using Keras (Chollet et al., 2015). After the best parameter settings were found, the results of 10 system runs to produce our predictions were averaged (note that this is different from averaging our different *type* of models in Section 2.7). For the SVM (implemented in scikit-learn (Pedregosa et al., 2011)), the RBF kernel was used and a parameter search was conducted for epsilon. Detailed parameter settings for each subtask are shown in Table 2. Each parameter search was performed using 10-fold cross validation, as to not overfit on the development set.

2.6 Semi-supervised Learning

One of the aims of this study was to see if using semi-supervised learning is beneficial for emotion intensity tasks. For this purpose, the DISC (Mohammad et al., 2018) corpus was used. This corpus was created by querying certain emotion-related words, which makes it very suitable as a semi-supervised corpus. However, the specific emotion the tweet belonged to was not made public. Therefore, a method was applied to automatically assign the tweets to an emotion by comparing our scraped tweets to this new data set.

First, in an attempt to obtain the query-terms, we selected the 100 words which occurred most frequently in the DISC corpus, in comparison with their frequencies in our own scraped tweets corpus. Words that were clearly not indicators of emotion were removed. The rest was annotated per emotion or removed if it was unclear to which emotion the word belonged. This allowed us to create *silver* datasets per emotion, assigning tweets to an emotion if an annotated *emotion-word* occurred in the tweet.

Our semi-supervised approach is quite straightforward: first a model is trained on the training set and then this model is used to predict the labels of the silver data. This silver data is then simply added to our training set, after which the model is retrained. However, an extra step is applied to en-

sure that the silver data is of reasonable quality. Instead of training a single model initially, ten different models were trained which predict the labels of the silver instances. If the highest and lowest prediction do not differ more than a certain threshold the silver instance is maintained, otherwise it is discarded.

This results in two parameters that could be optimized: the threshold and the number of silver instances that would be added. This method can be applied to both the LSTM and feed-forward networks that were used. An overview of the characteristics of our data set with the final parameter settings is shown in Table 3. Usually, only a small subset of data was added to our training set, meaning that most of the silver data is not used in the experiments. Note that since only the emotions were annotated, this method is only applicable to the EI tasks.³

2.7 Ensembling

To boost performance, the SVM, LSTM, and feed-forward models were combined into an ensemble. For both the LSTM and feed-forward approach, three different models were trained. The first model was trained on the training data (regular), the second model was trained on both the training and translated training data (translated) and the third one was trained on both the training data and the semi-supervised data (silver). Due to the nature of the SVM algorithm, semi-supervised learning does not help, so only the regular and translated model were trained in this case. This results in 8 different models per subtask. Note that for the valence tasks no silver training data was obtained, meaning that for those tasks the semi-supervised models could not be used.

Per task, the LSTM and feed-forward model's predictions were averaged over 10 prediction runs. Subsequently, the predictions of all individual models were combined into an average. Finally, models were removed from the ensemble in a step-wise manner if the removal increased the average score. This was done based on their original scores, i.e. starting out by trying to remove the worst individual model and working our way up to the best model. We only consider it an increase in score if the difference is larger than 0.002 (i.e. the difference between 0.716 and 0.718). If at some point the score does not increase and we

³For EI-Oc, the labels were normalized between 0 and 1.

	SVM	Feed-forward		LSTM			
Task	Epsilon	Layers	Nodes	Layers	Nodes	Dropout	Dense
<i>EI-Reg-a</i>	0.01	2	(600, 200)	2	400	0.001	✗
<i>EI-Reg-f</i>	0.04	2	(700, 200)	2	400	0.01	✓
<i>EI-Reg-j</i>	0.05	2	(500, 500)	2	200	0.1	✗
<i>EI-Reg-s</i>	0.06	2	(400, 300)	2	600	0.001	✗
<i>EI-Oc-a</i>	0.005	2	(600, 200)	2	200	0.001	✗
<i>EI-Oc-f</i>	0.06	2	(700, 300)	2	200	0.001	✗
<i>EI-Oc-j</i>	0.04	2	(800, 200)	3	400	0.001	✓
<i>EI-Oc-s</i>	0.005	2	(500, 200)	3	800	0.01	✓
<i>V-Reg</i>	0.07	3	(400, 400, 400)	2	200	0.001	✓
<i>V-Oc</i>	0.09	3	(400, 400, 100)	3	600	0.01	✓

Table 2: Parameter settings for the algorithms used. For feed-forward, we show the number of nodes per layer. The *Dense* column for LSTM shows whether a dense layer was added after the LSTM layers (with half the number of nodes as is shown in the *Nodes* column). The feed-forward networks always use a dropout of 0.001 after the first layer.

			Feed-forward		LSTM		
	Words	Tweets	Task	Threshold	Tweets added	Threshold	Tweets added
Anger	23	81,798	<i>EI-Reg</i>	0.1	2,500	0.05	2,500
			<i>EI-Oc</i>	0.1	1,000	0.1	2,500

			<i>EI-Oc</i>	0.125	2,000	0.05	2,500

Table 3: Statistics and parameter settings of the semi-supervised learning experiments.

are therefore unable to remove a model, the process is stopped and our best ensemble of models has been found. This process uses the scores on the development set of different combinations of models. Note that this means that the ensembles for different subtasks can contain different sets of models. The final model selections can be found in Table 4.

3 Results and Discussion

Table 5 shows the results on the development set of all individual models, distinguishing the three types of training: regular (r), translated (t) and semi-supervised (s). In Tables 4 and 5, the letter behind each model (e.g. SVM-r, LSTM-r) corresponds to the type of training used. Comparing the regular and translated columns for the three algorithms, it shows that in 22 out of 30 cases, using translated instances as extra training

data resulted in an improvement. For the semi-supervised learning approach, an improvement is found in 15 out of 16 cases. Moreover, our best individual model for each subtask (bolded scores in Table 5) is always either a translated or semi-supervised model. Table 5 also shows that, in general, our feed-forward network obtained the best results, having the highest F-score for 8 out of 10 subtasks.

However, Table 6 shows that these scores can still be improved by averaging or ensembling the individual models. On the dev set, averaging our 8 individual models results in a better score for 8 out of 10 subtasks, while creating an ensemble beats all of the individual models as well as the average for each subtask. On the test set, however, only a small increase in score (if any) is found for stepwise ensembling, compared to averaging. Even though the results do not get worse, we can-

<i>V-Oc</i>	0.767	0.772	0.706	0.707

Table 6: Results on the dev and test set for averaging and stepwise ensembling the individual models. The last column shows our official results.

not conclude that stepwise ensembling is a better method than simply averaging.

Our official scores (column *Ens Test* in Table 6) have placed us second (EI-Reg, EI-Oc), fourth (V-Reg) and fifth (V-Oc) on the SemEval AIT-2018

leaderboard. However, it is evident that the results obtained on the test set are not always in line with those achieved on the development set. Especially on the anger subtask for both EI-Reg and EI-Oc, the scores are considerably lower on the test set in comparison with the results on the development set. Therefore, a small error analysis was performed on the instances where our final model made the largest errors.

3.1 Error Analysis

Due to some large differences between our results on the dev and test set of this task, we performed a small error analysis in order to see what caused these differences. For *EI-Reg-anger*, the gold labels were compared to our own predictions, and we manually checked 50 instances for which our system made the largest errors.

Some examples that were indicative of the shortcomings of our system are shown in Table 7. First of all, our system did not take into account capitalization. The implications of this are shown in the first sentence, where capitalization intensi-

Example sentence	Pred.	Gold	Possible problem
QUIERES PELEA FSICA? DO YOU WANT A PHYSICAL FIGHT?	0.25	0.80	Capitalization
Ojal una precuela de <i>Imperator Furiosa</i> . I wish a prequel to <i>Imperator Furiosa</i> .	0.64	0.24	Named entity not recognized
Odio estar tan enojada y que me de risa I hate being so angry and that that makes me laugh	0.79	0.46	Reduced angriness
Yo la mejor y que te contesten as nomas me infla la vena I am the best and that they answer you like that, it just inflates my vein	0.45	0.90	Figurative speech

Table 7: Error analysis for the EI-Reg-anger subtask, with English translations.

fies the emotion used in the sentence. In the second sentence, the name *Imperator Furiosa* is not understood. Since our texts were lowercased, our system was unable to capture the named entity and thought the sentence was about an angry emperor instead. In the third sentence, our system fails to capture that when you are so angry that it makes you laugh, it results in a reduced intensity of the angriness. Finally, in the fourth sentence, it is the figurative language *me infla la vena* (it inflates my vein) that the system is not able to understand.

The first two error-categories might be solved by including smart features regarding capitalization and named entity recognition. However, the last two categories are problems of natural language understanding and will be very difficult to fix.

4 Conclusion

To conclude, the present study described our submission for the Semeval 2018 Shared Task on Affect in Tweets. We participated in four Spanish subtasks and our submissions ranked second, second, fourth and fifth place. Our study aimed to investigate whether the automatic generation of additional training data through translation and semi-supervised learning, as well as the creation of stepwise ensembles, increase the performance of our Spanish-language models. Strong support was found for the translation and semi-supervised learning approaches; our best models for all subtasks use either one of these approaches. These results suggest that both of these additional data resources are beneficial when determining emotion intensity (for Spanish). However, the creation of a stepwise ensemble from the best models did not result in better performance compared to simply averaging the models. In addition, some signs of overfitting on the dev set were found. In fu-

ture work, we would like to apply the methods (translation and semi-supervised learning) used on Spanish on other low-resource languages and potentially also on other tasks.

Abstract

This paper presents a UIR-Miner system for emotion and sentiment analysis evaluation in Twitter in SemEval 2018. Our system consists of three main modules: preprocessing module, stacking module to solve the intensity prediction of emotion and sentiment, LSTM network module to solve multi-label classification, and the hierarchical attention network module for solving emotion and sentiment classification problem. According to the metrics of SemEval 2018, our system gets the final scores of 0.636, 0.531, 0.731, 0.708, and 0.408 in terms of Pearson Correlation on 5 subtasks, respectively.

1 Introduction

Recently, social media platforms are becoming more and more popular, such as Twitter microblogging, Facebook, and so on. Through these platforms, online users would like to share their opinions and emotions. Therefore, the analysis about the information on “affect” in the social media has attracted much interest from both academia and industries.

However, the short texts are usually consisted of informal expressions with much casual forms and emoticons, it brings great challenges for such research.

For this purpose, SemEval organized the evaluation of sentiment analysis on Tweet. This year comes the fifth edition that consists of new genres, including emotion intensity regression task, emotion intensity ordinal classification task, sentiment intensity regression task, sentiment degree ordinal classification task, and emotion classification task (Mohammad et al., 2018).

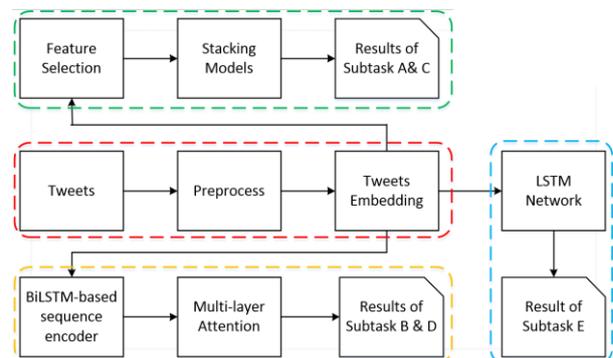

Figure 1: System architecture.

We participated in SemEval 2018 task 1 for English, i.e. Affect in Tweet. Our system considers EI-reg and V-reg (subtask A and C) as regression problems to get the emotion intensity and sentiment intensity by using regression models, while regards EI-oc and V-oc (subtask B and D) as categorization problems to classify each tweet into its corresponding emotion category and sentiment category by implementing hierarchical attention networks. Moreover, subtask E, i.e., E-c, is considered as a multi-label classification task.

This paper is organized as follows. Section 2 overviews the framework of our system. Section 3 describes the methods for subtask A and C. Section 4 describes the hierarchical attention networks for subtask B and D. Subtask E will be introduced in Section 5. Section 6 presents the evaluation results. Section 7 will conclude this paper.

2 System Overview

The architecture of UIR-Miner is shown in Figure 1. UIR-Miner system is comprised of 4 modules:

- (1) Preprocessing module: involves data cleaning, topic classification, and tweets embedding.

- (2) Regressor module: creates an ensemble regressor model by using different basic models simultaneously to calculate the emotion intensity and sentiment intensity, i.e. subtask A and subtask C;
- (3) Classification module: constructs an LSTM network with multi-layer attention mechanism for emotion and sentiment categorization, i.e. subtask B and subtask D;
- (4) Multi-label Classification module: builds a LSTM network for subtask E.

2.1 Preprocessing

Our system will firstly preprocess the Tweets data, and the main steps are as follows.

- Delete the unrelated texts, including the id, some mentions, stop words, and some meaningless punctuation combinations.
- Normalize synonymous words, like replacing “cant” and “can’t” with “cannot”.
- Extract emoticons from tweets through regular expressions, and then maintain the emotional ones.

2.2 Word embedding

In the preprocessing, we used the pre-trained word embedding by Glove (Penningto et. al, 2014), in which each word e_{it} will be represented by a 200-dimensional vector w_{it} , $i \in [1, L]$, $t \in [1, T]$. Here, i denotes the location of the sentence in the tweet and L is the maximum number of sentences for each tweet, t denotes the location of the word in the sentence and T is the maximum number of words for each sentence. Set $T = 140$ and $L = 5$.

3 Subtask A and C

This section will describe the methods for subtask A and C. Given a tweet and an emotion E (or a sentiment V), determine the intensity of E (or V) that best represents the mental state of the tweeter—a real-valued score between 0 and 1. We consider both of subtask A and C as a regression problem.

On the whole, we use a stacking framework to enhance the accuracy of final prediction. The original features are selected as input into the stacking model, including hashtags, emoticons, and *n-gram* features. Then, the stacking model is divided into two layer, the base layer and the stacking layer. In the base layer, we choose four basic regressors due to their excellent performance. In the stacking layer, we still use SVM model, especially, the NuSVR model, which can control its

error rate. Finally, we get the final result of intensity value.

3.1 Feature Selection

Since there are many irregular expressions in tweet, we combine the features, including emoticon, hashtag, and special punctuations. In our system, we mainly select the following features:

- Hashtags: the number of hashtags in one tweet;
- Ill format: the presence of ill format with some characters replacing by *;
- Punctuation: the number of contiguous sequences of exclamation marks, question marks, and both exclamation and question marks; whether the last token contains an exclamation or question mark;
- Emoticons: the presence of positive and negative emoticons at any position in the tweet; whether the last token is an emoticon;
- OOV: the ratio of words out of vocabulary;
- Elongated words: the presence of sentiment words with one character repeated more than two times, for example, ‘coool’;
- URL: whether the tweet contains a URL.
- Reply or Retweet: is the current tweet a reply/retweet tweet.

3.2 Stacking Model

To avoid overfitting, we test 6 basic models to construct our stacking model.

- B: Bayesian Ridge (Hsiang, T.C 1975)
- G: Gradient Boosting Regressor (Jerome H. Friedman, 2001)
- K: Kernel Ridge (Zhang Y et. al, 2013)
- L: Lasso Regressor (Tibshirani et al., 1996)
- M: MLP Regression (Pal and Mitra, 1992)
- R: Random Forest Regressor (Ho, 1995)
- S: SVR (Vapnik 1995)

To achieve the best performance, we also compare different combinations of our basic models with the metrics of Mean Squared Error (MSE) in the stacking method, and the experimental result is shown in Table 1.

- Baseline: we use SVR as the Baseline;
- Stacking1: B+K+S;
- Stacking2: M+K+R;
- Stacking3: B+K+R+S;
- Stacking4: B+G+K+M;
- Stacking5: G+K+L+ S;
- Stacking6: B+G+K+S.

Since Stacking 6 achieves the best performance, we use the same setting in our system.

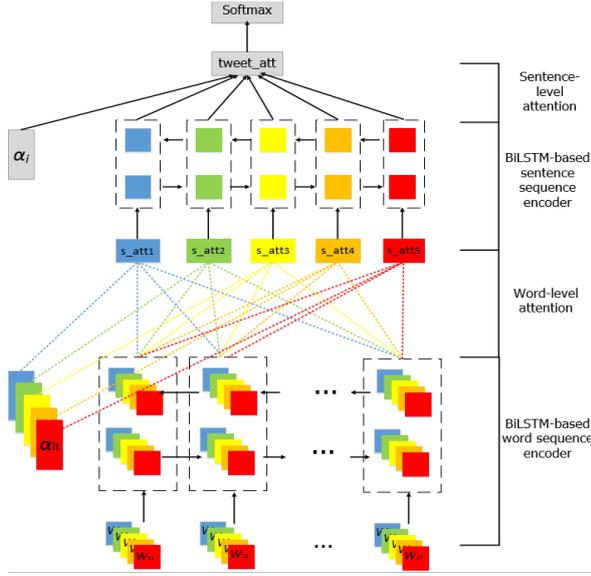

Figure 2: BiLSTM network with multi-layer attention mechanism.

Table 1: Evaluation on different combinations in stacking method.

Method	Metrics				
	Ang	Fear	Joy	Sad	Ave
Baseline	9.774	8.390	9.055	9.086	9.076
Stacking1	9.404	7.926	8.352	8.629	8.578
Stacking2	9.596	7.849	8.192	8.520	8.539
Stacking3	9.351	7.900	8.206	8.536	8.500
Stacking4	9.557	7.715	8.045	8.454	8.443
Stacking5	9.381	7.790	8.170	8.387	8.432
Stacking6	9.300	7.766	7.794	8.334	8.298

4 Hierarchical Attention Networks for Subtask B and D

This section will introduce our hierarchical attention model for subtask B and D. Given a tweet and an emotion category E (or a sentiment category V), classify the tweet into one of the ordinal classes of intensity of E (or V) that best represents the mental state of the tweeter. Note that, the number of category of E is 4, while that of V is 7. In our system, we consider both of subtask B and D as a classification problem.

Each tweet contains several sentences that are comprised by several words. In order to better represent the semantics of emotion or sentiment, we utilize the hierarchical structure of a tweet to capture the contextual information of both intra and inter-tweet. The architecture is shown as Figure 2.

We build a hierarchical model which contains two layers, word layer and sentence layer. Since words and sentences are highly sensitive to the con-

texts, recurrent neural networks based on bidirectional long short-term memory (BiLSTM) (Hochreiter and Schmidhuber, 1997) are implemented on both layers to get tweets’ representations. Furthermore, since the words in one sentence or different sentences in a given tweet can indicate different emotion intensity or sentiment intensity. To better represent the semantics, attention mechanisms are added to both layers respectively (Xu et. al., 2015). We then use softmax as the activation

4.1 BiLSTM-based Word Encoder

A word level BiLSTM (Hochreiter and Schmidhuber, 1997) is used to represent each word. The BiLSTM consists of the forward LSTM and the backward LSTM. Forward LSTM reads the sentence s_i from e_{i1} to e_{iT} and represents the word e_{it} as $\overrightarrow{LSTM}(w_{it}), t \in [1, T]$. Backward LSTM reads the sentence s_i from e_{iT} to e_{i1} and represents the word e_{it} as $\overleftarrow{LSTM}(w_{it}), t \in [T, 1]$. Then word e_{it} can be annotated by combining both forward information and backward information, $h_{it} = [\overrightarrow{LSTM}(w_{it}), \overleftarrow{LSTM}(w_{it})]$. The equations are listed as follows:

$$i_t = \sigma(W_i w_{it} + U_i h_{t-1} + b_i) \quad (1)$$

$$f_t = \sigma(W_f w_{ft} + U_f h_{t-1} + b_f) \quad (2)$$

$$o_t = \sigma(W_o w_{ot} + U_o h_{t-1} + b_o) \quad (3)$$

$$u_t = \tanh(W_u w_{ut} + U_u h_{t-1} + b_u) \quad (4)$$

$$c_t = i_t \odot u_t + f_t \odot c_{t-1} \quad (5)$$

$$h_t = o_t \odot \tanh(c_t) \quad (6)$$

where i_t , f_t and o_t are the input gate, forget gate and output gate, σ is the logistic sigmoid function, \odot denotes elementwise multiplication, \tanh is the network output activation function, and $softmax$ is used for categorization. To better support Twitter, we input the word embedding with 200 dimensions, and the max number of words in a sentence as 140.

4.2 Word Layer Attention

Different weights α_{it} are given to different words. Attention mechanism (Xu et. al., 2015) is added to the word layer and the sentence s_i can be represented as s_att_i .

$$u_{it} = \tanh(W_w h_{it} + b_w) \quad (7)$$

$$\alpha_{it} = \frac{\exp(u_{it}^T u_w)}{\sum_t \exp(u_{it}^T u_w)} \quad (8)$$

$$s_{att_i} = \sum_t \alpha_{it} h_{it} \quad (9)$$

More specifically, after putting h_{it} into a fully-connected layer, we get u_{it} . Then calculate weight α_{it} with a word level context u_w . Finally, we can get the sentence vector through an attention layer by calculating the sum of $\alpha_{it} h_{it}$.

4.3 Sentence Layer Attention

Similarly, a sentence level BiLSTM (Hochreiter and Schmidhuber, 1997) can be used to represent sentence s_i by adding sentence level context information,

$$h_i = [\overrightarrow{LSTM}(s_{att_{it}}), \overleftarrow{LSTM}(s_{att_{it}})].$$

We then add weights to different sentence. Take x_i as input and get *tweet_att* to represent each tweet through an attention layer.

$$u_i = \tanh(W_s h_i + b_s)$$

$$\alpha_i = \frac{\exp(u_i^T u_s)}{\sum_i \exp(u_i^T u_s)}$$

$$tweet_att = \sum_i \alpha_i h_i$$

More specifically, after putting h_i into a fully-connected layer, we get u_i . Then calculate weight α_i with a sentence level context u_s . Finally, we can get the tweet vector through an attention layer by calculating the sum of $\alpha_i h_i$.

5 Subtask E

This section will introduce neural network model for subtask E. Given a tweet, classify the tweet as “neutral or no emotion” or as one, or more, of eleven given emotions that best represent the mental state of the tweeter.

Each tweet will be classified with different numbers of labels. Since there exists eleven labels each of which may be suitable, considering one of these labels every time is reasonable. Our system will calculate a score for each of the eleven labels for each tweet, and select the top-3 as the final results.

We also used a LSTM network for this task, and get the classification result by using *softmax*. The other settings of this model is quite similar to that in Section 4 except for multi-label classification.

6 Experiment

In this section, we will report our evaluation results in SemEval 2018 based on the given dataset

as well as the metrics. The statistics of the dataset is shown in Table 2.

Note that any other extra external resources, such as sentiment lexicon, emoticons, and annotated corpus, are not used in the evaluation except for the training dataset provided by the organization.

Table 2: Statistics of the dataset.

	Training set	Dev set	Test set
El-reg	anger: 1701 fear: 2252 joy: 1616 sadness: 1533	anger: 388 fear: 389 joy: 290 sadness: 397	anger: 17939 fear: 17923 joy: 18042 sadness: 17912
El-oc	anger: 1701 fear: 2252 joy: 1616 sadness: 1533	anger: 388 fear: 389 joy: 290 sadness: 397	anger: 1002 fear: 986 joy: 1105 sadness: 975
V-reg	1181	449	17874
V-oc	1181	449	937
E-c	6838	886	3259

Table 3 shows the results of our UIR-Miner for all the subtasks on both Dev set and Test set, and the final ranking.

Table 3: The results on different datasets.

	Score in Dev	Score in Test	Ranking
El-reg	0.576	0.636	28/48
El-oc	0.495	0.531	15/39
V-reg	0.729	0.781	21/38
V-oc	0.694	0.708	16/37
E-c	0.421	0.407	23/35

7 Conclusion

In this paper, we present a framework for SemEval 2018 Affect in Tweet task. After the preprocessing, we firstly propose an ensembling method to calculate the intensity score of emotion and sentiment. Then a LSTM network model with multi-layer attention mechanism is constructed for emotion and sentiment classification. According to SemEval 2018’s metrics, our model runs got final scores of 0.636, 0.531, 0.731, 0.708, and 0.408 in terms of Pearson Correlation on 5 subtasks, respectively.

Abstract

This paper presents system description of our submission to the SemEval-2018 task-1: Affect in tweets for the English language. We combine three different features generated using deep learning models and traditional methods in support vector machines to create a unified ensemble system. A robust representation of a tweet is learned using a multi-attention based architecture which uses a mixture of different pre-trained embeddings. In addition, analysis of different features is also presented. Our system ranked 2nd, 5th, and 7th in different subtasks among 75 teams.

1 Introduction

In Natural Language processing, Sentiment analysis refers to the degree of positiveness or negativeness of the information presented in the text. Traditionally sentiment analysis is treated as either a binary classification task (positive, negative) or a multi-class classification task (very negative, negative, neutral, positive, very positive). Affect analysis on the other hand refers to detecting discrete sets of emotions present in the text such as anger, joy, sadness etc (Dalglish and Power, 2000; Plutchik, 2001). Predicting intensities of these emotions to fine granularity can help us better understand the sentiment and emotions of the writer.

Detecting sentiments or affect from text have a number of useful applications. For example, the degree of disgust or anger expressed in customer complaints or reviews can help us decide the priorities of issues to look at, or the joy or optimism expressed in customer feedbacks can be a major factor in deciding the marketing strategy for a company.

Sentiment or affect analysis for social media text is a challenging task due to the extensive use of slang, frequent spelling mistakes, innovative

and unpredictable use of hashtags and extensive use of emojis and smileys.

SemEval-2018 Task 1: Affect in tweets, provides data for 3 languages: English, Arabic, and Spanish. For each language, there are 5 subtasks that are presented, 2 Regression tasks, 2 classification tasks and 1 Multi-Label task. Further details of tasks are presented in section 3. This task was similar to the WASSA shared task (Mohammad and Bravo-Marquez, 2017) and dataset presented here is the extension of the data presented for WASSA shared task.

In this paper, we present our approach to solving these tasks for English language tweets. We have proposed a system which uses various pre-trained embeddings to handle out-of-vocabulary words and emoji present in the text along with cleaning of raw text. In addition, to create a better representation of the text, we use two sets of embeddings learnt over two different corpus which results in parallel attention mechanism - one set from the twitter space and another from a common crawl corpus. Finally, we combine features generated from the deep learning model with other features to generate an ensemble system.

Major contributions of this paper are:

1. Generating word vector representation of a tweet from three different set of pre-trained embeddings which can handle emoji/smiley and the out of vocabulary words in the dataset.
2. Deep neural network architecture which generates robust representation of the text with the help of parallel attention mechanism.

Rest of the paper is organized as follows, Section 2 presents the preprocessing step to generate mixed set of embeddings and the model architecture. It also presents the different sets of features that are used for final ensemble system. In section 3, data, training and experimentation setup is described for different subtasks. Section 4 states

the results of the proposed system and detailed discussion of the feature over development and test data. Finally, section 5 concludes the paper with summary of the approach presented.

2 Proposed Approach

Figure 1 describes the overall system architecture used for regression and classification subtasks. We have extracted different types of features from the raw text, which fall under three different categories. Deep learning features are the ones which are generated from the model that is trained and proposed in this paper. Lexicon-based features are generated from training sets. In addition, features from pre-trained models are used. These models were trained over large corpus.

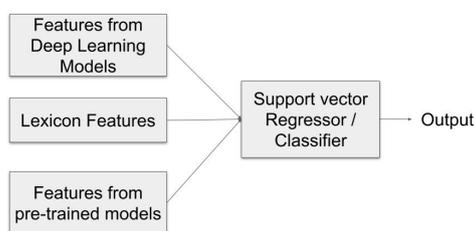

Figure 1: System Diagram.

Attention mechanism has been successful in sequence to sequence learning problems specifically for neural machine translation (NMT) (Bahdanau et al., 2014). These mechanism helps model to focus more on the task in hand. The proposed architecture uses two parallel processing towers which use attention as a means of focusing on sentiment specific words. Figure 2 presents a snapshot of the random sample for sadness emotion, first row denotes the output of the attention mechanism and row 2 denotes the output of the model. We observe that the attention mechanism helps in focusing on words which are relevant to the sentiment task in hand, such as crying, dying etc. which further helps in improving the performance of the model. The multi-attention mechanism is inspired from (Lin et al., 2017) where, they have used more multi-attention over the same embedding space to focus on more than one word. In contrast, we use limit our attention to at max 2 words as the tweet is much more compact in nature as well as we do it over different embedding space to encapsulate much more information.

For generating features as mentioned above, we employ pre-processing steps to normalize the text with respect to sentiment specific words and its usage.

2.1 Preprocessing

As mentioned earlier, tweets in the raw form are noisy and prone to many distortions in terms of syntactic and semantic structure. These pre-processing steps are common to all the features generated. Deep learning features require additional steps which are explained in respective section.

1. All the characters in the text are converted to lower case.
2. Twitter contains lot of words with more than 2 repeating characters such as happpyyyyyyy, we limited occurrence of each character to maximum of 2 successive times.
3. To handle hashtags, # symbol is removed from all the words.
4. Extra spaces and new line character is deleted from the tweet to ensure the compactness of the tweets.

2.2 Deep Learning Features

Figure 3 shows the model which was used to generate deep learning features. In this model, we have used different embeddings to enhance the representations of raw text. There are two parallel architectures which take the same raw input but generate the representation from a different embedding space. This helps in encapsulating the word and its usage in twitter space as well as keeping a general semantic and syntactic structure of word intact.

For tower one in the figure 3, text is pre-processed using steps mentioned earlier. In addition, following pre-processing steps are performed:

1. *Username*s in twitter which starts with @ is replaced by **mention** token.
2. Punctuations are removed except [,], [?], [!], [.]
3. Words that are most probably used as slangs in twitter are replaced with its corresponding expanded versions such as "y'all" is replace by "you all".

Embedding matrix is generated from the pre-processed text using combination of three pre-trained embeddings: Glove (Pennington et al.,

Figure 2: Attention Example.

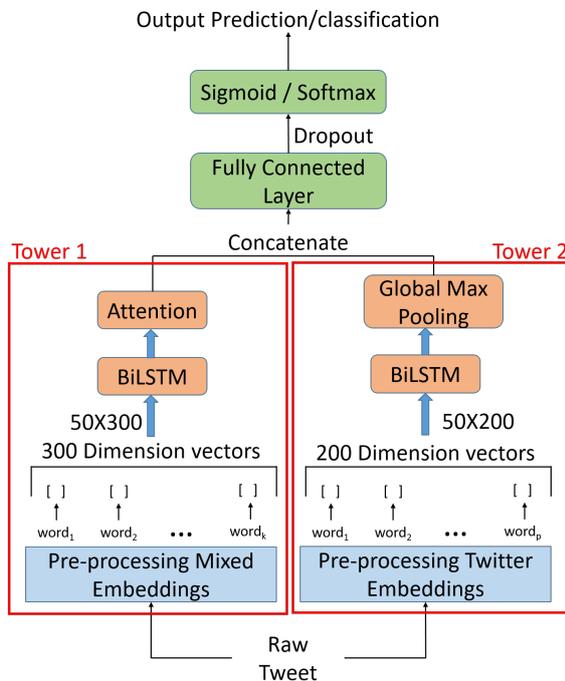

Figure 3: Model Diagram.

2014) trained over common crawl corpus with 300 dimension vector, Character¹ level embeddings trained over common crawl glove corpus providing 300 dimensional vectors for each character and emoji2vec (Eisner et al., 2016) which provides 300 dimension vectors for most commonly used emojis in twitter platform. Procedure to generate a representation of a text using all these embeddings is presented in Algorithm 1, where *get_vector* is a function of token and embedding type and returns the corresponding vector for the token from the pre-trained embedding specified.

Embedding vectors that are generated for each tweet are then converted to into matrix, with a number of rows being the size of maximum sequence, rest is zero padded. This matrix then forms the input to the Bidirectional LSTM(BiLSTM) layer (Graves and Schmidhuber, 2005), which helps in generating representations by taking all the words in sequence into account.

¹<https://github.com/minimaxir/char-embeddings>

```

word_token = Tokenize tweet
for each word in word_token do
    if word is in EmojiEmbb then
        word_vector =
            get_vector(EmojiEmbb,
                word_vector)
    else if word is in Glove then
        word_vector = get_vector(Glove,
            word_vector)
    else if word is in CharEmbb then
        word_vector = get_vector(charEmbb,
            word_vector)
    else
        chars = tokenize word_token into
            character
        n = length(chars) word_vector =
             $\sum_1^n get\_vector(charEmbb, chars)$ 
    end
end

```

Algorithm 1: Embedding Matrix generation

The output of each time-step is then fed to Attention Mechanism (Bahdanau et al., 2014). The core concept behind the attention mechanism forces the model to focus on important words that are related to the task.

Tower 2 in the Figure 3 uses pre-processed mechanism where, all the punctuations are removed, usernames are removed without any replacement with tokens and, special characters including smiley and emojis are removed. Embedding matrix is generated using pre-trained glove embeddings trained over twitter corpus and provides 200-dimensional vectors for each word. These are zero padded as mentioned earlier and is fed into another BiLSTM layer. Maxpooling is applied over the output of BiLSTM to extract the most prominent vector from the rest over the temporal dimension which act as a attention over word sequences. Maximum sequence length for the embedding space is kept at 50, as twitter has a character limit of 140 characters.

The output of tower 1 and 2 are then concatenated and then fed into the fully connected network with 2 layers. Final layer contains a different number of neurons and activation functions de-

pending on the subtasks which are stated in the experiments section 4. To handle overfitting we have used L2 regularization dropout in layers and batch size is kept at 512.

2.3 Traditional Features

We defined features that are used in most of the traditional sentiment analysis techniques are termed as traditional features. As per the baseline system provided in the WASSA Emotion Intensity Task we define baseline features. The knowledge sources that have been used to generate baseline feature are: MPQA subjective lexicon (Wilson et al., 2005), Bing Liu lexicon (Ding et al., 2008), AFINN (Nielsen, 2011), Sentiment140 (Kiritchenko et al., 2014), NRC Hashtag Sentiment Lexicon (Mohammad and Kiritchenko, 2015), NRC Hashtag Emotion Association Lexicon (Mohammad et al., 2013), NRC Word-Emotion Association Lexicon (Mohammad and Turney, 2013), NRC-10 Expanded Lexicon (Bravo-Marquez et al., 2016) and the SentiWordNet (Esuli and Sebastiani, 2007). Two more features are calculated on the basis of emoticons (obtained from AFINN (Nielsen, 2011)) and negations present in the text. This amounts to 45 features for each tweet.

In addition to this, we have used Vader Sentiment Lexicons (Gilbert, 2014), which provides the positive, negative, neutral and compound score for the text. These lexicons are specifically designed for social media texts.

2.4 Features from pre-trained models

We use **SentiNeuron** feature (Radford et al., 2017) from a model which is trained over 82 million Amazon review dataset. The aim of the model was to predict the next word in the review. They have used LSTM with 4096 units. The 2389th neuron was found to be specifically focusing on the sentiment for a given sentence. We use output of this 2389th as a feature. Further more, we have normalized it between 0-1 which helps in performance improvement.

3 Data and Experiments

We participated in all the subtasks of English language, namely: EI-reg (intensity score prediction of 4 emotions), EI-oc (intensity ordinal classification task of 4 emotions), V-reg (intensity score prediction of valence), V-oc (intensity ordinal classifi-

Table 1: Data Distribution.

	Train	Dev	Test
Anger	1701	388	1002
Fear	2252	389	986
Joy	1616	290	1105
Sadness	1533	397	975
Valence	1181	449	937
Multi-Label	6838	886	3259

cation task for valence) and E-c (Multi-label classification task over 11 emotions). Detailed analysis and distribution of the dataset are presented in the task paper (Mohammad et al., 2018).

For each subtask, deep learning model is same as mentioned earlier, although there is a variation in the feature being used for ensemble approach. Data distribution across train, dev and test dataset is given table 1.

3.1 EI-reg and V-reg: Regression

In this task, given a tweet and its corresponding emotion, we need to predict the intensity of the given emotion in 0-1 range. For this task, Deep learning models with *sigmoid* as activation function and number of hidden unit in last layer as one is used. Official evaluation metric for this is a pearson correlation, so we define a new loss function to train deep learning models.

$$Loss = 0.7 \times (1 - pearson) + 0.3 \times MSE \quad (1)$$

This is a slightly modified version than used by (Meisheri et al., 2017; Goel et al., 2017) for WASSA dataset, where they use the negative of pearson correlation as the loss function. We observe that using weighted sum of negation of pearson correlation and mean square error improved the performance.

Training data was split into 10 different folds, by using stratified splits which were achieved by generating 10 bins over the continuous bins. Ten different models were generated with permutations of 9 out of 10 folds as training and remaining 1 as validation dataset. Finally, dev dataset is passed over all the models and mean of all the models were considered as output. This can be seen as a variation of weak learners concept in decision trees.

For the testing dataset as mentioned earlier, we combine training and development set and then

generate 10 folds to create 10 models with 80-20 split for validation. Parameters used for models are stated in table 2. In addition, we have used Adam optimizer with 0.0001 as learning rate.

Table 2: Parameters for Regression Task.

Layers	Units	Activation	Regularization	Dropout
BiLSTM - Tower 1	70	Tanh	L2 - 0.05	0.35
BiLSTM - Tower 2	70	Tanh	L2 - 0.05	0.35
Attention	-	-	L2 - 0.01	-
Max Pooling	-	-	-	-
Fully Connected Layer 1	100	Selu	L2 - 0.001	0.5
Fully Connected Layer 2	50	Selu	L2 - 0.001	0.3
Output Layer	1	Sigmoid	-	-

The output of deep learning models is considered as a feature for our ensemble method, where we combine other features as mentioned in section 2.3 and section 2.4. In addition to this, the output of other emotion is also used as a feature for the ensemble model which provides an additional context for the prediction task. So, for each emotion in a task, we get additional features from deep learning model which we define as a cross emotion features.

All this features are then passed on to the support vector regression, whose parameters C and $Kernel$ are tuned using 10 fold cross validation over training set.

3.2 EI-oc and V-oc: Classification

Objective of this task was to classify tweet into one of the ordinal classes, given a tweet and its corresponding emotion. Number of classes for EI-oc were four and for V-oc it was seven. Official evaluation metric for this task was provided as pearson correlation. Output layer in the deep learning model contained four and seven neurons for EI-oc and V-oc respectively with softmax as the activation function. Loss function used for classification task was *categorical_crossentropy*. Similar settings of 10-fold as mentioned in regression task earlier was carried out resulting in 10 different models for each emotion and valence. Layer parameters for this task are summarized in table 3. Stochastic gradient descent with nesterov momentum and learning rate 0.01 was used as optimizer for this task.

Similar to regression task, for classification we create ensemble model by combining output of deep learning models with other features. In addition, we also consider output of regression models as additional features for classification. Support vector classifier is used as a final classifier,

Table 3: Parameters for Classification Task.

Layers	Units	Activation	Regularization	Dropout
BiLSTM - Tower 1	50	Tanh	L2 - 0.05	0.4
BiLSTM - Tower 2	50	Tanh	L2 - 0.05	0.4
Attention	-	-	L2 - 0.001	-
Max Pooling	-	-	-	-
Fully Connected Layer 1	50	Selu	L2 - 0.01	0.4
Fully Connected Layer 2	20	Selu	L2 - 0.01	0.4
Output Layer	5/7	Softmax	-	-

Table 4: Parameters for Multi-Label Classification Task.

Layers	Units	Activation	Regularization	Dropout
BiLSTM - Tower 1	120	Tanh	0	0.3
BiLSTM - Tower 2	120	Tanh	0	0.3
Attention	-	-	0	-
Max Pooling	-	-	-	-
Fully Connected Layer 1	100	relu	L2 - 0.01	0.3
Fully Connected Layer 2	50	relu	L2 - 0.01	0.2
Output Layer	11	Softmax	-	-

with C and $Kernel$ being tuned using 10-fold cross validation. Final submission is done with model being trained by combining training and development dataset and then taking 80-20 split for training and validation.

3.3 E-c: Multilabel Classification

In this task, we were provided with tweet and its corresponding labels among 11 emotion: *anger, anticipation, disgust, fear, joy, love, optimism, pessimism, sadness, surprise and trust*. For this task, output layer of our deep learning model contains 11 neurons and sigmoid as a activation function. *Binary cross entropy* is used as a loss function with *Stochastic gradient descent* with Nesterov momentum, 0.01 learning rate and 10^{-6} learning rate decay as optimizer. Parameters for other layers are presented in table 4.

Official evaluation metric for this task was Jaccard similarity score. The output of the deep learning model gives values between $0-1$ for each emotion. Since the task was to predict the presence or absence of any emotion continuous value must be converted to binary number. Threshold was applied which was learned from training and development set. For training set we found the threshold to be 0.35 , whereas for development set it was found to be 0.30 . For testing set, we take the mean of both the values as threshold.

4 Results and Discussion

In total 75 teams participated in the task, our system was ranked 2^{nd} for V-reg task, 5^{th} for EI-reg task and 7^{th} for both V-oc and EI-oc task. For

Table 5: Comparison of proposed deep Learning model and ensemble model over train and development set for regression task.

	Development Set				Test Set			
	Original Split		80-20 Split		Original Split		80-20 Split	
	Ensemble System	Deep Learning Model						
Fear	0.751	0.707	0.791	0.791	0.745	0.725	0.736	0.74
Anger	0.79	0.718	0.747	0.744	0.775	0.721	0.776	0.749
Sadness	0.735	0.689	0.77	0.767	0.764	0.723	0.776	0.741
Joy	0.723	0.675	0.812	0.775	0.767	0.724	0.77	0.731
Average	0.75	0.697	0.78	0.769	0.763	0.723	0.764	0.74
Valence	0.857	0.804	0.85	0.788	0.858	0.832	0.861	0.84

Table 6: Results of Regression and Classification task over test set.

	Reg		OC	
	Orginal Split	80-20 Split	Orginal Split	80-20 Split
Fear	0.745	0.735	0.595	0.561
Anger	0.775	0.775	0.626	0.641
Sadness	0.764	0.776	0.618	0.621
joy	0.767	0.77	0.65	0.655
Average	0.76275	0.764	0.62225	0.6195
Valence	0.858	0.861	0.727	0.777

Multi-Label classification, our system achieved 2nd rank among the teams, with Jaccard similarity score of 0.582.

Table 6 shows the result for EI-reg, V-reg, EI-oc and V-oc task on official evaluation metric i.e. pearson correlation. We also compare the results over the original split and 80-20 split generated after combining training and development dataset. It can be seen that both of these gives similar results while, for classification original split is better, for regression it is other way. Table 5 shows comparison of Ensemble model and Deep learning model for EI-reg and V-reg. We observe improvement in ensemble model over development dataset in both sets of splits. On the contrary, there is relatively less difference in the test set.

Table 7 contains results of different deep learning architecture for EI-reg and V-reg task. For both of these task, we can observe what is impact of attention over both the towers. We also present the results for each single tower which helps in understanding the need for two towers. Although adding attention over Tower-1 gives little improvement for EL-reg task it provides significant improvement for V-reg task. It is worthwhile to note that *sadness* emotion shows no improvement by adding attention over tower-2.

Table 7: Regression Task Results over model different architectures over test set:80-20 Split.

	Anger	Fear	Sadness	Joy	Average	Valence
Proposed Model	0.749	0.74	0.741	0.731	0.74	0.84
Tower-1	0.727	0.727	0.704	0.709	0.717	0.825
Tower-2	0.714	0.719	0.673	0.70	0.705	0.792
Tower-1 without Attention	0.721	0.709	0.69	0.704	0.711	0.783
Tower-2 without Attention	0.693	0.692	0.673	0.682	0.685	0.766

Table 8: Results of Individual Features in combination with Deep learning features over development set.

Features	Anger	Fear	Sadness	Joy	Valence
dl	0.744	0.791	0.767	0.775	0.788
dl+baselines	0.747	0.792	0.773	0.778	0.789
dl+vader	0.747	0.792	0.772	0.775	0.785
dl+sentineuron	0.748	0.79	0.773	0.778	0.79
dl+valence	0.751	0.792	0.77	0.785	-
dl+cross emotion	0.75	0.794	0.773	0.778	0.809

In table 8 and table 9, results on regression task for 80-20 split for each feature when combined with deep learning feature over development and test set respectively. We observe that adding lexicon features marginally increases the performance of the system. We can conclude from this that deep learning model that we presented can encapsulate most of the information regarding the sentiment which was present in traditional features. Including cross-emotion feature shows considerable increase in the performance.

Inter-feature correlation is presented in figure 4, where we can observe that apart from anger and valence baseline features are weak negatively correlated with other features. Furthermore, vader and sentineuron are less correlated except for valence and yet they provide similar improvement when combined individually with DL features. Although, when both these features are combined together they provide a significant boost.

Table 9: Results of Individual Features in combination with Deep learning features over test set.

Features	Anger	Fear	Sadness	Joy	Valence
dl	0.749	0.74	0.741	0.731	0.84
dl+baselines	0.755	0.739	0.742	0.731	0.84
dl+vader	0.753	0.744	0.746	0.731	0.841
dl+sentineuron	0.753	0.739	0.752	0.734	0.842
dl+valence	0.756	0.743	0.745	0.74	-
dl+cross emotion	0.759	0.744	0.753	0.738	0.849

For classification task across four emotion and valence we observed that, using threshold values obtained by comparing continuous values from regression task provides a better result in pearson correlation. Possible reason for this might be the loss function that we trained for classification model was categorical cross entropy.

4.1 Error analysis

We observe that high difference between the predicted value/class and truth value/class are present at the extreme end of the spectrum. One of the possible reason might be that the distribution of the data shows a Gaussian distribution and there are few samples at the extreme end as described in (Mohammad and Kiritchenko, 2018). In addition, we manually inspect some cases where our model failed, for example for sadness *You are MINE, my baby, my headache, my love, my smile, my frown, my wrong, my right, my pain, my happiness, my everything.* has truth value of 0.140 and our system predicted 0.568 which is way higher than what the writer is trying to convey. The model is predicting slightly above neutral sentiment. Possible reasons include the presence of both positive and negative words present in the alternate sequence. This kind of discourse and irony detection can help in better prediction if incorporated into the models.

In joy emotion, *when will i ever be happy with myself?* has a truth value of 0.109 and predicted value is 0.491 . These kind of rhetorical questions is hard to understand even for humans, for model to understand we need to put in some explicit context. By observing more such samples, we find that adding more context about the different physiological and linguistic phenomenon into the model with appropriate bias can greatly increase the accuracies of the models present.

Table 10 shows the error across different emotions in multi-label task. We observe that there is a high error rate in *anticipation, pessimism, sur-*

Table 10: Multi-label Error across Emotions.

Emotion	Error	Presence total	Ratio
Anger	521	1101	0.473
Anticipation	469	425	1.103
Disgust	646	1099	0.588
Fear	251	485	0.518
Joy	477	1442	0.331
Love	405	516	0.785
Optimism	704	1143	0.616
Pessimism	398	375	1.061
Sadness	539	960	0.561
Surprise	167	170	0.982
Trust	161	153	1.052

prise and trust, possible reasons might be that there are already fewer samples available and the ratio of percentage votes received to the percentage of tweets labeled is also high for this emotion as compared to other emotions (Mohammad and Kiritchenko, 2018). In addition, we observe that there are around 2% of the tweets contained no emotion in test set, where our model predicted at-least one emotion.

5 Conclusion

In this paper, we describe our approach to SemEval-2018 Task-1 for English tweet. We present ensemble system which is capable of handling noisy sentiment dataset over regression, classification as well as multi-label dataset. Use of the mixture of embedding in parallel makes this system unique in terms of generating better representations with respect to sentiment. Our system achieved 2^{nd} , 5^{th} and 7^{th} in different subtasks. Analyzing different feature combinations from individual results and inter-feature correlation over test data reveals that our deep learning model is able to capture most of the information that is provided by lexicon feature. Multi-label classification has proved to be a challenging task among all the subtask that has been provided as the evaluation score of all the team participating has been low.

We have also presented some examples where our model has performed poorly and conclude that including context feature for sarcasm, irony and rhetoric question can improve the performance further over all the subtasks presented in SemEval for English language.

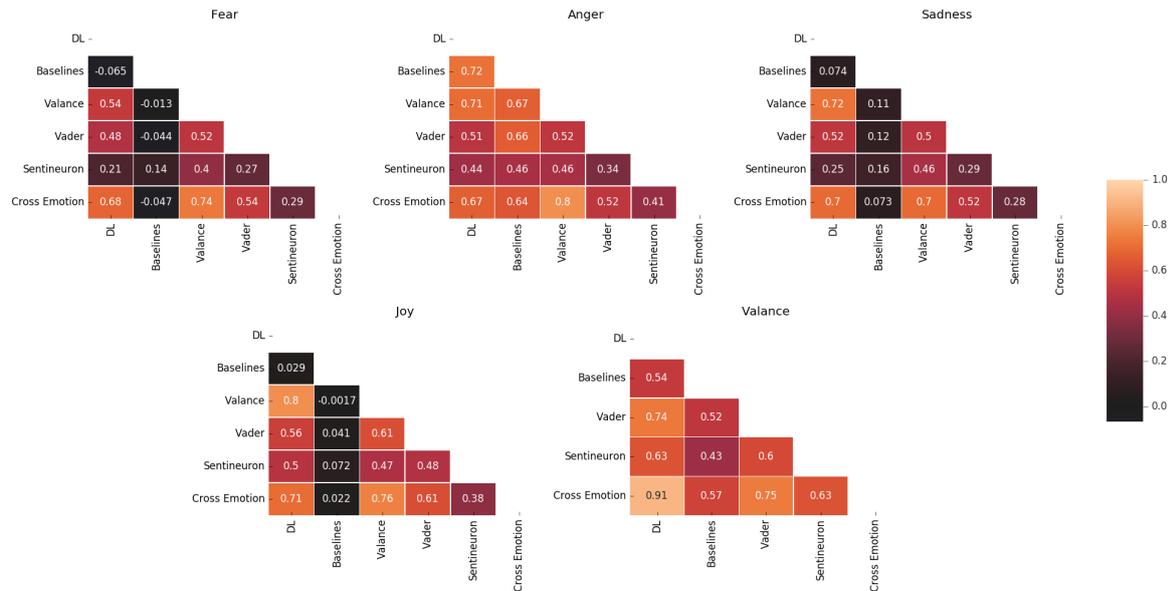

Figure 4: Correlation among various features for test set.

DMCB at SemEval-2018 Task 1: Transfer Learning of Sentiment Classification Using Group LSTM for Emotion Intensity prediction

Youngmin Kim, Hyunju Lee

Gwangju Institute of Science and Technology,
Data mining and Computational Biology Lab, Gwangju, Korea
{minok00, hyunjulee}@gist.ac.kr

Abstract

This paper describes a system attended in the SemEval-2018 Task 1 “Affect in tweets” that predicts emotional intensities. We use Group LSTM with an attention model and transfer learning with sentiment classification data as a source data (SemEval 2017 Task 4a). A transfer model structure consists of a source domain and a target domain. Additionally, we try a new dropout that is applied to LSTMs in the Group LSTM. Our system ranked 8th at the subtask 1a (emotion intensity regression). We also show various results with different architectures in the source, target and transfer models.

1 Introduction

Sentiment analysis is one of the most famous Natural Language Process (NLP) task. In this study, we perform a task that predicts emotional intensities of anger, joy, fear and sadness with tweet messages, where intensity values range from 0 to 1. This task is competed at SemEval-2018 Task 1 (Mohammad et al., 2018). In previous studies, neural networks with word embedding and affective lexicons were widely used (Goel et al., 2017; He et al., 2017). Also, many studies employed support vector regression (Duppada and Hiray, 2017; Akhtar et al., 2017).

Transfer learning was recently proposed as an effective approach to have higher performance, when data is not abundant. Using a pre-trained deep-learning model with an abundant data set has been popular and shows good results in various tasks (Donahue et al., 2014; Conneau et al., 2017). Especially in a medical image task, it is very efficient because of lacks of medical data (Tajbakhsh et al., 2016). Just as humans can learn new things better with their past knowledge, neural networks can also be trained on target domains by transferring knowledge from the source domain.

We make a transfer model that can be divided into a source model and a target model. The source model is constructed based on the paper (Baziotis et al., 2017). The model of this paper uses LSTM with attention. However, we introduce Group LSTM (GLSTM) (Kuchaiev and Ginsburg, 2017) with a new dropout. After then, we make the target model with LSTM.

In the result section, we provide comparison of LSTM and GLSTM in the source model, and results of various pre-trained word embeddings with target model. Finally, we discuss about the result of the transfer model that is a combined model with the source and target models.

2 System Description

2.1 Data and Label

For transfer learning, we use a source data provided by SemEval 2017 Task4 (a) (Rosenthal et al., 2017). The task of the source domain is to classify sentences to positive, negative and neutral sentences. Training data is 44,613 sentences (10% are used as a development set), and test data is 12,284 sentences for the source model evaluation. For transfer learning in this study, all training and test data are used as training data.

For the target domain, training data is about 2,000 sentences for each emotion. Although the main task is regression prediction, we change it as distribution prediction (Tai et al., 2015). In this way, we deal it as a classification problem. Intensity scores y are changed to labels \mathbf{t} satisfying:

$$t_i = \begin{cases} y' - \lfloor y' \rfloor & \text{if } i = \lfloor y' \rfloor + 1 \\ \lfloor y' \rfloor - y' + 1 & \text{if } i = \lfloor y' \rfloor \\ 0 & \text{otherwise} \end{cases}$$

where $i = [1, 2, 3, 4, 5]$ and $y' = 4y$

Size of the final output is 5. For example, if an intensity score y is 0.7, label \mathbf{t} is $[0, 0, 0.2, 0.8, 0]$.

With given $\mathbf{r} = [0, 0.25, 0.5, 0.75, 1]$, label y can be obtained again by dot product with \mathbf{t} and \mathbf{r} ($0.7 = 0.2 \cdot 0.5 + 0.8 \cdot 0.75$).

2.2 Text preprocessing

To normalize words and remove noise in sentences, we use ekphrasis library (Baziotis et al., 2017). It helps to apply social tokenizer, spell correction, word segmentation and various preprocessing. We normalize time and number, and omit URL, email and user tag. Annotations are added on hashtags, emphasized and repeated words. We annotate them as a group because hashtags are gathered in many cases (see Table 1). Lastly, emoticons are changed to words that represent emoticons.

#letsdance #dancinginthemoonlight #singing
$\Rightarrow \langle \text{hashtag} \rangle$ lets dance dancing in the moonlight singing $\langle / \text{hashtag} \rangle$

Table 1: Example of preprocessing hashtag

2.3 Word embedding

We try five pre-trained word embeddings to choose the best one for the target model. Two are trained with GloVe (Pennington et al., 2014) using different data sets: one¹ is trained with very large data in Common crawl, and the other² is made with tweets (Baziotis et al., 2017). Other word embedding methods are fastText³ (Bojanowski et al., 2016), word2vec⁴ (Mikolov et al., 2013) and LexVec⁵ (Salle et al., 2016). LexVec is the mixed version of GloVe and word2vec. Dimensions of them are all 300. Among them, GloVe with tweet is used for the source and transfer models.

Emoji can be good features but most of emoji ideograms are not contained in embedding vocabulary. Hence, we change a emoji to a phrase with python ‘emoji’ library. For example, 😊 is decoded to “Smiling Face with Open Mouth and Smiling Eyes”. Because it is quite long, embedding vectors of emoji are changed to mean of vectors of each decoded words. In this way, we reduce Out-Of-Vocabulary and prevent the sentence from lengthening.

2.4 LSTM and GLSTM

Recurrent Neural Network (RNN) works well in a sequence model like language by addressing its arbitrary length (Tai et al., 2015). However, RNN is difficult to be optimized because of a gradient vanishing problem. To solve it, LSTM suggested a cell state and gates as bridges to control the flow of error (Hochreiter and Schmidhuber, 1997).

GLSTM is just a group of several LSTMs, where outputs of LSTMs are concatenated. The idea is that LSTM can be divided into several sub-LSTMs (Kuchaiev and Ginsburg, 2017). This model has some advantages compared to the original LSTM. The number of parameters is reduced with a preserving feature size. Also, it can be parallelized and computation times are reduced because the computation of each sub-LSTM is independent.

2.5 Dropout

To avoid overfitting and achieve generality, we use three types of dropout. One is normal dropout between layers (Srivastava et al., 2014). If a shape of the layer is sequential, dropout mask is shared on sequential axis. Another dropout is inside cells of LSTM. In the each LSTM cell, the same dropout mask is applied on hidden values that come from the previous cell (Zaremba et al., 2014). Applying different dropout masks for each cell can mislead memory and information. With the same dropout mask, however, LSTM cell can dropout nodes consistently so that the model can forget or memorize information stably. The last one is dropout between sub-LSTMs. To get more generality, we dropped several LSTMs in GLSTM. For example, if GLSTM consist of five sub-LSTMs, we dropped two LSTMs and only use the rest three LSTMs.

3 Model structure

3.1 Source model

For the source model, Glove with tweets is used as input vectors of the embedding layer. After embedding layer, two GLSTM layers are stacked. GLSTM is made of 5 LSTMs with 40 feature size. Additionally, we concatenate forward and backward GLSTM to be bidirectional. So hidden size of each recurrent layer is 400 ($= 5 \times 40 \times 2$).

Next is an attention layer, which calculates importance of each time step. Attention mechanism shows good performance on sequential tasks like

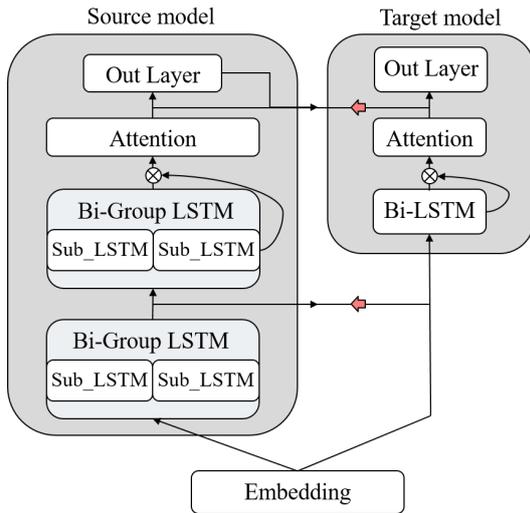

Figure 1: Structure of models. For the transfer model, connections between source and target models are used. Large arrows are paths of reduced gradient flow during backpropagation.

machine translation (Bahdanau et al., 2014) and sentiment analysis (Baziotis et al., 2017). It helps to concentrate position related to emotion. Attention values are calculated:

$$e_t = W_h h_t + b_t$$

$$a_t = \frac{\exp(e_t)}{\sum_i \exp(e_i)}, \quad \sum a_t = 1$$

Calculated attention values are multiplied by each current hidden state and they are all added up.

Passing through the attention layer, the output becomes non-sequential representation vectors. It enters a fully connected softmax layer as a final classification layer, where the size of the layer is 3.

3.2 Target model

Unlike the source model, a normal bi-LSTM is used with 100 feature size. After then, attention and output layers are stacked. The size of output layer is 5.

For transfer learning, outputs of several layers on the source model are used as additional features. The LSTM layer on the target model takes as input the concatenation of the embedding layer and the first LSTM layer output of the source model. After the attention layer, in a similar way, outputs of the attention and the final layers on the source model are concatenated and entered into the final layer as input.

3.3 Regularization

At the embedding layer, Gaussian noise is applied with $\sigma = 0.2$. It helps models to be robust by avoiding overfitting on specific features of words. Dropouts are used everywhere between layers with probability $p = 0.3$ except before the final layer. Before the final layer, $p = 0.5$ dropout is applied. Additionally, LSTM dropout was applied on every LSTM layers with $p = 0.3$. The probability of dropout at GLSTM on the source model is 0.3. Also, we use L2 normalization. It prevents weights to be large values by adding weight penalty to loss. We set up it with 0.001 for the source model and 0.0001 for the target model.

3.4 Training

For the source and target models, categorical cross-entropy is used as a loss function. For updating weights, we apply the Adam (Kingma and Ba, 2014) optimizer with a learning rate of 0.001. During training the transfer model, since we want to preserve target model weight parameters with a little updating, we decrease gradient flow of backpropagation from the source model to the target model by 0.05 times (see large arrows on Figure 1). Because there are many parameters on the final model, we take that constraint to prevent overfitting.

4 Result and discussion

4.1 GLSTM

Figure 2 shows the result of GLSTM and normal LSTM on the source model for Sentiment Classification (SemEval 2017 Task 1a). We tried various feature sizes. The number of sub-LSTM in GLSTM is fixed to 5 and the feature size of each sub-LSTM is changed. As the sizes of features increase, the performances of GLSTM increase. On the other hand, although the performances of LSTM gradually improve with larger feature sizes, it starts to decrease rapidly after 100. Thus, we infer that GLSTM with dropout is more effective on overfitting than LSTM with larger feature size. Based on this result, we use GLSTM for the source model.

4.2 Various Embedding

We tested five different word embedding vectors using the target model to choose the best embedding. To compare the performances of embeddings, the embedding layers was not trained

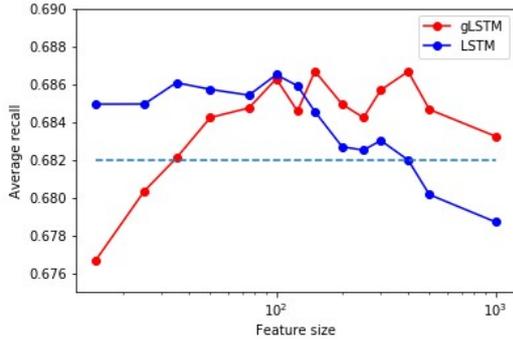

Figure 2: Performance comparison between GLSTM and LSTM on the source model for sentiment classification. A dotted line is the result of (Baziotis et al., 2017).

Embedding	Avg	Anger	Fear	Joy	Sadness
Tweet GloVe	.690	.730	.670	.675	.684
Common GloVe	.667	.690	.624	.656	.698
Fast Text	.639	.667	.586	.638	.665
Word2vec	.654	.704	.599	.631	.681
Lex vec	.648	.656	.630	.646	.659

Table 2: Pearsons correlation of Dev set on the target model for SemEval-2018 Task1(a).

(static). Note that we did not use transfer learning in this experiment. Table 2 shows Pearson correlation between the given emotion intensities and predicted intensities by the models on the development set. Tweet GloVe had the best score and Common GloVe showed the second best score. Hence, we decided to do transfer learning with Tweet GloVe and Common GloVe.

4.3 Transfer

Our main task results are described in Table 3. There are four models. Tweet GloVe and Common GloVe were picked from the conclusion of 4.2, and we performed two approaches: training the embedding layer or not (non-static or static) (Kim, 2014). Tweet GloVe with static showed the best performance as a single model and it is almost same to non-static. However, the non-static method had a higher score than the static for Common GloVe embedding. In addition, the ensemble model by averaging all single models showed better performance than the single models. We also found that compared to the scores without trans-

fer learning on dev set (Table 2), there were significant performance improvements when transfer learning used in Table 3.

5 Conclusion

This paper described the system submitted to SemEval-2018 Task 1: Affect in tweets and analysis of various models. Various embedding vectors were tried and we chose Tweet GloVe with static. The main method is LSTM with attention and transfer learning that uses sentiment classification as source domain. In future work, we will perform transfer learning with labeled data sets such as SNLI or SST data sets. Also, training tagging or tree parsing can be used for transfer learning.

Abstract

In this paper, we propose a regression system to infer the emotion intensity of a tweet. We develop a multi-aspect feature learning mechanism to capture the most discriminative semantic features of a tweet as well as the emotion information conveyed by each word in it. We combine six types of feature groups: (1) a tweet representation learned by an LSTM deep neural network on the training data, (2) a tweet representation learned by an LSTM network on a large corpus of tweets that contain emotion words (a distant supervision corpus), (3) word embeddings trained on the distant supervision corpus and averaged over all words in a tweet, (4) word and character n-grams, (5) features derived from various sentiment and emotion lexicons, and (6) other hand-crafted features. As part of the word embedding training, we also learn the distributed representations of multi-word expressions (MWEs) and negated forms of words. An SVR regressor is then trained over the full set of features. We evaluate the effectiveness of our ensemble feature sets on the SemEval-2018 Task 1 datasets and achieve a Pearson correlation of 72% on the task of tweet emotion intensity prediction.

1 Introduction

The widespread use of micro-blogging and social networking websites such as Twitter for conveying information, sharing opinions, and expressing feelings, makes the sentiment analysis of tweets an attractive area of research. However, sentiment analysis is challenging because people often convey their emotions indirectly and creatively, rather than explicitly stating how they feel. Sentiment analysis of tweets is additionally challenging because of the frequent occurrences of non-standard language and poor grammatical structure. Tweets also often contain misspellings, abbreviations, hashtags, and emoticons.

Various machine learning approaches have been developed for Twitter sentiment classification. Most of these algorithms train a classifier over tweets with manually annotated sentiment intensity labels and learn the most discriminative features. Hence, designing an effective feature engineering algorithm can improve classification performance, greatly. Mohammad et al. (2013; 2014) used many different sentiment lexicons (manually created and automatically generated), as well as a variety of hand-crafted features to build the top-ranked system for Twitter sentiment classification tasks in SemEval-2013 and SemEval-2014. Sentiment lexicons, either hand-crafted or algorithmically generated, consist of words and their associated polarity scores. However, since feature engineering is labour intensive and usually needs domain-specific knowledge, sentiment classification algorithms with less dependency on feature engineering are attracting considerable interest.

Socher et al. (2013) proposed a feature learning algorithm to discover explanatory factors in sentiment classification. They consider the representation of a sentence (or document) as a composition of the representations of its constituent words or phrases. This way, the sentiment classification problem reduces to learning an effective word representation (or word embedding) that not only models the syntactic context of words but also captures sentiment information of the sentence. Tang et al. (2014) extended the traditional word embedding methods (Mikolov et al., 2013b; Collobert et al., 2011) by encoding sentiment information into the existing continuous representation of words. They built sentiment-specific word embedding (SSWE) by developing three neural networks wherein the sentiment polarity of the tweet is incorporated in the neural networks' loss functions. Teng et al. (2016) proposed a context-sensitive lexicon-based method using recurrent and simple

Emotion	Train	Dev.	Test	Total
anger	1,701	388	1,002	3,091
fear	2,252	389	986	3,627
joy	1,616	290	1,105	3,011
sadness	1,533	397	975	2,905
Total	7,102	1,464	4,068	12,634

Table 1: Number of instances provided in the Tweet Emotion Intensity dataset (SemEval-2018 Task 1, EI-reg English). The data was divided into train, development, and test sets.

feed-forward neural networks to extract sentiment lexicons and produce a new polarity weight, respectively.

Unlike lexicon-based sentiment analysis, deep learning approaches are effective in exploring both linguistic and semantic relations between words (Liu et al., 2015). However, due to the limited amount of high-quality labeled data, it is difficult to train deep models with a large number of hyperparameters for sentiment analysis tasks. Additionally, manual labeling of data is costly and requires domain expert knowledge, which is not always available.

In this paper, we describe two systems: System I, our official submission to the competition, and System II, our best model. In both systems, we combine deep learning and lexicon-based approaches to extract the most informative semantic and emotion representations of tweets. We train two LSTM models, one on the provided training data and another one on a large corpus of tweets that contain emotion words, to obtain emotion-specific tweet representations. We augment this feature space with word and character n-grams, features derived from several sentiment and emotion lexicons as well as other hand-crafted features. Our best model achieves an average Pearson correlation of 71.96% on the official EI-reg test dataset.

2 Data

The English training, development, and test datasets used in our experiments were provided as part of the SemEval-2018 Task 1, EI-reg subtask (Mohammad et al., 2018).¹ The data files include tweet id, tweet text, emotion of the tweet, and the emotion intensity. An overview of the data is provided in Table 1.

¹A detailed description of the English datasets and the analysis of various affect dimensions is available in Mohammad and Kiritchenko (2018).

2.1 Data preparation

The following pre-processing steps were applied to each of the training and test tweets:

- Remove URLs and usernames.
- Lower-case all the tweet text.
- Substitute abbreviated phrases such as *I've*, *don't*, *I'd*, etc. with their long forms.
- Replace tweet-specific acronyms such as *gr8*, *lol*, *rofl*, etc. with their expanded forms.
- Substitute the elongated words with the same words but keeping at most two consecutive occurrences of repeated letters.
- Standardize all the emojis in data to their explanatory phrases using emoji Python package².
- Remove all the HTML character codes.
- Replace all occurrences of a multi-word expression (MWE) by a unique identifier. We use WikiMWE (Hartmann et al., 2012), which contains all multi-word expressions from Wikipedia.
- Generate the negated form of all the tokens that occur between any of the negation words, such as *no*, *not*, *never*, etc., and a punctuation mark.
- Remove special characters, numbers, non-English words or phrases.
- Normalize all adjectives and adverbs in test data that do not exist in train or development data sets with adjective or adverb in the training data which shares the most common Synsets of WordNet with it (if we find more than one candidate, we replace the adjective with the most frequent one in the training data).
- Applying WordNet lemmatizer to have the simple singular form of tokens with part-of-speech tags of adjective, adverb, verb or noun.

The tweets are now fed to the system.

²<https://pypi.org/project/emoji/>

3 System Description

We created two models: System I, our official submission to the competition, and System II, our best model. Both models address the task of emotion intensity prediction (EI-reg): given a tweet T and an emotion e , predict a real-valued intensity score (in the range $[0, 1]$) of e that represents the emotional state of the author of the tweet T .

3.1 System I

Our first model takes advantage of both embedding-based and lexicon-based features. In particular, the following feature sets are generated:

- Embedding-based features:
 - Average word embedding vector;
 - Representation of a tweet learned by an LSTM neural network on the provided training data;
- Lexicon-based and n-gram features:
 - Word and character n-gram features;
 - Vector of 43 lexicon-derived features, compiled using the AffectiveTweets package (Mohammad and Bravo-Marquez, 2017).³ The lexicons used include those created by Nielsen (2011); Mohammad and Turney (2013); Kiritchenko et al. (2014); Hu and Liu (2004); Bravo-Marquez et al. (2016); Thelwall et al. (2012); Wilson et al. (2005).

We use bag-of-words (BOW) (Pang et al., 2002) and term frequency-inverse document frequency (tf-idf) methods to extract different word and character n-grams. We train word embeddings on a large corpus of tweets that contain emotion words. Then, we refine our learned word embeddings to build emotion-specific word embeddings for every emotion. Specifically, we assign emotion-specific weights to every word in our learned word embeddings and multiply each word vector by weights. These emotion-specific weights are obtained by calculating the Pearson correlation between the extracted unigram features and intensity labels of the training and development datasets of each emotion.

³<https://affectivetweets.cms.waikato.ac.nz/>

We concatenate two learned embedding-based tweet representations, word and character n-grams, and the lexicon features in a multimodal feature layer. We train a Random Forest (RF) over this heterogeneous multimodal feature layer to predict emotion intensity of a tweet.

This approach was evaluated on the datasets of SemEval-2018 Task 1, EI-reg (an emotion intensity regression task) and EI-oc (an emotion intensity ordinal classification task), for which it obtained Pearson correlations of 57.5% and 48.5% on the test sets, respectively.

Further investigation revealed that our system I was overfitted to the training data and lost its generalization ability over new unseen data. The cause of this problem was the use of development dataset labels in our feature engineering algorithm. So, we modify our model to overcome overfitting and propose system II.

3.2 System II

Similarly to System I, our second model incorporates both embedding-based representations and linguistic knowledge in a unified architecture (see Figure 1). We train a Support Vector Regressor (SVR) over the following two categories of features:

- Embedding-based features:
 - Average word embedding vector;
 - Representation of a tweet learned by an LSTM neural network on the provided training data;
 - Emotion-polarized representation of a tweet learned by an LSTM neural network on a distant supervision corpus;
- Lexicon-based and hand-crafted features:
 - Word and character n-gram features;
 - Vector of 43 lexicon-derived features, compiled using the AffectiveTweets package (Mohammad and Bravo-Marquez, 2017);
 - Hand-crafted features based on either word similarities in learned word embeddings or emotion intensity similarities in accordance to train and development labels.

Below, different components of the two systems are explained in detail.

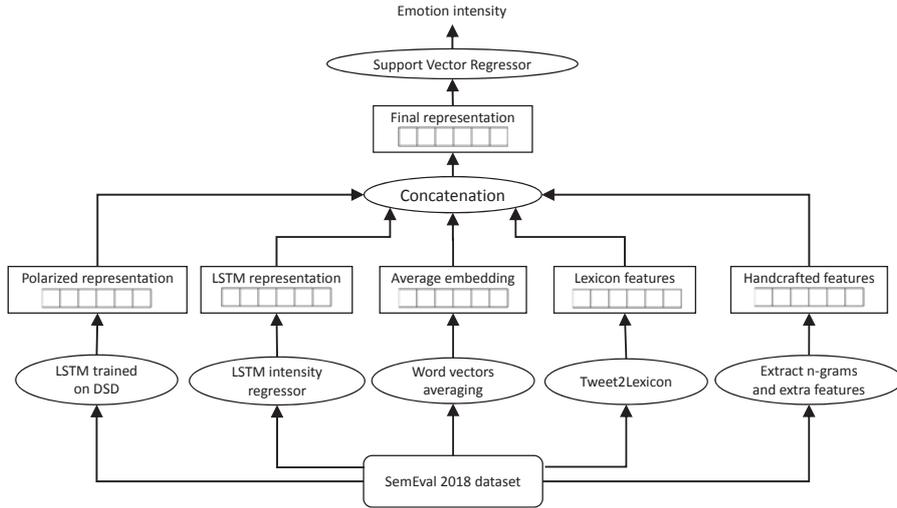

Figure 1: The architecture of our model (System II).

3.3 Word embedding layer

Since the input of our model is a sequence of tokens $\{w_1, w_2, \dots, w_n\}$, it is crucial to learn an effective word representation for automatic emotion analysis. A word embedding is a dense, low-dimensional and real-valued vector associated with each word w_i . We used word2vec (Mikolov et al., 2013a) and SVD-NS (Soleimani and Matwin, 2018) to learn word embeddings and trained it on an unlabeled corpus of 21M tweets provided as part of the SemEval-2018 Affect in Tweets Distant Supervision Corpus (SemEval-2018 AIT DISC) (Mohammad et al., 2018). SVD-NS works better for word and sentence similarity tasks and is much faster than word2vec. Such distributed word representations learned from massive text data make feature engineering less dependent on the task. However, unsupervised learning of word embeddings cannot thoroughly capture finer context-based semantic information of a specific task. Hence, to incorporate linguistic structure of tweets, we use the following two techniques to improve the word vectors:

1. Our model learns a unique distributed representation for every Multi-Word Expression (MWE). MWEs occur frequently in tweets, and their meanings are often not derivable from the meanings of the constituent words.
2. Additionally, our model learns an embedding vector to represent the negated form of every word occurring between a negation word (e.g., *no*, *shouldn't*) and the following punc-

uation mark. Due to the significant impact of negation words in changing the sentiment polarity of a sentence, we treat the negated tokens differently (Zhu et al., 2014; Kiritchenko et al., 2014). By adding a ‘NEG’ prefix to them, we consider the negated tokens as different entities and learn separate word representations for them.

To learn word embeddings, we applied two methods: the continuous skip-gram model (Mikolov et al., 2013a) with the window size of 5, and SVD-NS (Soleimani and Matwin, 2018) with the PMI threshold of $\alpha = -2.5$. The vector dimensionality was set to $d = 100$. We also filter words that occur less than 3 times in the corpus.

