Abstract

In this paper we describe our participation in the SemEval-2018 task 3 Shared Task on Irony Detection. We have approached the task with our low dimensionality representation method (LDR), which exploits low dimensional features extracted from text on the basis of the occurrence probability of the words depending on each class. Our intuition is that words in ironic texts have different probability of occurrence than in non-ironic ones. Our approach obtained acceptable results in both subtasks A and B. We have performed an error analysis that shows the difference on correct and incorrect classified tweets.

1 Introduction

With the existence of online social networks, a huge amount of information rapidly pervades, which attracting the attention of researchers to investigate the linguistic phenomenon that appears. One of these complex phenomenon is irony, where the speaker uses words that mean the opposite of the literal meaning and what others really think, especially in order to be funny¹. Moreover, irony can be considered as a strategy intended to criticise or to praise (Hernández-Farías et al., 2015). The detection of irony recently is quite a hot research topic due to its importance for efficient sentiment analysis (Ghosh et al., 2015). Also, another figurative language device noticed recently is sarcasm, where the writer intend to offend someone rather than creating a humor situation. In many research works, irony and sarcasm are often viewed as the same language device, or they considered irony as an umbrella term that covers also sarcasm (Wang,

2013). Several approaches have been proposed to detect irony, where most of them have turned the problem into a binary classification task using a set of features. (Carvalho et al., 2009) proposed one of the first works on irony detection. They worked on the identification of a set of patterns to identify ironic sentences. The adopted features were the use of punctuation marks and emoticons. (Reyes et al., 2013) proposed a model that employed four types of conceptual features: signatures, unexpectedness, style and emotional scenarios. (Barbieri and Saggion, 2014) proposed a model using lexical features, such as frequency of rare and common terms, synonyms, adjectives, emoticons, punctuation marks, positive and negative terms. Their results showed that the most important features are structure, frequency and synonyms for detecting irony in multiple datasets. (Karoui et al., 2015) presented a model to detect irony using a vector composed of six main groups of features: surface features (such as punctuation marks), sentiment (positive and negative words), sentiment shifter (positive and negative words in the scope of an intensifier), shifter (presence a negation word or reporting speech verbs), opposition (sentiment opposition or contrast between a subjective and an objective proposition) and internal contextual (the presence of personal pronouns). (Reyes et al., 2012) also studied the effect of multiple features to distinguish ironic and non-ironic tweets messages. The adopted features include quantifiers of sentence complexity, morphosyntactic and semantic ambiguity, polarity, unexpectedness, emotional activation, imagery, and pleasantness of words. (Wallace et al., 2015) presented a way to approach verbal irony classification by exploits contextual features, specifically by combining noun phrases and sentiment extracted

¹As defined in the Merriam Webster Dictionary, <http://www.merriam-webster.com/dictionary/irony>; accessed on Feb. 2018.

from comments using a dataset of comments collected from reddit site which is social news aggregation. Most of these features did well in detecting ironic sentences, where in general they relied on different types of high level features that use lexical resources, sentiment analysis methods or common terms occurrence. Based on these previous works, we investigate the using of low dimensional features extracted from a given text. LDR uses terms weights to represent the probability that each Twitter message belongs to a specific class (e.g. ironic vs. non-ironic). Our intuition is that words usage in ironic texts has different probability of occurrence than in non-ironic ones, and LDR is good at capturing these differences. LDR does not need external resources, hand-crafted features, and drastically reduces the dimensionality of the representation. This allows the method to deal with big data problems. In this paper, we present the participation of LDR in the SemEval-2018 task 3 on Irony Detection (Van Hee et al., 2018). The rest of the paper is structured as follows. In Section 2, the LDR method is presented. In Section 3, we discuss the results we have achieved in both tasks and further analyse the error in Section 4. For example, to know whether the terms usage changes depending on ironic and non-ironic tweets. Finally, we draw some conclusions in Section 5 together with future work proposals.

2 Low Dimensional Representation Description

We proposed the low dimensional representation (LDR) in (Rangel et al., 2017a). LDR has been used in multiple author profiling tasks (Rangel et al., 2017b; Litvinova et al., 2017), and especially in language variety identification (Franco-Salvador et al., 2015; Fabra et al., 2015). The key aspect of the LDR is the use of weights to represent the probability of each term belonging to each one of the different language varieties. In our approach we built a vector of features from a matrix of terms weights. Starting from a set of training documents, with using Tf-Idf weighting scheme, we built a matrix of terms weights where each row represents Tf-Idf terms weights of a document (specifically this row of term weights represents a unique class C of its document), and each column corresponds to a specific term. Therefore, we obtained another matrix where each term weight was built using the ratio between the weights of

the documents belonging to a concrete language variety C and the total distribution of weights for that term t over other documents, where each column in the matrix represents a term distribution overall documents.

AVG	The average weight of a document is calculated as the sum of weights $W(t,c)$ of its terms divided by the total number of vocabulary terms of the document.
STD	The standard deviation of the weight of a document is calculated as the root square of the sum of all the weights $W(t,c)$ minus the average.
MIN	The minimum weight of a document is the lowest term weight $W(t,c)$ found in the document.
MAX	The maximum weight of a document is the highest term weight $W(t,c)$ found in the document.
PROB	The overall weight of a document is the sum of weights $W(t,c)$ of the terms of the document divided by the total number of terms of the document.
PROP	The proportion between the number of vocabulary terms of the document and the total number of terms of the document.

Table 1: LDR features for each classification class

Then, a vector of features was built where each feature was obtained in a different way, Table 1 describes the used features in LDR. In this paper, we used LDR in order to investigate its performance in irony detection classification task. LDR was proposed for different application where its discriminative statistical features proved to be efficient for classification purposes. Therefore, in this task, we investigated the LDR efficiency in irony detection, where the implicit meaning of a sentence is required to identify the correct class type.

3 Experiments and Results

During the experiments, LDR was tested using different classifiers. In the following sections we will illustrate the experiments that we carried out. For the evaluation, we used both accuracy and macro-average F-score. Moreover, the error anal-

Dataset	# of tweets	# Positive	# Negative
SemEval-2018	3,834	1,911	1,923
(Karoui et al., 2017)	540	540	-
(Ptáček et al., 2014)	67,779	18,889	48890

Table 2: Number of positive and negative tweets in the used datasets - Task A.

ysis we did allowed us to further understand the behavior of LDR in irony detection.

3.1 Data

We trained our model using the provided task 3 dataset with other two datasets collected previously by other researchers. The task A training subset consists of 3,834 tweets, where 1,911 tweets labeled as irony and 1,923 as not. While in task B, the same number of tweets was used with different type of subcategories. The tweets distribution over the categories was as follows: 1,390 irony tweets with a polarity contrast (labeled as 1), 316 as situational irony tweets (labeled as 2), 205 irony tweets without a polarity contrast (labeled as 3), and finally 1,923 non-irony tweets (labeled as 0). The second dataset that we used was provided by (Karoui et al., 2017) by collecting tweets using the Twitter API. The authors searched a set of keywords for different topics, such as politics, sport, artists, locations, Arab Spring, environment, racism, health, social media. These topics have been discussed in the French and American media during a specific period. We used the English part of the dataset which consists of 540 tweets. The last dataset was created by (Ptáček et al., 2014). The dataset approximately consists of 67,800 tweets of sarcasm linguistic phenomenon. As in the previous dataset, they used the Twitter API to collect the tweets but looking for the "sarcasm" hashtag. Table 2 summarises the statistical numbers of the datasets. We have conducted several experiments by combining the described datasets.

3.2 Task A

We have tested LDR with different classifiers using the Weka toolkit with standard parameters and conducted 10-fold cross-validation to find out the classifier that achieves the best results. LDR has achieved 64% of accuracy and 65% of F-score

with the DecisionStump classifier. To improve the results, we adopted the Majority Vote (MV) algorithm using the results that were generated by the other two datasets with the training subset, each combined with the training part of task A subset in the 10-fold cross-validation. To note, none of the datasets improves the results more than using the task A subset independently. In spite of that, combining with Karoui *et al.* dataset achieved its highest results with Multilayer Perceptron classifier, and with Ptacek *et al.* dataset with REPTree classifier. By applying MV, we improved by 0.6% in accuracy the previous results obtained only with the task A training subset. Accordingly, we submitted two different runs, constrained and not. In the constrained one, we used the DecisionStump classifier with the task A training subset independently, while in the unconstrained, we used MV combining the three described datasets.

3.3 Task B

In this task, we experimented several runs that are similar to task A experiments. Since we did not find such a dataset with the used four subcategories, no other subset involved in this task experiments. Therefore, 10-cross validation technique was used without involving any other dataset. For the accuracy, the MultiClassUpdateable classifier achieved the highest result with 60.68%, while for the macro average F-score BayesNet achieved 38%. Accordingly, we adopted the classifiers that have the highest results in F-score to apply MV where BayesNet, NaiveBayes and NaiveBayesUpdateable classifiers are involved. By applying MV, we got a value 39% of macro average F-score. Finally, when the test subset for each task was released, we submitted our runs for each task. For the task A, both constrained and unconstrained runs were submitted while for task B, only the constrained run was submitted. Upon that, LDR attained the results that are in Table 2.

Tasks	Run Type	Accuracy	F-score
Task A	Constrained	0.56	0.43
	Unconstrained	-	0.43
Task B	Constrained	0.46	0.23

Table 3: LDR classification results of Task A and B using Accuracy and Macro average F-score.

The classification results for both runs in task A achieved the same score in terms of F-score mea-

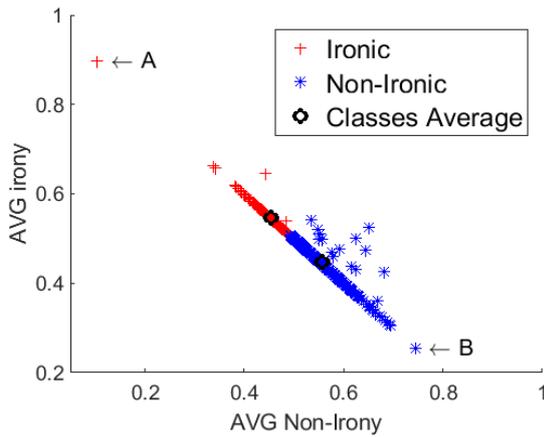

Figure 1: The distribution of **correctly classified** cases in term of AVG feature.

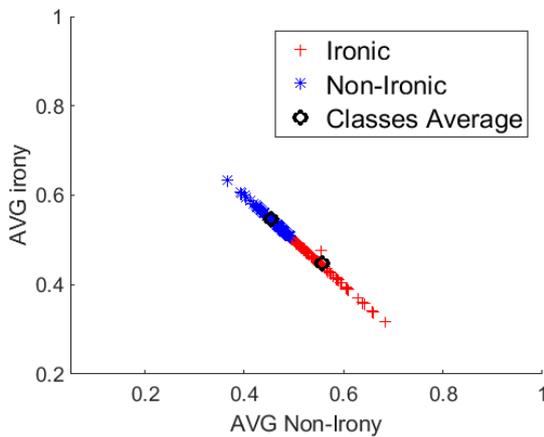

Figure 2: The distribution of **incorrectly classified** cases in term of AVG feature.

sure with some tiny progress to the unconstrained run. In the task B, LDR achieved a lower result comparing to task A. We believe that the reason is due to the number of training records for some classes in the training subset is small comparing to the other classes (unbalanced subset), where our model on these classes has a high bias (underfitting). Another possibility could be regarding to the LDR features, where maybe some of them could not be suitable for such task.

4 Error Analysis

We aim from analyzing the error of LDR to better understand the weak classification results that were obtained, especially in task B. We started with investigating the ability of LDR features to

discriminate the data. So, we applied the Gain-Ratio algorithm for features selection under the Weka toolkit to evaluate and to find out how much the LDR features are relevant to the irony training subset. The GainRatio result shows that LDR features were weak in discriminating the data, where the highest ranked attribute is the AVG feature for class 1 (ironic) with a value of 10%, followed by the AVG feature of class 0 (non-ironic) with 9%, where the rest of features are lower.

In the Fig. 1 and 2, we plotted the distribution of AVG feature of both correctly classified and incorrectly classified cases in test subset of task A, to show how they are distributed. In both figures, we can figure out that there is an overlapping between ironic and the non-ironic classes. To deduce which of them is more overlapped, we calculated the Euclidean distance (Ed) between the average points (the black circles) of both classes in each figure. As a result, the Ed in the Fig.1 of the correctly classified cases is 0.143, whilst in the second figure is 0.102. Therefore, the overlapping between both classes in the Fig.1 is lower than in the second figure, which clearly shows that the AVG feature is a good feature to infer both ironic and non-ironic classes.

As we discussed before, the LDR features are built based on a weighting scheme. Therefore, the larger is the training subset used, the more classification accuracy our model produces. To infer this fact, we investigated manually the AVG weights of two cases from the Fig. 1, to show how the weights are differentiated when: 1) a correctly classified ironic and non-ironic cases are far from each other in the figure, 2) and when they are near. Therefore, in the first case, we selected the cases A and B where they are far from each other. The tweets of A and B points in the figure are:

Ironic (A)

Yay jury duty #sarcasm

We found that the term "Yay" was mentioned frequently in the ironic cases, where the writer used it as a figurative term to represent an irony situation. Meanwhile, this term was presented rarely in the non-ironic tweets. Therefore, this term made a distinctive situation for this tweet. The other two terms "jury & duty" were not used in the process of weights building of the tweets, since we excluded terms that rarely appeared in the corpus.

Classes	Classified as				Correct
	0	1	2	3	
0	270	108	59	36	57%
1	36	104	19	5	64%
2	36	16	24	9	29%
3	32	9	17	4	6%

Table 4: Confusion matrix of the 4-class classification.

Non-Ironic (B)

```
Extended cut "NICHA"
https://t.co/qdzpcuRqc1
#trailer #spoof #film #dramatic
#action #film2014 #youtube
#fightscenes
```

Similarly in this tweet, the terms have a high probability of occurrence in the non-ironic tweets while a very small probability in the ironic tweets. For the second case, we took other two tweets from the overlapping area between the ironic and non-ironic tweets. The tweets' terms weights are very similar to each other where the terms in both sentences were mentioned. This is what makes the tweets AVG features near to each in the figure.

For the task B, we built a confusion matrix to clarify the predictions of test subset cases, as in Table 3. We can conclude that: in the classes that have a low number of training records (2 and 3), our model was highly confused in detecting their original labels, where a very small number of cases was classified correctly with a detection ratio of 29% and 6% for class 2 and 3 sequentially. Moreover, the highest confusion occurs from class 0 to class 1 where 108 cases were classified incorrectly, where the lowest was from class 1 to class 3. In general, both classes 1 and 2 were correctly classified better than 2 and 3 classes. In our view, our model did not fit the training subset for the classes 2 and 3.

5 Conclusion

In this paper, we have evaluated LDR on the irony detection task to investigate its performance on irony detection. Using LDR the classification task accomplished with accepted results without using any semantic, sentiment or contextual features. Despite the fact that LDR previously

showed its competitive results on language variety identification and author profiling tasks and outperformed traditional state-of-the-art representations, from the results of this shared task we can conclude that the low dimensionality features do not perform as good as other language dependent features do, and from our point of view, they are not suitable to infer of such language phenomenon as irony. As future work we will continue studying how LDR will perform on other language applications.

Abstract

In this paper we introduce our system for the task of Irony detection in English tweets, a part of SemEval 2018. We propose representation learning approach that relies on a multi-layered bidirectional LSTM, without using external features that provide additional semantic information. Although our model is able to outperform the baseline in the validation set, our results show limited generalization power over the test set. Given the limited size of the dataset, we think the usage of more pre-training schemes would greatly improve the obtained results.

1 Introduction

Sentiment analysis and emotion recognition, as two closely related subfields of affective computing, play a key role in the advancement of artificial intelligence (Cambria et al., 2017). However, the complexity and ambiguity of natural language constitutes a wide range of challenges for computational systems.

In the past years irony and sarcasm detection have received great traction within the machine learning and NLP community (Joshi et al., 2016), mainly due to the high frequency of sarcastic and ironic expressions in social media. Their linguistic collocation inclines to flip polarity in the context of sentiment analysis, which makes machine-based irony detection critical for sentiment analysis (Poria et al., 2016; Van Hee et al., 2015). Irony is a profoundly pragmatic and versatile linguistic phenomenon. As its foundations usually lay beyond explicit linguistic patterns in reconstructing contextual dependencies and latent meaning, such as shared knowledge or common knowledge (Joshi et al., 2016), automatically detecting it remains a challenging task in natural language processing.

In this paper, we introduce our system for the shared task of Irony detection in English tweets, a part of the 2018 SemEval (Van Hee et al., 2018). We note that computational approaches to automatically detecting irony often deploy expensive feature-engineered systems which rely on a rich body of linguistic and contextual cues (Bamman and Smith, 2015; Joshi et al., 2015). The advent of Deep Learning applied to NLP has introduced models that have succeeded in large part because they learn and use their own continuous numeric representations (Hinton, 1984) of words (Mikolov et al., 2013), offering us the dream of forgetting manually-designed features. To this extent, in this paper we propose a representation learning approach for irony detection, which relies on a bidirectional LSTM and pre-trained word embeddings.

2 Data and pre-processing

For the shared task, a balanced dataset of 2,396 ironic and 2,396 non-ironic tweets is provided. The ironic corpus was constructed by collecting self-annotated tweets with the hashtags *#irony*, *#sarcasm* and *#not*. The tweets were then cleaned and manually checked and labeled, using a fine-grained annotation scheme (Van Hee et al., 2015). The corpus comprises different types of irony:

- Verbal irony (polarity contrast): 1,728 instances
- Other types of verbal irony: 267 instances.
- Situational irony: 401 instances

Verbal irony is often referred to as an utterance that conveys the opposite meaning of what of literally expressed (Grice, 1975; Wallace, 2015), e.g. *I love annoying people*. Situational irony appears

in settings, that diverge from the expected (Lucariello, 1994), e.g. *an old man who won the lottery and died the next day*. The latter does not necessarily exhibit polarity contrast or other typical linguistic features, which makes it particularly difficult to classify correctly.

For the pre-processing we used the Natural Language Toolkit (Loper and Bird, 2002). As a first step, we removed the following words and hash-tagged words: *not*, *sarc*, *sarcasm*, *irony*, *ironic*, *sarcastic* and *sarcast*, in order to ascertain a clean corpus without topic-related triggers. To ease the tokenizing process with the NLTK TweetTokenizer, we replaced two spaces with one space and removed usernames and urls, as they do not generally provide any useful information for detecting irony.

We do not stem or lowercase the tokens, since some patterns within that scope might serve as an indicator for ironic tweets, for instance a word or a sequence of words, in which all letters are capitalized (Tsur et al., 2010).

3 Proposed Approach

The goal of the subtask A was to build a binary classification system that predicts if a tweet is ironic or non-ironic. In the following sections, we first describe the dataset provided for the task and our pre-processing pipeline. Later, we lay out the proposed model architecture, our experiments and results.

3.1 Word representation

Representation learning approaches usually require extensive amounts of data to derive proper results. Moreover, previous studies have shown that initializing representations using random values generally causes the performance to drop. For these reasons, we rely on pre-trained word embeddings as a means of providing the model the adequate setting. We experiment with GloVe¹ (Pennington et al., 2014) for small sizes, namely 25, 50 and 100. This is based on previous work showing that representation learning models based on convolutional neural networks perform well compared to traditional machine learning methods with a significantly smaller feature vector size, while at the same time preventing over-fitting and accelerates computation (e.g (Poria et al., 2016).

¹nlp.stanford.edu/projects/glove

GloVe embeddings are trained on a dataset of 2B tweets, with a total vocabulary of 1.2 M tokens. However, we observed a significant overlap with the vocabulary extracted from the shared task dataset. To deal with out-of-vocabulary terms that have a frequency above a given threshold, we create a new vector which is initialized based on the space described by the infrequent words in GloVe. Concretely, we uniformly sample a vector from a sphere centered in the centroid of the 10% less frequent words in the GloVe vocabulary, whose radius is the mean distance between the centroid and all the words in the low frequency set. For the other case, we use the special *UNK* token.

To maximize the knowledge that may be recovered from the pre-trained embeddings, specially for out-of-vocabulary terms, we add several token-level and sentence-level binary features derived from simple linguistic patterns, which are concatenated to the corresponding vectors.

Word-level features

1. If the token is fully lowercased.
2. If the Token is fully uppercased.
3. If only the first letter is capitalized.
4. If the token contains digits.

Sentence-level features

1. If any token is fully lowercased.
2. If any token is fully uppercased.
3. If any token appears more than once.

3.2 Model architecture

Recurrent neural networks are powerful sequence learning models that have achieved excellent results for a variety of difficult NLP tasks (Ian Goodfellow, Yoshua Bengio, 2017). In particular, we use the last hidden state of a bidirectional LSTM architecture (Hochreiter and Urgan Schmidhuber, 1997) to obtain our tweet representations. This setting is currently regarded as the state-of-the-art (Barnes et al., 2017) for the task on other datasets. To avoid over-fitting we use Dropout (Srivastava et al., 2014) and for training we set binary cross-entropy as a loss function. For evaluation we use our own wrappers of the the official evaluation scripts provided for the shared tasks, which are based on accuracy, precision, recall and F1-score.

4 Experimental setup

Our model is implemented in PyTorch (Paszke et al., 2017), which allowed us to easily deal with the variable tweet length due to the dynamic nature of the platform. We experimented with different values for the LSTM hidden state size, as well as for the dropout probability, obtaining best results for a dropout probability of 0.1 and 150 units for the the hidden vector. We trained our models using 80% of the provided data, while the remaining 20% was used for model development. We used Adam (Kingma and Ba, 2015), with a learning rate of 0.0001 and early stopping when performance did not improve on the development set. Using embeddings of size 100 provided better results in practice. Our final best model is an ensemble of four models with the same architecture but different random initialization.

To compare our results, we use the provided baseline, which is a non-parameter optimized linear-kernel SVM that uses TF-IDF bag-of-word vectors as inputs. For pre-processing, in this case we do not preserve casing and delete English stop-words.

5 Results

To understand how our strategies to recover more information from the pre-trained word embeddings affected the results, we ran ablation studies to compare how the token-level and sentence-level features contributed to the performance. Table 1 summarizes the impact of these features in terms of F1-score on the validation set.

Feature	Yes	No
Token-level	0.6843	0.7008
Sentence-level	0.6848	0.6820

Table 1: Results of our ablation study for binary features in terms of F1-Score on the validation set.

We see that sentence-level features had a positive yet small impact, while token-level features seemed to actually hurt the performance. We think that since the task is performed at the sentence-level, probably features that capture linguistic phenomena at the same level provide useful information to the model, while the contributions of other finer granularity features seem to be too specific for the model to leverage on.

Table 2 summarizes our best single-model results on the validation set (20% of the provided

data) compared to the baseline, as well as the official results of our model ensemble on the test data.

Split	Accuracy	Precision	Recall	F1-score
Baseline Valid	0.6375	0.6440	0.6096	0.6263
Ours Valid	0.6610	0.6369	0.8447	0.7262
Ours Test	0.3520	0.2568	0.3344	0.2905

Table 2: Summary of the obtained best results on the valid/test sets.

Out of 43 teams our system ranked 421st with an official F1-score of 0.2905 on the test set. Although our model outperforms the baseline in the validation set in terms of F1-score, we observe important drops for all metrics compared to the test set, showing that the architecture seems to be unable to generalize well. We think these results highlight the necessity of an ad-hoc architecture for the task as well as the relevance of additional information. The work of Felbo et al. (2017) offers interesting contributions in these two aspects, achieving good results for a range of tasks that include sarcasm detection, using an additional attention layer over a BiLSTM like ours, while also pre-training their model on an emoji-based dataset of 1246 million tweets.

Moreover, we think that due to the complexity of the problem and the size of the training data in the context of deep learning better results could be obtained with additional resources for pre-training. Concretely, we see transfer learning as one option to add knowledge from a larger, related dataset could significantly improve the results (Pan and Yang, 2010). Manually labeling and checking data is a vastly time-consuming effort. Even if noisy, collecting a considerably larger self-annotated dataset such as in Khodak et al. (2017) could potentially boost model performance.

6 Conclusion

In this paper we presented our system to SemEval-2018 shared task on irony detection in English tweets (subtask A), which leverages on a BiLSTM and pre-trained word embeddings for representation learning, without using human-engineered features. Our results showed that although the generalization capabilities of the model are limited, there are clear future directions to improve. In particular, access to more training data and the deployment of methods like transfer learning seem to be promising directions for future research in representation learning-based sarcasm detection.

PunFields at SemEval-2018 Task 3: Detecting Irony by Tools of Humor Analysis

Elena Mikhalkova, Yuri Karyakin, Dmitry Grigoriev,
Alexander Voronov, and Artem Leoznov

Tyumen State University, Tyumen, Russia
(e.v.mikhalkova, y.e.karyakin)@utmn.ru

Abstract

The paper describes our search for a universal algorithm of detecting intentional lexical ambiguity in different forms of creative language. At SemEval-2018 Task 3, we used PunFields, the system of automatic analysis of English puns that we introduced at SemEval-2017, to detect irony in tweets. Preliminary tests showed that it can reach the score of F1=0.596. However, at the competition, its result was F1=0.549.

1 Introduction

It requires no proof that usually language users can detect lexical ambiguity in figurative speech without classifying it into types like metaphor, pun, humor, irony, sarcasm, etc. At the same time, such terminology is necessary in studying these phenomena as well as solving problems of automatic classification. In our opinion, programs dealing with intentional lexical ambiguity should be more like natural language users, i.e. they should have one general mechanism of its detection optimized to a certain extent to different types of creative language. In Task 3 “Irony Detection in English Tweets” of SemEval-2018 (Van Hee et al., 2018), we attempted to employ PunFields, our previously introduced classifier of English puns (Mikhalkova and Karyakin, 2017b)¹, in the task of irony classification in tweets as the constrained submission. I.e. PunFields trained only on the Gold dataset released by the Organizers.

As for the unconstrained submission, we used a bag-of-words model with an SVM classifier. The training dataset was enriched with tweets from other SemEval competitions. We will discuss it in a separate paragraph later in detail.

The results of PunFields in this competition were above the chance value (cf.: Table 1) demon-

	Ac.	Prec.	Rec.	F1 s.
Con.	0.5765	0.4753	0.6495	0.5489
Unc.	0.6033	0.5000	0.5563	0.5266
Hom.	0.6782	0.7993	0.7337	0.7651
Het.	0.5747	0.7580	0.5940	0.6661

Table 1: Results of PunFields at SemEval 2018 Task 3 and SemEval 2017 Task 7. Ac. - accuracy, Prec. - precision, Rec. - recall, F1 s. - F1 score. SemEval-2018: Con. - Constrained submission, Unc. - Unconstrained submission. SemEval-2017: Hom. - homographic puns, Het. - heterographic puns.

strating higher scores of Recall and F1 score, but lower Accuracy and Precision compared to the enriched bag-of-words (unconstrained submission). In analysis of puns, PunFields is more efficient reaching F1=0.765.

In this paper we will briefly outline the state-of-the-art system and possible reasons for its competition results.

2 Lexical Ambiguity in Irony and Puns

We will demonstrate similarity between a pun and irony by the two following examples.

Christmas shopping on 2 hours sleep is going to be **fun**.

In this ironic tweet from the Gold dataset of the competition, the word **fun** is used simultaneously in the meaning “joy, amusement”, in the context of “Christmas shopping”, and in the meaning, opposite to it, “problem, trouble”, in the context of “2 hours sleep.” This *opposition* of meanings put into one word or phrase constitutes the essence of what many researchers call irony (Van Hee, 2017; Barbieri and Saggion, 2014).

I could tell you a chemistry joke, but I know I wouldn’t get a **reaction**.

¹<https://github.com/evrog/PunFields>

In the pun above from the Gold dataset of SemEval2017 (Miller et al., 2017), the word **reaction** is used simultaneously in the meaning “chemical reaction”, in the context of “chemistry”, and in the meaning “emotional response”, in the context of “joke”. The only difference between the pun and irony in these examples is that in puns the opposition of meanings is more pragmatic. I.e. the two meanings of **reaction** belong to different spheres of human activity. In irony, the opposition is binary: fun=not fun.

In the both cases, the two meanings are evoked by two contexts, scripts, or themes. Therefore, if a computer program detects coexistence of two topics within an utterance, it is likely to classify correctly both pun and irony, but would be unable to tell which type it deals with. But can ordinary sentences without an intentionally ambiguous word or phrase also contain two scripts? Let us demonstrate what happens to a pun and irony if we transform them into sentences without ambiguity:

Christmas shopping on 2 hours sleep is **not** going to be fun / is going to be a **problem**.

I could tell you a chemistry joke, but I know I wouldn't get an **emotional** reaction / a **chemical** reaction.

When we transform these sentences, one of the scripts in a pun starts to dominate, for example the three word unity “joke + emotional reaction” would outnumber the one-word script of “chemistry”, and vice versa “chemistry + chemical reaction” would outnumber the script of “joke”.

However, in case of irony, this ambiguity is not so obvious. On the one hand, if we change “fun” to “problem”, words “sleep”, “hours” and “problem” *can* form a script. Although this script is not so easily recognizable and requires knowledge that two hours of sleep is too little (for example in the known semantic vector representations of words or documents sleep *can* be found close to lack, fatigue, and time). On the other hand, if we leave the word “fun” in the sentence and just add “not” to it (“not going to be fun”), our algorithm will need to process auxiliary words and other variants of negation: never, neither, don't, etc. But these stop-words often create noise in searching for the main topics. If we ignore “not”, the script “Christmas shopping + fun” would still form a union and dominate in the utterance.

In sum, intentional lexical ambiguity in irony is not easy for recognition compared to more explicit speech genres like puns. Another feature of irony that supports this statement is that otherwise there would be no need to mark irony with indicators of ambiguity like hashtags and emoji.²

3 PunFields

PunFields is a program that turns an utterance into a vector of length 39 based on 39 semantic classes of Roget's Thesaurus called Sections.³ A thesaurus is a kind of dictionary that unites words into classes that build a hierarchy. Unlike WordNet, the hierarchy is designed by the author/-s of a thesaurus beforehand (top-down approach). Roget's Thesaurus places all lexemes at the lowest level on the basis of their semantic proximity. The clusters of words then unite into Sections, Sections into Divisions, Divisions into Classes. The 39 Sections of Roget's Thesaurus are in a way similar to dimensions of the word2vec algorithm (Mikolov et al., 2013), but word2vec has a fine tuning of meaning proximities.

Data Preprocessing. Before submitting data to PunFields, tweets are put into a preprocessing pipeline. The first step in the pipeline is separating symbols from words in a way that mentions (start with “@”) and hashtags (start with “#”) are left intact. Emoji are processed as word combinations (“:ok_hand_sign:” is simply “ok hand sign”). Words in hashtags are often separated with a “_”. Hence, we add a space before and after each “_”. For example, the line “@kennychesney, :ok_hand_sign: #New#color#new#beginning” becomes “@kennychesney , : ok _ hand _ sign : #New #color #new #beginning”.

The next step is treatment of emphatic devices in words that are not mentions and hashtags. We judge words with one letter repeated more than

²There are cases when it is impossible to recognize ambiguity without such indicators. For example, “Luv this” or “Sitting in this hall is fun” can be expressions of the real state of things unless the user adds a hashtag “#not”, an emoji like “unamused face”, etc. Note that these indicators quite often come at a particular place - end of the utterance. This fact also brings irony and puns together: in puns, usually the target word (the word used in the two senses) also occurs in the end.