3.4 Average embedding layer

To capture the global context of a tweet, we build a tweet embedding by vertically concatenating embedding vectors of its n words. This yields a tweet embedding matrix $X \in R^{n \times d}$. Then, we take the mean of these word embeddings across the tweet length. Therefore, an average embedding will add d features (equal to the number of our word embedding dimensions) to our multimodal feature layer.

3.5 Tweet embedding vector learned by LSTM layer

To learn a semantic representation of a tweet, we use an LSTM neural network, which we found effective in detecting salient words of a sentence while automatically attenuating unimportant

words. The LSTM model sequentially takes each word in a sentence, extracts its information, and embeds it into a semantic vector. Due to its ability to capture long-term memory, LSTM accumulates increasingly richer information as it goes through the sentence, and when it reaches the last word, the hidden layer of the network provides a semantic representation of the whole sentence (Palangi et al., 2016). To be able to train sequential neural networks in batches, we normalize tweet length by zero padding and then feed the zero-padded tweet embedding matrix to an LSTM layer. We apply dropout (Srivastava et al., 2014) on the LSTM layer to prevent network parameters from overfitting and control the co-adaptation of features. Our LSTM layer is then followed by two fully connected hidden layers, and one output layer. Each of these layers computes the transformation $f(W_i * x_i + b_i)$ for $i = \{1, 2, 3\}$, where W is the weight matrix, b is the bias vector and f is a *Relu* non-linear activation function for hidden layers and a *Sigmoid* neuron for output layer. The full network is trained on the provided training data to predict the intensity score of the input tweet. We consider the representation obtained from the first hidden layer as a sentence embedding vector of an input tweet.

The network parameters are learned by minimizing the mean squared error (MSE) between the actual and predicted values of emotion intensity on the training data. We optimize this loss function by back-propagating through layers via mini-batch gradient descent, with batch size of 32, 40 training epochs, and Adam optimization algorithm (Kingma and Ba, 2014) with learning rate of $\alpha = 0.001$. We use one LSTM layer with 64 neurons, followed by a dropout of 0.2, and two hidden layers of sizes 32 and 16, respectively. We use the same network parameters for an LSTM model trained on the distant supervision data (see Section 3.6).

3.6 Emotion-polarized tweet representation learned by LSTM

We leverage large amount of Twitter data with distant supervision to polarize our word embeddings for each emotion. Hence, we use SemEval-2018 AIT DISC distant supervision corpus of tweets released by the competition organizers, which includes around 100M English tweet ids associated with tweets that contain emotion-related

query terms such as ‘#angry’, ‘annoyed’, ‘panic’, ‘happy’, etc. We collected 21M tweets by polling the Twitter API with these tweet ids. Based on the query terms, one or more emotion labels of {‘anger’, ‘fear’, ‘joy’, ‘sadness’} have been assigned to every tweet in this dataset. For each emotion, we randomly select 200,000 tweets labeled with that emotion (e.g., ‘anger’) and 200,000 tweets labeled with other emotions (‘not anger’) to build the emotion-specific word embeddings. Since the four basic emotions are not independent and may be correlated, we build these emotion-polarized word embeddings in two ways: (i) one against all strategy: for example, ‘not anger’ tweets are selected from tweets labeled with any of the other three emotions, i.e., ‘fear’, ‘joy’, or ‘sadness’; (ii) considering emotions with similar valence as one group of labels: tweets labeled with ‘anger’, ‘fear’, and ‘sadness’ are treated as they have the same label. So, here ‘not anger’ tweets are selected from tweets that are labeled only as ‘joy’. Then, we train an LSTM neural network using these emotion-specific word embeddings to build emotion-specific representations of tweets. Our final emotion-specific tweet representation obtained by concatenating two hidden state layers learned by the same LSTM neural network trained twice on the same data but with different emotion labeling according to the above two labeling strategies.

3.7 Hand-Crafted Features

In addition to the two kinds of tweet representations described above, we use bag-of-words (BOW) representation to extract most and least frequent word n-grams (unigrams, bigrams, and trigrams) as well as character n-grams (three, four, and five consecutive characters) from the training, development, and test datasets. BOW represents each word as a one-hot vector which has the same length as the size of the vocabulary, and only one dimension is 1, with all others being 0. However, the one-hot word representation cannot sufficiently capture the complex linguistic characteristics of words. We augment our feature space by generating additional hand-crafted features. We define a set of binary features by adding n adjectives with highest and lowest intensities for each emotion according to the emotion’s training data. The intensity of a word (unigram) is obtained as an average emotion intensity of tweets in the train-

	Experiment	Anger	Fear	Joy	Sadness	Average
System I (EI-reg)	WE + TE + lex	58.15	57.06	57.51	57.36	57.54
System I (EI-oc)	WE + TE + lex	49.07	41.09	55.62	48.45	48.56
	WE	62.37	60.07	56.46	60.69	60.12
	WE + MWEs	63.26	61.55	57.91	61.89	61.15
	WE + MWEs + negation	62.80	62.66	58.21	63.32	61.75
	ngram	48.30	52.65	52.44	52.01	51.35
	polTE	30.12	36.81	33.95	48.86	37.44
	TE	68.91	68.93	69.21	70.14	69.30
System II (EI-reg)	WE + lex	67.74	68.74	66.20	67.21	67.48
	WE + ngram	63.70	66.38	60.87	64.55	63.87
	WE + ngram + lex	66.99	70.27	67.46	67.67	68.10
	WE + lex + handcrafted	68.82	71.63	67.74	69.27	69.37
	WE + ngram + TE	69.69	69.54	68.49	69.66	69.35
	WE + ngram + TE + lex	69.98	73.44	69.14	73.33	71.47
	all features	72.30	70.46	71.55	73.13	71.96

Table 2: Pearson correlation (r) % obtained on the test sets. The highest score in each emotion is shown in bold. System I indicates the results of our first overfitted model and System II shows the results of our modified model. In every experiment on system II, we train SVR regressor with linear kernel to predict emotion intensity of a tweet while in system I experiments, we use RF regressor and SVM classifier for SemEval-2018 Task 1 and 2, respectively. The all-features experiment represents the model built on concatenation of all six groups of features including WE, ngram, TE, polTE, lex, and handcrft.

ing data that contain that unigram. We also add the weighted average intensity of all extracted unigrams and the intensity of their k nearest neighbors in learned word embeddings (sorted based on cosine similarity) to our feature set.

4 Results

We train the SVR regressor on the combined set of tweets in the training and development sets and apply the model on the test set. The Pearson correlation between the predictions and the gold labels was used by the competition organizers as the official evaluation measure. The percentage of Pearson correlation scores obtained by all of our individual and combined models on the test set are shown in Table 2. To make the result table easier to understand, we shortened the feature groups’ names as follows: 1) average word embedding vectors \rightarrow WE, 2) tweet embedding vectors learned by LSTM \rightarrow TE, 3) emotion-polarized tweet embeddings learned by LSTM \rightarrow polTE, 4) word and character n-gram features \rightarrow ngram, 5) AffectiveTweets lexicon features \rightarrow lex, 6) hand-crafted features based on word similarities in emotion intensity \rightarrow handcrft. All the results reported in the table use word embeddings that are obtained by SVD-NS (Soleimani and Matwin, 2018) method which was slightly better than word2vec (Mikolov et al., 2013b).

The ‘all-features’ row shows the results obtained by the model that concatenates all six groups of features including WE, ngram, TE,

polTE, lex, and handcrft. This model achieves the highest Pearson correlation score among all of our proposed models. The tweet representation learned by LSTM is the best learned unimodal feature. Considering MWEs as independent semantic units improves the average embedding model’s performance by 1.03 percentage points. Learning independent embedding vectors for negated form of words further improves the score by 0.6 percentage points.

5 Conclusion

We described a deep learning framework to predict emotion intensity in tweets. We implemented an ensemble of embedding-based feature representations and sentiment lexicon-based feature learning approaches. Our best model obtained a Pearson correlation of 71.96% on Task 1 of SemEval-2018 competition (EI-reg: an emotion intensity regression task). The tweet representation feature vector learned by LSTM was the most effective feature group amongst those that we used. Various sentiment and emotion lexicon features, our hand-crafted features and word n-grams features also helped improve prediction quality.

Abstract

This paper presents a method for Affect in Tweets, which is the task to automatically determine the intensity of emotions and intensity of sentiment of tweets. The term affect refers to emotion-related categories such as anger, fear, etc. Intensity of emotions need to be quantified into a real valued score in $[0, 1]$. We propose an ensemble system including four different deep learning methods which are CNN, Bidirectional LSTM (BLSTM), LSTM-CNN and a CNN-based Attention model (CA). Our system gets an average Pearson correlation score of 0.682 in the subtask EI-reg and an average Pearson correlation score of 0.784 in subtask V-reg, which ranks 19th among 48 systems in EI-reg and 17th among 38 systems in V-reg.

1 Introduction

Affect determination is a significant part of nature language processing. Especially, affect in tweets becomes a focus in recent years. Sentiment Analysis in Twitter, which is a task of SemEval, was firstly proposed in 2013 and not replaced until 2018. In SemEval 2018, the task Affect in Tweets (AIT) (Mohammad et al., 2018) was proposed and the objective is to automatically determine the intensity of emotions (E) and intensity of sentiment (aka valence V) of tweets. In this paper, we focus on two subtasks:

- EI-reg (emotion intensity regression) – Given a tweet and an emotion E, determine the intensity of E that best represents the mental state of the tweeter – a real-valued score between 0 (least E) and 1 (most E)
- V-reg (sentiment intensity regression) – Given a tweet, determine the intensity of sentiment or valence (V) that best represents the mental state of the tweeter – a real-valued

score between 0 (most negative) and 1 (most positive)

Before 2016, most systems use Support Vector Machine (SVM), Naive Bayes, maximum entropy and linear regression (Nakov et al., 2013; Rosenthal et al., 2014, 2015). In SemEval 2014, deep learning methods started to appear and a team using them won the second place. Since 2015, more and more teams who were rank at the top used deep learning methods and now deep learning methods including CNN and LSTM networks become really popular (Nakov et al., 2016; Rosenthal et al., 2017).

The system described in this paper is an ensemble of four different DNN methods including CNN, Bidirectional LSTM (Bi-LSTM), LSTM-CNN and a CNN-based Attention model (CA). In these methods, words in tweets are firstly mapped to word vectors. After intensity scores are calculated by these models, we use a logistic regression and finally give the scores.

The rest of the paper is organized as follows. Section 2 describes the four various methods and the ensemble method used in our system. Section 3 and Section 4 give the implementation and training details of our system for subtask EI-reg and V-reg. Section 5 states the results and discussion in the evaluation period. Finally, Section 6 makes a conclusion on this work.

2 System Description

2.1 CNN

Inspired by Kim's work on sentence classification (Kim, 2014), the architecture of the CNN model used in our system is almost identical to his model. As it is shown in Figure 1, tweets are first fed into the embedding layer, which converts words into word vectors. Then the tweet is mapped into a matrix M of size $n \times d$. In order to reduce the number

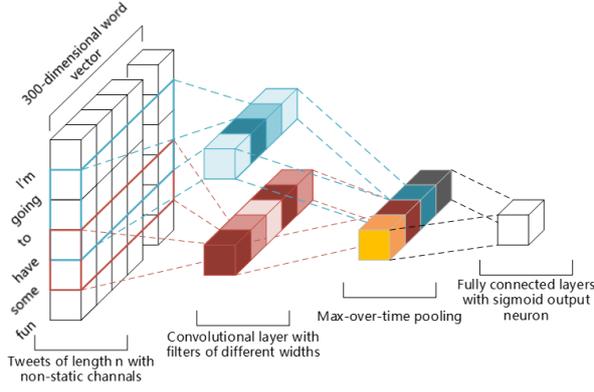

Figure 1: The architecture of our CNN model

of parameters in the neural network, we just use the single channel non-static model, which sets pre-trained word vectors in the embedding layer and can be modified in the training period. In the convolution layer, convolution operations are applied on the submatrixes of M . The convolution operation here is defined as:

$$c_k = f_k(\sum_i \sum_j \omega_{ij} x_{[i:i+h-1]} + b)$$

where $b \in \mathbb{R}$ is a bias term and f is a non-linear function such as ReLU (Jarrett et al., 2009), which is used in our approach. Filters are applied with different size of windows and in each window of size h , feature matrix $c \in \mathbb{R}^{(n-h+1) \times m}$ is produced corresponding to the filters:

$$c = [c_1, c_2, \dots, c_k, \dots, c_m]$$

where m is the number of filters and $c_k \in \mathbb{R}^{n-h+1}$ represents the features extracted from a word sequence. In the pooling layer, we apply a max-over-time pooling operation (Collobert et al., 2011) over feature matrix and take the maximum in each column to preserve the most important features. These maximums are concatenated and then fed into a fully-connected network (L1, L2). L2 is followed by a single sigmoid neuron node to generate the prediction of the affect on the interval $[0, 1]$.

2.2 Bidirectional LSTM

The LSTM architecture used in our system is a kind of modern Recurrent Neural Networks (RNN). Comparing to CNN, the way RNN work is more similar to that how humans read sentences. A word vector sequence x , which is converted from a tweet, will be fed to the RNN in order.

$$h_t = \sigma(W_{hx}x_t + W_{hh}h_{t-1} + b_h)$$

$$y^t = \text{softmax}(W_{yh}h_t + b_y)$$

At time t , the RNN takes the input from the cur-

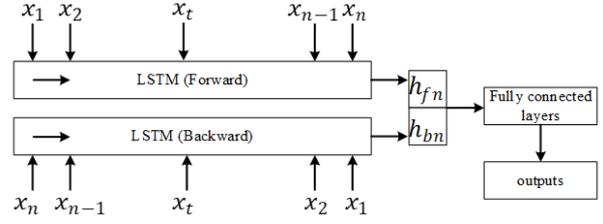

Figure 2: The architecture of our bidirectional LSTM model, where h_{fn} and h_{bn} represent the last hidden state of the forward and backward LSTM respectively.

rent word x_t and also from the previous hidden state h_{t-1} to calculate the hidden state h_t and the output \hat{y}_t , which means \hat{y}_t at time t is in the influence of all previous input words x_1, \dots, x_{t-1} . However, this regular RNN suffers from the exploding and vanishing gradient problem when using the backpropagation algorithm (Hochreiter, 1998), which makes RNN hard to train. Therefore, we use the Long short-term memory (LSTM) network (Hochreiter and Schmidhuber, 1997) to overcome this problem. Each ordinary node of hidden layer in LSTMs is replaced by a memory cell and the following equations describe the LSTM:

$$g_t = \phi(W_{gx}x_t + W_{gh}h_{t-1} + b_g)$$

$$i_t = \sigma(W_{ix}x_t + W_{ih}h_{t-1} + b_i)$$

$$f_t = \sigma(W_{fx}x_t + W_{fh}h_{t-1} + b_f)$$

$$o_t = \sigma(W_{ox}x_t + W_{oh}h_{t-1} + b_o)$$

$$s_t = g_t \odot i_t + s_{t-1} \odot f_t$$

$$h_t = \phi(s_t) \odot o_t$$

The vector h_t is the value of hidden layer of LSTM at time t , g_t is the input node, i_t is the input gate, f_t is the forget gate, o_t is the output gate and s_t is the internal state where \odot is pointwise multiplication. According to Zaremba and Sutskever (2014), the function ϕ used here is the tanh function.

For every point in a given sequence, Graves et al. (2005) shows that a bidirectional LSTM can preserve more sequential information about all sequential points before and after it. As the Figure 2 shows, we concatenate the hidden states of two separate LSTMs after they process the word sequence in opposite direction and get the concatenated state $h' \in \mathbb{R}^{2m}$, which is fed to fully connected layers and finally give the result with a single sigmoid neuron node.

2.3 LSTM-CNN

The architecture of LSTM-CNN is a combination of previous two model. Instead of feeding the out-

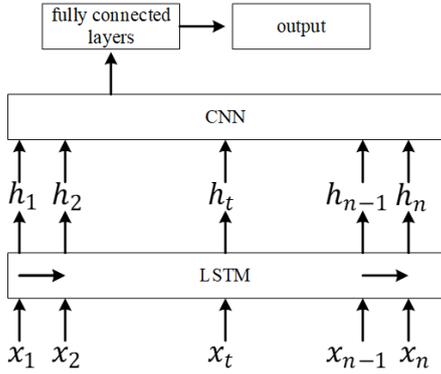

Figure 3: The architecture of our LSTM-CNN model.

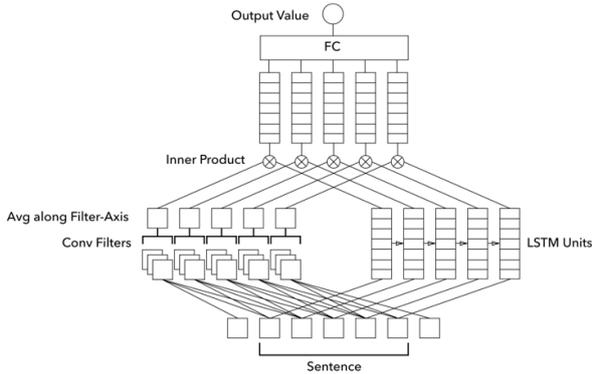

Figure 4: The architecture of CNN-based Attention Model (CA)

put of LSTM to the fully connected layers, the output of LSTM h_t at each time t are regarded as the input of CNN and Figure 3 shows the architecture.

2.4 A CNN-based Attention Model (CA)

Since attention mechanism has achieved significant improvements in many NLP tasks, including machine translation (Bahdanau et al., 2014), caption generation (Xu et al., 2015) and text summarization (Rush et al., 2015), it becomes an integral part of compelling sequence modeling and transduction models in various tasks. Motivated by Du’s work on sentence classification (Du et al., 2017), the architecture of our CNN-based attention model resembles his model. We first use a CNN-based network to model the attention signal in sentences. The convolution operation here is same as that described in Section 2.1. The attention signal of original text is represented by the output of convolutional filter. In order to reduce the noise, multiple filters with same size of windows are applied. After that, we get the corresponding attention similarity:

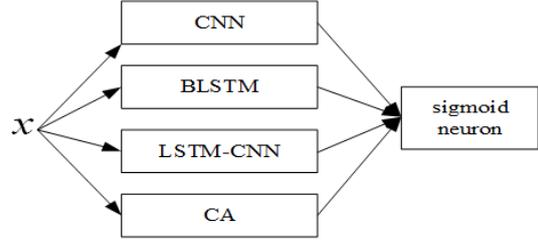

Figure 5: The architecture of the ensemble model

$[c_1, c_2, \dots, c_k, \dots, c_m]$. Then we obtain the attention signal of each element which represents the importance of the corresponding word by averaging the attention similarities along the filter-axis:

$$c = \frac{1}{m} \sum_{i=1}^m c_i$$

An RNN with LSTM units is used to encode the sentence. According to the equation in Section 2.2, the hidden state $h_t \in \mathbb{R}^d$ (where d is the dimension of the RNN) at time t is $h_t = \phi(s_t) \odot o_t$.

So far, we have obtained attention signal c_t and the corresponding hidden state vector of RNN h_t . The representation of the whole sentence can be computed by

$$s = \frac{1}{T} \sum_{t=0}^{T-1} c_t h_t$$

And then $s \in \mathbb{R}^d$ is fed into a fully-connected network (L1, L2). L2 is followed by a single sigmoid neuron node to generate the prediction of the affect on the interval $[0, 1]$. The architecture of this model is shown in Figure 4.

2.5 Ensemble Model

According to the results of SemEval-2017 task 4, the use of ensembles stood out clearly. Therefore, we use a mix of deep learning methods to make our system obtain better predictive performance. Inspired by the boosting algorithms, we use a logistic regression to improve the accuracy of these four methods and the architecture is shown in Figure 5. In order to make the model simple, it only takes the output of the four methods as input rather than training data.

3 Implementation

We implemented our system with PyTorch (Paszke et al., 2017) in Python 3.

Preprocessing: For making tweets string clean, we apply a preprocessing procedure on the input tweets which removes the abbreviations like ‘s, ‘ve and make them lowercased.

Word Embeddings: We utilize pre-trained 300-dimensional word embeddings of Stanford’s

Methods	L1	L2
CNN	300	150
BLSTM	30	Nil
LSTM-CNN	256	100
CA	150	75

Table 1: Fully connected layers hyper-parameters, the numbers represent the size of outputs of liner layers.

Methods	p	CNN	LSTM
CNN	0.2	[2, 3, 4], 256	Nil
BLSTM	0.5	Nil	300
LSTM-CNN	0.5	[3], 200	300
CA	0.5	[3], 50	150

Table 2: Network hyper-parameters for the filters of CNN and hidden size of LSTM, and p is the dropout rate. For example, [2, 3, 4], 256 means the filter height is set to 2, 3 and 4, and the number of filters is set to 256 for different sizes of filters.

GloVe (Pennington et al., 2014) trained by Common Crawl.

Model Hyper-parameters: Table 1 and Table 2 show the hyper-parameters we use in our system.

For fully connected layers, no more than two fully-connected layers are used in the four methods and all fully-connected layers are followed by ReLU. Before the outputs of pooling layers and LSTMs are fed to the fully connected layers, a dropout is applied and the details are described in Table 2.

4 Training

The dataset used in our system is provided by the AIT task and no external datasets are used in training period. For the subtask EI-reg and subtask V-reg, they are trained with the same model hyper-parameters which are listed in Table 1 and Table 2. Also, the four methods use the same word embeddings, which is a pre-trained 300-dimensional word vectors with common crawl by GloVe algorithm. For different emotions, we train the models for 10 epochs respectively. The network parameters are learned by minimizing the Mean Absolute Error (MAE) between the gold labels and predictions and the four methods used in our system are trained separately. We optimize the loss function by back-propagating algorithm via Mini-batch Gradient descent with batch size of 8 for the 4 deep learning models and full batch learning for the ensemble model, as well as the Adam opti-

mization algorithm (Kingma and Ba, 2014) for all models with initial learning rate of 0.001 and 0.01 for the four deep learning models and the ensemble model, respectively.

5 Result and Discussion

We compare the results of the four methods used in our system, the ensemble system, the SVM.Unigrams.Baseline provided from the AIT task and the best-performing system – SeerNet in Table 3. The metric for evaluating performance is Pearson Correlation.

Its remarkable that, comparing to the individual models, our ensemble model has an improvement of at least 2% on EI-reg subtask and 1.1% on V-reg subtask. However, it’s obvious that there is a gap between our models and the best-performance system. The rough preprocessing method of our system is one of the reason for the low score. Because of some words in tweets are misspelled or in a special format like ‘yaaaaay!’, some of the information is lost in this process. So we added an experiment on the V-reg task to study the effect of preprocessing method. We replace the text preprocessing method with the *ekphrasis*¹ for the tokenization, word normalization, word segmentation (for splitting hashtags) and spell correction and the keep the other parameters unchanged. As it is shown in Table 4, the four methods as well as the ensemble model all get an improvement on the results. Actually, some expressions like dates, urls, hashtags and emoticons are converted into the special tokens like <date> , <url>, <hashtag> and <joy>, but these tokens are not in the dictionary of pre-trained word vectors, which means the information of these tokens is still wasted in the embedding process.

There is much room for the improvement of our method:

1. In our system, a single pre-trained word embedding is used, which lack experimental evidence. For future work, combining more kinds of word embeddings should be taken into consideration.
2. We adjust the hyper-parameters by doing evaluation on dev dataset. For future work, we can apply a more advanced strategy like Cross Validation.

Table 3: Results on Subtask EI-reg and V-reg.

Methods	Rough method	ekphrasis
CNN	0.773	0.788
BLSTM	0.731	0.733
LSTM-CNN	0.759	0.767
CA	0.761	0.773
Ensemble	0.784	0.793

Table 4: Results of different text preprocessing method on V-reg task when the other parameters are kept unchanged.

- For the input features, we only use the word vectors. We are supposed to experiment with more features like lexicons.
- In our system, we just use a simple logistic regression but achieve an impressive result on the two subtasks. There is an interesting idea that we can do more work on finding a better ensemble model.

6 Conclusion

In this paper, we propose a model on the sub-task EI-reg and V-reg of SemEval-2018 Task 1: Affect on Tweets. The submitted system is an ensemble model based on CNN, Bidirectional LSTM (BLSTM), LSTM-CNN and a CNN-based Attention model (CA). All methods are described in detail to make our work replicable.

For future work, it would be significant to make an improvement on preprocessing of tweets, doing more experiment on word embeddings and feature selection, model validation and ensemble method.

Abstract

In this paper we did an analysis of "Affects in Tweets" which was one of the task conducted by SemEval 2018. Task was to build a model which is able to do regression and classification of different emotions from the given tweets data set. We developed a base model for all the subtasks using distributed representation (Doc2Vec) and applied machine learning techniques for classification and regression. Distributed representation is an unsupervised algorithm which is capable of learning fixed length feature representation from variable length texts. Machine learning techniques used for regression is 'Linear Regression' while 'Random Forest Tree' is used for classification purpose. Empirical results obtained for all the subtasks by our model are shown in this paper.

1 Introduction

Most basic form of communication between humans is through language. Thus it can act as a medium of how we are feeling at any particular instance. For example, if we are angry at someone rather than just hitting him first we would express our feeling through our words. Thus from a conversation we can make out the different emotions a person is going through at that time. Apart from this social media texts can be used for determining the class of a person as described in (Ganesh H. B. et al., 2016b). In this work we are doing 2 ordinal classification, 1 classification and 2 regression of different emotions that people exhibits through tweets obtained from twitter (Mohammad and Kiritchenko, 2018; Bravo-Marquez et al., 2014; Mohammad et al., 2013) for three different languages namely Arabic, English and Spanish. The data set given has tweets from all the three languages for each subtask (Mohammad et al., 2018; Mohammad and Kiritchenko, 2018). There is a total of

five subtask an emotion intensity regression task, an emotion intensity ordinal classification task, a sentiment intensity regression task, a sentiment analysis ordinal classification task and an emotion classification task.

We used distributed representation (Le and Mikolov, 2014; Ganesh H. B. et al., 2016a) to create feature vector which can be feed as input to machine learning algorithms for classification and regression. Bag-of-words is one of the most common method used to create fixed length feature vectors but the ordering and semantics of the words are ignored in this method. By using Doc2Vec, an unsupervised learning algorithm, we can create fixed length features from variable length data. Thus by using Doc2Vec we can preserve the ordering as well as the semantics of data. Another method for word representation is distributional representation (Ganesh H. B. et al., 2018) which is an extension of co-occurrence based representation and have the same disadvantages as co-occurrence based methods.

Once the feature vector is created it is pushed into machine learning algorithm for classification and regression. We have used Random Forest Tree for classification which is an ensemble learning method that creates a number of decision trees during training and gives an output class which appears most often. For regression we used Linear Regression which tries to fit a line between the actual and predicted values by minimizing the error sum of squares between them. The final model is obtained after doing hyper parameter tuning for Doc2Vec *size* and *n_estimator*, *max_depth* for Random Forest Tree which are fixed through a grid search method before pushing to machine learning algorithms.

Section 2 of this paper gives a brief introduction to corpus. Section 3 describes the theory of different methods used. Section 4 describes the method-

ology used. Section 5 covers result and discussion. Section 6 talks about our conclusion.

2 Corpus

The given corpus consists of tweets from three different languages for all five subtasks. The languages are English, Arabic and Spanish. Each language have training, development and test data set (Mohammad et al., 2018; Mohammad and Kiritchenko, 2018).

While building the model training data set was splitted into 80% for training and 20% for testing. Training and development data set consist of tweet id, tweet, affect dimension and intensity score while test data set has entries as none at intensity scores.

3 Methodology

3.1 Distributed Representation

Doc2Vec is an unsupervised learning algorithm which gives a fixed length vector representation of a variable length text. The text can be a sentence, paragraph or document. It is an extension of Word2Vec in which a vector representation of words are given inorder to predict a word given the vector representation of context words are given. Word2Vec is inspired because it can be used to predict the next word in a sentence given the context word vectors thus capturing the semantics of the sentence even though the word vectors are randomly initialized. Instead of word vector we will use document vector to predict next word given context from a document in Doc2Vec. In document vector every document is represented by a column of unique vector called document matrix and words are represented by unique vectors called word matrix. Next word in a context is predicted by the concatenation or averaging of document and word vectors.

In Doc2Vec the document vector is same for all context generated from same document but differs across documents. However word vector matrix is same for different document, i.e., the vector representation of same word across different document have the same vector representation.

3.2 Linear Regression

For regression tasks Linear Regression was used. Linear Regression tries to fit a line between the actual and predicted values by minimizing the error

sum of squares between them. In a Linear Regression problem there will be one dependent variable and an independent variable. A regression tries to verify two objective, firstly whether a satisfactory prediction can be made by a set of predictor variables and secondly which all variables play an important role in predicting the outcome variable. The estimated regression outputs are used to explain the connection between independent and dependent variables.

3.3 Random Forest Tree

For classification problem we used Random Forest Tree. It is an ensemble learning method that creates a number of decision trees during training and gives an output class which appears most often. Advantage of Random Forest Tree is its ability to control over-fitting by taking an average of all the decision trees for prediction. If more than one algorithm of same or different kind are combined to classify an object such an algorithm is called ensemble algorithm. For example it may run a prediction on SVM, Naive Bayes and Decision Tree before taking the vote for classification of test object.

3.4 Experiment

The corpus was obtained from SemEval2018 website. Once the data was obtained the first process was to extract tweets from the data for all the languages. Once every thing was extracted from the document next step was to build a Doc2Vec model from the extracted tweets which will produce feature vectors which can be used as inputs for our machine learning techniques for regression and classification tasks. Gensim library was used to build the Doc2Vec model. Sklearn library was used for Random Forest Tree and Linear Regression.

Before fixing the Doc2Vec base model we did hyper parameter tuning for all subtasks in all languages. The parameters tuned for regression tasks was Doc2Vec *size* and for classification were Doc2Vec *size* and *n_estimator*, *max_depth* for Random Forest Tree. *size* of Doc2Vec means the dimensionality of the feature vector, i.e., in which dimension each document in a corpus is represented as. *n_estimator* of Random Forest Tree means the number of decision trees used in the forest, i.e., before taking vote of a class how many different algorithms are to be run. *max_depth* of Random Forest Tree gives the maximum depth of

Tasks	size	n_estimator	max_depth
Task 1	140	-	-
Task 2	250	40	17
Task 3	280	-	-
Task 4	820	30	12
Task 5	150	10	8

the tree in algorithm. We did a grid search method to find out the optimum parameter values for each subtasks.

For emotion intensity regression task (Task 1) and sentiment intensity regression task (Task 3) Doc2Vec *size* was varied from 10 to 1000 with an increment of 10 in each iteration. For emotion intensity ordinal classification task (Task 2), sentiment analysis ordinal classification task (Task 4) and emotion classification task (Task 5) Doc2Vec *size* was varied from 10 to 1000 with an increment of 10 in each iteration, *n_estimator* of Random Forest Tree was varied from 10 to 150 with an increment of 10 in each iteration and *max_depth* of Random Forest Tree was varied from 2 to 20 with an increment of 1 in each iteration. Variables used to estimate the ideal parameters for regression tasks were mean square error (MSE) and variance of Linear Regression algorithm. We selected those parameters that gave the least MSE value and large variance value. Variables used to estimate the ideal parameters for classification tasks were accuracy of the Random Forest Tree algorithm. Once the parameters were fixed we build the model for each subtask and used it to predict the values for test data. Development data was used for hyper-parameter tuning while training data was used for building Doc2Vec model.

The ideal parameters obtained after hyper-parameter tuning for each subtask for English is consolidated in Table 1, Arabic is consolidated in Table 2 and Spanish is consolidated in Table 3. The control parameter values obtained for the optimum parameters which in turn are used to build the model is consolidated in Table 4 for task 1 Table 5 for task 3 Table 6 for task 2 Table 7 for task 4 Table 8 for task 5

4 Results and Discussion

The output of test data obtained by our model was compared with golden label available with SemEval2018 and the following results were ob-

Tasks	size	n_estimator	max_depth
Task 1	20	-	-
Task 2	50	90	19
Task 3	110	-	-
Task 4	90	140	17
Task 5	80	1	18

Table 8: Control variable value for optimum parameters for Task 5.

tained. The metric used for evaluation is macro average F-Score and Pearson correlation coefficient. In macro average method precision and re-

call on different sets of system is averaged. The harmonic mean of precision and recall will give us the F-Score. Such an obtained value is called macro F-Score. In Pearson correlation coefficient the linear correlation between two variables $X1$ and $X2$ is calculated. For emotion intensity regression task, emotion intensity ordinal classification task, sentiment intensity regression task and sentiment analysis ordinal classification task Pearson correlation coefficient is used as metric while for emotion classification task macro average F-Score is used as metric.

For emotion intensity regression task on English tweets our model obtained an accuracy of 20.0% when compared with the golden label under Pearson correlation coefficient. When compared for individual emotions we got an accuracy of 21.6%, 21.0%, 11.2%, 26.2% for anger, fear, joy and sadness respectively. On Arabic tweets our model obtained an accuracy of 22.1% when compared with the golden label under Pearson correlation coefficient. When compared for individual emotions we got an accuracy of -0.3%, 17.9%, 31.5%, 39.3% for anger, fear, joy and sadness respectively. On Spanish tweets our model obtained an accuracy of 21.8% when compared with the golden label under Pearson correlation coefficient. When compared for individual emotions we got an accuracy of 24.1%, 21.4%, 14.2%, 27.3% for anger, fear, joy and sadness respectively.

For emotion intensity ordinal classification task on English tweets our model obtained an accuracy of 3.7% when compared with the golden label under Pearson correlation coefficient. When compared for individual emotions we got an accuracy of 2.6%, -0.2%, 6.7%, 5.5% for anger, fear, joy and sadness respectively. On Arabic tweets our model obtained an accuracy of 13.8% when compared with the golden label under Pearson correlation coefficient. When compared for individual emotions we got an accuracy of -6.2%, 5.0%, 28.7%, 27.5% for anger, fear, joy and sadness respectively. On Spanish tweets our model obtained an accuracy of 2.5% when compared with the golden label under Pearson correlation coefficient. When compared for individual emotions we got an accuracy of 2.0%, -5.2%, 6.3%, 6.8% for anger, fear, joy and sadness respectively.

For sentiment intensity regression task on English tweets our model obtained an accuracy of 28.1% when compared with the golden label under

Pearson correlation coefficient. On Arabic tweets our model obtained an accuracy of 47.0% when compared with the golden label under Pearson correlation coefficient. On Spanish tweets our model obtained an accuracy of 19.3% when compared with the golden label under Pearson correlation coefficient.

For sentiment analysis ordinal classification task on English tweets our model obtained an accuracy of 12.5% when compared with the golden label under Pearson correlation coefficient. On Arabic tweets our model obtained an accuracy of 38.3% when compared with the golden label under Pearson correlation coefficient. On Spanish tweets our model obtained an accuracy of 12.7% when compared with the golden label under Pearson correlation coefficient.

For emotion classification task on English tweets our model obtained an accuracy of 14.8% when compared with the golden label under macro average F-Score. On Arabic tweets our model obtained an accuracy of 25.0% when compared with the golden label under macro average F-Score. On Spanish tweets our model obtained an accuracy of 6.0% when compared with the golden label under macro average F-Score.

5 Conclusion

The task was to analyze the 'Affects of Tweets' from tweets comprising of different emotions from three different languages. We used distributed representation (Doc2Vec) for creating feature vector which was passed as the input to machine learning algorithm such as Linear Regression for regression tasks and Random Forest Tree for classification tasks. The model was fixed after doing hyperparameter tuning and the results obtained using the model on test data was evaluated using golden label by SemEval2018. The results obtained with the model after comparing with the golden label using some evaluation metric have been discussed in the paper.

Abstract

The system developed by the SSN MLRG1 team for Semeval-2018 task 1 on affect in tweets uses rule based feature selection and one-hot encoding to generate the input feature vector. Multilayer Perceptron was used to build the model for emotion intensity ordinal classification, sentiment analysis ordinal classification and emotion classification subtasks. Support Vector Regression was used to build the model for emotion intensity regression and sentiment intensity regression subtasks.

1 Introduction

Twitter is a huge microblogging service with more than 500 million tweets per day from different locations of the world and in different languages (Saif and Felipe, 2017). Tweets are often used to convey ones emotions, opinions towards products, and stance over issues (Nabil et al., 2016). Automatically detecting emotion intensities in tweets has several applications, including commerce (Jansen et al., 2009), crisis management (Verma et al., 2011), tracking brand and product perception, tracking support for issues and policies, and tracking public health and well-being (Chew and Eysenbach, 2010). The task is challenging because of the informal writing style, the semantic diversity of content as well as the “unconventional” grammar. These challenges in building a classification model and regression model can be handled by using proper approaches to feature generation and machine learning.

There are several machine learning techniques that can be used for sentiment intensity prediction or emotion intensity prediction. Some of the approaches include Artificial Neural Network (ANN) (Sudipta et al., 2017), Random Forests, Support Vector Machine (SVM), Naive Bayes (NB) (Tabari et al., 2017), Multi-Kernel Gaussian

Process (MKGP) (Angel Deborah et al., 2017a,b), AdaBoost Regressor (ABR), Bagging Regressor (BR)(Jiang et al., 2017) and Deep Learning (DL)(Pivovarova et al., 2017).

2 Multi-Layer Perceptron

A Multilayer Perceptron (MLP) as shown in Figure 1 is a feed-forward Neural Network model that maps input data sets onto appropriate output sets. An MLP has many layers of nodes in a directed graph, with each layer connected to the next layer. A neuron is a processing element with activation

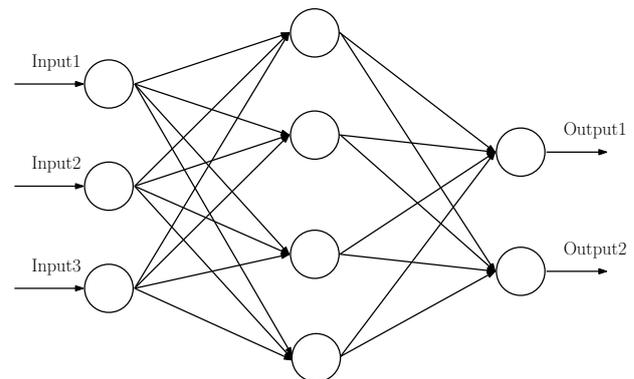

Figure 1: Multi-Layer Perceptron.

function (in the input layer the activation function is not applied). The output layer has as many neurons as the number of class labels in the problem. Each connection has a weight assigned to it. Output of each neuron is calculated by applying the activation function on the weighted sum of the inputs. Linear, sigmoid, tanh, elu, softplus, softmax and relu are some of the commonly used activation functions. The supervised learning problem of the MLP can be solved with the backpropagation algorithm (Haykin, 1998). The algorithm consists of two steps. In the forward pass, the predicted outputs are calculated for the given inputs. In the backward pass, partial derivatives

of the cost function with respect to the weight parameters are propagated back through the network. The chain rule of differentiation gives very similar computational rules for the backward pass as the ones for the forward pass. The network weights can then be adapted using any gradient-based optimisation algorithm.

MLP was used in implementing for the following subtasks:

1. **EI-oc** (an emotion intensity ordinal classification task): Given a tweet and an emotion E, classify the tweet into one of four ordinal intensity classes of E that best represents the mental state of the tweeter.
2. **V-oc** (a sentiment analysis, ordinal classification task): Given a tweet, classify it into one of seven ordinal classes, corresponding to various levels of positive and negative sentiment intensity, that best represents the mental state of the tweeter.
3. **E-c** (an emotion classification task): Given a tweet, classify it as neutral or no emotion or as one, or more, of eleven given emotions that best represent the mental state of the tweeter.

3 Support Vector Regression

Support Vector Machines (SVM) are characterized by usage of kernels, absence of local minima, sparseness of the solution and capacity control obtained by acting on the margin or on number of support vectors, etc. As in classification, support vector regression (SVR) is characterized by the use of kernels, sparse solution, and Vapnik-Chervonenkis control of the margin and the number of support vectors. Although less popular than SVM, SVR has been proven to be an effective tool in real-value function estimation (Awad and Khanna, 2015). The idea of SVR is based on the computation of a linear regression function in a high dimensional feature space where the input data are mapped via a non-linear function. It contains all the main features that characterize maximum margin algorithm: a non-linear function is learned by a linear learning machine mapping into high dimensional kernel-induced feature space. The capacity of the system is controlled by parameters that do not depend on the dimensionality of feature space. Instead of minimizing the observed training error, Support Vector Regression (SVR) attempts to minimize the generalization error bound so as to achieve generalization perfor-

mance.

SVR was used in implementing for the following subtasks:

1. **EI-reg** (an emotion intensity regression task): Given a tweet and an emotion E, determine the intensity of E that best represents the mental state of the tweeter, a real-valued score between 0 (least E) and 1 (most E).
2. **V-reg** (a sentiment intensity regression task): Given a tweet, determine the intensity of sentiment or valence (V) that best represents the mental state of the tweeter, a real-valued score between 0 (most negative) and 1 (most positive).

4 System Overview

The system consists of the following modules: data extraction, preprocessing, rule based feature selection, feature vector generation and building the model – Multilayer Perceptron model for classification subtasks and Support Vector Regression for regression subtasks. The algorithm for preprocessing of the data is outlined below:

Algorithm: Data extraction and Preprocessing.

Input: Input dataset.

Output: Tokenized words and their parts of speech.

begin

1. Separate labels and sentences
2. Perform tokenization using `word_tokenize`, the function for tokenizing in the NLTK toolkit.
3. Perform Parts of Speech tagging using `pos_tag` function from the NLTK toolkit.
4. Return the tokenized words and their parts of speech as inputs to rule based feature selection.

end

The algorithm for rule based feature selection and feature vector generation is outlined below:

Algorithm: Rule based feature selection and feature vector generation.

Input: Tokenized words and their parts of speech.

Output: Feature vector.

begin

For each of the tokenized words, falling under one of the categories listed in Table 1, do the following steps.

1. Lemmatize the word using `WordNetLemmatizer` from the NLTK toolkit.
2. Insert the lemmatized word into the dictio-

nary.

3. Represent each sentence as a feature vector using one-hot encoding by looking up the dictionary.
4. Return the feature vector generated as the input to build the model.

Table 1: Parts of speech categories.

The Multi-Layer Perceptron (MLP) model is built by the following algorithm.

Algorithm: Build a Multi-Layer Perceptron model.

Input: Feature vectors and actual output labels.

Output: Learned MLP model.

begin

1. Represent feature vectors as X_{Train} and actual output label as Y_{Train} .
2. Build the initial classification model with two hidden layers and the output layer, using `relu` and `softmax` activation functions, respectively.
3. Optimize the classification model using `nadam` optimizer of `keras` package
4. Return the learned model.

end

The Support Vector Regression(SVR) model is built with the following algorithm.

Algorithm: Build a SVR model.

Input: Feature vectors and actual output labels.

Output: Learned SVR model.

begin

1. Represent feature vectors as X_{Train} and ac-

tual output label as Y_{Train} .

2. Build the initial classification model using appropriate kernel function.
3. Optimize the model parameters using a heuristic approach.
4. Return the learned model.

end

5 Performance Evaluation

We evaluated the system only for English language. The results obtained using MLP and SVR for the subtasks are tabulated in Table 2 to Table 6. From Table 2 which shows the Pearson scores obtained for SVR, we can infer that SVR predicts joy better compared to anger, fear and sadness. Similarly, from Table 3 which shows the Pearson scores obtained for MLP, we observe that MLP model predicts joy better compared to anger, fear and sadness. The Pearson score for valence intensity regression and sentiment intensity ordinal classification are given in Table 4 and 5 respectively.

anger	fear	joy	sadness	macro averaged
0.490	0.490	0.502	0.461	0.486

Table 2: Pearson score for EI-reg (emotion intensity regression) using SVR.

anger	fear	joy	sadness	macro averaged
0.365	0.363	0.390	0.383	0.375

Table 3: Pearson score for EI-oc (emotion intensity ordinal classification) using MLP.

Pearson (all instances)	Pearson (gold in 0.5-1)
0.582	0.424

Table 4: Pearson score for V-reg (valence intensity regression) using SVR.

Pearson (all classes)	Pearson (some-emotion)
0.427	0.479

Table 5: Pearson score for V-oc (Sentiment intensity ordinal classification) using MLP.

The Pearson score r is calculated using the Equation 1.

$$r = \frac{\sum_{i=1}^n (Y_i - \bar{Y})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^n (Y_i - \bar{Y})^2} \sqrt{\sum_{i=1}^n (y_i - \bar{y})^2}} \quad (1)$$

Accuracy	Micro-avg F1	Macro-avg F1
0.468	0.595	0.476

Table 6: Pearson score for E-c (multi-label emotion class) using MLP.

where Y is actual output and y is predicted output. The accuracy, micro-averaged F score and macro-averaged F score for emotion classification are given in Table 6. The metrics are defined from Equations 2 to 5.

$$\text{Accuracy} = \frac{1}{|T|} \sum_{t \in T} \frac{|G_t \cap P_t|}{|G_t \cup P_t|} \quad (2)$$

where G_t is the set of the gold labels for tweet t , P_t is the set of the predicted labels for tweet t , and T is the set of tweets.

$$\text{Micro-avearge } F = \frac{2 \times \text{micro-}P \times \text{micro-}R}{\text{micro-}P + \text{micro-}R} \quad (3)$$

where micro- P is micro-averaged precision and micro- R is micro-averaged recall

$$F = \frac{2 \times P_e \times R_e}{P_e + R_e} \quad (4)$$

$$\text{Macro-average } F = \frac{1}{|E|} \sum_{e \in E} F_e \quad (5)$$

where P_e is precision, R_e is recall and E is the given set of eleven emotions.

6 Conclusion

We have presented the results of using MultiLayer Perceptron for emotion intensity ordinal classification, sentiment analysis ordinal classification and emotion classification. We built a basic MLP, which has an input layer, two hidden layers with 128 and 64 neurons, and an output layer with as many neurons as the number of class labels. We have used nadam optimizer with learning rate as 0.01. We have also presented the results of using Support Vector Regression for emotion intensity and sentiment intensity regression. It is observed that both MLP and SVR predict joy more accurately when compared to anger, fear and sadness. We analyzed the feature vectors generated for various emotions. Feature vectors generated for joy helps to achieve better results than for other emotions. We used rule based feature selection and one-hot encoding to generate input feature vectors for buliding the models. The results obtained can

be enhanced by using different feature selection approaches and incorporating sentiment lexicons.

Abstract

This paper discusses on task 1, "Affect in Tweets" sharedtask, conducted in SemEval-2018. This task comprises of various subtasks, which required participants to analyse over different emotions and sentiments based on the provided tweet data and also measure the intensity of these emotions for subsequent subtasks. Our approach is to come up with a model for all the subtasks on count based representation and use machine learning techniques for regression and classification related tasks. In this work, we use bag of words technique for supervised text classification and regression. . Further, fine tuning on various parameters for the bag of word, representation model we acquired better scores over various other baseline models (Vinayan et al.) participated in the sharedtask.

1 Introduction

A huge portion of analysis in natural language processing try to find better understand and process various kinds of info in text. Day by day the development of social websites, blogging and the consummation of technologies gives vast amount text data on the internet, which opened a space to study peoples feeling, reviews, and emotion from their own written languages, called sentimental analysis. Sentimental analysis has so many attractions and has done so many research (Zhu et al., 2014) in this area.

Sentiment analysis remains a sequence of techniques, approaches, and tools about sensing and mining subjective info (such as opinion and attitudes) from language (Bravo-Marquez et al., 2014). Traditional approaches (Kiritchenko et al., 2014; Mohammad et al., 2013) are finding out the polarity of the positive, negative, neutral classification problem (Mohammad, 2018; Bravo-Marquez et al., 2015). Recent research in sentimental analysis (Mohammad and Kiritchenko,

2018) are done on the data-driven algorithm view point. But at the same time combination of good linguistic awareness data can increase the performance and insights about the task. We used machine learning techniques to build the model. Linear regression, random forest methods are used respectively for prediction and classification tasks. A mathematical system or an algorithm need some form of numeric representation to work with. The naive way of representing a word in vector form is one hot representation but it is a very ineffective way for representing a large corpus. In a more effective way, we need some semantic similarities (Soman et al., 2016) to nearby points, thus creating the representation bring beneficial info about the word actual meaning, called word embedding models that are categorized based on count and predictive word embedding models. Both embedding models at least some way share semantic meaning. We used here count based word embedding methods for inputting the word. In more specific, Feature representation is done based on the term-document matrix (TDM) and term frequency-inverse frequency (TFIDF) matrix. The optimum value of n-gram range, depth of classifier, mindf are obtained by hyper parameter tuning.

2 Corpus

Dataset provided by shared task was sourced from Twitter API by focusing emotion-correlated words. The tweets were annotated separately for 4 emotions namely anger, joy, fear and sadness. The data provided were annotated with best-worst scaling technique (Kiritchenko and Mohammad, 2016) that gave better annotation consistency and emotion intensity scores for tweets. There were 5 subtasks in task1 (Mohammad et al., 2018). For each sub-tasks, separate training and testing data

sets are given for Spanish, English, and Arabic. Subtasks 1 and 3 focused on emotion intensity and sentiment intensity tasks respectively which were categorized into regression tasks (EI-reg and V-reg). In that emotion intensity and sentimental intensity is a real-valued scale between 0 and 1, where 0 represents least and 1 represents the most intensity of the tweeters from written tweets. Rest of the subtasks EI-oc, V-oc, E-c were multi-class classifications problems that are emotion intensity ordinal classification, sentiment analysis ordinal classification, emotion classification subtasks respectively. For subtask 2(EI-oc) distinct training and testing, dataset are provided for anger, fear, joy, and sadness. Subtask 4(V-oc) gives 7 ordinal classes, according to different levels of positive and negative valence state of the tweeter. Table 1-2 shows various vocabulary sizes based on the different count and n-gram parameters, for 3 different languages.

(min,n-gram)	vocabulary size		
	English	Arabic	Spanish

Table 1: EI-reg vocabulary size with variation of parameters.

3 Background

3.1 TDM

TD is the most basic method of representation of a text used in NLP. In this technique, for every individual document present in a corpus, we take the raw count of the words present in that document over all the unique words present in the entire corpus as its representation (Larson, 2010). That is to say, a vocabulary is created using all the word in the entire corpus and for a single document representation, the count of the words are incremented in view of their occurrence only for that docu-

(min,n-gram)	vocabulary size		
	english	Arabic	Spanish
(1,1)	9019	12581	15400
(2,1)	2830	2928	2204
(3,1)	1761	1536	1291
(1,2)	38795	37013	29299
(2,2)	7157	3764	4626
(3,2)	4099	1754	2320
(1,3)	78139	60856	53978
(2,3)	10915	3922	5262
(3,3)	5670	1782	2454
(1,4)	117210	83021	186213
(2,4)	13209	4011	36876
(3,4)	6955	1799	28418

Table 2: V-reg vocabulary size with variation of parameters.

ment. The drawback of this method is that this creates a very sparse matrix where only a few of the columns are accumulated with numbers whereas, the rest of the columns are all zeros, thus bringing to the term frequency method.

3.2 TF-IDF

One of the problems that occur due to the term document representation is that, it takes a raw count of all the words present in the document where most frequently occurring words like conjunction, preposition appear very often across most of the articles, thus not adding any significant importance to the individual article. On the other hand, seldom occurring words, like proper nouns give a more individual identification to the article. Thus, coming to a method where we take in the frequency of the words over the entire corpus, this method is termed as term-frequency(tf). In language processing technique a collection of commonly appearing words with apparently less significance to a document are called as 'stop words', these can be removed at pre-processing level. Whereas, more often than not a list of stop words is not a sophisticated approach to adjusting term frequency for commonly used words. Inverse document frequency (*idf*) is a technique (Ramos et al., 2003) wherein, less weight age is given to more commonly occurring words (not restricted to only stop words) and vice-verse for seldomly used words across the entire corpus.

$$idf_t = \ln \left(\frac{N_{tot\ docs}}{n_{docs\ containing\ t}} \right)$$

Combining the two ideologies (*tf-idf*) brings, the rarity of the term intended to measure how important a word can be to the document in a collection (or corpus) of documents. it can be considered as a heuristic quantity. The term inverse document frequency for any given term is defined as

$$tf-idf_{t,d} = tf_{t,d} * idf_t$$

3.3 Linear Regression

Linear regression is a commonly used supervised learning approach for prediction. The key goal is to fit a best fit line between a dependent and independent variable so as to minimize the error sum of squares between the actual and predicted value using the model. The model for linear regression is usually fitted using least square approach, or by minimizing the error sum of squares between the actual and predicted value. In certain cases, the model can also be framed by adding a regularization term. The regularization term is added to avoid overfitting (François and Miltsakaki, 2012).

3.4 Random Forest

Random forest, an ensemble decision tree based classifier which averages various combination of trees created on arbitrary samples from the data set. A decision tree breakdown the data into minor sub-classes while instantaneously construe a tree using decision and leaf nodes. The category is embodied by leafs nodes. A decision node takes two or extra divisions with choices or leafs. Every tree in the RF is made on an arbitrary decent subclass of features present (Liaw et al., 2002) on the entire data. The RF algorithm medians trees to generate a system with short variance and insignificant trees are canceled out, left trees produce the output.

4 Methodology

The model will be effective based on how it is extracting meaningful information from raw text. The system is created with the help of scikit-learn library ¹ which is a python based library very much useful for classification, regression, clustering, data preparation, dimensionality reduction etc.

¹<http://scikit-learn.org/stable/>

The training, development and test data set are taken from SemEval18 website.

1. Importing training and cross-validation from the given data set
2. Removes all the stop words from data that are insignificant.
3. Create a bag of words model which is a simple numeric representation of piece of text that is easy to classify. We just count the frequency of each word in the piece of text and created a dictionary of them which is called tokenization process in NLP which is then passed to countvectorize object in scikit learn package to create a set of maximum features. We use fit transform method to model (Ganesh et al., 2016) the bag of words feature vector which are stored in an array.
4. Same tools and methods are followed for creating TDM matrix as mentioned in step 3
5. We created a classifier or prediction with the help of machine learning model. Here we used random forest classifiers consisting of one hundred trees. RF is a set of decision trees graphs that model all possibility of certain outcomes.

model is created 3 different languages, Spanish, English and Arabic. Both TDM and TFID feature matrix are tuned on the basis of accuracy and Fscore values. Accuracy shown in bold letter are used for making prediction and classification task model.

5 Result

The group of tasks is particularly focusing on automatic detection of the intensity of emotion (EI-reg) and sentiment (V-reg) of the tweeter. In this task, they have presented with the problem of classifying multi-class emotion of tweets, such as EI-oc, V-oc, E-c . We have approached these tasks with a count based representation model, where every individual tweet is represented based on varied vocabulary size, and how these will perform for different category of subtasks over three different language dataset namely English, Spanish and Arabic. We base the model, considering in mind

lang	Rep	min_df	n-gram	depth of tree	accur
Sp	TDM	3	11	12	95.58
Sp	TFIDF	1	9	17	95.58
En	TDM	2	5	15	95.25
En	TFIDF	2	7	15	95.25
Ara	TDM	1	1	2	93.81
Ara	TFIDF	2	10	10	94.41

Table 7: E-c cross validation results.

that an algorithm should not be narrowed down to a certain problem. That is it should not be biased towards a particular problem overall, this inference is made on the fact that all subtasks under task1 are focused on understanding the effect of tweets from the same corpora. As all the subtasks under task1 follow a generic grid search models, which are varied over min-df, n-gram parameters. The EI-reg task was tuned on mean square error and variance for all 3 languages. EI-reg gave comparatively better accuracy in TF-IDF matrix than TDM matrix.so we used TF-IDF for creating feature matrix. This regression task gave macroavg between 32-44 percentage. English tweets gave least macro-avg value (32) and Spanish data gave high macro-avg value, among them angry got un-wavering values in 3 languages.

Pearson (all instances)					
	macro -avg	anger	fear	joy	sadness
english	0.328	0.315	0.415	0.178	0.404
arabic	0.399	0.267	0.392	0.487	0.447
spanish	0.441	0.348	0.533	0.414	0.471

Table 8: EI-reg result.

V-reg is a regression task where sentiment intensity was predicted. Spanish and English used TF-IDF and Arabic corpora used term document matrix for feature input matrix. These feature are found out by grid search method. Arabic and Spanish data give 58 % prediction and English data give slight high result which is 62

Pearson (all instances)	
Valence	
English	0.622
Arabic	0.583
Spanish	0.580

Table 9: V-reg result.

Subtasks 2,4,5 are multi-label classification problems whose models are also generated by bag of words method. But the classification which was done by random forest did not yield expected result comparing to regression tasks.

6 Conclusion

Affect in tweets has been found out by the bag of words representation and classical machine learning algorithms. Random Forest and linear re-

gression were used as machine learning tasks for predicting classification tasks and regression tasks respectively in which regression task gave fairly good results while classification task yield not so favorable results. TF-IDF seems to give better results for English and Spanish languages whereas TDM gave better results for the Arabic language. Emotion intensity and valence were captured by our model for the validation given data. Algorithms performed nearly same with TF-IDF and TDM but with slightly better results while using TF-IDF.

Abstract

Emotions are a way of expressing human sentiments. In the modern era, social media is a platform where we convey our emotions. These emotions can be joy, anger, sadness and fear. Understanding the emotions from the written sentences is an interesting part in knowing about the writer. In the amount of digital language shared through social media, a considerable amount of data reflects the sentiment or emotion towards some product, person and organization. Since these texts are from users with diverse social aspects, these texts can be used to enrich the application related to the business intelligence. More than the sentiment, identification of intensity of the sentiment will enrich the performance of the end application. In this paper we experimented the intensity prediction as a text classification problem that evaluates the distributed representation text using aggregated sum and dimensionality reduction of the glove vectors of the words present in the respective texts.

1 Introduction

Emotion detection from text has been an important task in recent years since the development of Natural Language Processing. Finding the affect in tweet enlarges the business intelligence towards the consumer behaviour analysis, peoples likeness towards the person, organization and policies of the government.

Intensity of the sentiment present in the text can be predicted by performing a text classification by taking texts as the observations and their intensity classes or scores as a target labels. Representation is a key part in any text classification task which can affect the further feature extractions and predictions (Ganesh et al., 2016; Soman et al., 2016; B. et al., 2016). A bad representation of the word vector can make the further

predictions fruitless. Hence we use a meaningful representation of words, that is, global vectors (Glove) for the representation of words into vectors of a tweet. This paper explains the use of global vectors representation for representing the words in a tweet and their further processing using machine learning techniques for classification and regression tasks. SemEval-2018 Task 1 provided the twitter corpus for classification and regression tasks for the emotion detection.

After representing the words in the tweets, the vector for tweets is obtained by computing the aggregated sum and dimensionality reduction. The final tweet vectors are used for further classification and regression.

2 Global Vectors

Global Vectors (GloVe) creates word vectors and it is an unsupervised machine learning technique (Pennington et al., 2014). Unlike word2vec representations like skip-gram and continuous bag of words (CBOW), word-word co occurrence statistics is taken for the vector representation. It also retains the relations between words and gives a better feature extraction. The vectors represented in space gives more meanings than the traditional methods. global matrix factorization methods and local context window methods, such as the skip-gram model (Mikolov et al., 2013) is the main two types of vector representations. The word-word co occurrence count on the whole set of words are used for training and hence it captures more information.

3 Datasets

Dataset consists of tweets from three languages that are English, Spanish and Arabic. These are mainly focused on the emotions contained in it. These are annotated for the different emotions

such as joy, fear, anger and sadness. Separate datasets are provided for each emotions. The classification tasks consists of annotations marked as different intensity values for each emotion. They also contains the value corresponding to how much emotion value can be inferred from the tweets. For the regression tasks, the values between 0 and 1 are provided along with it. The value 0 means no information can be inferred and 1 means maximum information can be inferred. Sub-tasks EI-oc, V-oc, E-c are multi-class classification problems. EI-reg and V-reg are regression problems. EI-reg and EI-oc are emotion intensity tasks and V-reg is a sentiment intensity task. V-oc is a sentimental analysis task and E-c is a emotion classification task. (Mohammad and Kiritchenko, 2018)

4 Methodology

Pre-trained model of GloVe with 100 dimensions computed from 27 billion tokens and 2 billion tweets from the twitter is used in this experiment¹. From the tweet datasets, the words are taken and checked if it is present in the downloaded GloVe model. If it is present then the vector representation corresponding to that word is taken and added to the model. After obtaining the vector representation for all the words in a tweet, the vector representation for each tweet is made after pre-processing steps like unimportant symbols and space removal. The representation for a tweet is made by writing the word vector as columns of a matrix concatenated till the tweet ends. This matrix is reduced into a single vector by two methods:

- SUM: Taking the sum of each rows and making it a new vector. This is an easy method which has less computation but the disadvantage includes the loss of word order in a tweet.
- SVD: Singular Value Decomposition is a decomposition method widely used for reducing the dimension of matrices. Here the sentence matrix is reduced to a rank one matrix by taking only the most important singular value. This is then used to take the important vector from the matrix which can be the most information containing (Golub and Reinsch, 1970). The tweet matrix is decomposed 3

¹<https://nlp.stanford.edu/projects/glove/>

parts using SVD. The most important singular value occurs in the first value of the diagonal matrix. A new vector is formed by using only one singular value from the SVD. Reducing the dimension using SVD preserves the important spread of data rather than simple summing operations of columns.

$$A = U \sum V^T \quad (1)$$

These vectors are used as the input for the different machine learning techniques. A part of the training data is split into training and validation data and is given to learning methods like Random Forest and Support Vector Machine (SVM). These methods will learn and give predictions about the classification or regression task that is assigned. Experiments are done to find out which hyper parameters give the better value for the validation accuracy. These are stored and used for predicting the new unseen data from the test set.

4.1 Random Forest

Random Forest is a powerful and popular machine learning algorithm capable of performing both regression and classification tasks. This algorithm creates a number of decision trees. When the number of these decision trees are more, the predictions will have more robustness and accuracy. Random Forest consists of multiple trees to classify a new object based on attributes. A classification is given by each tree and the tree votes for that class are saved. Choice is made for the classification by taking the most votes for consideration. It can handle the missing values and can maintain accuracy for the missing data. It can also work on large datasets which are high dimensional. It is not that good at regression like it does for the classification tasks. The control over the model is less as there are less parameters to tune.

Test features are passed through the rules of each randomly created trees for the predictions. Each tree will be predicting an output and the voting is done for the prediction to get the highest vote for a particular class of prediction. This is called majority voting. It is called ensemble machine learning algorithm. Divide and conquer approach is used for the improvement of performance. Each classifier in this group may be weak learner, but when they come together, it acts as a strong learner (Liaw et al., 2002).

4.2 Support Vector Machine (SVM)

SVM is used to classify different classes in a dataset. It draws a decision boundary after looking at the extreme data points in a dataset. This boundary is called the hyper-plane which has one dimension less than the dimension of the data points. It is drawn near the extreme points of the dataset. SVM is a popular algorithm which segregates the different classes of data points in a dataset. If the decision boundary is drawn without making it optimized, then the further classifications will have less accuracy on new data. Support Vectors are the data points that are closer to the other classes and they are the ones pushing the boundary farther to make better predictions. This algorithm says that only those support vectors or the margins are needed for the further classifications and the other data points are ignored. This is because the margin is drawn by considering the extreme case in a class and all the other points can easily be classified with that prior knowledge.

SVMs can also be used in higher dimensional datasets and the data points will be called as vectors and they will have their coordinates lying inside the space of data. For the cases in which our function is not linearly separable, our data should be transformed in to a higher dimension using a function. Data points in higher dimensions are computationally complex for predictions. Kernel trick can be used to reduce this computational cost. A kernel function or a kernel trick is a function that takes the input vectors from the original vector space and returns the dot product of the vectors in the features in the feature space. To map every point into a higher dimensional space, dot product between two vectors can be applied using some transformation. Transformation on non-linear space into linear space is possible using that (Suykens and Vandewalle, 1999). Common kernel types are,

1. Linear Kernel
2. Polynomial Kernel
3. Radial Basis Function (RBF) Kernel

Table 1 shows the kernel functions of different kernel. Here x and y are the data points and the kernel function is found using the equations corresponding to it. d is the dimension of the space and γ is a hyper parameter. To get better performance using any kernel, parameter tuning is required. SVMs

Kernel Name	Kernel Function
Linear Kernel	$k(x, y) = x \times y$
Polynomial Kernel	$k(x, y) = (x \times y + 1)^d$
RBF Kernel	$k(x, y) = e^{-\gamma \ x-y\ ^2}$

Table 1: Kernel Functions

are effective in higher dimensions and it is possible to add custom kernels to it making it adaptive. It performs poor when the number of features are greater than the number of samples.

We have reported the observations made using the linear and RBF kernel.

5 Results and Observation

Mean Squared Error (MSE) is noted for all the regression tasks and accuracy is noted for all the classification tasks. MSE near the value 0 is always better and accuracy value can be a maximum of 100%. Accuracy measures are in percentage. Validation scores for the test data provided is measured and reported for observations.

Using the SVD method always gave slightly better result compared to the SUM method. From this we can understand that the the reduction of a matrix in to vector should be done with SVD instead of SUM method. Scores for the language English gave better results compared to Spanish and Arabic. This can be due to the use of pre-trained GloVe vectors which was trained on more English data.

Table 2 has MSE for validation set in EI-reg (emotion intensity regression). For English, Random Forest gave slightly better results than the other two SVM methods. Random Forest and SVM with RBF kernel were performing nearly same for the Spanish and Arabic datasets.

Table 3 has Accuracy of validation set in EI-oc (emotion intensity ord.class.). Random Forest Classifier was performing better than the other two classifiers for all the three languages. English language showed better accuracy than the other two languages and Arabic showed least accuracy.

Table 4 has MSE for validation set in V-reg (valence intensity regression). All the three regressors were performing in a similar way for English whereas Random Forest and the SVM with RBF kernel performed better for the other languages.

Table 5 contains Accuracy for validation set in V-oc (valence ord.class.). Random Forest was performing better for all the classification tasks

	Random Forest		SVM (Linear)		SVM (RBF)	
	SUM	SVD	SUM	SVD	SUM	SVD

	macro-avg	anger	fear	joy	sadness
English	0.077 (44)	0.062 (44)	0.076 (44)	0.079 (43)	0.090 (44)
Arabic	0.230 (10)	0.213 (10)	0.230 (10)	0.207 (11)	0.269 (11)
Spanish	0.131 (12)	0.184 (11)	0.117 (12)	0.143 (11)	0.078 (12)

Table 7: Published Results score for EI-reg where the number in brackets is the ranking

given. Accuracy for Arabic stayed down and English stayed up. Table 6 contains Accuracy for validation set in E-c (multi-label emotion class.). All the classifiers for all languages were performing nearly same for this task. English still remained on top where as SVD always gave a slight boost in accuracy like the previous cases.

The published results for all these are also tabulated. The algorithm did not give the score and accuracy that was giving on the validation sets.

Table 7 contains published Results score for EI-reg where the number in brackets is the ranking. The minimum value is 0 and maximum value is 1. Our algorithm has lower score but comparatively the sentiment "sadness" has slightly better score. Score of published results for EI-oc was not satisfactory and the score values were less. In published results score for V-reg, Valence score for Arabic language (0.319) was better than the other 2 languages and English had the lowest. For the published results score for V-oc, algorithm's performance was not satisfactory but the arabic language had better valence (0.163) than the other 2 languages. In the published results score for E-c, the accuracy for Spanish was slightly better compared to the English and Arabic languages.

6 Conclusion

Five different tasks with common framework is experimented to find out the affect in tweets in 3 different languages. From the scores and accuracy obtained from the validation data we can conclude that the Global Vector Representation gives good results for the sentiment analysis tasks. Using a pre-trained model for the GloVe made the task simpler and easy to use for vector representation. Reducing the tweet matrix into vector using SVD always gave better results than taking the column wise sum of the matrices. This shows the importance of the word order. Random Forest algorithms gave better results for the classification tasks were as the SVD algorithm with RBF kernel performed nearly well in the regression tasks. English language showed better scores in the validation data compared to other languages. From these observations, it can be noted that this approach performed satisfactorily better in the validation step and was able to get the semantic features from the tweets. Hence the future work will be focused more on the performance of the experimented methods.

Abstract

This paper discusses the experiments performed for predicting the emotion intensity in tweets using a generalized supervised learning approach. We extract 3 kind of features from each of the tweets - one denoting the sentiment and emotion metrics obtained from different sentiment lexicons, one denoting the semantic representation of the word using dense representations like Glove, Word2vec and finally the syntactic information through POS N-grams, Word clusters, etc. We provide a comparative analysis of the significance of each of these features individually and in combination tested over standard regressors available in scikit-learn. We apply an ensemble of these models to choose the best combination over cross validation.

Our resources and the details of implementation are publicly available at :

<https://github.com/prashanth470/affect-in-tweets>

1 Introduction

In Natural Language Understanding, the field of sentiment analysis deals with the process of determining the polarity of a given text, such as positive, negative, neutral and mixed. In extension to this analysis, we have the emotion recognition task which deals with associating the text with pre-defined set of emotions like anger, fear, joy, etc. A general method of performing the emotion recognition task is to employ weak supervision models like emojis, hashtags and emoticons to mine emotion. Instead of using this discreet approach to emotion, continuous models that map text to an n - dimensional space with valence, arousal and dominance can be used.

Another interesting problem in the NLP space is the abundance of social media texts, especially twitter. Twitter is a micro-blogging site where

people express themselves and react to content in real-time. An estimated 500 million tweets are generated on a daily basis. The peculiar nature of such micro-blogging sites is the form of expression through hashtags, emojis, slang and informal words etc. But analyzing this abundant information would help us to realize several insights about an event, person or organization.

It is with this motivation that the SemEval shared task on Emotion Intensity was conducted.([Mohammad et al., 2018](#)) Given a tweet and an emotion (anger, fear, sadness, joy) the aim is to determine the intensity score that can be seen as an approximation to the intensity felt by the reader or expressed by the author. The paper is divided into 3 sections hereon - the second section talks about the system description, the third section on a comparative analysis of results and finally a discussion on the future scope.

2 System Description

The datasets for anger, joy, fear and sadness were created using a technique called the Best Worst Scaling.([Mohammad and Kiritchenko, 2016](#)) These annotations lead to reliable fine grained intensity scores which can be used to imply the intensity or the degree of an emotion expressed. The detailed data collection information can be found in Mohammad et al.([Mohammad and Turney](#))

2.1 Pre Processing

This step includes modifying the raw tweets to a form that can be easier to process for the further steps. It has already been asserted that the nature of the text in question is peculiar as it is mined from social media. In addition to regular usage of words emoticons, user ids and URLs are common in social media. It is very important to note that

while the tweet is tokenized into words, the process is twitter-aware, or the splitting is done keeping in mind the utility of User IDs and URLs as separate entities.

We tried 2 kinds of tokenizers : tweetokenize and regular expressions using the regex expression matching in python. We demonstrate below the difference in tokenizing for each of these and why we chose tweetokenize as it was more tweet aware.

The sentence used is :

What are some good #funny #entertaining #interesting accounts I should follow ? My twitter is dry

1. **Regex Python**

'what', 'are', 'some', 'good', 'funny', 'entertaining', 'interesting', 'accounts', 'i', 'should', 'follow', '?', 'my', 'twitter', 'is', 'dry'

2. **Tweetokenize**

'What', 'are', 'some', 'good', '#funny', '#entertaining', '#interesting', 'accounts', 'I', 'should', 'follow', '?', 'My', 'twitter', 'is', 'dry'

2.2 **Feature Extraction**

The baseline feature made available is the **Affective Tweets** package, which includes a number of lexicon based and syntactic feature extraction modules. After a thorough analysis of various systems of NLP competitions from Kaggle, KD Nuggets and various other conferences, we narrowed down to 3 type of important features.

1. **Lexicon Based**

Many of the tasks related to sentiment and emotion are using these features extensively (Mohammad and Kiritchenko, 2018). A lexicon is a dictionary of words with labels specifying their sentiments and scores to identify the intensity of text. Table 1 shows the different lexicons used, the scores they contribute and the size of the corpus. Using the above features selectively leads to a 135 dimensional feature vector, which as we observe is still relatively sparse with only a few non zero values.

2. **Semantic Based**

To overcome limitations of using the sparse

lexicon based features and to add the semantic meaning of the words, compactly represented low dimensional dense vector encodings called word embeddings are also included. Glove embeddings, which are 200 dimensional vectors trained on 2 billion corpus are integrated. Although these vectors accurately represent the significance of a word in a context, the sentence embeddings or the representation in a sequential manner is not focused on in this section. The sentence embedding is considered to be the average of the individual word embeddings of the sentence. The final represented sentence embedding is a 25 dimensional vector.

3. **Syntactic Based**

Although the meaning of the individual words have been taken into account in the semantic based vectors, it is essential to encode certain other aspects of the word, like part of speech tags, brown clusters and word n grams.

The final feature vector is chosen based on the significance of each of the individual features, when input to regressors to maximize the pearson coefficient.

2.3 **Regressors**

Each of the above features have very little correlation between each other as they represent different aspects of the text. Hence the regressors such as Support Vectors Regression, AdaBoost, Random Forest Regressor and Bagging regressor, etc can be used effectively. The feature vectors are used without any kind of normalization.

2.4 **Hyper Tuning**

The sci-kit package enables an extensive grid search mechanism to find the optimum value of the various hyper parameters of a regressor. Figure 1 shows the different values of C and gamma taken by the regressor to maximize the cost function of pearson coefficient using 10 fold cross validation. It shows anger, fear, joy and sadness metrics in a clockwise manner. Table 2 also shows the parameter values of the SVR for different emotions.

The best combination of hyper parameters are denoted by the grey spot in the grid search for each of the emotions.

Affect Lexicon	Description	Corpus Details
NRC Hashtag Emotion	Positive and negative variables by aggregating the positive and negative word scores provided by this lexicon created with tweet annotated with emotional hashtags	emotions: anger, anticipation fear, joy, sadness, surprise, trust size : 16,862 unigrams score : 0 to infinite
Sentiment140	Aggregating positive and negative scores	emotions : anger, fear size : 45,255 unigrams score : -inf to +inf
NRC 10	Adds the emotion associations of the words matching the Twitter Specific expansion	emotions : +ve, -ve size : 62,468 unigrams score : -inf to +inf
SentiStrength	Weighted average of the sentiment distributions of the synsets for word occurring in multiple synsets	emotions : anger, anticipation, fear, joy, sadness, surprise, trust size : 14,000 words score : 0 to 1
NRC Emotion	Calculates a positive and a negative score by aggregating the word associations provided by a list of emoticons	size : 76,400 terms score : count

Table 1: Lexicons used for feature extraction.

Emotion	C	Gamma
Anger	100	1e-05
Fear	1.0	1e-04
Joy	1.0	1e-04
Sadness	10	1e-05

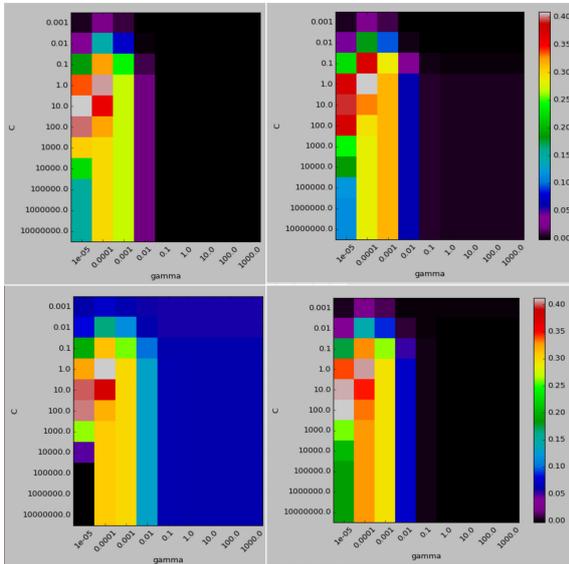

Figure 1: Hypertuning of SVR.

Table 2: Final Parameters for Support Vector System.

3 Results

Only the semantic and lexicon based features are seen to be having a positive affect on the pearson coefficient while the syntactic feaatures show almost no improvement. Hence, they are discarded from further analysis. The 10 fold cross validation shows best performance in the case of employing all the different lexicons available in concatenation with the average word embedding.

3.1 Experimental Results

Table 4 shows the performance of this feature vector when trained across various regressors. The gradient boosting with XGBOOST ensemble regressor is observed to give the best results. The spearman coefficient has been skipped in the analysis as it had the same insights offered by the pearson coefficient.

Emotion	Tweet	Predicted	Gold
Anger	'Pope fuming after police broke up drug-fuelled Vatican priest gay orgy' some headline.	0.539	0.545
	Lugubrious face, crestfallen eyes, forlorn heart and an agitated soul seeking serenity.	0.418	0.437
	I talked to an Asian yesterday.	0.374	0.000
	You are MINE, my baby, my headache, my love, my smile, my frown, my wrong, my right, my pain, my happiness, my everything.	0.433	0.172
Fear	i'm nervous	0.777	0.741
	The moment I joined BTS, I was nervous and amp; felt lost. I still have those feelings but whenever I do, the people who bring me back are you guys	0.713	0.732
	Considering I am 101% fine with getting tattoos, blood tests terrify me and I AM HAVING TO GET ONE AAAAAHHHH	0.435	0.845
	Every time I fart my dog jumps in fear hahahaha lol	0.610	0.242

	I wonder how many Lexas and Alexandrias there will be in 10 tears.	0.653	0.321
	Me at Start of Semester Expecting = A+ After Mids = B+ After Finals = Passing Marks. Thinking to quit	0.343	0.696

Table 3: Analysis of sample predictions in each emotion.

3.2 Limitations

The features that were chosen to represent the sentences, although having limitations in terms of missing context, perform significantly well in estimating the emotion. Table 3 analyzes the system's predictions in cases where the gold labels were close to the final value as well as the erroneous cases.

In cases where there are multiple instances of displaying emotion the model is very successful as seen in the first samples of every emotion. We also observe that the emoticons and punctuation are very well accounted for, like @SteveConteNYC lovely! :) and @rohandes Lets see how this goes. We falter in SL and this goes downhill. :(It can

also be said that the model is twitter aware as it often attributes an intensity based on the relative importance of the hashtag and emoticon.

There are broadly three cases where the system has trouble - one where there is very little context to decide an emotion, which is problematic even for the manual annotation, like *I talked to an Asian yesterday*. This should not be misunderstood with racial bias but merely a lack of training data. The second case is Sarcasm, like *Every time I fart my dog jumps in fear hahahaha lol*. While the lexicon based features attribute high intensity of fear due to direct usage of the word *fear*, it has to be understood that words such as *hahahaha*, *lol* have a diminishing effect on this sentiment. Finally, we

Abstract

This paper describes MuTuX, our system that is designed for task 1-5a, emotion classification analysis of tweets on SemEval2018¹. The system aims at exploring the potential of context information of terms for emotion analysis. A Recurrent Neural Network is adopted to capture the context information of terms in tweets. Only term features and the sequential relations are used in our system. The result submitted ranks 16th out of 35 systems on the task of emotion detection in English-language tweets.

1 Introduction

Emotion analysis on social media is attracting more and more research interests (Strapparava and Mihalcea, 2008; Balahur et al., 2011; Agrawal and An, 2012; Wang et al., 2012; Hasan et al., 2014a; Canales and Martínez-Barco, 2014) from industry and academia. Commercial applications such as product recommendation, online retailing, and marketing are turning their interests from traditional sentiment analysis to emotion analysis as well. Emotion analysis is generally taken as a multi-label classification problem. Given a piece of text, such as a tweet, it assigns several labels such as depressed, sad, angry and so on to it (Mohammad et al., 2018) based on the meaning contained in the text.

Techniques related to emotion detection can be divided into lexicon-based approaches (Valitutti, 2004; Strapparava and Mihalcea, 2008; Balahur et al., 2011) and machine learning approaches (Hasan et al., 2014b; Wang et al., 2012; Roberts et al., 2012; Suttles and Ide, 2013). Lexicon-based approaches leverage lexical resources to detect emotions, the resources can be keywords (Hasan et al., 2014a), WordNet-Affect (Valitutti,

2004), ontologies (Balahur et al., 2011) and so on. Machine learning based approaches (Balabantaray et al., 2012) generally take emotion detection as a classification problem using SVM, neural network (Abdul-Mageed and Ungar, 2017; Bravo-Marquez et al., 2016), naive bayes, Decision Tree, KNN and so on, or using certain unsupervised techniques such as LSA (Deerwester et al., 1990; Wang and Zheng, 2013; Gill et al., 2008), pLSA, NMF to transform the feature space into a more reasonable one before conducting classification. The main challenges of emotion analysis of tweets are the following:

1. Informal languages used on social media are not always obeying formal grammar, which makes traditional grammatical features less reliable for detecting emotions on social media.
2. New words are frequently created on social media, making it difficult to understand their emotional meaning even for a human being.

To address the challenges above, we use recurrent neural network to make use of terms, sequential information, and contextual information simultaneously for emotion detection. We believe that contextual information can partly solve the new-term problem and grammar-breach problem. To use recurrent neural network, a pre-trained embedding is used as our initial input of each term.

2 External Resource

We only used one external resource in our analysis, which is a pre-trained word embedding (Mikolov et al., 2013) word2vec provided by Google. It is trained on a part of the Google News dataset (about 100 billion words) and it contains 300-dimensional vectors for 3 million words and phrases.

¹<https://competitions.codalab.org/competitions/17751>

3 System Description

To explore the limit of term features with RNN for emotion detection, we did not use various features other than term embedding. The system could be improved by using features like emojis or emoticons. We will conduct further analysis afterwards by addressing problems in combining different feature space.

As for the system used for SemEval18 task 1, the main steps, features used in the model are described in this section.

3.1 Preprocessing

Since the method heavily depends on terms appear in the text, the corpus is carefully pre-processed as described below.

- **Normalization** Each word in each tweet is converted into lowercase. Non-linguistic content such as URLs, emojis, emoticons, user names are removed (some important features such as emojis and emoticons will be explored in the future).
- **Tokenization** Each tweet is split into a word sequence. No stemming is applied since some special word forms may convey more apparent emotions than its original form.
- **Stop-words Removing** NLTK² toolkits is leveraged to remove stop words from tweets. Some other meaningless terms such as single characters, digits, their compositions and so on, are also eliminated.

3.2 Embedding Usage

Word embeddings are a widely used semantic presentation of words for almost any neural network based text analysis approach. A vector of real numbers is used for a single word to represent its distributional semantics in the embedding space. Since the space is generated by the language model, words that are functional similar in certain language are close with each other in the embedding space, for example, "cat" and "dog" could be similar in the space.

In this system, a tweet is represented by concatenating embeddings of the words in it.

3.3 Our Approach

The system submitted is based on a recurrent neural network approach, GRU, to be specific.

²<https://www.nltk.org/>

3.3.1 The Basic Idea

Lexicons play the key role in lexicon-based approaches and bag-of-feature based machine learning approaches for emotion analysis. However, in addition to the emotion lexicons, we believe that linguistic characteristics may also contribute a lot to emotion analysis. For example, the context of the emotion lexicon such as negation could revert the emotion of the utterance if it is neglected. The sequence of the sentence terms also play an important role for understanding its meaning, hence important for uncovering the true emotions. Lack of newly created terms in vocabulary or grammatically incorrect utterances can also lead to poor performance of traditional emotion analysis approaches. By modeling long-term dependencies of terms inside a tweet, fusing the semantics of the terms and their contexts together with GRU, a recurrent neural network, we hope that above problems can be alleviated in the new space.

3.3.2 Problem Statement

We take emotion analysis as a multi-label classification problem in our system as usual. A tweet is represented as a sequence of terms

$$x_i = \{w_i^0, w_i^1, \dots, w_i^M\} \quad (1)$$

where M is the length of the tweet x_i . Given a tweet x_i , the task aims at predicting the labels of it as y_i , where y_i is a d -dimensional Boolean vector $y_i \in B^d$, $d = 11$ in this case. Each dimension of vector y_{ij} indicates an emotion label of the 11 labels space *anger*, *anticipation*, *disgust*, *fear*, *joy*, *love*, *optimism*, *pessimism*, *sadness*, *surprise*, and *trust* respectively. For example $y_{i0} = 1$ means emotion of *anger* is detected in the tweet x_i , $y_{i9} = 0$ means emotion of *sadness* does not appear in the tweet.

3.3.3 The model architecture

The architecture of the model is shown in Figure 1. The model is composed of 3 layers. The input of the network is the pre-trained embedding of each term occurs in a tweet. The sequential term embeddings are then turned into a tweet level representation by a classical GRU, the output of GRU is directly inputted into a linear perceptron layer, and maps the tweet representation into class representation directly by this layer. The output of the linear perceptrons are then processed by a sigmoid function to get the final predictions.

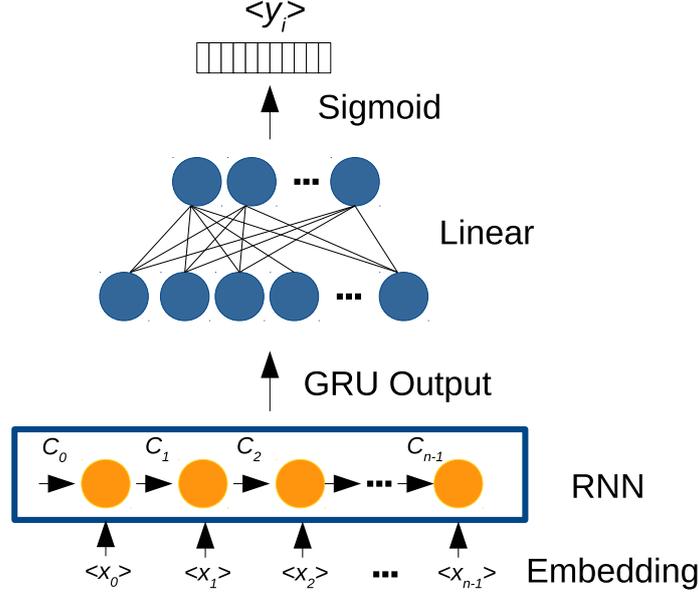

Figure 1: Overview of the architecture

3.3.4 The GRU Layer

The input of the GRU layer is the sequence of term embeddings of the tweet. We denote by $H = h_1, \dots, h_n$ the input sequence of length n , where $h_i \in R^d$ is the term representation for the i -th token w_i . The new representation of the whole tweet r_i is then obtained from h_i via a GRU network:

$$r_i = (1 - z_i) \odot r_{i-1} + z_i \odot \tilde{r}_i \quad (2)$$

where,

$$\begin{aligned} g_i &= \sigma(W_g r_{i-1} + U_g h_i) \\ z_i &= \sigma(W_z r_{i-1} + U_z h_i) \\ \tilde{r}_i &= \tanh(W_r (g_i \odot r_{i-1}) + U_r h_i). \end{aligned} \quad (3)$$

Here, g_i and z_i are reset and update gates respectively that control the information flow from the previous timestamp. W_g, U_g, W_z, U_z, W_r , and U_r are weight matrices to be learned for transforming r_{i-1} and h_i to gate units. By applying GRU on h_i , the tweet representation $r_i \in R^K$ encodes the context information and historical information simultaneously.

3.3.5 The Perceptron Layer

With the output of GRU, a vector $r_j \in R^K$ representing the overall information of a tweet, we use a perceptron layer together with a sigmoid activation function to map the tweet from feature space

to label space $y_j \in R^L$, where L is dimension of the label space.

$$\begin{aligned} \hat{y}_j &= \sigma(W_p r_j) \\ \sigma(x) &= \frac{1}{1 + e^{-x}} \end{aligned} \quad (4)$$

The predicted label vector \hat{y}_j of each tweet t_j is then compared with the true label vector y_j on training data to guide the training process with an appropriate loss function.

3.3.6 The Loss Function

Binary cross entropy loss can be used for multi-label classification problems, it is computed as the formula below:

$$\begin{aligned} \text{loss}(p, q) &= -\frac{1}{N} \sum_{i=1}^N H(p_n, q_n) \\ &= -\frac{1}{N} \sum_{i=1}^N [y_i \log \hat{y}_i + (1 - y_i) \log(1 - \hat{y}_i)] \end{aligned} \quad (5)$$

where y_i is the true label vector of the tweet x_i , and \hat{y}_i is its predicted label vector.

4 Training

To train these models, we use the training data provided by SemEval18 task 1, which includes 6, 839

human labeled english tweets for Subtask 1. A data set of 887 labeled english tweets for development is also available, we leverage this set for validation. The trained model is then applied on the testing set with 3260 unlabeled tweets in it. A vocabulary is generated by extracting terms from all the training set, validating set and testing set to ensure its coverage.

The parameter configuration for the best system performance on validation set is defined as follows:

- **Hidden Dimension** The initial embedding of each term is 300 as we adopt the pre-trained word embedding trained on part of the Google News dataset³. The hidden dimension of GRU is set to 200 when we get the best validation result.
- **Maximum Tweet Length** The length of each tweet is different, we regularize the length with a maximum limit of 30 meaningful terms after preprocessing steps. A tweet that is longer than that is trimmed, and shorter than that is populated with zero paddings.
- **Learning Rate** We adopt an Adam optimizer to train the model for the submitted system. The learning rate for the optimizer is set to 0.0001 when we get the best system performance on validation set.
- **Dropout Rate** Dropout operation is reported to have similar effects of boosting approaches in neural network based models. A dropout operation is executed on the linear perceptron layer with a dropout rate of 0.4 when achieving the optimum.
- **Batch Size** The batch size settings also affect the performance of the proposed system. The optimum is obtained with a setting of 20 as the batch size.

The number of epochs is used for terminating the training process when optimum is obtained. Terminating condition depends on not only the values of the loss function, but also its transient performance on the validating dataset. Some random factors, such as the initial state of various random variables also show their impacts on it. In our experiments, the optimum is achieved at the 3-rd

³<https://code.google.com/archive/p/word2vec/>

epoch, it may vary with different initial states of other parameters.

Using the model parameters above, which produced the best performance on validating dataset, we predicted the labels of each tweet in the testing dataset. The evaluation results provided by SemEval18 is described in the next section.

5 Results

Among all the 35 systems which participated in the task of emotion classification subtask of task 1 (Mohammad et al., 2018), our only submission is ranked 16-th on the evaluation metric of Accuracy, and 19-th on both metrics of micro-avg F1 and macro-avg F1, as is shown in Table 1. Our

Rank	System	Acc.	mi-F1	Ma-F1
1	cbaziotis	0.588	0.701	0.528
15	mutex	0.473	0.591	0.446
21	SVM	0.442	0.570	0.443
28	Random	0.185	0.307	0.285

Table 1: System Evaluation Results

model structure and feature space are designed as simple as possible intentionally, so that it can test the idea without distractive factors. As shown in above table, the system outperforms SVM-based approach consistently on all three different evaluation metrics.

6 Conclusion

We have presented a GRU-based multi-label classifier to leverage context information and historical information for emotion analysis. It outperforms the unigram SVM model consistently on three evaluation metrics, even though only term features and a pre-trained word embedding are used. Some key factors such as emojis, emoticons, emotion lexicons and multi-layer neural structures will be explored in the future for further analysis.

Acknowledgments

This work is partly supported by an NSERC discovery grant, as well as a donated GPU by NVIDIA.

mabdull5, sshaikh2@uncc.edu

Abstract

Task 1 in the International Workshop SemEval 2018, Affect in Tweets, introduces five sub-tasks (El-reg, El-oc, V-reg, V-oc, and E-c) to detect the intensity of emotions in English, Arabic, and Spanish tweets. This paper describes TeamUNCC’s system to detect emotions in English and Arabic tweets. Our approach is novel in that we present the same architecture for all the five subtasks in both English and Arabic. The main input to the system is a combination of word2vec and doc2vec embeddings and a set of psycholinguistic features (e.g. from AffectiveTweets Weka-package). We apply a fully connected neural network architecture and obtain performance results that show substantial improvements in Spearman correlation scores over the baseline models provided by Task 1 organizers, (ranging from 0.03 to 0.23). TeamUNCC’s system ranks third in subtask El-oc and fourth in other subtasks for Arabic tweets.

1 Introduction

The rise and diversity of social microblogging channels encourage people to express their feelings and opinions on a daily basis. Consequently, sentiment analysis and emotion detection have gained the interest of researchers in natural language processing and other fields that include political science, marketing, communication, social sciences, and psychology (Mohammad and Bravo-Marquez, 2017; Agarwal et al., 2011; Chin et al., 2016). Sentiment analysis refers to classifying a subjective text as positive, neutral, or negative; emotion detection recognizes types of feelings through the expression of texts, such as anger, joy, fear, and sadness (Agarwal et al., 2011; Ekman, 1993).

SemEval is the International Workshop on Semantic Evaluation that has evolved from Sense-

val. The purpose of this workshop is to evaluate semantic analysis systems, the SemEval-2018 being the 12th workshop on semantic evaluation. Task 1 (Mohammad et al., 2018) in this workshop presents five subtasks with annotated datasets for English, Arabic, and Spanish tweets. The task for participating teams is to determine the intensity of emotions in text. Further details about Task 1 and the datasets appear in Section 3.

Our system covers five subtasks for both English and Arabic. The input to the system are word embedding vectors (Mikolov et al., 2013a), which are applied to fully connected neural network architecture to obtain the results. In addition, all subtasks except the last one, use document-level embeddings doc2vec (Le and Mikolov, 2014) that are concatenated with different feature vectors. The models built for detecting emotions related to Arabic tweets ranked third in subtask El-oc and fourth in the other subtasks. We use both the original Arabic tweets as well as translated tweets (to English) as input. The performance of the system for all subtasks in both languages shows substantial improvements in Spearman correlation scores over the baseline models provided by Task 1 organizers, ranging from 0.03 to 0.23.

The remainder of this research paper is organized as follows: Section 2 gives a brief overview of existing work on social media emotion and sentiment analyses, including for English and Arabic languages. Section 3 presents the requirements of SemEval Task1 and the provided datasets. Section 4 examines the TeamUNCC’s system to determine the presence and intensity of emotion in text. Section 5 summarizes the key findings of the study and the evaluations. Section 6 concludes with future directions for this research.

2 Related work

Sentiment and Emotion Analysis: Sentiment analysis was first explored in 2003 by Nasukawa and Yi (Nasukawa and Yi, 2003). An interest in studying and building models for sentiment analysis and emotion detection for social microblogging platforms has increased significantly in recent years (Kouloumpis et al., 2011; Pak and Paroubek, 2010; Oscar et al., 2017; Jimenez-Zafra et al., 2017). Going beyond the task of mainly classifying tweets as positive or negative, several approaches to detect emotions were presented in previous research papers (Mohammad and Kiritchenko, 2015; Tromp and Pechenizkiy, 2014; Mohammad, 2012). Researchers (Mohammad and Bravo-Marquez, 2017) introduced the WASSA-2017 shared task of detecting the intensity of emotion felt by the speaker of a tweet. The state-of-the-art system in that competition (Goel et al., 2017) used an approach of ensembling three different deep neural network-based models, representing tweets as word2vec embedding vectors. In our system, we add doc2vec embedding vectors and classify tweets to ordinal classes of emotions as well as multi-class labeling of emotions.

Arabic Emotion Analysis: The growth of the Arabic language on social microblogging platforms, especially on Twitter, and the significant role of the Arab region in international politics and in the global economy have led researchers to investigate the area of mining and analyzing sentiments and emotions of Arabic tweets (Abdullah and Hadzikadic, 2017; El-Beltagy et al., 2017; Assiri et al., 2016). The challenges that face researchers in this area can be classified under two main areas: a lack of annotated resources and the challenges of the Arabic language’s complex morphology relative to other languages (Assiri et al., 2015). Although recent research has been dedicated to detect emotions for English content, to our knowledge, there are few studies for Arabic content. Researchers (Rabie and Sturm, 2014) collected and annotated data and applied different preprocessing steps related to the Arabic language. They also used a simplification of the SVM (known as SMO) and the NaiveBayes classifiers. Another two related works (Kiritchenko et al., 2016; Rosenthal et al., 2017) shared different tasks to identify the overall sentiments of the tweets or phrases taken from tweets in both English and Arabic. Our work uses the state-of-the-

art approaches of deep learning and word/doc embedding.

3 Task Description and Datasets

SemEval-2018 Task 1, Affect in Tweets, presents five subtasks (El-reg, El-oc, V-reg, V-oc, and E-c.) The subtasks provide training and testing for Twitter datasets in the English, Arabic, and Spanish languages (Mohammad and Kiritchenko, 2018). Task 1 asks the participants to predict the intensity of emotions and sentiments in the testing datasets. It also includes multi-label emotion classification subtask for tweets. This paper focuses on determining emotions in English and Arabic tweets. Figure 1 shows the number of tweets for both training and testing datasets for individual subtasks. We note that subtasks *El-reg* and *El-oc* share the same datasets with different annotations, and the same for subtasks *V-reg* and *V-oc*.

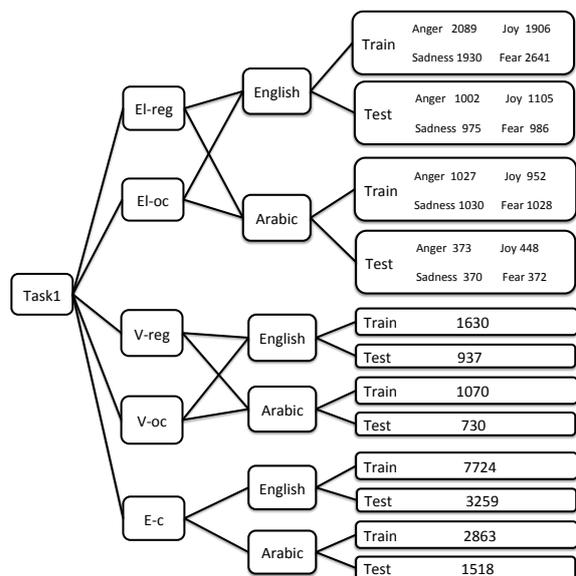

Figure 1: Datasets of SemEval-2018 Task 1.

The description of each subtask is:

El-reg: Determine the intensity of an emotion in a tweet as a real-valued score between 0 (least emotion intensity) and 1 (most emotion intensity).

El-oc: Classify the intensity of emotion (anger, joy, fear, or sadness) in the tweet into one of four ordinal classes (0: no emotion, 1, 2, and 3 high emotion).

V-reg: Determine the intensity of sentiment or valence (V) in a tweet as a real-valued score between 0 (most negative) and 1 (most positive).

V-oc: Classify the sentiment intensity of a tweet into one of seven ordinal classes, corresponding to

various levels of positive and negative sentiment intensity (3: very positive mental state can be inferred, 2, 1, 0, -1, -2, and -3: very negative mental state can be inferred)

E-c: Classify the tweet as 'neutral or no emotion' or as one, or more, of eleven given emotions (anger, anticipation, disgust, fear, joy, love, optimism, pessimism, sadness, surprise, and trust).

4 The TeamUNCC System

Our team, TeamUNCC, is the only team that participated in all subtasks of Task 1 of SemEval-2018 for both English and Arabic tweets. Subtasks *El-reg* and *V-reg* are considered similar because they determine the intensity of an emotion or a sentiment (respectively) in a tweet as a real-valued score. While subtasks *El-oc* and *V-oc* classify the intensity of the emotion or the sentiment (respectively) to ordinal classes. Our system, designed for these subtasks, shares most features and components; however, the fifth subtask, *E-c*, uses fewer of these elements. Figure 2 shows the general structure of our system. More details for the system's components are shown in the following subsections: Section 4.1 describes the system's input and preprocessing. Section 4.2 lists the feature vectors, and Section 4.3 details the architecture of neural network. Section 4.4 discusses the output details.

4.1 Input and Preprocessing

EngTweets: The original English tweets in training and testing datasets have been tokenized by converting the sentences into words, and all uppercase letters have been converted to lowercase. The preprocessing step also includes stemming the words and removal of extraneous white spaces. Punctuation have been treated as individual words ('.,?!:;()[]#@'), while contractions (wasn't, aren't) were left untreated.

ArTweets: The original Arabic tweets in training and testing datasets have been tokenized, white spaces have been removed, and the punctuation marks have been treated as individual words ('.,?!:;()[]#@').

TraTweets: The Arabic tweets have been translated using a powerful translation tool written in python (translate 3.5.0)¹. Next, the preprocessing steps that are applied to EngTweets are also applied on TraTweets.

¹<https://pypi.python.org/pypi/translate>

4.2 Feature Vectors

AffectTweets-145: Each tweet, in either EngTweets or TraTweets, is represented as 145 dimensional vectors by concatenating three vectors obtained from the AffectiveTweets Weka-package (Mohammad and Bravo-Marquez, 2017; Bravo-Marquez et al., 2014), 43 features have been extracted using the TweetToLexiconFeatureVector attribute that calculates attributes for a tweet using a variety of lexical resources; two-dimensional vector using the Sentiment strength feature from the same package, and the final 100 dimensional vector is obtained by vectorizing the tweets to embeddings attribute also from the same package.

Doc2Vec-300: Each tweet is represented as a 300 dimensional vector by concatenating two vectors of 150 dimensions each, using the document-level embeddings ('doc2vec') (Le and Mikolov, 2014; Lau and Baldwin, 2016). The vector for each word in the tweet has been averaged to attain a 150 dimensional representation of the tweet.

Word2Vec-300: Each tweet is represented as a 300 dimensional vector using the pretrained word2vec embedding model that is trained on Google News (Mikolov et al., 2013b), and for Arabic tweets, we use the pretrained embedding model that is trained on Arabic tweets (Twt-SG) (Soliman et al., 2017).

PaddingWord2Vec-300: Each word in a tweet is represented as a 300 dimensional vector. The same pretrained word2vec embedding models that are used in Word2Vec-300 are also used in this feature vector. Each tweet is represented as a vector with a fixed number of rows that equals the maximum length of dataset tweets and a standard 300 columns using padding of zero vectors.

4.3 Network Architecture

Dense-Network: The input 445 dimensional vector feeds into a fully connected neural network with three dense hidden layers. The activation function for each layer is RELU (Maas et al., 2013), with 256, 256, and 80 neurons for each layer, respectively. The output layer consists of one sigmoid neuron, which predicts the intensity of the emotion or the sentiment between 0 and 1. Two dropouts are used in this network (0.3, 0.5) after the first and second layers, respectively. For optimization, we use SGD (Stochastic Gradient Descent) optimizer (lr=0.01, decay= 1×10^{-6} ,

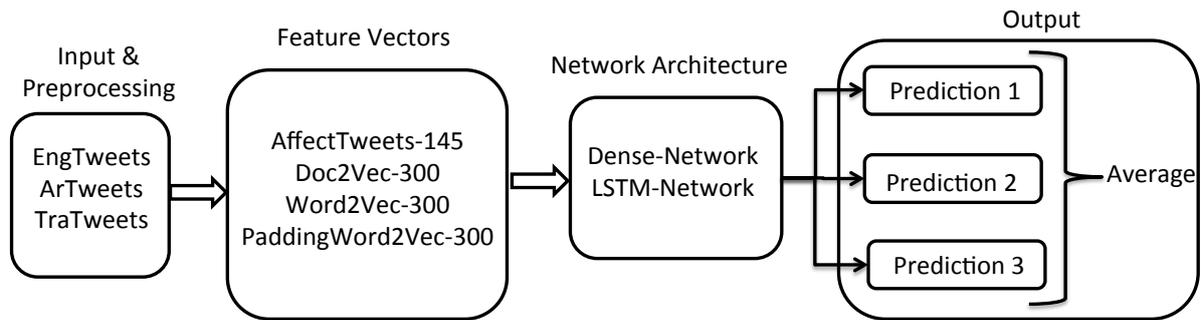

Figure 2: The structure for our system.

and momentum=0.9)², optimizing for 'mse' loss function and 'accuracy' metrics. Early stopping is also applied to obtain best results.

LSTM-Network: The input vector feeds an LSTM of 256 neurons that passes the vector to a fully connected neural network of two hidden layers and two dropouts (0.3, 0.5). The first hidden layer has 256 neurons, while the second layer has 80 neurons. Both layers use the RELU activation function. The output layer consists of one sigmoid neuron, which predicts the intensity of the emotion or the sentiment between 0 and 1. For optimization, we use SGD optimizer (lr=0.01, decay= 1×10^{-6} , and momentum=0.9), optimizing for 'mse' loss function and 'accuracy' metrics as well as early stopping to obtain the best results.

4.4 Output

Subtasks *El-reg*, *El-oc*, *V-reg*, and *V-oc*: These four subtasks for each language (English and Arabic) share the same structure as shown in Figure 2, the only difference is in the output stage. Each subtask passes the tweets to three different models that produces three predictions. See Table 1 and Table 2 for more comprehensive details on how each prediction with English and Arabic language is produced, respectively. The average of the predictions for each tweet is a real-valued number between 0 and 1. This output is considered the final output for both subtasks *El-reg* and *V-reg*, while subtasks *El-oc* and *V-oc* classify this real-valued number to one of the ordinal classes that are shown in Section 3. We note that *El-reg* and *El-oc* shares the same datasets. We also noticed that *V-reg* and *V-oc* shares the same dataset. Therefore, we found the ranges of values for each ordinal class by comparing the datasets. Table 3 shows the range of

values to obtain the ordinal classes for *El-oc* subtask in English, Table 4 shows the same for *El-oc* subtask in Arabic, and Table 5 shows the for *V-oc* in both English and Arabic.

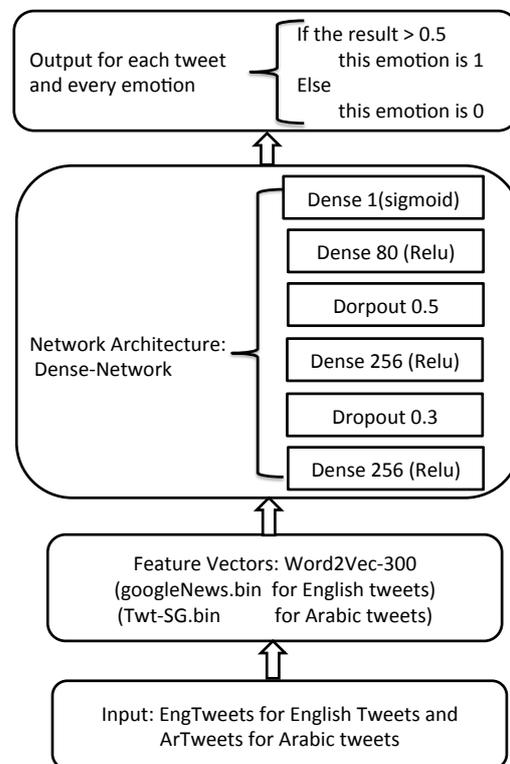

Figure 3: The detailed structure for our system related to subtask E-c.

Subtask *E-c*: In this subtask, our system makes only one prediction. See Figure3 for more details on the process of predicting the results. The input is *EngTweets* for English language and *ArTweets* for Arabic language. We use *Word2Vec-300* as the feature vector with *GoogleNews* for English tweets and *Twt-SG* for Arabic tweets. The network architecture is Dense-Network. This process is applied for each emotion of the eleven emotions:

anger, anticipation, disgust, fear, joy, love, optimism, pessimism, sadness, surprise, and trust. The output of each individual tweet is a real-valued number between 0 and 1. This output is normalized to either 1 (contains an emotion) if it is greater than 0.5 or 0 (no emotion) if it is less than 0.5.

5 Evaluations and Results

Each participating system in the subtasks *El-reg*, *El-oc*, *V-reg*, and *V-oc*, has been scored by using Spearman correlation score. The subtask *E-c* has

been scored by using accuracy metric. Table 6 shows the performance of our system in *E-reg* and *El-oc* with each emotion and the average score for both English and Arabic. Table 7 shows the results for subtasks *V-reg*, *V-oc*, and *E-c*. The performance of our system beats the baseline model’s performance, which is provided by the Task’s organizers, see Figure 4 to capture the difference between the two performances. Our system ranks third in the subtask *El-oc* for Arabic language, and Fourth in the subtasks *El-reg*, *V-reg*, *V-oc*, and *E-*

Task	Angry	Joy	Fear	Sadness	Average
El-reg (English)	0.722	0.698	0.692	0.666	0.695
El-reg (Arabic)	0.524	0.657	0.576	0.631	0.597
El-oc (English)	0.604	0.638	0.544	0.610	0.599
El-oc (Arabic)	0.459	0.538	0.483	0.587	0.517

V-reg (Arabic)	0.773
V-oc (English)	0.736
V-oc (Arabic)	0.748

Task	Accuracy score
E-c (English)	0.471
E-c (Arabic)	0.446

Table 7: The results for subtasks V-reg, V-oc, and E-c.

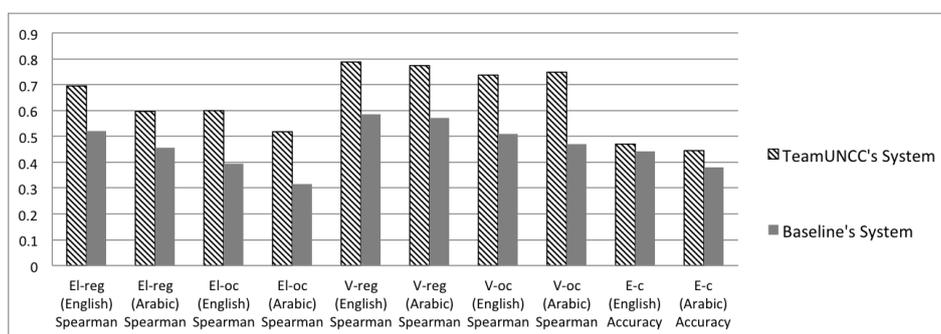

Figure 4: Comparing performances of the TeamUNCC and the baseline systems.

c for Arabic language too. It is worth mentioning that these results have been obtained by using the task datasets without using any external data.

6 Conclusion

In this paper, we have presented our system that participated in Task 1 of Semeval-2018. Our system is unique in that we use the same underlying architecture for all subtasks for both languages - English and Arabic to detect the intensity of emotions and sentiments in tweets. The performance of the system for each subtask beats the performance of the baseline's model, indicating that our approach is promising. The system ranked third in El-oc for Arabic language and fourth in the other subtasks for Arabic language too.

In this system, we used word2vec and doc2vec embedding models with feature vectors extracted from the tweets by using the AffectTweets Weka-package, these vectors feed the deep neural network layers to obtain the predictions.

In future work, we will add emotion and valence detection in Spanish language to our system by ap-

plying the same approaches that have been used with Arabic. We also want to investigate the Arabic feature attributes in order to enhance the performance in this language.

RIDDL at SemEval-2018 Task 1: Rage Intensity Detection with Deep Learning

Venkatesh Elango, Karan Uppal
Bloomberg
New York, NY, USA
{velango, kuppal8}@bloomberg.net

Abstract

We present our methods and results for affect analysis in Twitter developed as a part of SemEval-2018 Task 1, where the sub-tasks involve predicting the intensity of emotion, the intensity of sentiment, and valence for tweets. For modeling, though we use a traditional LSTM network, we combine our model with several state-of-the-art techniques to improve its performance in a low-resource setting. For example, we use an encoder-decoder network to initialize the LSTM weights. Without any task specific optimization we achieve competitive results (macro-average Pearson correlation coefficient 0.696) in the El-reg task. In this paper, we describe our development strategy in detail along with an exposition of our results.

1 Introduction

Sentiment analysis is a technique to classify documents based on the polarity of opinion expressed by the author of the document (Pang et al., 2002). Traditionally this involved extracting coarse sentiment (positive, negative, or neutral) from documents such as news articles, product or movie reviews (Wiebe et al., 2005; Hu and Liu, 2004). In order to get a fine grained view of the opinion, sentiment analysis was applied at the sentence and phrase level (Yu and Hatzivassiloglou, 2003; Wilson et al., 2005). With the advent of social media, Twitter in particular, sentiment towards a wide range of topics could be extracted at a much larger scale than before. This however came with its own set of problems, viz., a lack of proper grammatical structure, prevalence of slang, acronyms, and misspellings (Jansen et al., 2009; Barbosa and Feng, 2010).

SemEval tasks have provided a curated testing environment for analysis on Twitter data with tasks to quantify sentiment on two-point, three-

point, and five-point scales (Nakov et al., 2016; Rosenthal et al., 2017). While a finer gradation in polarity of the text could be inferred by introducing more nuanced categories, it faces the problem of needing to collect more labeled data as the number of classes increase. Therefore, this approach requires that the intensity of the sentiment expressed be measured on a continuous scale rather than through discrete categories. SemEval 2018 Task 1 takes a novel step in this direction by introducing tasks for predicting intensity of emotion, or sentiment expressed (Mohammad et al., 2018).

We participated in SemEval-2018 Task-1 (El-Reg, V-reg, V-oc) and our contributions through this paper are as follows:

- We present an LSTM network combined with known state-of-the-art techniques to improve performance on low-resource setting tasks.
- The proposed model requires no task specific hyper-parameter tuning.
- We perform error analysis of our model to obtain a better understanding of strengths and weaknesses of a deep learning-based approach for these tasks and propose improvements.

2 Methods

2.1 Datasets

For each subtask, the organizers provide training and development datasets for model training and hyperparameter selection. The details on how much data and how it was labeled can be found here (Mohammad and Kiritchenko, 2018). We concatenate the training and development datasets and sample 10% of this combined dataset, to use as validation data. Our model training involves an

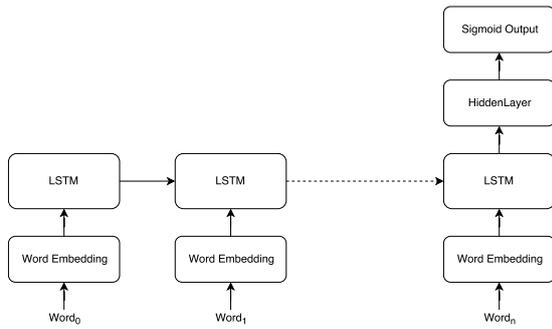

Figure 1: Network architecture.

unsupervised phase and a supervised phase, which is described in detail in Section 2.3. For the unsupervised learning phase, we use the concatenated training data from all the tasks, and for the supervised learning phase, we use the task specific training data.

2.2 Model

We start by pre-processing and tokenizing the tweets by adapting the pre-processing used in training GloVe word embeddings for Twitter (Pennington et al., 2014). Following the pre-processing techniques used in GloVe, we retain punctuations, normalize mentions, numbers, URLs, smileys (happy, neutral, and sad separately), and include tags for hashtags, repeating, and all upper case characters. In addition, we also pre-process emojis by replacing them with their Unicode text description¹.

After a tweet is broken down into a sequence of tokens, it is then converted to a sequence of vectors using the 200-dimensional GloVe word embeddings for Twitter which was trained on 2 billion tweets with a vocabulary of size 1.2 million (Pennington et al., 2014).

This sequence of word vectors is next input to an LSTM network (Hochreiter and Schmidhuber, 1997), with h_1 hidden units. The output from the last time step of the LSTM cell is passed through a layer of h_2 hidden units with ReLU activation. A final sigmoid layer then produces the output. Since all of the tasks, including the ordinal classification task, have an innate sense of ordering, we cast them as regression problems. The network architecture is shown in Figure 1.

¹<http://unicode.org/emoji/charts/emoji-list.html>

2.3 Training

We tried two different training strategies. The results submitted before the official deadline used the first strategy. Since then, we identified a few key areas of improvement and used the second training strategy to get much better results. Both strategies are described below and the results are discussed in Section 3.

2.3.1 Strategy 1

We divide the training of our model into two phases, an unsupervised phase and a supervised phase.

Unsupervised Phase

Since the amount of training data is small (approximately 2000 labeled samples on average across all tasks) in comparison to the number of parameters (approximately 500,000) of the model, the training of the model could be unstable and prone to over-fitting. To counter this problem, the weights of the LSTM are initialized using a modified sequence auto-encoder (Dai and Le, 2015). This modified sequence auto-encoder uses separate encoder and decoder networks, attempting to reconstruct the input to the encoder at the output of the decoder by minimizing the mean squared error between them (Elango et al., 2017; Srivastava et al., 2015). For this unsupervised learning phase, we pool the training data from all the tasks and use 10% of it as a validation set. The validation set is used to tune the number of epochs. The validation loss is minimized for 5 epochs. Then, we fine-tune these weights with task specific training + validation data and this fine-tuning is run for another 10 epochs.

The unsupervised learning procedure is crucial for the good initialization of weights in the supervised task. As the model optimizes its weights for reconstruction of the sequence, it is able to learn the structure of the data.

Supervised Phase

For the supervised phase, the weights from the encoder network are used as initialization. To learn a generalizable model, instead of optimizing the hyper-parameters for each task separately, we optimize the hyper-parameters only for the anger intensity regression sub-task (EI-reg anger) which was picked arbitrarily. For tuning the hyper-parameters we combine the training and development set provided for the task and randomly sam-

Hyperparameter	Value
h_1	256
h_2	32
n_{mb}	32
e	5
p_{do}	0.5

Table 1: Hyperparameters used for network training.

ple 10% of the data from this task as a validation set. The set of hyper-parameters optimized are the number of hidden units (h_1 , h_2), mini-batch size (n_{mb}), number of epochs to train the network (e) and dropout probability (p_{do}). For all the other tasks, the same optimized set of hyper-parameter values are used in training the model with all of the task specific training data.

Also, per recommendation from (Gers et al., 2000; Jozefowicz et al., 2015), to enable gradient flow, the bias term in the forget gate of the LSTM is initialized to 1. We apply dropout to the recurrent states (Gal and Ghahramani, 2016) and the hidden nodes with a probability of p_{do} , to prevent over-fitting to the training data. The model optimization is carried out by back-propagation using Adam optimizer (Kingma and Ba, 2014).

Using the above approach, the set of hyper-parameters that provide the best performance are reported in Table 1.

2.3.2 Strategy 2

After observing the results for all the subtasks we noticed that variance is fairly high in the predicted intensities. This is also visible in the scatter plots of true and predicted intensity, shown in Figures 2 and 3. We also noticed during the hyper parameter optimization on the anger task that the gap between the validation loss and training loss was high.

Simpler Model and Regularization

The above observations led us to believe that we might be over-fitting to the training data. Hence we tried the following steps to reduce over-fitting:

1. Reduced number of parameters: Number of hidden units of LSTM was reduced to 100.
2. Increased dropout rate: Increased the dropout in the hidden layer to 0.75.

Additional Unlabeled Data

Furthermore, we believed that the unsupervised phase of our training could benefit from more un-

labeled data. So we pooled in all the development and test data across all the tasks along with the training data, and used it in the unsupervised learning of weights of the LSTM. To tune the number of epochs, we set aside 10% of the combined training, development, and test as validation set. It is important to note that at no point were gold labels of test data used in any phase of training. This was simply an inexpensive way to get more data for training the unsupervised phase.

Ensemble

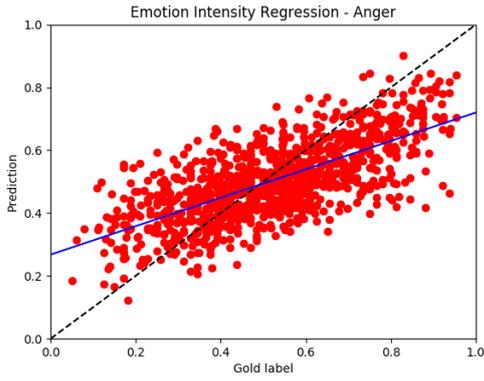

To further improve the prediction performance, we take an ensemble of 5 versions of our model and also optimize the number of epochs of training for each task for each of the 5 models. All the other hyper-parameters are kept the same across all tasks. For each of the 5 models, a random validation set with 10% of the labeled data is set aside to tune the number of epochs. Therefore, each model of the ensemble is being trained 90% of randomly sampled data. The supervised phase is trained, with random initialization for the dense layer, for 15 epochs, and the model state is saved at the end of every epoch. Finally the model corresponding to the epoch with the lowest validation loss is picked. All 5 models are used to predict on the test set, and the average of the 5 predictions is used as the final prediction of the ensemble.

3 Results

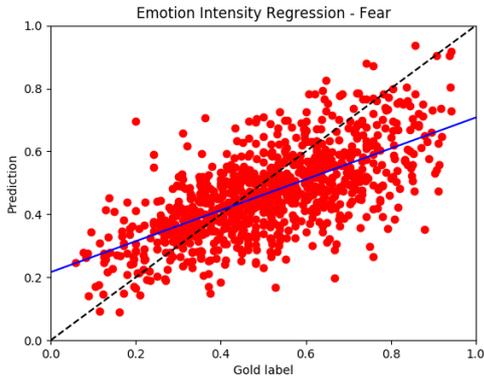

Models trained with both strategies are evaluated using Pearson correlation as the metric. We compare our performance with an unigram SVM baseline, as well as the best submission for each subtask. The official submitted results using Strategy 1 are reported in Tables 2 and 3 for subtask EI-reg and in Tables 4 and 5 for subtasks V-reg and V-oc respectively. The improved results using strategy 2 are reported in Table 6. The results in table 6 are averaged over 5 runs and report the standard deviation over the runs as well. We find that strategy 2 improves the macro-average Pearson correlation from 0.666 to 0.696.

To further analyze the results for the regression tasks, we created scatter plots shown in Figures 2 and 3. We plot the predicted intensity score against the gold label intensity score and also show the line of best fit.

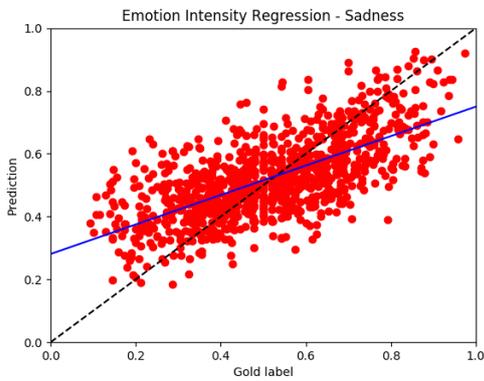

Analyzing the scatter plots, we note that our model consistently overestimates the intensity

Emotion	Pearson Correlation	
	Average	Std Dev
Anger	0.717	0.0021
Fear	0.695	0.0020
Joy	0.688	0.0054
Sadness	0.685	0.0020
Macro-average	0.696	0.0054

Table 6: Pearson correlation (average and standard deviation of 5 runs) on emotion intensity regression task (EI-reg) in English using Strategy 2.

when the gold label score is low and underestimates the intensity when the gold label score is high. The overestimation of low gold label score is most pronounced in the case of emotion intensity regression for *joy* and this is reflected in its low Pearson correlation in Table 2. Emotion intensity regression for *fear* has larger variance in predicted intensities for high gold label scores and

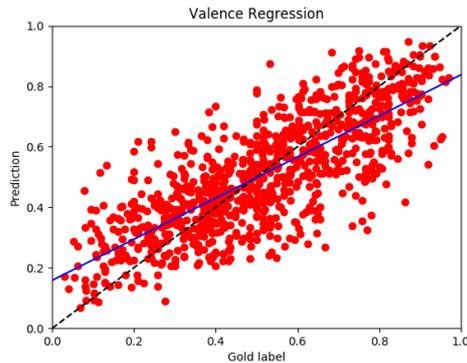

Figure 3: Plot of predicted against gold intensity score for valence regression using Strategy 1.

this too can be seen in the relatively low Pearson correlation reported in Table 2. While *anger* and *sadness* emotions also make under estimation error for high gold label scores, the line of best fit as well as the Pearson correlation are better than the corresponding ones for *joy* and *fear*.

The performance of the model in the valence regression task is markedly better in comparison to the performance in the emotion intensity regression tasks, as seen from the Pearson correlation, in Table 3, as well as the line of best fit, in Figure 3.

4 Conclusion

We presented an LSTM based approach for affect and emotion intensity regression and described our training strategy which did not involve any task specific hyper-parameter optimization. We did not employ any task specific hyper-parameter optimization to demonstrate that the training procedure is robust and that the model can be trained to achieve reasonable performance without being highly sensitive to values of hyper-parameters. We also show how the traditional LSTM network can be combined with known state-of-the-art techniques to get improvements in low resource settings. We use an encoder-decoder network to initialize the LSTM weights and use ensembles of our network to further improve performance. On the other hand, when the goal is to maximize performance, task specific hyper-parameter optimization could be employed, which is shown in strategy 2 where tuning the number of epochs on a per task basis helps the performance.

e.nagoudi@lagh-univ.dz

Abstract

This article describes our proposed Arabic Sentiment Analysis system named *ARB-SEN*. This system is designed for the International Workshop on Semantic Evaluation 2018 (SemEval-2018), Task1: Affect in Tweets. *ARB-SEN* proposes two supervised models to estimate the sentiment intensity in Arabic tweets. Both models use a set of features including sentiment lexicon, negation, word embedding and emotion symbols features. Our system combines these features to assist the sentiment analysis task. *ARB-SEN* system achieves a correlation score of 0.720, ranking 6th among all participants in the valence intensity regression (V-reg) for the Arabic sub-task organized within the SemEval 2018 evaluation campaign.

1 Introduction and Related Work

According to [Mohammad \(2016\)](#) the Sentiment Analysis (SA) task is used to refer to the “*task of automatically determining the valence or polarity of a piece of text, whether it is positive, negative, or neutral*”.

Nowadays, social media platforms like Twitter, Facebook, LinkedIn, and Quora are widely used ([Lenze, 2017](#)). For instance, [Ranginwala and Towbin \(2017\)](#) estimate that Twitter has 320 million active monthly users. These social media platforms allow people to communicate not only the sentiment they are feeling (positive or negative) but also the intensity of this sentiment. For example, from the tweet of your friend, you can estimate that: he is very happy (most positive), slightly angry (slightly negative), absolutely sad (most negative) or neutral ([Mohammad et al., 2017](#)).

Automatically determining the sentiment intensity is an important task in several application fields, such as public health, intelligence gathering, commerce and social welfare ([Mohammad and Bravo-Marquez, 2017](#)).

In the Semantic Evaluation (SemEval), sentiment analysis in Twitter task has been proposed for the first time in *SemEval-2013* by ([Nakov et al., 2013](#)). Since *SemEval-2013*, this task has become a principal task in SemEval : *SemEval-2014* ([Rosenthal et al., 2014](#)), *SemEval-2015* ([Rosenthal et al., 2015](#)), *SemEval-2016*, ([Nakov et al., 2016](#)) and *SemEval-2017* ([Rosenthal et al., 2017](#)).

In the Arab world, [Salem \(2017\)](#) estimates that the number of monthly active Arabic users was 11.1 million in March 2017, which makes Arabic an emergent language for sentiment analysis in Twitter ([Rosenthal et al., 2017](#)). Sentiment analysis task in Arabic is particularly a challenging research task ([Rosenthal et al., 2017](#)) due to its complex morphological and syntactic structure ([Habash, 2010](#)).

Many Arabic sentiment analysis tools and studies have been proposed in order to overcome this challenge. For example in Arabic newswire, the most relevant works are: ([Abdul-Mageed et al., 2011](#)), ([Elarnaoty et al., 2012](#)). In Arabic reviews we find ([Elhawary and Elfeky, 2010](#)), ([Elnagar, 2016](#)), ([Altowayan and Elnagar, 2017](#)). In Arabic Twitter many researches are focused on the sentiment analysis task such as ([Mourad and Darwish, 2013](#)), ([Abdul-Mageed et al., 2014](#)), ([Refaee and Rieser, 2014](#)), , ([Salameh et al., 2015](#)) and ([Al-dayel and Azmi, 2016](#)).

In this article we present our *ARB-SEN system* devoted to enhancing the detection of sentiment intensity in Arabic tweets. *ARB-SEN system* proposes two methods to measure this valence. Our best submitted method achieves a correlation of 0.720, ranking 6th in the Arabic Detecting Sen-

timent Intensity shared task (Mohammad et al., 2018a), SemEval-2018.

2 System Description

The sentiment intensity detection in ARB-SEN system relies on a set of features. In what follows we describe the considered features:

2.1 Sentiment Lexicon Features (SLF)

We employed the following four sentiment lexicons to extract the SLF features:

Arabic Sentiment (Valence) Lexicons

Created as part of *SemEval-2016* by Kiritchenko et al. (2016), this Arabic sentiment lexicon is a list of 1,168 single words and 198 simple phrases and their associations with positive and negative sentiment. The lexicon include both standard and dialectal Arabic terms.

Arabic Sentiment (Valence) Lexicons

This is a annotated Arabic sentiment lexicon that is created by (Saif M. Mohammad and Kiritchenko, 2016). These lexicons were created by measuring the extent to which the words in a tweets corpus co-occurred with a set of seed positive and seed negative terms. This lexicon includes about 43k entries (23k positive and 20k negative).

ArabSenti sentiment lexicon

ArabSenti is a manually annotated Arabic sentiment lexicon of 14k words that was created and by Abdul-Mageed et al. (2011). Each word in *ArabSenti* is associated with a positive/negative sentiment label.

Dialectal sentiment lexicon

This is a freely available Arabic sentiment lexicon with more than 480 dialectal Arabic words. The lexicon is proposed by Refaee and Rieser (2014) and it is manually annotated by native Arabic speakers. Using these sentiment lexicons, we extract for each tweet four features:

- 1) **Sum Score** The sum of sentiment scores of all the words in the tweet.
- 2) **Average Score** This feature computes the average of sentiment scores of all the words in the tweet.
- 3,4) **Min and Max Score** Represent the minimum and maximum sentiment score of words in the tweet.

For each of these features, if one word in the tweet does not exist in a sentiment lexicon, its corresponding sentiment score is not considered.

2.2 Negation Feature (NF)

Negation refers to words that reverse the sentiment of the word/phrase coming after them. For example: أنا لست سعيد (I'm not happy), in this example the word سعيد (happy) has a *positive* sentiment, however, due to the negation word لست (I'm not) the sentiment of expression becomes *negative*. This feature is used by *ENCU* system (Wang et al., 2016) the best system in SemEval-2016 (Sentiment Intensity Task). Wang et al. (2016) they showed that the sentiment of the phrase can be reversed by adding a negation. Thus, for this binary feature, we have used a list of five main negation word in the Modern Standard Arabic (MAS) { ليس , ما , لن , لا , لم } proposed by (Abdulla et al., 2013). If the tweet contains at least one negation, this feature is set to 1, else 0.

2.3 Word Embedding Feature (WEF)

One of the main advantages of word embedding model is the fact that it allows for the retrieval of a list of words that are used in the same contexts with respect to a given word (Mikolov et al., 2013). In fact , we use the Arabic CBOW model (Zahran et al., 2015) to construct a list of *5-closet* words for each word in the tweet as described in (Nagoudi et al., 2017). Then, we extract for each tweet the same features described in the section 2.1, with the difference that we compute the sentiment score for each word based on their *5-closet* in word embedding:

- 1) **Sum Score** The sum of the average sentiment scores of all the *5-closet* words in tweet.
- 2) **Average Score** This feature computes the average of sentiment scores of the *5-closet* words in the tweet.
- 3,4) **Min and Max Score** Represent the minimum and maximum average sentiment score of the *5-closet* words in tweet.

To compute these features, we have used the same sentiment lexicons presented in the section 2.1.

2.4 Emoticons and Emojis Features (EEF)

The emoticons and emojis are already used in the sentiment analysis task in twitter (Read, 2005)

Positive	
Emoticons	Emojis
:-) :) :D :o) =]	😊 😄 😁 😂 😃
:] :3 :c) 8) :-]	😁 😎 😊 😇 😆
Negative	
Emoticons	Emojis
:[:-(:(:-c :c	😡 😠 😞 😓 😔
:-C :C :-[:[:{	😭 😡 😠 😞 😔
Neutral	
Emoticons	Emojis
:/ :-/ :-, :/ :t :s	😐 😑 😒 😓 😔
=/ =I :L =L :Z	😏 😐 😑 😒 😓

Table 1: A sample of the positive, negative and neutral emoticons and emojis.

and (Wolny, 2016). Therefore, we have used the Emoticons and Emojis as an indicator to predict the sentiment intensity of the tweet. We have used 3 set of emoticon and emoji positive, negative and neutral. Table 2 shows a sample of the positive, negative and neutral of emoticons and emojis.

2.5 Models Construction

The previously described features are fed into two different regression classifiers : Linear Regression (*LR*) and Support Vector Regression (*SVR*). We have used the python-based machine learning *scikit-learn* library¹ to trained these classifiers on the training and development data set of SemEval 2018 (Mohammad et al., 2018b), along with the previously discussed features to predict the sentiment intensity score for each tweet. Figure 1 illustrates an overview of the *ARB-SEN* system.

3 Experiments And Results

3.1 Training Data

The organisers of SemEval 2018 provided a training and development data set, which contained 933 and 139 Arabic tweets respectively. Thus, the trial and development are used as training data for our supervised models.

3.2 Data Pre-processing

In order normalize tweets, many pre-processing techniques have been proposed in the literature, such as:(Agarwal et al., 2011), (Ahmed et al.,

¹<http://scikit-learn.org>

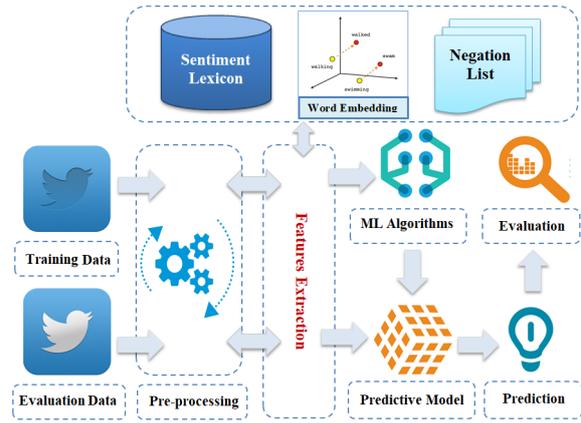

Figure 1: Architecture of the *ARB-SEN* system.

2013), and (Rosenthal et al., 2014). Therefore, we normalize our tweets using the following pre-processing steps:

1. Removing @user_names, RTs, and URLs;
2. Removing diacritics and non-alphanumeric characters;
3. Tokenizing the #hashtags of each tweet by breaking them into words, e.g: #very_nice_day becomes very, nice and day;
4. Normalizing the exchangeable Arabic letters as described in (Darwish et al., 2012), e.g: normalizing أ, إ, آ to ا and replacing final ع followed by ء with ع.

3.3 Tests and Results

To evaluate the performance of our system, our two supervised models were assessed based on their accuracy on the 731 tweets in the Arabic Sentiment Intensity Evaluation Set². In addition, we studied the impact of sentiment lexicon, negation, word embedding and emotion symbols features on the prediction efficiency.

We calculate the Pearson correlation between our assigned Sentiment Intensity scores and the gold labels. The results are presented in Table 2.

These results demonstrate that *SVR* classifier with all features succeed in predict the sentiment intensity in Arabic tweets with a Pearson correlation score of 0.720. However, the *LR* classifier with all features achieves a correlation score of 0.617. Thus, we can easily observe that *SVR* classifier with all features outperforms the *LR* classi-

Methods	Features	Correlation
LR	SLF	0.523
	SLF+NF	0.524
	SLF+NF+WEF	0.561
	SLF+NF+WEF+EEF	0.617
SVR	SLF	0.647
	SLF+NF	0.649
	SLF+NF+WEF	0.683
	SLF+NF+WEF+EEF	0.720
Baseline	-	-0.052

Table 2: Correlation results

fier with a gain of +11%. Regarding the impact of the extracted features, all of them improve the results of the sentiment intensity prediction. Interestingly, we notice that the word embedding and emotion symbols features play a key role in improving the performance of the prediction accuracy in both classifiers with a mean of +3.5% and +4.7% respectively.

4 Conclusion and Future Work

In this article, we have presented two supervised models to predicate the sentiment intensity in Arabic tweets. Both classifiers are trained along with a set of Arabic tweets characterised by a set of features including: sentiment lexicon, negation, word embedding and emotion symbols features. The performance of our proposed system was confirmed through the Pearson correlation between our assigned sentiment scores and the golden labels. As future work, we are going to extend our features by using an Arabic Combined-Sentiment Word Embedding model. We would also like to further investigate the Arabic sentiment analysis task with more recent classifiers, namely Neural Deep learning.

psyML at SemEval-2018 Task 1: Transfer Learning for Sentiment and Emotion Analysis

Grace Gee, Eugene Wang
psyML, Inc.
grace.eugene@psymml.co

Abstract

In this paper, we describe the first attempt to perform transfer learning from sentiment to emotions. Our system employs Long Short-Term Memory (LSTM) networks, including bidirectional LSTM (biLSTM) and LSTM with attention mechanism. We perform transfer learning by first pre-training the LSTM networks on sentiment data before concatenating the penultimate layers of these networks into a single vector as input to new dense layers. For the E-c subtask, we utilize a novel approach to train models for correlated emotion classes. Our system performs 4/48, 3/39, 8/38, 4/37, 4/35 on all English subtasks EI-reg, EI-oc, V-reg, V-oc, E-c of SemEval 2018 Task 1: Affect in Tweets.

1 Introduction

SemEval-2018 Task 1: Affect in Tweets (Mohammad et al., 2018) is a shared task expanding on previous SemEval sentiment tasks and the WASSA-2017 Shared Task on Emotion Intensity (Mohammad and Bravo-Marquez, 2017). It presents 5 tasks:

1. Emotion intensity regression (EI-reg): given tweet and emotion (fear, anger, joy or sadness), predict real-valued emotion intensity from 0 to 1.
2. Emotion intensity ordinal classification (EI-oc): given tweet and emotion (fear, anger, joy or sadness), predict emotion intensity ordinal class from 0 (no emotion) to 3 (high emotion).
3. Sentiment intensity regression (V-reg): given tweet, predict real-valued sentiment intensity from 0 (no sentiment) to 1 (high sentiment). In this subtask, the directionality of the tweet sentiment is ignored. A negative tweet will

be given the same score as a positive tweet with the same valence.

4. Sentiment intensity ordinal classification (V-oc): given tweet, predict sentiment ordinal intensity class from -3 (very negative) to 3 (very positive).
5. Emotion classification (E-c): given tweet, predict for each one of 11 emotions (anger, anticipation, disgust, fear, joy, love, optimism, pessimism, sadness, surprise, trust) whether the emotion is neutral (0) or present (1).

The task is particularly challenging since E-c and EI-oc are completely new subtasks. Thus, no prior data or working models are available for comparison. The leaderboard is also not public during the competition. As shown in Table 1, taken from (Mohammad and Kiritchenko, 2018), the development sets are particularly small compared to the test sets, and the test sets are comparable in size to the training sets, so the model must generalize.

For EI-oc and EI-reg, the development and test sets are also annotated separately from the training sets. This impacts performance as our system would have placed 1st with average pearson score 0.755 on the WASSA 2017 task, in which the EI-reg train, development, and test data are annotated in the same format. Furthermore, tweets are difficult to analyze due to the unstructuredness of its language (hashtags, emoticons, slang, misspellings, poor grammar).

Previously submitted systems in SemEval sentiment analysis use deep learning models such as CNN, RNN and LSTMs (Baziotis et al., 2017; Cliche, 2017; Rouvier, 2017). In a previous run of EI-reg in WASSA-2017 Shared Task on Emotion Intensity, top performing teams use deep learning models (Goel et al., 2017; Köper et al., 2017) and

Dataset	train	dev	test	Total
EI-reg, EI-oc				
anger	1,701	388	1,002	3,091
fear	2,252	389	986	3,627
joy	1,616	290	1,105	3,011
sadness	1,533	397	975	2,905
V-reg, V-oc	1,181	449	937	2,567
E-c	6,838	886	3,259	10,983

Table 1: Number of tweets in SemEval-2018: Affect in Tweets Dataset.

classifiers such as Support Vector Regressors or Random Forest Regressors (Duppada and Hiray, 2017; Köper et al., 2017). In both tasks, some participants use an ensemble approach (Goel et al., 2017; Duppada and Hiray, 2017; Rouvier, 2017).

To extract linguistic features, some systems employ pre-trained word embeddings (Baziotis et al., 2017; Cliche, 2017) or a combination of manually created features and/or lexicons (Köper et al., 2017; Duppada and Hiray, 2017). However, exclusively relying on hand-crafted features for EI-reg may result in a model that fails to encompass unforeseen linguistic relationships. Similarly, relying exclusively on deep learning models without lexicon inputs can lead to simple misclassifications due to the small training data.

To combine the best of both worlds, previous systems collapse high-dimensional word embeddings into a single dimension arithmetically, before combining it with hand-crafted features (usually one-dimensional). Goel et al. for instance averaged the word embeddings for each word in a tweet in order to concatenate it with a 43-dimensional vector. Duppada and Hiray simply averaged the two top performing model outputs.

In this paper, we present a deep learning system whose variants competed competitively in all English subtasks in SemEval-2018 Task 1: Affect in Tweets, specifically EI-reg, EI-oc, V-reg, V-oc, and E-c. We make the following contributions:

- A deep learning system that can take in a combination of one-dimensional hand-crafted and multi-dimensional word embedding inputs.
- A deep learning system that uses transfer learning from sentiment tasks to overcome the lack of training data compared to test data. To the best of our knowledge, this is the

first instance of transferring knowledge from sentiment to emotion.

- Specifically for Task E-c, procedures for training correlated target classes.

2 Overview

Fig 1 shows an overview of our system, which consists of three steps: (1) preprocessing input using a text processor and the Weka AffectiveTweets package¹ (Mohammad and Bravo-Marquez, 2017) (2) pre-training Components A to C using sentiment data (3) training the entire system, including Components A, B, C, E, using subtask-specific dataset.

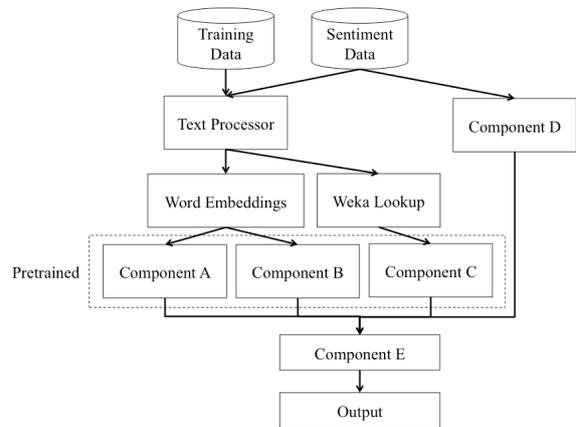

Figure 1: System Overview.

2.1 Preprocessing

We use the ekphrasis text processor² and word embeddings³ built by Baziotis et al. Ekphrasis corrects for spelling, emoticons, emojis, splits hashtags and recognizes emphasized words. Its 300-dimension word embeddings are trained on 330M Twitter messages using GloVe. Other embeddings such as Stanford’s GloVe (Pennington et al., 2014) do not incorporate newer popular unicode emojis. To build the Weka Lookup, we pass all 658,114 tokens in Baziotis et al. embedding dictionary into the TweetToLexiconFeatureVector filter in the Weka AffectiveTweets package. Of the 658,114, only 59,235 tokens returned nonzero

¹<https://github.com/felipebravom/AffectiveTweets>

²<https://github.com/cbaziotis/ekphrasis>

³<https://github.com/cbaziotis/datastories-semeval2017-task4>

vectors. The TweetToLexiconFeatureVector returns a 43-dimension feature vector using sentiment and emotion lexicons such as Bing-Liu, AFINN, Sentiment140, and NRC-10 Expanded.

2.2 Transfer Learning

Transfer learning is the process of using knowledge from solving a source task to help performance in a target task. In particular, transfer learning is useful when the target task training set is small.

Another common way to deal with small data is distant supervision (Mintz et al., 2009), a process for generating labelled data from an unlabelled set according to a set of rules. For instance, for a sentiment analysis task, distant supervision can involve labelling tweets with smileys as positive and those with sad emojis as negative (Read, 2005).

Transfer learning has historically performed well on computer vision problems (Yosinski et al., 2014; Razavian et al., 2014). Traditionally, the CNN layer weights are frozen, its output treated as a feature vector input to a fully-connected layer, which will learn the new target task. Intuitively, the CNN will learn low-level image features on the source task while the dense layers will use these low-level features to predict a new target task.

Another strategy is to unfreeze the later layers weights of the pre-trained network and instead backpropagate all the way to the pre-trained network. In this case, the later layers of the pre-trained network can be fine-tuned. We choose to leave all weights from the pre-trained network unfrozen.

Transfer learning in natural language processing applications has been largely successful only within the same task such as POS tagging or sentiment (Blitzer et al., 2006, 2007). For different domains, good results are only achieved in semantically equivalent transfer (in which a source task and target task have the same objective but different data) but not for semantically different transfer (in which a source and target task have different objectives) (Mou et al., 2016).

For all subtasks, we will use transfer learning to pre-train our models on sentiment data. The source task objective is to predict sentiment categorical classes ('positive', 'negative', or 'neutral') given a tweet. Since the source task is not equivalent to any of the target tasks, we'd expect lower performance than those experiments on domain

adaptation.

There are two main ways to perform transfer learning, the parameter initialization approach, in which a model is trained on a source task and the weights are transferred to a target task, and multi-task learning, in which a model is trained to learn multiple tasks simultaneously. We choose to implement the parameter initialization approach as Mou et al. has shown both approaches to be comparable.

2.3 Neural Network

The Recurrent Neural Network (RNN) is an extension of the traditional neural network that allows sequential data. Fig 2 shows the architecture of a standard RNN which takes in a sequence of word embeddings x_1, x_2, \dots, x_N and outputs hidden states h_1, h_2, \dots, h_N , where N is the length of the tweet.⁴

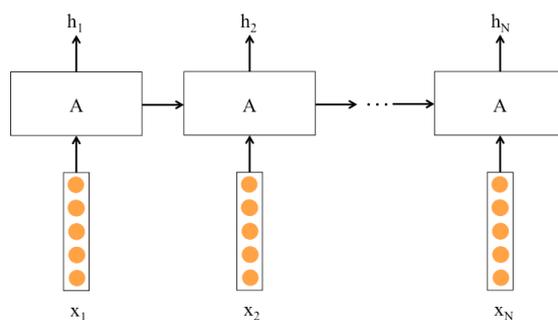

Figure 2: RNN basic structure.

In its simplest form, the hidden state $h_t \in \mathbb{R}^d$ (where d is the size of the RNN at time step t) is a function f of the current word embedding x_t , the past hidden state h_{t-1} , and the learned θ parameters.

$$h_t = f(x_t, h_{t-1}; \theta) \quad (1)$$

Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) is a special form of RNN with a memory cell and input, forget, and output gates that allow it to take into account long-term dependencies. It is more widely used than RNN since it overcomes the vanishing or exploding gradient problem common in RNNs. The architecture of a standard LSTM will be the same as that of an

⁴Figure recreated from <http://colah.github.io/posts/2015-08-Understanding-LSTMs/>

RNN as shown in Fig 2, but with a different repeating A module. Formally, each LSTM cell is computed as follows:

$$X = \begin{bmatrix} h_{t-1} \\ x_t \end{bmatrix} \quad (2)$$

$$f_t = \sigma(W_f \cdot X + b_f) \quad (3)$$

$$i_t = \sigma(W_i \cdot X + b_i) \quad (4)$$

$$o_t = \sigma(W_o \cdot X + b_o) \quad (5)$$

$$c_t = f_t \odot c_{t-1} + i_t \odot \tanh(W_c \cdot X + b_c) \quad (6)$$

$$h_t = \sigma_t \odot \tanh(c_t) \quad (7)$$

where f_t is the forget gate, i_t the input gate, c_t the cell state, h_t the hidden state, σ the sigmoid function and \odot element-wise multiplication.

We use bidirectional LSTM (biLSTM) to incorporate both past and future context. A biLSTM employs two LSTMs, one reading forward, \overrightarrow{LSTM} , on the input sequence and another backward, \overleftarrow{LSTM} .

Whereas in a traditional LSTM, output h_i only incorporates information up till time step i , or x_1, x_2, \dots, x_i , a bidirectional LSTM would incorporate information from both past input x_1, x_2, \dots, x_i and future input x_i, x_{i+1}, \dots, x_N . Fig 3 shows the architecture of a standard biLSTM.

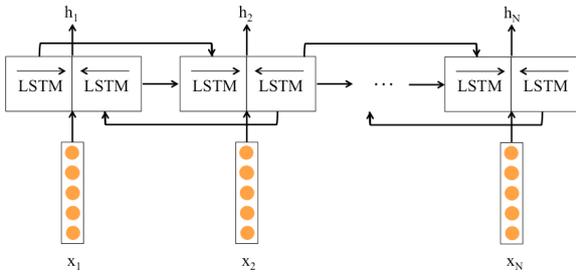

Figure 3: Bidirectional LSTM.

We use an attention mechanism (Rocktäschel et al., 2015) to learn which words in a tweet contribute more to a target task. Fig 4 shows the architecture of a standard LSTM with attention mechanism.

The attention layer is usually a 1 or 2-layer neural net that takes the output of an LSTM or RNN as input. It assigns "attention weight" α_i to each hidden state h_i and outputs a weighted representation r of the hidden states.

$$e_i = \tanh(W_h h_i + b_h) \quad (8)$$

$$\alpha_i = \text{softmax}(e_i) \quad (9)$$

$$r = \sum_N \alpha_i h_i \quad (10)$$

where α is an attention weight vector, r is a weighted representation of the hidden states, and W_h and b_h are learned during backpropagation.

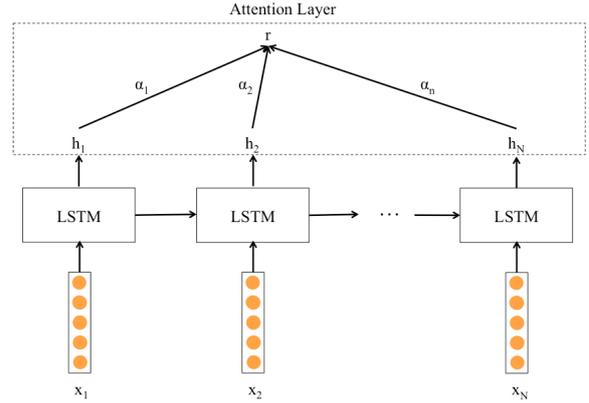

Figure 4: LSTM with Attention.

Components A and C are bidirectional LSTMs. Component B is a LSTM with attention mechanism.

3 Data

We used the dataset provided by the SemEval challenge.

For transfer learning, we pre-train Components A to C using train, development and test data from 2013 to 2017 SemEval Task 4A sentiment analysis classification tasks⁵. In total, this provided 7,723 negative, 22,195 neutral and 19,652 positive tweets.

4 Model

Component A is a 1-layer biLSTM. The input is a matrix $A \in \mathbb{R}^{n \times d}$, where n is the number of words in the tweet and d is the dimension of the word embedding. Component B is an LSTM with attention and takes in the same input as Component A. The attention layer is a 1 unit dense layer. Component C is also a 1-layer biLSTM like Component A, except the input is a matrix

⁵<http://alt.qcri.org/semeval2017/task4/>

$C \in \mathbb{R}^{n \times 43}$, since Weka’s TweetToLexiconFeatureVector returns a 43-dimension vector and C is just a concatenated sequence of 43-dimension vectors of words passed into the TweetToLexiconFeatureVector. The tweet input for Components A through C are all zero padded. Component D just takes in an entire tweet and returns the 43-dimension TweetToLexiconFeatureVector vector. Component E is a 5-layer fully-connected neural net.