³In (Mikhalkova and Karyakin, 2017a), we tried to join some of these classes together for a better performance, but it appeared that such enlargement does not improve it. And vice versa when we reach a certain number of general classes - approximately 4 - the performance starts to decrease significantly.

two times as emphasized. The words are “de-emphasized”. For example, the word “everrrrrr” becomes “ever”.

We then proceed to mentions and hashtags. As there can be capitalized real names or titles, we de-capitalize them starting with the second letter and add a space before the capital letter and after the word, for example, “#ElektrikBLOOM” becomes “Elektrik Bloom”. If there are (successions of) numbers, a space is added on the both sides of the number. If there are names spelt as one word like “@WhoopiGoldberg”, we add a space after every succession starting with a capital letter: “Whoopi Goldberg”.

Some mentions and hashtags are problematic to process as words are written without any indication that they should be separate, e.g. “kenny-chesney”. We check in the NLTK names dictionary (Bird et al., 2009) if the glued hashtag starts with any name of length more than 5 characters. If yes, we unglue the word at the name borderline capitalizing the first letters: “Kenny Chesney” (as luck would have it, most names consist of just two parts). Otherwise, we consider the word to be something other than a name. To separate words with spaces, we use Wordninja⁴. This library has problems with names and titles, so we have to check the names before using it. Words of more than two characters are also checked in a list of slang abbreviations. For example, “bbq” becomes “barbeque”.⁵

Tweet to Vector. Preprocessed tweets go into the classifier. PunFields collects Section numbers for every word and collocation in a sentence, removing duplicates and excluding stop words. Then, it builds a semantic vector of the sentence weighing how many of its elements belong to each Section. For example, the tweet “Christmas shopping on 2 hours sleep is going to be fun” has 7 words belonging to different Sections: shopping - 33; 2 - 4; sleep - 11, 27, 14, 34; go - 11, 0, 14, 35, 7; christmas - 38, 5; fun - 35; hour - 5. Its vector will be as follows: {1, 0, 0, 0, 1, 2, 0, 1, 0, 0, 0, 2, 0, 0, 2, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 1, 0, 0, 0, 0, 0, 1, 1, 2, 0, 0, 1}.

Classification. When the vectors are ready, we split them into a training and test set. The classification is conducted using different Scikit-learn (Pedregosa et al., 2011) algorithms. At the

present competition, we used SVM with the linear kernel, because preliminary tests using the Gold dataset with a 5-fold cross validation showed that it has the highest result among the tested algorithms: Precision=0.556, Recall=0.646, F1-score=0.596 (766 samples in a training set). However, when we used all the 3834 samples for training during the competition, they obviously created a too noisy feature space for a good generalization. Hence, the decrease in the result. At SemEval2017 (Miller et al., 2017), when we tried larger datasets for training, the result grew better. Tweets generally seem to be more “noisy” than puns due to slang, contractions, glued words, etc. although there are no strict ways of calculating this “noisyness”.

Instead of SVM, we also tested a deep learning network with different architectures implemented in the Python library Keras (Chollet et al., 2015) with TensorFlow (TensorFlow Development Team, 2015) and Theano (Theano Development Team, 2016) backends, but we only managed to reach as much as 0.56 for F1-score.⁶ Furthermore, we tried to replace Roget’s semantic classes with a vector model realization via the Gensim library (Řehůřek and Sojka, 2010) summing every score in the 300 long word2vec representations similarly to what PunFields does with the 39 Sections. However, it did not bring any significant result either.

All in all, PunFields appears to better classify such cases where there are two evidently different topics in one utterance that are expressed by two groups of words that outnumber other (noisy) groups. In the toy examples from the previous paragraph, the “chemistry” pun belongs to the so-called homographic puns, i.e. such puns where one word is used in two meanings. Unlike them, heterographic puns are such puns where the word used in one meaning resembles in form/sounding another word. That creates a disbalance between the two groups of words representing the two clashing topics: one of the groups gets the mentioned word and the other one does not (as the word is only implied). For example, in the heterographic pun “I relish the fact that you have mustard the strength to ketchup to me” the group of “mastered” and “catch up” is hidden. Similar to heterographic puns, ironic tweets have one word

⁴<https://pypi.python.org/pypi/wordninja>

⁵The pipeline is available at <https://github.com/evrog/PunFields>.

⁶Due to limitations in the size of papers, we will not describe the architecture here. Some of the code we used for the neural network is available at our PunFields repository.

expressed in full and its opposite implied. Consequently, PunFields processes such cases worse than homographic puns.

4 Unconstrained Submission

As for the unconstrained submission, we decided to use it to test another assumption that irony is close not only to puns, but to different kinds of humor. However, as in this competition we deal with irony in Twitter, we decided to check this assumption on humorous *tweets*. We took 1,000 humorous tweets from SemEval 2017 #HashtagWars: Learning a Sense of Humor (Potash et al., 2017) and 1,000 tweets with 0 to +2 positive polarity from SemEval 2016 Task 4: Sentiment Analysis in Twitter (Nakov et al., 2016) and combined them with 2,000 tweets from the Gold dataset. For the classifier, we used Bernoulli bag-of-words SVM model with the linear kernel given as the benchmark system by the competition Organizers. After reshuffling the dataset several times, we chose that result which had a more or less equal number of items in the both classes.

The result of this test shows a decrease in the efficiency of the benchmark system. However, to our surprise it was also slightly above the chance value.

5 Conclusions

With this research, we continue to elaborate on the universal mechanism of detecting intentional lexical ambiguity in creative language. We tried to demonstrate that irony and puns share some features which can be processed by a similar algorithm. However, the results of our system, PunFields, at this competition leave much to be desired.

We are planning to replace the core of the system, the semantic scheme of 39 classes, with a more elaborate system of word2vec representations and, maybe, a deep learning classifier if it provides a better result. So far, we were unable to get the system working with these elements, but the problem was, very likely, in the technical side.

All in all, PunFields shows the result that is higher than the chance operating on the data it was not meant to process. With due elaboration, we believe, it has a greater classifying potential than what was gained at the competition.

Abstract

This paper proposes a novel feature extraction process for SemEval task 3: *Irony detection in English tweets*. The proposed system incorporates a concatenative featurization of tweet and hashtags, which helps distinguishing between the irony-related and the other components. The system embeds tweets into a vector sequence with widely used pretrained word vectors, partially using a character embedding for the words that are out of vocabulary. Identification was performed with BiLSTM and CNN classifiers, achieving F1 score of 0.5939 (23/42) and 0.3925 (10/28) each for the binary and the multi-class case, respectively. The reliability of the proposed scheme was verified by analyzing the Gold test data, which demonstrates how hashtags can be taken into account when identifying various types of irony.

1 Introduction

Nowadays, opinion mining from social media has become an important issue in natural language processing (NLP). Since tweets are globally used social media text that can influence the worldwide readers with just a short arrangement of words, the analysis on tweets has been widely studied in the semantic aspects such as sentiment classification (Rosenthal et al., 2017), hate speech detection (Waseem and Hovy, 2016), and irony detection (Karoui et al., 2015; Liebrecht et al., 2013). Especially, the automatic detection of ironic tweets can help the readers who are having difficulty recognizing sarcasm to notice such figurative instances from excessive amount of text data.

Despite the potential usage of the tasks, irony and sarcasm are difficult to grasp simply by analyzing word distribution. They require understandings on the language and social context, which are dependent on time and space; this implies that the study should accompany constant updates on the database used for the analysis. Also,

it is important to construct a concrete criteria set to distinguish between ironic and non-ironic tweets.

In this paper, we incorporate a classification on manually labeled irony tweet corpus. The corpus contains 2,396 English tweets for ironic/non-ironic each (4,792 total), which were annotated under the scheme suggested in Van Hee et al. (2016). For the competition, the corpus was split into a training (80%, or 3,834 instances) and test (20%, or 958 instances) set. A training procedure for the system was all performed with the former (constrained).

2 Task Description

Two tasks were proposed for ironic English tweet analysis. Task A deals with the binary classification involving ironic tweets and non-ironic ones, and in Task B the ironic ones are categorized into three types (i.e. *verbal irony by means of a polarity contrast*, *other types of verbal irony*, and *situational irony*) (Van Hee et al., 2018). The original corpus contains 1,728/267/401 instances for each type.

3 System Description

3.1 Feature Engineering

For feature extraction, significant user behaviors were taken into account. We observed several tendencies in tweets: a large portion of irony-relevant information is conveyed by hashtags, and the hashtagged words are usually out-of-vocabulary (OOV) or non-segmented; at the same time drawing attention of the readers and emphasizing the user's point.

While extracting the features, the importance of hashtagged information was reflected in the co-extensive placement of the original tweet and hashtags. This connotes the idea that the hashtagged

About once a yr I get a little nutty and reach for the orange marmalade. #livingontheedge #sarcasm

Figure 1: The capture of tweet number 63 in training set: *About once a yr I get a little nutty and reach for the orange marmalade. #livingontheedge <http://t.co/sF9o6OWE1v>* (ironic)

component is the metadata which needs highlighting.

3.1.1 Metadata handling

There are mainly three kinds of metadata observed in the tweets: ID tags (e.g. @someone), uniform resource locators (URLs, e.g. <http://hyperlink>), and hashtags (e.g. #something). The example sentences in this section are from the training set, not the Gold test data, thus they don't contain any irony hashtags, namely #not, #irony, and #sarcasm.

ID tags: In an empirical point of view, the ID tag of a tweet mainly delivered information on whether the user intends to notify someone the content (1a). This was not considered supportive information for irony detection, since sarcasm was observed to be conveyed in both a human-directive and non-human-directive way (1b,c) and that the presence of an ID tag ('@') could not be a crucial evidence in detecting irony.

- (1) a. @mrjamieeast I think it was the hotel owners... (non-ironic)
- b. @LifeCheating doesn't lucky and fortunate mean the same thing? (ironic)
- c. 3 hours sleep yay loving life (ironic)

URLs: The URLs are usually used as a hyperlink of the photo (Figure 1). However, as shown in the example, presence of photo doesn't necessarily affect the ironic nature of a tweet; we cannot infer the semantics of a photo just given an URL. Based

on this observation, the URLs were not specially addressed; they were omitted in the word embedding process.

Hashtags: We paid attention to hashtagged words which were expected to contain information that can actually influence the nuance of the tweet (Chang, 2010). Thus, we created a placeholder for the vector embeddings of the hashtags (hashtag vector placeholder, HVP) and augmented it to the word vector sequence of the original tweet (Figure 2). This may cause a repetition on words in both the dictionary and the hashtags (e.g. keep of Figure 2), but it was assumed that the repetition would not degrade the performance. The reason for this assumption is because such words were expected to have a strong influence on the content, in that the user would have left it as a single word to notify its significance.

Firstly, a tweet was investigated whether it contains a hashtags. If not, the tweet would be compared to others based on the semantics of the original message. If any hashtag exists, the array of hashtagged words is embedded to the HVP to provide an useful evidence for the comparison with other tweets with hashtags. The numericalization of hashtags is demonstrated in the following passage.

3.1.2 Hashtag embedding

Given the nature of hashtags that does not allow spaces, most of the hashtagged words came under a category of either a single word (2a), concatenation of words with/without capital letters (2b,c), or an acronym (2d).

- (2) a. *It will be impossible for me to be late if I start to dress up right now. #studing #university #lazy* (ironic)
- b. *I picked a great week to start a new show on Netflix. #HellOnWheels* (ironic)
- c. *Casper the friendly ghost on 2 levels! #thingsmichelleobamathinksaraceracist* (non-ironic)
- d. *Another great day on the #TTC.* (ironic)

Instead of following the previous studies on hashtag segmentation (Bansal et al., 2015) that requires additional training processes, a simple guideline for hashtag embedding is proposed for such possible cases. Let *hash* be any hashtagged word, *dict* be a dictionary, *lower(w)* be the character lowering process, and *D(w)* be the vector

Figure 2: Feature extraction procedure for tweet number 1494. Word vector (or character-embedded vector) sequences are obtained for the original tweet and hashtags, denoted with length of 30 and 20 respectively. *keep* was colored purple since it belongs to both categories.

embedding for a word w .

- If $lower(hash)$ in $dict$: Trivial case. Compute output $O = D(lower(hash))$ and append it to the HVP.
- If $lower(hash)$ not in $dict$ (OOV) and $hash$ is a concatenation of words that each has a capitalized first letter:
 - 1) Split $hash$ by the capital letters.
 - 2) One of the following strategies is chosen:
 - a) **Summation** Compute the average $\sum_i D(lower(w_i))/W$ where w_i denotes each segmented word and W denotes the number of w_i s. Assign it as an output O and append it to the HVP.
 - b) **Enumeration** Append $D(lower(w_i))$ to the HVP one by one, for all w_i s.
- Otherwise (character embedding): Compute $\sum_i D(lower(c_i))/C$ where c_i denotes each character in the $hash$ and C denotes the number of c_i s. Assign it as an output O and append it to the HVP.

The three dotted cases above can be respectively applied to the examples in Figure 2, namely *keep*, *ThingsBetterThanTitansJags*, and *bigjoefavorite*. To make it clear for the second case, for *ThingsBetterThanTitansJags*, the number of vectors appended to the HVP is 1 and 5 for the case of **Summation** and **Enumeration** respectively. Note

again that only one heuristic method is chosen between those two - not being used simultaneously - in the aggregation of the word vectors from tweets.

The total size of the input feature is $(wdim, 50)$, where $wdim$ denotes the word vector size and 50 denotes the length of the vector sequence after the augmentation. The size was considered sufficient to cover the tokens of each tweet.

3.2 Classification

Classification was performed in a quite standard manner, utilizing both baseline sparse features and the proposed dense features. Although there have been some approaches that take into account the whole semantic relationship between terms (Kim et al., 2016; Cho et al., 2017), in this task we incorporated only the augmented feature constructed in the last section¹.

Since the sequential vectors were employed as features, descriptive models such as convolutional neural network (CNN) (Kim, 2014) and the bidirectional long short-term memory (BiLSTM) (Schuster and Paliwal, 1997) were adopted. In BiLSTM with an input size of 50 units, hidden layers had an output size of $32*2 = 64$ units. In CNN, two $32*32$ -dim convolutional layers (for single channel) were used with a max-pooling layer between, summarized by a window of size 3. The output layer of the classifiers was fully connected

¹Finding only the semantic contrasts could not cover the cases regarding situational irony.

F1 score	Task A	Task A (emoji)	Task B	Task B (emoji)
<i>Baseline</i>	0.6263	0.6200	0.3469	0.3455
<i>CNN-text</i>	0.6651	0.6425	0.3580	0.3647
<i>CNN-enum</i>	0.6723	0.6607	0.3785	0.4009
<i>CNN-sum</i>	0.6418	0.6543	<u>0.4084</u>	0.3517
<i>BiLSTM-text</i>	0.6568	0.6776	<u>0.4022</u>	0.3890
<i>BiLSTM-enum</i>	0.6701	0.6681	0.4091	0.4378
<i>BiLSTM-sum</i>	0.6616	0.6852	0.3843	0.3928

Table 1: 10-fold cross validation on the constrained training dataset. In task B, F1 score was obtained by macro averaging used in the scoring of competition. Bolded cases denote the best performing system for each labeled corpus. Underlined ones denote the systems that were originally submitted to the competition for each task. The score was updated according to an additional experiment.

	Accuracy	Precision	Recall	F1 score
Task A	0.6441	0.5426	0.6559	0.5939
(Best)	0.7972	0.7879	0.6688	0.7235
Task B	0.5982	0.4117	0.4096	0.3925
(Best)	0.7321	0.5768	0.5044	0.5074

Table 2: The submitted systems evaluated with the measurements, compared with the best scoring ones.

to the layer of 32 and then to decision layer of size 1 or 4, with either a sigmoid or a softmax activation, depending on the task.

4 Evaluation

The preprocessing was performed based on the example code², where the corpus was tokenized with NLTK (Bird et al., 2009). The 100dim GloVe (Pennington et al., 2014) pretrained with 27B token Twitter data³ was employed as a dictionary for word embedding. All the training and validation procedure were carried out with Keras (TensorFlow backend) (Chollet et al., 2015). The code is provided online⁴.

In this part, two main results are investigated. One deals with the comparison of performance according to classifiers and features. This is based on 10-fold cross validation using training data. In other words, the systems are trained using 3,450 instances and validated on 384 instances. In the other result, the competition score acquired using the submitted systems is inspected. Afterwards, we analyze the Gold test data, finding supportive evidences for the validity of the proposed approach regarding hashtags.

4.1 Result

The overall result tells that using the proposed features outperforms the baseline - term frequency-inverse document frequency (TF-IDF) on support vector machine (SVM), which was the system presented along with the train data. Table 1 shows the performance for each proposed system (*Classifier-Feature*) in each task. Here, *text* denotes the feature that includes only the original tweet (i.e. *Original tweet (30)* in Figure 2), and *enum/sum* denotes the feature that involves **Enumeration** and **Summation**, respectively.

The result suggests that employing *enum* and *sum* outperforms the vanilla case of *text* in general (Table 1). This supports our assumption in Section 3.1.1 and will be verified in Section 4.2. Although there were exceptions, employing BiLSTM outperformed the CNN-based method. This implies that the detection of irony is heavily influenced by specific terms (e.g. polarity items (Krifka, 1995)) or word sequence of the tweets. It is likely that the summarizing property of CNNs weaken the influence of such information. Also, unlike the intuition that more information will induce higher accuracy, there was no noticeable tendency regarding emoji.

4.2 Competition

The submitted systems showed F1 score of 0.5939 (ranked 23/42) and 0.3925 (ranked 10/28) in the competition, for Task A and B respectively.

Task A: The system submitted for Task A equals to the best performer of Table 1, *BiLSTM-sum* with emoji. However, it showed little an improvement compared to the CNN-based method (*CNN-enum* without emoji);%. It implies that the binary classification is less influenced by specific

Instances	Total	With @	With #	Correct	With # (>1)	Correct with # (>1)
Non-ironic	473	217 (45.8%)	255	301 (63.6%)	164 (34.6%)	125 (76.2% given #>1)
Ironic	311	84 (27.0%)	311	204 (65.5%)	139 (44.6%)	97 (69.7% given #>1)

Table 3: Analysis with the Gold test data of Task A. @ and # each denotes ID tag and hashtag.

Instances	Total	Correct	With # (>1)	Correct with # (>1)
Non-ironic	473	339 (71.6%)	164	134 (81.7%)
Polar	164	108 (65.8%)	74	51 (68.9%)
Situational	85	21 (24.7%)	40	10 (25.0%)
Other	62	1 (1.65%)	25	0 (0.0%)

Table 4: Analysis with the Gold test data of Task B.

terms or word sequence. From this, it could be inferred that the type classification of irony itself can be more difficult than just a detection.

Task B: The system submitted for task B, namely *CNN-sum* without emoji, differs from the lately-achieved best performer (*BiLSTM-enum* with emoji) which relatively outperforms the submitted model by 7.19%. The initial choice is based on overlooking the superiority of using BiLSTM, where the influence of the specific terms on nuance of the tweet has not been recognized.

There was a significant decrease in recall, compared with Task A. Since the feature is fixed, there may exist possible issues of classifier and emojis. Considering the analysis in the last subsection, it is presumed that the classifier issue is dominant over other problems. CNN seems to be a more cautious model than BiLSTM, but this is not considered a good property for the detector. In the aspect of the nature of sarcasm that at least ‘sensitive’ false alarms are better than generous ignorance, it is considered a reasonable decision to use a recurrent classifier model with high recall.

4.3 Gold Test Data

Further investigation regarding the Gold test data was performed for both tasks. We examined the composition of correct predictions, in terms of how the presence of hashtags positively affected the outcome.

Task A: We first figured out how ID tags and hashtags are distributed over the whole test cor-

pus. It was revealed that non-ironic tweets more frequently accompany ID tags than the ironic ones (Table 3), but we did not conclude that ID tags convey a non-ironicalness for the reasons given in 3.1.1.

For hashtags, there was an important thing to consider in counting; all ironic tweets included at least one irony hashtag, which led to 100% presence of ‘#’ for ironic instances. Thus, only the ‘effective’ hashtags were taken into account in a way of identifying tweets with more than one ‘#’; in other words, a single default hashtag was ignored⁵.

In terms of tweet ratios with effective hashtags, ironic tweets outperformed the non-ironic ones. In addition, the rate of correct prediction in instances with #>1 was observed to be higher than the ratio in the whole instance, for both cases (63.6% < 76.2% and 65.5% < 69.7% in Table 3). These validates the utility of the proposed modeling which emphasizes hashtags as indispensable metadata.

We also observed that 79, 41, and 19 instances of ironic tweets possessed one, two, and three or more effective hashtags, respectively. Except for 172 tweets with a single default hashtag, the most common case is to convey sarcasm in one word as in (3), inducing a contradiction between the literal evaluation and the intended one (Van Hee et al., 2016).

(3) *Just a @ScienceDaily article re: a robot arm you can control with your mind. Meh. Nothing huge. #sarcasm #science http://t.co/AK4bAorhBc*

Task B: We further investigated the detailed types of ironic tweets. Except for the case of *Other* where the accuracy was particularly low, hashtags performed as supportive information for correct prediction (Table 4).

Of the three irony types, *Polar* recorded the highest accuracy of correct answer prediction, also showing the most amount of enhancement given a condition of at least one effective hashtag. To be more specific than what was discussed above,

⁵This was also applied to non-ironic cases to match the proportion of instances.

Number of effective #s	0	1	2	>2
Polar	57/90 (63.3%)	27/42 (64.2%)	18/21 (85.7%)	6/11 (54.5%)
Situational	11/45 (24.4%)	6/26 (23.1%)	2/9 (22.2%)	2/5 (40.0%)
Other	1/37 (2.7%)	0/11 (0.0%)	0/11 (0.0%)	0/3 (0.0%)

Table 5: The number of effective instances for each irony types (correct/total) regarding the number of hashtags. The irony hashtags were not counted.

the number of effective hashtags was found to be most supportive in one or two cases (Table 5). This property can be effectively utilized, e.g. varying the weight given to the hashtag vector, depending on the number.

For *Situational*, the percentage was not reliable due to the shortage of the number of instances. We concluded that the case regarding the tweets only with default irony tags (11/45) is rather valid, in that the tone of the *Situational* ironic tweets appeared to be descriptive than provocative (4a). It was even more difficult to identify tendencies for the case of *Other* (4b); thus, it was assumed to resemble the case of *situational*.

(4) a. *The thirstiest of thirst buckets calling other people thirsty #irony*

b. *@BarryBlackNE I don't think the Hereditary Baronet wants to encourage a something-for-nothing culture :-\$ #irony*

5 Discussion

There are a few more schemes to consider in the future implementation. First, Additional normalization of words can be done. The proposed scheme focused on the featurization of the original tweet and hashtags, and no lemmatization or stemming was carried out. This was mainly because normalization can inadvertently erase important information; but it would be tolerable if carried out just on the non-hashtagged lexical words.

It would also be effective to apply the advanced segmentation algorithm to hashtags, taking into account the improved performance of proposed systems. This does not necessarily involve an algorithm that requires additional training and a huge database. Lighter and fancy segmentation techniques that fully utilize the dictionary are expected to be introduced.

Finally, fusion of classifiers can be undertaken. This was not considered in the proposed system, since in mixed networks, it is difficult to recognize the influence of using each feature and classifier. Nonetheless, such networks can be chosen in terms of boosting performance for real-life applications.

6 Conclusion

In this paper, the feature engineering based on the coextensive placement of tweet and hashtags was presented. Two embedding schemes for hashtag vector placeholder (HVP) were employed, and concatenation of HVP and original word vector sequences was used as inputs to CNN and BiLSTM classifiers. The implementation verified that the proposed systems outperform the baseline, and the system's reliability was supported by analyzing the correlation of hashtags and prediction accuracy with the Gold test data. Future works include lemmatization that do not affect content, development of an efficient hashtag segmentation, and fusion of classifiers.

Abstract

This paper describes the systems submitted to SemEval 2018 Task 3 “Irony detection in English tweets” for both subtasks A and B. The first system leveraging a combination of sentiment, distributional semantic, and text surface features is ranked third among 44 teams according to the official leaderboard of the subtask A. The second system with slightly different representation of the features ranked ninth in subtask B. We present a method that entails decomposing tweets into separate parts. Searching for contrast within the constituents of a tweet is an integral part of our system. We embrace an extensive definition of contrast which leads to a vast coverage in detecting ironic content.

1 Introduction

In figurative language (also known as trope), there is a departure from literal use of words. In order to decode meaning, therefore, it is not enough to rely solely on the literal sense of individual words. Irony and sarcasm are two types of such language that exploit this technique in similar ways. They “both involve deliberately saying something that is incongruous or the opposite of what the speaker knows to be true” (Hanks, 2013). This is sometimes formulated as a transgression of the Gricean maxim of quality (Grice, 1975)¹.

Under this assumption it follows that the violation is only permissible thanks to shared knowledge between the speaker and the hearer. In order to achieve this goal, the speaker frames the message with some form of commentary or metamesage that signals the ironic or sarcastic nature of the message. This is usually realised through negation of the original meaning (Haiman, 1998).

Regardless of their similarities, irony and sarcasm are not technically the same as they might be

employed for different purposes. It is widely accepted that sarcasm involves some degree of verbal aggression and ridicule directed at the hearer, whilst irony can simply be used for humorous or emphatic effect. It has been shown that computational processing of irony and sarcasm requires some knowledge of the context in which they appear, sometimes including paralinguistic information (Wallace et al., 2014).

Exploring irony has practical implications, since performance of sentiment analysis systems is directly affected by knowledge about irony and sarcasm (Pozzi et al., 2016).

As part of the 12th workshop on semantic evaluation (SemEval-2018), Shared Task 3 defines two subtasks with regards to irony detection in English tweets (Van Hee et al., 2018). Subtask A involves binary classification. The objective is to train a system that can label tweets as ironic or not. Subtask B is a multi-class classification problem with the objective to label tweets with one of the four specified labels describing the type of irony (verbal irony by means of a polarity contrast, situational irony, other verbal irony, and non-ironic).

To tackle these problems, in this paper we describe two rich feature-based systems addressing each subtask. Our systems use a combination of sentiment, distributional semantic, and text surface features. The code and data for this project is freely available².

The rest of this paper is organised as follows: Section 2 describes related work. Section 3 provides a comprehensive description of the overall methodology including pre-processing, feature representation, and system architecture. Sections 4 and 5 discuss experiments and results, Section 6 involves error analysis and finally Section 7 concludes the paper with some closing remarks.

¹“Do not say what you believe to be false.”

2 Related Work

There has been a recent surge of interest in the tasks of irony and sarcasm detection due in large part to increasing popularity of social media and the availability of data from websites like Twitter and Reddit. Some recent work focus exclusively on irony or sarcasm in isolation (Joshi et al., 2016), under the assumption that sarcasm has a stronger impact on changing the sentiment of the overall message. However in many cases, these terms are taken to be practically synonymous (Pozzi et al., 2016; Wallace et al., 2014; Ptáček et al., 2014). SemEval has a long-standing shared task on sentiment analysis that has also involved processing of figurative language including irony and sarcasm (Ghosh et al., 2015; Nakov et al., 2016). Results from recent tasks on sentiment analysis confirm that the top performing teams increasingly employ deep learning methodologies, while classical machine learning models like SVM and logistic regression remain popular (Ghosh et al., 2015; Rosenthal et al., 2017).

3 Methodology

We train our supervised systems using an ensemble soft voting classifier with logistic regression (LR) and support vector machine (SVM) as component models, and create our feature sets using a combination of sentiment, semantic, and surface features. We leverage these handcrafted features in combination with dense vector representations which differ in details between subtask A and B. The differences in feature engineering and representation between the two subtasks will be discussed in 3.2.

3.1 Pre-processing

Tweets were tokenised using NLTK’s tweet tokeniser (Loper and Bird, 2002). Additional pre-processing was done to obtain a subset of the features that concerned surface orthographic features (e.g. all capitals, elongations, emoticons, etc) and pattern-based named entities (e.g. time, place, user, etc). For this we used the ekphrasis toolkit (Baziotis et al., 2017). It employs an XML-based annotation scheme that made it easy to extract this information.

For sentiment features and embeddings, however, pre-processing beyond tokenisation was deemed unnecessary as our emoji and word vectors were pre-trained on raw tweets.

3.2 Feature Representation

In our observation of the training data, we noticed that tweets often follow a fairly consistent spatial pattern. Informative words are more likely to cluster at both ends of a tweet. Hashtags, while scattered throughout the whole text, tend to occur at the end. In ironic tweets, negative sentiments are more likely to be preceded by neutral or positive ones. An example is given in (1).

(1) What a golden morning. 😊

In order for our models to capture these spatial patterns and to provide a more rigorous representation of a tweet’s structure, we propose the idea of decomposing a tweet into separate chunks and extracting features for each one separately. By concatenating these features we are able to partially preserve information about linear precedence. To this end, we simply split the sentences to two sections as represented in example (2) and (3).

(2) 8ams are just | so LOVELY .

surface features: *time1* | *allcaps2*

(3) SEEING @AlpEmiel ON | SATURDAY
whaddddddup #legend

surface features: *allcaps1*, *user1* |
elongated2, *hashtag2*

In examples (2) and (3), the numbers ‘1’ and ‘2’ signify the first and second sections of the tweet respectively.

We use the same split structure for representation of other features, and pre-trained dense vectors.

Contrast is one of the most important properties of ironic language. One contribution of this work lies in the particular manner in which the notion of contrast is defined. Contrast is a marker of polarity shift and is usually seen as the presence of a positive sentiment referring to a negative situation, or vice versa (Riloff et al., 2013) which is sometimes referred to as “asymmetry of affect” (Clark and Gerrig, 1984).

Twitter language is non-standard and informal. Polarity shift can be realised through contrast between different elements of the tweet. The elements of a tweet are: text, hashtagged tokens, and emojis. We adopt a more inclusive stance with regards to the concept of contrast with the following scenarios:

1. Contrast between different parts of the same

element of a tweet

- a. antithetical emojis
- b. antithetical hashtagged tokens

2. Contrast between two different elements of a tweet

- c. text and hashtagged tokens
- d. text and emojis
- e. hashtagged tokens and emojis

A sizable proportion of the tweets contain multiword hashtags, such as *#NotExcitedAboutThisAtAll* or *#goodluck*, that require segmentation. For this we used ekphrasis’ hashtag segmentation tool (Baziotis et al., 2017).

We separate the tweet and its segmented hashtagged tokens and run each group through the sentiment analysis tool from Stanford CoreNLP (Manning et al., 2014). CoreNLP assigns to an input any of 5 sentiment classes from very negative to very positive (0 to 4). If the resulting hashtag and text scores are on opposite sides of this spectrum, we consider this as contrast type c. as defined in 2.

For d. and e. we follow a similar procedure. To approximate the sentiments present in emoji tokens, we use Emoji Sentiment Ranking (Kralj Novak et al., 2015). This is a lexicon of 751 emojis whose sentiments are ranked based on human annotation of 70,000 tweets in 13 European languages.

The resulting contrast feature is a binary value that is set to True if any one of the aforementioned forms of contrast is present in the tweet.