4.1 Regularization

In Components A through C, we apply dropout to both input and recurrent connections. Dropout (Srivastava et al., 2014) is a technique that involves randomly dropping units during training to prevent overfitting and co-adaptation of neurons. By randomly dropping units, neighboring neurons make up for the dropped units and learn representations for the target, resulting in a more robust network.

In Components A and C we apply global max pooling for the final layer.

We incorporate mini-batch gradient descent in all our models. Mini-batch gradient descent is calculated over small batches of data instead of the entire dataset as in traditional gradient descent. Compared to stochastic gradient descent, where gradient descent is calculated after every example, it is not as computationally intensive.

In the E-c dataset and sentiment classification dataset, some classes are overrepresented. This class imbalance can lead to bias in model output. To overcome this, for E-c we apply class weight to the loss function to boost recall of the minority class.

4.2 Hyper-parameters

We train all our models using mini-batches of size 8, and Adam (Kingma and Ba, 2014) optimization. For the E-c subtask, we minimize binary cross entropy loss. For EI-oc, EI-reg, V-oc and V-reg, we minimize mean squared error.

Models Components A through C all have dropout of 0.2 for their input layer and recurrent connections.

Components A and C are both biLSTM with 256 units. Component A takes in $A \in \mathbb{R}^{50 \times 300}$, while Component C takes in $C \in \mathbb{R}^{50 \times 43}$. We chose 50 since none of the tweets are longer than 50 words. Finally, we add a global max pooling layer.

Component B is a LSTM of 256 units, and takes in $B \in \mathbb{R}^{50 \times 300}$.

For source task learning, we apply a dense layer of 3 hidden units with sigmoid activation function to Components A through C.

Component E is 5 dense layers with 300, 125, 50, 25, and 1 hidden units. We use Rectified linear unit (ReLU) as the activation function for the former four layers.

4.3 Training

Source Task Learning During source task learning, we train each of Components A through C individually on the sentiment dataset with 10% hold out validation. The source task objective is to predict sentiment categorical class (‘positive’, ‘negative’, or ‘neutral’). For each of the models, we train it for 1, 2, 3, 4, and 5 epochs and save the best performing one.

We experimented with RNN, CNN, LSTM, and biLSTM before settling on biLSTM and LSTM with attention.

Target Task Learning During target task learning, the final dense layers in Components A through C are removed and the penultimate layers are concatenated together with the output from Component D into a single vector as input to Component E. None of the weights are frozen and the entire system (Components A through E) is trained for between 5 to 10 epochs for subtasks EI-oc, EI-reg, V-oc, and V-reg. We choose the best performing model based on performance on the development set.

The final layer in Component E uses sigmoid as an activation function for EI-reg, EI-oc, V-reg, E-c and hyperbolic tangent for V-oc. The following functions are used to transform the ordinal classes of EI-oc, $d_{EI-oc} \in \{0, 1, 2, 3\}$, and V-oc, $d_{V-oc} \in \{-3, -2, -1, 0, 1, 2, 3\}$, to the output space of $[0, 1]$ and $[-1, 1]$ respectively.

$$d'_{EI-oc} = d_{EI-oc} * 0.25 + 0.125 \quad (11)$$

$$d'_{V-oc} = d_{V-oc} * 2/7 \quad (12)$$

For E-c, we notice the emotion classes are intercorrelated. The following Figure 5 is a dendrogram generated from E-c training data. The emotions are hierarchically clustered based on their correlations. The horizontal axis labels correspond to the 11 classes. The shorter the length of

the sideways n-shape, the more correlated the two classes.

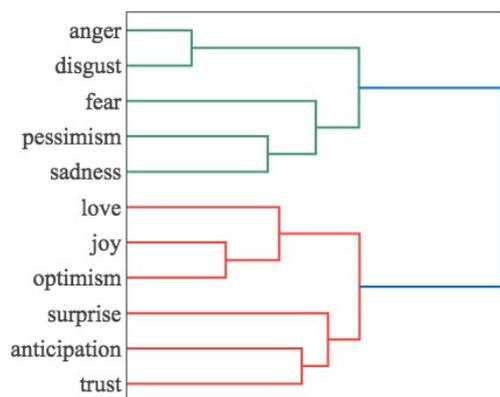

Figure 5: Dendrogram of 11 emotions, clustered using correlation and hierarchical clustering.

For E-c, we obtain the following emotion clusters from the dendrogram: [anger, disgust], [sadness, pessimism, fear], [joy, optimism, love], [anticipation, surprise, trust]. For each of the clusters, we obtain a fresh copy of the entire pre-trained system and train it for 2 epochs consecutively for each target class in the aforementioned order within the emotion cluster. The pseudocode is as follows. We call this method "cluster training":

Algorithm 1 Cluster training

- 1: **for** *emotionCluster* in *emotionClusters* **do**
 - 2: $S \leftarrow$ System from Fig 1
 - 3: **for** *emotion* in *emotionCluster* **do**
 - 4: Train S for 2 epochs on *emotion* training
 - 5: Predict *emotion* test with S
-

4.4 Experimental Setup

We build all the models with the Keras library and train them on Google Datalab. The dendrogram diagram is built with Plotly.

5 Evaluation & Results

SemEval Results Our model ranks 4/48 in EI-reg, 3/39 in EI-oc, 8/38 in V-reg, 4/37 in V-oc, 4/35 in E-c (Mohammad et al., 2018). Our performance for V-reg is less than satisfactory because V-reg measures sentiment intensity without regards for directionality, whereas our source task takes into account directionality. This supports findings by

Mou et al. that pre-training is less useful in a semantically different transfer.

System To evaluate our system, we assess the performance of each Component and various combinations of them. Table 2 shows the development set performance. In particular, we note that Component A+B performs better than Component A or Component B separately, as with Component C+D. Furthermore, Component A+B+C+D perform better overall compared to Component A+B and Component C+D.

Cluster training Subtask E-c classes are imbalanced, with 95% of "Trust" and "Surprise" training examples being negative. Table 3 shows the breakdown of negative and positive training examples for each of the E-c classes.

To assess our cluster training procedure, we evaluate the performance of independently training each of the E-c emotion classes (using a fresh copy of the pre-trained system for each of the 11 emotions) as well as with various class weighing schemes. Table 4 shows our experiment results.

Within independent training experiments, squared inverse weights performed best as measured by accuracy and micro-avg F1. Using squared inverse weights, cluster training performs better than independent training, attesting to the utility of cluster training.

6 Conclusion

In this paper, we present the first attempt to perform transfer learning from sentiment to emotions. Model weights are pre-trained with past SemEval sentiment categorization tasks and the penultimate layers of the models are concatenated into a single vector as input to new dense layers. The entire system is then trained for each subtask with the weights unfrozen.

Our deep learning system combines multi-dimensional word embeddings with single dimensional lexicon-based features. Specifically we combine features of $X \in \mathbb{R}^{50 \times 300}, \mathbb{R}^{50 \times 43}, \mathbb{R}^{1 \times 43}$, which results in better performance than systems using just one of the features.

For the E-c subtask, we utilize hierarchical clustering to group correlated emotions together and train the same model incrementally for emotions within the same cluster. This novel method outperforms a system which trains on each emotion independently.

Experiment	Anger	Sadness	Fear	Joy
Component A	0.729	0.706	0.677	0.719
Component B	0.710	0.719	0.646	0.689
Component C	0.584	0.561	0.567	0.564
Component D	0.602	0.597	0.546	0.585
Component A+B	0.722	0.714	0.701	0.732
Component C+D	0.659	0.619	0.631	0.601
Component A+B+C+D	0.761	0.720	0.723	0.745

Table 2: Results on development set comparing Component experiments.

Emotion	Percentage negative	Percentage positive
Anger	63%	37%
Disgust	62%	38%
Sadness	71%	29%
Pessimism	88%	12%
Fear	82%	18%
Joy	64%	36%
Optimism	71%	29%
Love	90%	10%
Anticipation	86%	14%
Surprise	95%	5%
Trust	95%	5%

Table 3: E-c training set, breakdown of percentage of positive and negative examples.

Experiment	Accuracy	Micro-avg F1	Macro-avg F1
Cluster training, squared inverse weights	0.576	0.695	0.522
Independent training, equal weights	0.513	0.639	0.439
Independent training, inverse weights	0.447	0.586	0.545
Independent training, squared inverse weights	0.558	0.684	0.527

Table 4: E-c experiment results on development set.

We participated in all of the English subtasks of SemEval 2018 Task 1: Affect in Tweets and obtained top 4 in 4 out of the 5 subtasks, testifying to our model robustness.

For future work, we would like to experiment with other training methods such as multi-task learning and distant supervision, as well as tune the hyper-parameters of our model to augment its performance across all subtasks (Mohammad and Kiritchenko, 2018).

Abstract

Our submission to the SemEval-2018 Task1: *Affect in Tweets* shared task competition is a supervised learning model relying on standard lexicon features coupled with word embedding features. We used an ensemble of diverse models, including random forests, gradient boosted trees, and linear models, corrected for training-development set mismatch. We submitted the system's output for sub-tasks 1 (emotion intensity prediction), 2 (emotion ordinal classification), 3 (valence intensity regression) and 4 (valence ordinal classification), for English tweets. We placed 25th, 19th, 24th and 15th in the four subtasks respectively. The baseline considered was an SVM (Support Vector Machines) model with linear kernel on the lexicon and embedding based features. Our system's final performance measured in Pearson correlation scores outperformed the baseline by a margin of 2.2% to 14.6% across all tasks.

1 Introduction

Affective computing deals with the recognition, interpretation, processing, and simulation of human affects. It is a highly interdisciplinary field at the heart of a broad range of technological applications in health care, media & advertisement, automotive, and others.

Although emotions are a fundamental feature of human experience, they have been long ignored by technology development mainly due to their complex and subjective nature, as well as the lack of learning capabilities to detect them. Current affective computing systems focus mainly on facial expressions, body language, speech (tone of voice, rhythm, etc.), keystroke as well as physiological input (e.g., heart rate, body temperature) to capture and process changes in a user's emotional state. However, in environments such as social

media and Internet forums, most often the only signal is written language. And since language per se is the smallest portion of human communication (Mehrabian, 1981), emotions are not easy to detect.

Although emotion detection is directly related to the more popular task of sentiment analysis, they differ in many respects. Sentiment Analysis aims to detect the positive, neutral, or negative orientation of the text, while emotion detection focuses on recognizing and classifying text snippets into a set of predefined, more or less universal emotions. Various such classification models have been proposed, two famous ones being Ekman's (Ekman, 1997) six basic emotions (anger, happiness, surprise, disgust, sadness, and fear) and Plutchik's wheel of eight emotions (Plutchik, 2001), where each primary emotion has a polar opposite (joy, trust, fear, surprise, sadness, anticipation, anger, and disgust).

To date, there are many freely available tools for sentiment polarity classification of input text, yet not so many exist for emotion detection. Major challenges are: (1) the difficulty in establishing ground truth for various emotions, (2) the high variability, vagueness, ambiguity, and implicitness of language that can make the detection very problematic, (3) the scarcity of non-verbal clues in written communication, as well as (4) the challenge of getting access to and being able to process the right type of context. This can be explained by the "7% Rule" (Mehrabian, 1981): only 7% of human communication is verbal while over 90% is comprised of tone of voice (38%) and body language (55%).

This year, SemEval 2018 hosts Task1: *Affect in Tweets* (Mohammad et al., 2018) - a shared task competition aiming to predict emotions and sentiment in tweets. There are five sub-tasks (Table 1). The participating systems have to automati-

cally determine the intensity of emotions (E) and intensity of sentiment (i.e., valence V) from a collection of tweets, as experienced by the authors of these tweets. The organizers also include a multi-label emotion classification task for tweets. For each task, separate training and test data sets for each language considered are provided to the participants.

ID	Task Label	Input	Output
1	El-reg	Tweet (t), Emotion (e)	Intensity(e, t) \in (0, 1)
2	El-oc	Tweet (t), Emotion (e)	$0 \leq$ Intensity(e, t) \leq 3, Intensity(e, t) \in \mathbf{N}
3	V-reg	Tweet (t), Sentiment (s)	Intensity(s, t) \in (0, 1)
4	V-oc	Tweet (t), Sentiment (s)	$-3 \leq$ Intensity(s, t) \leq 3, Intensity(s, t) \in \mathbf{N}
5	E-c	Tweet (t), Emotions (s)	Class: neutral/ no emotion/ multiple emotions

Table 1: Description of the five sub-tasks of Task1: Affect in Tweets at SemEval 2018.

The contributions of the UIUC system are as follows: (1) In this competition, we demonstrate the use of a system that uses lexicon- and embedding-based features in an ensemble model of diverse approaches such as random forests, gradient boosted trees, and linear classifiers. We demonstrate how their combination in the final ensemble outperforms each of the individual methods. (2) We account for the train-development mismatch in the dataset by training a separate model to learn this mismatch. (3) We analyze the UIUC system and several variants of it, some of which improve on its performance. (4) We also perform an error analysis of “difficult” tweets, and explore areas for improvement of the model.

2 Related Work

Word-Emotion Lexicons: Word-emotion lexicons are a mapping between the words in the vocabulary to an emotion rating. Some lexicons map words to discrete emotions, such as General Inquirer (Stone et al., 1962), Wordnet Affect (Strapparava et al., 2004) and the NRC-10 Emotion Lexicon (Mohammad and Turney, 2013). Others, such as Affective Norms for English Words (ANEW) (Bradley and Lang, 1999) and WKB Corpus (Wariner et al., 2013), map them to dimensions such as valence, arousal and dominance.

Sentence-Level Labeled Corpora: Large scale corpora annotated with sentence-level emo-

tion labels are uncommon in the literature. Affective Text (Strapparava and Mihalcea, 2007), created for SemEval 2007, contains emotion annotations headlines of news articles. Alm et al. annotated about 185 children’s stories with the Ekman labels. Aman and Szpakowicz created annotated 5,000 sentences with additional labels for intensity and emotion bearing phrases. Preotiuc-Pietro et al. annotated 3,000 social media posts for valence and arousal, making this one of the few datasets that contains annotations based on the VAD model.

Approaches: *Rule-based approaches* incorporate domain knowledge. This can include term-based n-gram features, distance between certain terms or pre-specified POS patterns. Early work in this area focused mainly on linguistic heuristics (Hatzivassiloglou and McKeown, 1997). However, a major drawback of these rule-based approaches is that they are unable to detect novel expression of sentiment. *Keyword based approaches* classify text based on the detection of unambiguous words in language. They depend on large scale lexicons with affective labels for words, such NRC (Mohammad and Turney, 2013). *Knowledge-based approaches* use web ontologies or semantic networks. A major advantage of such systems is that they enable the system to use conceptual ideas derived from world knowledge (Cambria and Hussain, 2012). Recently, *distributed approaches* have been proposed that leverage word embeddings and train deep neural networks on the embedding space (Mohammad and Bravo-Marquez, 2017a).

Shared evaluations have encouraged the community to create benchmarks over shared tasks, and have been organized frequently. The Affective Text task at SemEval 2007 (Strapparava and Mihalcea, 2007) asked its participants to predict emotion labels for headlines of news articles. More recently, the Shared Task on Emotion Intensity (EmoInt) at WASSA 2017 (Mohammad and Bravo-Marquez, 2017a), had 22 participating teams who were given a corpus of 3,960 English tweets annotated with a continuous intensity score for each of four of Ekman’s basic emotions: anger, fear, joy and sadness.

3 Dataset

Tasks 1 and 2 share the same training and development data sets: a total of 7,500 sentences in training and about 1,600 sentences in development

across the four emotions: anger, fear, joy, sadness. It is interesting to note that the training data sets for the emotions of fear, anger and sadness overlap significantly: all pairs have a Jaccard similarity of over 0.5. This means that over 67% of the data sets across these emotions contain the same tweets.

Tasks 3 and 4 share the same data sets as well, for a total of 1,200 tweets in training and 450 tweets in development across the four emotions.

Another interesting overlap is between the tweet collections for Tasks 5 and 1 (and therefore Task 2): The data set for Task 5 appears to be made up largely of the tweets for Task 1, for both the training and development sets. These overlaps of the training and development data sets across all emotions gave us the idea to tackle all tasks using a common set of features. For instance, Tasks 2 and 4 may be solved by simply transforming the output of Tasks 1 and 3, respectively. Task 5 involves a multi-label classification and thus, needs more thought.

In the test set, with the exception of the first 1,000 or so sentences, nearly 95% of the total sentences for Tasks 1A and 3A (i.e., for English) are the so called “mystery” sentences – meaning, essentially neutral sentences without any emotional content. The scores reported by the organizers are for the non-mystery sentences only (i.e., non-neutral).

4 The UIUC System

Our system takes as input features from affective lexicons and word embeddings trained on affective Twitter corpora. We then train an ensemble of diverse models over these features. Given that the training and development labels are not directly comparable, we also model the mismatch between the two sets. Moreover, we also describe additional models that we constructed after the competition deadline (section 4.4). We report results for tasks 1A, 2A, 3A and 4A (where ‘A’ identifies the target language: English).

4.1 Feature Space

We have used the *AffectiveTweets* (Mohammad and Bravo-Marquez, 2017b), a package in Weka (Hall et al., 2009) for extracting certain features from a tweet. The features extracted are: MPQA (Wilson et al., 2005), BingLiu (Bauman et al., 2017), AFINN (Nielsen, 2011), Sentiment-140 Emoticon (Kiritchenko et al.,

2014), NRC Hashtag Emotion Lexicon (Mohammad and Kiritchenko, 2015), NRC emotion lexicon (wordlevel) (Mohammad and Turney, 2013), SentiWordNet (Baccianella et al., 2010), NegatingWordList (Mohammad and Bravo-Marquez, 2017b). We call these *lexicon features*. In addition, we also extract *Embedding based features* (Twitter Edinburgh 100D / 400D corpus) using the AffectiveTweets package.

4.2 Models

The UIUC system contains an ensemble constructed using stacking of several base learners. A schematic of this ensemble is shown in figure 1. We obtained out-of-fold predictions for each of these three models using 5-fold cross validation on layer 1. These predictions were concatenated and provided as input to layer 2. Parameters of the models in this ensemble are detailed below:

Layer 1

Random Forests:

n_estimators=100, max_features= \sqrt{F} (F=total features), max_depth=5, min_samples_leaf=2

XGB¹: max_depth=5, min_child_weight=150, gamma=0, n_estimators=150, reg_alpha=0.01, reg_lambda=0.87, learning_rate=0.1

SVM:kernel=linear, C=0.1

Layer 2

XGB: max_depth=3, min_child_weight=1, gamma=0, n_estimators=100, reg_alpha=0.1, reg_lambda=1, learning_rate=0.1, random_state=0

4.3 Modeling the Mismatch Between the Training and Development Sets

According to the organizers, the training set for the task was created from an annotation effort in 2016 (Mohammad and Bravo-Marquez, 2017a). The development and test sets were created from a common 2017 annotation effort. As a result, the scores for tweets across the training and development sets or across the training and test sets are not directly comparable. We therefore devise a model that can predict and eliminate the mismatch between the two sets of labels. As a means to model the mismatch in the distributions of the two label sets, we train a linear model that, for the labels in the development set, learns a function between the predictions made for the development set and

¹Note: XGB stands for the XGBoost implementation of gradient boosted decision trees. SVM was implemented using sklearn (<http://scikit-learn.org/stable/>).

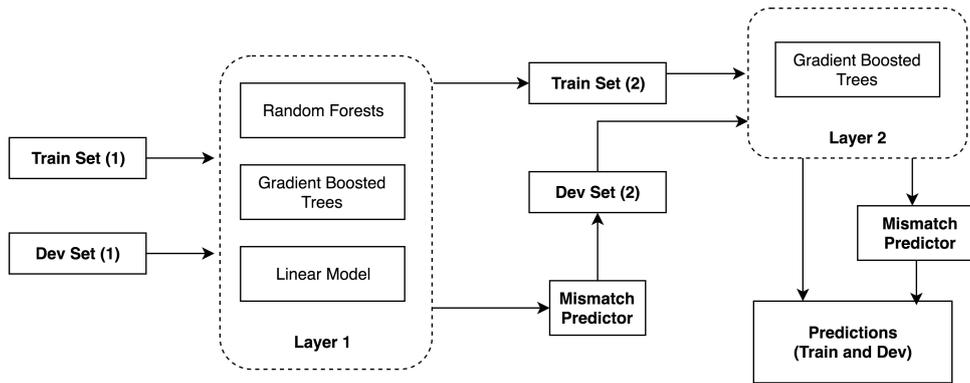

Figure 1: Ensemble used in the UIUC system.

the ground truth. This learner does not affect the training in any way, but is a way to transform the predictions made for the development set so that they are comparable to the ground truth labels.

4.4 Additional Models

After the competition deadline, we built and evaluated additional models. The overall model was an ensemble with the same structure as the official submission. Additions include implementation of neural models of computation. In particular, we implement feed-forward neural networks (using the average word embeddings as input), LSTM-CNN (using individual word embeddings) and character level LSTM (using the character stream). The neural networks were implemented in Keras (Chollet et al., 2015) with the Tensorflow (Abadi et al., 2016) backend. Details about these additional models are shown below.

Layer 1:

SVM (layer 1): $C=0.1$, kernel=RBF

XGB: max_depth=5, reg_lambda=0.87, min_child_weight=150, n_estimators=150

FFNN (feed forward neural network): Dense (256, sigmoid), Dropout (0.2, sigmoid), Dense (64, sigmoid), Dense (32, sigmoid), Dense (1, relu)

LSTM-CNN: Conv1D (300, 3, relu), Dropout (0.2), LSTM (150), Dropout (0.2), Dense (32, sigmoid), Dense (1, relu)

Character level language model (Char): LSTM (150), Dropout (0.2), Dense (64, sigmoid), Dense (1, relu)

Layer 2:

SVM: $C=1$, kernel=RBF

5 Results

In this section, we describe the results of our official submission to SemEval 2018 (subsection 5.1) as well as the results of experiments on additional models constructed after the competition deadline (section 5.2).

5.1 Performance of the UIUC system

Tables 2 and 3 show the performance of our model for Tasks 1A, 2A, 3A and 4A, respectively. We have shown the results by comparing our model against the baseline, which has been trained using an SVM with linear kernel on the lexicon and embedding based features. Our submission outperforms the baseline in nearly all the task-emotion pairs.

In particular, we observe that the results for the prediction of data points in the 0.5 – 1 range are poorer than in the overall range. The reason for this is that the finer prediction is a harder task than the overall prediction, and exactly predicting the emotion intensity given that it is high has significant variance. Scores for Task 2A are worse than those for Task 1A in spite of the similarity of the tasks. This is because in Task 2A, we essentially discretize the output, thereby either increasing or decreasing the absolute error between the intensity predicted and the actual intensity, depending on whether the discretized output is correct or not. On the whole, evidently, the correlation drops as the effect of the latter case (increase in the absolute error) dominates over the former.

Tasks 3 and 4 follow similar trends as Tasks 1 and 2 respectively, but we see a higher correlation for these tasks as compared to Tasks 1 and 2, respectively. This leads to the conclusion that predicting the sentiment is an easier task than pre-

Subtask	Submission	Pearson (all instances)					Alternate evaluation				
		macro-avg	anger	fear	joy	sadness	macro-avg	anger	fear	joy	sadness
1	UIUC System	0.647	0.663	0.646	0.649	0.628	0.463	0.514	0.431	0.422	0.485
	Baseline	0.630	0.652	0.625	0.632	0.610	0.462	0.523	0.418	0.424	0.481
2	UIUC System	0.518	0.514	0.449	0.576	0.533	0.463	0.414	0.392	0.562	0.484
	Baseline	0.448	0.512	0.258	0.527	0.493	0.334	0.335	0.219	0.415	0.366

Table 2: Results of the UIUC system for subtasks 1a (emotion intensity regression) and 2a (emotion ordinal classification) and comparison with baseline. The alternate evaluation is Pearson correlation for tweets with scores between 0.5 and 1 for subtask 1 and the Cohen Kappa (Cohen, 1960) for subtask 2.

Subtask	Model	Pearson	Alternate evaluation
3	UIUC system	0.762	0.582
	Baseline	0.746	0.565
4	UIUC system	0.724	0.694
	Baseline	0.688	0.673

Table 3: Results of the UIUC system for tasks 3a (valence intensity regression) and 4a (valence ordinal classification) and comparison with baseline. The alternate evaluation was Pearson correlation for tweets with score 0.5-1 for subtask 3a and Cohen’s Kappa for subtask 4a.

dicting the intensity of a given emotion.

5.2 Performance of Additional Models

Ablation Study for Task 1: Given the multiple subsections of data, it is difficult to optimize the architecture and parameters for all emotions for all subtasks. Therefore, we focus on optimizing the architecture and parameters for only the first subtask (emotion intensity prediction) for the emotion *anger*. Given the many models developed and presented here, it is interesting to see how they perform individually on this subtask. Table 4 shows the performance of various feature-model combinations. Note that **L** and **E** in the *Features* column indicate lexicon-based and embedding-based features respectively.

Feature	Model	CV	Dev	Test
L	SVM	0.646	0.616	0.654
	XGB	0.648	0.646	0.634
	FFNN	0.699	0.674	0.664
	SVM+XGB	0.662	0.651	0.663
	SVM+XGB+FFNN [M1]	0.695	0.674	0.673
E	SVM	0.564	0.553	0.555
	LSTM	0.640	0.635	0.633
	LSTM-CNN	0.641	0.639	0.635
	LSTM-CNN (Att) [M2]	0.651	0.642	0.644
L+E	M1+M2	0.733	0.713	0.701
	M1+M2+Char	0.735	0.711	0.704

Table 4: An ablation study of various features and models for subtask 1: emotion intensity prediction for the specific case of the emotion *anger*.

We use the SVM trained on lexical features as the baseline. We can see that the SVM+XGB+FFNN (referred to as M1) performs

better than the SVM alone. LSTM-CNN with attention (referred to as M2) performs similarly to the SVM baseline. However, when combined together, the model M1+M2+Char performs better than each of the individual models on the test set. This means that the different models capture complementary information about the input, and work better in unison, thus demonstrating the efficacy of the idea of ensembling.

Henceforth, we use **M1** to refer to the SVM + XGBoost + Feedforward Neural Network architecture trained on lexical features, **M2** to refer to the LSTM-CNN architecture with attention trained on the embedding features and **Char** to refer to the character level LSTM model trained on the individual characters.

Task	Features	Model	Pearson Correlation Coefficient			
			Anger	Fear	Joy	Sadness
1	L	SVM	0.654	0.646	0.649	0.628
	L	M1	0.673	0.668	0.698	0.642
	E	M2	0.644	0.659	0.685	0.644
	L+E	M1+M2+Char	0.704	0.688	0.713	0.652
2	L	SVM	0.514	0.449	0.576	0.533
	L	M1	0.549	0.462	0.58	0.557
	E	M2	0.544	0.455	0.571	0.542
	L+E	M1+M2+Char	0.558	0.461	0.601	0.566

Table 5: Evaluation for subtask 1 (emotion intensity prediction) and subtask 2 (emotion ordinal classification) for all emotions with various features and models.

Tasks 1 and 2 with with Additional Models: Table 5 shows the performance of the models described above to the first two subtasks: emotion intensity prediction and emotion ordinal classification. We have shown the results for all the four emotions. As we can see, here too, the model combination M1+M2+Char combination performs the best for all emotions in subtask 1. The performance of the model is the best for the emotion *joy*, and the worst for the emotion *fear*.

Tasks 3 and 4 with with Additional Models: Coming to subtasks 3 and 4 (valence intensity prediction and valence ordinal classification respectively), Table 6 shows the performance of the var-

Task	Features	Model	Alternate Evaluation
3	L	SVM	0.762
	L	M1	0.78
	E	M2	0.764
	L+E	M1+M2+Char	0.784
4	L	SVM	0.724
	L	M1	0.733
	E	M2	0.745
	L+E	M1+M2+Char	0.75

Table 6: Evaluation for subtask 3 (emotion valence regression) and subtask 4 (valence ordinal classification) for various features and models. The alternate evaluation is the Pearson correlation for tweets with scores 0.5 - 1 for subtask 3 and the Cohen’s Kappa for subtask 4.

ious models on these tasks. Consistent with the results of subtasks 1 and 2, the combined model M1+M2+Char performs the best for both tasks.

In general, we note that the correlation is significantly higher on valence prediction tasks as compared to the emotion intensity tasks. This is likely because the emotion intensity prediction is a fine grained task, requiring the model to observe patterns specific to an emotion. Valence is more of an “aggregated” effect of all the emotions.

Had the best model in additional experiments for all subtasks been submitted to SemEval with all other factors constant, its rank based on the macro-average for the first four subtasks would have been 15th, 15th, 18th and 13th respectively.

6 Discussion

In order to identify areas where the model can improve, it is necessary to study cases where it performs poorly. To do so, we select 5 sentences where the baseline SVM model performs very poorly while predicting anger intensity (based on absolute error) and 1 sentence where it performs well. We have restricted the number of sentences to 6 for brevity. In particular, for sentences 1 and 2, the model significantly overestimates the intensity, for sentence 3, the model predicts the intensity accurately. For sentences 4, 5 and 6, the model significantly underestimates the intensity. Table 7 shows the sentences considered and the true value of emotion intensity for the emotion anger.

We then compare the absolute error between the true value and model prediction for various models. This comparison is shown in Table 8. Given that 5 of the 6 sentences are “difficult” for the models, we observe that there is no clear

#	Tweet	Intensity
1	never had a dull moment with u guys	0.078
2	Fast and furious marathon soon!	0.118
3	They cancelled Chewing Gum. #devastated	0.625
4	Its taking apart my lawn! GET OFF MY LAWN!	0.797
5	I need a beer #irritated	0.806
6	Working with allergies is the most miserable shit in the world #miserable #allergies	0.856

Table 7: Test Examples for Error Analysis with intensity annotations for anger.

winner over these sentences. However, we observe that for sentences 1 and 2, the model M1 performs relatively well. For sentences 4, 5 and 6, the models involving M2 perform relatively well. This suggests that M1 is better at predicting the lower intensities, while M2 is better at the higher intensities. This may explain why though the overall scores for the two models was similar, the ensembled model outperformed the individual models. Another interesting observation is that for sentence 4, the presence of the capital letters is the reason for the high intensity. The model M1+M2+Char is able to identify this well, and contributes to reducing the error significantly as compared to all the other models.

Features	Model	Sentence-wise error					
		1	2	3	4	5	6
L	SVM	0.310	0.308	0.004	-0.377	-0.326	-0.327
L	M1	0.305	0.287	-0.067	-0.391	-0.286	-0.245
E	M2	0.344	0.366	0.051	-0.265	-0.241	-0.199
L+E	M1+M2+Char	0.339	0.373	0.071	-0.213	-0.242	-0.203

Table 8: Absolute error values for various features and models for subtask 1: emotion intensity prediction for emotion *anger*.

7 Conclusion

In this paper we presented the UIUC system that performs regression and ordinal classification of the emotion and sentiment present in English tweets. Our system comprised an ensemble trained on lexicon based and embedding based features. We also provided an account for the training and development mismatch in a given data set by training an adaptive model between the model predictions and the final test predictions. We finally perform an error analysis over the various models to identify potential sources of improvement to the model.

Abstract

We take a multi-task learning approach to the shared Task 1 at SemEval-2018. The general idea concerning the model structure is to use as little external data as possible in order to preserve the task relatedness and reduce complexity. We employ multi-task learning with hard parameter sharing to exploit the relatedness between sub-tasks. As a base model, we use a standard recurrent neural network for both the classification and regression subtasks. Our system ranks 32nd out of 48 participants with a Pearson score of 0.557 in the first sub-task, and 20th out of 35 in the fifth subtask with an accuracy score of 0.464.

1 Introduction

We consider the task of identifying affect in tweets, as described in [Mohammad et al. \(2018\)](#). Given a tweet, the task is to predict the emotions and their corresponding intensities which the tweet portrays. Previous approaches to this task are outlined in [Mohammad and Bravo-Marquez \(2017\)](#). The winning team of the SemEval EmoInt 2017, presented in [Goel et al. \(2017\)](#), tackled a similar task as the regression task presented in this year's SemEval Task 1. The winning system utilised an ensemble approach consisting of 5 sub-models and using a weighted average of these models to come up with the final result. This model is utilising most of the different approaches mentioned in the literature and combining them into one and with great success.

Our work bears resemblance to the runner up in the SemEval EmoInt 2017, [Köper et al. \(2017\)](#), who used a comparatively simple model consisting of a CNN-LSTM neural network. The difference between the models presented in this paper and the IMS system is the utilisation of lexicons, and that we take a multi-task learning approach.

We focus on two subtasks of this shared task, namely *emotion intensity regression* and *emotion classification* (Sub-tasks 1 and 5). These were chosen because of the overlap in tweets but differing truth labels value and types. Furthermore, we only consider the English versions of the subtasks.

2 System Description

Our system is a standard RNN, with the exception that we approach the task using multi-task learning via hard parameter sharing ([Caruana, 1993](#)). We will now present the details of our implementation.

2.1 Preprocessing of Text and Textual Representation

We use embedded word representations as input to our system, initialised to the weights from a large set of pre-trained embeddings which have been trained on Twitter data (~400 million tweets). These embeddings were obtained from [Godin et al. \(2015\)](#). Words which are out-of-vocabulary are replaced with UNK. Furthermore, user mentions and numbers get mapped to a place-holder instead of their actual values.

Since the model used both word and character representations, the characters are read in separately, although the same basic principle is followed. Every character is represented by an embedded representation, which is initialised randomly prior to training.

2.2 Augmentation of Data

Since the tweets have different formats of truth labels, one is a singular value (regression) and one is a multi-label list (classification), reading in the labels has to be augmented. Since the tweets are reused in the two tasks, some of the regression tweets can be augmented with their respective classification label, although, if no classification label is present, the truth labels are set to -1, which

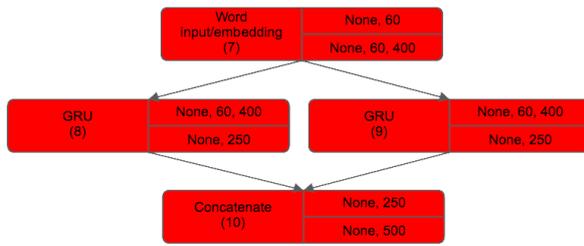

Figure 1: The word input part of the full model.

then acts as a mask. Since there are more regression tweets than classification, the augmentation is done this way around. All the tweets are padded differently based on whether or not the tweet is being read as a word representation or character representation, and tweets longer than the specified padding values are cut down to size.

2.3 Word Input Model

The word input to the model is $60 \cdot 400$ dimensional vectors that have been passed through the preprocessing and augmentation specified in section 2.1 and 2.2 ((7) in Figure 1). These vectors are then passed into two 250-dimensional, bidirectional GRUs which traverse the tweet front to back and vice versa, and the outputs of the two GRU layers are then concatenated ((8) and (9) in Figure 1). This output is then batch normalised and dropout is applied ((10) in Figure 1). This output of the word submodel is then concatenated later with the character submodel.

2.4 Character Input Model

The character input to the model is $256 \cdot 400$ dimensional vectors that have been through the same preprocessing and augmentation as the word inputs ((1) in Figure 2). These vectors then get passed into a residual neural network which works as a loop of batch normalisations, dropout applications and one-dimensional convolutions ((2) in Figure 2). Each loop ends with an addition of the values at the start of the loop and the current result and then a max pooling. These vectors are then passed into two GRU layers similar to the word input ((4) and (5) in Figure 2) which are then concatenated and passed along to be connected with the word input part ((6) in Figure 2).

2.5 Full Model

The combined model consists of four submodels, one for each regression emotion. The combined

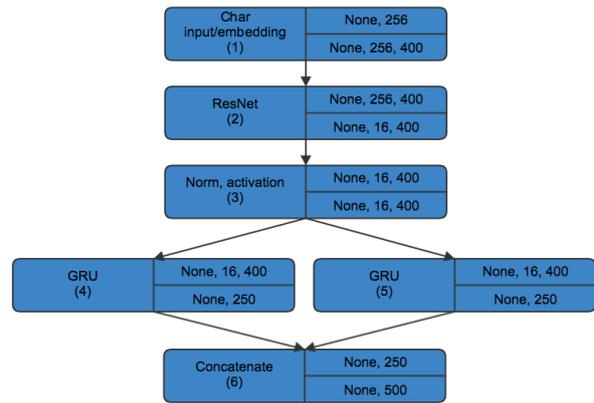

Figure 2: The character input part of the full model.

embeddings are used to generate classification labels. A high level overview can be seen in Figure 3.

2.6 Loss Functions

Since the model is a multitask model, more than one loss function was needed. The model solves two tasks which can not share loss functions because of the inherent nature of the problem, one being a regression problem and the other a classification problem.

Regression loss function For the regression output of the model, mean squared error was chosen as a way to optimise the model with regards to Pearson-score. Since mean squared error seeks to minimise the difference between the prediction and the gold score, a low mean squared error will bring the Pearson score closer to one.

Classification loss function The loss function for the classification is a bit more convoluted since all regression tweets have regression labels, but not all regression tweets have classification labels. This is handled by way of a mask and the augmentation specified in section 2.2. Since the model has eleven output layers, there is a loss function for each of the eleven emotions/layers. The loss function ensures that tweets with no classification labels do not impact the updating of the weights of the model by giving the predicted values a loss of zero. The binary cross entropy loss function was modified to include a weighting parameter because of the uneven distribution of ones and zeros. The objective of the model is to identify the emotions indicated by a tweet, and as such a value of one is assigned a higher value.

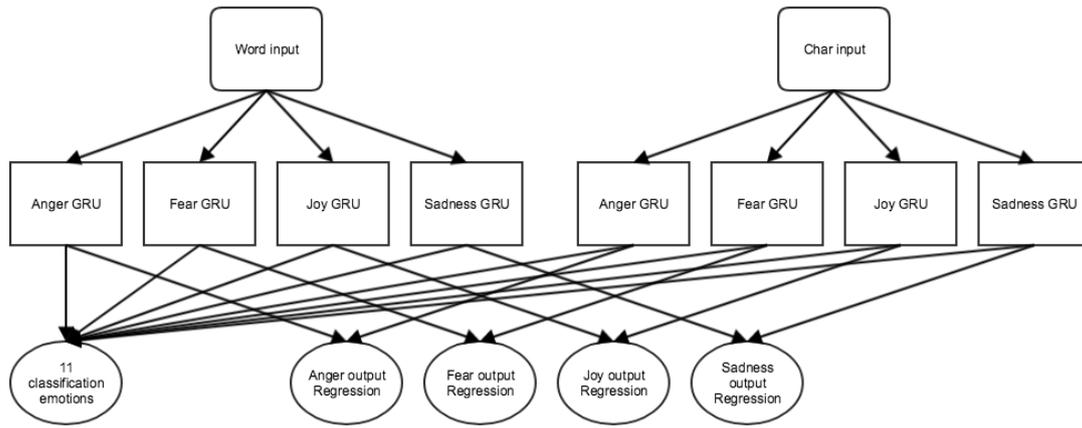

Figure 3: The character input part of the full model.

3 Error Analysis

3.1 Regression Scores

Since there is a considerable overlap in tweets, some tweets are reused in multiple emotions from Task 1 which then in turn can be reused a single time in Task 5. The actual numbers of unique and “duplicate” tweets are hard to resolve and presented a challenge in the first iterations of the model. Gold and predicted scores for an example instance are shown in Table 1 and 2.

Anger score	Fear score	Joy score	Sadness score
Gold : 0.517	Gold : 0.800	Gold : 0.197	Gold : 0.707
Pred : 0.449	Pred : 0.953	Pred : 0.139	Pred : 0.756

Table 1: Good prediction for regression task with the following tweet:

“we need to do something. something must be done!!!!” your anxiety is amusing. nothing will be done. despair.”.

Anger score	Fear score	Joy score	Sadness score
Gold : 0.953	Gold : 0.621	Gold : —	Gold : 0.680
Pred : 0.620	Pred : 0.346	Pred : 0.430	Pred : 0.326

Table 2: Bad prediction for regression task with the following tweet:

”Don’t fucking tag me in pictures as ‘family first’ when you cut me out 5 years ago. You’re no one to me.”.

It is noticeable from the scoring shown in Table 1 and 2 that keywords such as ‘family’, ‘anxiety’ and ‘fucking’, for example, have a very large effect on the values predicted. These keyword cor-

relations might have been better handled with the use of external data, such as emotive lexicons and the likes.

3.2 Classification Scores

Keeping in mind that the classification labels represent the emotions *anger*, *anticipation*, *disgust*, *fear*, *joy*, *love*, *optimism*, *pessimism*, *sadness*, *surprise* and *trust*, exemplary classification predictions are presented in Table 3 and Table 4.

Predictions	Hit percentage
Gold : 0 0 1 0 0 0 0 0 1 0 0	82%
Pred : 0 1 1 0 0 0 0 0 0 0 0	

Table 3: Scores for classification task with the following tweet:

“Not sure tequila shots at my family birthday meal is up there with the best ideas I’ve ever had #grim”.

Predictions	Hit percentage
Gold : 0 1 0 0 1 1 1 0 0 0 1	36%
Pred : 1 0 1 0 0 0 0 0 0 0 0	

Table 4: Bad prediction scores for classification task with the following tweet:

”SheenKL I assume the manga is #good?”.

There are certain structures that are prevalent in the correct and incorrect predictions. When looking at the amount of labels that are set in the datasets, it is evident just from the small amount of *surprise* or *trust* labels that have been set that these

emotions will be harder to predict, since there are so few points of reference. Furthermore, when both *anger* and *disgust* labels are present in a tweet the model predicts better. This can be explained by the fact that there are a significant amount of tweets with these two labels.

Average score	Anger	Fear	Joy	Sadness	Classification
0.551	0.521	0.606	0.538	0.563	0.464

Table 5: Overall scoring of the model, both regression and classification (Task 1 and 5).

Table 5 describes the overall scores from the model run on the test set in the evaluation period of the shared task.

4 Related Work

Multi-task Learning Neural networks make multi-task learning via (hard) parameter sharing particularly easy (Caruana, 1993) and has shown to be successful for a variety of NLP tasks, such as machine translation (Dong et al., 2015; Luong et al., 2016), keyphrase boundary classification (Augenstein and Søgaard, 2018), tagging (Martínez Alonso and Plank, 2017; Bjerva et al., 2016), complex word identification (Bingel and Bjerva, 2018), and natural language understanding (Augenstein et al., 2017). For sequence labelling, many combinations of tasks have been explored, e.g., by Martínez Alonso and Plank (2017); Bjerva (2017a,b). An analysis of different task combinations was performed by Søgaard and Goldberg (2016); Bingel and Søgaard (2017). Ruder et al. (2017) presented a more flexible architecture, which learned what to share between the main and auxiliary tasks, and might require further investigation in future work. Augenstein et al. (2017) combine multi-task learning with semi-supervised learning for strongly related tasks with different output spaces. For this shared task, we opt for a simple hard parameter sharing strategy, though we would expect to see improvements with more involved architectures.

5 Conclusion

In this paper, we present our system for SemEval-2018 Task 1. We employed a simple multi-task architecture with hard parameter sharing to model Subtasks 1 and 5 jointly. The model achieved an average performance compared to the rest of the

participants. We argue this is due to our not using external data or performing extensive additional engineering.

EmoNLP at SemEval-2018 Task 2: English Emoji Prediction with Gradient Boosting Regression Tree Method and Bidirectional LSTM

Man Liu

liumanlalala@gmail.com

Abstract

This paper describes our system used in the English Emoji Prediction Task 2 (Barbieri et al., 2018) at the SemEval-2018. Our system is based on two supervised machine learning algorithms: Gradient Boosting Regression Tree Method (GBM) and Bidirectional Long Short-term Memory Network (BLSTM). Besides the common features, we extract various lexicon and syntactic features from external resources. After comparing the results of two algorithms, GBM is chosen for the final evaluation.

1 Introduction

Short text messages from social media websites such as Twitter and Facebook have become an important communication channel in our daily life. Although the writing styles of such short text messages are extremely diverse, the usage of emojis are generally shared. Emojis are ideograms and smiles that can be electronic expressions of natural emotions. Genres of emojis vary from facial expression, places, types of weather to animals. Emojis are used every day, rapidly changing the communication way in the social network. Due to the importance of emojis, investigations about emojis have been performed in recent years. For example, the previous work (Barbieri et al., 2017) has shown that there are relations between words and emojis, in other words, emojis are predictable given its surrounding words. Task 2 of SemEval 2018 provides a platform for the further prediction of emojis on tweets.

Our system addresses the first subtask: English emoji prediction. Note that all the emojis in the training data are removed. We model this problem as a multiclass classification problem. Specif-

ically, we leverage on semantic and syntactic resources to extract varieties of features. After feature engineering, two models are adopted: gradient boosting regression tree method (GBM) and bi-directional long short-term memory network (BLSTM). After comparing results of these two models, GBM is selected for the final evaluation.

The remainder of this paper is structured as follows. In section 2, we describe our system in detail, including the feature description and approaches. In section 3, results of 5-fold experiments and feature ablation are presented. Finally, section 4 summarizes our work.

2 System Description

In this section, we present the details of our English emoji prediction system. In the dataset, each tweet corresponds to one label indicating one type of emojis. There are 20 types of emojis, most of which are emotions.

We treat the problem as a multiclass prediction task and extract a variety of features. For the model GBM, besides the common features such as word *n-gram* features, we utilize extensive external resources to build diverse word clusters, lexicon and syntactic features. For the model BLSTM, we adopt the pre-trained word embedding GloVe (Pennington et al., 2014).

2.1 Preprocessing

As the first step, we perform preprocessing for tweets tokenization and normalization. The tokenization of all tweets are performed using `tweetokenize`¹. In addition, we normalize tweets by replacing all the URLs (e.g. `https://t.co/bihPimeeV9`) with `"_url_"` and all the mentions (e.g. `@Preston Hall`) with `"@mention"`.

¹<https://github.com/jaredks/tweetokenize>

different regions. With additional regression trees added to the model, the fitted model may achieve a small training error. In other words, the gradient boosting method sequentially fits the training data by correcting base models at each step to strategically yield the best combination of trees. Therefore, the gradient boosting method is potential to produce more accurate predictions results (Zhang and Haghani, 2015). The tool we used to build GBM model is lightGBM³. We tune the hyperparameters on the training set by grid search. Because of the time constraints, it is impossible to tune all the hyperparameters in the GBM model. We choose two hyperparameters to tune and we set learning rate to 0.1 and minimal number of data in one leaf to 20. Table 1 summarizes the final settings and the search space of hyperparameters.

Parameters	Setting	Search space
number of leaves per tree	64	16, 32, 64, 128
number of trees	300	100, 300, 700, 1000

Table 1: Tuned hyperparameter values and search space for GBM.

BLSTM: We experiment BLSTM with published word embedding, namely Stanford’s GloVe embedding⁴ trained on 6 billion words from Google and Web text. Instead of a traditional feed-forward network, we use the bi-directional long-short term memory network. LSTM (Hochreiter and Schmidhuber, 1997) is a powerful connectionist model that can capture time dynamics and it has special capability to cope with these gradient vanishing problems compared with the traditional recurrent neural network (RNN). However, LSTM only has access to process one directional information in the sequence which is contradictory with most of the practical situations where the bi-directional information is both beneficial. BLSTM is designed to deal with this problem with the basic idea to process the sequence backward and forward and feed the output into two separate hidden states to catch the past and future information (Ma and Hovy, 2016).

We exploit this BLSTM transforming word embedding into classification results. Figure 1 shows the network in detail. We also tuned the hyperpa-

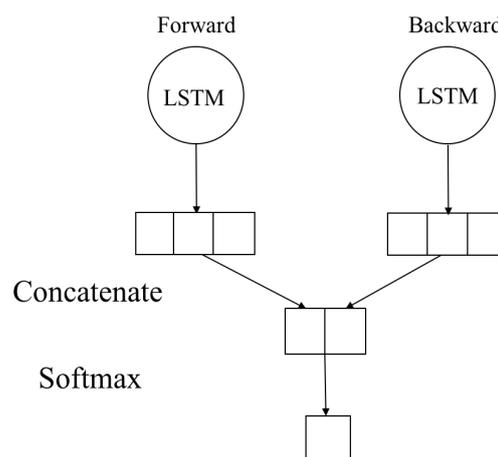

Figure 1: Architecture of BLSTM. The word embeddings of each word are fed into forward LSTMs and backward LSTMs. The outputs of each network are concatenated and decoded by a softmax function into probability for each category.

Parameters	Setting
LSTM units	64

rameters in BLSTM to achieve the best result. The tuned parameter values used are illustrated in table 2.

2.4 Results

Our system is trained on two models. With the fine-tuned hyperparameters exhibited in table 1 and 2, we train the two separate models to determine the final classifier for evaluation.

To find out the optimum settings, we explore all the training data and conduct 5-fold cross-validation experiments. Table 3 shows the 5-fold cross-validation performances on the two models. Comparing the 5-fold cross-validation results, we observe that there is no significant difference across these 5 experiments.

By comparing results of the two models, GBM outperforms in the official macro F1 score. We finally submit the evaluation result of GBM. The precision, recall and macro F1 score of the final evaluation are 39.426, 33.695 and 33.665 respec-

tively. Our system achieves the best accuracy in this task. In addition, the precision, recall, F1 and percentage of occurrences in the test set of each emoji are shown in table 4.

2.5 Further Analysis of Feature Engineering

Table 5 shows the F1 score and loss on the test set resulting from training with each group of feature removed. The experiment performance reveals that all features except SSWE in our system are helpful. The performance drops after adding SSWE features. This observation is probably caused by overfitting on the training set because of the curse of dimension.

Feature	F1 loss	F1 score

POS	0.167	33.73
Cluster	0.15	33.75
Word ngram	0.503	33.40
Counting	0.176	33.72
SSWE	-0.235	34.14
Lexicon	0.094	33.81

Table 5: Feature ablation study using the GBM model. The quantity is the F1 loss and score resulting from the removal of each feature group.

3 Conclusion

In this paper, we present the systems used in SemEval 2018 task 2 for English emoji prediction. Our effort focuses on putting forward two models to improve the multi emojis classification. By leveraging on general features (i.e. word ngram feature, character ngram feature and counting features), external resources (i.e. a variety of manual constructed lexicons, CMU brown cluster), feature selection and hyperparameters fine-tuning, GBM achieves better performance than BLSTM. This observation is attributed to the extensive usage of sentimental and syntactic features. Due to most of the target emojis are related emotions, these sentimental features can reveal the relation from words with the emotional emojis. In future, we hope to improve our BLSTM model by taking advantage of more features and incorporating more effective architecture.

UMDSUB at SemEval-2018 Task 2: Multilingual Emoji Prediction Multi-channel Convolutional Neural Network on Subword Embedding

Zhenduo Wang and Ted Pedersen

Department of Computer Science

University of Minnesota

Duluth, MN 55812, USA

{wang7211, tpederse}@d.umn.edu

Abstract

This paper describes the UMDSUB system that participated in Task 2 of SemEval-2018. We developed a system that predicts an emoji given the raw text in a English tweet. The system is a Multi-channel Convolutional Neural Network based on subword embeddings for the representation of tweets. This model improves on character or word based methods by about 2%. Our system placed 21st of 48 participating systems in the official evaluation.

1 Introduction

People use emojis on social media with text in order to express their emotions or reveal meanings hidden by figurative language. However, understanding the semantic relationship between texts and emojis is a challenging task because emojis often have different interpretations that depend on the reader. (Barbieri et al., 2018) shows that a carefully designed machine learning system can perform better than humans on an emoji prediction task. The system which gives the best predictions in that paper is a long short term memory (LSTM) network with pre-trained character embeddings as the text representation method.

(Barbieri et al., 2018) provides a new task in the context of Twitter and describes several powerful models in text sequence modeling and classification. Our work explores other possible configurations for the system, including subword embedding as a text representation method and multi-channel Convolutional Neural Networks as a feature extraction method. We conduct experiments on the Semeval-2018 Task 2 Multilingual Emoji Prediction data set and compare our results with other methods. Our results show that subword embedding based Convolutional Neural Network system is effective. It improves on character embedding by 2.1% and word embedding by 1.8%.

2 Task Description

SemEval-2018 Task 2 has two subtasks which are similar but in different languages. Subtask A is emoji prediction on English tweets, while subtask B is on Spanish. Both tasks are to predict 1 out of 20 emojis (19 in Spanish subtask) given only the text of a tweet. There are ~500K tweets in the English training set and ~100K tweets in the Spanish training set. The organizers use the macro F-score to evaluate the performance of the systems.

This is by definition a text classification task. It is more challenging than tasks such as sentiment analysis or authorship identification because it is on Twitter data which is extremely large and changes frequently. We build UMDSUB for the English subtask and conduct several experiments with different settings.

3 System Description

UMDSUB is a multi-channel Convolutional Neural Network based on subword embedding as the text representation. We use byte-pair-encoding for subword segmentation.

3.1 Word Segmentation

The goal of the word segmentation step is to break the words into subwords in order to have better representations for tweet texts.

Existing text representation methods mostly work on whole word level (Mikolov et al., 2013)(Pennington et al., 2014) or character level (Zhang et al., 2015) (Xiao and Cho, 2016). In these works, character embedding as the basis for feature extraction were shown to be more effective on text classification tasks. Also there are works such as (Bojanowski et al., 2016) which try to enrich word representations with subword information and improve upon the original word embedding methods. We believe that subword is a in-

triguing level for text representation. However, the method used to generate subwords in (Bojanowski et al., 2016) is to divide words into fixed length n-grams, which fails to use knowledge of word morphology. We believe that *Language is never, ever, ever, random* (Kilgarriff, 2005). Subwords as character n-grams could be detected by measuring their frequencies.

We detect subwords with the byte-pair-encoding (BPE) algorithm (Shibata et al., 1999), which is a frequency based text compression algorithm. The original algorithm first splits the text into bytes (characters). Then it ranks all the byte pairs (which are simply bigrams) according to their frequencies. The most frequent byte pair is then joined together and encoded by a single byte. By repeating this simple process, the original text will be compressed. In our system, we use BPE as a word segmentation algorithm. We join characters together by frequency but do not replace them with new symbols. This method was also shown to be successful in (Sennrich et al., 2015).

For example, suppose the text to be segmented is

$$S_0 = \textit{workers work in workshop.}$$

First, we split S_0 into character sequence.

$$S_1 = \textit{w o r k e r s w o r k i n w o r k s h o p.}$$

Then in the first iteration, we choose the most frequent bigram *wo* and join them together.

$$S_2 = \underline{\textit{wo}} \textit{rk e r s } \underline{\textit{wo}} \textit{rk i n } \underline{\textit{wo}} \textit{rk s h o p.}$$

In the second iteration, we choose the most frequent bigram *wor* and join them together.

$$S_3 = \underline{\textit{wor}} \textit{k e r s } \underline{\textit{wor}} \textit{k i n } \underline{\textit{wor}} \textit{k s h o p.}$$

Similarly, the next bigram should be *work*.

$$S_4 = \underline{\textit{work}} \textit{ e r s } \underline{\textit{work}} \textit{ i n } \underline{\textit{work}} \textit{ s h o p.}$$

The text is represented by a subword sequence after the algorithm finishes in N iterations, and will look like this :

$$S_N = \underline{\textit{work}} \underline{\textit{er}} \textit{s } \underline{\textit{work}} \underline{\textit{in}} \underline{\textit{work}} \underline{\textit{shop}}.$$

3.2 Subword Embedding Layer

Embeddings can be categorized into two types based on how they are trained, saved (or static) and reused (or dynamic). Static embeddings are separately trained from large open corpus (such as Wikipedia) and saved for reuse. Word2vec and GloVe models are two such examples. Dynamic embeddings are jointly trained with other parts of

specific systems. The Twitter corpus is not like a standard corpus, since it is extremely large and it changes frequently. We choose to use a dynamic embedding strategy since it may fit better for our system.

After word segmentation the text is made up of subword sequences. In order to use subword embedding to represent the text, we first represent each subword type with a one-hot vector. The one-hot vector for the i th subword in vocabulary is a sparse binary vector o_i which has 1 as the i th element and 0 for all others. This step results in a representation similar to a vector space model. We put all the subwords in the subword one-hot hyperspace where each unique subword type owns one dimension. The one-hot embedding is so sparse and it suffers from the Dimension Disaster. Hence we project it to a smaller hyperspace by multiplying the one-hot embedding with a projection weighting matrix $W \in \mathbb{R}^{d \times |V|}$, where d is the dimension for the target embedding hyperspace and $|V|$ is the subword vocabulary size. Now each subword is represented by a dense vector $s_i = W o_i$, and the tweet text T with length of L is represented by a sequence of subword embedding vectors $T = (s_1, s_2, \dots, s_L)$.

3.3 Multi-channel Convolutional Layer

As we mentioned in Section 2, this is a text classification task. A key step in any classification system which uses the feature-classifier scheme is to choose indicative features. In NLP tasks, n-grams are commonly used features because they capture word collocations as found in text. But this may not be effective if we have no sense of what kind(s) of n-grams could be useful for a certain problem. Recently, a trend (Zhang et al., 2015) (Xiao and Cho, 2016) for solving text classification tasks is to break the text into the smallest units and build a representation for them. Then this approach can use a complex neural network such as Convolutional Neural Network (CNN) or recurrent neural network (RNN) to find abstract features upon the representations. This system configuration takes advantage of the ability of complex neural networks to extract features. (Kim et al., 2016) tries to explain the mechanism of character-entry-CNN by showing that the features extracted by CNN are specific n-grams. We believe this scheme could be very useful for finding features for classification when we have little knowledge of the corpus, as is

often the case for Twitter.

In our system, we use a multi-channel CNN layer for feature extraction. Since tweets are generally short, higher-level features for classification may not exist. Instead of adding depth to our network, we add diversity to the kernel sizes in order to keep as much n-gram information as possible. A similar model is used in (Ruder et al., 2016) (Shrestha et al., 2017).

The multi-channel convolution layer consists of three parallel convolution units. They have a similar structure but different convolutional kernel sizes. Each convolution unit consists of two steps, the convolution and pooling. The convolution step is to calculate the convolutions of the resulting vector sequence from the subword embedding vector sequence $T = (s_1, s_2, \dots, s_L)$ and convolution kernels $k_{1:M} \in \mathbb{R}^{d, M \times r}$, where M is the kernel number, r is the kernel size. The kernel size represents the context window of feature extraction and the kernel number represents the number of patterns.

$$f_{l=1:L}^{m'} = \sigma(k_m * [s_{l-r/2+1}, \dots, s_l, \dots, s_{l+r/2}])$$

where σ is the activation function.

Then the pooling step is to trim the resulting sequence F' by leaving only the maximum in every r consecutive f_l^m 's.

$$f_{q=1:L/r}^m = \max\{f_{l=(q-1) \times r + 1}^{m'}, \dots, f_{l=q \times r}^{m'}\}$$

Then the convolution unit outputs features extracted by each kernel. The output of can be seen as all the features extracted within a certain size of context window.

$$F = [f_1^1, \dots, f_1^M]$$

Each CNN unit works as above. We concatenate all the three feature maps and flatten the resulting matrix to one single vector. This single vector is later used for classification.

3.4 Classification Layer

We make two assumptions of how texts affect the usage of emojis, and how emojis are chosen to express emotions as an auxiliary symbol for the text.

1. Emojis are chosen and used to indicate the emotion of the whole tweet or the emotion of the tweeter at the moment, independent of position.

2. Emojis are tied to its context only, enhancing or revealing the true underlying meaning. This can vary depending on the position or content of the tweet.

In case 2, a “verbose” tweet which contains several sentences may map to different emojis at different positions. Given this nature of how emojis are used in tweets, the task could have been very different from traditional text classification since only a part of the text decides the classification output. Fortunately, most the tweets are chosen so that they contain only one sentence and the dataset does not provide the position information of the removed emoji, which makes the task easier. Hence we assume all the emojis are used as in case 1 and we will use the whole tweet to do prediction.

From the convolutional layer we get output of the features extracted from the whole tweet. We first reshape the features matrix into a single vector, then we feed it to a logistic regression layer for the final classification. The layer consists of a fully connected network layer and a softmax function as activation function. It takes the the one dimensional feature vector generated from convolutional layer as input and outputs a distribution over the 20 emojis denoting their probabilities of being used in the original tweet. Hence this layer can be represented by:

$$P[y = k | \vec{X}] = \frac{\exp(W_k^\top \vec{X} + b_k)}{\sum_{i=1}^{20} \exp(W_i^\top \vec{X} + b_i)}$$

Figure 1 is a summary of our system.

4 Parameter Settings

We use the training and test tweets collectively for the byte pair encoding algorithm with 2,000

Embedding	$ V $	d	M	r	#param	System config	F1	Precision	Recall
Word	10K	256			4.16M	sub-CNN (E)	.260	.330	.267
subword	2K	64	128	3, 4, 5	0.63M	Word-CNN (P)	.283	.355	.285
Character	200	16			0.13M	sub-CNN (P)	.301	.352	.302
						Char-CNN (P)	.289	.382	.291
						BOW	.29	.32	.34
						Word-LSTM	.33	.35	.36
						Word-LSTM + P	.32	.34	.36
						Char-LSTM	.32	.36	.37
						Char-LSTM + P	.34	.42	.39

Table 1: Network parameter settings.

iteration. Each iteration of BPE algorithm generates a new character n-gram, resulting in a vocabulary size around 2,000. Then we embed each subword with a vector with dimension $d = 64$. In our concatenated Convolutional Neural Network, each unit has $M = 128$ filters with filter sizes and max pooling size $r = \{3, 4, 5\}$. For comparison, we also build character based system containing not only the ascii characters with vocabulary size $|V| = 200$ and embedding dimension $d = 16$ and word based system with vocabulary size $|V| = 10,000$ and embedding dimension $d = 256$. We use the same network structure for all different text representation methods. We train the network for 50 epochs. Table 1 summarizes the parameter settings used.

5 Experimental Results

Table 2 shows our experimental results and reveals that our methods have a preference towards precision. In the task evaluation, UMDSUB attained precision of .330 which was 9th of 48 systems, and recall of .267 which was 20th. The overall F-score was .260 and placed 21st. This emphasis on precision can be seen in that our system was particularly accurate in predicting the most frequent emoji in the training and test data (the red heart), achieving an accuracy of .854 which was 4th among the 48 participating systems.

Our submission for the evaluation phase (sub-CNN (E)) was produced by a 4-layer single channel Convolutional Neural Network. After we changed it to the post-evaluation version of our multi-channel network (sub-CNN (P)), we saw a significant improvement where the F-score rose to .301 which would have placed 10th in the evaluation. The reasons for this success have to do with the nature of tweets, which are difficult to represent in a deep network given their very limited content. A Multi-channel CNN captures more information using various kernels in a single layer and so the content of short and somewhat noisy tweets is well represented.

Table 2: Experimental results (both evaluation (E) and post-evaluation (P) phase). -LSTM refers to the models used in (Barbieri et al., 2018), with results from this paper. +P refers to pre-trained embeddings.

6 Conclusion

Our work shows that subword embedding is an effective method of text representation for the emoji prediction task. Under the multi-channel CNN framework, it improves word embedding by 1.8% and character embedding by 2.1% while maintaining a modest computational cost.

We try to explain the reason of our results with the success of byte pair encoding (BPE) segmentation. We check the segmented text after byte pair encoding algorithm and we find a very representative example:

Before BPE: Playing the drums on RockBand made it look much easier than it is.

After BPE: Pl ay ing the dr um s on Rock B and made it look much ea si er than it is.

We observe that some of the segmentations correspond with word morphology, others not. This is because the segmentation is based on frequency and not a knowledge of morphology. Based on these observations, we consider the BPE algorithm a method that dynamically decides which n-grams are most frequent in a corpus and thus deserving of a unique representation that is included in the vocabulary. The vocabulary generated by BPE is a mixture of characters, roots, affixes, whole words and even random n-grams, chosen as such to make the representation of text statistically efficient. The advantage of such a system is that it does not consider Twitter language as a compound made of characters or atomic words. Therefore it does not limit text representation on only one single level, making the later feature extraction more efficient.

Abstract

In this paper, we present our system for assigning an emoji to a tweet based on the text. Each tweet was originally posted with an emoji which the task providers removed. Our task was to decide out of 20 emojis, which originally came with the tweet. Two datasets were provided - one in English and the other in Spanish. We treated the task as a standard classification task with the emojis as our classes and the tweets as our documents. Our best performing system used a Bag of Words model with a Linear Support Vector Machine as its classifier. We achieved a macro F1 score of 32.73% for the English data and 17.98% for the Spanish data.

1 Introduction

An AI system that can associate text with appropriate emojis could be useful for generating content that is sparkled with emojis among other uses (Barbieri et al., 2017). Given only the text from a tweet in English or Spanish, the SemEval (Barbieri et al., 2018) task was to determine the emoji that was in the original tweet. To learn how users associate emojis with text, a dataset comprised of 489,609 tweets in English and 98,289 tweets in Spanish was provided. Each tweet had a corresponding label representing the emoji that was in the tweet. The labels were assigned based on the frequency of the emoji, 0 being assigned to the most frequent emoji. The total number of labels was 20 for the English data and 19 for the Spanish data. We classified the tweets, our documents, by their emojis, our classes. We viewed the emojis as approximations of the sentiment expressed in the text.

For our baseline, we implemented a Bag of Words model using a Bernoulli Naive Bayes classifier. We analyzed the results and used the insights to implement our final system, which used

a Linear Support Vector machine for classification and also used a Bag of Words model to represent each document. This system performed better than our baseline by ~3.5 percentage points for our English data and ~1.5 percentage points for our Spanish data. It also performed better than several neural network models we experimented with. Our macro F1 score were 32.73% and 17.98% for our English data and Spanish data respectively.

2 Baseline

For our Baseline, we used a Bag of Words model (BOW) with a Bernoulli Naive Bayes Classifier. We also implemented a Most Frequent Class Model (MFC) and a Random Model (RAND) to help draw insights from our baseline. The results of these models for the English and Spanish data are shown in Table 1 and Table 2 respectively. The tables show mean and standard deviation over the folds using 10-fold cross-validation. We reserved 10% of the data for testing and trained on the remaining 90% for each fold. We followed the same approach in all our experiments. The Micro F1 scores are heavily influenced by the performance of the dominant classes. Since ~21% of the tweets belong to label 0 (♥) for English, the micro F1 score was ~21% for the MFC model. Macro F1 scores, on the other hand, give equal weight to each class, since they average the F1 scores of each class.

We chose Bernoulli style Naive Bayes because it generally works better for short texts (e.g. Tweets) than its Multinomial counterpart (Manning et al., 2008). We empirically verified this with our task and data. To implement this model, we used the NLTK library for preprocessing and the scikit-learn framework for the model training (Bird et al., 2009; Pedregosa et al., 2011).

Our data pipeline consisted of four steps: Tok-

	Macro F1		Micro F1	
	Mean	S-Dev	Mean	S-Dev
BOW	29.1	0.2	42.1	0.3
MFC	1.8	0.0	21.7	0.2
RAND	4.5	0.1	5.0	0.1

Table 1: Baseline results for English

enization, Bagination, Tf-idf transform and Training. For tokenization we used NLTK’s Tweet-Tokenizer function. We configured it to convert all text to lowercase, crop repeating characters to a max of 3 and remove tweeter handles. We created the BOW by making a set of the tokens which appeared per the document. The next step was to normalize the frequency data into term-frequency times inverse document-frequency(tf-idf) representation. Finally, we trained a Bernoulli Naive Bayes classifier on this data.

2.1 Insights from BOW English Results

For the English tweets, the difference between the macro and micro F-scores for our Bernoulli model lies in the fact that the distribution of classes is very unbalanced. This is demonstrated from the results shown in Table 1.

Table 3 shows a confusion matrix for some labels of our BOW results for the English data. A mapping of select labels to emojis and their descriptions is shown in Table 4. The matrix illustrates the struggles of the BOW model. Generally many tweets are misclassified as 🍷 and 😊. Take 🍷 for instance. While only 332 tweets were correctly labeled, 558 tweets and 385 tweets that should have been labeled 🍷 were labeled 🍷 and 😊 respectively. This misclassification of 🍷 as 🍷 and 😊 is not only the case for the selected classes represented in the matrix but also for most of the classes. Emojis 😊 and 🍷 illustrate another pattern we observed. 653 out of 2312 tweets that should have been classified as 😊 were misclassified as 🍷. Since 😊 is a smiling face with smiling eyes and 🍷 is smiling face with heart eyes, we inferred that the model might have trouble discriminating between classes with similar semantics.

That inference is supported by the fact that the model also struggles to discriminate between 📷, a camera, and 📷, a camera with flash. 458 tweets out of 1344 tweets (34%) that should have been labeled as 📷 where incorrectly labeled as 📷. This is more significant when one notes that only 148 of 📷 tweets (11%) where labeled correctly.

	Macro F1		Micro F1	
	Mean	S-Dev	Mean	S-Dev
BOW	16.5	0.4	29.6	0.4
MFC	1.7	0.0	20.0	0.4
RAND	4.8	0.2	5.5	0.2

Table 2: Baseline results for Spanish

	❤️	🍷	😊	😊	🍷	Total
❤️	8637	618				10752
🍷		2358	832			5145
😊		1022	2718			5114
😊		653	437	251	139	2313
🍷		558	385		332	2092

Table 3: BOW Confusion Matrix for English. We have choose to leave some numbers out to prevent distraction from the patterns we are trying to show. All left out numbers are negligible.

To measure the impact of these semantically similar classes on our model, we collapsed classes that were semantically similar and reran the BOW model. All of the “heart” emojis were put into a single class; the “smiling” emojis (except the hearty eyes one) were put into another class; the “camera” emojis were collapsed into one class; and each remaining emoji had its own class. In the end, we had 13 classes after merging.

After running the model on these new set of classes, the macro F1 score improved by 6 percent points suggesting that the semantic similarity between emojis, such as 📷 and 📷, has an effect although the effect was not nearly as significant as we had expected. It is worth noting that after collapsing the semantically similar classes, plenty of tweets were misclassified as the most frequent class. Thus, it may be that the semantic similarity of the classes does really matter but the gain in performance from collapsing the classes was offset by the fact that we had a class that was relatively much larger than the largest class before.

The BOW performed relatively well for labels 0, 1, 2, 4 and 17 (❤️, 🍷, 😊, 🍷 and 🌲 respectively) for the English data.

2.2 Insights from BOW Spanish Results

The Spanish results were much worse than the English results. Table 5 illustrates the major trend we noticed with the BOW model’s performance on the Spanish data. Count is the number of tweets that correctly belong to a class. %C is what per-

Label	Emoji	Description
0	❤️	Red heart
1	😍	Smiley face with heart eyes
2	😂	Face with tears of joy
4	🔥	Fire
5	😊	Smiling face with smiling eyes
6	😎	Smiling face with sunglasses
13	💜	Purple Heart
10	📷	Camera
17	🎄	Christmas Tree
18	📷	Camera with Flash

Table 4: Some English Emojis

	%C	❤️	😍	😂	Count
❤️	62	-	14	0	1882
😍	43	16	-	14	1338
😂	46	0	25	-	908
❤️	15	32	24	0	641
😊	9	14	32	17	647
😎	11	22	29	11	438
🇪🇸	63	5	17	4	331
😎	7	12	30	20	332
🎵	24	13	19	27	283

Table 5: BOW Spanish results. %C refers to the percent correctly labeled and %emoji refers to the percent mislabeled as emoji.

centage of tweets were correctly labeled. ❤️, 😍 and 😂 are the percentages of tweets that our model misclassified as labels 0, 1 and 2 respectively. Thus for ❤️, there were 1882 tweets in the test data; 62% of these were labeled correctly while 14% was incorrectly as 😍. As the table shows, a significant percentage of tweets were either misclassified as ❤️, 😍 or 😂. The exception to this is 🇪🇸 - the Spanish flag. Table 6 shows the emojis corresponding to the numerical labels.

2.3 Neural Network

Upon reading about how neural models achieved high scores on similar tasks, we decided to try out methods based on (Barbieri et al., 2017) and (dos Santos and Gatti, 2014). The task this paper tries to solve is based on Barbieri et al.’s work where they do the same task. Their best performing model was a character based Bi-directional Long

Label	Emoji	Description
0	❤️	Red heart
1	😍	Smiley with heart eyes
2	😂	Face with tears of joy
3	❤️	Two hearts
4	😊	Smiley with smiling eyes
5	😘	Face blowing a kiss
9	🇪🇸	Spain
10	😎	Smiling face with sunglasses
16	🎵	Musical notes

Table 6: Some Spanish Emojis

Short-term Memory Network (char-BLSTM). We also took inspiration from dos Santos and Gatti’s work. They were able to achieve very good results using a Convolutional Neural Network (CNN) to do sentiment analysis. We tested four different types of neural network models: LSTM, BLSTM, CNN-LSTM and CNN-BLSTM. For the LSTM based models, we used a network size of 128. The only difference between our LSTM and our BLSTM is that we added a layer to train each input bidirectionally. Our CNN’s convolution layer had an output dimension of 64 and a kernel size of 5. For it’s pooling layer we chose a pool size of 4. When training each of the neural network models we used a development set which was 10% of the training set to select the best parameters and to know how many epochs to train for. We settled on these specific parameters after trying out different parameters on the development set. None of our neural network models performed significantly better than our baseline.

2.4 Linear SVM

Realizing that our neural network models did not perform any better than our BOW baseline, we decided to try a BOW model with other classifiers which were not neural networks. We settled on a Linear Support Vector Machine. To enable multi-class classification we used a one-vs-rest approach.

2.5 Sampling

Roughly 20% of the tweets in the English data belong to label 0. The performance of classifiers such as Naive Bayes degrades when there is such a

	English		Spanish	
	Mean	S-Dev	Mean	S-Dev
Base	29.10	0.20	16.49	0.42
C+L	29.30	0.36	-	-
C+L(f)	29.35	0.44	-	-
LSVM	32.73	0.24	17.98	0.31

Table 7: Macro F1 scores. Base is baseline, L is LSTM, C is CNN, (f) means each class was equally represented.

dominant class (Rennie et al., 2003). This data imbalance exists in the Spanish data as well. To improve the performance of our classifiers, we perform a sampling of the data so that we train on a data set where the classes are roughly equally represented. We performed a simple under sampling by randomly selecting an equal number of tweets from each class even though a more sophisticated re-sampling method will likely improve the results (Estabrooks et al., 2004).

3 Results

The neural network models that we tested ended up achieving around the same score as our BOW baseline. The BOW model with a Linear Support Vector Machine for classification provided the best results. Table 7 shows the results of the LSVM along with the results of our baseline and our best performing neural network models for comparison. The effect of sampling the dataset to balance the frequency of each class was negligible as shown in Table 7. The improvement to employing sampling was 0.05 percentage points for our CNN combined with LSTM model. The F1 score of our LSVM model on the test data from the task organizers was 31.834 which is within one percent of the 32.73 from our 10-fold cross-validation. Precision on the test data was 39.803, recall was 31.365 and accuracy was 45.732.¹

4 Discussion

The first important trend we observe with our system (BOW model with LSVM classifier) is the most frequently seen emojis ❤️, 😊 and 😄 perform well in terms of true positives - ~83% for ❤️ (8848/10622), ~57% for 😊 (2903/5077) and ~63% for 😄 (3171/5067) while at the same time being

¹Task Scoreboard https://docs.google.com/spreadsheets/d/1on1Oj53EFcE4n-yO_sJc1JEo6x8hcUh5hsWTkTYdc_o/edit#gid=885431079. We submitted under the team name: Hopper.

false positives for many classes. Take 😄 (label 5) for instance. 327 tweets are correctly classified as belonging to 😄. However, 732 tweets that should have been classified as 😄 are misclassified as 😊. The trend of misclassifying more tweets as 😊 was seen for labels 6, 7, 8, 13, 14, 15, 16 and 19 as well. This trend carried through from our baseline; the final system performs better only because of marginal improvements in the classification itself.