Relying on sentiment information from CoreNLP, we define an additional binary feature named Intensity. It checks whether the sentiment in a segment of the tweet is sharply positive/negative. This translates to a value of 0 or 4 in the sentiment scores for that particular segment. The rationale behind definition of this feature is that too much of a positive emotion can, in certain contexts, imply a negative sentiment. To a lesser extent, the opposite is also true of an excessively negative emotion.

To track the changes of sentiment expressed throughout the whole tweet, we define sentiment patterns of Rise (R), Fall (F), and Stable (S) on a word-by-word basis and encode this information in a vector representing the number of S, R, F, RF,

and FR patterns. For these features, we rely on information from Vader sentiment lexicon (Gilbert, 2014).

For dense vectors we use word2vec embeddings pretrained on a large twitter corpus as described in Godin et al. (2015). One limitation of these embeddings is that they don’t contain information on emojis. Therefore we have to complement this resource with additional embeddings specifically trained on emojis (Eisner et al., 2016).

3.3 Task-specific Selected Features

3.3.1 Subtask A

For subtask A, we found that the best way to combine embeddings is through averaging, separately for left and right parts³. Features we combine with these vectors are the following: Surface features, Intensity (for left and right), and Contrast.

3.3.2 Subtask B

For subtask B, concatenation of the embeddings was deemed more effective. Furthermore, we augment the combined embeddings with bigram tf-idf count vectors.

As a rhetorical trope, irony can often have subtle political and social dimensions, and is used frequently to express opinionated thoughts in general (Hutcheon, 1994). We noticed that adding topic modeling features to our system in subtask B slightly improves classification performance as these features can help the model capture more subtle forms of irony that tend to co-occur with certain topics and are not necessarily realised as polarity contrasts. Topic modeling of the tweets is done using Latent Dirichlet Allocation (LDA) and Non-negative matrix factorization (NMF).

Other features we add to the above are: Surface features (we consider these with regard to both the whole tweet and its left and right splits), Intensity (for left and right), Contrast, and Vader-based Rise and Fall sentiment patterns.

4 Experimental Settings

We use the data (text including emojis) as provided by the organisers of the shared task. We train our models on the training set using 10-fold cross-validation. Predictions were made on the held-out test data.

³word and tweet embeddings are averaged independently, and subsequently the averages are concatenated.

	ironic	non-ironic	total
train	1911 (49.84%)	1923 (50.15%)	3834
test	311 (39.66%)	473 (60.33%)	784

sad1, surprise1, url1, date2,
elongated2, laugh2, sad2, shocking2,
url2, user2
```

Figure 1: The most informative features for subtask A

Train and test data in both subtasks A and B are the same and only differ in their annotation. Tables 1 and 2 present the breakdown of the classes and the number of their instances in each subtask.

The most informative features are selected using recursive feature elimination (RFE) (Guyon et al., 2002). As a result, the algorithm uses 13 features for subtask A as listed in figure 1. They are concatenated with the vectors that were derived by separately averaging the words and emoji vectors of the left and right parts of tweets.

The best features derived from RFE for subtask B did not improve the performance of the model. Therefore we use all of the 87 features which are consequently augmented with the concatenation of the word and emoji vectors of tweets.

The baseline system provided by task organisers is an SVM classifier which uses tf-idf feature vectors. We consider this as the benchmark and report the results for 2 different settings of our system as follows:

- setting 1: average of word and emoji vectors of bi-sectioned tweets
- setting 2: concatenation of word and emoji vectors

In both settings we combine vectors with best features and feed them to the classifiers. To achieve the best system for subtask A (best system A) we apply a voting classifier with soft voting between LR and SVM whose model components are based on setting 1 plus the 13 best features that were selected using RFE for subtask A.

The best system for subtask B is a voting classifier between 3 LRs with 3 different class weights as shown in Table 3. The components of the models are based on setting 2 plus all features for subtask B.

5 Results and Discussion

Table 4 details the results for subtask A, and the results for subtask B are presented in Table 5. After cross-validation on the TRAIN set, the best system which is an ensemble voting classifier trained on models based on setting 1 + best features of subtask A achieves the highest record in F1-score and recall, but is outperformed in accuracy by its own component model. In terms of precision it also scores lower than the system based on setting 2 + all features.

When tested on the TEST data, our best system for subtask A ranked third overall on the shared tasks’s official leaderboard among 44 teams with an F-score of 0.65. It has the second highest score for recall. This indicates that the coverage of the model is extensive.

For subtask B, our best system is an ensemble voting classifier comprised of three logistic regression models based on setting 2 + all features with the set-up indicated in Table 3.

As can be seen in Table 5, it gives the best F1-score, accuracy, and recall when cross-validated on the TRAIN data. On the held-out TEST data, the system ranked 9th in terms of F1-score, and with 0.6709 accuracy ranked second out of all participating systems in the shared task.

Table 6 shows the F1-scores for subtask B based on the system’s performance on each individual label. In the case of irony by clash, our system achieves an F1-score of 0.6584. This confirms that our features are informative enough to help the model capture this type of irony fairly well, even though only 20.91% of the tweets belong to this class (Table 2).

However, in the case of situational irony the system performs much worse. There are several possible factors that collectively contribute to this poorer performance. Situational irony is less studied in the literature and designing effective features to model it is more difficult. By definition, it involves a situation that does not conform to the expectations of the speaker and elicits an emotional response (Shelley, 2001). Expectations differ among individuals and people often react differently to the same events and stimuli which further complicates the problem.

In the provided dataset, the number of instances of this type of irony is small (only 8.24% of the total in the TRAIN set), and there are no salient tex-

	non-ironic	clash	situational	other	total
train	1923 (50.15%)	1390 (36.25%)	316 (8.24%)	205 (5.34%)	3834
test	473 (60.33%)	164 (20.91%)	85 (10.84%)	62 (7.90%)	784

Table 2: Statistics of the data for subtask B

	non-ironic	clash	situational	other
LR1	1	1	1	1
LR2	1	1	2	2
LR3	1	1	3	3

Table 3: Weights each LR classifier assigns to the 4 classes in subtask B

tual characteristics that can signal their occurrence while distinguishing them from irony by clash.

6 Error Analysis

Vast coverage in subtask A also means that the model is quick to judge a tweet as ironic which translates to a large number of tweets getting tagged as 1. According to Table 1 the distribution of labels is slightly skewed towards non-ironic labels, but in our predictions 0.62% of the tweets are tagged as ironic (Table 4) which explains higher recall and lower precision. This can be traced back to the inclusive definition of contrast as defined in 3.2.

The gold standard provided is not without faults. As an example (4) is obviously an ironic tweet that is incorrectly labeled as 0 in the gold-standard⁴. Also in example (5) the word *tit* (altered in spelling for censorship), is being used in two ways; first in its literal sense, and the other to sarcastically refer to a politician as foolish. This was labeled as non-ironic in the dataset, which is subject to debate. Our system correctly identified both of these instances.

(4) Corny jokes are my absolute favorite

(5) #farage a t1t in public who doesnt agree with seeing t1ts in public #breastfeeding

Looking at the per-class performances in subtask B (Table 6), the best system is predicting non-ironic instances with a high F1-score of 0.7652. However the F1-scores for other classes remain low.

The numbers for situational is lower than irony by clash, which seems logical because in order to

⁴*corny* has a negative connotation, implying that the joke is unfunny, and uninteresting

effectively pinpoint a tweet as ironic by situation it is sometimes necessary to have access to information beyond the text which could involve a broader context (social, cultural, political, etc) as exemplified in the following examples that are taken from the TRAIN set:

(6) Sure Staff... Now Hiring.
<http://t.co/HDgfxG7eIF>

(7) #mondaymorning pouring rain and i am singing 'the most wonderful time of the year' as i walk to the office

(8) Patrick Kielty hosting Radio 2's Comedy Awards...

In (6), textual information does not provide anything of significant value. If the user clicks on the link, it seems like the image is about an employment agency that is hiring. Normally, they supply staff to clients who are recruiting but in this case, it is the agency itself which is recruiting. This goes against expectation. Realisation of this instance as situational irony requires interpretation of the image which in turn requires linking the name *Sure Staff* to an agency, and the background knowledge about the role of employment agencies.

Example (7) involves the interpretation of a rainy day on Monday morning as unpleasant, which is subjective. Example (8) implies that the comedian is not particularly known to be funny, which again requires background knowledge and is also dependent on the opinion of the annotator, as it could also read as a non-ironic sentence if the reader does not share the same impression of the comedian.

7 Conclusion

In this paper, we have described our supervised systems to identify ironic tweets and categorise them into three types. Our systems leveraging a combination of word/emoji vectors and features related to polarity contrast, intensity and text surface features achieved competitive results for bi-

Table 6: Per-class F1-scores for the best system in subtask B

nary classification of tweets as ironic/non-ironic. The system is ranked third out of 44 participating systems due to its high coverage in identifying ironic-tweets. For the subtask of multi-class classification, we have also used topic modeling features and features related to the distribution of polarity. The system is ranked ninth out of 32 participating systems with a very competitive accuracy.

In future, we intend to extract more sophisticated features related to situational irony. Observation of the dataset confirms that in cases where the tweet involves a URL, the contents of the external web page can play an important role in discriminating between ironic and non-ironic tweets. Therefore introduction of multimodal features is one future direction to enhance performance of such models.

Random Decision Syntax Trees at SemEval-2018 Task 3: LSTMs and Sentiment Scores for Irony Detection

Aidan San

University of Illinois at Urbana-Champaign

asan2@illinois.edu

Abstract

We propose a Long Short Term Memory Neural Network model for irony detection in tweets in this paper. Our model is trained using word embeddings and emoji embeddings. We show that adding sentiment scores to our model improves the F1 score of our baseline LSTM by approximately .012, and therefore show that high-level features can be used to improve word embeddings in certain Natural Language Processing applications. Our model ranks 24/43 for binary classification and 5/31 for multiclass classification. We make our model easily accessible to the research community¹.

1 Introduction

Recently, irony detection has become an increasingly important problem with new applications appearing every day. In discourse analysis, it is extremely important to understand if a politician is making an ironic or a literal response, or understanding can be completely lost. In chatbots, if a chatbot misinterprets an unhappy sarcastic comment from a customer, the customer could become even more frustrated. In sentiment analysis, if irony is not taken into account, the actual sentiment could be the opposite of the prediction.

The aim of irony detection is generally a binary classification problem: Is the piece of text ironic or literal? In SemEval2018 Task 3 (Van Hee et al., 2018), there are two subtasks. First, subtask A, is our standard binary classification problem. We are provided with a corpus of tweets annotated with 0 or 1's to specify if a tweet is ironic or literal. Second, in subtask B, we are tasked with a more challenging problem. In subtask B, participants must determine which type of irony a particular tweet contains. Is it verbal irony based on polarity,

another type of verbal irony, situational irony or not ironic at all?

Recently, research has shown that neural approaches are particularly effective in sarcasm detection (Ghosh and Veale, 2016) and similar problems such as sentiment analysis (Rosenthal et al., 2017). In this paper, we present neural network model designed to tackle the challenge of irony detection.

In subsection 2.1, we give a brief overview of the entire model. In subsection 2.2 and 2.3, we describe our neural architecture and approach. In subsection 2.5 and 2.6, we describe the embeddings and sentiment scores that are used as the input to our neural network. In section 3, we describe our results, and give quantitative evidence of the effectiveness of our features. In section 4 we conclude, and in section 5, we describe ways that our approach could be improved.

2 System Description

2.1 Overview

Our system is composed of three stages: Preprocessing, Feature Creation, and the Neural Network. Preprocessing is composed of tokenizing the input text. Feature creation is generating the word and emoji embeddings and sentiment scores and concatenating them together to form a feature vector. Finally in the third stage, the feature vector is fed into the neural network which makes a prediction. Our full model is illustrated in Figure 1.

2.2 Long Short Term Memory

In traditional Feed Forward Neural Networks, there is not a good way to represent temporal inputs. Recurrent Neural Network (RNN) cells are like traditional neural network cells, except they have the key difference of feeding their output

¹github.com/Muakasan/RDST-semeval2018-task3

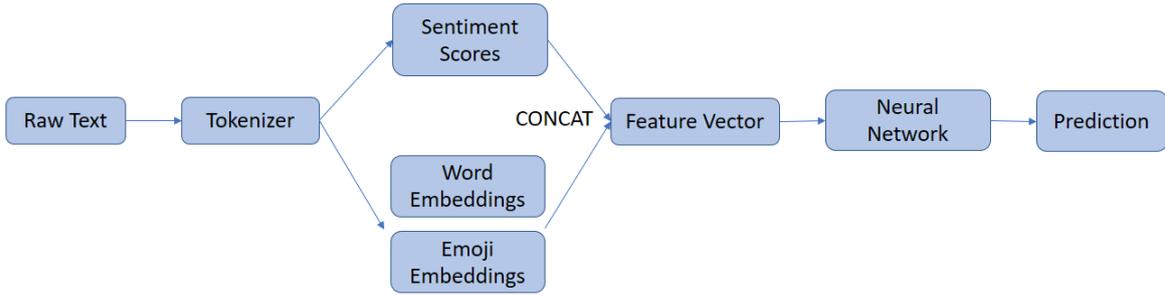

Figure 1: Overview of the entire model.

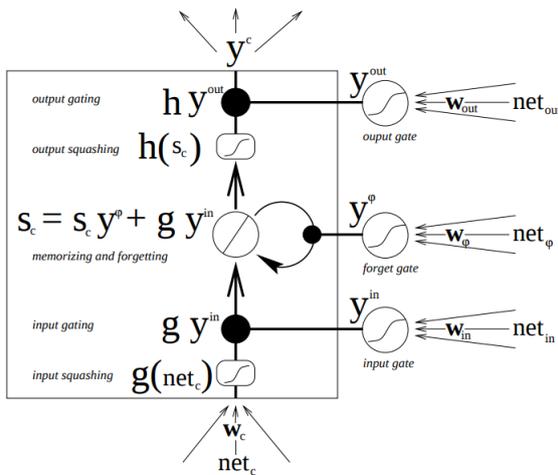

Figure 2: The various gates of the LSTM Cell and the connections between them. The data path is shown from the input w_c to the output y^c . Taken from Gers et al. (1999).

back into themselves. Each time a new word representation is passed into the RNN, the RNN will take its output and pass it back into the RNN, so the RNN receives 2 inputs (the current word and the output from the previous iteration). The output of the previous iteration can be thought of as a representation of the previous words in the sentence. This is repeated until the sentence is finished. Additionally, context units can be added to the cell to imitate the idea of memory (Elman, 1990). This improves language modeling, because when reading a sentence, prior context of previous words is very important for the understanding of the current word. When we use an RNN, our model can be fed in with context from previous words.

The Long Short Term Memory Model (LSTM) improves over the naive RNN, with the addition of a memory cell and input and output gates (Hochreiter and Schmidhuber, 1997). In the naive RNN, it is easy to lose important information over many iterations of the cell. In an LSTM cell, the memory cell combats this problem. The original LSTM cell is composed of two gates. The output gate can protect other units from irrelevant information from the current iteration, and the input gate can control which information is passed into the current iteration. Additionally, Gers et al. (1999) include a forget gate which can reset memory once it is no longer relevant. Figure 2 taken from Gers et al. (1999) illustrates the architecture of the cell.

2.3 Neural Network Architecture

Our model is built with the high-level Python neural network library called Keras (Chollet et al., 2015). We use a 5 layer model. Our first layer is the input layer, where we feed integer ranks (a number representing how often a word appears in the corpus where “1” is the most common) of

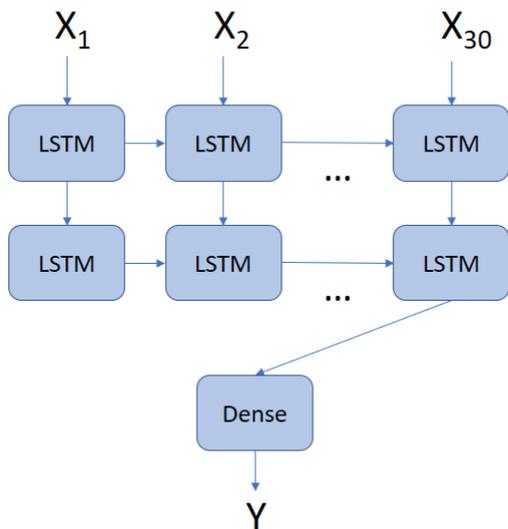

Figure 3: An unrolled Neural Network. X_1 to X_{30} represent the first 30 words in the input tweet. Y represents the irony prediction of the given tweet.

words into the layer. Then we pass the inputs into an embedding layer. This layer takes our inputs and converts them into a word or emoji embedding representation. Our third and fourth layers are both Long Short Term Memory layers. We take the outputs of the first LSTM layer and feed them into our second layer. Both LSTM layers are given a dropout of .25 (chosen by experimentation) to prevent overfitting (Srivastava et al., 2014). The output of the second LSTM is then passed into a single Dense layer. Our Dense layer has a sigmoid and softmax activation for subtask A and B respectively. We use binary cross entropy and categorical cross entropy for subtask A and B respectively. We train our model over 30 epochs (approximately when the model converged) with a batch size of 32. Our architecture is shown in Figure 3.

2.4 Preprocessing

We preprocess using Pandas (McKinney, 2010) for csv reading along with basic data processing. We then run our tweets through the Keras Tokenizer (Chollet et al., 2015). The Keras Tokenizer handles splitting, removing punctuation and lowercasing words.

2.5 Word/Emoji Embeddings

When dealing with a relatively small training set, such as a small number of tweets, pretrained word embeddings can be a very effective way of encod-

ing additional information into the model without needing additional training data. We used the Google News pretrained Word2Vec (Mikolov et al., 2013) word embeddings for our model. The word embeddings were trained using 100 billion words taken from the Google News dataset. We additionally added Emoji2Vec (Eisner et al., 2016) embeddings. As is shown by Hogenboom et al. (2013), emoticons encode a large amount of sentiment information. As the descendants of emoticons, we hypothesize emojis can encode sentiment information as well.

2.6 Sentiment Scores

We use NLTK (Bird and Loper, 2004) to get sentiment scores using the SentiWordNet (Esuli and Sebastiani, 2007) corpus. SentiWordNet is a library which uses a semi-supervised approach to give synsets (groupings of words which have the same meaning) an objective, positive, and negative sentiment score. Riloff et al. (2013) show that sentiment can be an effective way to improve sarcasm detection in tweets. For simplicity, we always use the first synset of a particular word. We take the positive and negative scores from SentiWordNet and then concatenate the results with our word/emoji embedding.

2.7 Memory Constraints

Standard practice is to pass the word embedding matrix with every word as a layer into the Neural Network. In this task, we had the additional constraint of a relatively small amount of RAM (about 8GB). To resolve this problem, instead of building our embedding matrix and then tokenizing our dataset, we tokenized first. Then, rather than building our embedding matrix with every possible entry, we could simply look through the words that we had seen during tokenization, and only put those vectors into our matrix. To put this into context, while we were storing all the embeddings in memory we were using about 6GB of RAM. After we created our much smaller embedding matrix, we were only using about 3GB of RAM.

3 Results

Task	F1	Accuracy
A (Binary)	.5822(24)	.6173(21)
B (Multiclass)	.4352(6)	.6327(6)

Table 1: Official results from the competition on the test set. The numbers between parentheses indicate ranking compared to other models.

As shown in Table 1, in the binary classification task, we achieved an F1 score of .5822 and an accuracy of .6173, and in the multiclass classification task, we achieved an F1 score of .4352 and an accuracy of .6327. This earned us a rank of 24 and 6 in tasks A, and B respectively, because teams were ranked using F1 score.

Model	F1	Accuracy
Without Emoji	.6127	.6121
Without Sentiment	.6093	.6097
Emoji & Sentiment	.6210	.6091

Table 2: Accuracy and F1 scores of various models tested on a 75%-25% split of the training data.

To test the effectiveness of the emoji embeddings feature and sentiment scores feature, we tested our binary classification model without each feature separately and compared these models to our combined model. We ran our tests over the training set with a 75%-25% split, where 75% of the training data was used to train the model and 25% of the model was designated as validation data, to verify the effectiveness of the model on unseen data. We ran 10 trials and took the average accuracy and F1 score over the 10 trials for each of the 3 models.

The task was ranked using F1 score, so we optimized for F1 score. As can be seen in Table 2, the combined model achieves an F1 score .0083 higher than not including emoji embeddings and an F1 score .0117 higher than not including sentiment scores. Interestingly, we see that the combined model actually achieves a lower accuracy score than both of the individual models. We can draw the conclusion that the combined model has more balanced predictions between the two classes, which overall creates a higher F1 score at the cost of lower accuracy in one of the classes.

4 Conclusion

In this paper, we have described our system for SemEval-2018 Task 3. We discussed LSTM-based neural models, and how we incorporate sentiment features and emoji embeddings. We show that additional high-level features such as sentiment scores can improve neural based models. We achieve rank 24/43 in subtask A and 6/31 in subtask B.

5 Future Work

Possible improvements to the model fall under two primary categories: the neural architecture and additional high-level features.

To implement our neural architecture, we experimented with other types of layers such as Bidirectional LSTMs and CNNs, but we would like to further explore these approaches in the future. We especially think Attention Layers used by models such as Baziotis et al. (2017) could be particularly effective in irony detection, because of their effectiveness in sentiment analysis. We could also try different activation functions in different layers and test out different batch sizes. Another possible direction would be to use ensemble methods which have been shown to be particularly effective by Cliche (2017) for similar tasks.

Regarding additional high-level features, we could also include sentence-level features. Goel et al. (2017) showed that high-level features could be included in a Feed Forward Neural Network which improved accuracy in an ensemble method for the task of emotion detection. Additionally, we could continue in the vein of the model we created and add other word-level features such as capitalization. To improve our sentiment features, we could also use a more advanced method of choosing the correct synset for a better fitting sentiment score.

Acknowledgments

We would like to thank the task organizers for providing the dataset and putting together the competition. We would like to thank Assma Boughoula and Julia Hockenmaier for their help in this project.

Abstract

This paper describes the participation of ELiRF-UPV team at tasks 1 and 3 of Semeval-2018. We present a deep learning based system that assembles Convolutional Neural Networks and Long Short-Term Memory neural networks. This system has been used with slight modifications for the two tasks addressed both for English and Spanish. Finally, the results obtained in the competition are reported and discussed.

1 Introduction

The study of figurative language and affective information expressed in texts is of great interest in sentiment analysis applications because they can change the polarity of a message. The objective of tasks 1 and 3 of Semeval 2018 is the study of these phenomena on Twitter.

Task 1 (Mohammad et al., 2018) is related to Affect in Tweets. Systems have to automatically determine the intensity of emotions and intensity of sentiment or valence of the tweeters from their tweets. The task is divided in five subtasks: emotion intensity regression (EI-Reg), emotion intensity ordinal classification (EI-Oc), sentiment intensity regression (V-Reg), sentiment analysis ordinal classification (V-Oc) and emotion classification (E-C).

Task 3 (Van Hee et al., 2018) addresses the problem of Irony detection in English Tweets. It consists of two subtasks. The first subtask is a two-class (or binary) classification task where the system has to predict whether a tweet is ironic or not. The second subtask is a multiclass classification task where the system has to predict one out of four labels describing i) verbal irony realized through a polarity contrast, ii) verbal irony without such a polarity contrast (i.e., other verbal irony), iii) descriptions of situational irony, iv) non-irony.

This paper describes the main characteristics of the developed system by the ELiRF-UPV team for tasks 1 and 3. We addressed all subtasks of task 1 both for English and Spanish, and all subtasks of task 3.

2 Data Preprocessing

In this work we have taken into account different aspects when preprocessing the tweets. First we removed the accents and converted all the text to lowercase. In general, *emoticons*, *web links*, *hashtags*, *numbers*, and *user mentions*, were substituted by generic tokens. For instance, “#hashtag” → “hashtag”, ☺ → “Slightly Smiling Face”, etc. After that, we used TweetMotif (Krieger and Ahn, 2010) as tweet tokenizer, moreover we adapted it to work with Spanish tweets.

3 Resources

On the one hand, for English, we used the following polarity/emotion lexicons: AFFIN (Nielsen, 2011), Bing Liu’s Opinion Lexicon (Hu and Liu, 2004), MPQA (Wilson et al., 2005), Sentiment140 (Go et al., 2009), SentiWordnet (Baccianella et al., 2010), NRC Emotion Lexicon (Mohammad and Turney, 2013), NRC Hashtag Emotion Lexicon (Mohammad, 2012) and LIWC2007 (Pennebaker et al., 2014). We also used Word2Vec embeddings (Mikolov et al., 2013a) (Mikolov et al., 2013b) pre-trained by (Godin et al., 2015) with 400 million English tweets.

On the other hand, for Spanish, we used the following polarity/emotion lexicons: EIHPolar (Saralegi and San Vicente, 2013), ISOL (Molina-González et al., 2013), and MLSenticon (Cruz et al., 2014). In addition, we also pre-trained Word2Vec embeddings from 87 million Spanish tweets collected by our team by means of a twitter crawler. In this case, it is a skip-gram architecture

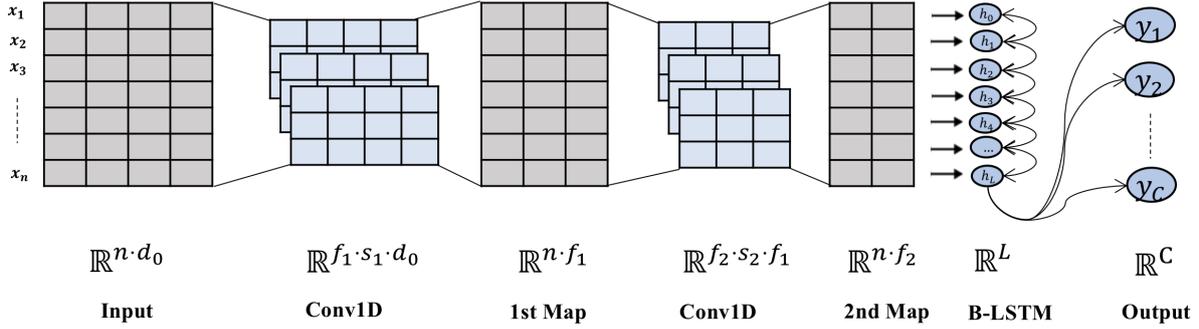

Figure 1: System architecture.

with 300 dimensions per word, negative sampling with 5 negative samples and a 5-term context on the left and right was used.

Through a tuning process on the development sets with a fixed system architecture, we selected the best lexicons for each task. For English, all the lexicons stated above for both tasks were used. For Spanish, only EIHPolar and ISOL lexicons were used.

4 System Description

In this section, we briefly describe the general characteristics of the system developed for Task 1 and Task 3 at SemEval 2018. This description includes the input representation and the system architecture.

4.1 Input representation

Regarding the representation used, in those subtasks where the input is only a tweet (V-Reg, V-Oc and E-C in task 1 and both subtasks in task 3), each tweet is represented as a matrix $M \in \mathbb{R}^{n \cdot d}$ where n is the maximum number of words per tweet and d is the embedding dimensionality. To include the information from the polarity lexicons, for each word, x , the vector of its embedding is concatenated with the vector of polarities/emotions for this word, $v(x)$. In this way, the representation matrix of a tweet finally results in $M \in \mathbb{R}^{n \cdot (d+|v|)}$.

For the EI-Reg subtask, where in addition to a tweet an emotion p is also provided, we add the representation of the word p as the last row of the M matrix. Moreover, we concatenate one column to the word embeddings to indicate if the words belong to the tweet (0) or belong to the emotion (1).

4.2 System architecture

We propose a general architecture for all subtasks. This architecture is based on a two-layer Convolutional Neural Network (CNN) (Fukushima, 1980) ensembled with a final Long Short-Term Memory (LSTM) neural network (Hochreiter and Schmidhuber, 1997) as in (González et al., 2017). We use the representation of the tweet in terms of the M matrix defined above as input to the system. Finally, a fully connected layer computes the outputs of the system. The activation function of this layer depends on the subtask.

Figure 1 shows the general architecture of the system, where d_0 is the dimensionality of the representation of each word (size of the embedding), f_i is the number of filters in the convolutional layer i , s_i the height of each filter in layer i , L is the dimensionality of the *output-state* of the LSTM network, and C is the number of outputs for a specific task.

Although the architecture was the same for all subtasks, the parameters are subtask dependent and were experimentally defined by means of a tuning phase with the development sets. The values studied for the parameters of the convolutional network are $f_i \in [64, 256]$ and $s_i = 3$. The number of neurons of the last layer depends on the subtask. We also tested a simplified version of the architecture without the convolutional network and using only the LSTM network with $L = 256$.

Moreover, we use Batch Normalization (Ioffe and Szegedy, 2015) between all convolutional layers, Dropout (Srivastava et al., 2014) after the LSTM with $p = 0.2$, ReLU activation functions (Nair and Hinton, 2010) and RMSProp (Tieleman and Hinton) as optimization algorithm.

Task 1	EI-Reg (Pearson)		V-Reg (Pearson)		E-C (Jaccard)	
	En	Sp	En	Sp	En	Sp
LSTM + Lexicons (MSE)	67.57	68.98	75.46	74.37	N/A	N/A
CNN-LSTM + Lexicons (MSE)	64.12	66.56	81.13	80.01	N/A	N/A
CNN-LSTM + Lexicons (CCE)	N/A	N/A	N/A	N/A	52.11	42.18
CNN-LSTM + Lexicons (Jaccard)	N/A	N/A	N/A	N/A	55.23	44.59

Table 1: Task 1 development results.

Task 3	Subtask A (F1)	Subtask B (Macro F1)
CNN-LSTM + Lexicons (CCE)	68.44	44.59
CNN-LSTM + Lexicons (F1)	68.63	N/A
CNN-LSTM + Lexicons (Macro F1)	N/A	45.45

Table 2: Task 3 development results.

Regarding the loss function, we used *Mean Squared Error* (MSE) for the regression subtasks. However, for subtask E-C and both subtasks of task 3, we used an adaptation of the evaluation metrics (*Jaccard Index*, F_1 for binary classification, and macro-average F_1) as loss functions. In future work we will define and study in more detail this kind of loss functions. In addition, we also tested Cross Entropy (CCE) to extend the comparison.

The strategy used in the ordinal classification subtasks of task 1 (EI-Oc and V-Oc) consisted in the discretization of the outputs of the equivalent regression subtasks (EI-Reg and V-Reg). The discretization process is as follows, be \mathbb{C} the classes set of a ordinal classification subtask and $v_x \in \mathbb{R}$ the score assigned to sample x using a regression model. We compute $|\mathbb{C}| + 1$ thresholds by searching the minimum output for each class, according to the regression train sets. Concretely, $\{th_0, \dots, th_{|\mathbb{C}|}\}$ where $th_i \in \mathbb{R}$, $th_i < th_{i+1}$, $th_0 = 0$, and $th_{|\mathbb{C}|} = 1$. Sample x is assigned to the class i such that $th_i < v_x \leq th_{i+1}$.

5 Experimental Results

We performed a tuning process with the development sets in order to select the best model for each task. We tested different ways of preprocessing the tweets, we fit the parameters of the models and we evaluated some external lexicons. Next, we summarize the best results obtained in the tuning process by considering some combinations of the tested models and configurations.

Table 3 shows the results for 3 of the subtasks in the tuning process for Task 1. For the two remaining tasks (EI-Oc and V-Oc) we do not learn spe-

cific models, in these cases we used the best models obtained for EI-Reg and V-Reg, respectively.

As it can be seen, LSTM achieved the best results for subtasks EI-Reg. The rest of subtasks performed better when we combined CNN and LSTM models. In addition, when we consider the evaluation metric as loss function we improved the results (see the differences between CNN-LSTM + Lexicons (Jaccard) and CNN-LSTM + Lexicons (CCE)).

Table 3 shows the results for the two subtasks in the tuning process for Task 3. We can observe the same behavior as Task 1. The best results are obtained using a combination of CNN and LSTM models and if we consider the evaluation metric as loss function the results are improved.

Once our best system for each subtask with the development set was chosen, we tested it on the official test set and we compare it with the best results obtained by another participant. These results are shown in Table 5 for Task 1, and in Table 5 for Task 3.

Task 1	English		Spanish	
	Our	Best	Our	Best
EI-Reg	69.60 _(13/42)	79.90	64.80 _(3/12)	73.80
EI-Oc	59.00 _(10/36)	69.50	57.50 _(4/13)	66.40
V-Reg	80.40 _(15/33)	87.30	74.20 _(2/12)	79.50
V-Oc	75.90 _(12/34)	83.60	72.90 _(2/11)	75.60
E-C	55.20 _(9/35)	58.80	45.80 _(2/14)	46.90

Table 3: Task 1 test results.

Task 3	Our	Best
Subtask A	62.94 (7/44)	70.54
Subtask B	42.11 (8/32)	50.74

Table 4: Task 3 test results.

6 Conclusions and Future Work

We presented a deep learning based system that assembles CNN and LSTM neural networks for tasks 1 and 3 of Semeval-2018. This system has been used with slight modifications for the two tasks addressed.

We want to highlight the improvements obtained when the evaluation measures have been adapted as loss functions. In addition, we have also incorporated information extracted from different lexical resources into the models.

As future work, we will continue to study different loss functions and the incorporation of new lexical resources as well as to carry out a detailed study of the obtained results.

`tony.veale@ucd.ie`

Abstract

This paper describes our system, entitled IronyMagnet, for the 3rd Task of the SemEval 2018 workshop, “Irony Detection in English Tweets”. In Task 1, irony classification task has been considered as a binary classification task. Now for the first time, finer categories of irony are considered as part of a shared task. In task 2, three types of irony are considered; “Irony by contrast” - ironic instances where evaluative expression portrays inverse polarity (positive, negative) of the literal proposition; “Situational irony” - ironic instances where output of a situation do not comply with its expectation; “Other verbal irony” - instances where ironic intent does not rely on polarity contrast or unexpected outcome. We proposed a Siamese neural network for irony detection, which is consisted of two subnetworks, each containing a long short term memory layer (LSTM) and an embedding layer initialized with vectors from Glove word embedding¹. The system achieved a f-score of 0.72, and 0.50 in task 1, and task 2 respectively.

1 Introduction

Irony is one of the most prominent and pervasive figures of speech in human communication, dating back to ancient religious texts to modern microtexts. According to literary scholars (Grice, 1978; Lakoff, 1993), irony has been defined as a trope where the speaker intends to communicate a contradictory situation or the opposite meaning of what is literally said. It adopts a subtle technique where incongruity is used to suggest a distinction between reality and expectation in order to produce a humorous or emphatic effect on the listener. Irony poses an important challenge not only from a linguistic perspective but also from a cognitive one. Even without a solid understanding of irony, one can still recognize and produce

ironic utterances from as early as childhood (Harris and Pexman, 2003). Such capabilities are often associated with one’s ability to correctly infer others’ communicative intentions and perspectives towards a given situation. Psychological theories, such as “echoic reminder theory” (Kreuz and Glucksberg, 1989), “allusion pretense theory” (Kumon-Nakamura et al., 1995), and “implicit display theory” (Utsumi, 2000), confirm that cues for understanding ironic intent are not restricted to language. Ironic intent involves several other aspects including, but not limited to, the context of an utterance, the world’s perception and familiarity between the listener and the speaker, and psychological dimensions. Thus, as a purely text classification task, the irony detection task poses a significant challenge for computational linguists. Computational approaches focus on identifying the subtle incongruity between different parts of the text. Often, an ironic statement starts with an overtly positive attitude (“Yay I love”) and ends up in an disappointment (“working on my birthday”) or a negative attitude/statement (“another outage in less than 8 hours.”) followed by an appreciation (“Keep up the good work!”) or an incident (“I asked God to protect me from my enemies”) resulting in a completely unexpected output (“shortly after I started losing friends”).

Due to the limited scope of expression in social media such as Twitter², authors often end up lacking their statements with ironic cue words (‘Yay’) or social media specific features such as hashtags (‘#irony’) to make their ironic intent more obvious for the reader. Following this intuition, most of the attempts were made using probabilistic classification models which relied on textual cues such as lexical indicators like punctuation symbols (e.g., ‘?’), interjections (e.g., “gee” or “gosh”), and intensifiers (Kreuz and Caucci, 2007); the juxtaposition of positive sentiment and

¹<https://nlp.stanford.edu/projects/glove/>

²www.Twitter.com

negative situations (Riloff et al., 2013); discriminative N-grams like ‘yay!’ or ‘great!’ or “oh really” or “yeah right” (Tsur et al., 2010; Lukin and Walker, 2013); social media markers like hashtags (Davidov et al., 2010); emoticon usage (González-Ibáñez et al., 2011); and topics associated with irony (e.g. schools, dentists, church life, public transport, the weather). Carvalho et al. (2009) exploited text patterns in comments on articles of online newspapers to detect ironic statements, while Van Hee et al. (2016) developed a irony detection model using support vector machine (SVM) with a combination of lexical, syntactic, sentiment, and semantic (Word2Vec embedding) features. In recent times, multiple research attempts, founded on variants of the deep neural network built on top of word embeddings, showed a significant improvement over traditional methods over several natural language processing (NLP) tasks. A few representative works in this direction for detecting sarcasm, a demeaning variant of irony, especially in the colloquial form, are based on Convolutional Neural Networks(CNN) (Mishra et al., 2017), Recurrent Neural Networks (RNN) (Zhang et al., 2016) and a combination of CNNs and RNNs (Ghosh and Veale, 2016). Siamese networks (Bromley et al., 1994), widely used in image classification, have displayed a good performance over sentence similarity or document similarity tasks. A Siamese architecture contains two identical sub-networks, which are trained with two different inputs to distinguish the difference among them. Since in irony, different parts of a sentence can be incongruous with each other, we adopted the Siamese architecture to detect such incongruity between different sections of a sentence. In this implementation, each of the subnetworks consists of an embedding layer and a LSTM layer. We slice each input sentence into two fragments and feed them to the subnetworks. The output representations of subnetworks are then compared to distinguish if the two fragments are incongruous or not i.e. a sentence is considered as non-ironic if two fragments of a sentence are semantically non-incongruous, otherwise it is ironic.

2 Dataset Preparation & Resources

The train and test dataset consists of 3834 tweets and 784 tweets, respectively. The train dataset for Task 1 is balanced but in task 2, the prominent category was “irony by polarity contrast” (table 1).

2.1 Data Normalization

The distorted language, use of abbreviation, and high number of one-off words, prevents a model from being robust. Thus, each tweet is preprocessed, normalized, and cleaned with the following criteria.

1. To emphasize the ironic effect, an author often uses repetition of a character or a word. A set of regular expressions is used to normalize the word (“loooong” to “long”) and the word is replaced with a word from WordNet³ which has the lowest minimum edit distance⁴ between them. The repeated word sequence is split using a regular expression into multiple words (“YAYYAYYAYYAYYAY” to “YAY YAY YAY YAY YAY”).
2. Since this is a text based classification task, each link from the tweets is discarded.
3. The limited scope of social media incentivizes users to exploit different features of social media such as hashtags and emoticons more creatively and efficiently to express an opinion. Hashtags are often used by authors to emphasize key parts or themes in their texts or to convey their attitude or feeling towards the subject. This can provide a threshold for NLP techniques in order to infer the intended sense behind an ironic statement. Thus, each hashtag is processed and split into words. For example, “#TheReasonForTheSeason” is converted in “The Reason For The Season”.
4. Emojis have played a significant role in expressing the hidden feelings of a person not evident in plain text. Each individual emoji is replaced with their official name⁵.