Below are some tweets for 📷 that the LSVM succeed in classifying that the Bernoulli Naive Bayes could not find. We choose 📷 because the percentage difference in performance (in favor of the LSVM) is the greatest here.

Different angles to the same goal. by
@user @ New

When iris.apfel speaks...knowledge and
wisdom is all you hear so listen up...
:@drummondphotog

Our supposition is that the Linear Support Vector Machine is able to make associations that the Bernoulli Naive Bayes is unable to make. "Angles", we suspect, correlates with camera than the other emojis and the LSVM finds that association. The second tweet is interesting because it would seem that the LSVM is able to connect the "photog" in "@drummondphotog" despite our use of a Bag of Words Model unless the prediction was based on some other less obvious word in the tweet.

Acknowledgments

This project was carried out as a part of CS 8761, Natural Language Processing, offered in Fall 2017 at the University of Minnesota, Duluth by Dr. Ted Pedersen. We are grateful to Dr. Ted Pedersen for his support and guidance in this project. Authors are listed in alphabetical order.

Abstract

The “Multilingual Emoji Prediction” task focuses on the ability of predicting the correspondent emoji for a certain tweet. In this paper, we investigate the relation between words and emojis. In order to do that, we used supervised machine learning (Naive Bayes) and deep learning (Recursive Neural Network).

Keywords

Virtual, emojis, human sentiment, understanding of emojis.

1. Introduction

In the last few years, Social Media has evolved very fast, becoming at the moment a very important part of our daily life. There are several social networking platforms such as Twitter, Facebook, Instagram, WhatsApp, which were created in order to allow us to communicate with each other, to share our feelings or opinions related to different topics. Despite their differences or their purposes, each of these platforms shares one aspect: the use of emojis. From facial expressions to animals, objects or places, they are all used to communicate simple things or to enhance feelings and emotions. Due to the fact that their meaning is not always the same, processing emojis remains a challenge for the NLP researchers. From a language to another, for different cultures or depending on the user’s sentiments, emojis meaning can vary a lot. Understanding their meaning depending on the context of use has a huge relevance in multiple

fields, like: human computer interaction, multimedia retrieval, etc.

Twitter Emojis are pictures usually combined with text in order to emphasize the meaning of that text. Although these pictures are the same all over the world, they can be interpreted and used in different ways, depending on culture differences. Despite their widely usage in social media, their underlying semantics have received little attention from a Natural Language Processing standpoint.

2. Related work

Over the past few years, there has been an increased public and enterprise interest in social media. Therefore, analyzing emojis has become an important aspect for NLP researchers, because their meaning has remained for the time unexplored.

Go et al. [9] and Castellucci *et al.* [6] used in their papers distant supervision over emotion-labeled textual contents in order to train a sentiment classifier and to build a polarity lexicon. Aoki *et al.* [1] described in his research a methodology to represent each emoticon as a vector of emotions, while Jiang [10] proposed a sentiment and emotion classifier based on semantic spaces of emojis in the Chinese Website Sina Weibo. In his research, Cappallo *et al.* [5] proposed a multimodal approach for generating emoji labels for images (Image2Emoji). Boia *et al.* (2013) [4] analyzed sentiment lexicons generated by considering emoticons, showing that in many cases they do

not outperform lexicons created only with textual features.

Barbieri et al. [2] tried to predict the most likely emoji a Twitter message evokes. They used a model based on Bidirectional Long Short-term Memory Networks (BLSTMs) with standard lookup, word representations and character-based representation of tokens. For the word representations they replaced each word that occurred only once in the training data with a fixed representation (out- of-vocabulary words vector) (similar to the treatment of word embeddings by Dyer et al. (2015)). For the character-based representations, they computed character- based continuous-space vector embeddings (Ling et al., 2015b; Ballesteros et al., 2015) of the tokens in each tweet, using bidirectional LSTMs.

3. Data Set and Methods

In this Section, we present the data set format and the architecture we used to predict emojis. We implemented two main modules: first one is based on a Recurrent Neural Network (3.3.1) and the second one implements Naïve Bayes algorithm (**Error! Reference source not found.**).

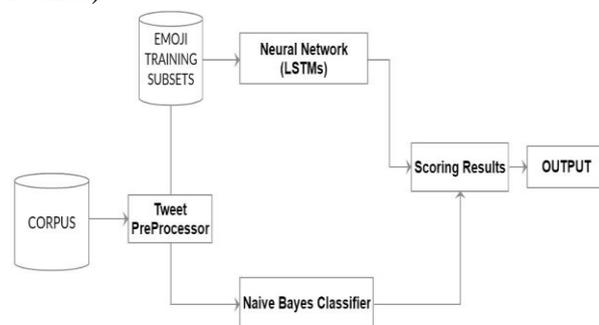

Figure 1. Architectural Diagram

3.1 Data Set

The corpus is formed from 500k tweets in English and 100K tweets in Spanish. The tweets were retrieved with the Twitter APIs, from October 2015 to February 2017, from United States and Spain. The dataset includes tweets that contain one and only one emoji from the 20 most frequent emojis. Data was split into Training Data (80%), Trial Data (10%) and Test Data (10%).

Data set is related to the 20 most frequent emoji of each language.

Figure 2. Emoji labels distribution

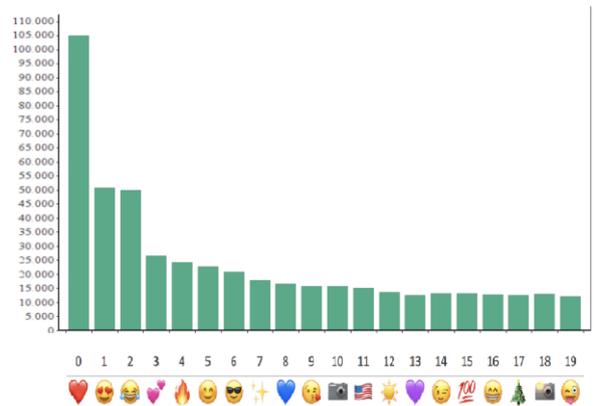

Figure 3. Label frequency in training dataset

In order to generate the training data, we used the tools given by organizers: a crawler for extracting the tweets and an emoji extractor.

For each language, data is represented through two files: one file containing one tweet per line and the other file containing the corresponded emoji label.

3.2 Tweet Pre-Processor

The first step from the preprocessor module consists in cleaning up the data set (punctuation, stop words) in order to avoid noise in the implemented algorithms.

This step consists in removing punctuation marks and links. We identify them by using the regular expression:

```
(([-'"/_ %$&*+<>^•()=|; ¨ ;:.,!#@#~]+)|([0-9]+))
```

We removed stop words and user mentions, but we decided not to eliminate the hashtag word because many tweets were made only by this kind of words. We removed instead the Hashtag sign and passed the words to the next step of preprocessing.

For the last step, we used Stanford Tokenizer in order to obtain the list of tokens for each tweet. Then we replaced each word with the correspondent lemma using WordNet Dictionary. The words that didn't have a lemma were considered noise and we choose to eliminate them.

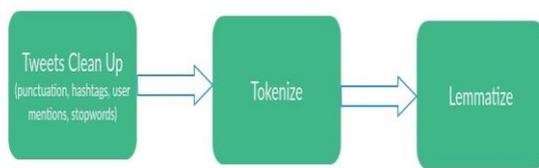

Figure 6. Preprocessing architecture

```
public String findWordLemmaWithWordNet(String word) {
    if (!this.isInitialized)
        return word;
    if (word == null)
        return null;
    if (this.morphProcessor == null)
        this.morphProcessor = this.dictionary.getMorphologicalProcessor();

    IndexWord baseForm;
    try {
        baseForm = this.morphProcessor.lookupBaseForm(POS.NOUN, word);
        if (baseForm != null)
            return baseForm.getLemma().toString();
        baseForm = this.morphProcessor.lookupBaseForm(POS.VERB, word);
        if (baseForm != null)
            return baseForm.getLemma().toString();
        baseForm = this.morphProcessor.lookupBaseForm(POS.ADJECTIVE, word);
        if (baseForm != null)
            return baseForm.getLemma().toString();
        baseForm = this.morphProcessor.lookupBaseForm(POS.ADVERB, word);
        if (baseForm != null)
            return baseForm.getLemma().toString();
    } catch (JWNLException e) {
    }
    return null;
}
```

3.3 Deep Learning Models

3.3.1 Recursive Neural Networks

Recursive neural network (RvNN) is a kind of deep neural network created by applying the same set of weights recursively over a structure, in order to produce a structured prediction over variable-size input structures, or a scalar

prediction on it, by traversing a given structure in topological order.

Given the proven effectiveness and the impact of recurrent neural networks in different topics (sentiment analysis, etc.), we intend to build an emoji prediction model based on a Long Short-Term Memory Network (LSTM).

For each subtask, we divided the train data set into twenty smaller train sets, one for each emoji label. Each train subset contains tweets with only two labels (classes). For instance, the train set for label "0" contains tweets with classified with 0 or !0. We then created a model for every emoji label a trained it with the correspondent train dataset.

In order to unify the models output, we run the test dataset on each one of these model. Then, based on the probabilities of each classified label, we chose the emoji with the highest score.

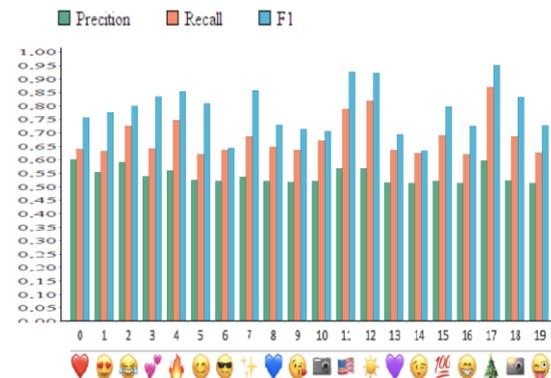

Figure 8. Evaluation for English models

3.3.2 Naïve Bayes Classifier

Naïve Bayes it's a classification technique based on Bayes' Theorem with an assumption of independence among predictors. In simple terms, a Naive Bayes classifier assumes that the presence of a particular feature in a class is unrelated to the presence of any other feature.

$$P(c|x) = \frac{P(x|c)P(c)}{P(x)}$$

Likelihood
Class Prior Probability

Posterior Probability
Predictor Prior Probability

$$P(c|X) = P(x_1|c) \times P(x_2|c) \times \dots \times P(x_n|c) \times P(c)$$

- $P(c|x)$ is the posterior probability of class (c , target) given predictor (x , attributes).
- $P(c)$ is the prior probability of class.
- $P(x|c)$ is the likelihood which is the probability of predictor given class.
- $P(x)$ is the prior probability of predictor.

Naïve Bayes Classifier is written in JavaScript. We used several libraries, applications already made to make the best and smarter module. Train data receives as input ex: “en_train.txt” and “en_train.labels”, after the files are read, it reads files line by line, makes a tweet array, then it assigns to each tweet from the array a number from the label file, then it calls the Naïve Bayes algorithm implementation. Finally, the test data is entered and the values are generated for them. It represents an interface that easily generates a label according to the introduced text. Moreover, it does not change values if the same tweet is entered multiple times. The output format is txt and a label is generated for each line from test data.

Figure 10. Short example of ES result

4. Discussions

Based on the things observed during the project implementation, we think that a possible improvement consists in trying to minimize the tweets noise. For instance, many words from tweets have duplicated letters (e.g. “aaaaand”). Eliminating those duplicated letters till the word

has a correspondent lemma could significantly reduce the noise.

5. Conclusions

Emojis are very used on social sites, but not much is known about their use and semantics. However, it has been noticed that emojis are used in different communities. In this paper, we tried to predict the correspondent emoji for a given tweet using a deep learning module based on a Recurrent Neural Network and a Naïve Bayes module. The results for the Naïve Bayes implementation were better than those from the network module.

Abstract

Emojis are widely used by social media and social network users when posting their messages. It is important to study the relationships between messages and emojis. Thus, in SemEval-2018 Task 2 an interesting and challenging task is proposed, i.e., predicting which emojis are evoked by text-based tweets. We propose a residual CNN-LSTM with attention (**RCLA**) model for this task. Our model combines CNN and LSTM layers to capture both local and long-range contextual information for tweet representation. In addition, attention mechanism is used to select important components. Besides, residual connection is applied to CNN layers to facilitate the training of neural networks. We also incorporated additional features such as POS tags and sentiment features extracted from lexicons. Our model achieved 30.25% macro-averaged F-score in the first subtask (i.e., emoji prediction in English), ranking 7th out of 48 participants.

1 Introduction

Emojis such as ❤️ and 😂 are widely used in social media and social network messages such as tweets. They are frequently combined with plain texts to visually complement the meaning of a message and convey various opinions and emotions (Novak et al., 2015; Barbieri et al., 2017). Social media platforms such as Twitter has accumulated a large number of emoji-incorporated messages. Analyzing the relationships between the textual message and emojis has many potential applications, such as emoji recommendation, automatic emoji-enriched message generation, and accurate sentiment analysis of social media messages (Barbieri et al., 2017).

However, the research on the relationships between textual message and emojis is limited. Existing studies on emojis mainly focus on analyzing

the semantics, usage or sentiment of emojis (Aoki and Uchida, 2011; Barbieri et al., 2016a,b,c; Ljubešić and Fišer, 2016; Novak et al., 2015). For example, Barbieri et al. (2016b) explored the meaning and usage of emojis across different languages. Wijeratne et al. (2017) proposed to utilize the emoji sense definitions to improve the performance of emoji embedding model. However, these approaches cannot reveal the interplay between plain texts and emojis. In order to fill this gap, Barbieri et al. (2017) proposed a novel task to predict which emojis are evoked by text-based tweets. For example, given a tweet message “*Love my coworkers ! @user*”, a system is required to predict that emoji ❤️ is associated with this tweet.

As an extension, the SemEval-2018 Task 2¹ aims to predict emojis for English and Spanish tweets (Barbieri et al., 2018). Given a plain tweet message without emoji, systems are required to predict which emoji is evoked by this message. We proposed a residual CNN-LSTM with attention model (**RCLA**) for this task.² Our model combines LSTM and multi-level CNN layers to capture both long-range and local information to learn tweet representation. In addition, attention mechanism (Yang et al., 2016) is incorporated into our approach to select important components. Besides, we applied residual connection technique (He et al., 2016) to CNN layers in our model to facilitate the training of neural networks. We also incorporated additional features such as POS tags and sentiment features extracted from sentiment lexicons. Our model achieved 30.25% macro-averaged F-score on the test data of the first subtask (i.e., emoji prediction in English), and ranked 7th out of 48 participants.

²The codes of our **RCLA** model are publicly available at https://github.com/wuch15/SemEval-2018-task2-THU_NGN

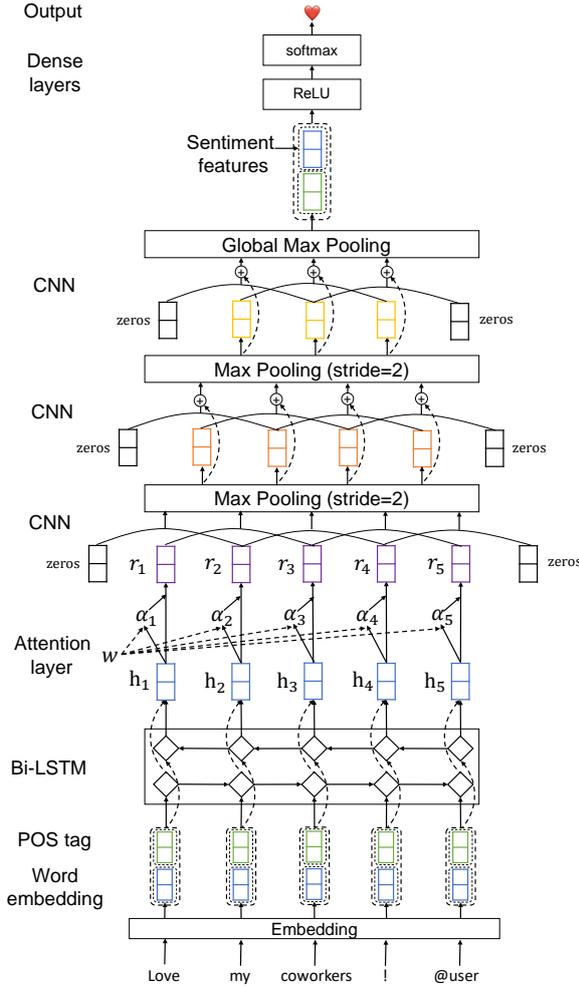

Figure 1: The architecture of our model. The dashed lines in CNN layers represent residual connections.

2 Residual CNN-LSTM with Attention

The framework of our residual CNN-LSTM with attention model (**RCLA**) is illustrated in Figure 1. Next, we will introduce each layer in our model from bottom to top in detail.

The first layer in our model is the embedding layer. This layer is used to convert a sentence from a sequence of words into a sequence of dense vectors. An embedding lookup table is used in this layer, whose parameters are obtained from pre-trained word embeddings and fine-tuned during training. POS tags have proven useful for many natural language processing tasks such as dimensional sentiment analysis (Wu et al., 2017). Motivated by existing studies, we also incorporate POS tags as additional features in our approach, and combining them with the word embeddings to form the final word features as the input of next

layer. We use the Ark-Tweet-NLP³ tool to obtain the POS tags of tweets.

The second layer in our model is bidirectional long short-term memory (Bi-LSTM) layer. This layer is used to capture long-range contextual information from tweets. At time step i , a hidden state \mathbf{h}_i is generated which contains both previous and future context information. Since different words and phrases have different importance for emoji prediction, we incorporate an attention layer after the Bi-LSTM layer to help our model focus on important words and contexts. The input of the attention layer is the hidden state vector \mathbf{h}_i at each time step. The attention weight α_i for this time step can be computed as:

$$\begin{aligned} \mathbf{m}_i &= \tanh(\mathbf{h}_i), \\ \hat{\alpha}_i &= \mathbf{w}^T \mathbf{m}_i + b, \\ \alpha_i &= \frac{\exp(\hat{\alpha}_i)}{\sum_j \exp(\hat{\alpha}_j)}, \end{aligned} \quad (1)$$

where \mathbf{w} and b are the parameters of the attention layer. The output of attention layer at the i_{th} time step is formulated as follows:

$$\mathbf{r}_i = \alpha \mathbf{h}_i. \quad (2)$$

The third layer in our model is a 3-layer convolutional neural networks (CNN) to capture local context information. Each CNN layer has multiple kernels with different window sizes. In addition, we apply residual connections (He et al., 2016) to the CNN layers as shown in Figure 1, which have shown effectiveness in facilitating the training of deep neural networks. Max pooling is applied to the output of the last CNN layer to obtain the hidden representation of tweets.

Tweets with specific emojis such as ❤️ usually convey strong sentiment information. Thus, sentiment information is helpful for emoji prediction. We incorporate sentiment features into our model to enhance its performance. These sentiment features are extracted using AffectiveTweets⁴ (Mohammad and Bravo-Marquez, 2017) package in Weka⁵. Two filters are involved, i.e., TweetToLexiconFeatureVector (Bravo-Marquez et al., 2014) and TweetToSentiStrengthFeatureVector (Thelwall et al., 2012). These sentiment features are combined with the hidden tweet representations

³<http://www.cs.cmu.edu/ark/TweetNLP>

⁴<https://github.com/felipebravom/AffectiveTweets>

⁵<https://www.cs.waikato.ac.nz/ml/weka>

generate by neural networks to form the final feature representation of tweets. Finally, a softmax layer is used to predict the emoji label.

The tweets with different emojis in the training set are very imbalanced. For example, the ratio of ❤️ is higher than 20%, while the ratio of 😬 is only 2.4%. Motivated by the cost-sensitive cross-entropy method (Santos-Rodríguez et al., 2009), the objective function of our model is defined as:

$$\mathcal{L} = - \sum_{i=1}^N w_{y_i} y_i \log(\hat{y}_i), \quad (3)$$

where N is the number of tweets, y_i is the emoji label of the i_{th} tweet, \hat{y}_i is the prediction score, and w_{y_i} is the loss weight of emoji label y_i . w_{y_i} is defined as $\frac{\sum_{k=1}^C \sqrt{N_k}}{\sqrt{N_{y_i}}}$, where C is the number of emoji labels and N_j is the number of tweets with emoji label j . Thus, the infrequent emojis have relatively larger loss weights.

3 Experiment

3.1 Dataset and Experimental Settings

The dataset⁶ for this task is collected from Twitter. There are 20 emojis in total. 489,277 tweets are used for model training. The number of tweets in the trial and test sets are both 50,000. We used the pre-trained word embeddings provided by Barberi et al. (2016b). They were trained on 20 million geo-localized tweets and their dimension is 300. These word embeddings were fine-tuned during model training.

The hyperparameters in our model were selected via cross-validation on the trial set. More specifically, the dimension of Bi-LSTM hidden states is 300, the window sizes of CNN filters are 2, 3, 4 respectively. The number of CNN filters is 200 and the number of sentiment features is 45. The dimension of dense layer is 300, and the dropout rate is 0.2 for each layer. The batch size is 500, and the maximal training epoch is set to 100. We use RMSProp as the optimizer for network training. The performance is evaluated by macro-averaged F-score.

3.2 Performance Evaluation

The performance of our model on the test set is shown in Table 1. According to Table 1, our model can achieve good performance on predicting frequent emojis, since their training data is sufficient.

⁶<https://competitions.codalab.org/competitions/17344>

In addition, the performance of our approach on some infrequent emojis is also satisfactory. For example, the F-score on emoji 🌲 is high. This is probably because specific words such as “Christmas” are frequently associated with this emoji, making it relatively easy to predict.

Emo	P	R	F1	%
❤️	82.9	79.55	81.19	21.6
😬	27.52	41.61	33.13	9.66
😂	33.69	52.43	41.02	9.07
💕	20.94	20.54	20.74	5.21
🔥	51.74	45.67	48.51	7.43
😏	10.38	11.59	10.95	3.23
😎	16.16	18.44	17.22	3.99
🌟	35.51	23.54	28.31	5.5
💙	22.73	14.4	17.63	3.1
😜	14.93	15.23	15.08	2.35
🇺🇸	22.0	25.63	23.68	2.86
🇺🇸	64.0	60.03	61.95	3.9
☀️	64.04	53.36	58.21	2.53
💜	20.6	9.78	13.27	2.23
😇	9.99	6.89	8.16	2.61
🏆	26.58	22.03	24.09	2.49
😏	8.16	6.24	7.08	2.31
🌲	66.22	67.12	66.67	3.09
🇺🇸	31.84	18.58	23.46	4.83
😬	7.1	3.47	4.66	2.02

Table 1: Precision, Recall, F-score and percentage of occurrences of each emoji in the test set.

The visualization of the confusion matrix of our model is shown in Figure 2. From this figure, we find two pairs of emojis which are difficult for our model to discriminate between them. The emoji ❤️ is often wrongly identified as ☀️. This is probably because these two emojis are often used to express similar meaning and feelings. For example, they both can be used in tweets which convey happy emotion. Another pair of emojis is 🇺🇸 and 🇺🇸. These two emojis look quite similar, and discriminating them is quite difficult.

In order to further validate the effectiveness of our model, we compare the performance of our model with several baseline methods. The methods to be compared include: 1) LSTM, using Bi-LSTM for tweet presentation; 2) CNN, 3-layer CNN without residual connections; 3) CNN-LSTM (denoted as *CL*), using the combination of LSTM and CNN; 4) Residual CNN-LSTM (denoted as *RCL*), CNN-LSTM with residual connections; 5) Residual CNN-LSTM with attention (denoted as *RCLA*). The results are shown in Table 2. According to Table 2, the combination of

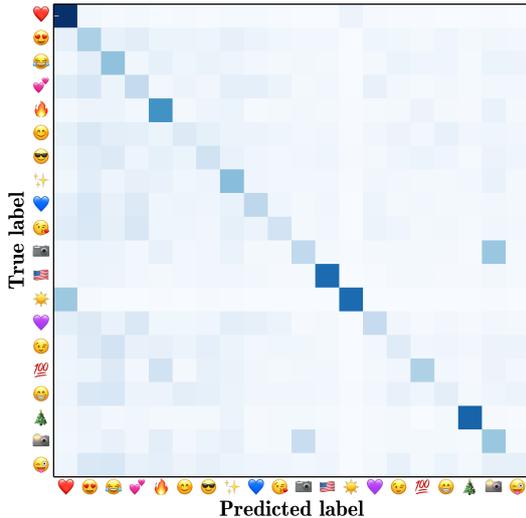

Figure 2: The confusion matrix of our model.

LSTM and CNN (*CL*) usually outperforms the single CNN and LSTM. It indicates that combining CNN and LSTM to capture both local and long-range context information is beneficial for tweet emoji prediction. In addition, by comparing *RCL* with *CL*, we find that the residual connections can improve the performance of *CL* model. It shows that the residual connections can facilitate the training of neural networks. Besides, the attention mechanism can also significantly improve the performance. It validates that employing attention mechanism to capture the important contexts for emoji prediction is useful.

3.3 Influence of Additional Features

The influence of the POS tags and sentiment features is illustrated in Table 3. The results show that both POS tags and sentiment features can help improve the performance of tweet emoji prediction. It indicates that POS tags contain useful information for predicting emojis, since important emoji clues such as hashtags, emoticons and sentiment words usually have specific POS tags. Thus, incorporating POS tag features is beneficial. Incorporating sentiment features is also useful. This is because the sentiment features we extracted from sentiment lexicons can identify both formal and information sentiment signals such as hashtags and emoticons, and these sentiment signals usually have strong associations with specific emojis. Thus, incorporating the sentiment features is also beneficial to predict emojis.

Emo	LSTM	CNN	CL	RCL	RCLA

4 Conclusion

In this paper, we introduce our residual CNN-LSTM model with attention model (**RCLA**) for SemEval-2018 Task 2, i.e., emoji prediction for tweets. Our model combines CNN and LSTM layers to capture both local and long-range context information for tweet representation, and incorporates an attention layer to select important information. Besides, we applied residual connections to CNN layers to facilitate the training of our model. In addition, we incorporated additional features such as POS tags and sentiment features to further improve the performance. The experimental results validate the effectiveness of our model on emoji prediction for English tweets.

Abstract

In this paper, we describe a methodology to predict emoji in tweets. Our approach is based on the classic bag-of-words model in conjunction with word embeddings. The used classification algorithm was Logistic Regression. This architecture was used and evaluated in the context of the SemEval 2018 challenge (task 2, subtask 1).

1 Introduction

Over the years, technology has significantly changed the way people communicate. It was changed especially due to social media like Twitter¹, Facebook², WhatsApp³, among others. Such media provide users with the ability to express their opinions/emotions not only with words, but through images, the so-called *emojis*.

However, within the context of the sentiment analysis, little research has been dedicated to explore the semantics of *emoji* (Barbieri et al., 2016), thus becoming an interesting challenge to investigate.

Understanding the meaning of *emojis* in relation to their context of use is important for indexing multimedia information, retrieval, or content extraction systems. In addition, *emoji* can complement the meaning of a message, that is, an *emoji* can determine the feeling of a text, however, such emotive figures may become fragile in the ironic/sarcastic context.

In this paper, we developed a methodology to predict *emoji* in tweets, especially our method is based on the bag-of-words model in conjunction with word embeddings (GloVe⁴ pre-trained) and n-grams⁵, applying a classification algorithm.

¹<https://twitter.com/>

²<https://www.facebook.com>

³<https://www.whatsapp.com/>

⁴<https://nlp.stanford.edu/projects/glove/>

⁵terms composed by n words.

This configuration was employed and evaluated in the SemEval 2018 challenge (task 2, subtask 1), in which the goal is to predict the *emoji* of a tweet (Barbieri et al., 2018).

This work is organized as follows: section 2 explains some related works, section 3 describes the data set, section 4 addresses the methodology applied in the task, section 5 presents the results, and finally section 6 final considerations as well as future work.

2 Related Works

Emojis can express diverse types of contents in a visual way, adapting to the informal style of communication in social networks. The meaning expressed by emoticons has been explored to allow or improve various tasks related to the sentiment analysis, as in (Hogenboom et al., 2013, 2015).

Emojis can also be used to label excerpts of texts where they occur, thus making it possible to construct sentiment lexical. In this context, in (Go et al., 2009) and (Castellucci et al., 2015) use a distant supervision over the emotionally marked textual contents to form a sentiment classifier and construct a lexicon of polarity. While Novak et al. 2015 constructed lexicons and drew a map of sentiments of the 751 most used *emoji*.

In the work of Barbieri et al. 2017, the authors investigated the relationship between words and *emojis*, studying the new task of predicting which *emoji* are evoked by text-based tweet messages. The authors trained several models based on Long Memory Short-Term networks (LSTMs).

In (Barbieri et al., 2016) the authors explore the meaning and use of *emojis* in four languages: American English, British English, Peninsular Spanish and Italian. By performing several experiments the researchers were able to compare

how the semantics of *emoji* vary according to the languages. In a first experiment, they investigated whether the meaning of a single *emoji* is preserved in all variations of language. In the second experiment, they compared the general semantic models of the 150 most frequent *emoji* in all languages. In this study it was possible to find out that the general semantics of the most frequent *emoji* is similar.

Finally, given the context of the challenge of Semeval 2018 (task 2, subtask 1), we propose a model capable of predicting *emoji* corresponding to the tweets.

3 Dataset and Task

Dataset. The data for the task consists of 500k tweets in English for training, 50k for trial and 50k for test. The tweets were retrieved with the Twitter APIs, from October 2015 to February 2017, and geolocalized in United States. The dataset includes tweets that contain one and only one *emoji*, of the 20 most frequent *emojis*. The amount of tweets for dataset can be seen in Figure 1.

Task details. Because of the importance of visual icons with the ability to provide additional meaning for social messaging and Twitter’s key role as one of the most important communication platforms, the Semeval 2018 team invites participants to predict the *emoji* associated with a tweet in English (Barbieri et al., 2018).

Figure 1: Number of labels per classes.

4 Methodology

The methodology applied in this task consists of two phases, one based on the bag-of-words model and another based on the word embeddings (GloVe) model, in the end both are concatenated, as shown in Figure 2.

4.1 Preprocessing

This step consists in eliminating noises and terms that have no semantic significance in the sentiment prediction. For this, we perform the removal of links, removal of numbers, removal of special characters, removal of *stop words* (words with low discriminative power, for example, “is”, “that” etc.). The standardization of tweets in lowercase was also applied, and finally, *stemming*. The purpose of stemming is to reduce words to their radical, for example, the word “*belivies*” will be transformed into “*believ*” (Perkins, 2014).

4.2 Bag-of-words

We apply bag-of-words as baseline, since it has been successfully employed in various classification tasks (Da Silva et al., 2014; Barbieri et al., 2017; Pak and Paroubek, 2010; Kouloumpis et al., 2011; Socher et al., 2013). We represent each message with a vector of tokens, selected using term frequency-inverse document frequency (TF-IDF) with quadrigrams, and $min_df = 1$, $max_features = 3500$, and $ngram_range = (1,4)$. In the Logistic Regression it was considered $C = 10.0$, while in the Support Vector Machine and Random Forest the hyperparameters were used by default.

4.3 Word embeddings

Word Embeddings (Bengio et al., 2003) is a supervised statistical language model trained using deep neural networks. The purpose of this model is to predict the next word, given the previous context in the sentence, so similar words tend to be always close. The vector presentation of words was a great advance in relation to the strategies based on bag-of-words. For the proposed task we apply the GloVe model (with 200 dimensions) by (Pennington et al., 2014), GloVe is based on a counting model, in which the vectors are derived from an array of co-occurrences used to extract statistical information about the corpus. With this model an array was generated through the simple arithmetic mean of the word vectors.

4.3.1 Challenges

Because of the need for high computational power to perform the task and the high dimensionality of the table, both in terms of number of attributes and number of rows, only a sampling of 10% of training data was used, this sampling reflects the distribution of real classes.

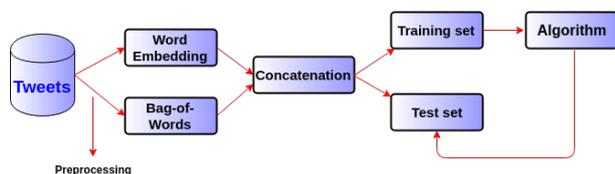

Figure 2: Model used in competition.

5 Results

In this section, we report the obtained results by our model according to the metric evaluation of the challenge, macro f1, precision and recall, accuracy, and f1 for all the *emojis* (Barbieri et al., 2018). Results are reported for five diverse configurations: (i) the system based on word embeddings and baf-of-words with Logistic Regression (LR); (ii) the system based on word embeddings and baf-of-words with Support Vector Machine (SVM); (iii) the bag-of-words system with Logistic Regression (LR); (iv) the bag-of-words system with Support Vector Machine (SVM); and (v) the bag-of-words system with Random Forest (RF). In Table 1 we show model’s performances and in Figure 3 we present the predicted score for one of the 20 *emojis*.

Model	F1	P	R	Acc
WE+BoW-LR	21.497	26.208	20.843	31.588
WE+BoW-SVM	21.023	27.034	21.403	32.570
BoW-LR	20.351	24.923	19.824	30.830
BoW-SVM	20.194	26.659	20.518	31.966
BoW-RF	15.793	19.890	15.310	25.842

Table 1: Result Semeval-2018.

The obtained results on the testing data indicate that word embedding together with bag-of-word produces the best F1, on the other hand the three configurations represented only by bag-of-word obtained their results close to the central work model (Word Embedding + Bag-of- Words). It is important to remember that only 10% of training data was used, such choice directly influenced the final result.

Figure 3: F1 per classes.

6 Conclusion

In this paper, we propose several configurations based on word embeddings and bag-of-words for the Semeval 2018 task 2, subtask 1. As base classifiers we use Logistic Regression (LR), Support Vector Machine (SVM) and Random Forest (RF) to predict *emojis* in tweets. Our best model got F1 of 21.497.

As future works we intend to explore the semantics of *emojis* more, as well as apply new word embeddings templates, such as Word2Vec (Mikolov et al., 2013), FastText (Joulin et al., 2016) and Doc2Vec (Le and Mikolov, 2014) with more computational resources.

EICA Team at SemEval-2018 Task 2: Semantic and Metadata-based Features for Multilingual Emoji Prediction

Yufei Xie, Qingqing Song

East China Normal University, Shanghai, P.R.China

yufeixie@ica.stc.sh.cn

Abstract

The advent of social media has brought along a novel way of communication where meaning is composed by combining short text messages and visual enhancements, the so-called emojis. We describe our system for participating in SemEval-2018 Task 2 on Multilingual Emoji Prediction. Our approach relies on combining a rich set of various types of features: semantic and metadata. The most important types turned out to be the metadata feature. In sub-task 1: Emoji Prediction in English, our primary submission obtain a MAP of 16.45, Precision of 31.557, Recall of 16.771 and Accuracy of 30.992.

1 Introduction

Emojis are ideograms which are naturally combined with plain text to visually complement or condense the meaning of a message (Barbieri et al., 2017). Despite being widely used in social media, their underlying semantics have received little attention from a Natural Language Processing standpoint. Barbieri et al. (2016) compare the meaning and usage of emojis across two Spanish cities: Barcelona and Madrid. Ljubešić et al. (2017) present a set of experiments and analyses on predicting the gender of Twitter users based on languageindependent features extracted either from the text or the metadata of users tweets.

Miller et al. (2016) performed an evaluation asking human annotators the meaning of emojis, and the sentiment they evoke. People do not always have the same understanding of emojis, indeed, there seems to exist multiple interpretations of their meaning beyond their designers intent or the physical object they evoke¹. Their main conclusion was that emojis can lead to misunderstandings. The ambiguity of emojis raises an interesting question in human-computer interaction: how

can we teach an artificial agent to correctly interpret and recognise emojis use in spontaneous conversation? The main motivation of our research is that an artificial intelligence system that is able to predict emojis could contribute to better natural language understanding (Novak et al., 2015) and thus to different natural language processing tasks such as generating emoji-enriched social media content, enhance emotion/sentiment analysis systems, and improve retrieval of social network material.

2 Our Approach

2.1 Features

We use several semantic features and metadata features to represent the twitter.

2.1.1 Semantic Features

Semantic features represent the basic conceptual components of meaning for any lexical item (Fromkin et al., 2018). An individual semantic feature constitutes one component of a word’s intension, which is the inherent sense or concept evoked (O’Grady et al., 1997).

Semantic Word Embeddings. We use semantic word embeddings obtained from Word2vec models for GoogleNews. For each twitter, we construct the centroid vector from the vectors of all words in that text.

$$centroid(w_{1..n}) = \frac{\sum_{i=1}^n w_i}{n} \quad (1)$$

TF-IDF. In information retrieval, tfidf or TFIDE, short for term frequencyinverse document frequency, is a numerical statistic that is intended to reflect how important a word is to a document in a collection or corpus (Leskovec et al., 2014). It is often used as a weighting factor in searches of information retrieval, text mining, and user modeling. The tf-idf value increases proportionally to

the number of times a word appears in the document, but is often offset by the frequency of the word in the corpus, which helps to adjust for the fact that some words appear more frequently in general. Nowadays, tf-idf is one of the most popular term-weighting schemes; 83% of text-based recommender systems in the domain of digital libraries use tf-idf (Beel et al., 2016).

$$tf(t, d) = 0.5 + 0.5 * \frac{f_{t,d}}{\max\{f_{t',d} : t' \in d\}} \quad (2)$$

t represents the term, d represents the document (Luhn, 1957).

$$idf(t, d) = \log \frac{N}{|\{d \in D : t \in d\}|} \quad (3)$$

N is total number of documents in the corpus $N = |D|$, $|\{d \in D : t \in d\}|$ is the number of documents where the term t appears. If the term is not in the corpus, this will lead to a division-by-zero (Robertson, 2004). It is therefore common to adjust the denominator to $1 + |\{d \in D : t \in d\}|$.

2.1.2 Metadata Features

Metadata-based features provide clues about the social aspects of the twitter. Thus, except for the semantic features described above, we also used some common sense metadata features:

Twitter containing a question mark. We think if the twitter has a question mark, it may be a question, which might indicate a negative emotions (Castillo et al., 2011).

The presence and the number of links in the twitter. We count both inbound and outbound links. Our hypothesis is that the presence of a reference to another resource is indicative of a positive emotions (Adamic and Huberman, 2000).

Twitter length. The assumption here is that longer twitter could bring more useful detail (Ogasawara, 2009).

2.2 Classifier

For each twitter, we firstly extract the features described above. Then we concatenate the extracted features in a bag of features vector and have them normalized. After the normalization, the value are mapped to interval [-1,1]. At last, we input them into the classifier. In our experiments, we use L2-regularized logistic regression classifier (Buitinck et al., 2013) and SVM classifier (Zweigenbaum

and Lavergne, 2016) respectively. For the logistic regression classifier, we tune the classifier with different values of the C (cost) parameter (Aono et al., 2016), and we take the one that yield the best accuracy on 10-fold cross-validation on the training set. For the SVM classifier, we choose different kernels (Moreno et al., 2004) and achieve the best results with RBF kernel. We only show the better results of above two classifiers in the next section.

3 Experiments and Evaluation

3.1 Dataset

3.1.1 Training and Evaluation Data

The data for the task will consist of 500k tweets in English and 100K tweets in Spanish (Barbieri et al., 2018). The tweets were retrieved with the Twitter APIs, from October 2015 to February 2017, and geolocalized in United States and Spain. The dataset includes tweets that contain one and only one emoji, of the 20 most frequent emojis. Data will be split into trial, training and test.

3.1.2 Label set

As labels we will use the 20 most frequent emojis of each language. They are different across the English and Spanish corpora. In the following we show the distribution of the emojis for each language (numbers refer to the percentage of occurrence of each emoji)

3.2 Evaluation Criteria

For evaluation, the classic Precision and Recall metrics over each emoji are used. The official results will be based on Macro F-score, as the fundamental idea of this task is to encourage systems to perform well overall, which would inherently mean a better sensitivity to the use of emojis in general, rather than for instance overfitting a model to do well in the three or four most common emojis of the test data. Macro F-score can be defined as simply the average of the individual label-wise F-scores. The official will also report Micro F-score for informative purposes.

3.3 Subtask 1 Result

We can see the results in Table 1. The cagri team obtains the best F1 value. The derpferd team gets

Table 1
Experimental Results on the SemEval-2018 Task 2

EICA	16.45	31.557	16.771	30.992

the best Precision. The cbaziotis obtains the best Recall and the liu_man obtains the best Accuracy. The F1 value of our team is 16.45.

4 Conclusion

We have described our system for SemEval-2018, Task 2 Multilingual Emoji Prediction. Our approach rely on semantic and metadata-based features. Our primary submission obtain a F1 of 16.45 and accuracy of 30.992.

In future work, we plan to use our best feature combinations in a deep learning architecture, as in the Qius system (Qiu and Huang, 2015), which outperforms the other methods on two matching tasks. We also want to use information from entire threads (Joty et al., 2015) to make better predictions. How to combine them efficiently in the system is an interesting research question

Abstract

This paper presents our single model to Sub-task 1 of SemEval 2018 Task 2: Emoji Prediction in English. In order to predict the emoji that may be contained in a tweet, the basic model we use is an attention-based recurrent neural network which has achieved satisfactory performs in Natural Language processing. Considering the text comes from social media, it contains many discrepant abbreviations and online terms, we also combine word-level and character-level word vector embedding to better handling the words not appear in the vocabulary. Our single model¹ achieved 29.50% Macro F-score in test data and ranks 9th among 48 teams.

1 Introduction

SemEval-2018 shared task 2 (Barbieri et al., 2018) provides a platform for us to explore the relationship between text and emoji in Twitter. The participants are expected to predict, given a tweet in English or Spanish, its most likely associated emoji. As the number of frequently-used emojis up to 20, this is also a multi-category classification task. Overall, both the prediction of emoji and the multi-category classification have undoubtedly increased the difficulty of task 2.

Before choosing a suitable model, we first analyze the data characteristics in detail. For each emoji, we count the total number of all tweets words under this emoji and enumerate the top 10 meaningful words with the highest frequency. And we can explore the following observations from the statistics:

- In almost all emojis, the first three words that appear frequently include “@user” suggesting that Twitter is a highly interactive social

networking site (all the person names unified as “users” during the data preprocessing). Such a tweet should include an unwritten but important context information.

- Because people do not always have the same understanding of emojis, some words can evoke more than one emoji. The greater the repetition of high-frequency words among different emojis, the harder it is to distinguish among these tweets.
- There are also some easily recognizable words. They are just common words under a certain emoji, almost do not appear under others, such as “lit” and “fire” under 🔥; “photo” under 📷; “usa”, “america” and “vote” under 🇺🇸; “beach” and “summer” under ☀️.
- When glancing over the data, we find that tweets have the following characteristics: a) Non-standard language, some discrepant shorthand or Internet jargon causes the model to get confused about the word; b) Misspelled words, although the human can easily realize the correct words, but if the model takes word-level as the processing unit, it cannot process them correctly. All of these can affect the ability of text representation seriously.

Taking all of these factors into consideration, we explore solutions from three perspectives:

- The second observation indicates that traditional statistical-based model may not achieve good performance, so we decide to adopt a neural network.
- Considering that the importance of each word is different in one tweet although text is very

¹<https://github.com/wwmmqq/SemEval-2018-Task-2-Multilingual-Emoji-Prediction>

short no more than 140 words, we introduce an attention mechanism to extract the key words in tweets.

- As the last observation can generate some tokens do not appear in the vocabulary (OOV), we utilize both word-level and character-level word vector embedding.

In a word, our single model is an attention-based neural network with word-level and character-level sentence embedding.

2 System Description

Our model architecture is depicted in Fig. 1 and it consists of the following three subparts: word embedding layer, BiLSTM layer and attention layer.

2.1 Word Embedding Layer

Assuming there are n words in a giving sentence x , we denote it as $x = \langle w_1, w_2, \dots, w_n \rangle$. At each time step t , both the word lookup table and a bidirectional LSTM take the same word w_t as an input.

Word-level embedding The word-level input is projected into a high-dimensional space by a word lookup table $\mathbf{E} \in \mathbb{R}^{|V| \times d}$, which you can get from publicly available *word2vector*² tool, where $|V|$ is the vocabulary size and d is the dimension of a word vector. Then we refer to the obtained vector as $\mathbf{x}_{w_t}^{word}$.

Character-level embedding The character-level input is converted into a vector by using a recurrent neural network. In order to better capture the interaction between adjacent characters, we use a bidirectional LSTM (BiLSTM) (Graves, 2005) to model the words. BiLSTM contains a forward LSTM processing the input from the first char to the last char, and a backward LSTM performing the opposite action. The last hidden states of the forward and the backward recurrent networks are linearly combined to $\mathbf{x}_{w_t}^{char}$.

Combine word-level and character-level embedding We generate the final vector representation of a word by combining two distinct representations of the word:

$$\mathbf{x}_{w_t} = g_{word} \mathbf{x}_{w_t}^{word} \oplus g_{char} \mathbf{x}_{w_t}^{char} \quad (1)$$

where \oplus is a concatenation operator, g_{word} and g_{char} are weights which can be calculated as:

$$g_{word} = \sigma(\mathbf{W}_1 \mathbf{x}_{w_t}^{word} + b_1) \quad (2)$$

²<https://code.google.com/p/word2vec/>

$$g_{char} = \sigma(\mathbf{W}_2 \mathbf{x}_{w_t}^{char} + b_2) \quad (3)$$

here \mathbf{W}_1 , \mathbf{W}_2 , b_1 and b_2 are trainable parameters, $\sigma(\cdot)$ is a sigmoid function.

2.2 BiLSTM Layer

Recurrent Neural Network (RNN) (Elman, 1990) (Mikolov et al., 2010) (Chung et al., 2014) is proposed for modeling long-distance dependence in a sequence, but it tends to suffer from the gradient vanishing and exploding problems. RNN with Long Short-Time Memory Network unit (Hochreiter and Schmidhuber, 1997) solves such problems by introducing a memory cell and gates into the network. In order to better model the tweets, we use a bidirectional LSTM (BiLSTM) (Graves et al., 2014) (Graves, 2005) to process the inputs.

Each single LSTM ($LSTM_{forward}$ and $LSTM_{backward}$) can be formalized as shown in (Gers and Schraudolph, 2003):

Then we use \oplus to obtain the hidden layer representation as below:

$$\vec{\mathbf{h}}_{w_t} = LSTM_{forward}(\mathbf{x}_{w_t}, \vec{\mathbf{h}}_{w_{t-1}}) \quad (4)$$

$$\overleftarrow{\mathbf{h}}_{w_t} = LSTM_{backward}(\mathbf{x}_{w_t}, \overleftarrow{\mathbf{h}}_{w_{t-1}}) \quad (5)$$

$$\mathbf{h}_t = \vec{\mathbf{h}}_{w_t} \oplus \overleftarrow{\mathbf{h}}_{w_t} \quad (6)$$

here $\vec{\mathbf{h}}_t$, $\overleftarrow{\mathbf{h}}_t$ are the hidden layer states for single word w_t , which generate from the combination of the current word information \mathbf{x}_{w_t} and previous state information $\vec{\mathbf{h}}_{t-1}$ ($\overleftarrow{\mathbf{h}}_{t-1}$). For simplicity, we note all the n \mathbf{h}_t as $H = (\mathbf{h}_1, \mathbf{h}_2, \dots, \mathbf{h}_n)$.

2.3 Attention Layer

In our model we introduce an attention mechanism to focus on certain part of the tweet (Santos et al., 2016) (Yang et al., 2017). The motivation mainly comes from the following two observations: a) although tweet is short, it always introduces much noise; b) the emoji decided by a relative small part of tweet content itself. The attention layer produces a weight vector applied to hidden states of BiLSTM.

The attention mechanism takes the whole hidden states H as input, and outputs a vector of weights a :

$$a = softmax(\mathbf{W}_3 tanh(\mathbf{W}_4 H^T)) \quad (7)$$

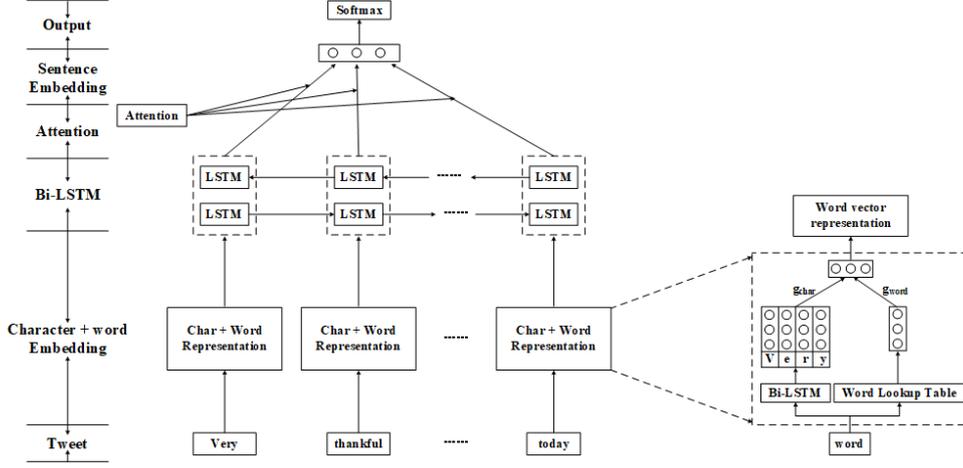

Figure 1: Our model architecture

here W_3 and W_4 are trainable parameters, the $\text{softmax}()$ ensures all computed weights sum up to 1.

Then we sum up the BiLSTM hidden states H according to the weight provided by a to get the input representation r :

$$r = aH \quad (8)$$

2.4 Output

At the output layer, we need to predict the emoji evoked by the tweet. We use the softmax function to predict the probability distribution over all emojis:

$$p(\hat{y}|r) = \text{softmax}(W_5 r + b_5) \quad (9)$$

where W_5 and b_5 are the parameters of softmax function.

The training loss based on cross-entropy is defined as follow:

$$J(\theta) = -\frac{1}{N} \sum_{t=1}^N \mathcal{H}(y_i, \hat{y}_i) + \beta \|\theta\|^2 \quad (10)$$

where θ is the whole trainable parameters of the model, and β is the weight for the regularization term. \mathcal{H} is the cross-entropy function for instance i between the gold category y_i and predict category \hat{y}_i . N is the number of training instance.

3 Experiment

3.1 Dataset

SemEval-2018 provided 500k tweets in English and 100k in Spanish for task 2, while our model

is only for English. Dataset is split into train, training and test sets. However, it was unable to download all the training set because some tweets were deleted or not available due to modified authorization status, and we finally collected 471, 455 training tweets.

3.2 Data Pre-processing

All of the tweets before feeding to any model are pre-processed as follows: all tweets are lowercased; URLs are replaced by $\langle url \rangle$ token; USERNAMES are replaced by $\langle @user \rangle$ token; NLTK3 is employed to tokenize input tweets.

3.3 Training

We use the 200-dimensional vectors (Barbieri et al., 2016) to initialize our words matrix E , and set max length of one word to 10, max length of one sentence to 30. All of the models are trained for 10 epochs, and the final model is selected by train dataset. Adam optimizer (Kingma and Ba, 2014) with initial learning rate of 0.001 is used to minimize cross-entropy loss. The learning rate is reduced by a factor of 10 for the first 3 epoch. The models were implemented in TensorFlow and experiments were run on an Intel(R) Core(TM) i7-4790 CPU.

3.4 Baselines

We compare our model with the following baselines: FastText (Joulin et al., 2016), NBOW, Convolutional Neural Networks (CNN) (Kim, 2014) (Kalchbrenner et al., 2014), Recurrent Convolutional Neural Networks (RCNN) (Sentences are first separately embedded with CNN, and then joined up with RNN) (Kalchbrenner and Blunsom,

Model		Representation	F1	P	R	Acc
Basic	FastText	Word Only	25.19	30.07	24.60	34.74
	NBOW		24.62	28.19	24.28	32.98
	CNN		20.34	22.54	23.00	34.73
	RCNN		26.89	26.97	29.62	32.53
	BiLSTM		20.36	22.41	23.00	34.74

Table 1: Experimental results on test data and result of rank 1 system

2013), BiLSTM (Graves et al., 2014) and BiLSTM+ATT (Graves et al., 2014).

3.5 Results and Discussion on Training Data

A series of comparison experiments on training set have been performed to explore the performance of our model in macro F-score(F1), precision(P), recall(R) and accuracy(Acc). The experimental results are shown in Table 1 in percentage. For the first part, we choose some basic models which only use the word-level word vector embedding as input; for the second part, we present ablation experiments showing usefulness of word-level and character-level embedding.

Statistics show the following three conclusions: 1) among the basic model, the best performance according to different evaluation metrics achieved by RCNN (F1), BiLSTM+ATT (Precision), RCNN (Recall) and BiLSTM+ATT (Accuracy) respectively; 2) when compare the two model (Word Only and Char Only) about BiLSTM+ATT, word-level model and character-level model complement each other on the four measurements. So we consider combining the two to obtain Char+Word BiLSTM model; 3) as the ablation experiments show, our model can get best result when combine word-level input with character-level input.

4 Results on Test Data

Detailed official results of our model are shown in Table 2. And we focus on analyzing performance of our model under each emoji combined with the characteristics of tweets summarized in section 1.

On the one hand, our model achieved promising results in the following emojis: 🌲 (F1: 69.06), 🇺🇸 (F1: 64.01), and 🔥 (F1: 55.46). As for the reason, section 1 gives us inspiration: the common words evoke these emojis are easily recognizable, in oth-

Emo	P	R	F1	%
❤️	40.3	64.38	49.57	21.6
😍	30.82	32.96	31.86	9.66
😂	38.6	55.56	45.55	9.07
💕	31.23	4.57	7.97	5.21
🔥	57.83	53.28	55.46	7.43
😊	13.39	8.56	10.44	3.23
😎	22.11	17.94	19.81	3.99
✨	33.41	26.26	29.41	5.5
💙	36.05	10.26	15.98	3.1
😘	20.81	7.83	11.38	2.35
📷	31.9	53.7	40.02	2.86
🇺🇸	64.94	63.11	64.01	3.9
☀️	36.24	50.59	42.23	2.53
💜	56.49	7.81	13.72	2.23
😏	16.33	9.19	11.76	2.61
🏆	32.18	26.13	28.84	2.49
😊	20.39	6.42	9.76	2.31
🌲	64.12	74.82	69.06	3.09
📷	43.31	23.05	30.08	4.83
😏	12.95	1.78	3.13	2.02

Table 2: Precision, Recall, F-measure and percentage of occurrences in the test set of each emoji.

er words, the word “christmas” evoking emoji 🌲 is barely used in emoji 🇺🇸.

On the other hand, for those emojis that are easily confused, our model does not perform well, such as 😏, 💕 and 😊. So we analyze data and find that these three emojis have the highest rate of repetition of common words with other emojis. For example, the common words under emoji 💕 include “love” (top2) and “happi” (top5), but the two words also evoke ❤️ and 😊 frequently.

Overall, the Macro F-score of our model ranks 9th in the subtask 1.

Abstract

This paper describes our participation in SemEval 2018 Task 2: Multilingual Emoji Prediction, in which participants are asked to predict a tweet’s most associated emoji from 20 emojis. Instead of regarding it as a 20-class classification problem we regard it as a text similarity problem. We propose a vector similarity based approach for this task. First the distributed representation (tweet vector) for each tweet is generated, then the similarity between this tweet vector and each emoji’s embedding is evaluated. The most similar emoji is chosen as the predicted label. Experimental results show that our approach performs comparably with the classification approach and shows its advantage in classifying emojis with similar semantic meaning.

1 Introduction

Participants for SemEval 2018 Task 2 (Barbieri et al.) are asked to predict the most likely associated emoji given the tweet. For simplicity purposes, each tweet contains one and only one emoji, which belongs to the 20 most frequent emojis. We participate in its subtask 1: Emoji Prediction in English.

With the wide-spread use on many social platforms, emoji has attracted more and more attention of researchers recently. Miller et al. (2016) explored whether emoji renderings or differences across platforms gave rise to diverse interpretations of emoji. For the same emoji, the sender and the receiver may have different interpretations of its meaning. This misinterpretation occurs when *joint perceptual experience* of sender and receiver lacks or the platforms’ rendering style differs. Some efforts have been devoted to studying emoji through its distributed representation.

Barbieri et al. (2016a,b) trained emoji embeddings with a skip-gram model through millions of tweets, and explored the similarity and relatedness among these embeddings in various languages. Their results suggested that the overall semantic of emoji was preserved across languages, but some emojis were interpreted differently due to users’ socio-geographical differences. Eisner et al. (2016) trained emoji embeddings with their short descriptions and demonstrated that emoji embeddings trained through this way were beneficial to sentiment analysis task.

We believe that the key to better classify emojis is understanding their meaning, since people intend a particular meaning when they send an emoji. People view the same characters during the exchange of plain text. Unlike plain text, emoji is not definite enough and doesn’t have a general acknowledgement of how we should use it. It is common for different readers to have different interpretations of the same emoji, which naturally results in different ways of using emoji. Na’aman et al. (2017) investigated a wide range of emoji usage and showed that emojis served at least two very different purposes: content and function words or multimodal affective markers.

Word embeddings (Bengio et al., 2003; Mikolov et al., 2013a,b) are continuous distributed representations of words, with two good properties: 1. take word’s semantic meaning into account, 2. distances between words are interpretable and can be measured using cosine distance. Based on such previous work, we proposed our *vector similarity based approach* for emoji prediction: first the neural network model is trained to generate a 300-d¹ vector, which is considered as the overall sentence vector of the tweet. Then this tweet vector’s semantic similarity with

*corresponding author.

¹The embedding dimension is 300 in this paper.

each emoji’s pre-trained embedding is evaluated. The predicted label is the one with the highest similarity.

2 Approach Description

This section describes our approach in detail. It consists of two parts, one is tweet representation, the other is similarity computation between tweet vector and emoji embedding. Whether tweet vector or emoji embedding is text representation. Thus we start by discussing previous researches about text representation.

Many efforts have been made to generate vectors for variable-length texts such as phrases, sentences, paragraphs or documents (Mitchell and Lapata, 2010; Larochelle and Lauly, 2012; Mikolov et al., 2013b; Le and Mikolov, 2014). The generated vectors are of fixed-size, which can be used as input features for many machine learning methods.

Word embeddings are distributed word representations trained using word2vec models such as CBOW and skip-gram, which can be interpreted as the probability distribution of the context the word exists in. If we take emoji as a normal token and train it together with its context words using word2vec models, then its embedding represents the context this emoji may exist in. We associate a tweet with its related emoji using tweet’s vector and emoji’s embedding.

Formally, our vector similarity based approach can be described as follows: first the tweet’s vector $\hat{\mathbf{y}}$ is generated using the neural network model, then its most similar emoji p is decided by calculating the cosine similarity(1) between $\hat{\mathbf{y}}$ and each emoji’s embedding \mathbf{y}_i ² in the candidate emoji set E whose size is 20.

$$\text{cosine}(\hat{\mathbf{y}}, \mathbf{y}_i) = \frac{\hat{\mathbf{y}} \cdot \mathbf{y}_i}{\|\hat{\mathbf{y}}\| \cdot \|\mathbf{y}_i\|} \quad (1)$$

$$p = \underset{i}{\operatorname{argmax}} \text{cosine}(\hat{\mathbf{y}}, \mathbf{y}_i) \quad (2)$$

where $\|\cdot\|$ is L2 norm and p is the predicted emoji label.

During training, we use the opposite of cosine similarity as the loss function, which aims to make the generated tweet vector $\hat{\mathbf{y}}$ closer to the target emoji’s embedding \mathbf{y} .

$$\text{loss}_1 = - \sum \left(\frac{\mathbf{y}}{\|\mathbf{y}\|} \cdot \frac{\hat{\mathbf{y}}}{\|\hat{\mathbf{y}}\|} \right) \quad (3)$$

² \mathbf{y}_i can be found in pre-trained embeddings.

We also tried another loss function which has similar idea with SVM. That is, minimize the cosine distance(4) between $\hat{\mathbf{y}}$ and target emoji embedding \mathbf{y} , meanwhile maximize the minimum cosine distance between $\hat{\mathbf{y}}$ and non-target emoji embedding $\tilde{\mathbf{y}}$. We hope to make \mathbf{y} more distinctive when similar emojis exist.

$$d(\mathbf{a}, \mathbf{b}) = 1 - \text{cosine}(\mathbf{a}, \mathbf{b}) \quad (4)$$

$$\text{loss}_2 = \alpha d(\hat{\mathbf{y}}, \mathbf{y}) - (1 - \alpha) \min_{\tilde{\mathbf{y}} \in F} d(\hat{\mathbf{y}}, \tilde{\mathbf{y}}) \quad (5)$$

where α is a parameter to control the proportion of each part, F is the set which consists of 19 non-target emojis’ pretrained embeddings for this tweet.

3 Models

This section describes the two models we used for generating tweet vector. Barbieri et al. (2017)’s previous work showed that LSTM neural networks performed well in emoji prediction. Inspired by their research, we implement two LSTM based models: a 2-layered LSTM model and a BiLSTM model.

3.1 2-layered LSTM

Our first model is a 2-layered LSTM model. This model consists of one trainable embedding layer for mapping words into vector representations, two stacked LSTM layers for processing and extracting useful information from the tweet, and one dense layer outputs the tweet vector.

Our experiments show that 2-layered LSTM works better than single layer LSTM. When stacked LSTM layer num gets larger than 2, the system performance doesn’t increase much. Besides, deeper network structure costs more time to train and more parameters make it easy to overfit.

Long Short-Term Memory network, or LSTM (Hochreiter and Schmidhuber, 1997) is an enhanced version of basic recurrent neural network (RNN), which uses purpose-built memory cells to store information selectively (Graves et al., 2013). LSTM model can better exploit long range context, and is widely used in natural language processing tasks.

3.2 BiLSTM

Our second model is a bidirectional LSTM (BiLSTM) model (Schuster and Paliwal, 1997). This

model consists of one trainable embedding layer, one bidirectional LSTM layer, and one dense output layer.

BiLSTM splits the neuron of a regular LSTM into two directions, one for positive time direction (forward states), and another for negative time direction (backward states). Output state o_i can be the concatenation or summation of the forward and backward state fw_i and bw_i :

$$o_i = fw_i \odot bw_i \quad (6)$$

where \odot operator can be concatenate, element-wise add, etc.

4 Experiments

Our system is implemented using Keras³ and the code is available on github⁴. We use the official evaluation metric *macro fl*, which evaluates both precision and recall of each class regardless of its sample num.

Three groups of experiments are achieved to evaluate our approach and models. To compare the vector similarity based approach with the classification approach, we implement the above 2-layered LSTM model and BiLSTM model with the same experiment settings for both approaches. To figure out which model structure is better, we compare the 2-layered LSTM model and BiLSTM model’s performance on both approaches. We also test the loss functions $loss_1$ and $loss_2$ ’s effects on 2-layered LSTM model. Next, we will describe the key experiment settings. More detailed model settings can be found in Table 1.

Text Preprocessing: The whole tweet is lowercased. We split it into token sequence using Keras’ default tokenizer, which split a sentence by spaces and following punctuations: `!"#$%&()*+,-./:;<=>?@[\\]^_`~\t\n{|}`. Long sequences are truncated and short ones are padded with 0s from the head to meet fixed length 20.

Embedding Layer: The embedding layer is set to be trainable. It is initialized by looking up from a pre-trained twitter embedding matrix (Barbieri et al., 2016a), <UNK> is initialized as 0.

Output Layer: For classification approach, the output layer’s unit num is 20 (same with the num

VS	2-LSTM($loss_1$)	27.188	25.444
	2-LSTM($loss_2$)	27.089	25.496
	BiLSTM($loss_1$)	26.441	25.281

Table 2: Experiment Results. CL for classification approach, VS for vector similarity based approach, 2-lstm for 2-layered LSTM model. The results marked with asterisk (*) are our submissions for final evaluation.

of emoji classes). For vector similarity based approach, the output layer’s unit num is 300 (same with the size of the pre-trained emoji embedding).

Training Loss: For our vector similarity approach, $loss_1$ and $loss_2$ described in section 2 are tested separately. For classification approach, *categorical_crossentropy* is used.

5 Discussion

As is shown in Table 2, the vector similarity based approach’s performance is comparable with the classification approach on both validation set and test set.

For both our vector similarity based and classification approaches, the 2-layered LSTM model outperforms the BiLSTM model, which shows that a deeper network structure contributes to capturing higher level features. Our 2-layered LSTM model consists of two stacked LSTM cells which are combined vertically. The first LSTM layer learns the shallower representation of the tweet, the second LSTM layer learns more abstract representation. Our BiLSTM layer also consists of two

³<https://keras.io/>

⁴https://github.com/MonkandMonkey/amyjing_emoji_predict.git

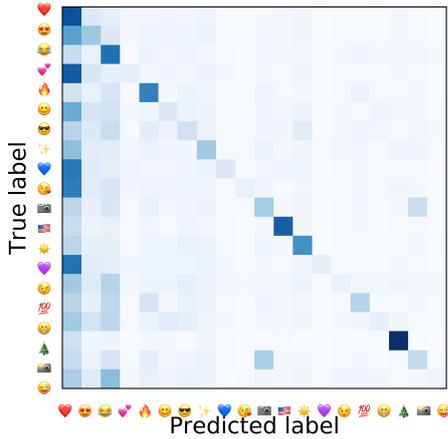

Figure 1: classification BiLSTM: confusion matrix

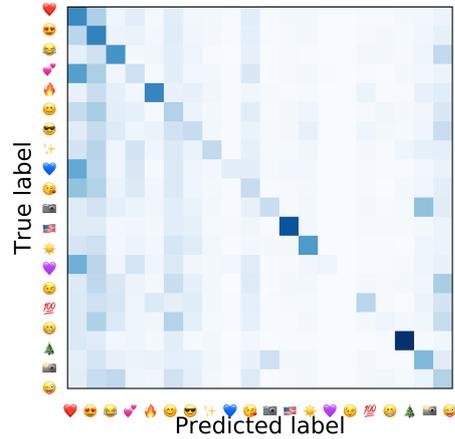

Figure 2: vector similarity BiLSTM: confusion matrix

LSTM cells, but are combined in a horizontal way. With the same number of parameters, the deeper structure (2-layered LSTM) works better than the wider structure (BiLSTM).

Experiments show that the $loss_1$ is slightly better than the $loss_2$ function. They are different in that $loss_1$ only considers the most similar emoji’s distance, whereas $loss_2$ considers both most similar emoji’s distance and the second most similar emoji’s distance. We tested several α values in $loss_2$ from 0.8 to 0.99, and 0.9 gives the best performance, which is also dominated by the most similar emoji’s distance.

Figure 1 and Figure 2 plot the confusion matrix of BiLSTM model’s predictions for classification and our vector similarity approach. The ❤️ (red heart) column in Figure 1 shows that the classification approach tends to misclassify other classes into the most frequent emoji ❤️. And for emojis with similar semantics, it is more likely to confuse them. Like the 😘 (face-throwing-a-kiss) row, the classification approach misclassified most 😘 to ❤️, whereas the vector similarity based approach only misclassified a smaller part of them, and its correctly predict num is relatively higher. In short, the classification approach is good at distinguishing emojis with concrete meanings, such as 🔥, 🇺🇸, and 🌲, but poor at distinguishing emojis with similar semantic meanings. The vector similarity based approach can make a trade-off between both situations.

Besides, for both our proposed approach and classification approach, the performance on *test set* is relatively lower than that on *validation set*. Thus dataset will also make an influence, espe-

cially for tweet, which is time-sensitive text. If the test set contains many words that unseen during the training stage or its class distribution differs from the training set, the performance will be influenced.

6 Future Work and Conclusion

The pre-trained embeddings we used are trained with a skip-gram model, which treats emojis and words equally, whereas for this task we need to concentrate more on emoji’s semantic, instead of its syntactic. Thus we suppose that treating emoji in a different way from word during the training stage will do a favor. That is, whether the emoji is in the head, center or tail of the tweet, its relative part can be used to train the emoji’s embedding, despite it is outside the context window. Another attempt worth trying is to use a Logistic Regression or Linear SVM classifier to find tweet’s most appropriate emoji, instead of cosine similarity.

In this paper, we present our work for SemEval-2018 task 2: Multilingual Emoji Prediction. We propose a vector similarity based approach which generates a vector for tweet and then use cosine similarity to find its most appropriate emoji. Through which we hope to explore the relationship between words and emojis. Experimental results show that the vector similarity based approach performs comparably with the classification approach. It provides an innovative thinking for solving the emoji prediction problem.

Abstract

This paper describes our submissions to Task 2 in SemEval 2018, i.e., Multilingual Emoji Prediction. We first investigate several traditional Natural Language Processing (NLP) features, and then design several deep learning models. For subtask 1: Emoji Prediction in English, we combine two different methods to represent tweet, i.e., supervised model using traditional features and deep learning model. For subtask 2: Emoji Prediction in Spanish, we only use deep learning model.

1 Introduction

Visual icons play a crucial role in providing information about the extra level of social media information. SemEval 2018 shared task for researchers to predict, given a tweet in English or Spanish, its most likely associated emoji (Barbieri et al., 2018, 2017) (Task 2, Multilingual Emoji Prediction), which is organized into two optional subtask (subtask 1 and subtask 2) respectively in English and Spanish.

For subtask 1, we adopt a combination model to predict emojis, which consists of traditional Natural Language Processing (NLP) methods and deep learning methods. The results returned by the classifier with traditional NLP features, by the neural network model and by the combination model are voted to get the final result. For subtask 2, we only use deep learning model.

2 System Description

For subtask 1, we explore three different methods i.e., using traditional NLP features to learn a supervised machine learning-based classifier, learning a deep learning model to make prediction and combine features captured by neural networks with traditional NLP features to train a supervised machine learning-based classifier. For subtask 2,

we simply implement deep learning method to make prediction.

2.1 Traditional NLP Features

In this task, we extract the following three types of features to capture effective information from the given tweets, i.e., linguistic features, sentiment lexicon features and tweet specific features.

2.1.1 Linguistic Features

- *N-grams*: We extract 3 types of Bag-of-Words features as *N-grams* features, where $N = 1, 2, 3$ (i.e., *unigram*, *bigram*, and *trigram* features).
- *POS*: Generally, the sentences carrying subjective emotions are inclined to contain more adjectives and adverbs while the sentences without sentiment orientation would contain more nouns. Thus, we extract POS tag from the sentence as features with the Bag-of-Words form.
- *Correlation Degree*: For each word appear in training data, the ratio of the number of occurrences under each class and the total occurrences is counted as the correlation degree of the word to a certain class. When the feature is created, the sum of the correlation degree of words in tweet is counted as the correlation degree of the tweet to a certain class:

$$CorrDeg(s, l) = \sum_{t=1}^{|s|} \frac{O(w_t, c_l)}{\sum_i^N O(w_t, c_i)}$$

Where $|s|$ is the length of tweet and N is the number of classes, w_t means t^{th} word in tweet and c_i means i^{th} class, $O(w_t, c_i)$ denotes the number of tweets of c_i that contain w_t . The dimension of this feature is equal to the number of classes, value is correlation

degree of the tweet to each class, i.e., $CorrDeg(s,l)$.

2.1.2 Sentiment Lexicon Features (SentiLexi)

We also extract sentiment lexicon features (SentiLexi) to capture the sentiment information of the given sentence. Given a tweet, we first convert all words into lowercase. Then on each sentiment lexicon, we calculate the following six scores for one message: (1) the ratio of positive words to all words, (2) the ratio of negative words to all words, (3) the maximum sentiment score, (4) the minimum sentiment score, (5) the sum of sentiment scores, (6) the sentiment score of the last word in tweet. If the word does not exist in one sentiment lexicon, its corresponding score is set to 0. The following 8 sentiment lexicons are adopted in our systems: *Bing Liu lexicon*¹, *General Inquirer lexicon*², *IMDB*³, *MPQA*⁴, *NRC Emotion Sentiment Lexicon*⁵, *AFINN*⁶, *NRC Hashtag Sentiment Lexicon*⁷, and *NRC Sentiment140 Lexicon*⁸.

2.1.3 Tweet Specific Features

- *Punctuation*: Considering that users often use exclamation marks and question marks to express strongly surprised and questioned feelings, we extract 7-dimensions punctuation features by recording rules of punctuation marks in the tweets.
- *All-caps*: One binary feature is to check whether this tweet has words in uppercase.
- *Bag-of-Hashtags*: We construct a vocabulary of hashtags appearing in the training data and then adopt the bag-of-hashtags method for each tweet.

2.2 Deep Learning Modules

In addition to manually constructing features, we build deep neural models to capture the semantics of the text. Figure 1 shows the network structure of our model. The input of the network is a tweet, which is a sequence of words. The output of the network contains class elements.

⁸<http://help.sentiment140.com/for-students/>

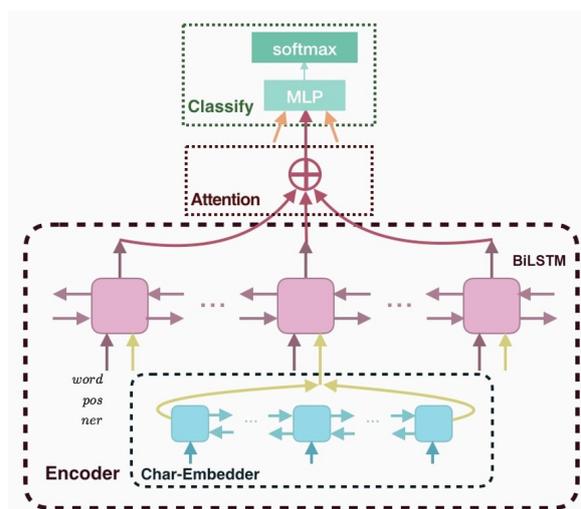

Figure 1: Deep learning model architecture.

2.2.1 Word-Level Representations

We use pre-trained word embedding concatenated with char embedding, POS embedding and NER embedding obtaining a final representation for each word type, which are learned together with the updates to the model.

- *Word Embedding*: Word embedding is a continuous-valued vector representation for each word, which can capture meaningful syntactic and semantic regularities. In this task, we use the 300-dimensional word vectors pre-trained on Twitter provided by SemEval task organizers, available in *SWM*⁹
- *Char Embedding*: We randomly initialize the representation of the character and compute character-based continuous-space vector embeddings of the words in tweets by bidirectional LSTM. The dimension of char embedding is 50.
- *POS Embedding*: We randomly initialize the representation of the POS tag in tweet with a vector size of 50.
- *NER Embedding*: We also randomly initialize the representation of the NER tag in tweet with a vector size of 50.

2.2.2 Sentence-Level Representations

- *Bi-Directional LSTM*: We apply a recurrent structure to capture contextual information as far as possible when learning word representations, to model the tweet with both of the

⁹<https://github.com/fvancesco/acmmm2016>

preceding and following contexts, we apply a Bi-directional Long Short-term Memory Networks (BiLSTM, Graves et al. (2005)) architecture as shown in Figure 1.