5. The high number of one-off words increases the vocabulary size of a network. Due to the sparsity in the dataset because of one-off words, the model finds it difficult to train. Thus, all non-valid English words, according to WordNet dictionary, occurring less than twice in the entire dataset are removed.
6. Neural network models are data hungry and their success often relies on the size of the

train dataset. Since the train dataset is relatively small, it can not extract the distinctive, robust features for detecting irony. Thus, the dataset is extended by replacing the overtly positive and negative words with “positive” and “negative” respectively using the Sentiwordnet⁶.

7. In order to capture the incongruity between topics, the dataset is further extended by replacing words with its category type extracted from WordNet.

2.2 Building Train Dataset

Since a Siamese network expects two inputs and performs a comparison between the generated weights, each tweet is split into two parts. A number of training examples are generated by splitting the tweets where each split contains a minimum r number of words. Consider as an input a tweet containing n words with label y . The tweet will be split into $(n - 2 \times r + 1)$ combinations. In this experiment, the value of r is chosen as 3. For example, “Working on Boxing Day is so fun” will produce the following combinations:

1. (“Working on Boxing”, “Day is so fun”)
2. (“Working on Boxing Day”, “is so fun”)

For training purposes, the train dataset is split with a 90%-10% split ratio.

3 Siamese Network

3.1 Input Layer

Each tweet, with length n , is converted to a vector by replacing a word with its index value in the dictionary $s \in \mathbb{R}^{1 \times n}$. To resolve different lengths of input, each tweet is either padded or truncated to convert into a vector of size $s \in \mathbb{R}^{1 \times l}$ where l is the maximum allowed length. The maximum allowed length for the input vector for each sub-network is set to the average length of the tweets. The input vector is fed to an embedding layer which converts each word into a distributional vector of dimension D . Thus, the input tweet matrix is converted $s \in \mathbb{R}^{l \times D}$. The embedding layer is initialized with the embeddings extracted from Glove word embedding. We freeze the embedding layer to keep the general meaning of a word intact.

Table 1 Train Data Statistics

3.2 LSTM Layer

Among the variants of RNN networks, LSTM has demonstrated the power of semantic modelling by efficiently handling long term dependencies (Hochreiter and Schmidhuber, 1997) by defining each memory cell with a set of gates \mathbb{R}^d , where d is the memory dimension of hidden states of LSTM. It does not suffer from a vanishing or exploding gradient problem while performing back propagation through time. There are three gates, which are functions of x_t and h_{t-1} : input gate i_t , forget gate f_t , and output gate o_t . The gates jointly decide whether the memory update mechanism will occur or not. Equation (2) and (1) denotes the amount of information to discard and what to store in memory. Equation (4) denotes the output of a cell c_t . Equation (3), (5), and (6) denotes the input activation, cell state, and output vector of a LSTM cell respectively.

$$i_t = \sigma(W_i[h_{t-1}, x_t] + b_i) \quad (1)$$

$$f_t = \sigma(W_f[h_{t-1}, x_t] + b_f) \quad (2)$$

$$q_t = \text{sigmoid}(W_q[h_{t-1}, x_t] + b_q) \quad (3)$$

$$o_t = \sigma(W_o[h_{t-1}, x_t] + b_o) \quad (4)$$

$$c_t = f_t \odot c_{t-1} + i_t \odot q_t \quad (5)$$

$$h_t = o_t \odot \text{sigmoid}(c_t) \quad (6)$$

Due to the small dataset size, extra attention has been paid in order to prevent the network from overfitting. A recurrent Dropout is used between each time step of an input. Each LSTM layer outputs a weight matrix $s \in \mathbb{R}^{l \times m}$ (m = number of hidden memory units), which is passed to a Dropout layer.

3.3 Subtract Layer

The generated weights of each LSTM layer carries the conceptual representation of its input. Intuitively, the weight difference between the output of two LSTM layers should signify conceptual representations as either incongruous to each other or not. A subtract layer is used to calculate the weight difference between two sub networks.

The subtract layer produced an output matrix $s \in \mathbb{R}^{l \times m}$, which is passed as an input to a fully connected layer.

3.4 Fully Connected Layer

The fully connected layer produces a higher order feature set, based on the weight matrix obtained from the LSTM layer, which is easily separable into different classes. At the end, a Softmax layer is added on top of the fully connected layer.

4 Experimental Setup

Success with a neural network model largely depends on the apt input and optimal hyper-parameters settings. After investigating different combinations of hyper-parameters, the optimal setting is obtained for each layer of the network. The LSTM has 32 hidden memory units with a *sigmoid* activation function and recurrent dropout ratio of 0.5. The fully-connected layer consisted of 16 hidden memory units and uses *ReLU* as the activation function. Both of the layers are initialized with *Xavier normal initializer* (Glorot and Bengio, 2010). As an optimizer function, Adam optimization is used with a learning rate set to 0.001, while categorical cross-entropy is chosen as a loss function. The code is developed using the *keras*⁷ library.

5 Results

For both of the tasks, our model is compared with the state-of-the-art composite neural network model (Ghosh and Veale, 2016). Each model is trained with the same datasets. For the composite model, the entire tweet is fed as an input instead of just fragments of the tweet.

6 Output Analysis

In both tasks, the Siamese network outperforms the composite neural network model. The composite neural network model, trained with original tweets, is only able to capture certain ironic utterances where a similar pattern is encountered in the training dataset. The model responds well to obvious ironic markers such as “Ohh” in figure 2. Without the obvious ironic markers, the model mis-classifies the statement as non-ironic. Whereas the Siamese network classifies the statement correctly even without the obvious ironic

marker, the subtract layer captures the incongruity between two concepts in an ironic statement. However, the Siamese network fails to detect ironic statements with dropped negations. For example, the network could not figure out the ironic intent behind the following statement “Hey there! Nice to see you Minnesota/ND Winter Weather”, the model has no information about “Minnesota/ND Winter Weather”.

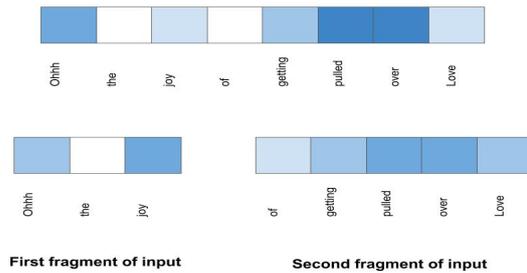

Figure 2 Output Vector of LSTM Layer

7 Conclusion and Future Works

We introduced *IronyMagnet*, a Siamese neural network model that is capable of separating ironic statements from non-ironic statements, as well as at a fine-grained level. Even with small datasets, the Siamese neural network is able to robustly capture the incongruity between two concepts. However, the system lacks the sophistication of understanding incongruity at a pragmatic level. Take, for example, “Whatever happened to the Guano Apes? Did they ever make it “Big in Japan?””. In this example, none of the models are able to establish the incongruity between “Guano Apes” and “Big in Japan”. Also, it can not correctly detect if the incongruous elements are located very close to one another within the tweet. However, since the Siamese network is able to correctly classify simple cases of irony, we can therefore hypothesize that the Siamese network can be a stepping stone towards determining contrastive figurative languages. In the future, we would like to extend our model by incorporating an attention network and other psychological stimuli which pertain to Irony.

Abstract

The objective of this paper is to provide a description for a system built as our participation in SemEval-2018 Task 3 on Irony detection in English tweets. This system classifies a tweet as either ironic or non-ironic through a supervised learning approach. Our approach is to implement three feature models, and to then improve the performance of the supervised learning classification of tweets by combining many data features and using a voting system on four different classifiers. We describe the process of pre-processing data, extracting features, and running different types of classifiers against our feature set. In the competition, our system achieved an F1-score of 0.4675, ranking 35th in subtask A, and an F1-score score of 0.3014 ranking 22th in subtask B.

1 Introduction

Irony detection in text has extended to different data forms (tweets, reviews, TV series dialogues), our domain of data in this task is a Twitter corpus provided by SemEval2018 organizers. Here, irony detection refers to computational approaches to predict if a given text is sarcastic. This problem is hard because of the nuanced ways in which irony may be expressed. The most difficult part of the problem mentioned is the process of feature engineering, because it defines the parameters and the relationships and dependencies between semantic meanings, and gives us the numerical model that the classifier would proceed to work on, thus being crucial to the soundness and efficiency of the system.

This led us to dive into deeper questions, such as the nature of tweets, and how we are dealing

with a version of the English language that is not directly workable. We need to perform pre-processing to deal with annotations and hashtags. Another question is how to analyze irony in English language and derive a rule-based approach that can be implemented to better understand the semantics of ironic text.

The problem, as described by the SemEval-2018 task organizers, addresses both the binary distinction between irony and non-irony, as well as different types of irony.

1.1 Task Description

The SemEval-2018 Task 3 is divided into two subtasks:

Subtask A is a binary classification problem where we are asked to classify a tweet as ironic or not ironic, based on a given training set of labeled tweets (0 for non-ironic and 1 for ironic).

Subtask B is a multi-classification problem where we classify the tweets to which type they belong as either situational irony or verbal irony or other irony or not ironic. Each tweet in the training set is labeled as follows: (0 for non-ironic, 1 for situational irony, 2 for verbal irony, and 3 for other forms of irony).

1.2 The Dataset

The used dataset in this assignment is the one provided in SemEval-2018 task 3. It consists of 3,842 tweets in total. The tweets were collected by searching Twitter for the hashtags #irony, #sarcasm and #not.

The dataset was presented in two phases:

1- Training data: already labeled tweets used to train the classifiers. Each tweet was provided with a binary classification label and an index.

2- Testing data: unlabeled tweets to test the classifiers against. For each instance in the test

data, participants submitted a predicted label. Based on these predictions, competition scores were calculated using four metrics (F1-score, precision, recall, and accuracy).

2 Literature overview

There has been much research involving the definition of irony and the distinction between irony and sarcasm. To date, however, experts do not formally agree on the distinction between irony and sarcasm as shown by Aditya Joshi et al., (2016). Moreover, when describing how irony works, Antonio Reyes et al., (2013), distinguish between situational irony and verbal irony. Situational irony is an unexpected or incongruous quality in a situation or event, as shown by Shelley (2001). Whereas verbal irony, in contrast, is a playful use of language in which a speaker implies the opposite of what is literally said.

In his work on the Sarcasm Detector website, Mathieu Cliche collected tweets from Twitter that were labeled with the hashtag #sarcasm. His hypothesis was that sarcastic tweets carry what he calls a contrast of sentiments (e.g. start with a positive sentiment and end with a negative sentiment). He also uses features such as n-grams and topics as accompanying features then trains an SVM algorithm as a classifier. Cliche's system harbored an F1-score of 0.60, an improvement from previous work on sarcasm detection as shown in Cliche (2014).

Chun-Che Peng et al., (2015) followed up on Cliche's work to acquire improved results and stated that irony detection models are prone to suffer from high variance, which be the effect of having a high dimensional feature space, therefore making it important to reduce the dimensions of the feature space and only use the most relevant features. Their paper also suggests that using a Gaussian kernel instead of a linear kernel might be a better approach, given that the data itself is not linearly separable.

In our work, we build upon Cliche's (2014) hypothesis and try to benefit from Peng et al.'s (2015) remarks on using the most relevant features.

3 Implementation

The system is based on natural language processing where we are targeting to improve performance for classifying tweets as ironic or

non-ironic by combining many data features and a voting system on many classifiers, we design pattern-based features that indicate the presence of discriminative patterns as extracted from a large irony-labeled dataset.

3.1 Text Preprocessing

To generate good results and to control the number of unneeded computations, the tweets are filtered according to certain criteria. We will briefly go through the steps of pre-processing a tweet.

3.1.1 Tokenization

The first step to handle textual data is tokenization, which is the process of splitting sentences into single words.

3.1.2 Stop Words

The second step is to filter the data and remove any insignificant and redundant words. There are known words, called stop words, as shown by Alani (2014) are always removed to enhance the performance.

For the objective of the task, irony detection in tweets, we removed some words from the **Stop Words** sets because they are significant in detecting irony, especially in the sentiment analysis model. In sentiment analysis, we removed any negating words and conjunctions, such as: ("no", "not", "until", "but"). Whereas in BoW, keeping negation was unnecessary.

3.1.3 Lemmatization

Lemmatization is the process of getting the root of a word. It takes into consideration the morphological analysis of words. A lemma is the same for variations of a word, therefore; it reduces sparsity.

3.2 Extracting Features

We here convert the tweet into a vector of dimensional attributes. While feature mapping is the hardest step in the code, the pattern of feature engineering in task A and task B is all the same, we follow the same steps of mapping and classifying to get different outputs due to different training data on the models.

We have tried three different directions in regards to extracting features from the dataset. The first being the bag of words (BoW) model, the second is rule-based sentiment analysis, and the third being word embedding.

Four classifier models were used to train and test the three feature sets implemented. Each feature set of which is tested on each classifier model. In other words, we test (feature set ‘1 of 3’, classifier ‘1 of 4’) pairs. Then we used a voting system to compare between the results of (feature set, classifier) pairs, and then the classification with the higher number of votes is picked as the final classification.

3.2.1 Bag of Words Feature

First, we create three arrays. The first array for the words in ironic tweets, the second array for the words in non-ironic tweets and the final array for words in all tweets. **Second**, we calculate the number of repetitions of every word in the ironic tweets array across all ironic tweets. We repeat the same step for every word in the non-ironic tweets across all non-ironic tweets. **Third**, we extract the most common words (with highest frequency) across both tweets to eliminate them from our processing to the data - since they will not be effective in determining if a tweet is ironic or not. **Fourth**, we create hash-maps for the words as 'key' attribute and their frequency value as 'value' attribute - one hash-map for words in ironic tweets, another for words in non-ironic and the last one for the common ones. **Fifth**, we sort the hash-maps for easy acquiring of the words with highest frequencies. **Finally**, we add the hash-maps as another feature for the data processing procedure.

3.2.2 Sentiment Analysis

According to Van Hee et al., (2016), verbal irony arises from a clash between two evaluation polarities. We use sentiment analysis to help detect irony in a tweet via contrasting polarity. We used the **polarity** feature of a word to determine if the feelings in the tweet changed 180 degrees. We did not apply lemmatization prior to extracting this feature because it affects polarity. We also handle **emojis** and **negation words** in the tweets since they contribute to the polarity of the sentence. Below are the steps we perform.

- a. Split the tweet into two parts on a conjunction from a list created by hand. We gather all the available conjunctions in English Grammar. We handle all the conjunctions except the ones that consist of more than one word like “not only... but also”... etc.

- b. Perform pre-processing on each part of the tweet individually.
- c. Evaluate polarity of each word of each part of the sentence, and then define the polarity of each part given the ratios of positive, negative, and neutral words to the total length of the sentence.
- d. Each part is given a tag as positive (POS), negative (NEG), or neutral (NEU).
- e. We tune the parameters that define the threshold of positivity or negativity of each part of the sentence, being 0.5 in this case.
- f. Compare the polarities of the sentence parts.

To sum up: The **Sentiment Analysis** method uses contrasting polarity or extra positivity and extra negativity as an indication of irony. We split the tweet into two parts, taking each part as input into the **Sentiment Intensity Analyzer**, the polarity of each word is returned by the analyzer as either positive (POS), negative (NEG) or neutral (NEU). To calculate the **overall polarity** of one part of the tweet, we search for the polarity category that has **highest** number of words and return it as the **overall** polarity. The overall polarity of both parts of a tweet is then examined and classified as ironic if contrasting polarity (e.g. POS-NEG or NEG-POS) is found.

3.2.3 Word Embedding

First, we build a model using training data to act like a dictionary for upcoming processing. The model used in this step is a Word2Vec model. **Second**, we process each tweet in the training dataset, using every word in every tweet and passing it to the model - which as a result, returns an equivalent numerical vector to the word with a fixed length, in our case; we choose a length of one hundred (100) as a moderate length value. **Third**, we add all the vectors of the words in each tweet and divide this sum by their number. Thus, we acquire a numerical representation of a fixed length for every tweet. Fourth, we append all those vectors of all tweets. Finally, we pass the resulting appended vectors of all tweets to the classifier. If the word did not exist in the dictionary we made beforehand, a vector of length 0 is returned.

3.3 Choosing a classifier

We use four models for classification and we build a voting system for them all, tune the parameters, and record the findings to enhance the performance, the classification models are selected based on the literature review. The classification algorithms used are listed below:

- Naive Bayes Classifier.
- Support Vector Machine (SVM).
- Decision Trees.
- K-Nearest Neighbor Classifier: After some tuning, $k=1$ generated the best results for all the features.

4 Results

Our system is divided into three classes one for each feature. Then the result of each is classified using the four different classifiers stated above. Below we present a chart of the accuracies obtained with different classification algorithms and different feature types.

	BoW	Sen-A	Word-E
NB	65	44	49
SVM	62	45	53
Trees	57	59	57
1-NN	52	60	48

Table 1: accuracy of feature-classes when tested against classifiers using the training set for task A.

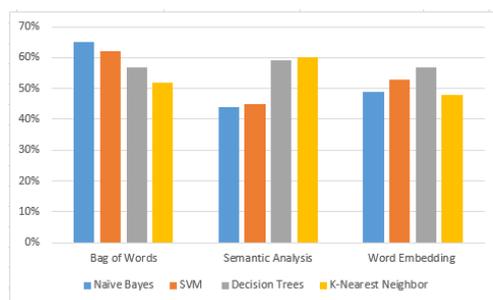

Figure 1: results obtained by two voting systems using three feature set types as shown.

4.1 Classifiers Voting System

We used a voting system to combine the predictions from the four classifiers exploiting different feature types.

4.2 Features Voting System

This voting system uses the four output results from the four classifiers voting system to get an overall result for the whole system.

The results of the system evaluation phase are as follows:

	Accuracy	Precision	Recall	F1-score
Task A	0.5089	0.4102	0.5434	0.4675
Task B	0.4923	0.2998	0.3108	0.3014

Table 2: The score obtained by the system in subtasks A and B as evaluated by SemEval.

4.3 Analysis

Looking at the results, we hypothesize that the system's performance can be improved by combining all features instead of testing them individually. It was also remarkable that the best accuracy was obtained by the bag-of-words model using the Naïve Bayes classifier.

We also believe better results can be achieved if there was a bigger dataset at hand to train upon, and if we had sufficient time to perform grammar checking on the tokens and other operations that can reduce noise.

5 Conclusion

This paper describes our irony detection system that was built in the framework of SemEval-2018 Task 3. We used the same architecture for subtask A and B and obtained F1-scores of 0.4675 and 0.3014, respectively. Our binary classification results are much better compared to multi-classification, which implies that we need to implement another feature model that could represent a whole sentence (e.g. Sentence2Vec rather than Word2Vec). In future work, we aim to enhance the performance of our classifier by combining all features. Moreover, we will add new features to solve the problem of word dependencies (by this we mean that all system features do not account for dependencies between words in the same sentence) so that the system gives more accurate results.

Acknowledgements

The authors would like to thank Prof. Ayman Khalafallah of Alexandria University for his constant guidance and support throughout the process of developing this system.

Abstract

This paper describes the Irony detection system that participates in SemEval-2018 Task 3: Irony detection in English tweets. The system participated in the subtasks A and B. This paper discusses the results of our system in the development, evaluation and post evaluation. Each class in the dataset is represented as directed unweighted graphs. Then, the comparison is carried out with each class graph which results in a vector. This vector is used as features by machine learning algorithm. The model is evaluated on a hold on strategy. The organizers randomly split 80% (3,833 instances) training set (provided to the participant in training their system) and testing set 20% (958 instances). The test set is reserved to evaluate the performance of participants systems. During the evaluation, our system ranked 23 in the Coda Lab result of the subtask A (binary class problem). The binary class system achieves accuracy 0.6135, precision 0.5091, recall 0.7170 and F measure 0.5955. The subtask B (multi-class problem) system is ranked 22 in Coda Lab results. The multiclass model achieves the accuracy 0.4158, precision 0.4055, recall 0.3526 and f measure 0.3101.

1 Introduction

Social media are deemed as a diverse web-based network that serves as an online platform to communicate and disseminate information or ideas among individuals and fraternities. Since its advent, people all around the globe harness it as a major source to express their opinions or emotions, however, an expeditious increase in its usage has been reported in the last decade (Kelly et al., 2016; Perrin, 2015). Among the multifarious range of social media platforms, Twitter is the most popular one. It is basically a microblogging site diffuses information pertaining to what is

happening around the world, and what are the current top-interest areas among the wider population (Rosenthal et al., 2017). According to a recent survey, 6000 tweets per second are sent by 320 million active monthly users, thus 500 million tweets per day (Statistics, 2014). This poses a challenge for the scientific community to accurately discern the sentiment of a tweet out of this plethora. Since certain aspects associated with sentiment analysis are quite arduous yet feasible to ascertain (such as negative, positive, a neutral aspect of the opinion) than irony.

Irony detection has its implications in sentiment analysis (Reyes et al., 2009), opinion mining (Sarmiento et al., 2009) and advertising (Kreuz, 2001). For the past few years, irony-aware sentiment analysis has attained significant computational treatment due to the prevalence of irony on the web content (Farías et al., 2016). It is a broad concept, which has an association with multiple disciplines such as psychology, linguistics, etc. The irony is to efficaciously delineate a contrary aspect of the utterance (Grice, 1975). Irony cannot be detected with the simple scrutiny of words expressed in a statement, whereas, an aspect of irony is implicitly connected with the utterance. Furthermore, it could be deemed as a stance that has been expressed in an ironic or sarcastic environment (Grice, 1975; Alba-Juez and Attardo, 2014). Detection of this implicit aspect poses a strenuous computational challenge over the scientific community in terms of initiating effective models in this regard. In the stream of irony detection, the first-ever computer model was proposed by (Utsumi, 1996). Subsequently, various other models have been presented that have specifically addressed the irony detection among tweets by using different features such as, cue-words or user-generated tags (i.e., Hashtags) etc (Van Hee, 2017; Hernández-Farías et al., 2015; Reyes et al., 2013).

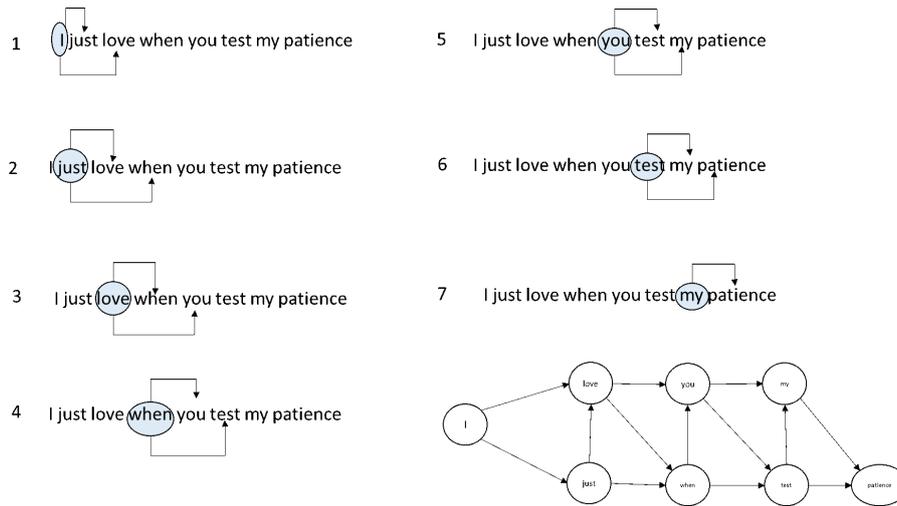

Figure 1: Graph Construction with vicinity size 2 illustrates how the vicinity size move toward the end of the tweet; in this example the frame is the two following words and for each word some edges and nodes are added to the graph.

Though, there does not exist any optimal model that could be considered as a baseline for irony detection. This paper presents a model to automatically detect sarcasm or irony from the plethora of tweets. The proposed model is used in the two subtasks. The first module assigns the binary value against tweets (i.e., 1 indicates that tweet is ironic and 0 indicates that a tweet is non-ironic). The second module performs multi-class classification: (i) verbal irony realized through a polarity contrast, ii) verbal irony without such a polarity contrast (i.e., Other verbal ironies), iii) descriptions of situational irony and iv) non-irony. For classification, data set is comprised of 4792 samples, taken from GitHub link provided by the SemEval 2018 organizers.

2 Task Overview

In SemEval-2018 (Cynthia Van Hee, 2018), task 3 contains two subtasks for the detection of Irony in English tweets. In the first task, the system has to determine whether a tweet is ironic or non-ironic, making it a binary classification problem. The second task is the multiclass classification problem where the ironic and non-ironic task is further divided into four categories as mentioned below:

1. verbal irony realized through a polarity contrast
2. verbal irony without such a polarity contrast (i.e., other verbal irony)
3. descriptions of situational irony

4. Non-irony

Systems are evaluated using standard evaluation metrics, including accuracy, precision, recall and F1-score.

3 Proposed Model

The proposed model is inspired by the previous work (Giannakopoulos et al., 2008; Maas et al., 2011), however, we used some additional features as well as a word graph similarity score. Each tweet is represented as directed unweighted word graph and the edge between each word is created based on the vicinity window size explained in 1. Each class in the dataset is represented as directed unweighted graphs. Then, the comparison is carried out with each class graph which results in a vector. This vector is used as features by machine learning algorithm. The graph is constructed based on a class assignment and then we measure the similarity of a tweet with each class graph. The similarity between two graphs (tweet graph and class graph) can be measured in multiple ways, but in this research, we used the containment similarity (non-normalized value), maximum common subgraph similarity and its variant compare graph in terms of similarity.

3.1 Graph Construction

The tweet contained a set of words. These words will be used to construct the word graph based on their vicinity. Each word in the tweet is represented by the labelled node. The nodes within

Class Name	Number of Coloumn
Verbal irony by means of a polarity contrast	1728
Other types of verbal irony	267
Situational Irony	401
Non-Ironic	604

Table 1: Data set Description

window size are joined by an edge. The sequence of the words is preserved by using directed edges. The size of the vicinity window can affect the accuracy of the method. In this research, we used a vicinity size of 2, as seen in 1

The graph similarity between the graph of a tweet and the graph of the irony class can define the degree of irony in the tweet. For the purposes of our study, we used the containment similarity (non-normalized value), maximum common sub-graph similarity and its variant compare graph.

3.2 Dataset

The dataset is provided on the [GitHub](#) source. This corpus is constructed of 3,000 English language tweets. These tweets are searched by using hashtags #irony, #sarcasm and #not. The data were collected from the period of five months (1st December 2014 to 1st April 2015) and represent 2,676 unique users. All tweets were manually annotated using the scheme of Van el al ([Van Hee et al., 2016](#)). The organizer used the services of three students in linguistics as well as English language speakers to annotate the entire corpus. The ([Stenetorp et al., 2012](#)) tool was used as the annotation tool. The percentage agreement score (kappa scores 0.72) is also calculated for the annotation. The number of instances for each class is mentioned in Table 1.

As seen in Table, 2396 instances are ironic (1,728 + 267 + 401) while 604 are non-ironic. The organizer balances the class data by using background corpus. After balancing the total data set contain 4,792 tweets that contain 2,396 ironic and 2,396 non-ironic tweets. The SemEval-2018 competition used the hold on the strategy to check the effectiveness of each participated system. The organizers randomly split 80% (3,833 instances) training set (provided to the participant in training their system) and testing set 20% (958 instances). The test set is reserved to evaluate the performance of participants systems.

3.3 Feature Engineering

3.3.1 Containment Similarity

The containment similarity measure has been used to calculate, graph similarity ([Aisopos et al., 2012](#)). In this research, we used bigram nodes. The measure expresses the common edges between two graphs by the number of edges of the smaller graph.

$$CS(G_T, G_S) = \frac{\sum_{e \in G_T} \mu(e, G_S)}{\min(|G_T|, |G_S|)} \quad (1)$$

Where GT (target graph) is the word graph of a tweet, G_s (source graph) is the word graph of an irony classes. The graph size can be the number of nodes or edges that are contained. e is an edge of a word graph.

3.3.2 Maximum Common Sub graph

The maximum common sub graph similarity is based on the size of the graph. We used the three variations of the metric are described in the equation 2, 3 and 4

$$MCSNS = \frac{MCSN(|G_T|, |G_S|)}{\min(|G_T|, |G_S|)} \quad (2)$$

Maximum Common Sub graph Node Similarity (MCSNS): where $MCSNS$ (GT (target graph) — G_s (source graph)) is the total number of nodes that are contained in the MCS of that graphs..

$$MCSUES = \frac{MCSUE(|G_T|, |G_S|)}{\min(|G_T|, |G_S|)} \quad (3)$$

Maximum Common Sub graph Edge Similarity (MCSNS): where $MCSUE$ (GT (target graph) — G_s (source graph)) is the total number of the edges contained in the MCS regardless the direction of them.

$$MCSDES = \frac{MCSDE(|G_T|, |G_S|)}{\min(|G_T|, |G_S|)} \quad (4)$$

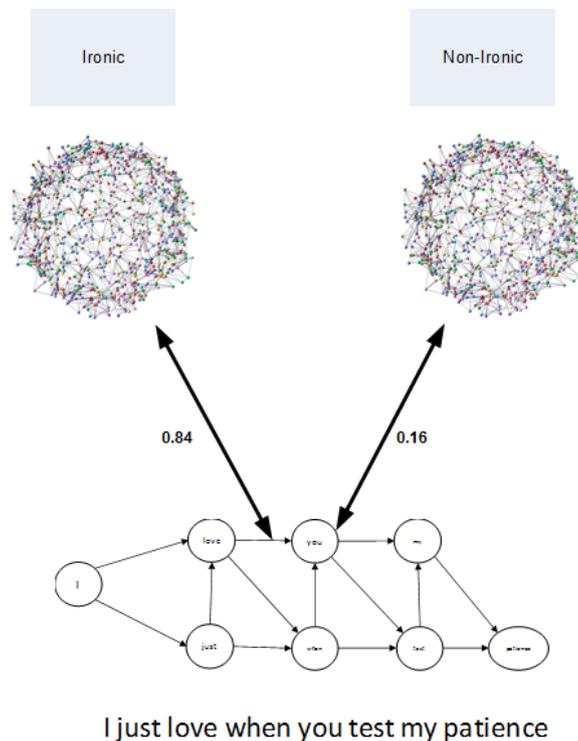

Figure 2: Graph Similarity Feature Extraction for one measure. The graph of a tweet used to compare with training data class graphs, in order to produce two numbers (depending upon the numbers of classes). These numbers will be used as a feature vector. The feature vector is provided to trained model to predict the class of the new tweet.

Maximum Common Sub graph Directed Edge Similarity (MCSDES): where MCSDES (GT (target graph) — Gs (source graph)) is the number of the edges contained in the MCS and have the same direction in the graphs.

3.3.3 Tweet Polarity and Latent Dirichlet Allocation

We used the SenticNet library to calculate the sentence polarity score as well as subjectivity score. Moreover, we also perform latent Dirichlet Allocation on the corpus and then used the trained model to calculate similarity helinger distance for each class (Blei et al., 2003; Beran, 1977).

3.4 Model Selection

In this paper, we used Tree-based Pipeline Optimization Tool (TPOT) that designs and optimizes the machine learning pipelines by using an evolutionary algorithm (Olson et al., 2016). The labelled data are provided for TPOT classification. Both TPOT classes return hyper tune model for both types of data (binary and Multiclass problem). After, data analysis, it was observed that the number of classes in the multiclass dataset is a

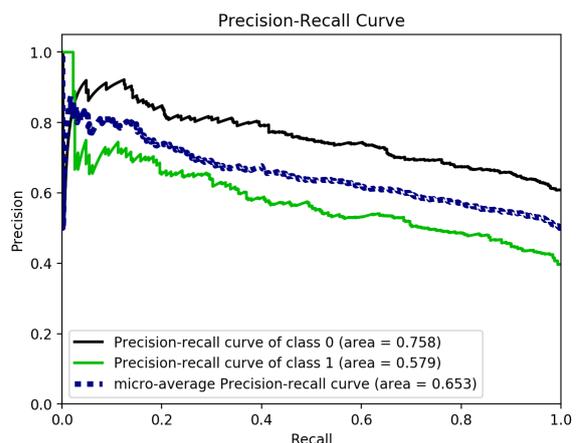

Figure 3: Precision Recall Curve of Binary Class problem

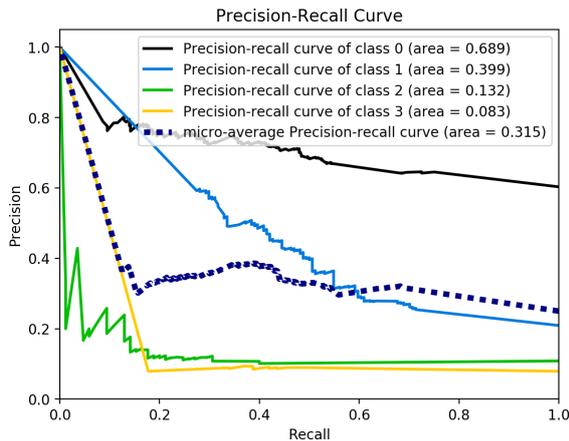

Figure 4: Precision Recall Curve of Multi Class problem

significant imbalance, which gives rise to the class imbalance problem. In order to handle this problem, we used SMOTE (Cummins et al., 2017) a Python toolbox to tackle the curse of imbalanced data. For binary classification problem, TPOT gives extreme gradient boosting classifier tune parameters. For the multiclass problem, TPOT gives stacking of extreme gradient boosting classifiers, extra trees classifier and random forest classifier.

4 Results Evaluation

For experimentation, we used efficient tool sklearn (Machine Learning Library) to train machine models mentioned above (Pedregosa et al., 2011). For both model hold on strategy was adopted. Training data contain 80% (3,833 instances) and testing sets 20% (958 instances). Our system ranked 23 in the Coda Lab result of the binary classification problem. The binary class system achieves accuracy 0.6135, precision 0.5091, recall 0.7170 and F measure 0.5955. After the release of the gold set, the model is again tuned by using TPOT library and result are evaluated as seen in Figure 3. Our system ranked 22 in the Coda Lab result of the multi-class problem. The multi-class model achieves the accuracy 0.4158, precision 0.4055, recall 0.3526 and f measure 0.3101. After the release of the gold set model was re-trained and evaluated. The result of the multiclass problem is shown in Figure 4

5 Conclusion and Analysis

An innovative citation classification technique is proposed that combines the well-described struc-

ture of graphs with classification algorithm. The word graphs can seize the collection of the words that are contained in a tweet. The tweet word graph is generated and then by using several graph similarity techniques is applied to the dataset. These graph similarity metrics output is represented as a feature vector by the classification algorithm. It is concluded that word graph with different vicinity window is a good source of information to classify irony in the tweet. The model can be improved by using a large dataset. The proposed method can be enhanced by using a different graph similarity metric as features. The word graph construction method with different vicinity window size might improve results.

Lancaster at SemEval-2018 Task 3: Investigating Ironic Features in English Tweets

Edward Dearden and Alistair Baron

School of Computing and Communications

Lancaster University

Lancaster, UK, LA1 4WA

initial.surname@lancaster.ac.uk

Abstract

This paper describes the system we submitted to SemEval-2018 Task 3. The aim of the system is to distinguish between irony and non-irony in English tweets. We create a targeted feature set and analyse how different features are useful in the task of irony detection, achieving an F_1 -score of 0.5914. The analysis of individual features provides insight that may be useful in future attempts at detecting irony in tweets.

1 Introduction

With so many people using social media and microblogs such as Twitter, a huge amount of natural language data is available to be analysed. It is desirable to be able to accurately interpret what people are saying. An example of this is in the field of sentiment analysis where the aim is to determine whether the language being used by an author is positive or negative.

These kinds of tasks are made more difficult by the presence of figurative language. Figurative language is a type of language where the contents of the text are not literally true, making it difficult to ascertain the true meaning of the text purely from the content. Irony is a particular type of figurative language in which the meaning is often the opposite of what is literally said and is not always evident without context or existing knowledge. A system capable of accurately detecting irony would be a valuable addition to sentiment analysis systems, and other systems for natural language understanding which are confounded by irony.

In online discourse, examples of irony are very common. Social media platforms capture natural language which often includes sarcastic sentences. An example of a use for irony detection is in the area of online product reviews (Tsur et al., 2010)

which can contain large amounts of ironic language. An irony detection system could be used to prevent ironic negative reviews being misinterpreted as positive and highlighted in advertising.

The system described in this paper aims to identify targeted features of irony and analyse how important they are in identifying ironic tweets. The annotated twitter data we use is that provided by the event organisers. The task is described in the task description paper (Van Hee et al., 2018).

2 Related Work

The task of irony detection is an inherently difficult one. Wallace (2015) suggests that to create a good system for irony detection, one cannot rely on lexical features such as Bag of Words, and one must consider also semantic features of the text.

There have been various methods employed to detect irony. Reyes et al. (2012) created a dataset generated by searching for user-created tags and attempted to identify humour and irony. The features used to detect irony were polarity, unexpectedness, and emotional scenarios. Their classifier achieved an F_1 -score of 0.54 for general tweets of various topics, rising to 0.65 when the irony features were combined with the ambiguity features used to detect humour. The score also improved when looking at domain specific tweets, suggesting domain knowledge and context can be useful for identifying irony.

More recently, Van Hee et al. (2016a) investigated annotated ironic tweet corpora and suggested that looking at contrasting evaluations within tweets could be useful for detecting irony. Van Hee et al. (2016b) also created a system to detect ironic tweets, looking beyond text-based features, using a feature set made up of lexical, syntactic, sentiment, and semantic features. They achieved an F_1 -score of 0.68. They also suggested

that irony by polarity clash was more simple to detect than other forms of irony, e.g. situational irony.

A number of works have looked at detecting sarcastic tweets. Sarcasm is a type of irony in which the meaning is the opposite of what is literally said. [Maynard and Greenwood \(2014\)](#) used a rule based system to supplement sentiment analysis systems by flipping the predicted polarity of a tweet if it contained a mismatch of sentiment between hashtag and text. They achieved an F_1 -Score of 0.91. [Davidov et al. \(2010\)](#) used pattern-based and punctuation-based features, achieving an F_1 -Score of 0.83. [González-Ibáñez et al. \(2011\)](#) combined lexical and pragmatic features, aiming to distinguish between sarcastic, positive, and negative utterances. Their classifiers achieved 70% accuracy distinguishing between sarcasm and positive tweets and between sarcasm and negative tweets. [Barbieri et al. \(2014\)](#) looked at distinguishing sarcasm from other domains of text including irony. They achieved an F_1 -score of 0.60 when differentiating between sarcasm and irony compared to 0.89 when differentiating between sarcasm and politics. These findings suggest that it is easier to distinguish sarcastic tweets over irony in general. This could link to [Van Hee et al. \(2016b\)](#)'s finding that situational irony and other types of irony are harder to detect than irony by polarity clash. Given much of the irony in tweets is sarcasm, looking at some of these features may be useful.

One challenge for irony detection is that the understanding of irony often relies on context. There is certain contextual information that is required for a human to parse a sentence as being ironic. For example, the sentence "I am soooo happy to be going to the dentist tomorrow" would only be noticed as being ironic if the reader understood that the word 'dentist' has certain negative associations. [Rajadesingan et al. \(2015\)](#) tries to address this challenge by looking at more behavioural aspects of irony including looking at positive and negative associations of certain words, achieving an accuracy of 83%.

Other approaches have aimed to capture the context in which a tweet was posted for irony detection. [Bamman and Smith \(2015\)](#) used author and audience features on top of tweet features. These features looked at the past tweets of authors and the people to whom the tweet is responding.

Their best performance was 85% accuracy. [Wang et al. \(2015\)](#) used three types of history of the tweet to try and bring in additional context: history of the conversation; history of the author; and history of the hashtag/topic. They improved the baseline F_1 -Score of 0.55 to 0.60.

3 System Description

The developed system uses only the text data of the tweets provided with the task. It does not handle any contextual features as these would require gathering previous tweets and responses. The classifier we used was a standard, untuned SVM. As much of the code as possible has been made publicly available so it can be replicated¹. There are certain parts of the system that cannot be shared, such as the USAS tagging system².

In the preprocessing stage the tweets were reduced to just the text, separately extracting emojis, hashtags, and user mentions, for use as features. Most of the processing of the text was performed with the python Natural Language Toolkit (NLTK) ([Bird and Loper, 2004](#)), including using the NLTK Tweet Tokeniser to tokenise the text.

For classification we used the Linear SVC implementation in the popular python machine learning package scikit-learn ([Pedregosa et al., 2011](#)). We performed no tuning of the model as we were more interested in features and their usefulness than gaining the maximum precision and we wanted to avoid overfitting. We also used a random forest classifier to compare results.

3.1 Features

The features used by this system fall into four main categories: Tweet-level features, Bag-of-X features, Sentiment features, and Complexity features. All feature values were normalised so they were between 0 and 1.

Tweet Features are the non-language features contained directly within the contents of the tweet. These features include punctuation, hashtags and emoji. These have been used in past research and found to be useful for the task. It is thought that these features are used to flag a tweet as ironic. As there were many different types of emoji used on Twitter, some very infrequently, the emojis, punctuation, and hashtags used were restricted to the

¹<https://github.com/dearden/SemEval2018-Irony>

²<http://ucrel.lancs.ac.uk/usas/>

top 50 by frequency over the whole training set of each. Each of these top 50 were a feature and their value was 0 or 1 based on whether or not the token was present in the text. The tweets were tokenised such that repeated punctuation marks were counted as a single token. For example, “...” would be counted as a single token, not 3 instances of “.”. We also count examples of repeated characters, e.g. in “Greeeeat!”, and the proportion of the tweet that is capitalised. Other tweet features were: Number of links, number of mentions, number of hashtags, Tweet length, average word length, and amount of punctuation.

Bag-of-X Features is the set of features which contain the 1000 most frequent tokens of various types. The tokens used for these features were: word unigrams, word bigrams, character trigrams, POS tags, and Semantic tags. For the POS tagging, we used the NLTK POS tagger (Bird and Loper, 2004) and for Semantic tagging, the USAS semantic tagger (Rayson et al., 2004). Semantic tags put each word (or multi-word expression) into semantic categories, providing knowledge if some texts contain more emotion-based terms or more science and technology terms, for example. This should provide a higher level view of the text than achieved by bag of words. Using these techniques is like casting a wide net over the text that may find characteristics of irony not picked up by the more targeted features. They are also included to test the theory that lexical features are not useful for the task of irony detection.

For **Sentiment Features** we used a popular python package VaderSentiment (Pedregosa et al., 2011). Sentiment features may be important because if irony involves saying something positive to mean something negative, it may be that contrasts in sentiment or extreme values of sentiment are features of irony. The sentiment features gathered were: Positive sentiment score, negative sentiment score, mean score, standard deviation, range, average change of sentiment between adjacent words, number of positive to negative transitions, and emoji sentiment. When looking at changing sentiments, we modelled each sentence as a collection of words that were either positive, negative or neutral. We looked at the way the words in the sentence transitioned between positive and negative. For example, the sentence “I love how awful everything is right now”, would have one transition between “love” and “awful”.

Emoji Sentiments were used from the work of Kralj Novak et al. (2015) on the sentiment of emojis. We included the mean, maximum, and minimum emoji sentiment, as well as the number of positive and negative emojis.

The **Complexity features** we gathered were: negations, function words, number of syllables, Automated Readability Index, ambiguity, lexical diversity, and lexical density. These features were included to examine the difference in complexity and style between ironic and non-ironic tweets. Ambiguity was calculated as the average number of meanings for each word in the sentence according to WordNet (Kilgarriff, 2000).

3.2 Feature Sets

We tested the system with seven feature sets. The first four feature sets (Tweet, Bag-of-X, Sentiment, and Complexity) are as described above. The other three are as follows:

Submission: A combination of Tweet, Complexity, and Sentiment Features as described above containing 126 features.

Reduced: A reduced version of the submission set with the token frequency features (Emoji, Punctuation) removed. The idea of this set is to see if keeping only a focussed set of features impacts performance. This set contains 27 features.

Combined: All the features combined together to see whether performance is increased by using all the features. Contains 3,537 features.

The features representing occurrences of individual hashtags were omitted as they did not repeat very often and we did not want the model to overfit. Also, as the data was gathered using hashtags we were concerned that certain hashtags would be used in conjunction with the hashtags used to gather the data and may not be representative of irony generally. We left the Bag-of-X features out of the submission feature set because we did not want this set being too large and overfitting. With our submission set, we aimed to use targeted features as opposed to data-driven features such as bag-of-words and character n-grams. This makes the system more explainable, with the reasoning pre-defined. With data-driven features, especially character n-grams, it can be difficult to explain

Feature set	Precision	Recall	F ₁ Score
Baseline	0.5296	0.5756	0.5516
Tweet	0.5209	0.7203	0.6046
Bag-of-X	0.5153	0.5949	0.5522
Sentiment	0.4691	0.5370	0.5007
Complexity	0.4350	0.6238	0.5125
Submission	0.5321	0.6656	0.5914
Reduced	0.5385	0.6527	0.5901
Combined	0.5387	0.6495	0.5889

Table 1: Results of Linear SVC on test set.

why features are useful for the task. For the reduced set we went further, omitting all of the data-driven features. This meant removing Emoji and punctuation features so the feature set was more likely to capture the true features of irony as well as being more explainable.

One drawback of our feature extraction is the noisiness of the text. The NLTK POS tagger and VADER Sentiment only perform well with standard text. If we had performed better normalisation on the text before extracting Bag-of-X and Sentiment features, these feature sets may have performed better.

4 Results and Discussion

We ran the classifier with a number of different feature sets to assess the power of different types of feature. Bag-of-Words using all word tokens was used as a baseline to compare the other feature sets to. The bag-of-words implementation we used was slightly different to the baseline provided with the task in so far as it does not use Scikit-learn’s in-built Vectoriser. As well as the baseline bag of words, seven feature sets were evaluated, as described in Section 3.2.

The results from our system can be seen in Table 1, with a Linear SVC. The tweet feature set was more useful than expected, with the highest F₁ Score. This suggests that twitter users communicate elements of what they mean via emojis, punctuation, and the way they present their tweets. The high recall means that this feature set is causing many tweets to be flagged as ironic. However, given in most real data there are likely to be fewer ironic tweets than non-ironic, high precision may be more desirable than high recall. Another concern with relying on these features is that an irony detection implementation that is clueless if a tweet contains no emojis or hashtags is not an effective

system. This may also explain why the Tweet features did not achieve higher results. Many ironic tweets do not contain emojis or punctuation that flag their irony. The bag-of-x features and the baseline performed similarly, both getting an F₁ Score of around 0.55. The addition of Bigrams, Trigrams, POS and Semantic tags does not seem to have increased the accuracy. The performance of these feature sets is not surprising as the features were in no way targeted to irony. This supports the findings of Wallace (2015) that lexical features alone are not effective at identifying irony. The sentiment features performed the worst. This is in line with the results of Van Hee et al. (2016b), which also showed sentiment to be the weakest individual group. The reduced set performed almost as well as the submission set which is promising given it contained 99 fewer features, showing that specific targeted features are of most use.

With a random forest classifier, the results also found the Tweet feature set achieved the highest F₁ score of 0.5903 compared to the Baseline feature set score of 0.4957. The next highest was the Reduced feature set which achieved a score of 0.5657, outperforming both the Submission and Combined sets. This might be because it contains less sparse features which tree classifiers prefer, or could suggest that the emoji and punctuation features are causing the classifier to overfit. Both the Tweet and Reduced feature set achieved much higher precision than with the Linear SVC, 0.5922 and 0.5936 respectively, but lower recall, 0.5884 and 0.5401.

Next we looked at features individually, rather than looking at groups. To do this we used the coefficients for each feature in the Linear SVC model. These are the weights used by the model to decide how much each feature should weigh in on the final decision.

First we look at the features in the reduced feature set. The results are shown in Table 2. This set is interesting because it only contains the more information-dense features. Number of links, the number of mentions, and the number of hashtags are all ranked highly for identifying non-ironic tweets. This may be because tweets that have high values for these features are more focussed on sharing links, for example images, with their friends. As the focus is more on the thing they are sharing rather than in the text, these tweets may be less likely to be ironic. These features are un-

Feature	Weight	Class
Number of Links	-2.52	Non-ironic
Number of Syllables	1.89	Ironic
Number of Mentions	-1.84	Non-ironic
Punctuation Count	-1.50	Non-ironic
Repeated Characters	1.42	Ironic
Function Words	-1.20	Non-ironic
Lexical Density	-1.18	Non-ironic
Mean Sentiment	1.09	Ironic
Capitalisation	-1.04	Non-ironic
Number of Hashtags	-1.04	Non-ironic

Table 2: Top 10 LinearSVC weightings in Reduced Feature Set.

likely to be useful for identifying non-irony outside of the twitter domain. Duplicate characters are highly weighted for identifying irony. This feature is often used to signpost irony by over-emphasising the emotion they are expressing ironically such as in the case of, “Looovvveeeeeee when my phone gets wiped”. Another common use is repeated punctuation to make the point clear, for example, “Gotta love being lied to....”.

Looking into the rankings of individual words also provides some insights. Three of the top ranking words indicating irony for the Linear SVC with the combined feature set were “love”, “great”, and “fun”. It is interesting that these are all positive emotional words. This could suggest that it is more common for such tweets to use positive language with a true negative meaning. A lot of tweets follow the format of “I love when...”, going on to describe a negative experience. These tweets are often given a positive sentiment as the negative part of the tweet doesn’t always use negative language. This highlights the effect a lack of irony detection can have on sentiment analysis. The system could be more effective if it took into account negative concepts, for example “going to the dentist”, that are not explicitly negative.

Our findings suggest that social elements and structure of tweets are important for distinguishing ironic tweets from non-ironic tweets. The words that rank highly support the claim of Van Hee et al. (2016b) that irony by contrast is the easiest to detect. Irony by contrast is the most highly represented type of irony in the corpus so in most cases of irony, such features will be useful for detection. A future system would look at semantic and contextual features in more depth.

4.1 Subtask B

Subtask B involved a more complex classification task in which the system had to distinguish between different types of irony. In this task, the potential labels given by the classifier were: 0 – Non-irony, 1 – Verbal irony realised through a polarity contrast, 2 – Descriptions of situational irony, and 3 – Verbal irony without a polarity contrast. These categories are explained in detail in the task description (Van Hee et al., 2018).

We used the same feature set used for task A, aiming to test whether the same features could classify between the different types of irony. The submitted result achieved an F_1 -score of 0.3130. This result was gained using a Linear SVC classifier with the submission feature set and compared to the bag-of-words baseline F_1 -score of 0.3198. The random forest classifier achieved an F_1 -score of 0.3465. These results suggest more complex, tailored features would be needed for this task.

Both classifiers labelled the majority of tweets as 0 – non-ironic. The next most frequent label was 1 – irony by polarity contrast. This is likely to be because the features were aimed at detecting irony from non-irony and did not take into account situational information. The results seem to support the idea that irony detection via polarity contrast is the easiest to detect. This is further supported by the fact that 76% of the examples of other irony and situational irony were classified as non-ironic.

To investigate this further, we looked at the results from subtask A and looked at how many ironic by polarity contrast tweets were correctly labelled as ironic compared to the other two forms of irony. This was to see if, when the classifier was dealing with a binary ironic/non-ironic decision, it still had the same problem of not detecting examples of irony with no polarity contrast. 82% of the ironic by polarity contrast tweets were correctly labelled as ironic by the classifier, compared to 50% of the other types. This suggests that the classifier was using the features of polarity contrast to make its decisions. This makes sense as some of the features, especially those from the sentiment set, were targeted at detecting this type of irony with features such as number of positive to negative sentiment transitions.

As a final experiment, we trained the classifier with the ironic by polarity contrast tweets removed. 164 tweets from the test set and 1,390

from the training set were removed, leaving a test set of 473 non-ironic and 147 ironic tweets and a training set of 1,923 non-ironic and 521 ironic tweets. The aim was seeing if the system could distinguish between non-irony and irony with the easiest to detect tweets removed. In this setup, the classifier only correctly labelled 4 out of the 147 ironic tweets as ironic. This suggests that it is much harder to distinguish between non-ironic text and these two forms of irony. More complex features that directly look at context may be needed for this task.

5 Conclusion

In this paper, we have described a system for the detection of irony using targeted features. The resulting F_1 -score of 0.59 was an improvement over the baseline bag-of-words. The analysis of our findings provided insight into the features that are particularly useful for detecting irony. Tweet features performed well suggesting that Twitter users potentially broadcast their meaning using features such as emojis and structure. We also investigated how our system performed when distinguishing between different types of irony. Our findings suggest that deeper, more complex features will be needed to accurately identify situational irony and irony with no polarity contrast. We could improve our system by looking into contextual and semantic features. For example, we looked into sentiment of words, but not at words with positive and negative associations in certain contexts. Our analysis provides insights that may be useful for future research into irony detection.

Abstract

This paper describes an ensemble approach to the SemEval-2018 Task 3. The proposed method is composed of two renowned methods in text classification together with a novel approach for capturing ironic content by exploiting a tailored lexicon for irony detection. We experimented with different ensemble settings. The obtained results show that our method has a good performance for detecting the presence of ironic content in Twitter.

1 Introduction

Social media provide a perfect scenario for exploiting language beyond its literal sense by using figurative language devices such as, for example, irony. Correctly identifying the real intention behind user-generated content is a big challenge for different areas related to computational linguistics. For example, in Sentiment Analysis (SA), the presence of irony could undermine the performance of systems dedicated to this task (Hernández Farías and Rosso, 2016). There are several disciplines studying irony from different perspectives. The most prevalent definition is that from Grice (1975), stating that the function of irony is to effectively communicate the opposite of the literal interpretation a given utterance.

Nowadays, with the growing interest in irony detection, there are several approaches¹ for addressing such an interesting task. Probably, the most widely used is that exploiting characteristics extracted from the text (such as n-grams, punctuation marks, part-of-speech labels, among others) on its own (Riloff et al., 2013; Ptáček et al., 2014). Inherent aspects of irony such as its very subjective component have also been considered (Reyes et al., 2013; Barbieri et al., 2014; Hernández Farías

¹For a more comprehensive overview of irony detection, see (Joshi et al., 2017).

et al., 2016). Other methods have opted for taking advantage of information coming from the context in which a given utterance is produced (Rajadesingan et al., 2015). There are also some approaches exploiting deep learning techniques and word embeddings (Poría et al., 2016; Ghosh and Veale, 2016; Joshi et al., 2016; Nozza et al., 2016). A less explored strategy for addressing irony detection is the use of ensemble methods. Fersini et al. (2015) and Liu et al. (2014) compared the performance of ensemble approaches against traditional classifiers; the best results were obtained by the ensemble strategy setting.

In this paper we describe our participation to the SemEval-2018 Task 3: Irony detection in English tweets (Van Hee et al., 2018). The INAOE-UPV system explores the use of an ensemble approach that considers different combinations of three methods. The main contribution of our approach lies on the use of a list of potentially ironic and non-ironic terms in order to identify irony in tweets.

2 Method Description

In order to determine the presence of ironic content in tweets, we propose an ensemble of different methods, namely, a bag-of-words and word embeddings classifiers, as well as a voting scheme based on a list of potentially ironic and non-ironic terms.

2.1 Individual classifiers

Ironic/nonironic Orientation (irO)

This approach attempts to capture the *ironic* and *non-ironic* connotation of the words in a tweet in order to identify the presence of ironic content. Building a lexicon for irony detection is not a trivial task. It has been recognized in (Nozza et al., 2016) that a lexicon for irony detection can be derived by using a huge amount of data.

To develop a lexicon for irony detection it is needed to calculate how much a word could be associated with an ironic or non-ironic sense. A widely exploited measure in SA for developing lexica is the Pointwise Mutual Information (PMI) (Church and Hanks, 1990). We decided to adopt a similar strategy to generate two lists of terms associated to ironic and non-ironic senses. As starting point we took advantage of a set of corpora from the state of the art in irony detection (henceforth *benchmark-corpora*). The datasets we used are described in (Reyes et al., 2013; Riloff et al., 2013; Barbieri et al., 2014; Ptáček et al., 2014; Mohammad et al., 2015; Ghosh et al., 2015; Sulis et al., 2016; Karoui et al., 2017). Overall, more than 165,000 tweets were used to generate the lists of words: *ironic_terms* and *nonironic_terms*. We calculate the PMI score for each term² in the *benchmark-corpora*. After that, we selected only those terms with a PMI score greater than zero.

In order to determine the class of an instance we assigned a vote (v) for each word (w) in a given tweet (t). First, we filter out the stopwords in each tweet. Then, we search for the most similar term in each of the lists in order to determine whether w is more related to an ironic or non-ironic sense. Mainly we compute a score that indicates the higher cosine similarity³ among w and each of the N terms defined in our lists of words. As expected, the score for the words in t that are directly included in *ironic_terms* or *nonironic_terms* will be 1.

$$simIro(w) = \max_{j=1\dots N} (sim(w, ironic_terms_j))$$

$$simNI(w) = \max_{j=1\dots N} (sim(w, nonironic_terms_j))$$

After this, the vote $v(w)$ is assigned according to the following criterion:

$$v(w) = \begin{cases} simIro & \text{if } simIro > simNI \\ -simNI & \text{if } simIro < simNI \end{cases} \quad (1)$$

Finally, the class of a tweet is determined by the sum of the votes from all words in t .

$$class(t) = \begin{cases} \text{irony} & \text{if } \sum_{i=1}^{|t|} v(w \in t) \geq 0 \\ \text{non-irony} & \text{otherwise} \end{cases}$$

²We removed those terms that occurred less than five times in each class.

³We calculated the cosine similarity exploiting pre-trained word vectors from the Google News Corpus.

Bag-of-words based classifier (BOW)

This approach is based on a bag-of-words (Salton et al., 1975) representation of the tweets. It uses unigrams as binary features. For the classification it employs a SVM classifier⁴. From here, we will use the acronym **BOW** to refer the use of the aforementioned individual approach.

Word Embeddings based classifier (wEmb)

This approach is based on the use of word embeddings. Particularly, it employs embeddings pre-trained on the Google News corpus (Mikolov et al., 2013) using the Continuous Bag-of-Words (CBOW) model⁵. In this case, tweets are represented by the centroid of the vectors from their words. Similar to the BOW approach, the classification is done by a SVM classifier. From now on the acronym **wEmb** will be used to refer to this approach.

2.2 Ensemble approaches for irony detection

We explored the use of different techniques relying on the words content in each tweet in order to identify the presence of irony. Each of the techniques we exploited has its own advantages and limitations. The **BOW** model allows to capture the existing topics in the vocabulary as well as discursive markers used in an ironic writing style. On the other hand, **wEmb** makes possible to catch abstract semantics of the words regardless of the available data for the task. With respect to **irO**, it attempts to simulate the interpretative process carried out to understand the ironic intention. Irony comprehension at an initial stage involves getting the literal sense of words (Giora and Fein, 1999) and then recognizing the figurative intention behind them. Thus, our method quantifies how many words are likely to be used in a literal or figurative sense before deciding whether a tweet is ironic or not. By proposing an ensemble using all the methods together we attempt to encompass different aspects of the use of vocabulary when the ironic phenomenon is present. Below, we introduce some

⁴We employed the SVM implementation of Weka (Hall et al., 2009).

⁵We also experimented with word embeddings trained using the benchmark corpora obtaining lower results than with Google News embeddings. Therefore, in order to participate in the shared task we decided to include only the latest kinds of embeddings.

ensemble approaches⁶ proposed for capturing the presence of irony in Twitter.

Coverage-based ensemble (ENS_cov)

It is composed by BOW and wEmb. In Twitter data, there are many terms such as mentions, hashtags, emoji, URL, etc., that are unlikely to have an embedding. However, such kinds of terms are indeed covered by a model like BOW. To take advantage of both methods, we decided to combine them by considering a simple criterion depending on the coverage rate of the word embeddings (*cov_emb*) in each single tweet. That is, if the *cov_emb* is greater than 75%, the tweet will be classified by the wEmb model, otherwise the decision will be made by the BOW approach.

Majority vote ensemble (ENS_vot)

In this approach, the decisions from the three individual methods (irO, BOW and wEmb) are combined following a majority vote strategy.

3 Experiments and Results

3.1 Task Description

This year, as part of SemEval-2018 the Task 3 on *Irony detection in English tweets* (Van Hee et al., 2018), was dedicated to the identification of ironic content in Twitter. The task is composed by two subtasks: **Task A. Ironic vs. non-ironic**, the aim was to identify whether a tweet contains an ironic intention or not. The objective of the second one, **Task B. Different types of irony**, was to classify a tweet in one out of four classes: (i) verbal irony realized through a polarity contrast, (ii) other verbal irony, (iii) situational irony, and (iv) non ironic. Participants were allowed to submit two different kinds of systems: *Constrained (C)* where only data provided for the task were used for training purposes, and *Unconstrained (U)* where additional data were exploited.

3.1.1 Task A

In order to address Task A, we applied two different ensemble approaches. Our first submission was based on the coverage-based ensemble using a constrained setting (henceforth *taskA_ENS_cov_C*).

The second submission (henceforth *taskA_ENS_vot_U*) used the majority vote ensemble built on an unconstrained setting. BOW

⁶Due to the lack of space we are not reporting all the experiments carried out.

and wEmb models were trained by using only the training set provided by the organizers. Instead, irO involves the use of the benchmark corpora. Additionally, we collected a set of tweets containing the hashtags #irony and #sarcasm during the 2016 US Elections week⁷ as well as the training data provided for the task for building the lists of ironic and non-ironic terms.

For experimental purposes, we applied a three fold cross-validation using the training data during the developing phase of the shared task. Table 1 shows the obtained results in F₁-Score.

Method	F ₁ -Score
BOW	0.62
wEmb	0.64
irO	0.63
<hr/>	
<i>taskA_ENS_cov_C</i>	0.63
<i>taskA_ENS_vot_U</i>	0.65

Table 1: Results during the developing phase in Task A.

First, we evaluated each of the methods described in Section 2 individually (the first three rows in Table 1). The first two rows present the obtained results when the performance of BOW and wEmb was assessed using only the training data. Meanwhile, irO exploits both data from the task and external data. The highest result was achieved by the wEmb model. Despite being a basic method for identifying irony in tweets, our proposed approach (irO) achieves good performance even in comparison to powerful techniques such as word embeddings. Regarding the ensemble approaches, the best performance was reached by the majority vote approach.

3.1.2 Task B

In order to address the Task B, we employed two different configurations of the majority vote approach (henceforth *taskB_ENS_vot_U1* and *taskB_ENS_vot_U2*), adding an additional criterion: in both cases, when the result of irO⁸ indicates the presence of irony, we assigned one of the ironic-related classes by exploiting three different lists of words (one for each class in Task B) created following the same strategy described in Section 2.1. For *taskB_ENS_vot_U1*, the BOW and wEmb models were trained using the four classes in Task B; while in *taskB_ENS_vot_U2* four binary classifiers considering the combinations between

⁷From 8th up to 18th November 2016.

⁸In this setting we also considered the corpora of the state of the art.

ironic classes and the non-ironic class in Task B. A weighted voting strategy was adopted in both ensembles. Table 2 shows the obtained results.

Method	F ₁ -Score
BOW	0.48
wEmb	0.31
irO	0.41
<i>taskB_ENS_vot_U1</i>	0.44
<i>taskB_ENS_vot_U2</i>	0.46

Table 2: Results during the developing phase in Task B.

The three methods were also evaluated individually for Task B. As it can be noticed, the best performance was achieved by BOW. The irO method performs better than wEmb. This is probably due to the fact of having few data for training the classifier. Neither of the ensemble methods improves the baseline, i.e., the BOW results.

3.2 Official Results

Table 3 shows the obtained results according to the official ranking of the shared task.

Task	Method	F1-score
A	<i>taskA_ENS_cov_C</i>	<u>0.6265</u>
	<i>taskA_ENS_vot_U</i>	0.6184
B	<i>taskB_ENS_vot_U1</i>	0.3497
	<i>taskB_ENS_vot_U2</i>	<u>0.2148</u>

Table 3: Official results obtained by our runs at the shared task. The underlined values are those in the official ranking of the task.

Our best result was in the constrained version of Task A (we ranked in the 11th position). Regarding this, our intuition is that having data retrieved during the same time-frame the probabilities of sharing a similar vocabulary⁹ (in terms of trending-topic hashtags, mentions, etc.) are higher than when using external data. Therefore, an approach exploiting only data provided in the task could perform better than one using additional data. With reference to the unconstrained setting, we observed a drop in the performance. In spite of this, we ranked in the 2nd position when only unconstrained systems were considered.

Concerning Task B, our approach showed worst performance than in Task A. The results of both submissions were quite different. Probably this is due to the amount of classifiers involved in each ensemble. Overall, all the teams participating in

⁹We found that training and test data for the task share around fifty percent of the vocabulary.

the shared task had a lower performance in Task B demonstrating the difficulty of such a task. It is important to highlight that the *taskB_ENS_vot_U2* submission ranked in the 3rd position when only the unconstrained setting was considered.

4 Error Analysis

We analyze those instances that were misclassified by our submissions in Task A observing different kinds of errors:

- Tweets where the ironic sense highly depends on the context where they are produced. In the following example it is not possible to understand the ironic intention without having more information: @LukeLPearson *hmm... let me think about that*¹⁰
- Tweets containing terms often used in ironic instances, such as “really”. This is a disadvantage of word-based methods where terms highly related to a particular class provoke misleading classifications when they appear in other classes. The following is an example of this: *I’m really excited for next semester*¹¹
- Tweets containing several hashtags. Most of the time our methods predicted such instances as ironic being in reality non-ironic: @NormanWalshUK *Stunning work. #british #textiles #footwear #madeinbritain #not-a-nike-clone*

5 Conclusions

In this paper we describe our participation at SemEval-2018 Task 3. We propose an ensemble method including well-known techniques together with a novel approach based on the words in a tweet to identify the presence of irony. From the results, we observe that our approach obtained relatively good results considering its simplicity. As future work, it could be interesting to enhance the tailored lexicon by exploiting more data and other strategies for collecting words which are likely to be used for achieving an ironic sense. Moreover, considering different criteria to assign the votes in our approach is also matter of further experiments.

Abstract

The paper describes our submissions to task 3 in SemEval 2018. There are two subtasks: **Subtask A** is a binary classification task to determine whether a tweet is ironic, and **Subtask B** is a fine-grained classification task including four classes. To address them, we explored supervised machine learning method alone and in combination with neural networks.

1 Introduction

Irony, also known as sarcasm, refers to the use of words and sentences, whose intended meanings contrary to their literal meanings. Modeling irony has a large potential for applications in various research areas, so SemEval2018-Task3 (Hee et al.) aims to classify irony into different classes.

There are two subtasks. In subtask A, when given a tweet, the classifier should predict whether the tweet is ironic or non-ironic, and in subtask B, the ironic class is further divided into another three categories, i.e., irony by **Polarity contrast**, by **Situational** and **Other verbal** irony.

Polarity contrast irony represents the tweets containing an expression whose polarity (positive, negative) is inverted between the literal and the intended meaning. **Situational** irony stands for the ones which don't contain explicit polarity contrast. However, the events or results described in them are contrary to the desired or expected common knowledge. **Other verbal** irony tweets also don't contain any explicit polarity contrast, but they can't be classified into the **Situational irony**. Finally, **non-ironic** contains instances which are clearly not ironic, or lack adequate context to be sure that they are ironic.

In the remaining of the paper, section 2 describes our system in details. Section 3 reports datasets, experiments and results discussions. Finally, Section 4 concludes our work.

2 System Description

In both subtasks we used supervised machine learning to model the irony in datasets. Moreover, we explored neural networks in subtask A.

- In subtask A, we built a binary classification system to make predictions (see in 2.2.1). Then, we combine it with a **Bi-LSTM** neural networks(see in 2.2.2).
- In subtask B, we used two machine learning systems to train and evaluate.

1. **4-class classification system:** We made use of classifier directly itself to make 4-class predictions.

2. **4 binary-classification system:** We designed a two-step system as follows:

- **Step 1** The entire problem was regarded as 4 binary-classification problems. Each tweet would be trained and evaluated within 4 classes, and 4 confidence values would be returned.
- **Step 2** The classifier would allocate each tweet with a label gaining the highest confidence, and then made evaluation.

2.1 Feature Engineering

4 types of features were designed to extract effective information from the given tweets.

2.1.1 Linguistic-informed Features

- **Word N-grams** We extracted word n-grams features ($n = 1, 2, 3$) from tweets. To accomplish that, we used **TweetTokenizer** from *NLTK tools* (Bird et al., 2009). Otherwise, N-grams features with the use of **Relevant Frequency (RF)** (Lan et al., 2009) were also applied to this system.

- **NER** There are different types of words in tweets. NER feature can effectively express aforesaid information. The 12 types (i.e., *DURATION*, *SET*, *NUMBER*, *LOCATION*, *PERSON*, *ORGANIZATION*, *PERCENT*, *MISC*, *ORDINAL*, *TIME*, *DATE*, *MONEY*) named entities are labeled by *Stanford CoreNLP tools* (Manning et al., 2014). We used a 12-dimensions binary feature to indicate the entities in tweets.

2.1.2 Word Embedding Features