- *Attention Mechanism:* Considering not all words contribute equally to the representation of the sentence meaning, we introduce attention mechanism (Bahdanau et al., 2014) to extract such words that are important to the meaning of the sentence and aggregate the representation of those informative words to form a sentence vector.

We first use BiLSTM and Attention Mechanism to obtain sentence-level representations and then concatenate it with several effective NLP features. At last, we use a Multi-layer Perceptron (MLP) and output the probability of emoji label based on a softmax function. The BiLSTM has a hidden size of 512. The MLP have 1 hidden layer of size 200 and *relu* non-linearity.

To learn model parameters, we minimize the KL-divergence between the outputs and gold labels. We adopt Adam (Kingma and Ba, 2014) as optimization method and set learning rate of 0.01.

3 Experimental Settings

3.1 Datasets

For training sets, the organizers provide only the list of tweet ID and a script for all participants to collect tweets. However, since not all tweets are available when downloading, participants may collect slightly different numbers of tweets for training sets. In addition, we find that the crawled training sets and the trial sets provided by the organizers have 37.26% overlap in English and 71.16% in Spanish. So we remove the duplicate data and combine train and trial sets to perform a 3-fold cross-validation. Table 1 shows the statistics of the tweets we collect in our experiments. In subtask 1, the number of class 0 is the largest, accounting for 22.28%, followed by class 1 and class 2, respectively, 10.37% and 10.20%, and the other 17 classes distribute between 2.46% and 5.51%. Subtask 2 has a similar data distribution.

3.2 Data Preprocessing

Firstly, we convert unicode encoding into corresponding characters, punctuation, emoticons. Then we use slangs¹⁰ to transform the informal

¹⁰<https://github.com/haierlord/resource/blob/master/slangs>

label \ Dataset	Subtask 1	Subtask 2
0	116693 (22.28%)	20495 (20.41%)
1	54313 (10.37%)	13688 (13.63%)
2	53432 (10.20%)	9342 (9.30%)
3	28855 (5.51%)	6859 (6.83%)
4	25778 (4.92%)	6535 (6.51%)
5	24475 (4.67%)	4765 (4.43%)
6	22301 (4.26%)	4444 (4.42%)
7	19236 (3.67%)	3868 (3.85%)
8	17908 (3.42%)	3687 (3.67%)
9	16996 (3.25%)	3544 (3.53%)
10	16755 (3.20%)	3399 (3.16%)

17	13474 (2.57%)	2551 (2.54%)
18	13867 (2.65%)	2552 (2.54%)
19	12900 (2.46%)	–
total	523653	100440

Table 1: The statistics of data sets in combination of training sets and trial sets which we used to perform a 3-fold cross-validation. The numbers in brackets are the percentages of different classes in each data set.

writing to regular forms, e.g., “LOL” replaced by “laugh out loud”. And we recover the elongated words to their original forms, e.g., “soooooo” to “so”. Finally, we implement tokenization, POS tagging, named entity recognizing(NER) with the aid of Stanford CoreNLP tools (Manning et al., 2014).

3.3 Learning Algorithm

Considering the large dimension of the features designed by traditional NLP methods, we use learning algorithms of Logistic Regression(LR) to build classification models, which is supplied in *Liblinear*¹¹.

3.4 Evaluation Metrics

The official evaluation measure is Macro F-score, which would inherently mean a better sensitivity to the use of emojis in general, rather than for instance overfitting a model to do well in the three or four most common emojis of the test data. Macro F-score can be defined as simply the average of the individual label-wise F-scores.

¹¹<https://www.csie.ntu.edu.tw/~cjlin/liblinear/>

4 Experiments on Training Data

4.1 Comparison of NLP Features

Table 2 lists the comparison of different contributions made by different features on cross-validation with Logistic Regression algorithm. From the results in Table 2, we observe the following findings:

(1) The combination of Uigram, Bigram, Correlation Degree, POS and SentiLexi achieves the best performance (i.e., 34.63).

(2) Correlation Degree feature makes more contributes than other features, as it reflects the degree of relevance between tweets and emoji label.

(3) Bigram feature makes contribution and is more effective than unigram feature. The reason may be that bigram feature can capture more contextual information and word orders.

(4) SentiLexi feature also makes contribution, which indicates that SentiLexi features are beneficial not only in traditional sentiment analysis tasks, but also in predicting the emoji in tweet.

Features	F_{macro}	change
Best Features	34.63	-
-Correlation Degree	30.59	-4.04
-Bigram	33.38	-1.25
-SentiLexi	33.63	-1.00
-POS	33.91	-0.72
-Uigram	34.22	-0.41

Table 2: Performance of different features on subtask 1. - means to exclude some features.

4.2 Comparison of Deep Learning Modules

Table 3 shows the results of different deep learning models described before. From Table 3, we observe the findings as follows:

(1) We explore the performance of three different deep learning model: Neural Bag-of-Words(NBOW, Iyyer et al. (2015)), Convolutional Neural Network (CNN, Collobert et al. (2011)) and Bi-directional Long Short-term Memory Networks (LSTM, Hochreiter and Schmidhuber (1997)). All models used only pre-trained word embedding to compare. Clearly, BiLSTM outperformed other models in this task, and our deep learning model is based on BiLSTM.

(2) POS embedding makes more contribution than other word-level representations. Since POS embedding can learn emotional tendencies, it is beneficial for tweet emojis prediction.

(3) The last two rows results shows that combine both SentiLexi and Punctuation features with sentence representations to train the deep learning model can make contribution.

Models	Subtask 1	Subtask 2
NBOW	23.73	18.67
CNN	23.64	18.91
BiLSTM	25.64	19.32
.+Char	25.66 (+0.02)	19.56
.+NER	26.57 (+0.91)	-
.+POS	30.55 (+3.98)	-
.+Attention	30.74 (+0.19)	-
.+Punctuation	32.10 (+1.36)	-
.+SentiLexi	32.59 (+0.49)	-

Table 3: Performance of different deep learning models on subtask 1 and subtask 2. .+ means to add current module to the previous model. The numbers in the brackets are the performance increments compared with the previous results.

4.3 Combination and Ensemble

For subtask 1, we also use the trained neural networks described in 4.2 to capture the features of tweets and combine it with traditional NLP features to train a Logistic Regression classifier, named *Combination Model*.

Table 4 shows the results of different methods. We find that combination model improved the performance and the ensemble of 3 methods achieve the best result. It suggests that the traditional NLP methods and the deep learning models are complementary to each other and their combination achieves the best performance.

Methods	F_{macro}
Traditional NLP Features	34.63
Deep Learning Model	32.59
Combination Model	35.21
Ensemble Model	35.57

Table 4: Performance of different methods on subtask 1.

4.4 System Configuration

Based on above experimental analysis, the two system configurations on test data sets are listed as followings:

(1) subtask 1: Logistic Regression with best NLP feature sets is used as model 1. Deep learn-

ing model is used as model 2. Logistic Regression with NLP features and the feature captured by deep learning model is used as model 3. Ensemble of three models is used as final submission.

(2) subtask 2: Deep learning model with word embedding and char embedding is used as submission.

5 Results on Test Data

	Subtask 1	Subtask 2
Our system	33.35 (5)	16.41 (7)
Rank 1	35.99 (1)	22.36 (1)
Rank 2	35.36 (2)	18.73 (2)
Rank 3	34.02 (3)	18.18 (3)

Table 5: Performance of our systems and the top-ranked systems for two subtasks on test datasets. The numbers in the brackets are the official rankings.

Table 5 shows the results on test datasets. From Table 5, we find that our system achieves almost the same performance as the cross-validation. The low performance of this task illustrates the difficulty of the task itself, especially the Spanish task.

6 Conclusion

In this paper, we extract several effective traditional NLP features, design different deep learning models and build a model in combination of traditional NLP features and deep learning method together. The extensive experimental results show that this combination improves the performance.

For the future work, we consider to focus on developing a neural networks model to handle unbalanced data and improve the performance of confusing labels.

Abstract

In this paper we present a deep-learning model that competed at SemEval-2018 Task 2 “Multilingual Emoji Prediction”. We participated in subtask A, in which we are called to predict the most likely associated emoji in English tweets. The proposed architecture relies on a Long Short-Term Memory network, augmented with an attention mechanism, that conditions the weight of each word, on a “context vector” which is taken as the aggregation of a tweet’s meaning. Moreover, we initialize the embedding layer of our model, with word2vec word embeddings, pretrained on a dataset of 550 million English tweets. Finally, our model does not rely on hand-crafted features or lexicons and is trained end-to-end with back-propagation. We ranked 2nd out of 48 teams.

1 Introduction

Emojis play an important role in textual communication, as they function as a substitute for non-verbal cues, that are taken for granted in face-to-face communication, thus allowing users to convey emotions by means other than words. Despite their large appeal in text, they haven’t received much attention until recently. Former works, mostly consider their semantics (Aoki and Uchida, 2011; Espinosa-Anke et al., 2016; Barbieri et al., 2016b,a; Ljubešić and Fišer, 2016; Eisner et al., 2016) and only recently their role in social media was explored (Barbieri et al., 2017; Cappallo et al., 2018). In SemEval-2018 Task 2: “Multilingual Emoji Prediction” (Barbieri et al., 2018), given a tweet, we are asked to predict its most likely associated emoji.

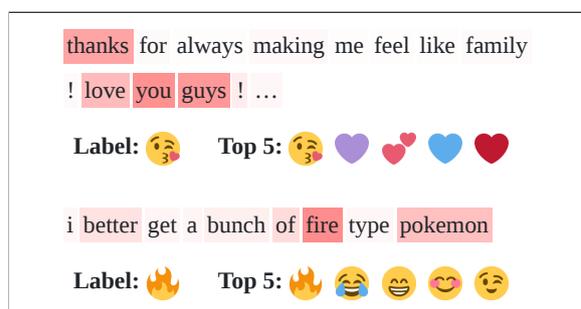

Figure 1: Attention heat-map visualization. The color intensity corresponds to the weight given to each word by the self-attention mechanism.

In this work, we present a near state of the art approach for predicting emojis in tweets, which outperforms the best present work (Barbieri et al., 2017). For this purpose, we employ an LSTM network augmented with a context-aware self-attention mechanism, producing a feature representation used for classification. Moreover, the attention mechanism helps us make our model’s behavior more interpretable, by examining the distribution of the attention weights for a given tweet. To this end, we provide visualizations with the distributions of the attention weights.

2 Overview

Figure 3 provides a high-level overview of our approach that consists of three main steps: (1) The *text preprocessing step*, which is common both for unlabeled data and the task’s dataset, (2) the *word embeddings pre-training step*, where we train custom word embeddings on a big collection of unlabeled Twitter messages and (3) the *model training step* where we train the deep learning model.

Task definition. In subtask A, given an English tweet, we are called to predict the most likely associated emoji, from the 20 most frequent emojis in English tweets according to (Barbieri et al., 2017). The training dataset consists of 500k tweets, retrieved from October 2015 to February 2017 and geolocalized in the United States. Fig. 2 shows the classes (emojis) and their distribution.

Figure 2: Distribution of emoji (class) labels.

2.1 Data

Unlabeled Dataset. We collected a dataset of 550 million archived English Twitter messages, from Apr. 2014 to Jun. 2017. This dataset is used for (1) calculating word statistics needed in our text preprocessing pipeline (Section 2.2) and (2) training word2vec word embeddings.

Word Embeddings. We leverage our unlabeled dataset to train Twitter-specific word embeddings. We use the *word2vec* (Mikolov et al., 2013) algorithm, with the skip-gram model, negative sampling of 5 and minimum word count of 20, utilizing the Gensim’s (Řehůřek and Sojka, 2010) implementation. The resulting vocabulary contains 800,000 words. The pre-trained word embeddings are used for initializing the first layer (embedding layer) of our neural networks.

2.2 Preprocessing¹

We utilized the *ekphrasis*² tool (Baziotis et al., 2017) as a tweet preprocessor. The preprocessing

¹Significant portions of the systems submitted to SemEval 2018 in Tasks 1, 2 and 3, by the NTUA-SLP team are shared, specifically the preprocessing and portions of the DNN architecture. Their description is repeated here for completeness.

processed	the new <emphasis> season of <hashtag> twin peaks </hashtag> is coming on <date> . cant <allcaps> wait <allcaps> <happy> ! <repeated> <hashtag> tv series </hashtag> <hashtag> david lynch </hashtag> <laugh>

Table 1: Example of our text processor

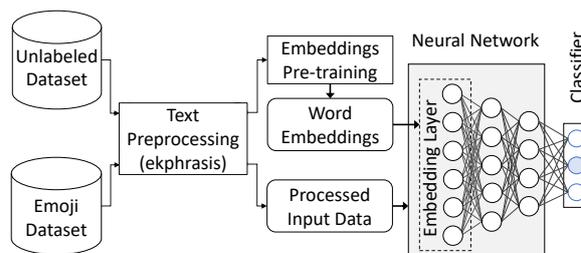

Figure 3: High-level overview of our approach

steps included in ekphrasis are: Twitter-specific tokenization, spell correction, word normalization, word segmentation (for splitting hashtags) and word annotation.

Tokenization. Tokenization is the first fundamental preprocessing step and since it is the basis for the other steps, it immediately affects the quality of the features learned by the network. Tokenization on Twitter is challenging, since there is large variation in the vocabulary and the expressions which are used. There are certain expressions which are better kept as one token (e.g. anti-american) and others that should be split into separate tokens. Ekphrasis recognizes Twitter markup, emoticons, emojis, dates (e.g. 07/11/2011, April 23rd), times (e.g. 4:30pm, 11:00 am), currencies (e.g. \$10, 25mil, 50€), acronyms, censored words (e.g. s**t), words with emphasis (e.g. *very*) and more using an extensive list of regular expressions.

Normalization. After tokenization we apply a series of modifications on extracted tokens, such as spell correction, word normalization and segmentation. Specifically for word normalization we lowercase words, normalize URLs, emails, numbers, dates, times and user handles (@user). This helps reducing the vocabulary size without losing information. For spell correction (Jurafsky and James, 2000) and word segmentation (Segaran and Hammerbacher, 2009) we use the Viterbi algorithm. The prior probabilities are initialized using uni/bi-gram word statistics from the unlabeled dataset. Table 1 shows an example text snippet and the resulting preprocessed tokens.

2.3 Recurrent Neural Networks

We model the Twitter messages using Recurrent Neural Networks (RNN). RNNs process their inputs sequentially, performing the same operation, $h_t = f_W(x_t, h_{t-1})$, on every element in a sequence, where h_t is the hidden state t the time step, and W the network weights. We can see that hidden state at each time step depends on previous hidden states, thus the order of elements (words) is important. This process also enables RNNs to handle inputs of variable length.

RNNs are difficult to train (Pascanu et al., 2013), because gradients may grow or decay exponentially over long sequences (Bengio et al., 1994; Hochreiter et al., 2001). A way to overcome these problems is to use more sophisticated variants of regular RNNs, like Long Short-Term Memory (LSTM) networks (Hochreiter and Schmidhuber, 1997) or Gated Recurrent Units (GRU) (Cho et al., 2014), which ensure better gradient flow through the network.

Self-Attention Mechanism. RNNs update their hidden state h_i as they process a sequence and the final hidden state holds a summary of the information in the sequence. In order to amplify the contribution of important words in the final representation, a self-attention mechanism (Bahdanau et al., 2014) can be used (Fig. 4). In normal RNNs, we use as representation r of the input sequence its final state h_N . However, using an attention mechanism, we compute r as the convex combination of all h_i , with weights a_i , which signify the importance of each hidden state. Formally: $r = \sum_{i=1}^N a_i h_i$, where $\sum_{i=1}^N a_i = 1$, and $a_i > 0$.

3 Model Description

We use a word-level BiLSTM architecture to model semantic information in tweets. We also propose an attention mechanism, which conditions the weight of h_i on a “context vector” that is taken

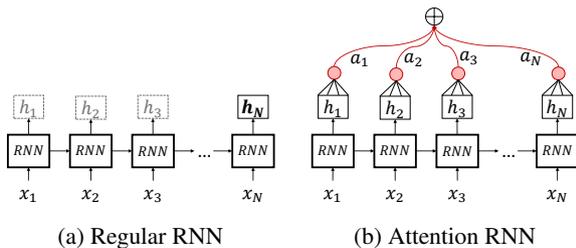

Figure 4: Comparison between the regular RNN and the RNN with attention.

as the aggregation of the tweet meaning.

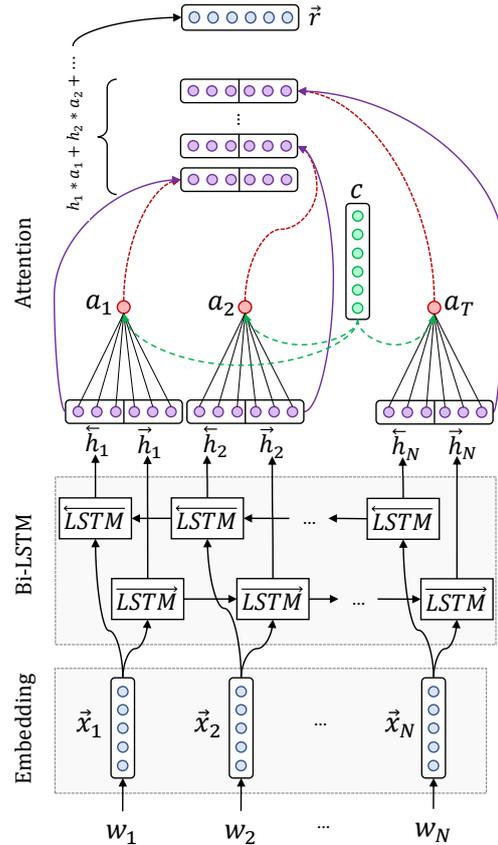

Figure 5: Architecture of the proposed model.

Embedding Layer. The input to the network is a Twitter message, treated as a sequence of words. We use an embedding layer to project the words w_1, w_2, \dots, w_N to a low-dimensional vector space R^W , where W the size of the embedding layer and N the number of words in a tweet. We initialize the weights of the embedding layer with our pre-trained word embeddings.

BiLSTM Layer. A LSTM takes as input the words of a tweet and produces the word annotations h_1, h_2, \dots, h_N , where h_i is the hidden state of the LSTM at time-step i , summarizing all the information of the sentence up to w_i . We use bidirectional LSTM (BiLSTM) in order to get word annotations that summarize the information from both directions. A BiLSTM consists of a forward LSTM \vec{f} that reads the sentence from w_1 to w_N and a backward LSTM \overleftarrow{f} that reads the sentence from w_N to w_1 . We obtain the final annotation for each word, by concatenating the annotations from both directions, $h_i = \vec{h}_i \parallel \overleftarrow{h}_i$, $h_i \in R^{2L}$ where \parallel denotes the concatenation operation and L the size of each LSTM.

Context-aware Self-Attention Layer. Even

though the hidden state h_i of the LSTM captures the local context up to word i , in order to better estimate the importance of each word given the context of the tweet we condition hidden state on a context vector. The context vector is taken as the average of h_i : $c = \frac{1}{N} \sum_1^N h_i$. The context-aware annotations u_i are obtained as the concatenation of c and h_i : $u_i = h_i \parallel c$. The attention weights a_i are computed as the softmax of the attention layer outputs e_i . W and b are the trainable weights and biases of the attention layer:

$$e_i = \tanh(Wu_i + b) \quad (1)$$

$$a_i = \frac{\exp(e_i)}{\sum_{t=1}^N \exp(e_t)} \quad (2)$$

The final representation r is again taken as the convex combination of the hidden states.

$$r = \sum_{i=1}^N a_i h_i, \quad r \in R^{2L} \quad (3)$$

Output Layer. We use the representation r as feature vector for classification and we feed it to a fully-connected softmax layer with L neurons, which outputs a probability distribution over all classes p_c as described in Eq. 4:

$$p_c = \frac{e^{Wr+b}}{\sum_{i \in [1,L]} (e^{W_i r + b_i})} \quad (4)$$

where W and b are the layer’s weights and biases.

3.1 Regularization

In both models we add Gaussian noise to the embedding layer, which can be interpreted as a random data augmentation technique, that makes models more robust to overfitting. In addition to that we use dropout (Srivastava et al., 2014) and we stop training after the validation loss has stopped decreasing (early-stopping).

4 Experiments and Results

4.1 Experimental Setup

Class Weights. In order to deal with class imbalances, we apply class weights to the loss function of our models, penalizing more the misclassification of underrepresented classes. We weight each class by its inverse frequency in the training set.

Training We use Adam algorithm (Kingma and Ba, 2014) for optimizing our networks, with mini-batches of size 32 and we clip the norm of the gradients (Pascanu et al., 2013) at 1, as an extra safety

measure against exploding gradients. For developing our models we used PyTorch (Paszke et al., 2017) and Scikit-learn (Pedregosa et al., 2011).

Hyper-parameters. In order to find good hyper-parameter values in a relative short time (compared to grid or random search), we adopt the Bayesian optimization (Bergstra et al., 2013) approach, performing a time-efficient search in the space of all hyper-parameter values. The size of the embedding layer is 300, and the LSTM layers 300 (600 for BiLSTM). We add Gaussian noise with $\sigma = 0.05$ and dropout of 0.1 at the embedding layer and dropout of 0.3 at the LSTM layer.

Results. The dataset for Task 2 was introduced in (Saggion et al., 2017), where the authors propose a character level model with pretrained word vectors that achieves an F1 score of 34%. Our ranking as shown in Table 2 was 2/49, with an F1 score of 35.361%, which was the official evaluation metric, while team TueOslo achieved the first position with an F1 score of 35.991%. It should be noted that only the first 2 teams managed to surpass the baseline model presented in (Saggion et al., 2017).

In Table 3 we compare the proposed Context-Attention LSTM (CA-LSTM) model against 2 baselines: (1) a Bag-of-Words (BOW) model with TF-IDF weighting and (2) a Neural Bag-of-Words (N-BOW) model, where we retrieve the word2vec representations of the words in a tweet and compute the tweet representation as the centroid of the constituent word2vec representations. Both BOW and N-BOW features are then fed to a linear SVM classifier, with tuned $C = 0.6$. The CA-LSTM results in Table 3 are computed by averaging the results of 10 runs to account for model variability. Table 3 shows that BOW model outperforms N-BOW by a large margin, which may indicate that there exist words, which are very correlated with specific classes and their occurrence can determine the classification result. Finally, we observe that CA-LSTM significantly outperforms both baselines.

Fig. 6 shows the confusion matrix for the 20

#	Team Name	Acc	Prec	Rec	F1

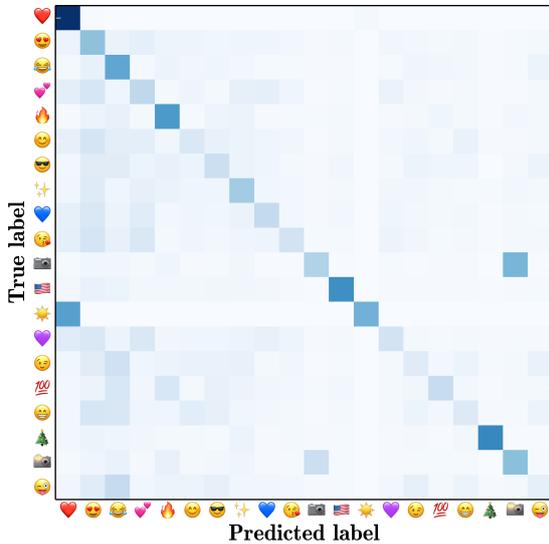

Figure 6: Confusion matrix

emojis. Observe that our model is more likely to misclassify a rare class as an instance of one of the 4 more frequent classes, even after the inclusion of class weights in the loss function (Section 4.1). Furthermore, we observe that heart or face emojis, which are more ambiguous, are easily confusable with each other. However, as expected this is not the case for emojis like the US flag or the Christmas tree, as they are tied with specific expressions. **Attention Visualization.** The attention mechanism not only improves the performance of the model, but also makes it interpretable. By using the attention scores assigned to each word annotation, we can investigate the behavior of the model. Figure 7 shows how the attention mechanism focuses on each word in order to estimate the most suitable emoji label.

5 Conclusion

In this paper, we present a deep learning system based on a word-level BiLSTM architecture and augment it with contextual attention for SemEval Task 2: “Multilingual Emoji Prediction” (Barbieri et al., 2018). Our work achieved excellent results, reaching the 2nd place in the competition and outperforming the state-of-the-art reported in

Figure 7: Attention Visualizations

the bibliography (Barbieri et al., 2017). The performance of our model could be further boosted, by utilizing transfer learning methods from larger, weakly annotated, datasets. Moreover, the joint training of word- and character-level models can be tested for further performance improvement.

Finally, we make both our pretrained word embeddings and the source code of our models available to the community³, in order to make our results easily reproducible and facilitate further experimentation in the field.

Abstract

As part of a SemEval 2018 shared task an attempt was made to build a system capable of predicting the occurrence of a language's most frequently used emoji in Tweets. Specifically, models for English and Spanish data were created and trained on 500.000 and 100.000 tweets respectively. In order to create these models, first a logistic regressor, a sequential LSTM, a random forest regressor and a SVM were tested. The latter was found to perform best and therefore optimized individually for both languages. During development f1-scores of 61 and 82 were obtained for English and Spanish data respectively, in comparison, f1-scores on the official evaluation data were 21 and 18. The significant decrease in performance during evaluation might be explained by overfitting during development and might therefore have partially be prevented by using cross-validation. Over all, emoji which occur in a very specific context such as a Christmas tree were found to be most predictable.

1 Introduction

It is said that a picture is worth a thousand words; inherently then, visual icons can provide additional meaning to text. One common example of this is the use of emoticons (emoji) accompanying primarily short, informal texts such as text messages and tweets. The role of these is interesting as they can be used in a variety of manners such as to complement text (e.g., 😊 to indicate happiness) and to replace text (e.g., I ❤️ you instead of I love you).

This research is concerned with the development of a system for predicting the occurrence of these emoji on the basis of Twitter data and is conducted as part of a *SemEval 2018* shared task (Barbieri et al., 2018). More specifically, given the text of an English or Spanish tweet, the system will attempt to predict the emoji originally found

in that tweet. The set of emoji used is limited to the twenty most frequent emoji for each language respectively.

2 Previous Work

A similar research on predicting emoji occurring in tweets was conducted by Barbieri et al. (2017). In this study a Bidirectional Long Short-Term Memory (BLSTM) network with standard look-up word representations and character-based representations of tokens was used. While it was found that profoundly dissimilar emoji could be predicted, this method did not succeed to accurately differentiate between twenty emoji classes.

Na'aman et al. (2017) meanwhile conducted a study to further explore the linguistic varieties of the purposes of emoji on Twitter. It was found that emoji can be an integral part of the content. One common example of this is a part of a phrase being replaced by an emoji, much like the 'I ❤️ you' example from the previous section. The notion of these word-emoji combinations is also mentioned by Dimson (2015). These findings inherently strongly support the idea that text could to some extent be used to predict emoji, given that fixed co-occurrences do exist.

3 Data

Since this study was conducted as part of a shared task, data was made available by the organization (Barbieri et al., 2018). For the English language, data consisted of a trial set containing 50.000 and a training set containing 500.000 tweets geolocated in the United States. For Spanish, a trial set of 10.000 and a training set of 100.000 tweets geolocated in Spain were available. For both languages, the trial portion of the data was used as a development set. Evaluation then was ultimately conducted on a held out data set sized similarly to the

Table 1: The distribution of training and test data as used during evaluation

trial set for both languages respectively.

Analysis of the supplied data showed the tweets originated from the period between October 2015 and February 2017 with a natural distribution to the extent that slightly more tweets originated from months with a large number of public holidays such as December. All of these tweets contain one of the twenty most used emoji for their respective language, although due to an error in the data ultimately only the top nineteen had to be predicted for Spanish. The distribution of the emoji over the tweets can be seen in Table 1. Note that in this table counts for the trial and training data have been merged as a data set combining these was used during final evaluation.

4 Method

In order to build capable models for predicting emoji in English and Spanish tweets, a two step procedure was followed. First, various forms of preprocessing and multiple machine learning algorithms were tested in order to identify what type of model would most likely be successful. Then,

a system built on these results was optimized for English and Spanish tweets separately in order to create a model for each language.

4.1 Initial Model Selection

In order to determine which type of model to use, four different classification methods were tested. Specifically, a *Logistic Regression* classifier was tested using word unigrams, word bigrams and a combination of both. Next, a sequential LSTM with maximum sentence length embeddings as features was tested. This model used 40 neurons and a *softmax* activation function. The model was compiled by implementing *Categorical Crossentropy* and the *Adagrad* optimizer. Then, a *Random Forest Regressor* was implemented using the same features as the initial *Logistic Regression* model. Finally, a *linear SVM* model was built using the SKLearn *SGDClassifier* with a hinge loss function.

For all models, four preprocessing steps were tested. Namely replacing URLs occurring in the data with a general identifier, replacing mentions occurring in the data with a general identifier, tokenizing the tweets using the *NLTK TweetTokenizer* and stemming the tweets using the *Snowball* stemmer.

After all tests had been executed it was found that the linear SVM using the *SGDClassifier* yielded the best results. Therefore this model was selected as a basis for the per language models.

4.2 English

4.2.1 Preprocessing

For the optimized English model, most of the preprocessing steps from the previous subsection; tokenization, URL replacement and mention replacement, were used. Use of the snowball stemmer was omitted as it did not appear to improve performance. Additionally, punctuation was removed as this seemed to yield better results on trial data.

4.2.2 Optimized Model

As set out in the *Initial Model Selection* subsection the SKLearn *SGDClassifier* was used as the basis for this model. The settings used for this classifier can be seen in Table 2 and are shared with the model for Spanish. The input for this classifier then was a tf-idf vector created from the preprocessed data, which was first converted to lowercase as this was found to improve performance.

The SKLearn *FeatureUnion* function was used in order to experiment with both word and character ngram ranges simultaneously. Ultimately it was found that using only word ngrams with a range of two to four yielded the best results. However, despite not using character ngrams in the optimized model, the *Featureunion* was kept as the 0.5 weight it applied to all features improved results by approximately two percent point. This effect is most likely caused by the reduction of the absolute differences between the predictiveness of features. After these optimizations, testing on the trial set resulted in an average f1-score of 61.

4.3 Spanish

4.3.1 Preprocessing

For the final model, the Spanish optimized model used the same preprocessing procedure as the English optimized model, as described in section 4.2.1 as this procedure was found to perform best on Spanish data as well. During the development of this model however the use of a lemmatizer at the preprocessing stage was also tested as a replacement of the Snowball stemmer. While neither were included in the final model as they did not yield a significant improvement, it is interesting to note that the model with lemmatizer scored better when its language was set to English as opposed to Spanish, despite the language of the data primarily being the latter.

4.3.2 Optimized Model

Much like the English optimized model, the final model for Spanish data used the SKLearn SGD-Classifier with the same parameter settings, as seen in Table 2. The only difference then is that for Spanish data using a ngram range of one to seven instead of two to four was found to yield the best results. When tested against the trial data this model yielded an average f1-score of 82.

5 Results

Once parameter optimization on both the English and Spanish models had been completed, the models were prepared for official evaluation on previously unseen data as explained in section 3. To this end, a merged data set containing both training and trial data was created for each language respectively as during development it was found that system performance would scale with the amount of

training data used¹. The models were then trained on these merged data sets and tasked with predicting the corresponding emoji for the tweets in the evaluation data. These predictions were submitted to and consecutively evaluated by the task’s organization. Results from this evaluation are detailed in the following subsections.

5.1 English Model

On average, the English optimized classifier achieved a f1-score of 21.438 with a precision of 25.965, a recall of 21.483 and an accuracy of 36.522. An overview of per class performance in the form of f1-scores can be seen in Table 3. Overall, the system performed best when predicting emoji which are likely to only occur in a specific context. ❤️ For example is likely to occur in tweets about love, 🇺🇸 is predominantly used in the context of independence day and 🎄 is used mainly in tweets concerning Christmas. On these emoji the system achieved f1-scores of over 50. Meanwhile, the system performed worst on emoji such as 😊 and 😞, which are likely to be used in a plethora of different contexts. These findings are in line with trends seen when testing on trial data during development.

5.2 Spanish Model

Contrary to scores seen when testing on trial data, the Spanish optimized classifier performed slightly worse than the English optimized system. When tested on evaluation data, this model achieved a f1-score of 18.729 with a precision of 20.662, a recall of 19.163 and an accuracy of 37.23. Compared to English, a similar trend of weaker performance on more generic emoji is seen. Furthermore, ❤️ ranked among the most accurately predicted emoji for Spanish as well. However due to lack of knowledge of the Spanish language no qualitative analysis of why other emoji such as 😂 and 🇪🇸 could be predicted relatively well was conducted.

6 Discussion

Although compared to other systems participating in the task the models did not do exceptionally bad, a significant drop in performance is seen when compared to results obtained during development. In fact, the English model saw a 40 per-

cent point drop and the Spanish model a 64 percent point drop. This decrease could partially be explained by differences in the distribution of certain emoji, as can be seen in Table 1. More importantly however, it is likely that the models were overfitted on the trial data as all testing during development was done on this portion of the data. In hindsight then, cross-validation might have been the better approach for evaluation during development.

Acknowledgments

Our contribution to this shared task was conducted as part of a course of the Information Science Master’s degree programme at the University of Groningen. As such we would like to thank H. Haagsma for his insightful feedback during progress meetings.

Abstract

This paper describes our approach, called *EPUTION*, for the open trial of the SemEval-2018 Task 2, Multilingual Emoji Prediction. The task relates to using social media — more precisely, Twitter — with its aim to predict the most likely associated emoji of a tweet. Our solution for this text classification problem explores the idea of transfer learning for adapting the classifier based on users’ tweeting history. Our experiments show that our user-adaption method improves classification results by more than 6 per cent on the macro-averaged F1. Thus, our paper provides evidence for the rationality of enriching the original corpus longitudinally with user behaviors and transferring the lessons learned from corresponding users to specific instances.

1 Introduction

Twitter sentiment analysis is an essential problem for companies and organizations to computationally measure customers’ perceptions which attracts attention from fields of both social media analytics and natural language processing (Rosenthal et al., 2017; Felbo et al., 2017; Mac Kim et al., 2017). A Twitter message, called a *tweet*, is generally composed of text, *emojis*, links, and mentioned users, known as *tweeters*. An emoji is a small picture or symbol of a standardized set to represent a feeling or another concept (Dictionary.com, 2018), contributing to the sentiment of its sender (Barbieri et al., 2017). Consequently, techniques for *emoji classification* are relevant and can be used to transfer information to subsequent tasks of sentiment, emotion, and sarcasm analysis (Felbo et al., 2017).

The SemEval-2018 Task 2 challenges its participants to perform multilingual *emoji prediction* in *English* and *Spanish*. The top-20 most frequent emojis of each language are annotated as tweets’

class labels. To encourage systems with better performance on less frequent emojis, the *macro-averaged F₁ score* (Macro-F) (Suominen et al., 2008) is used as the official evaluation measure.

Emoji prediction is widely formalized as a text classification problem in which the state-of-the-art systems fail to perform satisfactory (Barbieri et al., 2018). Because individual users enjoy diverse preferences in their emoji usage, it is hard to train a generalized classifier to tackle emoji prediction. As demonstrated in Table 1, with two examples of simple tweets with various annotations from the training set, even with exactly the same tweet texts, different tweeters have various choices of emojis, such as **i**) a user can select one of the emojis express the same emotion and **ii**) a user can have different attitudes towards the same objects or topics.

Tweet	Emoji
@user happy birthday	  
@ new york, new york	  

Table 1: The diversity emojis by different users.

In light of such observations, we propose to utilize a user adaption method to capture the specific preference for each individual user. We propose *Emoji Prediction with User Adaption* (*EPUTION*). It trains user-adapted classification models by applying tweeters’ tweeting history to personalize a basic model trained by the benchmark training data. We implement the method on SemEval-2018 Task2 in English, where the basic model is competitive to the state-of-the-art systems, while the user-adaptation model further improves the classification results.

2 System Description

In this section, we describe the text classification method and user adaption approach.

2.1 Text Classification

The text classification component of our system is based on *FastText*¹ (Joulin et al., 2017), which can achieve results comparable to those by the state-of-the-art deep learning methods but with many orders of magnitude less running time. FastText feeds a linear classifier with averaged word representations as follows:

$$P(y|x_n) = \text{Softmax}(BAx_n) \quad (1)$$

where y refers to the *class label* of a given document, x_n is the respective *normalized bag of features vector* of the document, and A and B are the *weight matrices*. The *cross entropy loss* is updated to optimized for parameter learning. The model is trained using the *stochastic gradient descent* algorithm with a linearly decaying learning rate.

To optimize the computing time, *Hierarchical Softmax* based on the *Huffman tree* (Mikolov et al., 2013) is used to estimate label distribution. The probability of the label node n_y in the Huffman tree, with parents n_1, \dots, n_p , is calculated as

$$P(n_y|x) = \prod_{i=1}^p P(n_i|x). \quad (2)$$

In order to capture the word order information in the text, bag of n -grams are used as features.

2.2 User Adaption Framework

Our *User Adaption* (UA) framework is composed of the following two main components (Figure 1): a *pre-training process* and an *adaption process*.

During the pre-training process, we train a basic classification model M_b using the training set of the benchmark corpus C_b through FastText. During the adaption process, for each user u_i , we adapt the basic classification model M_b to a user-adapted model M_i . Namely, we initialize the parameters B_i and A_i of M_i with pre-trained parameters from M_b , and train M_i for 5 epochs using the retrospective tweet collection C_i of u_i . Out-of-vocabulary words in C_i are randomly initialized in our experiments.

3 Experimental Setup

In this section, we will describe our supplementary data collection process, model, and test settings.

¹<https://fasttext.cc/>

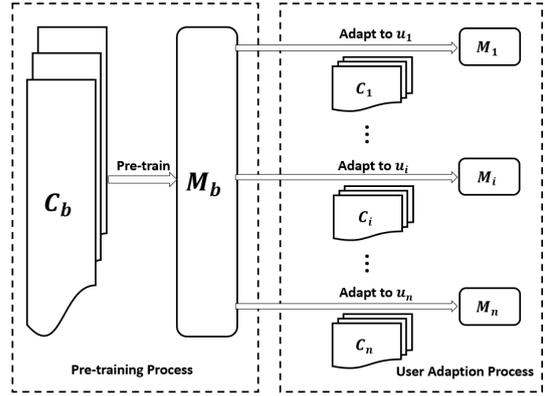

Figure 1: An overview of the user adaption framework.

3.1 Supplementary Data Collection

To implement our user adapted classification system, supplementary tweets are collected for each user. First, for each tweet of the emoji prediction task, the original tweeter who posted the tweet is retrieved by using the *Twitter Application Programming Interfaces*² (API). In order to map a tweet to its tweeter, we use the content of the tweet as a query to search for a match in Twitter. If precisely one result is retrieved and its content is precisely the same as the query text, the user who posted the retrieved tweet is assigned as the tweeter. Otherwise, no specific tweeter is assigned. Second, for each retrieved user, a retrospective collection of tweets is crawled from the most recent to the maximum number of 3,200 tweets³. The current tweet used to retrieve the additional tweeter data is excluded from the user’s tweet collection⁴.

After enriching the task corpus by these user-specific collections, text content of the tweets is extracted using official scripts (Barbieri et al., 2017), removing hyperlinks while keeping texts and emojis. The tweets with only one emoji are selected, where the emoji is considered as the class label of the tweet. To ensure no overlapping instances exist between the test set and additional data that is collected for the user adaptation model (i.e., the collection of users’ historical tweets), we remove the instances in the retrieved dataset that match the test tweets. More over, drawing from the use of the inverse document frequency in information retrieval as a way to scale down words

²<https://developer.twitter.com/>

³This number is determined by the Twitter API limitation.

⁴The crawling was performed for our SemEval-2018 Task 2 submission on 2nd February, 2018.

that only appear in few documents as too specific, all tweets that occur only in a single user’s tweet collection are filtered out. This post-processing eliminates accidentally collected test cases where a user name cannot be retrieved, but keeps general cases that commonly appears in a tweet message such as *Happy Birthday* and *Good Morning*.

To summarize the dataset setting, there are 487,088⁵ and 50,000 samples in the benchmark training and test sets, respectively. From all the tweets in the test set, 22,642 of them matched a tweeter, from 20,594 unique tweeters⁶. The final supplementary tweet collection contains 2,565,459 tweets, with user IDs. This is about five times the size of the benchmark training set.

3.2 Model and Test Settings

Because the number of retrospective tweets from a single user is limited⁷, the performance of training one model for each user is unsatisfactory in our preliminary experiments. Therefore, we apply a pre-training model to the benchmark training data of the task as a way to achieve properly initialized model parameters.

We implement the following three models:

- **FastText** is the baseline text classification model trained on the benchmark training set.
- **Data Augment** (DA) is the adapted model that used all tweeters’ tweets grouped as a whole.
- **Individual User Adaption** (IUA) model is the adapted model that tailored the model to each individual tweeter’s tweets.

After grid searching for the parameters on the benchmark development set, the *initial learning rate* α is set to be 0.01. The baseline model uses 100 dimensions of word vectors and 5 words in the context. It is trained over 50 epochs. The UA model has $\alpha = 0.05$ and is trained over 5 epochs. As the key point of this paper is the user adaption model, we explore the basic text classification features of *unigrams*, *bigrams*, and *trigrams* in our primary experiments. Trigram features achieve the best results. Thus, we follow such settings in all UA models while leaving room for further

⁵We retrieved 487,088 samples among the 500,000 tweet IDs provided by the task organizers.

⁶Some users have more than one instance in the test set.

⁷to approximately 23 tweets in the case of this paper

Model	Test-F	Test-R	Test-N
FastText	31.45	30.98	31.24
DA	33.17	34.94	30.81
IUA	37.54	43.25	31.24 [†]

†: We reuse M_b for tweets without the retrieved retrospective tweets for a given user.

Table 2: Macro-F [%] for the models on the test sets improvements of our system performance by introducing the features implemented in other leading systems.

To demonstrate the influence of retrieved user information, we compare our approaches on the test sets with the following settings:

- **Test-F** (*Full* set of 50,000 tweets) is the whole test set provided by the organizers of the SemEval2018 Task 2.
- **Test-R** (*Retrieved* set) is the subset of Test-F where the tweets are used to retrieve users’ retrospective tweets, containing 22,642 tweets.
- **Test-N** (*Non-retrieved* set) is the subtraction of Test-F and Test-R, where a user was not retrieved with this tweet or the retrieved user’s retrospective tweets were not available, containing 27,358 tweets.

4 Experimental Results

With additional retrospective data from the users, our model achieves more than 6 per cent better Macro-F than FastText. Consequently, it outperforms leading results from this competition.

Both DA and IUA achieve higher performance on the retrieved part of test set, Test-R, and thus improve the Macro-F on the full test set, Test-F (Table 4). This demonstrates the effectiveness of introducing the users’ retrospective tweets.

IUA outperforms DA, with a margin of more than 8 per cent on Test-R, indicating the necessity of training individual user adaptive models for the emoji prediction task. Compared with the best results in the task, on Test-F, — namely, 35.99 percent for *cagri* and 35.36 per cent for *cbaziotis* (Barbieri et al., 2018) — IUA achieves better results, even without an intensive feature engineering process.

5 Discussion

This section discusses and analyzes the success of our method in terms of its advantage on easily con-

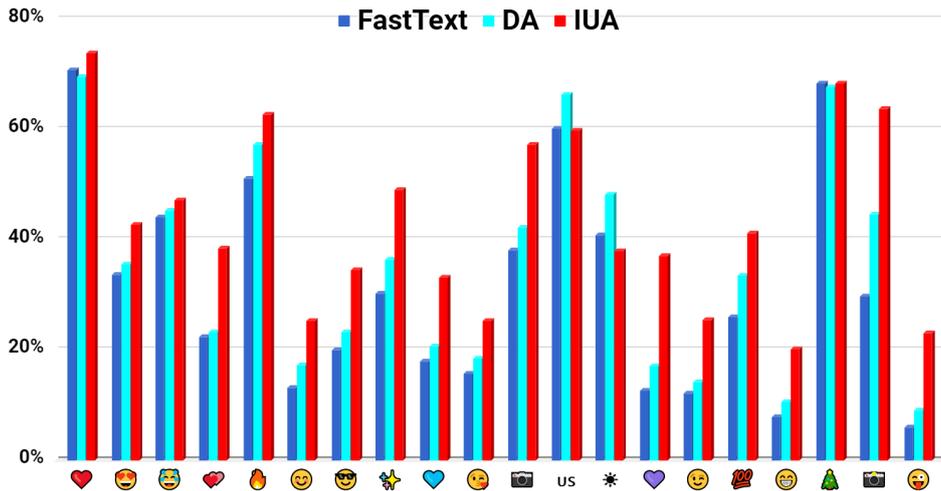

Figure 2: Class-specific results of the FastText, DA, and IUA models in emoji prediction on the Test-R data. We provide emoji labels on the x -axis and their respective label-specific F_1 score on the y -axis.

fused labels, and on users with certain amounts of historical tweets, over FastText.

We analyze the performance of IUA on different classes, by illustrating the Macro-F results of each emoji on Test-R in Figure 2. For the emojis, “Two Hearts”, “Blue Heart”, and “Purple Heart”, they carry similar meanings but different users have diverse preference when expressing their emotions. Both “Camera With Flash” and “Camera” without flash can be chosen under the same circumstances. Compared with DA, IUA achieves a marginal improvement on distinguishing the user preferences of those emojis. For other emojis such as “United States”, “Sun”, and “Christmas Tree”, IUA is competitive, as these emojis are aligned with single entities. These result show that our adaptive model is capable of learning user preferences in emojis with similar meanings, that is, the Case 1 of Section 1.

To demonstrate that IUA is also able to tackle the Case 2 of Section 1, we demonstrate some sample tweets that provide different emoji predictions using different user adapted models. For example, when the test tweet is *University life*, users have different attitudes towards “Red Heart”, “Two Hearts”, “Smiling Face With Smiling Eyes”, “Face With Tears of Joy”, “Hundred Points”, and other emojis Meanwhile, FastText is only able to predict “Two Hearts” for all users. IUA manages to capture the attitudes of individual users towards the same tweets, while FastText and DA tend to provide common attitudes of the tweets.

Both IUA and DA outperform FastText under

different scale settings of retrieved tweets, as illustrated in Figure 3. With more retrieved samples, the performance of DA increases. IUA reaches its peak performance on tweets with 64 retrieved historical tweets. More retrieved tweets do not further improve the results in our experiments. We have not observed much improvement for FastText for users with more retrieved tweets.

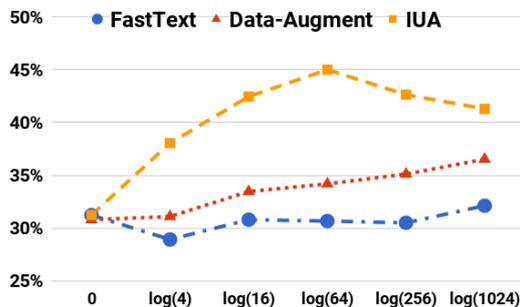

Figure 3: Macro-F of IUA, DA, and FastText on Test-R as numbers of tweets in each user collection increases.

6 Conclusion

This paper provides evidence for the rationality of enriching the original corpus longitudinally with user behaviors and transferring the lessons learned as user-adapted models to supervised machine learning tasks, such as the SemEval-2018 Task 2 on English emoji prediction. Our system achieves better performance than systems, which use all training data as a whole, even without much feature engineering. We believe this model can provide insight for introducing user-specific information for subsequent tasks of emoji prediction.

Abstract

We present a system for emoji prediction on English and Spanish tweets, prepared for the SemEval-2018 task on Multilingual Emoji Prediction. We compared the performance of an SVM, LSTM and an ensemble of these two. We found the SVM performed best on our development set with an accuracy of 61.3% for English and 83% for Spanish. The features used for the SVM are lowercased word n-grams in the range of 1 to 20, tokenised by a TweetTokenizer and stripped of stop words. On the test set, our model achieved an accuracy of 34% on English, with a slightly lower score of 29.7% accuracy on Spanish.

1 Introduction

The way people communicate with each other has changed since the rise of social media. Many people use visual icons, so-called emojis, to complement their social media messages. Emojis are frequently used on online platforms like Twitter, Facebook, Instagram and WhatsApp. The wide use of emojis in social media means that processing these emojis can be relevant for NLP applications dealing with social media data.

Social media text has been studied in the field of author profiling, but only recently the interest in the research on emojis started growing. Author profiling is used in different fields such as marketing, forensics, psychological research and medical diagnosis. Author profiling focuses on stylometric features, and since this new popular way of expressing meaning by using emojis has become mainstream, it's important to research if and how this data can be used in addition to the textual data. It could be possible that emojis reveal a great deal

about the author's gender, location, age or other characteristics.

We describe our approach to SemEval-2018 Task 2 on Multilingual Emoji Prediction (Barbieri et al., 2018) in this paper. We will discuss the features, the machine learning methods we used and analyse the performance of our best method.

2 Related Work

Author profiling tasks are focusing more and more on social media. Oftentimes, the data that is provided is data obtained from social media platforms Rangel et al. (2017). However, research on emojis is more scarce. Some research on emojis is done by Barbieri et al. (2017). They investigated the relation between words and emojis, and found that neural models outperform baseline bag-of-words models as well as humans when predicting which emojis are used in tweets.

Xie et al. (2016) researched automatic emoji recommendation using neural networks. Emojis can express more delicate feelings beyond plain text, and suggesting valid emojis to users of messaging systems can enhance user experience. They approached this problem with neural networks, and they found an Hierarchical-LSTM system significantly outperformed all other LSTM approaches.

Zhao and Zeng (2017) also looked at emoji prediction. The task described in this paper is very similar to the SemEval task. They achieved an accuracy of 40% using a CNN. As features they used the Twitter GloVe embeddings¹. Since they worked with a noisy dataset they constructed themselves and we are provided with a

¹<http://nlp.stanford.edu/projects/glove/>

clean dataset, a similar approach might yield high scores.

Author profiling on tweets is not new. At PAN 2017 (Rangel et al., 2017), Basile et al. (2017) were able to achieve a score of 82% on gender prediction of English tweets. They approached the task with an SVM using combinations of character and tf-idf word n-grams. This yields good results for predicting gender, and can provide a good basis for an emoji prediction system.

In the light of this task, sentiment analysis might be helpful. The sentiment of a tweet might point the classifier in the right direction. Mohammad et al. (2013), Han et al. (2013) and Da Silva et al. (2014) all looked into sentiment classification of tweets using machine learning algorithms. Da Silva et al. (2014) achieved an accuracy of 84.85% on predicting sentiment on a Tweet dataset using an ensemble where SVM, Random Forest and Multinomial Naive Bayes were combined using majority voting. It might be fruitful to try some features and methods used in these papers to see if sentiment can be a distinctive feature for emoji prediction. Unfortunately, we did not manage to experiment with these features.

3 Data

The dataset used for this task was provided by the organizers of the SemEval task, and is derived from Twitter and only includes Spanish and English tweets from respectively Spain and the United States. An overview of the emojis in the dataset is shown in Tables 1 and 2.

4 Method

For the task of emoji prediction, we explored a neural network approach and an SVM approach. We established a basic machine learning model per approach and improved on these models for both Spanish and English development dataset. With this approach, we aim to develop a robust model that is able to predict the emojis for both the Spanish and the English dataset accurately.

Architectures we tried for the neural network approach ranged from a simplistic sequential model with a few hidden layers to a stacked LSTM model with word embeddings.

The highest results for our neural network approach were achieved by a sequential neural network model. Our first layer was a 200-dimensional embedding layer, using the GloVe

Twitter embeddings (Pennington et al., 2014). Secondly, we used an LSTM layer. After the LSTM layer, our model included a Dropout of 0.2 (Srivastava et al., 2014). The output layer was a dense layer with the sigmoid activation function. Our model used a categorical cross-entropy loss and was optimized by the Adam optimizer (Kingma and Ba, 2014). We used zero masking, 20 epochs and a batch size of 128. Other parameters were left to the Keras defaults.

By establishing a basic SVM system, we tried to improve the system with divergent features. Our basic model consisted of word and character n-gram features. Improvements on this model were applied by using different kinds of preprocessing, tokenization, stemming and POS-tagging methods. We tried tokenization with the NLTK Word Tokenizer and the NLTK Tweet Tokenizer. For stemming, we tried the Porter and Snowball stemmer, also from NLTK. Both of them did slightly decrease the accuracy of our system. The POS tagger we tried was NLTK’s default POS tagger.

After trying several setups for both systems on the development dataset, we concluded that our SVM approach was the most accurate for both the English and Spanish tweets.

For our best SVM system, we found that some special characters and punctuation had to be removed. Besides, we replaced the Twitter URLs with the placeholder ‘URL’ and we substituted ‘...’, which was a reference to Instagram, with the placeholder ‘INSTAGRAM’. Lastly, we applied a method to reduce each character sequence to a maximum sequence of three characters. E.g., if a user uses the word ‘wooooooow’, we normalize it to ‘woow’, so the textual input to the system is less sparse.

The SVM system which yielded the best results on the development set, used the NLTK Tweet tokenizer and merely one feature, namely a tf-idf word vectorizer with a word n-gram range of (1,15), no lowercasing, removing of English stopwords for both the English and Spanish dataset (unconventional, but improved the scores) and a minimum document frequency of one. Our model was trained with sklearn’s `SGDClassifier`² with a hinge loss and a maximum number of 50 iterations. All other parameters were left to the sklearn defaults.

²http://scikit-learn.org/stable/modules/generated/sklearn.linear_model.SGDClassifier.html

Table 2: Macro F1-score per emoji on test-set for Spanish.

In addition to the SVM and LSTM, we tried an ensemble approach that combined both. Our assumption was that both systems performed slightly better or worse in different aspects. By combining our best SVM and LSTM, we tried to achieve a higher accuracy. When the LSTM system is 95% certain about a label prediction, our ensemble system takes this label as the predicted label. When the LSTM is less certain, the ensemble system takes the label predicted by our SVM system as the predicted label. This threshold was chosen after a short trial of different thresholds, where the 0.95 provided the best results. Yet, it turned out that combining both systems yielded a slightly worse accuracy than our best SVM system alone.

5 Results

The baseline results, obtained by always predicting the most frequent label from the training set, are presented in Tables 4 and 5

The results obtained on the development set are presented in Table 3, with the highest scores, i.e. those achieved by the best systems, are printed in bold.

The results of the final SVM model that we submitted on the test set are presented in Tables 4 and 5, for English and Spanish, respectively. The scores on individual classes (==emojis) are pre-

sented in Tables 1 and 2.

Our final system achieves a macro F1-score of 22.86% for English and 15.86%. In order to provide additional insights into the system’s performance, the confusion matrices for English and Spanish on the test set, are presented in Figure 1 and Figure 2.

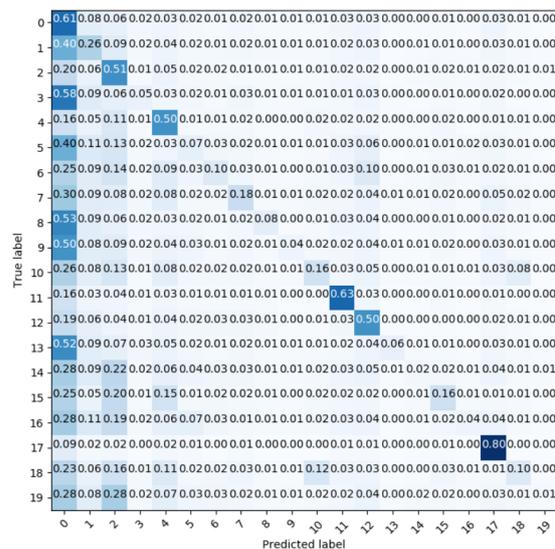

Figure 1: Confusion matrix for predicted and gold labels on the English test set.

6 Discussion & Conclusion

In the confusion matrices, the diagonal lines of correct predictions can be seen. However, as also reported in the paper of [Zhao and Zeng \(2017\)](#), there is also a bias towards predicting the most frequent emojis. For the English tweets, the Christmas tree emoji was predicted most accurately. This is understandable, since this is an emoji that is mostly used in very distinct circumstances. For emojis 3, 8, 9 and 13 this is not the case. They were often incorrectly predicted as emoji 0 (a red heart), which is explainable by the fact that all these emojis relate to love and hearts. For the Spanish tweets, the same issues can be seen with similar emojis.

In this paper, we explored two approaches (an LSTM and an SVM) and a combination of both for predicting emojis of English and Spanish Tweets. Ultimately, the SVM classifier achieved the high-

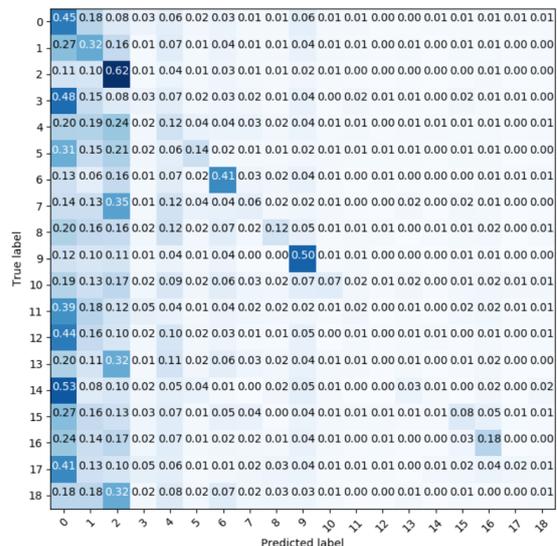

Figure 2: Confusion matrix for predicted and gold labels on the Spanish test set.

est results: F1-score of 22.86 for English and 15.86 for Spanish. Compared the other participating groups, the results were in the mid-range. These results showed that our system ranks 26th out of 49 for English and 10th out of 22 for Spanish. The results on the test set were lower than what we achieved on the development set. This is possibly due to the fact that there seemed to be an overlap between the training set and the development set. This would cause the classifier to be able to make more correct predictions, because it has seen the exact same tweets before.

Abstract

This paper describes our approach to SemEval-2018 Task 2, which aims to predict the most likely associated emoji, given a tweet in English or Spanish. We normalized text-based tweets during preprocessing, following which we utilized a bi-directional gated recurrent unit with an attention mechanism to build our base model. Multi-models with or without class weights were trained for the ensemble methods. We boosted models without class weights, and only strong boost classifiers were identified. In our system, not only was a boosting method used, but we also took advantage of the voting ensemble method to enhance our final system result. Our method demonstrated an obvious improvement of approximately 3% of the macro F1 score in English and 2% in Spanish.

1 Introduction

As a novel means of enhancing the visual effect and meaning of short text messages, emojis are almost indispensable to each social platform, such as Facebook, Twitter, and Instagram. These graphic facial expressions and other object symbols enrich the emotion the user wishes to express in a text-based message. Although they are significant as part of social messages, emojis have scarcely attracted attention from a natural language processing (NLP) standpoint. Notable exceptions include studies focused on emoji semantics and usages (Barbieri et al., 2017). However, the interplay between text-based messages and emojis remains virtually unexplored. The aim of SemEval-2018 task 2 (Barbieri et al., 2018) is to fill this gap by providing all participants with a large set of text-based tweets and their related emojis, which were extracted from original tweet messages, in order to determine the connection between text words and emojis.

In recent years, an increasing amount of research work has been conducted on the sentiment analysis of tweets. Emojis have always played an important role in the sentiment polarity of tweets. Novak et al. (2015) proposed a sentiment map of the 751 most frequently used emojis, by computing the sentiment emoji from the sentiment of tweets in which they occurred, and they determined a significant difference in the sentiment distribution of tweets with and without emojis. As opposed to sentiment polarity prediction of tweets, we further investigated potential tweet emojis in this task, evoked by the text part.

Neural networks involving attention mechanisms have been studied extensively in the image processing and NLP fields, and have demonstrated remarkable results, particularly convolutional neural networks (CNNs) (Collobert et al., 2011) and long short-term memories (LSTMs) (Hochreiter and Schmidhuber, 1997). Cliche (2017) assembled several CNNs and LSTMs and achieved first ranking in all of five English subtasks. Raffel and Ellis (2015) proposed a feed-forward network model with attention, which selects the most important element from each time step using learnable weights, depending on the target. As a variant of LSTM, the gated recurrent units (GRUs) (Cho et al., 2014) use gating units directly in order to modulate the data flow inside the unit, rather than consisting of separate memory cells. For this task, we firstly utilized bi-directional GRUs and the attention mechanism to train the base model, following which we boosted the base model with different sample weights. In order to achieve optimum performance, soft and hard voting ensemble methods were also used in our system.

The remainder of paper is structured as follows. Section 2 provides an overview of task 2. In

section 3, we describe the architecture of our base model, particularly the attention mechanism, as well as the multi-ensemble methods used in our submission. Section 4 describes our experiment, which consists of system parameters, evaluation metrics, and experimental results for the two subtasks. Finally, in section 5, we list several possible improvement points, and in section 6, we outline our main conclusions.

2 Task Overview

This multilingual emoji prediction task consisted of multi-labeled emoji classification of short tweet texts, and was divided into two subtasks based on the text language: subtask 1 in English and subtask 2 in Spanish. The most frequently used emojis in English and Spanish were employed as labels, so the two task labels differed.

Subtask-1: Emoji Prediction in English

Given a text of tweets in English, its potential emojis are predicted from 20 emoji labels, as follows:

Subtask-2: Emoji Prediction in Spanish

Given a text of tweets in Spanish, its potential emojis are predicted from 19 emoji labels, as follows:

2.1 Datasets

The organizers provided a huge amount of training data, including 500K tweets in English and 100K tweets in Spanish¹. We crawled almost the entire set of tweets with Twitter APIs², as parts of the training tweets were no longer available. Table 1 provides a detailed distribution of the datasets for subtasks 1 and 2.

Furthermore, all of the used emoji labels extracted from the tweets are the 20 or 19 most frequently used emojis in the languages themselves. Data samples for these classes are gradually decreasing; thus, datasets of the two

¹The crawler and extractor for this task can be downloaded from <https://github.com/fvancesco/Semeval2018-Task2-Emoji-Detection/tree/master/dataset>

²<https://apps.twitter.com/>

	Subtask-1	Subtask-2
Train	489660	98506
Develop	50000	10000
Test	50000	10000

Table 1: Datasets of Task2.

subtasks are both imbalanced. In subtask 1, the greatest majority class ❤️ includes 106352 (21.7%) samples, nearly ten times that of the lowest minority class 😞, which includes only 12190 (2.5%) samples. For subtask 2, similar to subtask 1, the greatest majority class ❤️ includes 19640 (19.9%) samples, while the lowest minority class 😊 includes 2525 (2.6%) samples.

Pre-trained Twitter embeddings for English and Spanish were offered in the task. We validated these by using another pre-trained embedding from GloVe³ (Pennington et al., 2014), and the English embedding offered in the task presented approximately the same performance in our test.

3 System Description

As these two subtasks were rather similar, with the exception of different emoji labels, we used exactly the same thought to train every system of the respective languages. In order to choose the best one as our base model, several models were tested (such as CNN, CNN+LSTM), and superior performance was achieved by using the multi-ensemble methods as the following subsection 3.2.

3.1 Base Model

We created our base model with Bi-GRU (Bahdanau et al., 2014) rather than Bi-LSTM, owing to its faster, efficient, and superior performance. Furthermore, the bi-directional model can concatenate the sentence matrix vector forward and backward at each time step to obtain full sentence information (Irsoy and Cardie, 2014). The attention mechanism was also involved in our model, the model architecture of which is illustrated in Fig. 1, where h_t denotes the hidden vector at each time step, and t means the time step in the input sequence. Vectors in hidden state sequence h_t are fed into the learnable function to produce attention weight α_t . A single vector is computed as the weighted average of h_t .

³glove.840B.300d from <https://nlp.stanford.edu/projects/glove/>

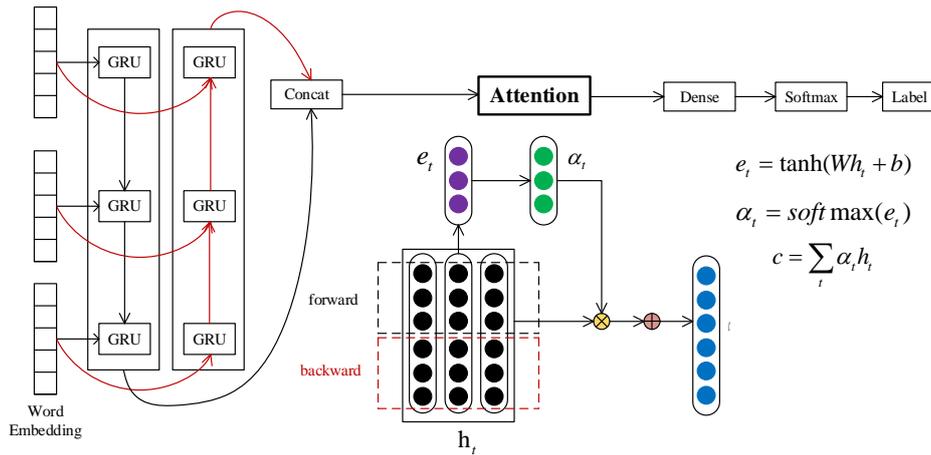

Figure 1: Architecture of Bi-GRU Model with Attention Mechanism.

The characteristic advantage of the attention mechanism over other reduction operations is that it takes an auxiliary context vector as input. The context vector is crucial because it indicates which information to discard, and a summary vector is therefore tailored to the network using it.

3.2 Ensemble

The ensemble classifier is a type of algorithm in which multiple learners are used to improve the individual classification performance by combining hypotheses. In this task, the multiple ensemble methods of boosting and voting were used to achieve the optimal result.

3.2.1 Boosting

The concept of boosting involves iteratively training the base classifier with the re-weighting method, which assigns a new list of sample weights to each round of training data samples. The weight distribution of each sample round depends on the results of the previous round classifier. Simple weights to instances are based on how arduous they are to the classification; thus, the boost classifier provides additional weights to those mis-classified instances following a round of classification in order to boost the following classifier result. Finally, the sequence-based linear weighting method was used to combine the classifiers. Although boosting is not intended for class imbalance problems, owing to this characteristic, it has become an ideal method for class imbalance problems.

3.2.2 Voting

The voting classifier can take a series of machine learning classification algorithms (possibly conceptually different) and average them to obtain final predictions. Two voting methods are available:

Soft voting: Each model outputs a probability vector for all classes, and the voting model is average-weighted to obtain a final probability vector for classification.

Hard voting: Each model outputs what it believes to be the most likely category, from which the voting model selects the category with the largest number of voting models as the final classification.

In several tasks, soft voting may obtain superior results over hard voting. In this case, both voting methods were used. We assembled our strong boosting classifier and weighted Bi-GRUATT by means of soft voting.

4 Experiment and Results

4.1 Pre-processing

Twitter messages include a great deal of irrelevant information that is useless for capturing text message features. Prior to building our model, we utilized a series of operations to normalize tweet messages, divided into the following steps.

Lowercase. We integrated all text words by converting them to lowercase.

Replace Emoticons. We began by pre-processing tweet messages with emoticon replacement. Typographic emoticon symbols that appear sideways, resembling facial expressions, such as :), :-), and (: all mean “smiley face”, while :-(, :(, and):

mean “frowny face”. In spite of the fact that these emoticons could barely be recognized in the pre-embedding vocabulary, they visibly advanced or changed the text message interpretation. We identified these emoticons and replaced them with the words “smile” or “sad” in the English task, and “sonreír” and “triste” in the Spanish task.

Remove marks. With Twitter as a large social communication platform, we detected user operations in order to remove them:

- remove URL link;
- do nothing with “@” and “@user”;
- remove hashtag mark and retweet mark, such as “#”, “rt”, “&”;
- remove numbers and other irrelevant punctuation marks, such as question mark “?”, exclamatory mark “!”, and quotation.

Revise elongated words. Incorrect words remained in the training samples, elongated with a single letter, such as “Helloooooo”. We searched for words containing repeated letters consecutively more than three times, and revised the number of letter replications to one.

Abbreviation. People are likely to use abbreviations of certain phrase to create Twitter message, and we changed these abbreviations back into original phrases in the English task. Above 60 common abbreviations of twitter were replaced in the pre-processing. For example, “thx” was changed back to “thanks” and “ASAP” to “as soon as possible”. We determined to skip this step in the Spanish task because we were not familiar with Spanish or its abbreviations.

4.2 Implementation

Following preprocessing, we used a multi-language tokenizer tool, Unitok⁴, for tokenization of each task, and then calculated the token number of the longest sentences in the training datasets. All tokens that could be recognized in the provided word embedding were converted into a 300-dimension vector, which would be filled in with zero if it was still unrecognized with the prefix “#”. All training samples were padded out to the same length L , which is 40 in English and 38 in Spanish.

We implemented our model using the Python Keras library with a TensorFlow backend. The

⁴<http://corpus.tools/wiki/Unitok>

properties of our Bi-GRUATT model were as follows.

1. The GRU dropout was set to 0.2, which was the same as the dropout layer following the attention layer.
2. The active function of the dense layer was \tanh with a length of 100, and softmax was used to output the prediction label.
3. Instead of using *Sequential.fit* to train the model, the *Sequential.fit_generator* was used for huge training samples in order to solve the memory problem.
4. The optimizer *Adam* and loss function cross entropy were used to deal with this multi-labeled task.
5. The training epoch was dependent on the early stopping monitor. If the training loss had not improved in the latest 10 epochs, the training process stopped. Both training processes in task 2 exhibited extremely slow improvement in every epoch. In English, the training epoch was approximately 180 to 230, and 280 to 400 in Spanish.

As the ratio of the majority to minority classes could be as high as 10:1, a simple means of enhancing the minority class performance is a cost-sensitive method that applies different costs for mis-classification errors to each class. Usually, there is a high cost for the minority class and a low cost for the majority class. We balanced the training samples with various class weights, and used these to train the cost-sensitive models in the English and Spanish tasks.

Boosting and voting were implemented using the AdaBoosting and Voting classifiers of scikit-learn (Pedregosa et al., 2011) in Python. During the boosting processing, we applied the Bi-GRUATT model with an equal sample weight of $1/N$ (where N is the total number of training samples) as the base estimator, and then iteratively trained a stronger classifier by paying more attention to mis-classified samples. The boosting learning rate was set to 0.001 and the number of estimators was dependent on the result of macro F1. The boosting model would be stopped if it already had three weak classifiers. Only the strong classifier in the boosting process would be used in the voting ensemble, and weak classifiers were ignored.

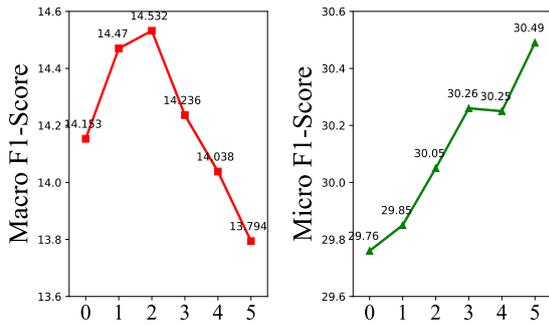

Figure 2: Macro F1 and Micro F1 of boosting classifiers in Spanish. (X-axis means the number of boosting iteration, and number '0' refers to the initial model which was trained with equal sample weight.)

4.3 Evaluation

For evaluation purposes, the official results were based on the macro F1 score for the two tasks. The F1 score was calculated as follows:

$$F_i = \frac{2\pi_i\rho_i}{\pi_i + \rho_i} \quad (1)$$

$$F_{macro} = \frac{\sum_{i=0}^M F_i}{M} \quad (2)$$

where F_i is the F1 score of the i -th class, and π_i and ρ_i denote the precision and recall of the i -th class, respectively. The macro average provides an equal weight to all the classes, regardless of how many samples belong to it. The micro average provides equal weights to all the samples, thereby favoring the performance of the majority classes. The macro F1 as well as micro F1 score were utilized to evaluate the performance of every model in our system.

4.4 Results

As the English datasets are fivefold the Spanish ones, we adjusted the system model and its parameters with the Spanish datasets in order to save time. We handled the two subtasks in the same manner; however, the results indicated that not all methods were appropriate for both the English and Spanish tasks.

Subtask-2: Spanish Emoji Prediction

Boosting had generated only six strong or weak classifiers, and the variation tendencies of the macro and micro F1 scores are displayed in Fig. 2.

Subtask-2	Macro F1	Micro F1
Boost_0	14.153	29.76
Boost_1	14.47	29.85
Boost_2	14.532	30.05
Soft Voting	15.016	31.55
Bi-GRUATT_1	13.768	18.93
Bi-GRUATT_2	14.144	18.86
Hard Voting	16.015	30.22

Table 2: Results of each model and voting ensemble in Spanish.

🌟	🎵	💞	😄	
14.19	19.77	2.82	4.38	

Table 3: Macro F1 of each emoji label in Spanish.

It was found that, as the iteration times increased, the micro F1 score (accuracy) of the boosting system continuously increased, while the macro F1 score was increased in the first three iterations and then decreased in the following iterations. As the macro F1 score provides the official evaluation index, we identified the first three strong boost classifiers for the further ensemble. In the voting ensemble part, the three strong boost classifiers were used to achieve stronger classification by means of soft voting, and eventually, we integrated the soft voting result and the results of the two basic Bi-GRUATT models trained with a balanced class weight (same model but trained twice). The results of these models can be seen in Table 2. Soft voting achieved a 0.9% improvement in the macro F1 score, while the hard voting achieved 1% compared to the soft voting results.

Furthermore, hard voting, which provided the final result, demonstrated a 2% improvement in the weighted Bi-GRUATT model. Table 3 displays the macro F1 for each emoji label.

Subtask-1: English Emoji Prediction

Similar to the process of subtask 2, we obtained four boosting classifiers, the variation tendencies of which are illustrated in Fig. 3. The macro F1

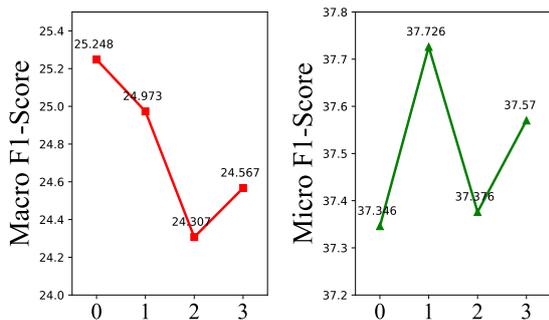

Figure 3: Macro F1 and Micro F1 of boosting classifiers in English. (X-axis means the number of boosting iteration, and number '0' refers to the initial model which was trained with equal sample weight.)

Subtask-1	Macro F1	Micro F1
Boost_0	25.248	37.346
Bi-GRUATT_1	25.656	27.556
Bi-GRUATT_2	25.552	27.28
Hard Voting	28.112	35.196

Table 4: Results of each model and voting ensemble in English.

score was decreased following each iteration. We could not conduct soft voting with only one strong classifier, but carried out the hard voting directly. Table 4 presents the results of the weighted Bi-GRUATT and hard voting. The hard voting in the English task demonstrated a 2.5% improvement in the weighted Bi-GRUATT and 2.9% improvement in the Bi-GRUATT without class weights. The macro F1 for each emoji label is displayed in Table 5.

All above-mentioned results were obtained following the competition, and we changed the learning rate from 0.01 to 0.001 for increased boost classifiers. The competition submission only used two boost classifiers for ensemble in Spanish and one was utilized in English. We ranked 16th among 48 teams in the English task and 13th among 21 teams in the Spanish task⁵.