A lot of recent studies on NLP applications were reported to have good performance through using word vectors, such as document classification (Sebastiani, 2002) and question answering (Lan et al., 2016). In our work, two widely-used word embedding features were adopted, respectively **Google Word2Vec** (Mikolov et al., 2013) and **GloVe** (Pennington et al., 2014).

For **Word2Vec**, a dictionary (Available in *Google*¹.) with 31622 words and 300 dimensions was applied. For **GloVe**, we used data from the dictionary with 2196017 words and 300 dimensions (*glove.840B.300d*, available in *GloVe*²).

2.1.3 Sentiment Lexicon Feature (SentiLexi)

Eight sentiment lexicons were used to extract sentiment lexicon features in our work. We adopted the following 8 sentiment features: **Bing Liu lexicon**³, **General Inquirer lexicon**⁴, **IMD-B**⁵, **MPQA**⁶, **NRC Emotion Sentiment Lexicon**⁷, **AFINN**⁸, **NRC Hashtag Sentiment Lexicon**⁹, and **NRC Sentiment140 Lexicon**¹⁰.

2.1.4 Tweet domain Features

We collected tweet related features, and used unigram to imply if a tweet contained such information.

⁹<http://www.umiacs.umd.edu/saif/WebDocs/NRC-Hashtag-Sentiment-Lexicon-v0.1.zip>

¹⁰<http://help.sentiment140.com/for-students>

- **Hashtags** All the tokens begin with “#” symbol are called hashtags. We extracted all the hashtags, removed its “#” symbol and built unigram features for them.

- **Word N-grams in Hashtags** We exploited hashtags by a small tool **WordSegment**¹¹ to cut linked-together hashtags into a series of words, like *ilikemonday* into [*i*, *like*, *monday*].

- **Punctuation** Online users often use emotion symbols (i.e., ! and ?) to express strongly feelings. Hence we extracted a 7-dimension binary features by recording the following rules, they were: **1**) if exclamations (!) exist; **2**) if questions (?) exist; **3**) if multiple ! exist (i.e. !!!); **4**) if multiple ? exist (i.e. ???); **5**) if alternative appearances of ! and ? exist (i.e. !? and ?!); **6**) if the last token is ! and **7**) if the last token is ?.

- **Emoticon:** We collected 67 emotions labeled with positive and negative scores from the Internet¹², and used a 67-dimension binary feature to record the sentiment score of the emotion in tweets.

- **Elongated Words Feature** In the sentence “*Ahhaaaaaa, that’s sooooo funny!*”, *Ahhaa..* and *so..* are the use of elongated words. The existence of these words will lead to the overfitting in unigram features. So we designed a feature to handle them.

In our work, elongated-word feature was defined as **the word which has characters repeated for 3-11 times**. We captured and handled them by using regular expression.

2.2 Classifiers and Models

2.2.1 Machine Learning Algorithm

In both subtasks, we used following supervised machine learning algorithms to train the model:

- Logistic Regression (LR) implemented in *Liblinear* (Fan et al., 2008).
- DecisionTree, NaïveBayes, KNN, Random Forest, LR, SVM, SGD and AdaBoost all implemented in *scikit-learn tools* (Pedregosa et al., 2011).

¹¹<https://pypi.python.org/pypi/wordsegment>

¹²<https://github.com/haierlord/resource/blob/master/Emoticon.txt>

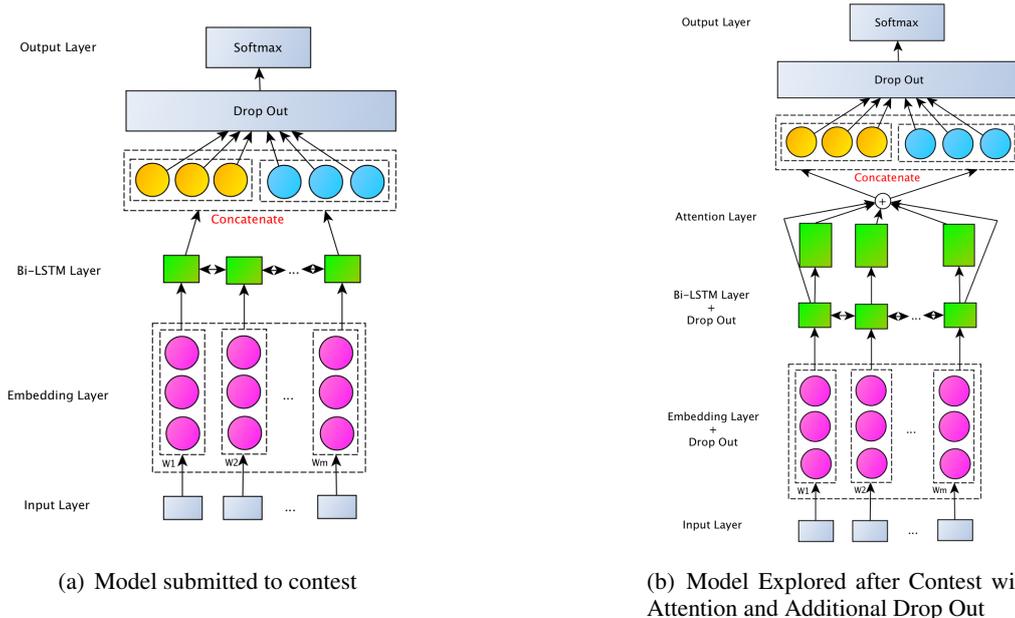

Figure 1: The architecture of our LSTM models. (a) The NN model submitted to Task A, which only incorporates a drop out layer after bi-lstm layer. (b) The NN model explored after contest, which adds attention layer and incorporates additional drop out at both embedding and lstm layers.

2.2.2 Deep Learning

Next, we explored neural networks in subtask A. We modeled all the tweets data through a Bi-LSTM network. The general architecture of the model was depicted in Figure 1.

- **Input and Embedding Layer:** Each tweet was preprocessed by normalizing hyper links and mentions to *someurl* and *someuser* as described in 2.1.1 and extracting word n-grams in hashtags as described in 2.1.4. Then the tweet was converted into a vector and padded to an equal length (or truncated if the tweet is longer than the pre-defined length). The input vector was fed to the embedding layer (i.e. pre-trained glove.twitter.27B vectors), which converted each word into a distributional vector.
- **Bi-LSTM Layer:** We used bi-directional LSTMs to model the input sequence. In the bidirectional architecture, two layers of hidden nodes from two LSTMs captured compositional semantics from both forward and backward directions of the word sequence.
- **Attention Layer:** We add attention layer to model the weights of input words follow (Raffel and Ellis, 2016), i.e. learning the weights of hidden states at each time stamp,

then computing the sentence representation via a weighted sum.

- **Output Layer:** The output of Bi-LSTM was passed to a fully connected (FC) layer, which produced a higher order feature set easily separable for 2 classes. Finally, a softmax layer was added on top of the fully connected layer. The network was trained by minimizing the binary cross-entropy error with ADAM (Kingma and Ba, 2015) for parameter optimization.

3 Experiments and Results

3.1 Datasets

The statistics of the datasets provided by SemEval 2018 task 3 are shown in Table 1.

Subtask A	Label 0(%)	Label 1(%)	-	-
train	1,923 (50.2%)	1,911 (49.8%)	-	-
test	473 (60.3%)	311 (39.7%)	-	-
Subtask B	Label 0(%)	Label 1(%)	Label 2(%)	Label 3(%)
train	1,923 (50.2%)	1,390 (36.3%)	316 (8.2%)	205 (5.3%)
test	473 (60.3%)	164 (20.9%)	85 (10.8%)	62 (7.9%)

Table 1: Statistics of datasets in train and test data. Label 0 stands for *non-ironic*, label 1 in subtask A is *ironic*, label 1, 2, 3 in subtask B is respectively *polarity contrast irony*, *situational irony* and *other verbal irony*.

3.2 Evaluation Metric

The official evaluation criterion is as follow:

- For **subtask A**, only F_1 -score of **Ironic** class is used.

$$F = F_{pos}$$

- For **subtask B**, macro-averaged F_1 -score calculated among all four classes is used.

$$F_{macro} = \frac{F_{polar_cont} + F_{senti} + F_{other} + F_{non}}{4}$$

3.3 Experiments on training data

3.3.1 Subtask A: Irony Detection

We used a series of features and explored different machine learning algorithms, in combination with neural networks, in subtask A.

Machine Learning

The count of the train data was only 3,834 and no dev datasets were provided. To fully exploit these data, we used 10-fold cross-validation with data shuffling. The major feature selection work was done with LibLinear L2-regularized logistic regression (*LibLinear LR*).

We used the following features in Table 2 as the baseline features. Since the cross validation operations were done with data shuffling, some fluctuations in result might exist. From the table it can be observed that all these features can make contributions to the classifier.

Features	$F_{pos,macro}$
GloVe	0.6314
+.Word2Vec	0.6336 (+0.0022)
+.Punctuation	0.6382 (+0.0046)
+.ners	0.6406 (+0.0024)
+.Sentiment Lexicon	0.6432 (+0.0026)
+.Emoticon	0.6462 (+0.0030)
+.Elongated	0.6465 (+0.0003)

Table 2: Performance of different features on cross-validation shuffling data test. “+” means to add current features to the previous feature set. The numbers in the parentheses are the performance increments compared with the previous results.

Then we added three other features: **Word N-grams**, **Hashtags** and **Hashtag unigrams**. Each feature had two versions, with or without **Relevant frequency (RF)**. Simultaneously, we set different word frequency when building lexicon for these features, from frequency threshold 1 to 5. In order to choose features which can improve the performance best, we used *Hill Climbing* method.

Hill Climbing is a method which can automatically extract the best features from a set of given features. Its principle is as follows:

1. Given a **Candidate Feature** set, traverse each feature and move the feature producing the best performance into **Best Feature** set.
2. Traverse the remaining features in **Candidate Feature** set, ensemble each one with **Best Feature** set to train the model. If one feature can lead to better performance than before, move it to **Best Feature** set.
3. Repeat step 2 until that **Candidate Feature** set is empty.
4. The best feature combination can be obtained by traversing **Best Feature** set according to the insertion order of each feature.

After running *Hill Climbing* 5 times and extracted the features from each first line, we selected 7 features, as shown in Table 3.

Feature	Threshold	With RF
Trigram	4	Yes
Bigram	2	Yes
Hashtag	2	Yes
Hashtag	1	Yes
Hashtag unigram	1	No
Trigram	2	Yes
Unigram	2	Yes

Table 3: The results of hill climbing.

Algorithms	$F_{pos,macro}$
SkLearn NaïveBayes	0.7111
Sklearn LR	0.6953
LibLinear LR	0.6947

Table 4: Performance of three best learning algorithms.

Then we explored the performance of different learning algorithms. Table 4 lists the comparison of best three supervised learning algorithms with all above features.

Finally, we made ensemble of three algorithms in Table 4. The ensemble score was 0.6982.

Neural Networks

In our LSTM framework, the dimension of word vector was set to 100 and the hidden layers for both LSTM and FC layers were set to 256. The drop out rate was set to 0.2 for preventing overfitting. 10% of the training data were randomly selected as validation set. The best model during training was used in test evaluation stage. We implement the framework based on **Tensor-flow** (Abadi et al., 2016) and **Keras**¹³.

¹³<https://keras.io/>

seed	precision	recall	f_1 -score
6815_seed3	0.683908	0.639785	0.661111
6867_seed7	0.705036	0.553672	0.620253
6684_seed11	0.658654	0.709845	0.683292
6789_seed13	0.668142	0.758794	0.710588
6658_seed23	0.692308	0.574468	0.627907

Table 5: Performance of partial neural networks on subtask A on train and dev datasets.

The performance results on train datasets are listed in Table 5, and the average is about 0.66.

Ensemble of Machine Learning and Neural Networks

The average performance of machine learning and neural networks were respectively 0.69 and 0.66. We ensembled different results of neural network and of machine learning. Here we used 4 algorithms, i.e., Scikit-Learn’s *NaïveBayes*, *LR*, *SVM* and LibLinear’s *LR*, to avoid that label 0 and label 1 were voted same times.

During the ensemble, we also tried another strategy. Since we wanted to higher the recall value of positive labels, we ensembled only the data predicted as “label 0” by neural networks. For those “label 1” data, we remained their original labels. The results of this strategy will be discussed in 3.4.

3.3.2 Subtask B: Irony Classification

When handling subtask B, we used only machine learning. **We conducted two steps in subtask B.**

In the first step, the average f_1 -macro score is between 0.42-0.43. Table 6 shows how much each class is graded, the f_1 -scores of label 2 and 3 are much lower than that of label 0 and 1. This is caused by imbalance in data distribution.

Features	f_1 -score of			
	Label 0	Label 1	Label 2	of Label 3
Other features	0.712455	0.649360	0.254167	0.066390
+.URL Unigram T1	0.710811	0.421364	0.282700	0.074074
+.URL Unigram T2	0.712627	0.655994	0.280922	0.105691
+.URL Unigram T3	0.703121	0.648396	0.241015	0.067511
+.URL Unigram T4	0.703121	0.650534	0.280922	0.074689
+.URL Unigram T5	0.709412	0.649573	0.278119	0.075630

Table 6: The f_1 -scores of each label in subtask B. Here label 0 represents for *Non-ironic*, 1 for *Polarity contrast*, 2 for *Situational irony*, 3 for *Other verbal irony*.

In the second step, to solve the problem of imbalance in data distribution, we enlarged the data size of label 2 and 3. Label 2 was expanded 6 times, and label 3 was expanded to 10 times. Then we ensembled multi-algorithms. Each algorithm would perform 4 binary-classifications successive-

ly. Finally, we used Scikit-Learn LR for label 0, 1, 2, and Scikit-Learn SVM for label 3. Results are listed in Table 7.

Label	precision	recall	f_1 -score
0	0.669960	0.705148	0.687104
1	0.656558	0.623022	0.639350
2	0.343333	0.325949	0.334416
3	0.167539	0.156098	0.161616
Average score			
-	0.459348	0.452554	0.455622

Table 7: The performances of using 4 binary classifications

However, when generating test files, the output results fluctuated remarkably. At last, we didn’t hand in the output result generated by step 2.

3.4 Results on Test Data

Subtask	System	f_1 -score (%)
Subtask A	ECNU	0.5931 (20)
	THU_NGN	0.7054 (1)
	NTUA-SLP	0.6719 (2)
	WLV	0.6500 (3)
Subtask B	ECNU	0.2326 (30)
	UCDCC	0.5074 (1)
	NTUA-SLP	0.4959 (2)
	THU_NGN	0.4947 (3)

Table 8: Performance of our systems and top-ranked teams on both two subtasks. The numbers in the parentheses are the official rankings. The evaluation metrics in mentioned in 3.2.

Table 8 shows the results of our system and the top-ranked systems provided by the official. Compared with the top ranked systems, there’s so much room for improvement in our work. There are several possible reasons for this.

- First, **the overfitting problems is very serious.** The scores during Training and dev period and test period differed significantly. It will be discussed in 3.5.
- Second, **possibly the features failed to extract useful information from the test data** Unlike Word N-Grams, some features, like hashtag, the probability of the same hashtag or matching words appearing in both test files and training files is quite low.

3.5 Supplement results beside the contest

3.5.1 Ensemble of Machine Learning and Neural Networks on subtask A

This is the performance of machine learning algorithms on subtask A after the contest.

Model	seed x	precision	recall	f_1 -score (%)
NN	6815 sd3	0.580282	0.662379	0.618619 (12)
NN	6867 sd7	0.626415	0.533762	0.576389 (27)
NN	6684 sd11	0.532895	0.781350	0.633638 (6)
NN	6789 sd13	0.529279	0.755627	0.622517 (10)
NN+additional dropout	6867 sd7	0.587393	0.65916	0.621212 (11)
NN+additional dropout	6684 sd11	0.525000	0.810289	0.637168 (6)
NN+additional dropout	6789 sd13	0.537079	0.768489	0.632275 (6)
NN+additional dropout+attention	6815 sd3	0.537383	0.739550	0.622463 (10)

NN+additional dropout+attention	6684 sd11	0.544118	0.7138264	0.617524 (13)
NN+additional dropout+attention	6789 sd13	0.574850	0.6173633	0.595349 (19)

Table 9: Performance of pure neural networks on subtask A on test datasets. The number in parentheses is the position of this result if submitted. Performances in Group ‘NN’ are based on Figure 1(a); Performances in Group ‘NN+more_dropout’ are based on Figure 1(a) with additional drop out settings; and Performances in Group ‘NN+more_dropout+attention’ are based on Figure 1(b).

Ensemble	precision	recall	f_1 -score (%)
TOP3	0.400000	0.553055	0.464238 (37)
4+NN, en0	0.450777	0.839228	0.586517 (24)
4+NN, en0	0.452340	0.839228	0.587838 (23)
4+NN	0.404651	0.559486	0.469636 (35)
4+NN, en0	0.493590	0.742765	0.593068 (20)

Table 10: Performance of ensemble on machine learning and neural networks on subtask A and test datasets. The numbers in parentheses represent positions in the official ranking if the result is submitted. The last record is the same as ECNU’s.

In Table 10, **TOP3** means the ensemble of 3 best algorithms on train datasets. The **4+NN** means using 4 best machine learning algorithms and ensemble them with the results of neural networks. **en0** means using the other strategy mentioned in 3.3.1. Hence, the ensemble data using the other strategy enjoys a particular high recall value. Nevertheless, the performance of these results differ greatly that on train datasets.

seed	precision	recall	f_1 -score (%)
6815_sd3	0.580282	0.662379	0.618619 (12)
6867_sd7	0.626415	0.533762	0.576389 (27)
6684_sd11	0.532895	0.781350	0.633638 (6)
6789_sd13	0.529279	0.755627	0.622517 (10)
6658_sd23	0.601911	0.607717	0.604800 (17)

Table 11: Performance of pure neural networks. The numbers in parentheses represent positions in the official ranking if the result is submitted.

In Table 11, the average of f_1 -scores on pure neural networks’ results is about 0.61. This phenomenon indicates that in our work the training of supervised machine learning appeared to have been overfitted.

3.5.2 Neural Networks on subtask A

In Table 9 the average of f_1 -scores on pure neural networks’ results are 0.61, 0.62 and 0.60 for three Groups respectively.

This phenomenon indicates that in our work, the training of supervised machine learning appeared to be overfitted. Moreover, turn on drop out settings in more neural network layers can further reduce overfitting.

However, our attempt of further incorporating attention layer brought negative affect on subtask A’s performance. This may suggest the weighted sum of hidden states probably is not a good representation of the sentence for irony detection.

4 Conclusion

In this paper, we explored supervised machine learning algorithms and neural networks, detected whether a given tweet was ironic or not, and classified them into four more detailed categories. The result was that the machine learning classifiers overfitted, and neural networks performed better than the traditional training methods. The system performance for subtask A ranked above average, and subtask B didn’t perform so well. In future work, we consider focusing more on exploring the neural networks.

KLUEnicorn at SemEval-2018 Task 3: A Naïve Approach to Irony Detection

Luise Dürlich

Friedrich-Alexander Universität Erlangen-Nürnberg / Germany

luise.duerlich@fau.de

Abstract

This paper describes the KLUEnicorn system submitted to the SemEval-2018 task on “Irony detection in English tweets”. The proposed system uses a naïve Bayes classifier to exploit rather simple lexical, pragmatic and semantic features as well as sentiment. It further takes a closer look at different adverb categories and named entities and factors in word-embedding information.

1 Introduction

Automatic irony and sarcasm detection has made great advances in recent years, evolving from considering purely lexical information (Kreuz and Caucci, 2007) to sentiment (González-Ibáñez et al., 2011) and semantics (Ghosh et al., 2015). With new approaches that are aware of the context a tweet is produced in, promising results of as much as 87% accuracy (Silvio et al., 2016) have been achieved.

In the following sections, I present a constrained contribution to the SemEval-2018 irony detection task (Van Hee et al., 2018). As useful context for the training data was rather hard to come by, a solely tweet based approach is explored. In the next section, the dataset provided by the task organizers will be discussed. Sections 3 and 4 will elaborate on data preprocessing and the types of features that were tested. Finally, sections 5, 6 and 7 will present experiments on the usefulness of different features to different classifiers, the settings used for the submitted systems and the competition results.

2 Data

To train the system, only the official training set consisting of 3,834 tweets was used. Of these tweets 1,911 were ironic and 1,923 were non-ironic. Depending on the subtask at hand, namely

binary irony detection (task A) or the differentiation between different types of irony (task B), the ironic tweets were further categorized as either *verbal irony by means of polarity contrast* (class 1), *other verbal irony* (class 2) or *situational irony* (class 3). This resulted in 1,390 examples for class 1, 316 examples for class 2 and 205 examples for class 3. The tweets still contained the original URLs, that were further analyzed to get an idea of whether or not they could provide useful context information. However, only as much as 14% of the ironic sample even contained URLs and most of these just linked to images and the original tweet on Twitter. As the data did not include the names of the authors or contained any additional context information,¹ context with respect to the authors user profile was not explored further.

3 Preprocessing

As preparation for tagging, segmentation problems – especially arising around emoji and punctuation marks – were corrected, user mentions were anonymized to “@user” and URLs replaced by “http://url.com”. Hashtags were stripped of the “#” and segmented using a simple hand-crafted hashtag tokenizer that relies on regular expressions and a dictionary consisting of the *Unix wordlist* and terms filtered from some 190,000 tweets to account for non-standard words and spelling. The tweets were then tagged using the part-of-speech tagger provided by *Ark TweetNLP* (O’Connor et al., 2013) and filtered using regular expressions. Conjunctions, determiners, existential uses of “there”, numerals, predeterminers, prepositions, pronouns, punctuation, URLs and user mentions were discarded. Finally, some per-

¹The profiles of users mentioned in the tweets were not considered.

sisting segmentation issues related to the tagging – e.g. sequences of emoji were not segmented and sometimes assigned the wrong tag – were resolved and proper nouns identified by the tagger were replaced by “^_NNP”.

4 Features

The features described in this section were either obtained from tagged tweets, raw tweets as string or tokenized raw tweets using the tokenizer provided by *Ark TweetNLP*. For tokenization, some adaptations had to be made to ensure correct segmentation around emoji. In general, the focus was laid on quick and easy-to-extract binary or count-based tweet properties (except for embeddings and named entities). The features used to train the model, can be assigned to the following categories:

Lexical: A bag-of-words was extracted from the tagged tweets using the *TfidfVectorizer* provided by *scikit-learn* (Pedregosa et al., 2011).

As more of a structural feature, tweet length both in terms of words and in terms of characters was exploited.

Pragmatic: The amount of punctuation, quotation marks, character repetition – and as special case ellipsis (expressed by “...”) – as well as uppercase words were added to the features by simply counting their occurrence. As Twitter-specific patterns, the presence and number of user mentions, urls and hashtags as well as the number of emoji in a given tweet were noted.

Sentiment: Two sentiment lexicons were used to capture the mean positive, objective and negative sentiment associated with the hashtags, emoji and normal words present in a given tweet:

1. *AFINN* (Nielsen, 2011), a list of about 2,500 entries assigned to a scale ranging from -5 to 5, that also covers some expressions common in texting and microblogging (e.g. “lol”).
2. *SentiWordNet* (SWN) (Esuli and Sebastiani, 2006), a much larger resource that provides different sentiment scores for the different meanings of a word, but restricted to more standard words.

To circumvent too complex disambiguation for the senses in *SWN*, the mean sentiment scores of the possible meanings were taken and whenever an

AFINN entry existed, scores were reweighted in favor of the *AFINN* sentiment. The scores on emoji were obtained using the emoji aliases provided by the *Python emoji* package.²

Semantic: Inspired by the use of word embeddings to contrast a tweet’s sarcastic reading with its non-sarcastic representation proposed by (Ghosh et al., 2015), separate models were trained on the ironic and non-ironic instances within the training set. The models were obtained using *word2vec* as provided by *gensim* and the model parameters were set to 100 dimensions and a window size of 5. Hierarchical softmax was used for training. To obtain the literal and ironic representations of a tweet, the sums of ironic and non-ironic word embeddings were calculated and the embedding vectors were normalized to length 1 respectively.

Other: In an attempt to capture ironic tweets referring to specific numbers or amounts in a more simplified way than Kumar et al. (2017), who also take the deviation of a given number in the context of a unit of measurement with respect to the mean number encountered with that unit into account, information about the presence of certain number expressions was added to the feature vector.

To get a more fine grained representation of the adverbs used in tweets, a list of different adverb categories and corresponding adverbs was collected from *Wiktionary*³. The list contains 19 different categories that are illustrated in table 1. A possible advantage of this representation could be that location or temporal location adverbs – that might be informative in situational irony – can be distinguished from adverbs modifying verbs or adjectives, possibly more useful to spot verbal irony containing e.g. hyperbole.

To record references to entities, the named entity recognizer provided by *Stanford CoreNLP* (Finkel et al., 2005) was used. After the submission for task A, some more features were added, namely the number of modals, negations and contrasting conjunctions or adverbs.

Weighting and Filtering: To account for less informative features, F-tests were performed on the features and only those that were among the 15% most significant were selected.

15	modal adverbs	<i>actually</i>
16	suppletive adverbs	<i>well</i>
17	duration adverbs	<i>always</i>
18	frequency adverbs	<i>constantly</i>
19	temporal location adverbs	<i>now</i>

Table 1: Adverb categories based on Wiktionary

5 Feature Evaluation:

In order to gain insight on the usefulness of the features, a set of experiments⁴ was performed, in which the features were assigned specific groups and a selection of classifiers was either trained on the group alone or on all features but those in the group. 10-fold cross-validation was performed on the training set comparing a Gaussian naïve Bayes classifier, support vector machines, a decision tree and a random forest classifier. The groups are reported in table 2.⁵

Results when training on the features without the bag-of-words, displayed in table 3, show that – with the exception of group 5 – most of the groups do not seem to make a big contribution to the rest of the feature set and their exclusion does not lead to substantial drops in performance. For group 5, a decrease in performance of as much as 10% can be observed for the random forest classifier compared to the performance on all features recorded in table 4.

Training on selected features from just one of the groups at a time shows that groups 3 and 5 are already very informative and can produce f-scores

⁴Note that these experiments only focussed on task A.

⁵The bag-of-words was restricted to uni- and bigrams with a minimum document frequency of 5.

Group	Features	# of Features
1	length in words, length in characters	2
2	character repetition, quotation marks, uppercase	4
3	presence and number of hashtags, URLs and user mentions, presence of emoji	7
4	number of negations, modals, comparison, adverbs	41
	contrasting conjunctions / adverbs, amounts / numbers and different types of adverbs and entities	
5	embedding dimensions	200
6	sentiment	9
7	full feature set (group 1 - 6)	263
8	bag-of-words	A: 1,408 B: 1,455

Table 2: Feature group description

Without group	NB	DT	SVM	RF
1	69.03	57.61	67.64	68.48
2	69.03	57.98	67.64	68.33
3	68.83	57.87	69.81	68.04
4	68.99	57.87	67.58	67.50
5	65.59	56.50	62.65	60.22
6	69.01	58.10	67.65	67.74

Table 3: F1-score when omitting one group at a time for binary irony detection

of 67.42% and 69.76% respectively. As we can see in table 4, the best score is still obtained when selecting from the entire feature set and training a random forest.

Taking a look at the importance weights assigned by the random forest classifier, it emerges that the embeddings range among the top 220 ranks and carry 91% of the importance weight. They are thus quite important for classification. Tweet length in characters is identified as the most important feature followed by positive word sentiment scores, which might indicate that the assumption by Clark and Gerrig (1984), that ironic utterances are more likely to convey negative sentiment through literally positive one, also holds for the observed tweets. Regarding adverb categories, demonstrative adverbs appear to be most informative.⁶ Generally, it can be noted that every group contributes to the top 250 important features with at least one or two features.

Group	NB	DT	SVM	RF
1	48.88	51.12	50.99	53.20
2	50.12	47.07	51.67	48.66
3	67.42	67.42	67.42	67.42
4	51.08	41.36	43.67	42.14
5	68.76	58.22	69.76	67.31
6	65.57	53.15	47.25	54.21
7	69.05	56.77	67.25	68.18
8	56.77	51.77	53.60	54.76
all	68.61	60.52	68.18	70.06

Table 4: F1-score when training on one group at a time in binary irony detection

6 Submission Settings

For the submission to task A, the parameters for the *TfidfVectorizer* were set to uni-, bi- and trigrams and a minimum document frequency of 2. The feature vectors did not account for modals, negations and contrasting conjunctions or adverbs since these were added to the feature set after the submission deadline for task A. As the two classes were balanced in training and test data, the priors of the Gaussian naïve Bayes classifier were set to 0.5 each.

⁶On the full feature set, location, degree, interrogative, conjunctive, temporal location and focus adverbs rank among the top 50 most important features when ignoring word embedding dimensions.

For task B, the bag-of-words was based on unigrams only with a minimum document frequency of 4. Binary features reporting the presence of hashtags, URLs and user mentions were not included. To distinguish different types of irony as well as non-irony, a two-step classification approach was adopted, first deciding whether a tweet was ironic and then labelling it as either situational or verbal irony with or without polarity change. No priors were defined for the second Gaussian naïve Bayes classifier.

7 Results

With respect to the competition results, the system did not perform very well, getting to rank 27 for task A and 23 for task B. Results compared to a benchmark system and random forest with the best settings are reported in table 5 for task A and in table 6 for task B.⁷ Note that *NB* in table 6 refers to a single Gaussian naïve Bayes classifier trained on the same features as KLUEnicorn*.

The results for task A indicate that the model cannot compete with the benchmark system provided by the task organizers (a linear SVM trained on bag-of-words only). Possible reasons for that might be the restrictions imposed during preprocessing and feature extraction – a minimum document frequency of 5 might not be feasible on such a small amount of tweets and summarizing all the mentioned user names under the same token instead of at least keeping the more frequent ones as well as discarding certain parts-of-speech such as personal pronouns for example, might not be beneficial to the model. The quality of the word embeddings, trained on a relatively small amount of data, represents another issue.

System	Accuracy	Precision	Recall	F1-score
Benchmark	63.52	53.25	65.92	58.91
KLUEnicorn	59.44	49.14	64.31	55.71
KLUEnicorn*	65.56	57.20	52.41	54.69
RF	60.84	59.54	59.80	54.79

Table 5: Results on test data – Task A

For task B, table 6 suggests, that the submitted system still performs worse than the benchmark, yet the version taking all features into ac-

⁷KLUEnicorn* refers to a version of the system trained on a selection of the 15% most significant out of all features including the bag-of-words.

System	Accuracy	Precision	Recall	F1-score
Benchmark	56.89	41.64	36.35	34.08
KLUEnicorn	34.69	32.14	35.39	29.82
KLUEnicorn*	49.11	42.51	48.62	40.42
NB	47.96	31.54	35.60	30.84
RF	51.53	40.67	33.40	30.11

Table 6: Results on test data – Task B

count shows a better performance, outperforming the benchmark by 6% in terms of f-score.

Looking at the predictions in particular, we can observe that the negative class is predicted with a rather high precision (71.55%) for task A, while in task B, non-irony is detected with a high recall of almost 80%. Apparently, the model is best at predicting non-irony. In task B, the model struggles most when predicting situational irony, achieving an f1-score of only 11%. This is not very surprising, given the small amount of examples for class 3 in the training data.

Tables 7 and 8 show examples from the test set for task A and B and the corresponding predictions made by the classifier. As we can see, short messages lacking more informative context such as the second example in table 7 or the first example in table 8 are still an issue, whereas tweets containing hashtags that oppose the initial content of the tweet text such as the third example in table 8 can correctly be assigned class 1. With “#not” not being part of the training data, this is more difficult for tweets like the fourth tweet, where only one hashtag is present.

Gold label	Pred.	Tweet
0	0	NOT GONNA WIN http://t.co/Mc9ebqjAqj
0	1	@mickymantell He is exactly that sort of person. Weirdo!
1	1	Just walked in to #Starbucks and asked for a ""tall blonde"" Hahahaha #irony

3	2	People complain about my background pic and all I feel is like ""they don't blame me, Albert E might have spoken those words"" #sarcasm #life
3	3	If you wanna look like a badass, have drama on social media #not

Table 8: Example predictions KLUEnicorn* – Task B

information to different adverb categories. While all feature groups seem to contribute to performance, the embedded tweets were found to be most informative and to bring a performance gain of 3-10% depending on the classifier. However, the presented system does not do a very good job at detecting irony on the given data set. Both naïve Bayes and random forest cannot compete with the simple baseline when it comes to just identifying irony, but when different types of irony are to be distinguished, a two-step model trained on a selection of all features can outperform the benchmark. For better prediction, more reliable embeddings using more training data should be trained and certain filter settings for preprocessing should be revisited.

Abstract

In this paper we present two deep-learning systems that competed at SemEval-2018 Task 3 “Irony detection in English tweets”. We design and ensemble two independent models, based on recurrent neural networks (Bi-LSTM), which operate at the word and character level, in order to capture both the semantic and syntactic information in tweets. Our models are augmented with a self-attention mechanism, in order to identify the most informative words. The embedding layer of our word-level model is initialized with word2vec word embeddings, pretrained on a collection of 550 million English tweets. We did not utilize any handcrafted features, lexicons or external datasets as prior information and our models are trained end-to-end using back propagation on constrained data. Furthermore, we provide visualizations of tweets with annotations for the salient tokens of the attention layer that can help to interpret the inner workings of the proposed models. We ranked 2nd out of 42 teams in Subtask A and 2nd out of 31 teams in Subtask B. However, post-task-completion enhancements of our models achieve state-of-the-art results ranking 1st for both subtasks.

1 Introduction

Irony is a form of figurative language, considered as “saying the opposite of what you mean”, where the opposition of literal and intended meanings is very clear (Barbieri and Saggion, 2014; Liebrecht et al., 2013). Traditional approaches in NLP (Tsur et al., 2010; Barbieri and Saggion, 2014; Karoui et al., 2015; Farías et al., 2016) model irony based on pattern-based features, such as the contrast between high and low frequent words, the punctuation used by the author, the level of ambiguity of

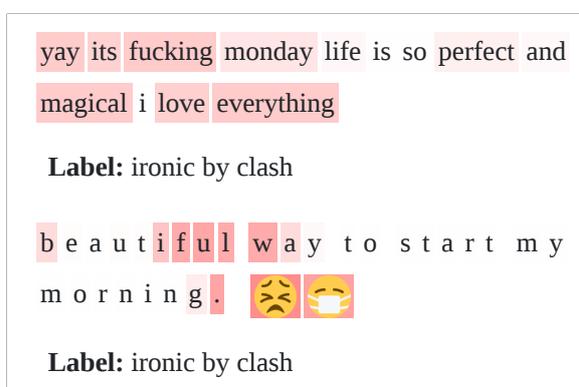

Figure 1: Attention heat-map visualization. The color intensity of each word / character, corresponds to its weight (importance), as given by the self-attention mechanism (Section 2.6).

the words and the contrast between the sentiments. Also, (Joshi et al., 2016) recently added word embeddings statistics to the feature space and further boosted the performance in irony detection.

Modeling irony, especially in Twitter, is a challenging task, since in ironic comments literal meaning can be misleading; irony is expressed in “secondary” meaning and fine nuances that are hard to model explicitly in machine learning algorithms. Tracking irony in social media poses the additional challenge of dealing with special language, social media markers and abbreviations. Despite the accuracy achieved in this task by handcrafted features, a laborious feature-engineering process and domain-specific knowledge are required; this type of prior knowledge must be continuously updated and investigated for each new domain. Moreover, the difficulty in parsing tweets (Gimpel et al., 2011) for feature extraction renders

their precise semantic representation, which is key of determining their intended gist, much harder.

In recent years, the successful utilization of deep learning architectures in NLP led to alternative approaches for tracking irony in Twitter (Joshi et al., 2017; Ghosh and Veale, 2017). (Ghosh and Veale, 2016) proposed a Convolutional Neural Network (CNN) followed by a Long Short Term Memory (LSTM) architecture, outperforming the state-of-the-art. (Dhingra et al., 2016) utilized deep learning for representing tweets as a sequence of characters, instead of words and proved that such representations reveal information about the irony concealed in tweets.

In this work, we propose the combination of word- and character-level representations in order to exploit both semantic and syntactic information of each tweet for successfully predicting irony. For this purpose, we employ a deep LSTM architecture which models words and characters separately. We predict whether a tweet is ironic or not, as well as the type of irony in the ironic ones by ensembling the two separate models (late fusion). Furthermore, we add an attention layer to both models, to better weigh the contribution of each word and character towards irony prediction, as well as better interpret the descriptive power of our models. Attention weighting also better addresses the problem of supervising learning on deep learning architectures. The suggested model was trained only on constrained data, meaning that we did not utilize any external dataset for further tuning of the network weights.

The two deep-learning models submitted to SemEval-2018 Task 3 “Irony detection in English tweets” (Van Hee et al., 2018) are described in this paper with the following structure: in Section 2 an overview of the proposed models is presented, in Section 3 the models for tracking irony are depicted in detail, in Section 4 the experimental setup alongside with the respective results are demonstrated and finally, in Section 5 we discuss the performance of the proposed models.

2 Overview

Fig. 2 provides a high-level overview of our approach, which consists of three main steps: (1) the *pre-training of word embeddings*, where we train our own word embeddings on a big collection of unlabeled Twitter messages, (2) the independent *training of our models*: word- and char-level,

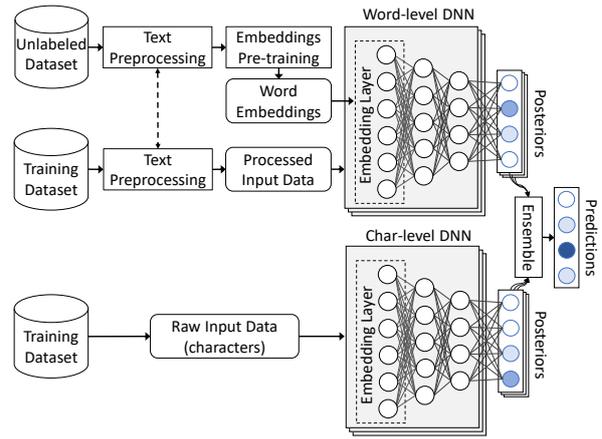

Figure 2: High-level overview of our approach

(3) the *ensembling*, where we combine the predictions of each model.

2.1 Task definitions

The goal of Subtask A is tracking irony in tweets as a binary classification problem (ironic vs. non-ironic). In Subtask B, we are also called to determine the type of irony, with three different classes of irony on top of the non-ironic one (four-class classification). The types of irony are: (1) **Verbal irony by means of a polarity contrast**, which includes messages whose polarity (positive, negative) is inverted between the literal and the intended evaluation, such as *"I really love this year's summer; weeks and weeks of awful weather"*, where the literal evaluation (*"I really love this year's summer"*) is positive, while the intended one, which is implied in the context (*"weeks and weeks of awful weather"*), is negative. (2) **Other verbal irony**, which refers to instances showing no polarity contrast, but are ironic such as *"Yeah keeping cricket clean, that's what he wants #Sarcasm"* and (3) **situational irony** which is present in messages that a present situation fails to meet some expectations, such as *"Event technology session is having Internet problems. #irony #HSC2024"* in which the expectation that a technology session should provide Internet connection is not met.