As indicated in Tables 4 and 5, predictions of similar smiley face emojis (😄😄😄😄 in Spanish and 😄😄😄😄 in English) exhibited unstratified results. There were not many characteristics to distinguish these from one another, as they all meant a happy feeling, and people had a different

⁵Results of all teams can be found in <https://goo.gl/P515KW>

❤️	😍	😂	💕	🔥

🎉	😁	🎄	📷	😞
25.22	11.68	66.86	24.97	4.59

Table 5: Macro F1 of each emoji label in English.

understanding and favorite emojis, which could cause certain confusion problems. Compared to the confused smiley face emojis, the label 🎄 demonstrated the best result, although it was a minority class. It was easy to predict, owing to the label 🎄 having an obvious feature to recognize, such as “tree”, “Christmas Tree” or everything relevant to Christmas.

Another confused set of emojis were series of heart emojis, particularly 💕💙💜💖💗, and in subtask 2, some of these labels even obtained a zero result. This illustrates that the model preferred to predict the highest majority class of the same series, such as ❤️ rather than its actual emoji 💕, 💙 or other heart.

5 Discussion

In this section, we briefly discuss several points that may enhance our system results. For time reasons, we have not validated these yet.

Pre-processing

1. We simply removed hashtag mark “#”, however, there were numerous unrecognized hashtag words, such as “Iamhappy”, “Iam_happy” or “I-Am-Happy”. A preferable method is decomposing the hashtag to invert it into a sequence of words that would enrich the information of the sentence samples (Billal et al., 2016).
2. We did not deal with the mis-spelled words, and changed all elongated words into the without repeated letters that would create mistake words, like “foooood”.

Model

1. As the official evaluation index is the macro F1 score, we should set the initial sample weight to be the same as the balanced class weight in the boosting process.

2. We only trained less than 10 estimators in the boosting, which may be too small to determine the boost variation tendency in this task.
3. We only used one base model to ensemble. Assembling with different model types may achieve improved results, such as CNN, a combination of CNN and LSTM, and random forest.

6 Conclusion

In this brief paper, we have presented the system we used to compete in the SemEval-2018 task 2: Emoji Prediction in English and Spanish. Our submission system was based on a Bi-GRU model with an attention mechanism, and we aimed to ensemble the base model with multi-method boosting and voting in order to achieve superior performance. In our work, multi-ensemble exhibited a 2 to 3% improvement in the task results.

In the future, we plan to validate the points in the Discussion section in order to verify their influence of them, and add useful points to our system to implement an improved model for emoji prediction.

Abstract

This paper describes the approach that was developed for SemEval 2018 Task 2 (Multilingual Emoji Prediction) by the DUTH Team. First, we employed a combination of pre-processing techniques to reduce the noise of tweets and produce a number of features. Then, we built several N-grams, to represent the combination of word and emojis. Finally, we trained our system with a tuned LinearSVC classifier. Our approach in the leaderboard ranked 18th amongst 48 teams.

1 Introduction

Emojis are used in everyday life to express words or feelings of microblogging users. They are commonly placed at the end of a sentence or alone. In this paper, we show how our emoji prediction framework was applied to SemEval-2018 Task 2 (Multilingual Emoji Prediction) (Barbieri et al., 2018), specifically on Subtask 1 (Emoji Prediction in English).

In the last few years, many studies concentrated on emoji prediction and analysis. The prediction of emojis, the connection of emojis and words, and their separation from content-based tweet messages, based on Long ShortTerm Memory networks (LSTMs), was examined by Barbieri et al. (2017). The combination of emojis and sentiment was investigated by Novak et al. (2015), who developed the first emoji sentiment lexicon and created a sentiment map of the 751 most frequently used emojis. The study of Barbieri et al. (2016) tested several skip-gram word embedding models to measure the difference in performance between machine-learning models and human annotation. Na’aman et al. (2017) analyzed the viability of a trained classifier to differentiate between those emojis utilized as semantic substance words and those utilized as paralinguistic or emotional

multimodal markers. Miller et al. (2017) investigated the hypothesis of previous works that emojis in their regular textual contexts would generously reduce and lead to miscommunication, but they found no such evidence; the potential for miscommunication appeared to be the same.

The rest of this paper is organized as follows. Section 2 describes the architecture of our system and the dataset. In Section 3, we discuss the various parameters that were used to fine-tune the system, and present the performance of our framework. In Section 4, we lay out our main conclusions and research issues for further investigation.

2 System Description

The principal goal of SemEval-2018 Task 2 - Subtask 1 was emoji prediction in English. The framework we utilized consists of a bag of-words representation and N-gram extraction. We used the popular machine learning tool for Python, called Scikit-Learn (Pedregosa et al., 2011).

2.1 Preprocessing

For the preprocessing of tweets, we were guided by the results of our previous research (Effrosynidis et al., 2017). We used the effective combination of the following techniques:

- Replace URLs and User Mentions to the tags ‘URL’ and ‘AT USER’, as the majority of tweets on Twitter contain a URL and mentions which are considered noise.
- Replace Contractions, as it reduces the dimensionality of the problem and improves speed and accuracy according to the above-mentioned paper.
- Remove Numbers, because they do not contain any sentiment.

Label	Sentences	Unique Words	Words/Sentence	Tweets	User tags	Hashtags	Unique Hashtags
0	160220	110305	7.191	107669	20471	110655	55287
1	75706	70430	7.351	51923	11097	57839	32922

Table 1: Statistics per emoji.

- Replace Repetitions of Punctuation, which merges in the same feature the intensity of emotions. For example, if we find more than two consecutive exclamation, question or stop marks, we replace them with a single one.

2.2 Dataset

The training and testing datasets were provided by the organizers. The training set contained approximately 500,000 tweets, where each tweet contained a single emoji, before they removed it and set it as class label. That emoji is used as the class label for the particular tweet.

We extracted various statistics for the dataset as it can be seen in Table 1. Some class labels contain more sentences per tweet, like label 10 (👍) and 0 (❤️). We also observe that the emoji 🍷 has on average much fewer hashtags per tweet, while the emoji 🇺🇸 has much more. All the other emojis range within reasonable limits. The emojis with labels 7 (🌟) and 3 (💖) are expressed using more words on average, while the emojis 10 (👍) and 11 (🇺🇸) are expressed with fewer words.

All the above observations are important to un-

derstand the dataset and how people are using each emoji. One can use these statistics in order to create more features and test them to see the changes in classification accuracy. For example, one can count the words of each new sentence for classification, and compare them with the ones derived from the training dataset.

In our study, we compared several machine learning algorithms (Ridge, Logistic Regression, Passive-Aggressive, and Linear SVC), and three different word to vector representations (tf-idf Vectorizer, count Vectorizer, and hashing Vectorizer). The macro F-measure score was computed for 10-folds cross-validation on the training set and on the trial set while using the training set for training. We employed word n -grams and character n -grams (n ranging from 1 to 4), with the latter ones performing poorly.

3 Experimental Results

In this section, we describe the different classifiers and vectorizers used and present our results.

Vectorizer	Macro-averaged F-measure			
	Ridge	Logistic Regression	Passive-Aggressive	LinearSVC
tfidfVectorizer	26.2	25.1	24.0	26.6
countVectorizer	25.9	26.7	20.9	25.5
hashingVectorizer	24.6	23.0	23.6	25.9

Table 2: Results per classifier and vectorizer using 10-fold unigrams.

3.1 Classifiers

In order to gain a better perspective on the problem, we trained four different classification algorithms. We test each classifier comparing their macro F-measure score. We choose LinearSVC, because of the stability we noticed in the results it returned. Below we discuss every classifier:

- Ridge: an algorithm belonging to the Generalized Linear Models family. Text classification problems tend to be quite high dimensional, and high dimensional problems are likely to be linearly separable; this is one reason why Ridge performs quite well.
- Logistic Regression: despite its name, it is used for classification and fits a linear model as well. In the multiclass case, the training algorithm uses the one-vs-rest (OvR) scheme.
- Passive-Aggressive: belongs to a family of algorithms for large-scale learning, which does not require a learning rate and includes a regularization parameter C . On the one hand, the aggressive mode of the algorithm means that if an incorrect classification occurs, the model updates to adjust to this misclassified example. On the other hand, the model stays unchanged in every correct classification and this is the passive behavior of the algorithm (Crammer et al., 2006).
- Linear SVC: the purpose of this algorithm is to fit the data by finding a set of hyperplanes that separate space into areas representing classes. The most efficient way is considered to be the max distance between data points and the hyperplane.

3.2 Vectorizers

Nowadays, one can find many vectorizers to use in order to extract features. We used the following three vectorizers provided by Python’s Scikit-Learn library (Pedregosa et al., 2011), in order to transform tweets into vectors of features.

- tf-idf Vectorizer: a vectorizer which scales the term frequency counts in each tweet by penalising terms that appear more frequently across the dataset.
- count Vectorizer: converts the collection of tweets to a matrix of token counts.
- hashing Vectorizer: a vectorizer which applies a hashing function to term frequency counts in each document. This vectorizer leads to a sparse matrix holding token occurrence counts (or binary occurrence information).

Each vectorizer we used is efficient under certain circumstances. In addition, we noticed that the combination of the vectorizer and classification algorithm is crucial for our problem. In our work, as we can see in Table 2, the combination of countVectorizer and Logistic Regression leads to the best result. However, the tfidfVectorizer achieves greater results than the countVectorizer and the hashingVectorizer in the majority of the algorithms; for this reason, we proceeded with the tfidfVectorizer.

3.3 Evaluation Results

We evaluate the performance of our system with the macro F-measure score. The macro F-measure score gives equal weight to each emoji category, regardless of its class size. The F-measure per emoji class is the harmonic mean of the precision and recall of the class:

$$\text{F-measure} = \frac{2(\text{Precision} \times \text{Recall})}{\text{Precision} + \text{Recall}}.$$

The macro-average F-measure score is obtained by taking the average of F-measure values across emoji classes:

$$\text{macro F-measure} = \frac{1}{M} \sum_{n=1}^M \text{F-score}(n),$$

where M is the total number of classes.

In Table 3 we present the macro F-measure score of `tfidfVectorizer` combined with `LinearSVC` classification algorithm. In the first column, the results of 10-folds cross validation on the training set are presented. In the second column we present the results when training with the training data and testing with the trial data. As it can be seen, four-grams performance on trial data has the highest value, but trigrams perform better on 10-folds cross-validation. This is the reason we used trigrams to train our model for the submitted runs.

	10-folds Training	Trial
word-unigrams	26.6	46.8
word-bigrams	29.3	61.4
word-trigrams	29.4	63.7
word-fourgrams	29.2	64.4

Table 3: F-measure results for word N-grams.

4 Conclusions

In this paper, we presented the framework we used to participate in the SemEval-2018 emoji prediction competition. We used a `tfidfVectorizer` combined with a `LinearSVC` classification algorithm, employing word tri-grams, to train our model. Our team ranked in the 18th place among 48 teams.

For future work, it would be interesting to test Neural Network approaches, to use emoji sentiment lexica (Novak et al., 2015), or additionally include more features. Furthermore, it would likewise be intriguing to investigate the miscommunication of emojis in their natural textual contexts.

Abstract

Emojis are widely used on social media; thus understanding their meaning is important for both practical purposes (e.g. opinion mining, sentiment detection) and theoretical purposes (e.g. How do different L1 speakers use them?, Do they have specific syntax?). This paper presents a set of models that predict an emoji given a tweet as a part of the SemEval-2018 Task 2: Multilingual Emoji Prediction. We built different models and we found that the test results were very different from the validation results.

1 Introduction

To some extent, Twitter can be considered a huge corpus and researchers exploit it in many different ways to get a proxy for various types of annotations. Purver and Battersby (2012) use distant supervision on tweets to build an emotion detection system; Bollen et al. (2011) show that it is possible to use Twitter data to predict the stock market; Mohammad et al. (2016) build a corpus from tweets for modelling stance.

Social media in general are very popular for building corpora for sentiment-related tasks since the users make a wide use of emojis. Pool and Nissim (2016) show that it is possible to achieve state-of-the-art performance in sentiment classification using only automatically gathered data.

The wide use of emojis on the web calls for systems that can automatically process them. When performing opinion mining tasks, for instance, it can be the case that all we have is just an emoji. For example, a single emoji could be used as a reply to an advertisement of a certain product; thus, being able to get the meaning of that emoji is important. Felbo et al. (2017) shows that given a text, it is possible to successfully automatically suggest the most appropriate emoji that can accompany that text.

In this paper we describe our participation in the SemEval-2018 Task 2: Multilingual Emoji Prediction (Barbieri et al., 2018), a challenge that originates from the work of (Barbieri et al., 2017). The task is structured as follows: given a tweet that originally contained one and only one emoji, predict that emoji; the emoji is removed and given as a training label.

We experimented using three different approaches: first we use a shallow feature representation with two different algorithms (Naïve-Bayes and Support Vector Machine); then we experimented with a dense feature representation (i.e. word embeddings) and a deep neural classifier; lastly, we modeled the problem as a translation problem (i.e. treating English and Spanish as the source language and ‘Emoji’ as the target language) using a state-of-the-art neural translation system to predict the labels as translated sentences.

To summarize, our main contributions presented in this paper are three machine learning models that predict an emoji given some text. We confirm a fact that is well known in the literature, i.e. that neural models can give good results but hyper-parameter tuning is a hard task and if it is not successful, then a good linear classifier with a bag-of-words representation can easily outperform the neural model. Our best English system was ranked 8th in SemEval Shared Task and our best Spanish system was ranked 4th¹.

2 Data

Both the training and testing data are tweet collections: overall, there are 500k English tweets and 100k Spanish tweets, provided as two distinct datasets. These tweets are accompanied by two

¹We submitted on January 10, 2018. Our submission was made under the name ‘The Fabulous EM-LCT Team from Malta’.

sets of labels — one per language — and these labels are the emojis that were originally in the tweet and later removed.

The English label set consists of 20 emojis, while the Spanish label set consists of 19 emojis.

We manually inspected some portions of the datasets and found that the English set contains some Spanish tweets and *vice versa*: this is due to the fact that the tweets were collected automatically using geographical information associated with the account of the user who wrote the tweet. We decided to ignore this fact and assume that the actual test set will also contain some noise. We did not perform any systematic language identification experiment since after the manual inspection it seemed to us that this would not be a problem.

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19
USA	❤️	😄	😂	💖	🔥	😎	🌟	💙	😏	🇺🇸	🇺🇸	☀️	💜	😄	🎯	🎄	🇺🇸	🇺🇸	🇺🇸	🇺🇸
ESP	❤️	😄	😂	💖	😄	👉	👉	👉	🇺🇸	💙	💜	😄	💖	🌟	🎯	🎄	🇺🇸	🇺🇸	🇺🇸	🇺🇸

Figure 1: The label set for both English (USA) and Spanish (SPA).

The distribution of the labels is highly skewed for both English and Spanish: Figure 2 shows that the most frequent label (i.e. the red heart) is much more frequent than the others.

We decided to conduct experiments with both the original skewed dataset and a balanced version of it. To balance the dataset, we randomly sample from all classes a number of tweets which is equal to the size of the smallest class.

2.1 Normalization

We decided not to perform any sort of normalization on the dataset. The reason for this is that we think that the information that is located at the sub-token level would probably get lost with normalization (e.g. ‘amaaaazing’ vs ‘amazing’). Character-level differences can be important in helping deciding which emoji is the most appropriate one. For instance, we can imagine that someone who writes ‘amaaaazing’ is more prone to choose a more sophisticated and less common emoji (e.g. a purple heart), while someone who writes in a more sober style would probably pick only the most common emojis.

Furthermore, considering the domain (i.e. Twitter), it is very hard to properly normalize text.

3 Experiments

We performed two groups of experiments: for one group we used a shallow feature representation (i.e. bag-of-words), and for the other we used a dense feature representation (i.e. word embeddings). In the following sections we present these two groups of experiments.

3.1 General Experimental Set-up

In order to facilitate our work, we utilized Python 3.6.3 and set up a Python working environment using `pipenv` to make our experiments easily reproducible; for the same reason we are releasing several Jupyter notebooks containing all the code that we wrote². To train our models, we utilized the standard machine learning package, `scikit-learn` (Pedregosa et al., 2011) for the models using a shallow feature representation. The neural models were built using Keras (Chollet et al., 2015). We used OpenNMT (Klein et al., 2017) to model the problem as a translation problem.

3.2 Traditional BoW Modelling

For our first set of experiments, we chose two different algorithms for text classification and common bag-of-words features.

Algorithms For our algorithms, we worked with Naïve-Bayes and Support Vector Machines. We chose these algorithms in particular because of their success in previous work such as in Wang and Manning (2012).

Features For our features, we worked with the raw counts of each word as well as the tf-idf scores, and n-grams. We used tf-idf to give more weight to the more prominent words within the tweets, and less weight to the more common words, while we used n-grams to capture sequences of words.

3.2.1 Baseline

We established our baseline by using a bag-of-words approach and the Naïve-Bayes classifier with five-fold cross validation. We chose this as our baseline as we felt that this was the most simple — but still reasonably strong — approach.

3.2.2 Dimensionality Reduction

As a test, we also looked at the effects of dimensionality reduction using truncated singular value

²They can be found here at: <https://github.com/anbasile/emojiprediction>

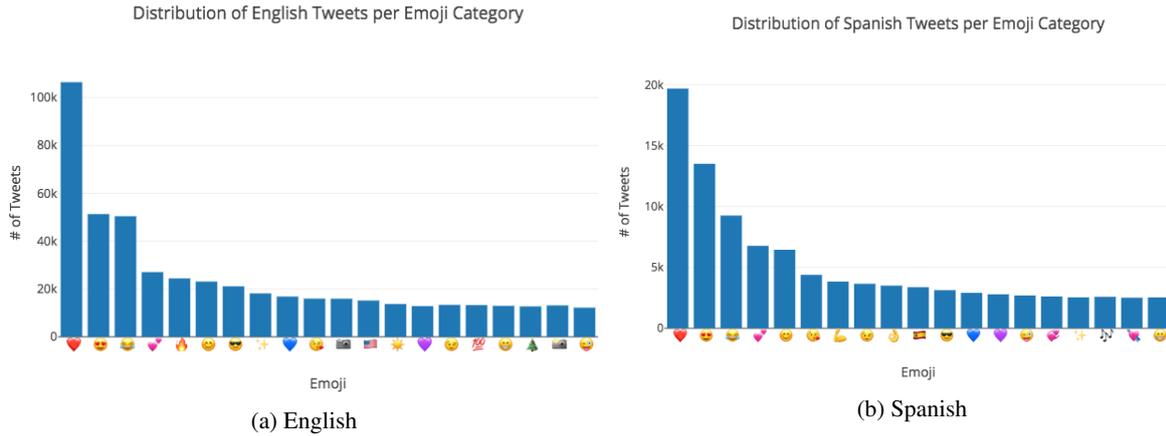

Figure 2: Distribution of emojis in the English and the Spanish datasets.

decomposition (SVD) (also referred to as latent semantic analysis (LSA) when used on textual data) on our best support vector machine model. This was only done with the support vector machine model as it was not possible to do it with the Naïve-Bayes classifier.

We hypothesized that SVD could potentially be useful as it would be able to model topics within the data. If we could model topics within the text, then it would be likely that certain topics would align with certain emojis.

To run the test, we used 10% of our data with dimensions of $n = 100$ and $n = 500$ on our best unbalanced model — the support vector machine model with tf-idf, bi-grams, and POS-tagging. We chose to only use 10% of the data as the runtime of utilizing SVD on the whole English dataset was particularly long.

3.3 Neural Models

In order to take advantage of the large dataset, we decided to try to model the problem using a neural network, which usually requires many instances to be trained properly.

We performed two sets of experiments: first, we trained a simple recurrent neural network. From there, we moved to a more complex recurrent network using bidirectional long short term memory (LSTM) layers in order to account for context from both the right and the left side of words; we then used an already optimized sequence-2-sequence model to model the problem as a translation problem and effectively treating emoji as a language.

The main advantage of using neural networks

for processing text is that the feature extraction process and the classification (or structured prediction process) can be optimized at the same time, possibly resulting in better performance.

Embeddings Word embeddings — one of the possible ways to extract feature from text — turned out to be very helpful in NLP and some of its properties (dense, high dimensional format) make it suitable to be used with neural networks. Baroni et al. (2014) have shown that word embeddings almost always perform better when compared to systems using the traditional bag-of-words approach.

To create the embeddings for our experiments, we used the Embedding layer provided in the Keras framework. This method does not make use of the most recent advancements in the field — as those described in Mikolov et al. (2013) — but it has the advantage of being fast and easily understandable.

3.3.1 Predicting Emojis with a Neural Classifier

Using Keras, we set up a network with the structure represented in Figure 3. One way to interpret this kind of modelling is to consider it as a list of matrices. The first layer is the embedding layer, where every node is a word, which is represented as an embedding; the 2 hidden layers are what makes the model able to discover eventual non-linear relationships; the last layer consists of a softmax function that gives in output a vector of probabilities: choosing the most probable class allows to get the most probable emoji.

By making the second hidden layer smaller in length than the external layers, the model implic-

itly performs a process of dimensionality reduction which allows it to eventually learn latent information (e.g. topic, style, etc.) present in the data.

Furthermore, following the work of Srivastava et al. (2014), we apply to our network a drop-out layer in order to avoid over-fitting and improve the capability of the network to generalize the results.

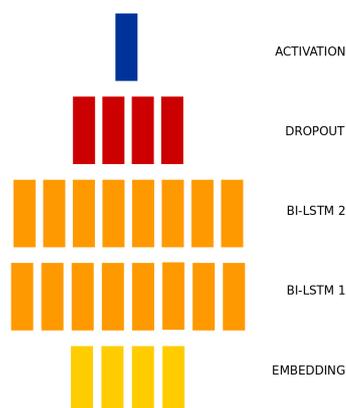

Figure 3: The structure of the neural network.

3.3.2 Seq2Seq Modelling

To some extent, we can say that emojis compress — or tend to compress — all the meaning of the English or Spanish texts that accompanies them. This suggests that the problem can be modelled as a translation problem, where the source language is either English or Spanish and the target language is the emoji language.

We use a state-of-the-art machine translation system and consider our emoji-annotated text as a parallel corpus, having English or Spanish as the source language, and the emojis as the target language.

We use the default network from the OpenNMT framework. This network consists of 2 LSTM layers with 500 hidden units each; furthermore, this implementation includes an attention layer that weights the importance of the different words in translating to the target language³.

We trained the same network for both English and Spanish — building one model for each language — and we got similar results, even though the English dataset is considerably larger than the

³We use the PyTorch implementation: see <https://github.com/OpenNMT/OpenNMT-py>

Spanish one. Surprisingly, the network learned for both languages that the syntax of the emoji language — so to say — specify that only one token can be used for each sentence.

4 Evaluation

4.1 Metrics

In order to quantify our results for the shallow representation models, we chose to use F-score as our main metric, as F-score is fairly standard and gives us a more unbiased view of the results.

With the dense representation and translation models, we utilized accuracy and perplexity as we could not extract precision and recall for these models for time constraints and technical issues. For the neural networks we did not perform cross-validation since it would have been too costly to perform; however, we use a development set during training and we tested on a blind test set when we finished training.

4.2 Results

Investigating the results of the experiments, we were able to confirm some of our linguistic intuitions.

First, it is evident that the best model for both the English and Spanish dataset based on macro F1 score was the most complex SVM model using tf-idf normalization, part-of-speech tagging and bi-grams. We see that POS-tagging added a substantial increase when comparing the SVM+tfidf model to the SVM + tfidf + 2grams model with an increase of 11% and 5% in the English and Spanish dataset respectively. This suggests that POS-tagging provides key information that helps the classifiers (at least SVMs).

However, dimensionality reduction — with $n = 100$ and $n = 500$ — did not prove to be as successful as we had hypothesized. Instead, we found that it had negative effects on the models as seen in Table 1. This is likely because we remove too much information that distinguishes the individual classes.

Table 1 and Table 2 describe the results for English and Spanish respectively. The models were trained and five-fold cross-validated with various configurations⁴. Models with * were with the bal-

⁴The naming of each model is built in the following way: classifier, feature extraction method, n-grams and potential extra features. The following are the acronyms of the configurations— NB: Naive-Bayes; SVM: Support Vector Ma-

anced dataset. The model submitted to the challenge has also been bolded for easy viewing.

Considering the neural models, we found out that the best model using an SVM and bag-of-words outperformed the more sophisticated neural classifier that we built. We believe that this is due to either the hyper-parameters not being optimized. Our networks (emoji-nn-dp) has a structure that is very similar to the one implemented in OpenNMT (except for the attention layer). About OpenNMT: since we got development results that are much higher than test results, we believe to have over-fitted the model. For the OpenNMT network we also report on perplexity since it is a machine translation system and that metric is reported by default. Table 3 highlights the results of the NN. The systems were tested on 100k tweets: we tested our network on the English dataset only because of time constraints. We managed to test the OpenNMT system on both English and Spanish⁵.

One of the most exciting things that we observed from our experiments was the impact of the skewed data on the models. In order to see what effect the skewedness had on the data, we tested the best unbalanced model by using a balanced dataset for both languages using the the number of tweets of the least frequent class.

This proved to be a huge success, as observed in the confusion matrix in Figure 4c. As we can see, there is a well-defined diagonal in the confusion matrix as compared to the best unbalanced model in Figure 4b, which shows that the balanced model is more capable of classifying tweets for *all* classes.

If we take a closer look at the matrix, we see that some categories are not retrieved at all. Of particular interest are the heart emojis, represented in categories 0, 3, 8 and 13 for the English dataset. In the best unbalanced model, categories 8 and 13 (blue heart and purple heart) are completely missing while these are actually retrieved by the balanced model. More interestingly, we see that there is a bit of confusion between these four hearts in the balanced model: we think that this is because the distribution of words that co-occur with all of the heart emojis overlap.

chines; tfidf: term-frequency inverse document frequency; POS: part-of-speech tagged data; 2grams: bi-grams; SVD: singular value decomposition.

⁵We are releasing both the OpenNMT systems and an hf5 version of our network with the model and the weights: this will make it easy to reproduce the results without having to train the network again.

In contrast, perhaps the most interesting observation in the balanced model is its success with certain categories. For example, if we take another closer look, we observe that the balanced model performs well at classifying tweets with the fire emoji, American flag, Christmas tree and camera emojis. This is likely due to the fact that these emojis, especially the American flag and the Christmas tree, have very predictable distributions. For example, the tweet ‘Things got a little festive at the office #christmas2016 @ RedRock...’ may be easy to classify because of the word ‘festive’ or because of the hashtag.

Table 3: The Result of Neural Network Models.

4.3 Test Results

All the previous discussion about the results is based solely on cross-validation (for the NB and SVM based models) and validation data (for the neural models). The results based on the test set show that we ended up over-fitting the neural models and that the high-scores obtained during validation do not hold for the test set: the model that looked like to be the best during validation (i.e.

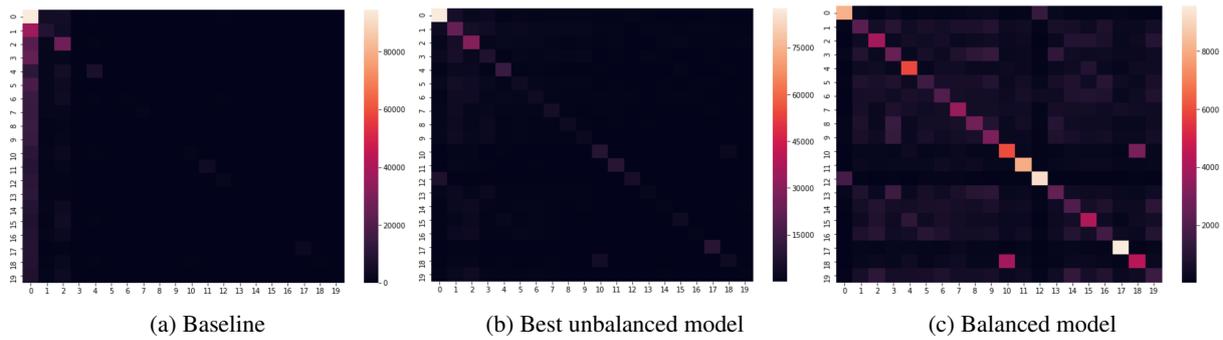

Figure 4: Confusion matrices of select English models.

OpenNMT-es, 71.02% accuracy) saw its performance dropping by over 50%. From investigation of the test set results, it seems that the loss in performance may also be due to the fact that the translation model is conflating the different variation of hearts with the more ‘plain’ red heart, as we observe this in the Spanish results.

5 Conclusions

To summarize, we performed several machine learning experiments on an automatically created corpus: we experimented with both traditional bow models and with recent neural models. We conclude that when optimized properly, the neural models can outperform linear classifiers; also, we have to note that training neural models requires a significant amount of computational power, which is not always available. When a big amount of data is available, neural networks usually tend to perform better than other models.

Due to time constraints, we did not perform a systematic optimization of the hyper-parameters of the models and instead we only tried some options that are known in the literature to work well (e.g. using a linear kernel for the SVM, since text data are usually linearly separable). Furthermore, we did not try using pre-trained embeddings with neither models: in the future we plan to use the Glove (Pennington et al., 2014) embeddings trained on Twitter. In particular, the next major experiment that we will try will be the following: modelling the problem as an image description problem. Considering the nature of the labels — emoji — it is easy to see that they cannot be treated as discrete indistinct labels, but instead they share many features that are easy to represent visually: as an example, we can clearly imagine that a camera with flash and no flash or a purple and a red heart are much more similar than, for instance, a

red heart and a smile. We had this idea during the last stage of conducting our experiments and for time reasons again we could not test this idea.

Acknowledgments

We are thankful to Amazon for providing us the AWS Educate Grant that allowed us to conduct all our experiments. Furthermore, this paper originates from an assignment for an exam at the University of Malta, where we are both enrolled as students. We are thankful to our supervisors J.P. Ebejer and Claudia Borg for their suggestions and feedback. We also would like to thank our reviewers for their detailed suggestions.

As an aside, we really wanted to find a name for our system that would link our experiences in Malta to this project and landed on *tajjeb*. *Tajjeb* is Maltese for ‘good’, which we think accurately depicts our work here. If you’ve noticed, ‘prediction’ begins with a ‘P’ and not a ‘B’, but we chose it as it was the most appropriate word for the acronym and because Maltese has word-final obstruent devoicing (thus reflecting how it actually sounds!)

Abstract

In this paper, we present *SyntNN* as a way to include traditional syntactic models in multilayer neural networks used in the task of Semeval Task 2 of emoji prediction (Barbieri et al., 2018). The model builds on the distributed tree embedder also known as distributed tree kernel (Zanzotto and Dell’Arciprete, 2012). Initial results are extremely encouraging but additional analysis is needed to overcome the problem of overfitting.

1 Introduction

Syntactic models of language have always played a crucial role in many natural language processing tasks but, in recent years, it has been marginalized by the advent of neural networks and in particular long-short term memory (LSTM). These latter networks have had a tremendous impact on how linguistic tasks are modeled and, sometimes, solved.

In this paper, we want to explore the use of “traditional” syntactic information within a neural network framework in the task of Semeval Task 2 of emoji prediction (Barbieri et al., 2018, 2017). We propose *SyntNN* as a way to include traditional syntactic models in multilayer neural networks. The model builds on the distributed tree embedder also known as distributed tree kernel (Zanzotto and Dell’Arciprete, 2012; Ferrone and Zanzotto, 2014; Zanzotto et al., 2015) that is a way to transpose syntactic information in small vectors. Initial results are extremely encouraging: *SyntNN* outperforms syntax-unaware neural networks on the trial set. Unfortunately, these promising results are not confirmed on the test set. Hence, we analyzed these results to try to understand why this has happened.

2 SyntNN: a Syntax-aware Multilayer Perceptron

SyntNN is a simple, non-recurrent neural network that aims to exploit traditional syntactic interpretations of tweets in classification tasks. This network wants to explore two questions: first, investigating whether “traditional” syntactic interpretation can be used within neural networks and, second, understanding if syntactic information is useful in modeling tweets for the specific task of emoji prediction.

The architecture of *SyntNN* is then organized around two sub-networks (see Fig. 1): (1) a syntactic sub-network and (2) a semantic sub-network. These two sub-networks are then merged to obtain the final classification layer.

The rest of the section describes the two sub-networks and the merging layer.

2.1 Syntactic Subnetwork with a Distributed Tree Embedding Layer

The syntactic subnetwork aims to take syntactic interpretations of tweets and make them available to a simple, non-recurrent neural network. The key point is how to obtain the transformation of the symbolic representation of syntactic trees into tensor-based representations that have meaningful properties.

The *Distributed Tree Embedding Layer* (DTE) (see Fig. 1) is the core component of the syntactic subnetwork. DTE is based on a technique to embed the structural information of syntactic tree into dense, low-dimensional vectors of real numbers (Zanzotto and Dell’Arciprete, 2012; Ferrone and Zanzotto, 2014; Zanzotto et al., 2015). This technique has been originated as a way to replace syntactic kernel functions (Collins and Duffy, 2002) in kernel machines (Cristianini and Shawe-Taylor, 2000) but it can be seen as a principled way to

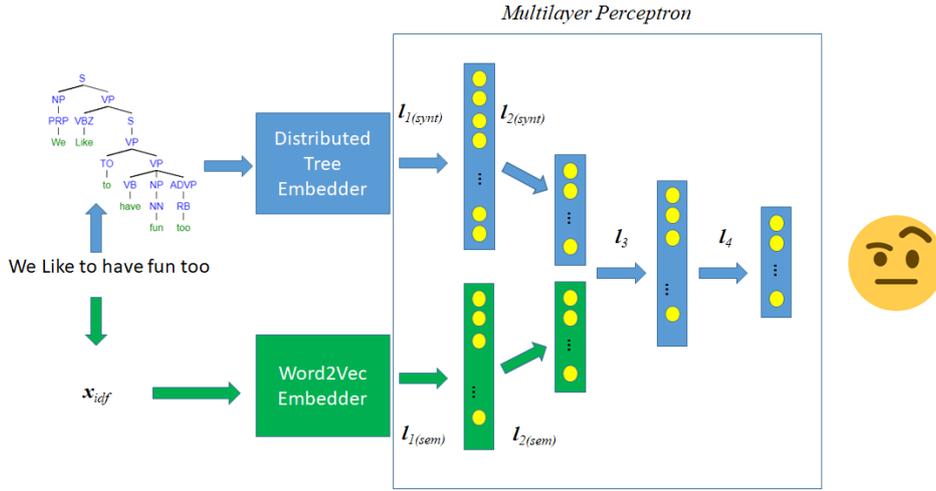

Figure 1: MultiLayer Perceptron Architecture for Syntactic and Semantic Representation of Tweets.

insert syntactic information into vectors. In this technique, trees are transformed into *distributed trees* that are low dimensional vectors. These distributed trees build on the recently revitalized research in Distributed Representations (DR) (Hinton et al., 1986; Plate, 1994; Bengio, 2009; Collobert et al., 2011; Socher et al., 2011).

DTE is a layer that maps trees into low-dimensional vectors in a space \mathbb{R}^d . This space is a low dimensional space that embeds the space representing trees according to their subtrees. DTE is then represented as the following embedding layer:

$$\mathbf{y} = W^{(DTE)}S(T) \quad (1)$$

where $S(T) = \mathbf{t}$ is a onehot layer that maps trees to vectors in the space of subtrees \mathbb{R}^n and $W^{(DTE)}$ is a transformation matrix that embeds the huge space of subtrees \mathbb{R}^n in a smaller space \mathbb{R}^d .

DTE is based on the Johnson-Lindenstrauss Transform (JLT) (Johnson and Lindenstrauss, 1984; Dasgupta and Gupta, 1999) and it is not learned. Using JLT, the layer DTE maps vectors representing trees in the space of subtrees in vectors in a reduced space where similarity is approximately preserved, that is, given two syntactic trees T_1 and T_2 and given a ϵ , it is possible to find a \mathbf{W} for which, if \mathbb{R}^d has a specific relation with \mathbb{R}^n (see (Dasgupta and Gupta, 1999)), this property holds:

$$|\mathbf{t}_1 - \mathbf{t}_2| - \epsilon < |\mathbf{W}\mathbf{t}_1 - \mathbf{W}\mathbf{t}_2| < |\mathbf{t}_1 - \mathbf{t}_2| + \epsilon \quad (2)$$

where $\mathbf{t}_1 = S(T_1)$ and $\mathbf{t}_2 = S(T_2)$. Hence, the space \mathbb{R}^d embeds the space \mathbb{R}^n of the subtrees.

However, directly producing a DTE with JLT is unfeasible as the space of subtrees \mathbb{R}^n is huge and intractable.

Our solution is using the recursive model for computing distributed trees (Zanzotto and Dell’Arciprete, 2012; Zanzotto et al., 2015), which empirically guarantees the property in Equation 2. This model is a mapping function that encodes trees in vectors by assigning random vectors to node labels and by recursively computing vectors for subtrees by composing vectors for nodes. The mapping function has a linear complexity with respect to the size of the tree.

After the DTE, the syntactic subnetwork has two dense layers with ReLU activation functions. These dense layers should select subtrees that are relevant for the final task of emoji prediction.

As it is designed, the syntactic subnetwork should take into consideration the syntactic information of tweets and it should be a valuable model to experiment with syntactic information on the task of emoji prediction.

2.2 Semantic Subnetwork with a (Bag-of-)Word Embedding Layer

The semantic subnetwork is composed by a classic multilayer perceptron (MLP) network that takes as input tweets represented as \mathbf{x}_{idf} . These vectors represent tweets in the following way. Each dimension represents a word w and, if a tweet contains the word w , the dimension has the inverse document frequency (idf) value of the word w , otherwise it has a 0. Hence, the first layer of the semantic subnetwork is a word embedding layer

working in the following way:

$$y = E\mathbf{x}_{idf} \quad (3)$$

where E is a word embedding matrix. As word embeddings, we used the Stanford’s Glove (twitter 27B, 200d) for the English task and the word embedding used in the paper *How Cosmopolitan Are Emojis?*(Barbieri et al., 2016)¹ for the Spanish task.

2.3 Merging Syntactic and Semantic Subnetworks

The merging layer of the syntactic and semantic subnetworks is composed by a concatenate layer that concatenate the syntactic vector with the semantic vector among the features axis. Then, a batch normalization layer performs the operation of batch normalization (Ioffe and Szegedy, 2015). At the end a 20 units layer compute the emoji’s probability through a softmax layer.

3 Experiments and Evaluation

3.1 Experimental Setting

To ensure replicability, this section fully describes the implementation details of *SyntNN* (Fig. 1) and the values of its metaparameters. Moreover, it introduces the networks used for comparison and the datasets used on the experiments.

For the *Syntactic Subnetwork* of SyntNN, we used the Python implementation of the Distributed Tree Encoder². Tweets’ parse trees are obtained by using Stanford’s CoreNLP³ probabilistic context free grammar parser. Distributed trees are represented in a space \mathbb{R}^d with $d = 4000$. Then, the layer $l_{1(synt)}$ is composed of 5512 units. The layer $l_{2(synt)}$ is a cascade of two dense layers composed, respectively, of 2018 units and 1024 units. All these tree layers have dropout 0.5 and a ReLU activation function.

For the *Semantic Subnetwork* of SyntNN, we used pretrained word embeddings as Stanford’s Glove⁴ and the word embeddings given by the organizers of the task (Barbieri et al., 2016)⁵. The rest of the semantic subnetwork is the following. The first layer, the *input layer I*, is composed by

200/300 neurons. Each neuron take in input a dimension of the BoW vector. The number of input neuron varies according to the word embedding used: 200 if the word embedding used is Glove; 300 if the word embedding used in the other word embedding cited in the word embedding section. The second layer $l_{1(sem)}$ consists of 512 neurons, dropout 0.5 and ReLU activation function. The third layer $l_{2(sem)}$ consists of 1024 neurons, dropout 0.5 and ReLU activation function.

To understand whether SyntNN positively uses syntactic information, we compared our system with two neural networks trained in comparable conditions: (1) BOW-MLP and (2) BiLSTM. BOW-MLP is basically the Semantic Subnetwork of SyntNN without the Syntactic Subnetwork. BiLSTM is a bidirectional LSTM (Huang et al., 2015), which has been proven effective in many natural language processing tasks. For the BiLSTM, we used the same embedding layer used in SyntNN, we used a recurrent layer of 100 Bidirectional Long Short Term Memory (LSTM) neurons with activation function tanh, recurrent activation function hard sigmoid, recurrent dropout and dropout probability 0.5 and weight l2 regularizer with $\lambda = 0.01$. The output layer is composed by 20 neurons and activation function softmax.

All models are implemented using Keras library (Chollet et al., 2015) and run on tensorflow (Abadi et al., 2015) back-end on different cuda GPUs. Models are trained with Adam(Kingma and Ba, 2014) gradient descent algorithm with $lr = 0.0001, \beta_1 = 0.9, \beta_2 = 0.999$. The loss function used is the categorical crossentropy function. The BOW-MLP model and SyntNN model are trained for 140 epochs and batch size = 50, while the BiLSTM model is trained for 18 epochs and batch size = 50.

We performed our tests on the emoji prediction dataset and we used the Macro F1 Score evaluator provided by the organizers (Barbieri et al., 2018). No additional datasets have been used.

3.2 Results and Analysis

Initial experiments (Table 1), performed using the trial dataset as testing set, are extremely positive with respect to our research question: syntactic information is definitely important for both languages and SyntNN seems to be the good way to represent syntactic relations among words. In

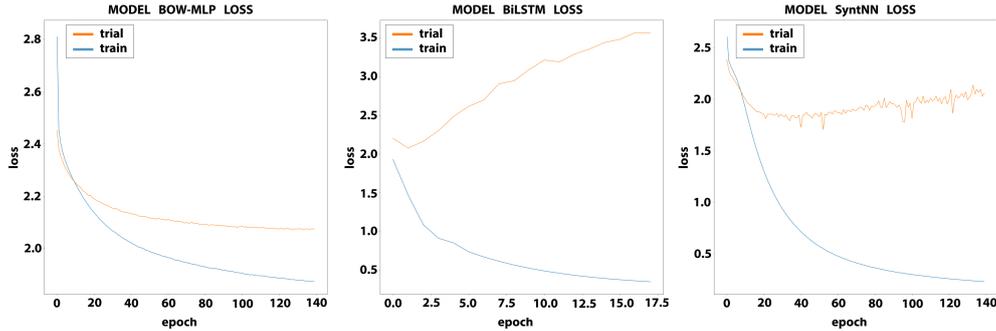

Figure 2: Loss comparison on English datasets.

<i>Dataset</i>	<i>BOW-MLP</i>	<i>BiLSTM</i>	<i>SyntNN</i>
en	30.832	47.535	61.777
es	74.077	72.875	80.474

Table 1: Macro F1 score on the Trial Set.

<i>Dataset</i>	<i>BOW-MLP</i>	<i>BiLSTM</i>	<i>SyntNN</i>
en	16.298	25.877	18.385
es	15.427	15.008	14.99

Table 2: Macro F1 score on the Test Set.

fact, SyntNN largely outperformed BOW-MLP in both languages: 61.777 vs. 30.832 for the English dataset (en) and 80.474 vs. 74.077 for the Spanish dataset (es). Moreover syntactic information captured by SyntNN seems to be totally different and more effective than the structural information exploited by recurrent neural networks as BiLSTMs. SyntNN has different results with respect to BiLSTM on both datasets with SyntNN outperforming BiLSTM (61.777 vs. 47.535 for *en* and 80.474 vs. 72.875 for *es*). These results seem to show that syntactic information is useful and distributed tree embedders are a possible, effective way to take into consideration syntactic information in multi-layer perceptrons.

Surprisingly, results on the official test set did not confirm results on the trial set (Table 2). The first observation is that Macro F1 scores on the test set are definitely lower of the results obtained with different models on the trial set. Moreover, the relative rank among the models is not fully respected. In fact, SyntNN outperforms BOW-MLP only for the *en* dataset but it is definitely worse than BiLSTM. Whereas, models are performing similarly for the *es* dataset. The question is: *Why? What happened?*

<i>Dataset</i>	<i>Test</i>	<i>Trial</i>
en	44.10%	19.81%
es	40.67%	7.21%

Table 3: Out-of-vocabulary words in the different datasets.

We then tried to analyze where the poor results on the test set came from. The first observation is that unknown words in the test set (Table 3) are larger than for the trial set for both datasets. The unknown words on the test set is more than double with respect to the unknown words in the trial for the English dataset and more than 4 times for the Spanish dataset. Test is definitely farer than trial with respect to the training set. This seems to be the first reason why results are poorer on the test set. The second observation is on the degree of overfitting. In fact, this seems to to be the major problem of SyntNN and of the other two models (see Fig. 2). By looking at the loss function, three models largely overfit with respect to the epochs: the loss functions on the train set and on the trial set diverge. This can partially explain poor results.

However, to have a more in-dept analysis we need to know what and how these networks are modelling symbols in general and syntactic information in particular.

4 Conclusions

In this paper we presented a way to include traditional syntactic information in neural networks and we experimented with this model within the emoji prediction task. Although results on the test set does not confirm results on the trial set, this approach is promising as it opens to an higher explainability of decisions of the neural network (Zanzotto and Ferrone, 2017).

Abstract

This paper describes the Duluth UROP systems that participated in SemEval-2018 Task 2, Multilingual Emoji Prediction. We relied on a variety of ensembles made up of classifiers using Naive Bayes, Logistic Regression, and Random Forests. We used unigram and bigram features and tried to offset the skewness of the data through the use of oversampling. Our task evaluation results place us 19th of 48 systems in the English evaluation, and 5th of 21 in the Spanish. After the evaluation we realized that some simple changes to pre-processing could significantly improve our results. After making these changes we attained results that would have placed us sixth in the English evaluation, and second in the Spanish.

1 Introduction

Emoji prediction of tweets is an emerging problem (Barbieri et al., 2017) which combines the nuances of sentiment analysis with the noisy data characteristic of social media. SemEval-2018 Task 2 (Barbieri et al., 2018) adds to this the challenge of multilingual processing, where both Spanish and English tweets are used.

Given the relatively large amount of training data available for the task (see Section 2) we decided to approach this as a classification task, where we used relatively simple unigram and bigram features in combination with standard machine learning algorithms. We particularly focused on the use of Multinomial Naive Bayes, Logistic Regression, and Random Forests, all of which were provided to us via the scikit learn package (Pedregosa et al., 2011). Given the challenging nature of this task we decided to employ a variety of ensemble approaches, since no single classifier seemed likely to perform well in all cases.

In the sections that follow we summarize the experimental data used in the task, and then describe the methods we employed for supervised learning, ensemble building, and oversampling. We close by interpreting and discussing our results.

2 Experimental Data

The task organizers created both training and test data made up of Spanish and English tweets (separately). The training data consists of 100,000 Spanish tweets and 500,000 English tweets. The test data is made up of 10,000 Spanish tweets and 50,000 English tweets. Each instance consists of a single tweet, where 19 different emojis were observed in the Spanish data, and 20 emojis were observed in the English.

We collected the training tweets via the Twitter API on November 10–11, 2017. By that time some of the tweets selected by the organizers had been deleted or made private, but we were still able to download the vast majority of training tweets. For English we downloaded 490,272 tweets, so 9,628 were unavailable. For Spanish we obtained 98,657 tweets, so 1,343 were unavailable.

One of the most striking aspects of this data for both English and Spanish is that the number of classes (emojis) is relatively large (20 and 19 respectively), and that the distribution of these classes is skewed. In the English training data the most common emoji is ❤️ which occurs 21.7% of the time. The next most frequent emoji is 😊 which occurs 10.5% of the time. The two emojis were also the most frequent in the Spanish data, occurring 19.9% and 13.7% of the time. By contrast 16 of the emojis occurred less than 5% of the time in English, and 14 occurred less than 5% in the Spanish.

The evaluation measure used to rank systems in this task is the F-measure, which rewards systems

that are able to predict instances in the low frequency classes correctly. Given that we decided to employ oversampling in order to try to improve our results on the low frequency classes which had the negative effect of degrading our performance on the more frequent classes.

3 System Description

3.1 Preprocessing

First, the text is normalized to lowercase. In preliminary experiments, we find that removing all punctuations reduces performance, thus we decided to only remove commas. In our task evaluation experiments we removed all non-ASCII characters, but then post-evaluation decided to keep most of them. Then, we tokenize the tweets with NLTK word tokenizer and identify unigrams and bigrams as potential features. To reduce noise, a document frequency cutoff of 5 is applied to sift out unigram and bigram features that occur in at least five tweets.

When applied to the English data, this process results in 166,681 features, including 35,197 unigrams and 131,484 bigrams. The Spanish data is made up of 40,420 features, including 12,356 unigrams and 28,061 bigrams. For text representation, we adopt the bag-of-words model. Each tweet is converted to a vector based on n-grams by Count Vectorizer.

3.2 Oversampling

Faced with the skewness of both the English and Spanish tweets, we introduce oversampling to adjust the class distribution to reduce bias. We use Synthetic Minority Oversampling Technique (SMOTE), where the minority classes are oversampled by creating synthetic examples using k nearest neighbors. We use imblearn in scikit-learn library for oversampling.

In our case, all classes are resampled to have equal number with the majority class ❤️. As a result, the resampled Spanish data has a size of 373,825, with class size of 19,675, and English has a size of 2,130,180, with class size of 106,509.

3.3 Base Classifier

We use scikit-learn library for the base classifiers and the first-level ensemble classifier below. And the second-level ensemble is constructed with mlxtend library, which is compatible with scikit-learn.

3.3.1 Multinomial Naive Bayes (MNB):

MNB is a probabilistic classifier based on integer feature counts. It is simple yet powerful for text classification, especially for short documents (Wang and Manning, 2012). To eliminate zero counts, we use additive smoothing with a parameter value of 0.5.

3.3.2 Logistic Regression (LR):

While NB assumes strong conditional independence, LR is more robust to correlated features. We use a LR with L2 regularization to reduce overfitting. It uses the one-vs-rest (OvR) scheme for multiclass classification.

3.3.3 Random Forest (RF):

As an enhancement of decision tree, we use the RF classifier, which ensembles a multitude of decision trees. By fitting on sub-samples of the dataset, RF improves accuracy and reduces overfitting by averaging. We use 20 trees here.

3.4 Ensemble Classifier

We build an ensemble classifier to combine the strengths of a collection of base models. The ensemble method is soft voting, where the calibrated member classifiers cast weighted votes for classes based on predicted probabilities. The ensemble is also a calibrated classifier, who can either predict associated probabilities based on weighted sum, or a class with maximum probability.

$$P(c_j) = \sum_{i \in ensemble} w_i P_i(c_j) \quad (1)$$

$$c = \operatorname{argmax}_{c_j} P(c_j) \quad (2)$$

Our ensemble has two levels. On the base level, we include a diverse collection of heterogeneous classifiers: MNB, LR, RF, with weights (1.1,1,1) for Spanish and (1.5,6,1) for English.

On the second level, we train the base ensemble respectively on the original task data (Ensemble1) and oversampled data (Ensemble2). On the one hand, oversampling can adjust class distribution so that rare classes are well represented. On the other hand, it may exacerbate overfitting problem in the context of noisy data, and consequently harms accuracy. To seek a balance, we devise a meta-ensemble classifier (Meta) including both Ensemble1 and Ensemble2, with weights (3,1) for Spanish and (4,1) for English.

Method	F1	P	R	Acc.
Ensemble1	26.37	28.10	27.41	34.43
Meta	26.59	27.18	27.87	33.80

Table 1: English Task Evaluation Results

Method	F1	P	R	Acc.
Ensemble1	16.59	18.03	17.84	29.67
Meta	16.75	17.11	18.10	28.51

Table 2: Spanish Task Evaluation Results

The weights for the ensembles were set in a non-systematic fashion via trial and error. In future work, we would like to arrive at these weights in a more rigorous fashion.

3.5 Evaluation Metric

For individual classes, F_1 score is calculated as:

$$F = \frac{2Precision \cdot Recall}{Precision + Recall}$$

The overall classification performance of the system is measured by macro-averaged F_1 score:

$$F_{macro} = \frac{1}{k} \sum_{i=1}^k F_i$$

where k is total number of classes.

4 Results and Discussion

4.1 Task Evaluation

For task evaluation, our two submitted systems are: Ensemble1 and Meta. The official results are shown for English in Table 1 and Spanish in Table 2. Our overall F-score was competitive in both the English (19th of 48) and Spanish tasks (5th of 21).

4.2 Post Evaluation

In post-evaluation experiments, we revised the preprocessing by including most non-ASCII characters and modified the weights assigned for ensembles. As a result, the system performance improved greatly, which was largely attributed to the changes in preprocessing.

The system was trained on the whole training data, and tested with the official test data. We show post-evaluation results for English in Table 3 and for Spanish in Table 4. The confusion matrices of Meta classifier are shown in Figure 1 and Figure 2.

Method	F1	P	R	Acc.
MNB-P	30.21	30.78	31.58	42.22
LR-P	32.73	35.05	32.08	44.79
RF-P	24.49	30.13	24.41	39.01
Ensemble1-P	33.03	34.68	33.09	45.68
Ensemble2-P	31.85	31.38	33.14	42.08
Meta-P	33.31	34.14	33.61	45.58

Table 3: English Post-Evaluation Results

Method	F1	P	R	Acc.
MNB-P	19.26	19.92	20.51	35.07
LR-P	18.43	20.98	18.28	35.23
RF-P	13.41	19.47	13.78	32.68
Ensemble1-P	19.58	21.13	20.51	37.05
Ensemble2-P	20.34	20.44	21.55	33.64
Meta-P	20.21	21.23	21.12	36.74

Table 4: Spanish Post-Evaluation Results

In the task evaluation we eliminated all non-ASCII characters during preprocessing. After the evaluation period we realized that this resulted in a significant loss of accuracy. We revised our preprocessing for our post-evaluation experiments and only removed the following non-ASCII characters (shown as Unicode value, description): (U+00B7, middle dot), (U+2019, right single quotation mark), (U+2018, left single quotation mark), (U+2022, bullet), (U+2026, horizontal ellipsis), and (U+30FB, katakana middle dot).

Preserving non-ASCIIs is important for both languages. Spanish using MNB has a F-score of 16.77 without non-ASCII and 19.08 when preserving all, and English has 25.47 without non-ASCII and 30.00 when including. While their importance for Spanish is apparent as accents are ubiquitous in Latin languages, their function for English is relatively vague. Nevertheless, they are clearly providing useful information in the tweets.

4.3 Discussion

In this section, we will discuss the results based on post-evaluation.

Ideally, we would hope an ensemble would outperform all of its components. Its performance counts on the accuracy and diversity of the members. While NB and LR are linear classifiers, RF is nonlinear. Also, the actual performance is sensitive to the assigned voting weights. Initially, we get a rough estimation based on individual per-

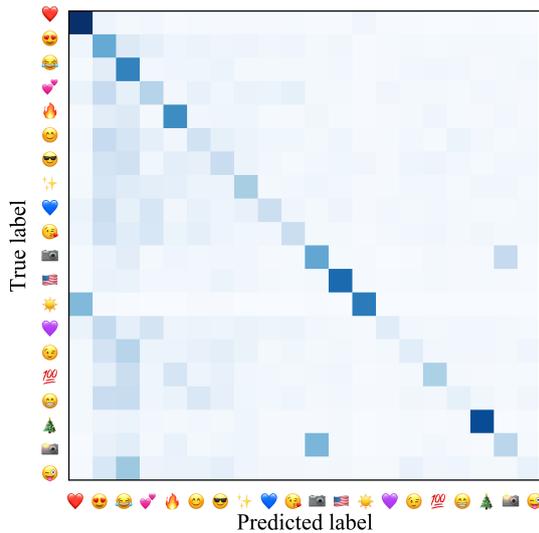

Figure 1: English Meta Confusion Matrix

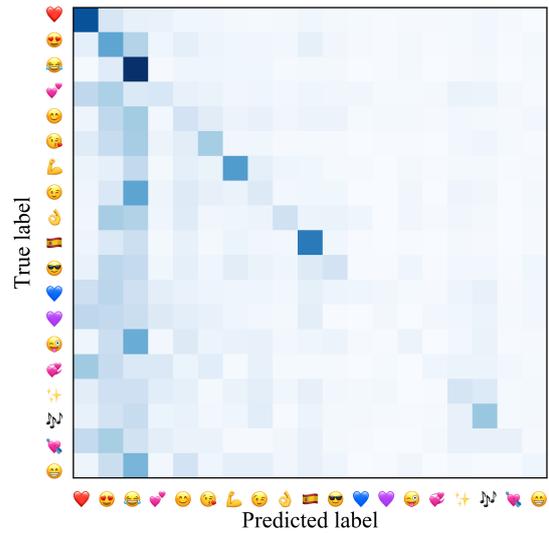

Figure 2: Spanish Meta Confusion Matrix

formances, especially accuracy. For both English and Spanish, RF has a notable inferior score, so lower weight is expected. Then we manually perform experiments to find better weights. Due to the large size of data, it is computationally expensive to perform grid search. In the future, we would like to investigate if other automated methods could find optimal hyper-parameters more efficiently.

By fitting the ensemble with oversampled data, the overall accuracy drops. However, the rare classes originally with low F-scores gain an increase. This is desirable as we attempt to maximize the overall classification performance for all classes, which is measured by macro-averaged F. In considering the weights in Meta, we perceive Ensemble1 a more reliable source as it shows notably higher accuracy. Meta tends to outperform Ensemble1 in F-score.

It is worth mentioning that the baseline classifiers like MNB and LR have robust performance compared to other more complex systems. This suggest that improvement from ensembles may be limited for this challenging problem, and new perspectives are necessary.

Additionally, there are some interesting observations from the confusion matrices. For English tweets, 🌞 is frequently misclassified as ❤️. And there is apparent confusion between 📷 and 📱. For Spanish tweets, 😊 has highest accuracy. Meanwhile, many other emojis are misclassified to this label, typical ones including 😊, 😊, and 😊.

Abstract

Emoji is one of the "fastest growing language" in pop-culture, especially in social media and it is very unlikely for its usage to decrease. These are generally used to bring an extra level of meaning to the texts, posted on social media platforms. Providing such an added info, gives more insights to the plain text, arising to hidden interpretation within the text. This paper explains our analysis on Task 2, "Multilingual Emoji Prediction" sharedtask conducted by Semeval-2018. In the task, a predicted emoji based on a piece of Twitter text are labelled under 20 different classes (most commonly used emojis) where these classes are learnt and further predicted are made for unseen Twitter text. In this work, we have experimented and analysed emojis predicted based on Twitter text, as a classification problem where the entailing emoji is considered as a label for every individual text data. We have implemented this using distributed representation of text through fastText. Also, we have made an effort to demonstrate how fastText framework can be useful in case of emoji prediction. This task is divided into two subtasks, they are based on dataset presented in two different languages English and Spanish.

1 Introduction

The consumption of technology in industry delivers potential tools for communication. Messaging has turned into a critical method of communication all through the world and is expanding at a quick rate. Adding emoji in the text convey little more information about the person's emotion, which otherwise is absent in the normal text. Emotions contents of text is better expressed by usage of emojis. Emojis are fundamentally kind of image which are logically connected with the written text. Tweets and online social media platforms are investigated to assess the emotion depth of the

several issues for sentiment analysis and Opinion mining in natural language platform. In recent times, the interest in these area received is very much increased and made several classifications which are polarity based classification such as positive, negative and neutral. In case of emojis certain remarkable studies on emoji semantic and usage find out in papers (Aoki and Uchida, 2011) Relevant study into emoji (Barbieri et al., 2018) are limited in number. The common exploration about emoji has inspired (Barbieri et al., 2017) on descriptive analysis or used them as a indication the emotional affect (Rathan et al., 2017) on social media. That is too restricted in face emojis.

2 Corpus

The shared task (Barbieri et al., 2018) provided 20 most commonly used emojis in tweets English as well as Spanish. That are distinct in nature for English and Spanish corpus (Barbieri et al., 2016). For the simplicity the corresponding emojis are labelled from 0 to 19. The data given for the task is 500k tweet ids for Spanish and 1000k tweet ids for English. Using the tweet ids, tweets are crawled from twitter using 4 different accounts. The crawled data was in JSON format, the raw data from twitter is preprocessed and the labelled data is converted into format suitable for the learning algorithm. For tuning the hyperparameters of the model 20% from the training data set is made into validation set and only the rest 80% is used for the training the model.

3 Related Works

Any mathematical system or an algorithm need some form of numeric representation to work with. One of most naive way of representing word in vector form is one hot representation but it is very ineffective way for representing words in a

large corpus since the length of one hot vector grows as the vocabulary increases, so we need a better and more effective way which captures some semantic similarities (Ganesh et al., 2016) between nearby words, thus creating the representation for words bring beneficial info about the word and its actual meaning, the methods which encodes these information about the words are called word embedding models, they are categorized into count based and predictive word embedding models. Both embedding models at least some way share syntactic meaning (Soman et al., 2016). But count based word embedding models does not preserve the word order and learn about word semantics

Predictive models attempts to calculate the word vector which captures the both syntactic and semantic meaning (Ganesh H. B. et al., 2016) of the word. This is done by calculating the softmax of the word over the context window. The word embeddings provided by the predictive model not only gives a representation for words but it is also able to learn word similarities and interesting word analogies like "king"- "man" + "woman" = "queen". The wor2vec and glove models are the popular predictive models used to learn the word embeddings in many NLP pipelines. The disadvantage of above predictive models are they does not form a sentence representation and morphology of the words is not considered. These shortcomings are overcome the FastText framework which is a recent development in predictive model. (Bojanowski et al., 2016) presented the fastText embeddings, which is development on the word2vec model. Since FastText is considering the char n-gram of the words it learns a good representation for words when compared to word2vec embeddings.

4 Methodology

This work explores the FastText Framework for text classification. It is a fast and lightweight implementation written in C++ to learn word embedding. FastText is a unified framework for text representation and text classification.

Generally text classification is done to categories the class of sentences or documents for task such as sentiment analysis, spam detection etc. In these tasks vector representation is assigned either to the words, sentences or documents depending upon the task. There are various methods for get-

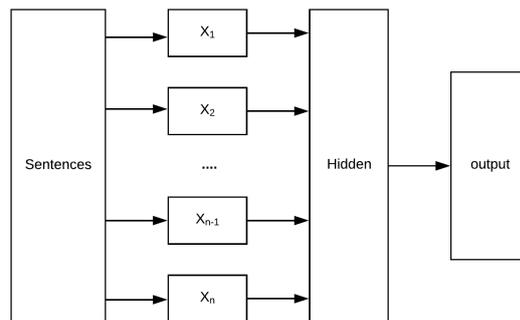

Figure 1: FastText architecture for emoji and classification.

ting the vector representation. In this work using distributed representation, the word embedding is assigned to the words in the vocabulary over the corpora. In FastText framework for doing text classification it extends the concept of Continuous Bag Of Words (CBOW) model introduced word2vec model. Since fastText is improvised version of word2vec model so to get a good understanding the full word2vec

The word2vec model by proposed by (Mikolov et al., 2013) is shallow neural network architecture, where word embedding is learnt in an unsupervised fashion. It was proposed in the paper Distributed Representations of Words and Phrases and their Compositionality. This paper proposed two architectures for learning the word embeddings, they are continuous bag of words (CBOW) and skip-gram. In the continuous bag of words architecture given the surrounding words, the centre word is predicted, while in the skip gram model given the center word, the context word is predicted.

In a CBOW architecture, as in the figure 1. Let us consider this example sentence we built a sandcastle in the beach in this sentence every word is predicted by taking the surrounding words in the window as the input and softmax is applied over the output to predict the corresponding word (Porria et al., 2016). To reduce the computational complexity of the softmax with large vocabulary, two techniques namely negative sub sampling and hierarchical softmax are applied.

In FastText, for text classification CBOW architecture of Word2vec is slightly modified to form a representation of sentences or document. In Bag of words (BOW), instead of predicting the center word given the context words, the center

word is flipped with the label which it is associated to. Then the softmax is applied over the pre-defined class. For N set of classes the negative log-likelihood is given by

$$-\frac{1}{N} \sum_{n=1}^N y_n \log(\int (BAx_n))$$

where y are the labels and x is the normalized bag of words feature. B and A are the weight matrix from the hidden layer. The BOW does not take the word order into consideration, which otherwise may increase the computation complexity of the model. The word2vec does not predict the word which it has not seen in the training time, to overcome this char N-gram is done within the word and it is given (Brown et al., 1992) to model during training along with word to overcome the unknown words at the test time. The model is trained with a decaying learning rate using stochastic gradient decent. The hierarchical softmax can come in very handy if the no of classes is very large, it basically works like a binary search tree, all the classes are arranged using the Huffmans encoding. By selecting the element in the tree, the search space for the class get reduced into half at each node, this brings the computation complexity in the order of log.

5 Result

Hyperparameter	English corpus	Spanish corpus
learning rate	0.1	0.1
dimension	200	100
window size	3	4
word n-gram	1	1
loss	softmax	softmax
neg	10	10

Table 1: Hyper parameters for english and spanish.

In this work, a classifier based on fast text framework is applied on the Sem-Eval 2018 task 2 emoji detection data set, the classifier is trained to predict the emoji on the English emoji corpus and Spanish corpus. Our team got placed in the 21th position in the English corpus and 13th position on the Spanish corpus. To make our model perform better we evaluated the classifiers hyper-parameter with various values and found the following hyper-parameter values to best performing on the English and the Spanish emoji corpus.

6 Conclusion and Future Scope

Every year we see a no of new words being added to the dictionary, most of these new words are the result of new culture trends, the same is applicable with the emojis, which expresses them visually and it is important for us to study its occurrence along with text in social media to better understand the sense of the message. A classifier trained on predicting the emoji from text is significant for understanding the interaction of emoji with the text. In this work a emoji is predicted for the sentences in English and Spanish using fast-Text framework which is known for being computationally efficient and the learned word represen-

tation is on par word representation learned from the standard models like Word2vec.

In this work, a single emoji is predicted for the sentence and since people usually people tend to use more the one emoji in tweets, comments and posts, so we can also extend this problem to a multi-label classification problem.

Abstract

We present our submission to the Semeval 2018 task on emoji prediction. We used a random forest, with an ensemble of bag-of-words, sentiment and psycholinguistic features. Although we performed well on the trial dataset (attaining a macro f-score of 63.185 for English and 81.381 for Spanish), our approach did not perform as well on the test data. We describe our features and classification protocol, as well as initial experiments, concluding with a discussion of the discrepancy between our trial and test results.

1 Introduction

Written digital communication is increasingly pervaded by the use of emoji. Classic NLP systems are not well geared to handle them. Linguists are still working out how to treat them (Stark and Crawford, 2015; Danesi, 2016). Even their users may disagree on meaning (Tigwell and Flatla, 2016; Miller et al., 2016). A simple approach could be to ignore all emoji and concentrate on the words of a text, however this approach may miss valuable meaning that can be obtained by treating the emoji as semantic units.

The emoji prediction task (Barbieri et al., 2018, 2017), encourages research into the creation of text classification systems which can identify which emoji was present in a tweet. This could lead to automated suggestion systems for emoji, as well as improving the NLP communities understanding of how to deal with emoji computationally.

2 Data Acquisition + Preprocessing

The dataset was compiled between October 2015 and May 2016 (Barbieri et al., 2018). Training, trial, and test data emerge from a 80:10:10 split based on chronological order. We followed the

organisers instructions to obtain the training data, however we were only able to extract 491,486 tweets as some had been removed by their authors. We tokenised the tweets using the NLTK tweet tokeniser (Bird et al., 2009), but did not perform any further normalisation.

3 Features

3.1 Word-Class Occurrences

We created a set of features that describe which words occur with each emoji. We created a map describing how often each token occurred alongside each class. Let V be the vocabulary in terms of tokens. Let C be the number of total classes, where each class represents one emoji. We created a matrix M with size $|V| \times |C|$ such that each element $M_{i,j}$ indicates the number of times that token V_i occurs with class C_j . This allowed us to see whether one token occurred mostly in the context of one or two classes, or whether it occurred with similar frequency across all classes. This metric is similar to document frequency in information retrieval.

To further improve our metric, we applied a normalisation transformation to the rows (scaling each row by the total size of the row):

$$M'_{ij} = \frac{M_{ij}}{\sum_{k=1}^{|C|} M_{ik}}$$

This method favoured lower frequency terms (i.e., a hashtag that occurs only a few times with one emoji), so we applied a further transformation to multiply each row by the log frequency of occurrence of the token:

$$M''_{ij} = M'_{ij} \times \sum_{k=1}^{|C|} \ln M_{ik}$$

These features produced intuitive results. The top words for a few select classes are as follows (❤️: love, heart, my, family; 😎: sunglasses, shades, cool; 🎄: christmas, merry, #christmas-tree)

These features are at the token level, however our classification labels are at the level of the sentence. To convert these features to the sentence level, we used two strategies: average and max. We calculated the average vector as the mean of all token vectors in a tweet. We calculated the max vector by taking the highest value across all tokens for each class. This led to 40 features (20 for average and 20 for max).

3.2 Sentiment

We employed Vader (Gilbert, 2014), a lexicon- and rule-based sentiment detection system to de-

rive a set of sentiment features. Vader fashions features, at sentence level, for positive, neutral, and negative polarities ranging from 0 to 1 and representing intensity. It also produces a combined sentiment score, with values between -1 (negative) and 1 (positive), where values in $[-0.5, 0.5]$ denote neutrality.

3.3 Psycholinguistic Features

We used the MRC psycholinguistic norms (imagery, concreteness, familiarity, meaningfulness, age of acquisition) (Coltheart, 1981) as token level features. These were averaged to give tweet level features in our classification scheme.

3.4 LIWC

We used the latest version of the Linguistic Inquiry Word Count (Tausczik and Pennebaker, 2010) system, LIWC2015, to produce a large set of features, at sentence level, concerning emotional, cognitive, and structural components derived from the texts. As shown in Table 2, our experiments with those features, arranged into different subsets, did not produce any significant improvement; therefore, we decided not to include those in our submissions.

4 Results

We performed subset analyses to determine the best feature grouping. In Table 2, we show our results for different feature sets when training on the training data and testing on the trial data.

We also optimised the number of trees in our random forest, finding 225 to be the best value for this parameter.

Table 3 shows the detailed classification report (precision, recall, F1, and support, by class), and Figure 1 displays the confusion heatmap for our best submission on the English test dataset. Our system ranked 24th, with a macro-averaged F1-score of **24.982** (n=48, median=23.919, min=2.038, max=35.991, Q1=18.278, Q3=28.410). On the Spanish challenge, our best submission (using only the average class-occurrence features) ranked 8th, with a macro-averaged F1-score of **16.338** (n=21, median=14.912, min=3.896, max=22.364, Q1=10.892, Q3=16.696) (see Table 4 and Figure 2 for detailed performance). For lack of space, we restrict our subsequent error analysis and findings

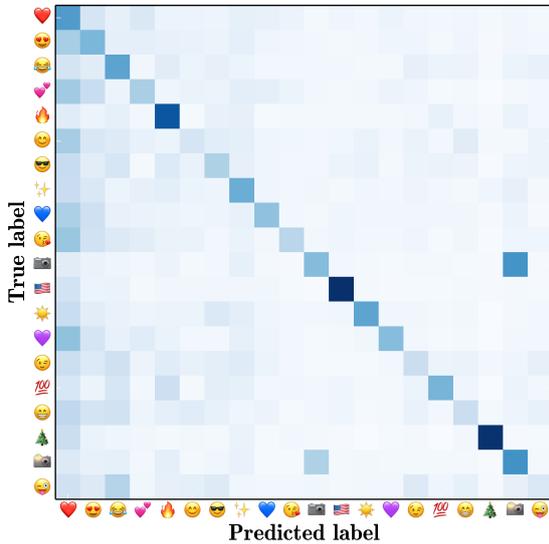

Figure 1: Confusion Heatmap For English Test Data

to the English challenge. However, these generalise to Spanish.

The F1-score on the test data was much lower than that on the trial data (**63.185**). We hypothesise that this discrepancy might be largely due to (1) our system overfitting the training data and to (2) a test dataset whose class distribution and discriminant features differ in some measure from those of training and trial.

Figure 4 shows the class (i.e., emoji ranks) distributions on trial and test data. With respect to training (omitted here for brevity) and trial data, the shape of the distributions match al-

Table 4: Detailed Precision, Recall, F-measure, and Support for Spanish Test Data

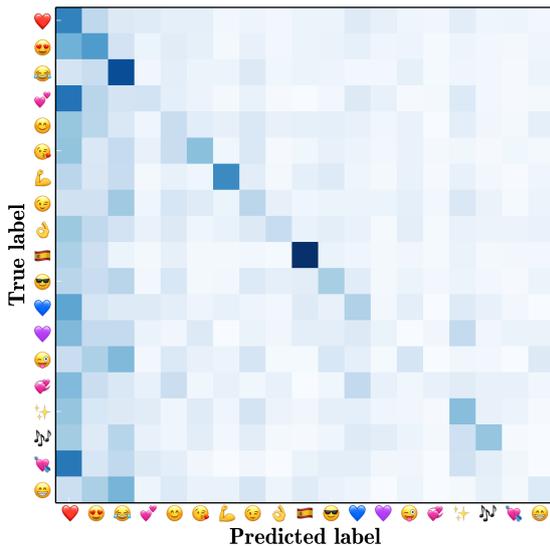

Figure 2: Confusion Heatmap For Spanish Test Data

most perfectly. Also, to a large degree, they are rank-preserving.¹ This is in contrast to the class distribution of the test data, which is not rank-preserving, particularly for those labels in the long tail (i.e., below the three most frequent).

From the classification report (Table 3) and the confusion heatmap (Figure 1) on the test data, one could infer, firstly, that our system revealed a propensity for predicting the most frequent emoji, particularly ❤️, 😍, and 😂 (accounting for about 40% of the data), which can be noticed from the consistent high values on the three left-most columns of the heatmap. Consequently, those within the surroundings of the peak of the class distribution, almost consistently, had recall significantly higher than precision.

For the majority of lower-support emoji, the system had a hard time in separating classes and quite frequently opted for higher-support ones. Secondly, it conflated classes into groups which, intuitively, could be seen as clusters of semantically-similar emoji, taking into account aspects such as emotions (e.g., joy), concepts (e.g., Christmas tree), and occasions (e.g., Christmas), to mention a few.

For instance, most of those associated with *affection, elation*, and other positive emotions and emotional states (e.g., 💕, 💙, 💜, 😊, 😘) presented extremely low recall and, frequently, were misclassified as ❤️. As an example, 💕 had a recall of 4.18%, with about 64% of its tweets predicted incorrectly as ❤️.

Our system performed better at separating other seemingly distinct clusters, such as *sunny weather* (🌞, 😎), *patriotism/national holidays/travelling* (🇺🇸), *occasions/special events/holidays* (🎄), *being humorous* (😏, 😜), *photography* (📷, 📸), to name a few. For example, 📷’s recall was 37.99%, with most of its misclassified instances (18%) being assigned to 📸. Conversely, 📸’s recall was 21.1%, with about 32% wrongly predicted as 📷.

5 Conclusions

We presented a system for the prediction a single emoji, out of a set of the twenty most-frequent, for Twitter datasets for (1) English and (2) Spanish. Our best model was based on a random forest (n=225) employing an ensemble of (a) max-

¹There a few discrepancies; for example, in the trial data’s class distribution, contrary to the ranking in Figure 3, (14, 😏) occurs slightly more often than (13, 💜).

Figure 3: Emoji Rankings For English (USA) and Spanish (ESP) (from (Barbieri et al., 2018))

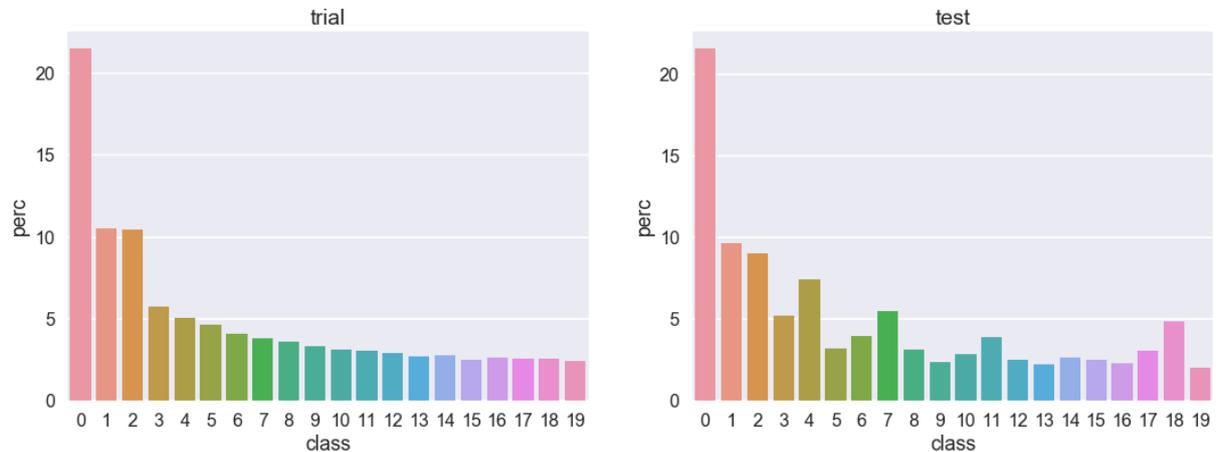

Figure 4: Class Distributions For English Trial and Test Data. The x-axis shows the classes (i.e., the emoji ranks in Figure 3), and the y-axis represents support (i.e., normalised frequencies)

and mean-aggregated normalised word-class occurrences, (b) sentiment and (c) psycho-linguistic features.

Our scores on the test data were significantly lower than those on the trial data, and we postulated that reasons for so were (1) a random forest that overfitted the training data and (2) large variance between trial and test data. It is worth investigating to which extent, and how, different periods of time explain that variance. For example, trial and test might have captured different, emerging trending topics and events; reflect drift in emoji usage; among others. It is reasonable to assume that, given the nature and the sparsity of the data, more representative samples might require much larger number of instances (say, billions of tweets) and time periods covered.

F1-scores were consistently low for all participants, which demonstrates the difficulty of the task. We are conscious that idiosyncrasies of Twitter-specific data (e.g., data sparsity, neologisms, informality, lack of grammatical structure) make it all more problematic, and some of our current research involves devising and incorporating features to address those challenges.

We believe it would be fruitful to investigate evaluation metrics that, rather than all-or-nothing

(e.g., misclassification rate), reflect the semantic similarity (or distance) between labels and predicted classes.

Abstract

We present the system built for SemEval-2018 Task 2 on Emoji Prediction. Although Twitter messages are very short we managed to design a wide variety of features: textual, semantic, sentiment, emotion-, and color-related ones. We investigated different methods of text preprocessing including replacing text emojis with respective tokens and splitting hashtags to capture more meaning. To represent text we used word n-grams and word embeddings. We experimented with a wide range of classifiers and our best results were achieved using a SVM-based classifier and a Hierarchical Attention Neural Network.

1 Introduction

SemEval 2018 Task 2 on Emoji Prediction (Barbieri et al., 2018) is a classical task for supervised learning. Given labeled data consisting of Twitter messages and a corresponding emoji as a label, the aim is to classify new examples (tweets) into 20 categories - the most frequent emojis of two languages: English (Subtask 1) and Spanish (Subtask 2). We participated only in **Subtask 1**. The labels are presented in Figure 1:

Figure 1: Labels ordered by frequency.

2 Related Work

Prior work includes using LSTM-RNN and CNN models (Zhao and Zeng) utilizing pre-trained Twitter embeddings with the latter achieving very good results. Other works (Barbieri et al., 2017) show that LSTMs have high accuracy and even outperform humans at the emoji prediction task.

In (Barbieri et al., 2016) the skip-gram neural embedding model is applied with different dimensions of the vectors and length of the windows applied to both words and emojis.

3 Data

We used the **500k training** and **50k trial** tweets provided by the organizers to train and validate our models respectively. One key mistake we made is that we did not compare those two datasets for duplicate entries. As we found out only after the submission deadline, the train and trial data had a 40% overlap, which unfortunately skewed our expected results and made them unrealistically high. The experimental results presented in Table 2 are on the data with removed duplicates.

We crawled additional 100k tweets via *Tweepy*¹ only 5k of which were compliant with the requirements to contain exactly one emoji. With this external data we aimed to improve the overall performance of our models, but since it was way too small, it did not have much effect.

Finally, when predicting on the test data, we trained our models on the combined train, trial and crawled data.

Looking at the emojis we immediately noticed two problematic groups: 1. two emojis with a **camera** - one with flash and one without; 2. four emojis containing a **heart** - three of them exactly the same, different only in color (red, blue, purple), and one with two pink hearts. We approach the second group with color-related features (see Section 4.2)

4 Method

4.1 Data Preprocessing

Replacing Text Emojis: Text emojis like :), :D, :o and others should in theory carry valuable

¹<http://www.tweepy.org/>

information, thus we encode them to unique strings that will not be removed in future pre-processing steps. The encoded strings are: `..smile..` `..laughing..` `..very_happy..` `..sad..` `..cry..` and `..surprise..`.

Removing Punctuation and Artifacts: The data given by the organizers comes with user mentions replaced by `@user` and all URLs removed. We remove `@user`, because the user mentions are taken into account in the feature engineering step, even though their position is lost. We also remove automatic location mentions in the form `@ Location`. Non-letter characters are also removed, exception is `#`, used to identify words in hashtags which we later attempt to split.

Hashtag Splitting: We try to break down each token starting with `#` to a set of words. The process iterates over the token until a word existing in a corpus is found. Then we take the rest of the token and recursively apply the same procedure until the whole original token is empty. The longest matching word is always taken first. For subtoken word identification we used the *Brown corpus*. As anticipated, adding a slang corpus seemed to worsen the splits. For simplicity we take the first found valid split, but an improvement would be to calculate and take the most probable one.

Tokenization and Lemmatization: A *WordNet* (Miller, 1995) lemmatizer is used on tokenized (*TweetTokenizer* from *NLTK*²) and lower-cased beforehand part-of-speech annotated tweets. High frequency words are removed.

4.2 Features

Textual Features: Since all we had was the text of the tweet without any metadata or context, we focused on extracting valuable information from the text itself. We gathered statistics like number of words, hashtags, stop-words, user mentions, mean word length and more. Some of those were specifically targeted at predicting certain emojis. For instance, we hoped counting the digits and percentage signs would help identifying 🎉. Punctuation such as question marks, exclamation marks or words with all title letters could signify an intensified face emotion like 😂 or 😄.

Semantic features: Looking at the train data, we noticed that 42% of the tweets end in the following pattern: `@ LocationName`, for instance *Happy birthday Nathan!!! @ Boca Gardens*. We

²<http://www.nltk.org/>

Cluster Id	Words

111010100011	haha hahaha hehe hahahaha hahah aha hehehe ahaha

Table 1: Twitter clusters.

figured that this was an automatically assigned location and extracted it as a separate feature.

Emotion-related features: To capture emotion, we used the *NRC Word-Emotion Association Lexicon* (Mohammad and Turney, 2013). It contains a list of English words and their associations with eight basic emotions - anger, fear, anticipation, trust, surprise, sadness, joy, and disgust.

Color-related features: Dealing with four emojis with the heart symbol in different colors, we decided to use another NRC Lexicon - on *Word-Colour Associations* (Mohammad, 2011). It consists of mappings for eleven colors - white, black, red, green, yellow, blue, brown, pink, purple, orange and grey, which covers the four heart colors in question.

Sentiment features: In order to capture sentiment in the tweets, we used *SentiWordNet* (Baccianella et al., 2010) to associate each token in the tweet with a positive and negative score.

Twitter clusters: Another observation we made while looking at the tweets is that there were a lot of misspelled words and words with identical meaning written with different syntax (mainly slang). To handle that we utilized *Hierarchical Twitter Word Clusters*³. The clusters also help identify synonymous words. Three exemplary clusters of words are shown in Table 1.

All features were used in all classification experiments, except in some of the stacking, where a subset was used.

4.3 Classifiers

Using the features above, we had represented each tweet into that vector-space. Experiments were made with classifiers from various types: Linear, Non-Linear, and Deep Learning.

Linear Classifiers: For our baseline we used Multinomial Naive Bayes, which we managed to outperform with ease. In the subsequent experiments we used linear classifiers - Logistic Regression with L-BFGS optimizer (Liu and Nocedal,

³<http://www.cs.cmu.edu/ark/TweetNLP>

1989) and Linear SVMs with SGD optimizer (Bottou, 2010).

Non-Linear Classifiers: As we wanted to overcome the linearity of the LR and SVMs we had moved to non-linear classifiers. We had fed our feature vectors into Random Forest with 300 estimators, and AdaBoost with Decision Tree base, again with the same number of estimators.

Stacking: Another idea was to combine count-based and semantic features. For this we applied two versions of Stacking ensembles. The first includes SVM (tf-idf), AdaBoost (embeddings) and Random Forest (semantic and sentiment extracted features). The second one is composed of SVM (tf-idf), AdaBoost (embeddings) and Multi-layer Perceptron (tf-idf). Both ensembles use hard weighted voting with coefficients 1.5 for the SVM prediction and 1.0 for the rest.

Deep Learning: We applied some of the state-of-the-art neural architectures for text-processing. Our experiments included Multi-layer Perceptrions, Recurrent NNs with LSTM (Hochreiter and Schmidhuber, 1997) and Convolutional NNs.

In the dev phase we achieved best results using *Hierarchical Attention Neural Network* (Yang et al., 2016) (HANN). The idea of HANN is to mimic the hierarchical structure of documents. It has two levels of attention mechanism: for word and for sentence. This enables them to capture and act differently on different levels of content importance. HANNs structure is build up from: word sequence encoder, word-level attention layer, sentence encoder and a sentence-level attention layer. Word Encoder gets word annotations from an embedding matrix summarizing information from both directions of the words. Word Attention (an attention mechanism), extracts the most important words, because not all words contribute equally to the sentence's meaning. Sentence Attention (another attention mechanism), is used to mark the important sentences at sentence level context.

As another experiment we used a two-layered bidirectional LSTM with a dropout rate of 0.35 and the Adam optimizer.

Another interesting approach that we adapted was to apply Convolutional Layer for text (Kim, 2014) that allows our network to learn and capture patterns for adjacent words in sentences. CNN are widely applied for image data, by using them for text classification we can learn and track correlations between close words and inputs. An ad-

vantage of CNN over RNN is that CNN are much faster than RNN architectures. CNNs allow our network to see the entire input at once and to parallelize all operations, because a convolutional kernel acts on each patch independently.

The key insight of boosting our Neural Network models was switching from ReLU to ELU as activation function. Proper Dropout Strategy (between 0.35 and 0.4) also improved our validation score.

5 Experiments and Evaluation

5.1 Experimental Setup

We transformed the training tweets into vectors using two mainstream techniques: tf-idf representation and word embeddings. While building the tf-idf weights we formed word 6-grams (without the stop words) and removed entries with DF greater than 0.5. The second approach consisted of using 200-dimensional GloVe embeddings (Pennington et al., 2014) trained on Twitter corpus with 27 billion tokens. Using the embedding of each term we concatenated the component-wise minimum and maximum vectors (De Boom et al., 2016). Some classifiers were tested using both representations when we found that appropriate.

5.2 Results

The results from those experiments on 10k train (sampled from the train dataset) and 1k test (sampled from the trial dataset) data are presented in Table 2. The experimental results are on the data with duplicates removed. The second stacking gave a better result than SVM, but we did not manage to run the model on the whole dataset in time for the submission. We placed 25th in the official ranking.

Precision, recall and Macro-F1 per class (on duplicated data) can be seen in Table 3.

The confusion matrix in Figure 2 reveals that two of the most confused classes are the ones with a camera, which was expected. Less anticipated is the strong confusion between the heart and the sun emojis. Overall, the heart emoji is confused the most with the rest of the classes, but since it's the most common one it's possible that classifiers often falsely predict it.

In terms of features, we found out that the n-gram representation of the tweets was the most important in terms of determining its label and the additional features did not have much influence.

Model	Precision	Recall	Macro-F1
Multinomial Naive Bayes	0.05	0.21	1.763
Logistic Regression with L-BFGS	0.22	0.28	13.16
Multi-Layer Perceptron 2-hidden (ReLU)	0.26	0.26	17.898
Random Forest (300 estimators)	0.20	0.26	16.167

6 Conclusion

The work we did on the Emoji Prediction task seems promising, even though we could make our process better by filtering train data, retrieving more tweets and focusing more on the preprocessing of the tweets. There’s a lot of room for improvement, given that the task is very challenging - tweets are short and full of slang words and ambiguous emoticons. We tried to combat those through some feature engineering, preprocessing and semantic approach for vectorization.

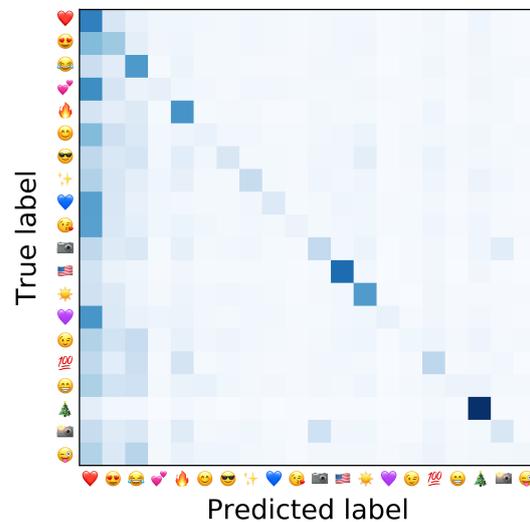

Figure 2: Confusion matrix per emoji type.

Improvements could be made with the semantic representation of the tweets. Because our embedding representations use coordinate-wise minimization and maximization, a lot of meaning is lost. Embedding approaches that work on a higher than word level text blocks like Skip-Thoughts vectors (Kiros et al., 2015) could decrease this loss. As future work we plan on using more sophisticated architectures like deeper CNNs and Squeeze-and-Excitation Networks for text.

Abstract

In this paper we present the system submitted to the SemEval2018 task2 : Multilingual Emoji Prediction. Our system approaches both languages as being equal by first; considering word embeddings associated to automatically computed features of different types, then by applying bagging algorithm RandomForest to predict the emoji of a tweet.

1 Introduction

Emojis were first used to emphasize conversations before becoming representations of specific emotions, objects or ideas. They are now used in almost every social medium and conversation devices, such as messaging applications or even emails¹.

Tweets and their emoticons were used as labels to predict polarity at first (Pak and Paroubek, 2010). However, emojis are not used the same way as emoticons in messaging applications. They can convey further information, even more when combined. The advantage of emojis is that they are becoming more standardized, even though existing emojis are still growing quickly². This is why emoji prediction is a relatively new task. It can be considered as a composite task mixing emotion prediction for face emojis, aspect/subject detection for object emojis, and other metadata prediction for more abstract emojis, representing ideas for instance.

This year, SemEval started the first emoji prediction task (Barbieri et al., 2018). It consists of a multiclass classification task for a total of 20 possible classes, *i.e.* emojis. This task is interesting in several ways. Firstly, it is a relatively new task that only a few studies did focus on. Secondly, it is

quite important not only for research, but also for companies willing to embrace the current trend of social network and interaction analysis. Both are important topics for Natural Language Processing (NLP) and Information Retrieval (IR).

Our system obtained good results (63.65% f1-score) while using the trial dataset, and lower results (13.53% f1-score) on the test dataset. Because this pattern occurred for both English and Spanish, and for all participants, we try to explain it.

The paper is organized as follows: we first summarize the existing work related to this task and to our approach (Section 2). Then we present what we identified as the most challenging areas from this task and the dataset used (Section 3). We go on by describing our system (Section 4) and detailing the pre processing and prediction steps. Finally, we conclude by discussing the performance limits and show the benefits of our participation in this task (Section 5).

2 Related Work

Several research studies focus on emoji prediction. Most of them use word embeddings in order to do a multiclass emoji prediction. At the beginning, images were used instead of text as the source of emoji prediction (Cappallo et al., 2015). Eisner (Eisner et al., 2016) used embeddings based on emoji description in the Unicode³ list, such as *smiling face with heart eyes*. They obtained 85% accuracy in their classification of emoji descriptions, predicting several keywords for one emoji. Xie (Xie et al., 2016) trained neural networks on Weibo⁴ to predict 10 possible emojis in conversations with 65% accuracy for the 3 mostly used emojis. Barbieri (Barbieri et al., 2017) then

¹http://cdn.emogi.com/docs/reports/2015_emoji_report.pdf

²<https://goo.gl/jbeRYW>

³http://unicode.org/emoji/charts/full_emoji.html

⁴<http://www.weibo.com/>

predicted 20 emojis in millions of tweets using LSTM (Hochreiter and Schmidhuber, 1997) and obtained 65% f1-score for the 5 most used emojis. Felbo (Felbo et al., 2017) tackled emoji prediction by LSTM with 43.8% accuracy for the top 5 emojis, while using emoji vectors to help detect sarcasm. In our recent work we considered another approach with 84.48% weighted F1-score using multi-label emoji prediction of 169 sentiment related emojis in real private messages (Guibon et al., 2018).

3 Task Specific Difficulties

Be it in English or Spanish, the proposed task has specific difficulties. Each of these difficulties represents challenges and obstacles for the classifier to make a good prediction.

First, the dataset is made of 20 classes of different types and concepts. Some are related to pure emotions ❤️, facial expressions of emotions 😂, or even classes representing objects 📷 or ideas ✨. Those different classes may sometimes appear in a same context (❤️💜, 💜💜, and 💜💜 for instance), even though the dataset was selected to only keep tweets with only one emoji.

Second, tweets are not private short messages. This means that some tweets are even difficult to understand for humans. This is the case for reaction tweets to a certain hashtag or social event. The appreciation of the event is totally dependent on the user’s subjective point of view. Thus, it is also the case for the resulting emoji associated to the message. Other types of tweet-emoji associations, such as advertisements, are not even humanly predictable.

Third, the dataset is really unbalanced, which has become quite common in real applied classification. However, it still represents a challenge when associated to the two previous difficulties. Taken together, they make emoji prediction quite difficult, especially for tweets, which justifies even more the necessity for this task.

Two datasets⁵ were used for emoji prediction in tweets: 500 000 tweets in training and 50 000 as trial and test for English, 100 000 tweets in training and 10 000 as trial and test for Spanish. Each dataset was made of tweets containing only one emoji between a set of 20 most frequent emojis from tweets containing only one emoji.

⁵<https://github.com/fvancesco/Semeval2018-Task2-Emoji-Detection>

The emoji set only contains positive or neutral emojis, making a sentiment analysis approach less relevant, but we still kept using polarity scores in order to include the intensity of the polarity as a feature.

4 System

4.1 Preprocessing

Cleaning. To prepare the data we first cleaned tweets by removing trailing three dots, user mentions and urls. Then we used Spacy⁶ to apply lemmatization and part-of-speech tagging (PoS).

Word Representation. For data representation, we compared different approaches for text vectorization. We first did a text representation using *FastText* (Bojanowski et al., 2016) but did not obtain an overall gain in the prediction in comparison to *Word2Vec* (Mikolov et al., 2013). We used *Word2Vec* in its Gensim⁷ (Rehurek and Sojka, 2010) implementation with the following hyper parameters:

- Architecture: Continuous Bag-of-Words
- Batch size: 32
- Minimum count: 1
- Embedding size: 50 or 300
- Iterations: 100

The minimum count was set to 1 in order to better capture rare items from really small tweets, and the Continuous Bag of Words (CBOW) architecture was preferred after empirical tests to determine if it was useful to use it or not. The best text vectorization was obtained using live-trained embeddings, without using external pre-trained embeddings, even though we trained word embeddings and character embeddings on millions of tweets to obtain better representation, and also used existing pre-trained embeddings (Barbieri et al., 2016). This is certainly due to the overlap between the training and the trial set. Thus the local vectorization is more representative to find already known contexts. Varying the size of the embedding matrix E did not show major improvements for the following prediction, whether its dimension was $d300$ or $d50$. Thus, we chose a dimension of $d50$ to train faster. Tweets are represented as the *mean* of each word embedding vectors, allowing

⁶<https://spacy.io/>

⁷<https://radimrehurek.com/gensim/about.html>

the same size ($d50$) for each tweet final embedding vector.

Computed Features. In addition to the embedding vectors, we computed several features represented as a feature vector F : binary features for the presence of a question or an interrogation mark, and their repetitions, another boolean feature for the usage of Title Case. Numerical counts were also added: word count, character count, average token length, number of nouns, adjectives, adverbs, interjections and verbs. Polarity prediction was also added by using SentiStrength (Thelwall et al., 2010) positive and negative scores. The advantage being that we then have polarity intensity, so it could be useful even if all 20 emojis are neutral or positive.

Finally, this feature vector F of dimension $d23$ was added to each embedding matrix E along the columns axis. The matrix is as follow: each row represents one tweet, and each column a feature. Each tweet information being represented by $E + F$. This means that before concatenation, a row (*i.e.* a tweet) has 50 columns, and after concatenation, it has 73 columns.

This pre-processing approach was used for all data separately, meaning that we based all our tests while training on the training set, and testing on the trial set. We used this approach for both English and Spanish.

4.2 Prediction

The system used was chosen after trying multiple approaches using the training set for train the model and the trial set to obtain macro F1-score. We explored multi-class RBF-SVM with gaussian distance function, LSTM network (3 LSTM layers with 64 unit cells, 0.5 dropout, then softmax layer) and decision tree based algorithms (XGBoost, decision tree, RandomForest). Decision tree based algorithms always gave us better results to take into account all classes during prediction. The number of systems were limited to 2, so we applied slightly different approaches.

In our system we used RandomForest with 700 estimators chosen empirically in order to predict emojis. To automatically find the best parameters we used a grid search with cross validation strategy for specific parameters visible in Table 1. The best parameters found were quite similar to the default one from the Scikit-Learn API except for the balanced subsample class weight. We also tried

setting the class weight manually to deal with unbalanced dataset. We gave more weight (5) to the 3 majority classes 🍀🍀🍀 and left the other classes to 1, without improving the results. The maximum depth for each tree was then set to None because we believe a bagging approach such as RandomForest with a number of estimators higher than the targetted classes can compensate overfitting issues coming from a higher complexity of each estimator.

Max Depths	20, 100, 200
Min Samples Splits	2, 5
Min Samples Leafs	1, 4
Max Features	sqrt, log2, None
Criteria	'gini', 'entropy'
Class Weights	None, 'balanced', 'balanced subsample'

Table 1: Grid search for RandomForest parameters.

The two submissions vary slightly, but are still the same system.

Version 1. On the one hand, data were scaled from 0 to 1 and we used a \log_2 parameters and χ^2 feature selection to minimize the number of features. This is based on the assumption that useful data in the word embeddings should be scaled before being concatenated with the features vector, then only embeddings and useful computed features should be used.

Version 2. On the other hand, we did not scaled any data nor limited the number of features, as suggested by the grid search.

According to feature importance scores from the classifier (Table 2), the best computed features were the average token length, the character and word counts, and the number of uppercases. The other features have minor impact even though PoS tag counts follow the top five features.

1	averageTokenLength (0.016)
2	charCount (0.015)
3	wordCount (0.012)
4	upperCharCount (0.011)
5	nounCount (0.009)
...	

Table 2: Top five computed features.

We first used only embeddings to predict, then predicted using concatenated embeddings and computed features vectors. The latter improved the overall prediction, which can also be seen by the feature importance scores.

We managed to obtain 63.65% macro f1-score on English, and 84.13% macro f1-score on Span-

ish while predicting on the official trial corpus. The English classification report is visible in Table 3. Also, the model obtained 61.92% accuracy on english and could be upgraded by sometimes choosing one of the best probabilities from each prediction according to the Mean Reciprocal Rank (MRR) score of 0.7126.

Avg.	0.76	0.62	0.62

Table 3: Precision, Recall, F-measure for each emoji on the trial set.

However, our system obtained poor results once applied on the official test set, with only 13.528% macro f1-score on English, and 8.808% macro f1-score on Spanish.

Performance decrease in test set. An overall drastic performance decrease was shown while applying the model on the test set. We believe this is due to multiple factors. First, as we have no means to identify very difficult tweets for which even humans could not predict emoji (see Section 3), it is difficult to know to what extent the model generalized well. Of course, by comparing our approach results with other ones, we know that the model or the approach should be improved in order to better take into account all classes, as it is visible in the test set confusion matrix (Figure 1).

Another element explaining the major performance decrease is the presence of overlapping elements between the trial set and the training set

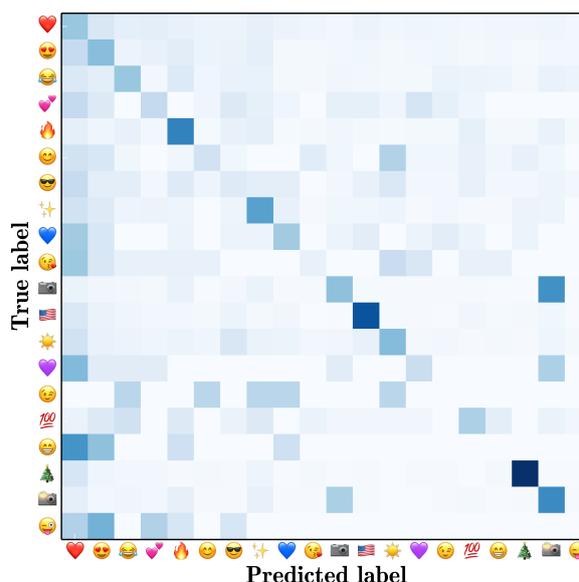

Figure 1: Confusion matrix from official test results.

that misled parameters tuning. Even though, we think a text representation enhancement is necessary, as this approach finally gave poor results.

5 Conclusion

In this paper we described the system we submitted to the SemEval-2018 Task 2 for Multilingual Emoji Prediction. The system presented uses text vectorization through word embeddings associated to a computed-features vector in order to represent each tweet by their polarity intensity and metrics. The classification is then done by using decision tree based algorithm for understanding, with bagging technique for better generalization to match the goal of macro F1-score metric. With this system we wanted to have a generic system for both languages without specific parameters for each language.

The system obtained good results on the trial set but the performances decreased drastically when applied to the test set. Even though this pattern was shown through all participants' systems, ours finally obtained poor results on the test set. We believe it is necessary to further process the data in order to identify recurrent difficult cases, such as really short and commons tweets. A more robust representation of each tweet is also required.

Finally, the python code used for this task is available on github⁸.

Abstract

This paper describes the ALANIS system that participated in Task 3 of SemEval-2018. We develop a system for detection of irony, as well as the detection of three types of irony: verbal polar irony, other verbal irony, and situational irony. The system uses a logistic regression model in subtask A and a voted classifier in subtask B, both of which rely on manually developed features to identify ironic tweets. ALANIS placed 34th of 43 systems in subtask A and 26th of 31 systems in subtask B.

1 Introduction

With the invention and growth of various social networking sites, irony and other creative linguistic devices have become increasingly prevalent in online content. Particularly when considering microblogging platforms like Twitter, which encourage users to share their thoughts and opinions on a wide variety of topics, the use of irony can be extremely common. This can have strong implications for various problems in natural language processing, which often have difficulty in processing this ironic content (e.g., (Liu, 2012; Ghosh and Veale, 2016; Maynard and Greenwood, 2014)), thus motivating the development of an accurate irony detection system.

While irony has many varying definitions, it is defined by the SemEval task organizers as a trope or figurative language whose actual meaning differs from what is literally enunciated. Our system, ALANIS (Automated Location and Naming of Ironic Sentences), uses a manually developed feature set and a logistic regression classifier for subtask A and a voted classifier for subtask B, achieving mean accuracies of .650 and .607 respectively on the training set and .512 and .434

respectively on the test set. The F1-scores are .469 and .276 on the test set.

2 Task Description

SemEval Task 3 involves two subtasks. In subtask A, a tweet simply must be identified as ironic or non-ironic. In subtask B, three types of ironic content must be individually differentiated from non-ironic content. These three types of irony are verbal polar irony, other verbal irony, and situational irony. The task organizers provided us with a training set of 3,834 tweets for both subtasks.

3 ALANIS

Our system, ALANIS, uses manually developed features indicative of ironic content, and passes a feature matrix for each tweet to a logistic regression classifier in subtask A and a voted classifier system which employs a logistic regression, SVM, and Random Forest classifier in Subtask B. It uses the scores from each of these classifiers to "vote" on the correct label for a tweet.

3.1 Feature Selection

We explored two types of features, structural features and affective features. Structural features included sentence semantic similarity, irony-rich word lists, indicative parts of speech, and content features. Affective features included sentiment polarity and subjectivity. These features were used to assign scores for each tweet, creating a feature matrix.

3.2 Structural Features

Our system combines a number of structural features that are identified as indicative of ironic content by previous solutions.

Sentence Semantic Similarity is a measurement of similarity in meaning between two sentences. This is a structural feature employed in a

*Authors are ordered alphabetically by their first name.

system designed by (Farías et al., 2016) with some success. Ironic tweets with multiple sentences should show a sharp change in meaning between sentences. To implement this feature we employed WordNet synsets. The similarity of the sentences is computed based on the semantic similarity of the words contained in the two sentences.

Irony-Rich Word Lists: Our system takes advantage of a number of words claimed to be indicative of irony. This involved several manually developed word lists. Most importantly, we used discourse markers, which are phrases that are indicative of discourse segments. Examples of these include *however*, *on the other hand*, and *in my opinion*. These have been cited as being more common in ironic content (Farías et al., 2016). Our system employs a list of 53 discourse markers. Also based on Farias et al, we measure intensifiers, like *very* and *really* that make adjectives stronger.

In addition to these, we build on our curated lists of irony-indicative words with features like swear words and top words, as well as textual markers of laughter like *lol* and *haha*, which was noted to be common in ironic content (Buschmeier et al., 2014). Another word list included interjections to detect irony. Interjections are word that express feeling rather than meaning, for example, words like *wow*, *gosh*, and *jeez*.

Indicative Parts of Speech: We also built features that measured the prevalence of several parts of speech thought to be indicative of ironic content. These included adjectives, adverbs, prepositions, and named entities. All of these features were identified by the NLTK¹ POS tagger in order to count their occurrence. These counts were then normalized for the length of the tweet. Adjectives and adverbs occur more frequently in ironic tweets than non-ironic according to (Kreuz and Caucci, 2007). We hypothesized that prepositions and named entities would occur more often in situational irony, due to the likely need to explain the situation.

Content Features: ALANIS also employs a number of features relevant to the content of the tweet in order to identify irony. These include Word Count, Punctuation, and URLs. According to Farias et al, ironic tweets tend to have excessive punctuation to catch the eyes of readers and to stress a point. Examples include "It is really

worth it!!!" or "Okay...". Thus, heavy punctuation sometimes implies irony. Farias et al. also identified that ironic tweets are likely to contain fewer words than non-ironic tweets, thus motivating the use of the word count feature.

URLs were also employed as a feature in our system. (Schifanella et al., 2016) found that ironic tweets often contain images and often the interpretation of the irony depends on the image. For example, a photo of a warm, sunny beach with the caption "Terrible weather we're having." However, the task data does not immediately give us images, only a link to images (which may not in fact exist online anymore), so the simplest way to identify this was to just check if a tweet had a URL.

Popular Hashtags and Keywords: Twitter hashtags and keywords are a good measure of public opinion on trending topics and current events. Through these hashtags, users express a wide variety of opinions, including irony. For example, the following hashtags were among the top Twitter hashtags for 2016: #GOPDebate, #PrayforJapan, #WomensRightsAreHumanRights. Our system finds hashtags that contain words related to global issues, sports, entertainment, and fashion using a manually created list of top hashtags.

3.3 Affective Features

While most work on irony detection (e.g., (Carvalho et al., 2009; Barbieri and Saggion, 2014; Vanin et al., 2013)) focus on the structural features, (Farías et al., 2016) show that introducing affective information can also improve state-of-the-art accuracy.

In our work, we included two commonly used sentiment features, polarity and subjectivity. Sentiment polarity reflects the general positivity of a piece of text, while subjectivity is measured against objectivity. Each of the two features is assigned a score within the range $[-1, 1]$. We used the TextBlob package in python² to implement the scoring functions for these features.

4 Classifiers

The classifiers we used for our system included Naive Bayes, logistic regression, Support Vector Machine (SVM) and Random Forest. We chose these because they are generally robust classifiers. As we added features to our feature list, we also

¹<http://www.nltk.org/>

²<http://textblob.readthedocs.io/en/dev/>

kept track of the performance of the the logistic regression, Random Forest, and SVM classifiers, while Naive Bayes was only used for the bag of words baseline.

In ALANIS, all the classifiers take the tweet features matrix as input and have as output a binary label vector for the categorical result. We separate the data into a training set and a test set using cross-validation. We train the classifiers with the training set to optimize the parameters including the hyperplane and kernel. Then we evaluate the trained classifier on the test set.

Support Vector Machine: We find that SVM is relatively powerful when the feature list is short, compared with other classifiers. Also, we noticed that SVM classifier scores the highest recall, which means that it detects the most ironic tweets.

Logistic Regression Classifier: We find that logistic regression is stable in terms of total accuracy. It becomes the most accurate classifier for our long final feature list. The logistic regression classifier does not show any tendency in detecting irony or avoiding error. Because of its linear kernel, we are able to get the trained weights for each feature. This helps us know the capacities of features and select them better. We rank the importance of features according to the magnitude of their weights. See Table 3 for details.

Random Forest Classifier: This classifier does not perform well compared to the others. However, it is worth mentioning that when the feature list grows long, it retains a higher accuracy than SVM.

Voting System: We find that the confusion matrices of the classifiers are different. This means the classifiers have different specialties. Therefore, we combined them in order to get a synthesized result. We make a voting system with the classifiers discussed previously. The voting system uses majority rule.

5 Experimental Results

Our final result is that logistic regression is most accurate classifier for subtask A and the voting system is most accurate for subtask B. Table 1 shows the average cross validation scores on the training set, while Table 2 shows the scores when our system is trained on the whole training set and evaluated on the test set.

BOW+NB stands for the Bag of Words Naive Bayes baseline, while LR, RF, and Vote represent

Model	TaskA Acc	TaskB Acc
BOW+NB	0.572	0.285
LR	0.650	0.603
SVM	0.596	0.545
RF	0.622	0.584
Vote	0.644	0.607

Table 1: Performance of classifiers on training set

Model	TaskA Acc/f1	TaskB Acc/f1
LR	0.512/0.469	-
Vote	-	0.434/0.276

Table 2: Performance of classifiers on test set

logistic regression, Random Forest, and the Voting System. Based on these results, we used logistic regression or subtask A and the voting system for subtask B.

The result in Table 1 are based on 5-fold cross validation with the training data. As such we expected comparable results when we applied our classifiers to the test data. However as can be seen in Table 2 this is not the case. The results for LR decline from .65 to .51, and for Vote from .607 to .434. While some variation is to be expected, this was surprising to us. We hypothesize one of two possible explanations. First, our methods may have overfit the training data and so do not generalize well to other data. However, since we employed cross validation we are not certain how likely this explanation proves to be. The second explanation may be that the test data is in some way different from the training data, to the extent that a model learnt on the training data may not fare well on the test data. We have not yet analyzed the test data closely enough to resolve this question, but consider this to be an important step in understanding our results.

6 Discussion and Future Work

We tried to interpret the importance of the features by the magnitude of their weights in logistic regression. The weights of the features' performance in subtask A and B are shown in Table 3. In interpreting this table, the further a feature is from 0, the stronger the feature's impact is on our classifier. For instance, of our features, stop words and laughters are relative weak features. Conversely, intensifiers, discourse markers, adjective/adverbs, and prepositions are much stronger features.

In order to understand the different performance

Feature	Weight	Feature	Weight
intensifier	1.05	subjectivity	0.20
discourse	0.90	named entity	0.18
adj./adv.	0.81	swear words	0.18
preposition	0.81	URLs	0.15
polarity	0.54	word count	0.12
political	0.39	similarity	0.11
interjections	0.34	stopwords	0.06
celebrity	0.33	laughter	0.01
punctuation	0.32		

Table 3: Weights (in absolute) of features

of the classifiers, we made confusion matrices for all the classifiers and then also did a weight analysis for logistic regression since it employs a linear kernel. From the confusion matrices, we found that although the classifiers have their specialties, the voting system does not always work out well. We believe that this is because SVM and Random Forest are both much weaker than the logistic regression classifier (shown in Table 1) so they neutralize logistic regression’s advantages.

In subtask B, we need to label a tweet with 0 (non-ironic) or 1,2,3 (three different subcategories of irony). However, the difference among these subcategories are so subtle that our features do not capture them very well. Overall these classifiers have a hard time with multi-class classification. Since all three classifiers have more similar results for task B, the voted system is more successful

We review our system and the output of our system and find several possible explanations. From the confusion matrix, we can see that class 2 (7%) and 3 (5.9%) are relatively rare. This makes the task very hard for classifiers because of lack of information to train on for class 2 and 3. However, because the majority of data in subtask B falls into class 0 and class 1 we are still able to get a high accuracy (0.6+). If the data was spread more evenly between the four classes our system would likely perform better. When analyzing individual tweets from class 1, 2 and 3, we found that their feature lists are more similar to each other than to class 0 (non-ironic). This means we miss features that are relevant for identifying different types of irony, making our feature-based classifier ill suited to this task.

To see the system’s effectiveness, it is often helpful to consider some indicative examples of the system in action. Consider examples (1) and

(2) below. Our system successfully classifies (1) as ironic, but fails to classify (2) as ironic.

1. Feeling like crap. And being treated horribly too. It’s a great day. #iwanttogohome
2. Hey there! Nice to see you Minnesota/ND Winter Weather

Our system likely successfully classifies (1) for a number of reasons. First, the word count of the sentences is low, which seems typical of ironic tweets. It has strong sentiment polarity between the sentences. The first two sentences are negative, and the last sentence is positive. There is also a strong shift in sentence similarity between sentences.

However, (2) is classified incorrectly. This is likely because it is identified by our system as similar sentiment in both sentences. There is also very little punctuation or emojis, and there are no indicative words, like discourse markers or interjections in the tweet, causing our system to fail.

These results demonstrate that a manually-selected feature-based system, using both structural and affective features can achieve reasonable success in identifying ironic content. This system is successful even when used with non-conventional language such as that seen in Twitter data. Our mean accuracy scores of .650 and .607 on the two subtasks on the training set demonstrates both a reasonable success, and an opportunity for future work in irony detection by extending the feature set further or even applying a deep learning approach to the problem when enough data is available.

7 Acknowledgments

This project was carried out as a part of CS 8761, Natural Language Processing, a graduate level class offered in Fall 2017 at the University of Minnesota, Duluth by Dr. Ted Pedersen.

NEUROSENT-PDI at SemEval-2018 Task 3: Understanding Irony in Social Networks Through a Multi-Domain Sentiment Model

Mauro Dragoni

Fondazione Bruno Kessler

Via Sommarive 18

Povo, Trento, Italy

dragoni@fbk.eu

Abstract

This paper describes the NeuroSent system that participated in SemEval 2018 Task 3. Our system takes a supervised approach that builds on neural networks and word embeddings. Word embeddings were built by starting from a repository of user generated reviews. Thus, they are specific for sentiment analysis tasks. Then, tweets are converted in the corresponding vector representation and given as input to the neural network with the aim of learning the different semantics contained in each emotion taken into account by the SemEval task. The output layer has been adapted based on the characteristics of each subtask. Preliminary results obtained on the provided training set are encouraging for pursuing the investigation into this direction.

1 Introduction

Sentiment Analysis is a natural language processing (NLP) task (Dragoni et al., 2015a) which aims at classifying documents according to the opinion expressed about a given subject (Federici and Dragoni, 2016a,b). Many works available in the literature address the sentiment analysis problem without distinguishing specific information context of documents when sentiment models are built.

The necessity of investigating this problem from a multi-domain perspective is led by the different influence that a term might have in different contexts. The idea of adapting terms polarity to different domains emerged only in the last decade (Blitzer et al., 2007; Dragoni and Petrucci, 2017). Multi-domain sentiment analysis approaches discussed in the literature focus on building models for transferring information between pairs of domains (Dragoni, 2015; Petrucci and Dragoni, 2015). While on the one hand such approaches allow to propagate specific domain in-

formation to others, their drawback is the necessity of building new transfer models every time a new domain has to be analyzed. Thus, such approaches do not have a great generalization capability of analyzing texts, because transfer models are limited to the N domains used for building the models.

The problem of detecting irony in text can be considered from a multi-domain perspective. The development of the social web has stimulated creative and figurative language use like irony. This frequent use of irony on social media has important implications for natural language processing tasks, which struggle to maintain high performance when applied to ironic text (Liu and Zhang, 2012; Maynard and Greenwood, 2014; Ghosh and Veale, 2016). Although different definitions of irony co-exist, it is often identified as a trope or figurative language use whose actual meaning differs from what is literally enunciated. As such, modeling irony has a large potential for applications in various research areas, including text mining, author profiling, detecting online harassment, and perhaps one of the most popular applications at present, sentiment analysis. As described by (Joshi et al., 2017), recent approaches to irony can roughly be classified into rule-based and machine learning-based methods. While rule-based approaches mostly rely upon lexical information and require no training, machine learning invariably makes use of training data and exploits different types of information sources, including bags of words, syntactic patterns, sentiment information or semantic relatedness. Recently, deep learning techniques gain increasing popularity for this task as they allow to integrate semantic relatedness by making use of, for instance, word embeddings.

In this paper, we discuss how the NeuroSent tool has been applied in SemEval 2018 Task 3 (Hee et al., 2018). The tool leverages on the

following pillars: (i) the use of word embeddings for representing each word contained in raw sentences; (ii) the word embeddings are generated from an opinion-based corpus instead of a general purpose one (like news or Wikipedia); (iii) the design of a deep learning technique exploiting the generated word embeddings for training the sentiment model; and (iv) the use of multiple output layers for combining domain overlap scores with domain-specific polarity predictions.

The last point enables the exploitation of linguistic overlaps between domains, which can be considered one of the pivotal assets of our approach. This way, the overall polarity of a document is computed by aggregating, for each domain, the domain-specific polarity value multiplied by a belonging degree representing the overlap between the embedded representation of the whole document and the domain itself.

2 Related Work

Sentiment analysis from the multi-task and multi-domain perspective is a research field which started to be explored only in the last decade. According to the nomenclature widely used in the literature (see (Blitzer et al., 2007; Dragoni and Petrucci, 2017)), we call *domain* a set of documents about similar topics, e.g. a set of reviews about similar products like mobile phones, books, movies, etc.. The massive availability of multi-domain corpora in which similar opinions are expressed about different topics opened the scenario for new challenges. Researchers tried to train models capable to acquire knowledge from a specific domain and then to exploit such a knowledge for working on documents belonging to different ones. This strategy was called domain adaptation. The use of domain adaptation techniques demonstrated that opinion classification is highly sensitive to the domain from which the training data is extracted. The reason is that when using the same words, and even the same language constructs, we may obtain different opinions, depending on the domain. The classic scenario occurs when the same word has positive connotations in one domain and negative connotations in another one, as we showed within the examples presented in Section 1.

Several approaches related to multi-domain sentiment analysis have been proposed. Roughly speaking, all of these approaches rely on one of the

following ideas: (i) the transfer of learned classifiers across different domains (Blitzer et al., 2007; Pan et al., 2010; Bollegala et al., 2013; Xia et al., 2013), and (ii) the use of propagation of labels through graph structures (Ponomareva and Thelwall, 2013; Tsai et al., 2013; Dragoni et al., 2015b; Dragoni, 2015, 2017; Petrucci and Dragoni, 2017, 2016, 2015; Dragoni et al., 2014; Dragoni and Petrucci, 2018).

While on the one hand such approaches demonstrated their effectiveness in working in a multi-domain environment, on the other hand they suffered by the limitation of being influenced by the linguistic overlap between domains. Indeed, such an overlap leads learning algorithms to infer similar polarity values to domains that are similar from the linguistic perspective.

The adoption of evolutionary algorithms within the sentiment analysis research field is quite recent. First studies focused on the use of evolutionary solutions for modeling financial indicators by starting from investors sentiments (Yamada and Ueda, 2005; Chen and Chang, 2005; Huang et al., 2012; Yang et al., 2017; Simoes et al., 2017). Here, the evolutionary component was used for learning the trend of financial indicators with respect to the sentiment information extracted from opinions provided by the investors. With respect to these papers, we propose an approach adopting evolutionary computation to a more fine-grained level where the evolution component affects also the polarities of opinion concepts.

Studies considering the use of evolutionary algorithms for optimizing the polarity values of opinion concepts have been proposed only recently (Ferreira et al., 2015; Onan et al., 2016, 2017). However, these works focused on learning candidate refinements of opinion concepts polarity without considering the context dimension associated with them. A variant of this problem is the use of polarity adaptation strategy in the field of social media and microblogs (Alahmadi and Zeng, 2015; Wang et al., 2014; Keshavarz and Abadeh, 2017; Hu et al., 2016; Fu et al., 2016; Gong et al., 2016).

With respect to state of the art, this work represents the first exploration of evolutionary algorithms for multi-domain sentiment analysis with the aim of learning multiple dictionaries of opinion concepts. Moreover, we differ from the literature by do not considering the propagation of polarity information across domain (i.e., we keep

them completely separated) in order to avoid transfer learning drawbacks.

3 System Implementation

NeuroSent has been entirely developed in Java with the support of the Deeplearning4j library¹ and it is composed by following two main phases:

- Generation of Word vectors (Section 3.1): raw text, appropriately tokenized using the Stanford CoreNLP Toolkit, is provided as input to a 2-layers neural network implementing the skip-gram approach with the aim of generating word vectors.
- Learning of Sentiment Model (Section 3.2): word vectors are used for training a recurrent neural network with an output layer customized based on the addressed subtask. The customizations have been explained in Section 4.

In the following subsections, we describe in more detail each phase by providing also the settings used for managing our data.

3.1 Generation of Word Vectors

The generation of the word vectors has been performed by applying the skip-gram algorithm on the raw natural language text extracted from the smaller version of the SNAP dataset (McAuley and Leskovec, 2013). The rationale behind the choice of this dataset focuses on three reasons:

- the dataset contains only opinion-based documents. This way, we are able to build word embeddings describing only opinion-based contexts.
- the dataset is multi-domain. Information contained into the generated word embeddings comes from specific domains, thus it is possible to evaluate how the proposed approach is general by testing the performance of the created model on test sets containing documents coming from the domains used for building the model or from other domains.
- the dataset is smaller with respect to other corpora used in the literature for building other word embeddings that are currently

freely available, like the Google News ones.² Indeed, as introduced in Section 1, one of our goal is to demonstrate how we can leverage the use of dedicated resources for generating word embeddings, instead of corpora's size, for improving the effectiveness of classification systems.

The aspect of considering only opinion-based information for generating word embeddings is one of the peculiarity of our system. While embeddings currently available are created from big corpora of general purpose texts (like news archives or Wikipedia pages), ours are generated by using a smaller corpus containing documents strongly related to the problem that the model will be thought for. On the one hand, this aspect may be considered a limitation of the proposed solution due to the requirement of training a new model in case of problem change. However, on the other hand, the usage of dedicated resources would lead to the construction of more effective models.

Word embeddings have been generated by the Word2Vec implementation integrated into the Deeplearning4j library. The algorithm has been set up with the following parameters: the size of the vector to 64, the size of the window used as input of the skip-gram algorithm to 5, and the minimum word frequency was set to 1. The reason for which we kept the minimum word frequency set to 1 is to avoid the loss of rare but important words that can occur in domain specific documents.

3.2 Learning of The Sentiment Model

The sentiment model is built by starting from the word embeddings generated during the previous phase.

The first step consists in converting each textual sentence contained within the dataset into the corresponding numerical matrix \mathbf{S} where we have in each row the word vector representing a single word of the sentence, and in each column an embedding feature. Given a sentence s , we extract all tokens t_i , with $i \in [0, n]$, and we replace each t_i with the corresponding embedding \mathbf{w} . During the conversion of each word in its corresponding embedding, if such embedding is not found, the word is discarded. At the end of this step, each sentence contained in the training set is converted in a matrix $\mathbf{S} = [\mathbf{w}^{(1)}, \dots, \mathbf{w}^{(n)}]$.

¹<https://deeplearning4j.org/>

²<https://github.com/mmihaltz/word2vec-GoogleNews-vectors>

Before giving all matrices as input to the neural network, we need to include both padding and masking vectors in order to train our model correctly. Padding and masking allows us to support different training situations depending on the number of the input vectors and on the number of predictions that the network has to provide at each time step. In our scenario, we work in a many-to-one situation where our neural network has to provide one prediction (sentence polarity and domain overlap) as result of the analysis of many input vectors (word embeddings).

Padding vectors are required because we have to deal with the different length of sentences. Indeed, the neural network needs to know the number of time steps that the input layer has to import. This problem is solved by including, if necessary, into each matrix S_k , with $k \in [0, z]$ and z the number of sentences contained in the training set, null word vectors that are used for filling empty word's slots. These null vectors are accompanied by a further vector telling to the neural network if data contained in a specific positions has to be considered as an informative embedding or not.

A final note concerns the back propagation of the error. Training recurrent neural networks can be quite computationally demanding in cases when each training instance is composed by many time steps. A possible optimization is the use of truncated back propagation through time (BPTT) that was developed for reducing the computational complexity of each parameter update in a recurrent neural network. On the one hand, this strategy allows to reduce the time needed for training our model. However, on the other hand, there is the risk of not flowing backward the gradients for the full unrolled network. This prevents the full update of all network parameters. For this reason, even if we work with recurrent neural networks, we decided to do not implement a BPTT approach but to use the default backpropagation implemented into the DL4J library.

Concerning information about network structure, the input layer was composed by 64 neurons (i.e. embedding vector size), the hidden RNN layer was composed by 128 nodes, and the output layers with a different number of nodes based on the addressed subtask. The network has been trained by using the Stochastic Gradient Descent with 1000 epochs and a learning rate of 0.002.

4 The Tasks

The SemEval 2018 Task 3 is composed by two different subtasks for the automatic detection of irony on Twitter. For the first subtask, participants should determine whether a tweet is ironic or not by simply assigning a binary value 0 or 1. While, for the second subtask, participants have to distinguish, among the ironic tweets, one of the three classes which tweets are further split.

Subtask #1: Ironic vs. Non-ironic The first subtask is a binary classification task where the system has to predict whether a tweet is ironic or not. Example of an ironic and non-ironic tweet are presented below, respectively:

- *I just love when you test my patience!! #not*
- *Had no sleep and have got school now #not happy*

The output layer of our neural network is composed by a single neuron implementing the SIGMOID activation function.

Subtask #2: Different types of irony The second subtask is a multiclass classification task where the system has to predict one out of four labels describing:

- i. verbal irony realized through a polarity contrast;
- ii. verbal irony without such a polarity contrast;
- iii. descriptions of situational irony; and,
- iv. non-irony

i

Instances of the category *Verbal irony by means of a polarity contrast* contains an evaluative expression whose polarity (positive, negative) is inverted between the literal and the intended evaluation. An example of this category is the following: “*I really love this year’s summer; weeks and weeks of awful weather.*”

Instead, instances of the category *Verbal irony without such a polarity contrast* do not show polarity contrast between the literal and the intended evaluation, but are nevertheless ironic. An example of this category is the following: “*Human brains disappear every day. Some of them have never even appeared.*”

Then, instances of the *Situational irony* category describe situations that fail to meet some expectations. An example is the following: “*Just saw a non-smoking sign in the lobby of a tobacco company.*”

Finally, the *Non-ironic* category contains instances that are clearly not ironic, or which lack context to be sure that they are ironic.

The output layer of our neural network is composed by four neurons and the SOFTMAX strategy has been implemented for selecting the most candidate class.

The NeuroSent system has been applied to both subtasks. In Section 5, we report the preliminary results obtained by NeuroSent on the training set compared with a set of baselines.

5 In-Vitro Evaluation

Approach	Task #3.1	Task #3.2
Support Vector Machine	0.4294	0.4415
Naive-Bayes	0.4388	0.4378
Maximum Entropy	0.4810	0.4629
CNN Architecture	0.5420	0.4891
NeuroSent	0.5687	0.5974

Table 1: Results obtained on the training set by NeuroSent and by the four baselines.

The NeuroSent approach have been preliminarily evaluated by adopting the Dranziera protocol (Dragoni et al., 2016).

The validation procedure leverages on a five-fold cross evaluation setting in order to validate the robustness of the proposed solution. The approach has been compared with four baselines: Support Vector Machine (SVM) (Chang and Lin, 2011), Naive Bayes (NB) and Maximum Entropy (ME) (McCallum, 2002), and Convolutional Neural Network (Chaturvedi et al., 2016).

In Table 1, we provide average Pearson correlation obtained on the five folds in which the training set has been split.

The obtained results demonstrated the suitability of NeuroSent with respect to the adopted baselines. We may also observed how solutions based on neural networks obtained a significant improvement with respect to the others for both tasks.

We performed a detailed error analysis concerning the performance of NeuroSent. In general, we observed how our strategy tends to provide

false negative predictions. An in depth analysis of some incorrect predictions highlighted that the embedded representations of some positive opinion words are very close to the space region of negative opinion words. Even if we may state that the confidence about positive predictions is very high, this scenario leads to have a predominant negative classification for borderline instances.

On the one hand, a possible action for improving the effectiveness our strategy is to increase the granularity of the embeddings (i.e. augmenting the size of the embedding vectors) in order to increase the distance between the positive and negative polarities space regions. On the other hand, by increasing the size of embedding vectors, the computational time for building, or updating, the model and for evaluating a single instance increases as well. Part of the future work, will be the analysis of more efficient neural network architectures able to manage augmented embedding vectors without negatively affecting the efficiency of the platform.

6 Conclusion

In this paper, we described the NeuroSent system presented at SemEval 2018 Task 3. Our system makes use of artificial neural networks to classify tweets by polarity or for detecting emotion levels. The results obtained on the training set demonstrated that the adopted solution is promising and worthy of investigation. Therefore, future work will focus on improving the system by exploring the integration of sentiment knowledge bases (Dragoni et al., 2015a) in order to move toward a more cognitive approach.

Abstract

This paper describes our system created for the SemEval-2018 Task 3: Irony detection in English tweets.

Our strongly constrained system uses only the provided training data without any additional external resources. Our system is based on Maximum Entropy classifier and various features using parse tree, POS tags, and morphological features. Even without additional lexicons and word embeddings we achieved fourth place in Subtask A and seventh in Subtask B in terms of accuracy.

1 Introduction

Frequent use of creative and figurative language on social media has important implications for natural language processing tasks such as sentiment analysis. The semantics of a sentence with creative or figurative language can be quite different from the same sentence with literal meaning and misinterpreting figurative language such as irony represents a significant challenge in sentiment analysis. Hercig and Lenc (2017) explored the effect of figurative language on sentiment analysis and confirmed that figurative language affects sentiment analysis.

The issue of automatic irony and/or sarcasm¹ detection has been addressed mostly in English, however there has been some research in other languages as well (e.g. Dutch (Liebrecht et al., 2013), Italian (Bosco et al., 2013), Brazilian Portuguese (Vanin et al., 2013), and Czech (Ptáček et al., 2014)).

2 Task

The goal of SemEval-2018 Task 3 (Van Hee et al., 2018) is to detect irony in English tweets. Subtask

¹There is only a weak boundary in meaning between irony, sarcasm and satire (Reyes et al., 2012)

A detects just binary score for irony and Subtask B also detects more detailed types of irony (non-ironic, ironic by clash, situational irony, and other forms of verbal irony). These subtasks correspond to their respective phases (A and B). Data for subtask B were available only after phase A was finished.

At the evaluation time the following descriptions of the submitted system labels were given:

- **Constrained:** only the provided training data were used to develop the system
- **Unconstrained:** additional training data were used

Only after the end of the phase A we learned that constrained systems can make use of additional resources like lexicons, dictionaries, embeddings, etc. Thus we introduce another system label to describe our system – strongly constrained.

- **Strongly Constrained:** using ONLY the the provided training/development data without any additional external resources (such as lexicons, embeddings, etc.)

Data statistics for Subtask A and Subtask B are shown in Table 1 and 2 respectively.

Label	Test	Train
Non-ironic	473 (60,3%)	1923 (50,2%)
Ironic	311 (39,7%)	1911 (49,8%)

Table 1: Data statistics for Subtask A.

3 System Description

For all experiments we use Maximum Entropy classifier with default settings from Brainy machine learning library (Konkol, 2014). Data pre-processing includes lower-casing and in some

Label	Test	Train
Non-ironic	473 (60,3%)	1923 (50,2%)
Ironic by clash	164 (20,9%)	1390 (36,3%)
Situational irony	85 (10,8%)	316 (8,2%)
Other irony	62 (7,9%)	205 (5,3%)

Table 2: Data statistics for Subtask B.

cases lemmatization². We utilize morphological analysis, parse trees, lemmatization, and POS tags from UDPipe (Straka et al., 2016).

3.1 Features

We tried to create the best strongly constrained feature set using various features using parse tree, POS tags, and morphological features. Most features listed below are based on the work of Hercig et al. (2016).

- **Character n -grams (ChN $_n$):** Separate binary feature for each n -gram representing the n -gram presence in the text. We do it separately for different orders $n \in \{1, 2, 3, 4, 5\}$ and remove n -gram with frequency $f \leq 2$.
- **Bag of Morphological features (BoM):** We use bag-of-words representation of a tweet, i.e. separate binary feature representing the occurrence of a morphological feature for all verbs in the tweet. The morphological features³ include abbreviation, aspect, definiteness, degree of comparison, evidentiality, mood, polarity, politeness, possessive, pronominal type, tense, verb form, and voice.
- **Bag of Parse Tree Tags (BoT):** We use bag-of-words representation of a tweet, i.e. separate binary feature representing the occurrence of a parse tree tag in the tweet. We remove tags with a frequency $f \leq 2$.
- **First Words (FW):** Bag of first five words with at least 2 occurrences.
- **Last Words (LW):** Bag of last five words with at least 2 occurrences.
- **List (List):** Binary feature representing the presence of the following words or characters (yay, yep, yes, ha, heh, um, uh, sh, so, no, !, ?, ., ', ") in tweet.

²Character n -grams and N-gram Shape use original words.

³<http://universaldependencies.org/u/feat/index.html>

- **N-gram Shape (NSh):** The occurrence of word shape n -gram in the tweet. Word shape assigns words into one of 24 classes⁴ similar to the function specified in (Bikel et al., 1997). We consider unigrams with frequency $f > 2$ and trigrams with frequency $f > 10$.
- **POS Count (POS):** We use the count of POS tags in a tweet as a feature. We remove POS tags with frequency $f \leq 10$.
- **POS Count Bins (POS-B):** We map the frequency of POS tags in a tweet into a one-hot vector with length three and use this vector as binary features for the classifier. The frequency belongs to one of three equal-frequency bins⁵. Each bin corresponds to a position in the vector. We remove POS tags with frequency ≤ 5 .
- **Root Bag of Words (R-BoW):** Bag of words for parent, siblings, and children of the root from the sentence parse tree. We use only words with POS⁶ matching adjective, interjection, noun, symbol, verb, and other.
- **TF-IDF:** Term frequency – inverse document frequency of a word computed from the training data for words with at least 5 occurrences and at most 50 occurrences.
- **Verb Bag of Words (V-BoW):** Bag of words for parent, siblings, and children of the verb from the sentence parse tree. We use only words with POS⁶ matching adverb, noun, adjective, verb, and auxiliary.
- **Word n -grams (WN $_n$):** Separate binary feature for each word n -gram representing the n -gram presence in the text. We do it separately for different orders $n \in \{1, 2, 3\}$ and remove n -gram with frequency $f \leq 2$.

3.2 Subtask A

We use a simple binary classification approach with the Maximum Entropy classifier and the features shown in Table 5. Blank space denotes that the corresponding feature has not been used.

⁴We use `edu.stanford.nlp.process.WordShapeClassifier` with the `WORDSHAPECHRIS1` setting available in Stanford CoreNLP library (Manning et al., 2014).

⁵The frequencies from the training data are split into three equal-size bins according to 33% quantiles.

* Original results achieved with all used features in the respective ablation study.

Table 6: Feature ablation study for Subtask B.

evaluation experiments using 10-fold cross validation on the training data for the team description *UWB submitted*. The team description *UWB best* represents the best settings according to the experiments on test data.

We performed ablation experiments to see which features are the most beneficial (see Table 5 and Table 6). Numbers represent the performance change when the given feature is removed.

We can see that many features in the submitted settings for both subtasks are not beneficial for the results, thus we remove them in the best settings for the given subtask. The best features apart from character n -grams include POS-B, FW, and BoM for both subtasks. In subtask A R-Bow, TF-IDF, and unigrams were also beneficial. In subtask B word shape n -grams were also helpful.

Detailed statistical analysis into the datasets and feature presence in the data would be needed in order to infer further insides.

5 Conclusion

We competed in both subtasks and ranked 4th in terms of accuracy in Subtask A and 7th in Subtask B. In terms of the F1-score measure we ranked 11th in Subtask A and 13th in Subtask B. However this comparison likely isn't fair because our system should not be considered just constrained

but strongly constrained.

Abstract

This paper describes our NIHRIO system for SemEval-2018 Task 3 “Irony detection in English tweets.” We propose to use a simple neural network architecture of Multilayer Perceptron with various types of input features including: lexical, syntactic, semantic and polarity features. Our system achieves very high performance in both subtasks of binary and multi-class irony detection in tweets. In particular, we rank third using the accuracy metric and fifth using the F_1 metric. Our code is available at: <https://github.com/NIHRIO/IronyDetectionInTwitter>.

1 Introduction

Mining Twitter data has increasingly been attracting much research attention in many NLP applications such as in sentiment analysis (Pak and Paroubek, 2010; Kouloumpis et al., 2011; Agarwal et al., 2011; Liu et al., 2012; Rosenthal et al., 2017; Cambria et al., 2018) and stock market prediction (Bollen et al., 2011; Vu et al., 2012; Bartov et al., 2015; Nofer and Hinz, 2015; Oliveira et al., 2017). Recently, Davidov et al. (2010) and Reyes et al. (2013) have shown that Twitter data includes a high volume of “*ironic*” tweets. For example, a user can use positive words in a Twitter message to her intended negative meaning (e.g., “*It is awesome to go to bed at 3 am #not*”). This especially results in a research challenge to assign correct sentiment labels for ironic tweets (Bosco et al., 2013; Ghosh et al., 2015; Farías et al., 2016; Nozza et al., 2017; Kannangara, 2018).

To handle that problem, much attention has been focused on automatic irony detection in Twitter (Davidov et al., 2010; Reyes et al., 2013; Barberi and Saggion, 2014; Rajadesingan et al., 2015; Farías et al., 2016; Sulis et al., 2016; Karoui et al.,

2017; Joshi et al., 2017; Huang et al., 2017; Ravi and Ravi, 2017). In this paper, we propose a neural network model for irony detection in tweets. Our model obtains the fifth best performances in both binary and multi-class irony detection subtasks in terms of F_1 score (Van Hee et al., 2018). Details of the two subtasks can be found in the task description paper (Van Hee et al., 2018). We briefly describe the subtasks as follows:

Subtask 1 (A): Ironic vs non-ironic This first subtask is a binary classification problem, in which we predict whether or not a tweet is *ironic*. For example, “*I just love when you test my patience!! #not*” is ironic, but “*Had no sleep and have got school now #not happy*” is non-ironic.

Subtask 2 (B): Different types of irony This second subtask is a multi-class classification problem, where we predict the correct label of a tweet from four classes: (1) *non-irony*, (2) *verbal irony by means of a polarity contrast*, (3) *other verbal irony* and (4) *situational irony*.

The remainder of this paper is organized as follows: We describe the ironic tweet dataset provided by the SemEval-2018 Task 3 in Section 2. We then describe our system in Section 3. The experimental results and conclusion are detailed in Section 4 and Section 5, respectively.

2 Dataset

The dataset consists of 4,618 tweets (2,222 ironic + 2,396 non-ironic) that are manually labelled by three students. Some pre-processing steps were applied to the dataset, such as the emoji icons in a tweet are replaced by a describing text using the Python emoji package.¹ Additionally, all the

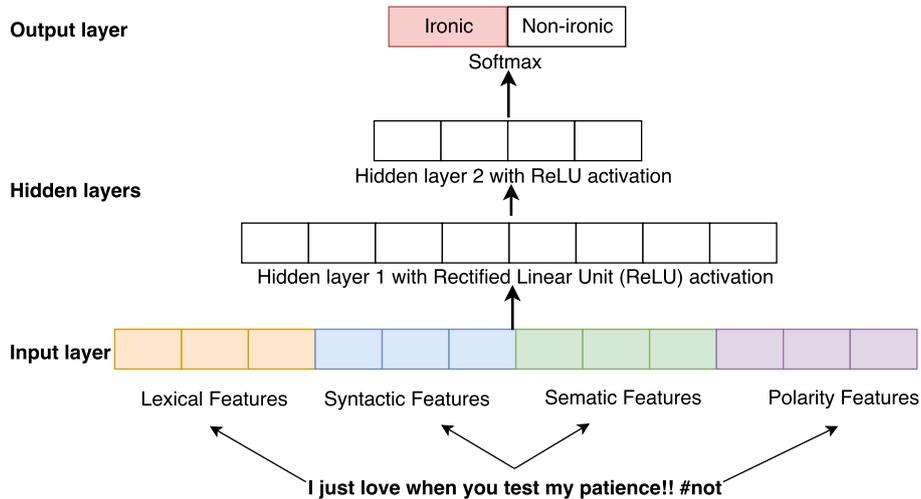

Figure 1: Overview of our model architecture for irony detection in tweets.

Statistics	Training	Test
#samples	3,834	784
#non-irony	1,923	473
#irony	1,911	311
- <i>polarity contrast verbal</i>	1,390	164
- <i>other verbal</i>	316	85
- <i>situational</i>	205	62

Table 1: Basic statistics of the provided dataset.

ironic hashtags, such as #not, #sarcasm, #irony, in the dataset have been removed. This makes difficult to correctly predict the label of a tweet. For example, “@coreybkking thanks for the spoiler!!!! #not” is an ironic tweet but without #not, it probably is a non-ironic tweet. The dataset is split into the training and test sets as detailed in Table 1.

Note that there is also an extended version of the training set, which contains the ironic hashtags. However, we only use the training set which does not contain the ironic hashtags to train our model as it is in line with the test set.

Our data pre-processing step: Tweet normalization is an important pre-processing step as there are around 15% of tweets containing 50% or more out-of-vocabulary tokens (Han and Baldwin, 2011). We normalize each tweet from the dataset using a lexicon-based approach proposed by Han et al. (2012), using a manually constructed normalization dictionary (e.g., “reeeaaalll” is normalized by “real”). We then replace all tagged users and urls by specific word tokens “<USER>” and “<URL>”, respectively. It is because they are likely not correlated with the ironic labels.

3 Our modeling approach

We first describe our MLP-based model for ironic tweet detection in Section 3.1. We then present the features used in our model in Section 3.2.

3.1 Neural network model

We propose to use the Multilayer Perceptron (MLP) model (Hornik et al., 1989) to handle both the ironic tweet detection subtasks. Figure 1 presents an overview of our model architecture including an input layer, two hidden layers and a softmax output layer. Given a tweet, the input layer represents the tweet by a feature vector which concatenates lexical, syntactic, semantic and polarity feature representations. The two hidden layers with ReLU activation function take the input feature vector to select the most important features which are then fed into the softmax layer for ironic detection and classification.

3.2 Features

Table 2 shows the number of lexical, syntactic, semantic and polarity features used in our model.

Lexical features: Our lexical features include 1-, 2-, and 3-grams in both word and character levels. For each type of n -grams, we utilize only the top 1,000 n -grams based on the term frequency-inverse document frequency (tf-idf) values. That is, each n -gram appearing in a tweet becomes an entry in the feature vector with the corresponding feature value tf-idf. We also use the number of characters and the number of words as features.

Name	# Features
Lexical features	2,002
Syntactic features	45
Semantic features	700
Polarity features	12
Total	2,759

Table 2: Number of features used in our model

Cluster	Word	Cluster	Word
110000	wife	11001000	adorable
110000	sister	11001000	excellent
110000	boyfriend	11001000	interesting
110000	daughter	11001000	blessed
110000	mum	11001000	easy
110000	son	11001000	perfect
110000	dad	11001000	cool
110000	family	11001000	funny

Table 3: Example of clusters produced by the Brown clustering algorithm.

Syntactic features: We use the NLTK toolkit to tokenize and annotate part-of-speech tags (POS tags) for all tweets in the dataset. We then use all the POS tags with their corresponding tf-idf values as our syntactic features and feature values, respectively.

Semantic features: A major challenge when dealing with the tweet data is that the lexicon used in a tweet is informal and much different from tweet to tweet. The lexical and syntactic features seem not to well-capture that property. To handle this problem, we apply three approaches to compute tweet vector representations.

Firstly, we employ 300-dimensional pre-trained word embeddings from GloVe (Pennington et al., 2014) to compute a tweet embedding as the average of the embeddings of words in the tweet.

Secondly, we apply the latent semantic indexing (Papadimitriou et al., 1998) to capture the underlying semantics of the dataset. Here, each tweet is represented as a vector of 100 dimensions.

Thirdly, we also extract tweet representation by applying the Brown clustering algorithm (Brown et al., 1992; Liang, 2005)²—a hierarchical clustering algorithm which groups the words with similar meaning and syntactical function together. Applying the Brown clustering algorithm, we obtain a set of clusters, where each word belongs to only

²<https://github.com/percyliang/brown-cluster>

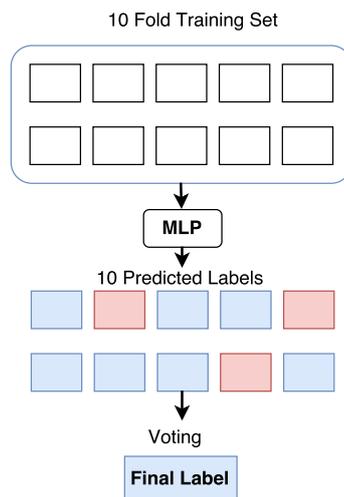

Figure 2: The training mechanism.

one cluster. For example in Table 3, words that indicate the members of a family (e.g., “mum”, “dad”) or positive sentiment (e.g., “interesting”, “awesome”) are grouped into the same cluster. We run the algorithm with different number of clustering settings (i.e., 80, 100, 120) to capture multiple semantic and syntactic aspects. For each clustering setting, we use the number of tweet words in each cluster as a feature. After that, for each tweet, we concatenate the features from all the clustering settings to form a cluster-based tweet embedding.

Polarity features: Motivated by the verbal irony by means of polarity contrast, such as “*I really love this year’s summer; weeks and weeks of awful weather*”, we use the number of polarity signals appearing in a tweet as the polarity features. The signals include positive words (e.g., love), negative words (e.g., awful), positive emoji icon and negative emoji icon. We use the sentiment dictionaries provided by Hu and Liu (2004) to identify positive and negative words in a tweet. We further use boolean features that check whether or not a negation word is in a tweet (e.g., *not*, *n’t*).

3.3 Implementation details

We use Tensorflow (Abadi et al., 2015) to implement our model. Model parameters are learned to minimize the the cross-entropy loss with L₂ regularization. Figure 2 shows our training mechanism. In particular, we follow a 10-fold cross-validation based voting strategy. First, we split the training set into 10 folds. Each time, we combine 9 folds to train a classification model and use the remaining fold to find the optimal hyperparameters.

Name	1 (A)	2 (B)
Hidden layers	(800, 400)	(800, 300)
# epoch	100	100
early stop	30	30
Learning rate	10^{-4}	10^{-4}
l_2	10^{-5}	10^{-5}

Table 4: The optimal hyperparameter settings for subtasks 1 (A) and 2 (B).

Accuracy	Precision	Recall	F_1
70.15 ₃	60.91	69.13	64.76 ₅

Table 5: The performance (in %) of our model on the test set for subtask 1 (binary classification). The subscripts denote our official ranking.

Table 4 shows optimal settings for each subtask.

In total, we have 10 classification models to produce 10 predicted labels for each test tweet. Then, we use the voting technique to return the final predicted label.

4 Experiments

4.1 Metrics

The metrics used to evaluate our model include *accuracy*, *precision*, *recall* and F_1 . The accuracy is calculated using all classes in both tasks. The remainders are calculated using only the positive label in subtask 1 or per class label (i.e., macro-averaged) in subtask 2. Detail description of the metrics can be found in Van Hee et al. (2018).

4.2 Results for subtask 1

Table 5 shows our official results on the test set for subtask 1 with regards to the four metrics. By using a simple MLP neural network architecture, our system achieves a high performance which is ranked **third** and **fifth** out of forty-four teams using accuracy and F_1 metrics, respectively.

4.3 Results for subtask 2

Table 6 presents our results on the test set for subtask 2. Our system also achieves a high performance which is ranked **third** and **fifth** out of thirty-two teams using accuracy and F_1 metrics, respectively. We also show in Table 7 the performance of our system on different class labels. For ironic classes, our system achieves the best performance on the verbal irony by means of a polarity contrast with F_1 of 60.73%. Note that the performance on the situational class is not high. The

Accuracy	Precision	Recall	F_1
65.94 ₃	54.46	44.75	44.37 ₅

Table 6: The performance (in %) of our model on the test set for subtask 2 (multi-class classification).

Class	Precision	Recall	F_1
Non-irony	72.97	79.92	76.29
Contrast verbal	53.21	70.73	60.73
Other verbal	48.78	23.53	31.75
Situational	42.86	4.84	8.70

Table 7: The performance (in %) of our model on the test set for each class label in subtask 2.

reason is probably that the number of situational tweets in the training set is small (205/3,834), i.e. not enough to learn a good classifier.

4.4 Discussions

Apart from the described MLP models, we have also tried other neural network models, such as Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) and Convolutional Neural Network (CNN) for relation classification (Kim, 2014). We found that LSTM achieves much higher performance than MLP does on the extended training set containing the ironic hashtags (about 92% vs 87% with 10-fold cross-validation using F_1 on subtask 1). However, without the ironic hashtags, the performance is lower than MLP’s. We also employed popular machine learning techniques, such as SVM (Hearst et al., 1998), Logistic Regression (Harrell, 2001), Ridge Regression Classifier (Le Cessie and Van Houwelingen, 1992), but none of them produces as good results as MLP does. We have also implemented ensemble models, such as voting, bagging and stacking. We found that with 10-fold cross-validation based voting strategy, our MLP models produce the best irony detection and classification results.

5 Conclusion

We have presented our NIHRIO system for participating the Semeval-2018 Task 3 on “Irony detection in English tweets”. We proposed to use Multilayer Perceptron to handle the task using various features including lexical features, syntactic features, semantic features and polarity features. Our system was ranked the fifth best performing one with regards to F_1 score in both the subtasks of binary and multi-class irony detection in tweets.