2.2 Data

Unlabeled Dataset. We collected a dataset of 550 million archived English Twitter messages, from Apr. 2014 to Jun. 2017. This dataset is used for (1) calculating word statistics needed in our text preprocessing pipeline (Section 2.4) and (2) train-

ing word2vec word embeddings (Section 2.3).

2.3 Word Embeddings

Word embeddings are dense vector representations of words (Collobert and Weston, 2008; Mikolov et al., 2013), capturing semantic their and syntactic information. We leverage our unlabeled dataset to train Twitter-specific word embeddings. We use the *word2vec* (Mikolov et al., 2013) algorithm, with the skip-gram model, negative sampling of 5 and minimum word count of 20, utilizing Gensim’s (Řehůřek and Sojka, 2010) implementation. The resulting vocabulary contains 800,000 words. The pre-trained word embeddings are used for initializing the first layer (embedding layer) of our neural networks.

2.4 Preprocessing¹

We utilized the *ekphrasis*² (Baziotis et al., 2017) tool as a tweet preprocessor. The preprocessing steps included in *ekphrasis* are: Twitter-specific tokenization, spell correction, word normalization, word segmentation (for splitting hashtags) and word annotation.

Tokenization. Tokenization is the first fundamental preprocessing step and since it is the basis for the other steps, it immediately affects the quality of the features learned by the network. Tokenization in Twitter is especially challenging, since there is large variation in the vocabulary and the used expressions. Part of the challenge is also the decision of whether to process an entire expression (e.g. anti-american) or its respective tokens. Ekphrasis overcomes this challenge by recognizing the Twitter markup, emoticons, emojis, expressions like dates (e.g. 07/11/2011, April 23rd), times (e.g. 4:30pm, 11:00 am), currencies (e.g. \$10, 25mil, 50€), acronyms, censored words (e.g. s**t) and words with emphasis (e.g. *very*).

Normalization. After the tokenization we apply a series of modifications on the extracted tokens,

¹Significant portions of the systems submitted to SemEval 2018 in Tasks 1, 2 and 3, by the NTUA-SLP team are shared, specifically the preprocessing and portions of the DNN architecture. Their description is repeated here for completeness.

²github.com/cbaziotis/ekphrasis

such as spell correction, word normalization and segmentation. We also decide which tokens to omit, normalize and surround or replace with special tags (e.g. URLs, emails and @user). For the tasks of spell correction (Jurafsky and James, 2000) and word segmentation (Segaran and Hammerbacher, 2009) we use the Viterbi algorithm. The prior probabilities are initialized using uni/bi-gram word statistics from the unlabeled dataset.

The benefits of the above procedure are the reduction of the vocabulary size, without removing any words, and the preservation of information that is usually lost during tokenization. Table 1 shows an example text snippet and the resulting preprocessed tokens.

2.5 Recurrent Neural Networks

We model the Twitter messages using Recurrent Neural Networks (RNN). RNNs process their inputs sequentially, performing the same operation, $h_t = f_W(x_t, h_{t-1})$, on every element in a sequence, where h_t is the hidden state t the time step, and W the network weights. We can see that hidden state at each time step depends on previous hidden states, thus the order of elements (words) is important. This process also enables RNNs to handle inputs of variable length.

RNNs are difficult to train (Pascanu et al., 2013), because gradients may grow or decay exponentially over long sequences (Bengio et al., 1994; Hochreiter et al., 2001). A way to overcome these problems is to use more sophisticated variants of regular RNNs, like Long Short-Term Memory (LSTM) networks (Hochreiter and Schmidhuber, 1997) or Gated Recurrent Units (GRU) (Cho et al., 2014), which introduce a gating mechanism to ensure proper gradient flow through the network. In this work, we use LSTMs.

2.6 Self-Attention Mechanism

RNNs update their hidden state h_i as they process a sequence and the final hidden state holds a summary of the information in the sequence. In order to amplify the contribution of important words in the final representation, a self-attention mechanism (Bahdanau et al., 2014) can be used

original	The *new* season of #TwinPeaks is coming on May 21, 2017. CANT WAIT \o/ !!! #tvseries #davidlynch :D
processed	the new <emphasis> season of <hashtag> twin peaks </hashtag> is coming on <date> . cant <allcaps> wait <allcaps> <happy> ! <repeated> <hashtag> tv series </hashtag> <hashtag> david lynch </hashtag> <laugh>

Table 1: Example of our text processor

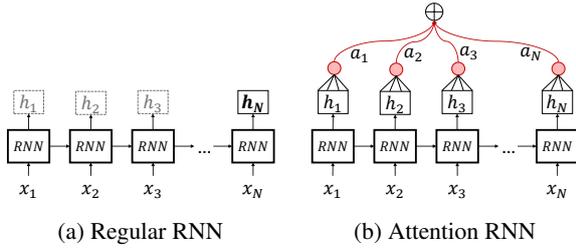

Figure 3: Comparison between the regular RNN and the RNN with attention.

(Fig. 3). In normal RNNs, we use as representation r of the input sequence its final state h_N . However, using an attention mechanism, we compute r as the convex combination of all h_i . The weights a_i are learned by the network and their magnitude signifies the importance of each hidden state in the final representation. Formally: $r = \sum_{i=1}^N a_i h_i$, where $\sum_{i=1}^N a_i = 1$, and $a_i > 0$.

3 Models Description

We have designed two independent deep-learning models, with each one capturing different aspects of the tweet. The first model operates at the word-level, capturing the semantic information of the tweet and the second model at the character-level, capturing the syntactic information. Both models share the same architecture, and the only difference is in their embedding layers. We present both models in a unified manner.

3.1 Embedding Layer

Character-level. The input to the network is a Twitter message, treated as a sequence of characters. We use a character embedding layer to project the characters c_1, c_2, \dots, c_N to a low-dimensional vector space R^C , where C the size of the embedding layer and N the number of characters in a tweet. We randomly initialize the weights of the embedding layer and learn the character embeddings from scratch.

Word-level. The input to the network is a Twitter message, treated as a sequence of words. We use a word embedding layer to project the words w_1, w_2, \dots, w_N to a low-dimensional vector space R^W , where W the size of the embedding layer and N the number of words in a tweet. We initialize the weights of the embedding layer with our pre-trained word embeddings.

3.2 BiLSTM Layers

An LSTM takes as input the words (characters) of a tweet and produces the word (character) annotations h_1, h_2, \dots, h_N , where h_i is the hidden state of the LSTM at time-step i , summarizing all the information of the sentence up to w_i (c_i). We use bidirectional LSTM (BiLSTM) in order to get word (character) annotations that summarize the information from both directions. A bidirectional LSTM consists of a forward LSTM \vec{f} that reads the sentence from w_1 to w_N and a backward LSTM \overleftarrow{f} that reads the sentence from w_N to w_1 . We obtain the final annotation for a given word w_i (character c_i), by concatenating the annotations from both directions, $h_i = \vec{h}_i \parallel \overleftarrow{h}_i$, $h_i \in R^{2L}$ where \parallel denotes the concatenation operation and L the size of each LSTM. We stack two layers of BiLSTMs in order to learn more high-level (abstract) features.

3.3 Attention Layer

Not all words contribute equally to the meaning that is expressed in a message. We use an attention mechanism to find the relative contribution (importance) of each word. The attention mechanism assigns a weight a_i to each word annotation h_i . We compute the fixed representation r of the whole input message. as the weighted sum of all the word annotations.

$$e_i = \tanh(W_h h_i + b_h), \quad e_i \in [-1, 1] \quad (1)$$

$$a_i = \frac{\exp(e_i)}{\sum_{t=1}^T \exp(e_t)}, \quad \sum_{i=1}^T a_i = 1 \quad (2)$$

$$r = \sum_{i=1}^T a_i h_i, \quad r \in R^{2L} \quad (3)$$

where W_h and b_h are the attention layer's weights.

Character-level Interpretation. In the case of the character-level model, the attention mechanism operates in the same way as in the word-level model. However, we can interpret the weight given to each character annotation h_i by the attention mechanism, as the importance of the information surrounding the given character.

3.4 Output Layer

We use the representation r as feature vector for classification and we feed it to a fully-connected softmax layer with L neurons, which outputs a

probability distribution over all classes p_c as described in Eq. 4:

$$p_c = \frac{e^{Wr+b}}{\sum_{i \in [1, L]} (e^{W_i r + b_i})} \quad (4)$$

where W and b are the layer’s weights and biases.

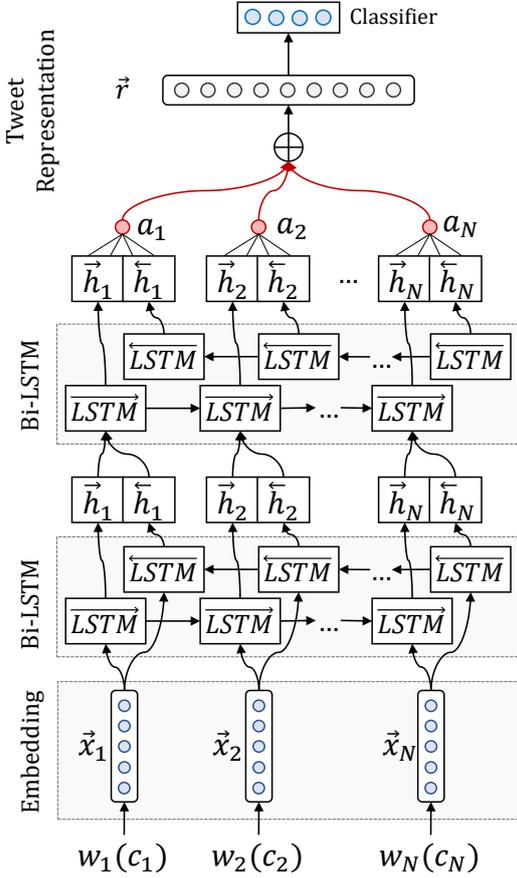

Figure 4: The word/character-level model.

3.5 Regularization

In order to prevent overfitting of both models, we add Gaussian noise to the embedding layer, which can be interpreted as a random data augmentation technique, that makes models more robust to overfitting. In addition to that, we use dropout (Srivastava et al., 2014) and early-stopping.

Finally, we do not fine-tune the embedding layers of the word-level model. Words occurring in the training set, will be moved in the embedding space and the classifier will correlate certain regions (in embedding space) to certain meanings or types of irony. However, words in the test set and not in the training set, will remain at their initial position which may no longer reflect their “true” meaning, leading to miss-classifications.

3.6 Ensemble

A key factor to good ensembles, is to utilize diverse classifiers. To this end, we combine the predictions of our word and character level models. We employed two ensemble schemes, namely unweighted average and majority voting.

Unweighted Average (UA). In this approach, the final prediction is estimated from the unweighted average of the posterior probabilities for all different models. Formally, the final prediction p for a training instance is estimated by:

$$p = \arg \max_c \frac{1}{C} \sum_{i=1}^M \vec{p}_i, \quad p_i \in \mathbb{R}^C \quad (5)$$

where C is the number of classes, M is the number of different models, $c \in \{1, \dots, C\}$ denotes one class and \vec{p}_i is the probability vector calculated by model $i \in \{1, \dots, M\}$ using softmax function.

Majority Voting (MV). Majority voting approach counts the votes of all different models and chooses the class with most votes. Compared to unweighted averaging, MV is affected less by single-network decisions. However, this schema does not consider any information derived from the minority models. Formally, for a task with C classes and M different models, the prediction for a specific instance is estimated as follows:

$$v_c = \sum_{i=1}^M F_i(c) \quad (6)$$

$$p = \arg \max_{c \in \{1, \dots, C\}} v_c$$

where v_c denotes the votes for class c from all different models, F_i is the decision of the i^{th} model, which is either 1 or 0 with respect to whether the model has classified the instance in class c or not, respectively, and p is the final prediction.

4 Experiments and Results

4.1 Experimental Setup

Class Weights. In order to deal with the problem of class imbalances in Subtask B, we apply class weights to the loss function of our models, penalizing more the misclassification of underrepresented classes. We weight each class by its inverse frequency in the training set.

Training We use Adam algorithm (Kingma and Ba, 2014) for optimizing our networks, with mini-batches of size 32 and we clip the norm of the gradients (Pascanu et al., 2013) at 1, as an extra safety

measure against exploding gradients. For developing our models we used PyTorch (Paszke et al., 2017) and Scikit-learn (Pedregosa et al., 2011).

Hyper-parameters. In order to find good hyper-parameter values in a relative short time (compared to grid or random search), we adopt the Bayesian optimization (Bergstra et al., 2013) approach, performing a “smart” search in the high dimensional space of all the possible values. Table 2, shows the selected hyper-parameters.

	Word-Model	Char-Model
Embeddings	300	25
Emb. Dropout	0.1	0.0
Emb. Noise	0.05	0.0
LSTM (x2)	150	150
LSTM Dropout	0.2	0.2

Table 2: Hyper-parameters of our models.

4.2 Results and Discussion

Our official ranking is 2/43 in Subtask A and 2/29 in Subtask B as shown in Tables 3 and 4. Based on these rankings, the performance of the suggested model is competitive on both the binary and the multi-class classification problem. Except for its overall good performance, it also presents a stable behavior when moving from two to four classes.

Additional experimentation following the official submission significantly improved the efficiency of our models. The results of this experimentation, tested on the same data set, are shown in Tables 5 and 6. The first baseline is a Bag of Words (BOW) model with TF-IDF weighting. The second baseline is a Neural Bag of Words (N-BOW) model where we retrieve the word2vec representations of the words in a tweet and compute

model	Acc	Prec	Rec	f1

Ens-MV	0.6888	0.5433	0.5442	0.5358
Ens-UA	0.6888	0.5361	0.4874	0.4959

Table 6: Results of our models for Subtask B

the tweet representation as the centroid of the constituent word2vec representations. Both BOW and N-BOW features are then fed to a linear SVM classifier, with tuned $C = 0.6$.

The best performance that we achieve, as shown in Tables 5 and 6 is **0.7856** and **0.5358** for Subtask A and B respectively³⁴. In Subtask A the BOW and N-BOW models perform similarly with respect to f1 metric and word-level LSTM is the most competitive individual model. However, the best performance is achieved when the character- and the word-level LSTM models are combined via the unweighted average ensembling method, showing that the two suggested models indeed contain different types of information related to irony on tweets. Similar observations are derived for Subtask B, except that the character-level model in this case performs worse than the baseline models and contributes less to the final results.

4.3 Attention Visualizations

Our models’ behavior can be interpreted by visualizing the distribution of the attention weights assigned to the words (characters) of the tweet. The weights signify the contribution of each word (character), to model’s final classification decision. In Fig. 5, examples of the weights as-

³The reported performance is boosted in comparison with the results presented in Tables 3 and 4 due to the utilization of unnormalized word vectors. Specifically, after further experimentation we found that normalization of word vectors provided to the LSTM is detrimental to performance, because semantic information is encoded by both the angle and length of the embedding vectors (Wilson and Schakel, 2015).

⁴For our DNNs, the results are computed by averaging 10 runs to account for the variability in training performance.

Abstract

This paper describes our proposed to participate in the first year of the irony detection in English tweets competition. Previous works have demonstrated that long short-term memory models have achieved remarkable performance in natural language processing; moreover, combining multiple classifications from various individual classifiers is generally more powerful than a single classification. In order to obtain more precise irony detection classification, our system trains several individual neural network classifiers and combines their results according to the ensemble-learning algorithm.

1 Introduction

In most sentiment analysis tasks, recognition of the precise emotional polarity of a sentence forms the basis for further work. However, much of the corpus we used for analysis and training contains numerous sarcasm and irony features that will have a negative impact on the results of our analysis and training. For example, although the tweets provided by Twitter constitute a valuable and widely applicable corpus for many natural language processing tasks, Twitter users express their feelings and opinions on social networks with frequent irony (Amir et al., 2016). Therefore, such tweets may contain converse sentiments information compared their literal meaning. For example, *@someuser Yeah keeping cricket clean, that's what he wants #Sarcasm*: ignoring the hash tag, this tweet would be positive, which would miss lead an analysis system that uses these types of tweets as input.

Thus, it makes sense to discriminate whether a text is ironic, particularly for social network texts such as tweets. Further applications including tweet sentiment analysis, will benefit from automatic irony detection. The SemEval-2018 Twitter

competition promotes research in this area, and is divided into two subtasks that involve binary and four-class classification.

Subtask A is a two-class (or binary) classification task whereby the system must predict whether or not a tweet is ironic. The subtask B is a multi-class classification task where the system has to predict one out of four labels describing i) verbal irony realized through a polarity contrast, ii) verbal irony without such a polarity contrast (i.e., other verbal irony), iii) descriptions of situational irony, and iv) non-irony (Cynthia Van Hee and Hoste, 2018). For a more detailed description, please see Carman et al. (2017).

In recent years, deep learning techniques have significantly outperformed traditional methods in several natural language processing (NLP) tasks (Cliche, 2017). In such task, several deep learning architecture-based methods have achieved outstanding performance in irony and sarcasm detection in social media. Silvio (Amir et al., 2016) presented a novel convolutional network-based method for learning user embeddings from their previous posts and used the user embeddings with lexical signals to recognize sarcasm. Ghosh and Veale (2016) proposed a combined convolutional neural network (CNN) model and long short-term memory (LSTM) method followed by a deep neural network (DNN), which also achieved an improvement compared to traditional machine learning approaches such as support vector machines (SVM). In this paper, we propose an ensemble of multiple deep learning models with a voting classifier in order to enhance the performance of individual neural network models for detecting the ironic tweets. We trained six individual classifiers, including LSTMs, bi-directional LSTMs, gated recurrent units (GRUs), bi-directional GRUs, attention-based BiLSTMs and attention-based BiGRU. Thereafter, we use a voting mechanism to

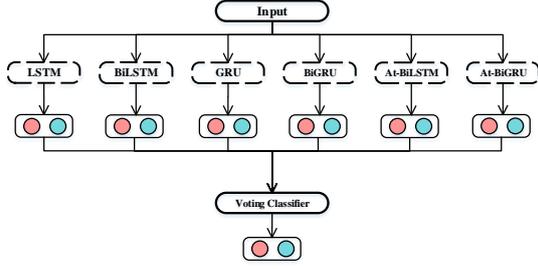

Figure 1: Ensemble voting classifier.

combine the results from the six classifiers in order to produce the final prediction label.

The remainder of this paper is organized as follows. In section 2, we describe the overall structure of our system and the LSTM-based models, as well as the selected individual classifiers. In section 3, we present the experimental results of our system, and conclusions are drawn in section 4.

2 System Description

2.1 Overview

Numerous previous research studies have demonstrated that the resulting classifier is generally more accurate than any of the individual classifiers making up the ensemble (Maclin and Opitz, 1999). For this reason, we decided to build our system following this strategy. Our system is based on ensemble learning and combined with various popular LSTM models. As illustrated in Figure 1, each classifier is a LSTM-based model, such as bi-directional LSTM (BiLSTM) and attention LSTM (AtLSTM). Each classifier is trained using the complete training set for that network. Following this, for each classifier, the predicted outputs of all classifiers are combined to produce the ensemble system output. As the ironic and non-ironic samples in the training set are evenly distributed (1911 irony samples; 3834 in total), and each classifier in our system is trained by the entire training set. Therefore, we selected the voting classifier as the combining scheme for our system. The principle of the voting classifier is the selection of the prediction supported by most of classifiers according certain rules. For example, if the predictions for a given sample are:

- classifier 1 - class 1
- classifier 2 - class 2
- classifier 3 - class 1

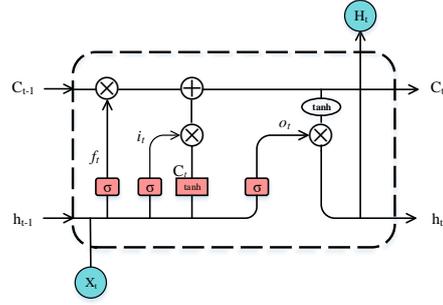

Figure 2: The LSTM memory cell

According to majority voting rules, the voting classifier would classify the sample as class 1.

Combining the output of several classifiers is useful only if disagreement exists among them. Thus, the selection of classifiers is rather important for our system.

Neural networks, particularly for recurrent neural networks (RNNs) (Mikolov et al., 2010), have achieved effective results in NLP. Owing to their circular network structure, which allows them to save previous information in a text sentence. Furthermore, conventional RNNs contain cyclic connections, making them powerful for modeling sequences. However, RNNs will face vanishing and exploding gradient problems when dealing with lengthy sequences. The LSTM, which is also a special type of RNN, was designed to address these problems. Therefore, we selected LSTM-based models as our individual classifiers.

2.2 LSTMs

The difference between the RNN and LSTM is that an LSTM (Sak et al., 2014) includes a different and more complex repeating module, as illustrated in Figure 2. This repeating module, also known as cell, provides the LSTM with the ability to discriminate whether input information is useful. A cell contains three gates, namely the input, forgotten and output gates. These gates determine the selection of information by means of the following formulae:

$$\begin{aligned} f_t &= \sigma(W_f \cdot [h_{t-1}, x_t] + b_f) \\ i_t &= \sigma(W_i \cdot [h_{t-1}, x_t] + b_i) \end{aligned} \quad (1)$$

where f_t and i_t are the forgotten and retained features; σ denotes the sigmoid function; x_t and h_t are the t -th input and output; and W and b are cell parameters.

Following this, the cell decides which new information will be stored in the cell state according

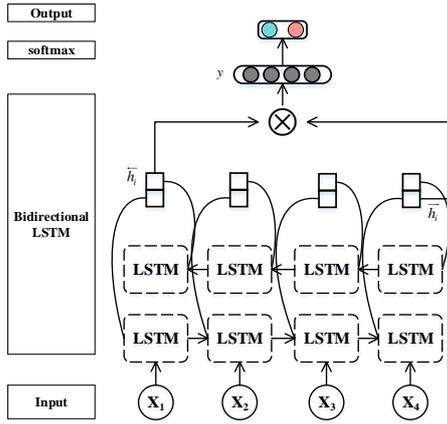

Figure 3: BiLSTM

to the next equation. Here \tilde{C}_t represents the candidate values, created by a tanh gate.

$$\tilde{C}_t = \tanh(W_c \cdot [h_{t-1}, x_t] + b_c) \quad (2)$$

Finally, updating of the cell state and calculating the output of the cell are carried out according to the equations,

$$\begin{aligned} o_t &= \sigma(W_o \cdot [h_{t-1}, x_t] + b_o) \\ C_t &= f_t * C_{t-1} + i_t * \tilde{C}_t \\ h_t &= o_t * \tanh(C_t) \end{aligned} \quad (3)$$

For an input tweet with length t , we firstly place it into an LSTM layer and generate vector h_t ; then, use this vector to calculate the possibility of whether it is ironic by means of a softmax layer.

2.3 BiLSTMs

Standard RNNs use only the previous context and ignore the future context information when dealing with sequence texts. Bidirectional RNNs process the data in both directions with two separate hidden layers which then feed forward to the same output layer (Schuster and Paliwal, 1997). BiLSTMs replace the RNN cell with an LSTM cell based on BiRNNs, as illustrated in Figure 3. BiLSTMs compute the forward hidden state \vec{h}_t and back forward hidden state \overleftarrow{h}_t , and then output the sequence y by calculating equation (4), following which the output layer is updated.

$$y = \vec{h}_t \otimes \overleftarrow{h}_t \quad (4)$$

2.4 Attention BiLSTMs

LSTMs have promoted RNNs to a great extent in NLP, and a further significant step is the attention

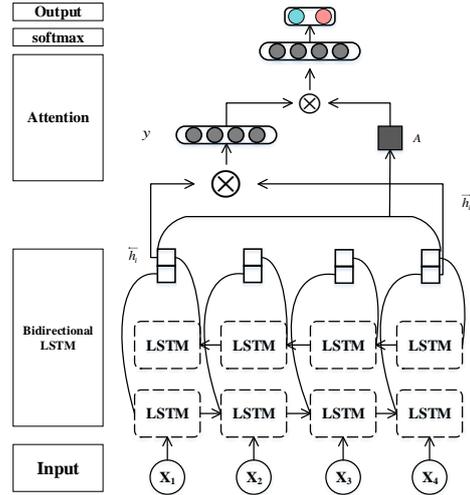

Figure 4: The LSTM memory cell

mechanism. We combined the attention mechanism (Wang et al., 2016) with the BiLSTM as illustrated in Figure 4. The attention captures the context information of an entire tweet, defined as follows:

$$\begin{aligned} e_t &= \tanh(W_e h_t + b_e) \\ \alpha_t &= \text{softmax}(e_t) \end{aligned} \quad (5)$$

where W_e and b_e denote the weight and bias, respectively, and e_t represents the attention vector that will be combined with the internal representation generated by BiLSTM layers. The remaining steps are consistent with the BiLSTMs.

2.5 GRUs

The GRU is a variant of LSTM. GRUs reduce the gating signals to two from LSTMs to two, namely reset and update gates. Although GRUs are simpler in terms of structure and calculation compared to LSTMs, their performance and efficiency in specific tasks are not reduced (Cho et al., 2014).

Therefore, we also trained three similar models using GRU cells. In total, we trained six individual classifiers: they are LSTM, BiLSTM, GRU, BiGRU, Attention BiLSTM and attention BiGRU.

3 Experiment

3.1 Datasets

The training dataset is constructed from 3834 English tweets collected by the organizers by means of searching Twitter for the hashtags #irony, #sarcasm, and #not. The training dataset for task A consists of tweets with a binary value score (0 or 1)

Subtask A	Accuracy	F1 score (macro)	Recall (macro)	Precision (macro)
LSTM	0.64163	0.64161	0.64174	0.65364
BiLSTM	0.64163	0.64161	0.64174	0.65364
GRU	0.63109	0.63108	0.63111	0.64031
BiGRU	0.64295	0.64099	0.64232	0.65110
Attention BiLSTM	0.64295	0.64085	0.64230	0.64519
Attention BiGRU	0.65744	0.65506	0.65673	0.66053
Ensemble	0.66007	0.66871	0.61894	0.62095

Table 1: Cross-validation results for subtask A.

Subtask B	Accuracy	F1 score (macro)	Recall (macro)	Precision (macro)
LSTM	0.7148	0.4939	0.5071	0.5341
BiLSTM	0.7330	0.4885	0.4964	0.5103
GRU	0.7369	0.5150	0.5017	0.5438
BiGRU	0.7031	0.4800	0.4946	0.5319
Attention BiLSTM	0.7200	0.5129	0.5315	0.5324
Attention BiGRU	0.7278	0.5081	0.5099	0.5216
Ensemble	0.7539	0.5172	0.5198	0.5385

Table 2: Cross-validation results for subtask B.

indicating whether the tweet is ironic. The training data for subtask B includes tweets with a numeric value corresponding to one of the subcategories, namely ironic by clash, other irony, situational irony and non-ironic. For subtasks A and B, the content of the tweet is exactly the same apart from the labels. The organizers also provided a version with no emoticons or hashtags and one with emoticons or hashtags. According to people’s tweeting habits, emoticons and hashtags are important tools for expressing emotions, thus, we used tweets with these features for training.

3.2 Preprocessing

Before feeding the tweets to any classifier, they are pre-processed by following procedure:

- All uppercase letters are converted to lowercase.
- URLs are replaced by `<url>`; instance of @someone are replaced by `<user>`.
- Certain emoticons and emojis expressing positive sentiments are transformed into words such as *smile*, *like*, and *happy*. Others that express negative emotions are all replaced by `<irony>`.
- For subtask A, all hashtags are replaced by `<hashtag>`; for subtask B: except for *#irony*,

#sarcasm and *#not*, all other hashtags are replaced by `<hashtag>`, and the remainder are all converted to the word *irony*.

We did not replace *#irony*, *#sarcasm* and *#not* with word irony for subtask A because it is easy for overfitting to occur while training. We consider that the reason for this is that the searching and labeling of these tweets mostly dependent on their hashtags. In the four-category subtask B, this does not lead to over-fitting, but aids in improving accuracy.

3.3 Word embedding

We obtain word embeddings by training with the corpus of English articles in Wikipedia pages using Global Vector (GloVe) (Pennington et al., 2014). Compared to Word2vec (Mikolov et al., 2013), GloVe achieves superior performance in this task under the same conditions. Moreover, we set the dimension of a single word as 300. Following the above steps, we create a look-up table that allows for most of the words in the training dataset to correspond to word vectors trained in advance, with the dataset containing 9056 unique words. However, 1266 words remain that cannot be matched, with most of these being numbers and certain user-created words.

	Accuracy	F1 score (macro)	Recall (macro)	Precision (macro)
Subtask A	0.5089	0.4086	0.4277	0.3912
Subtask B	0.466	0.3127	0.3229	0.3384

Table 3: Evaluation for Subtask A and B.

3.4 Parameters

We used earlystopping to observe the accuracy value convergence of each epoch, with patience set to 3 and min_delta set to 0.05; we found that each model stopped training with no more than 35 epochs or even less. Consequently, we set the number of epochs to 30 for the training of every classifier. Furthermore, we set the batch size to 100 and drop-out rate to 0.25 for training of each model. We selected the categorical cross-entropy as the loss function and Adagrad as the optimizer (Duchi et al., 2011).

For subtasks A and B, the individual classifiers are trained with the training dataset. Ow-ing to the lack of development dataset, we only evaluated the performance of the classifiers and prevented overfitting by cross-validation. The models were implemented in Keras using TensorFlow backend.

3.5 Results and analysis

The experimental results of the individual classifiers and ensemble are displayed in Table 1 for subtask A and Table 2 for subtask B.

As indicated in Table 1, BiLSTM and attention GRU achieved a superior performance. However, there is no significant difference among the results of each model. This may be the reason why the ensemble does not operate effectively, because a good ensemble is one in which the individual classifiers are both accurate and create their errors in different parts of the input space (Maclin and Opitz, 1999). Our input space is not sufficiently large and the classifiers are similar, creating their errors in the same place.

For subtask B, our preprocessing strategy aids in improving accuracy. However, the samples in the training set are not as evenly distributed as subtask A, reflecting the ensemble effect. The precision achieved by our system achieved in subtask B ranks 10th out of 32 participants. However, numerous aspects of our system require further improvement.

The evaluation results from the committee are illustrated in Table 3. Due to our negligence, we submitted a wrong result of Subtask B. After the

organizing committee reminded us that we have corrected the error and re-evaluated our result for Subtask b. Table 3 shows the corrected results for Subtask B. We apologize for the inconvenience caused by our own negligence and we thanked the organizers for prompt reminders so that we could correct the results in a timely manner.

4 Conclusion and future work

In this paper, we have presented the system we used to compete in SemEval-2018 task 3 - Irony detection in English tweets. The purpose of our participation in this competition is to deepen our understanding of irony detection as a novel NLP application. Moreover, we hope to determine an effective combination approach to ensemble learning and neural networks by means of practical application.

For future work, it would be meaningful to improve the neural network by combining the characteristic that ironic sentences are often inconsistent. Moreover, the goal is to identify superior practical ensemble methods to achieve improved performance in increased NLP applications.

Abstract

In this paper, we describe the system submitted for the SemEval 2018 Task 3 (Irony detection in English tweets) Subtask A by the team Binarizer. Irony detection is a key task for many natural language processing works. Our method treats ironical tweets to consist of smaller parts containing different emotions. We break down tweets into separate phrases using a dependency parser. We then embed those phrases using an LSTM-based neural network model which is pre-trained to predict emoticons for tweets. Finally, we train a fully-connected network to achieve classification.

1 Introduction

The micro-blogging site Twitter has created an abundance of data about opinions and sentiments regarding almost every aspect of daily life. A deeper study of the public opinion can be obtained by applying natural language processing techniques on this data. However, the performance of these NLP models is detrimentally affected by irony (Pozzi et al., 2016). As per the Oxford English Dictionary, irony is the expression of one’s meaning by using language that normally signifies the opposite, typically for humorous or emphatic effect. This deviation between what is said and what is intended makes irony hard to detect. Being a platform where users are free to communicate and express themselves colloquially, Twitter generates considerable data injected with irony. Studying this would provide us with a better sentiment analysis of these tweets.

Prior work on irony detection includes the use of unigrams and emoticons (González-Ibáñez et al., 2011; Carvalho et al., 2009; Barbieri et al., 2014). Maynard and Greenwood (2014) describe an unsupervised pattern mining approach where the sentiment of the hashtag in the tweet is proposed to be a key indicator of sarcasm. If the sentiment of the tweet does not match the sentiment

of the hashtag, it is predicted to be sarcastic. Riloff et al. (2013) illustrates a semi-supervised approach where rule-based classifiers are used to look for negative situation phrases and positive verbs in a sentence. Tsur et al. (2010) build pattern-based features that detect the presence of discriminative patterns as extracted from a large sarcasm-labelled corpus. N-gram-based approaches have also been used (Davidov et al., 2010; Ptáček et al., 2014; Joshi et al., 2015) with sentiment features. Joshi et al. (2017) use similarity between word embeddings as feature and Poria et al. (2016) use convolutional neural networks to extract sentiment, emotion and personality features for sarcasm detection.

SemEval-2018 Task 3 (the 12th workshop on semantic evaluation) specifies two subtasks in relation to irony detection in English tweets (Van Hee et al., 2018). In subtask A the goal was to train a binary classifier that detects whether a given tweet is ironic or not. Subtask B was a multi-class classification problem where four labels were specified to describe the nature of irony (verbal irony by means of a polarity contrast, situational irony, other verbal irony, and non-ironic). The goal was to assign one of the four labels to each tweet.

We propose a new method which considers ironical tweets to be collections of smaller parts containing different emotions. We break down tweets into these collections using a dependency parser and embed them using DeepMojji (Felbo et al., 2017) which is pre-trained to predict emoticons for tweets. Finally we train a classifier to detect irony. The paper is organized as follows: We discuss our methods in section 2. Section 3 contains the details about the experiments and the training data. In Section 4 we discuss the results and Section 5 concludes the paper with closing remarks.

2 Method

In order to identify the chunks of various emotions in an ironic tweet, we split the tweets into phrases using a dependency parser. We use Tweepoparser (Kong et al., 2014), which is a dependency parser for English tweets. The parser is trained on a subset of a labelled corpus for 929 tweets (12,318 tokens) drawn from the POS-tagged tweet corpus of Owoputi et al. (2013), Tweepbank. TweepoParser predicts the syntactic structure of the tweet represented by unlabelled dependencies. Tweets contain multiple sentences or fragments called “utterances” each with their own syntactic root disconnected from the others. Since a tweet often contains more than one utterance, the output of TweepoParser will often be a multi-rooted graph over the tweet. Also, many elements in tweets have no syntactic function. These include, in many cases, hashtags, URLs, and emoticons. TweepoParser attempts to exclude these tokens from the parse tree. For our purpose, we club the words arising from the same root to create a phrase. Multiple roots would create multiple phrases. As we can see from Figure 1, these phrases can convey the different sentiments attached to the different subjects of the tweet.

Figure 1: Parser results

After extracting a set of phrases for the sentence, we embed the phrases into vectors. We used the DeepMoji (Felbo et al., 2017) model, which is trained on 1.2 billion tweets with emojis to understand how language is used to express emotions. It encodes the provided phrase into a 2,304-dimensional feature vector. Under the hood, DeepMoji model projects each word into a 256-dimensional vector space followed by a hyperbolic

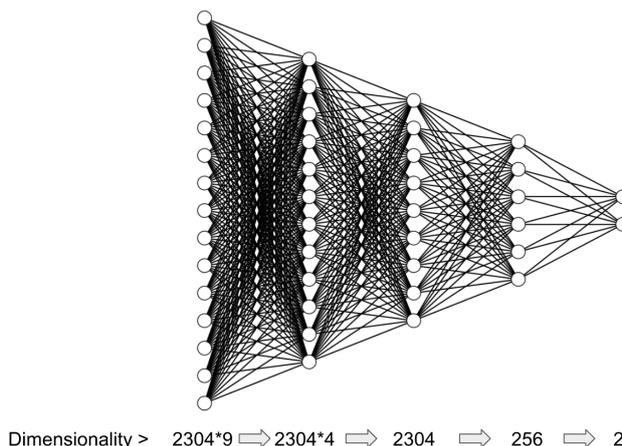

Figure 2: Neural network architecture

tangent activation function. After this, two bidirectional LSTMs with 1,024 hidden units each are used to capture the context of each word. Finally, the model uses skip connections from each layer to an attention layer and hence the attention layer outputs a 2,304 (256+1,024+1,024) dimensional vector. Now this 2,304-dimensional output is connected to a softmax layer for classification. We did not use the final softmax layer but took the 2,304-dimensional vector for each phrase. As the model was trained for prediction of emoticons, this feature vector contains information about the semantic and sentimental content of the phrases. To make the predictions we need to account for the sentiment behind every utterance. To this end, we concatenate these vectors and pass the resulting concatenated vector through a fully-connected network as described in Figure 2.

Tweets can have a varying number of roots, which implies that they split into a varying number of phrases. Our model considers a maximum of nine roots. A tweet with an excess of nine roots is truncated suitably. On the other hand, a tweet with less than nine roots is zero-padded. We have described the complete process flowchart in Figure 3.

3 Experiments

For subtask A, we were provided with a dataset consisting of tweets along with a binary class (0 or 1) which indicates whether this tweet is ironic or not (0 for non-ironic tweets and 1 for ironic tweets). The data was collected from Twitter API by querying tweets using the hashtags #irony, #sarcasm and #not, with subsequent manual an-

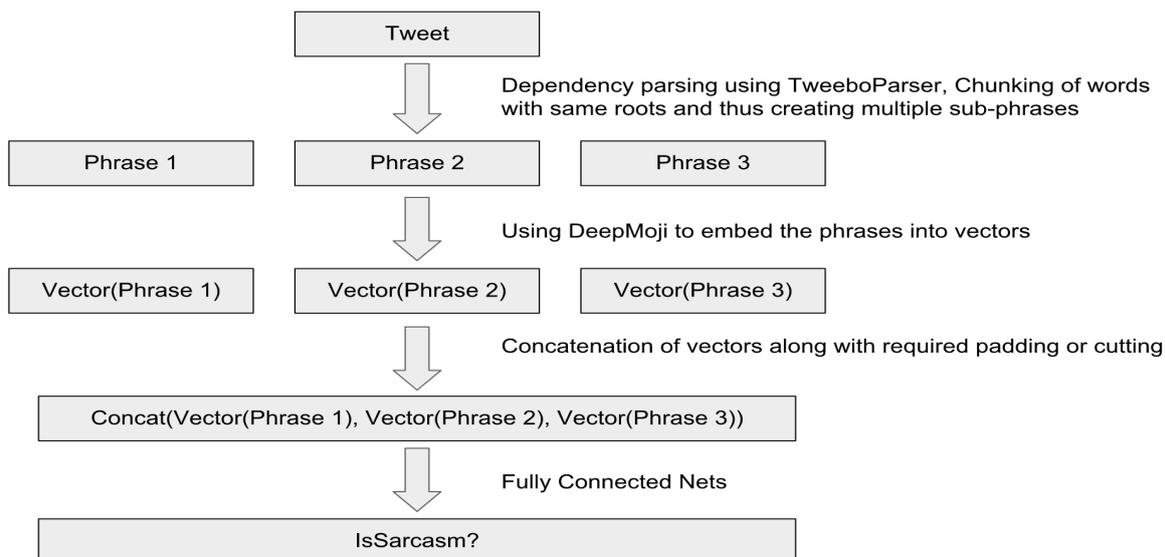

Figure 3: Process Flowchart

notation to remove noise. 3,833 tweets for training and 784 tweets for testing were provided. The evaluation was done by using accuracy, precision, recall and F1 score.

$$Accuracy : \frac{\text{number of correctly predicted instances}}{\text{total number of instances}}$$

$$Precision : \frac{\text{number of correctly predicted instances}}{\text{number of predicted labels}}$$

$$Recall : \frac{\text{number of correctly predicted instances}}{\text{number of labels in the gold standard}}$$

$$F1 \text{ score} : \frac{2 \times \text{precision} \times \text{recall}}{\text{precision} + \text{recall}}$$

We used the pipeline described in Figure 3. The final step of the process used a fully connected neural network with four layers. The input layer of the FC network has a dimension of 20,736 (2,304*9), the second layer has a dimension of 9,216 (2,304*4), the third layer has a dimension of 2,304 and the fourth layer has 256 dimensions. The final layer has 2 dimensions, with one for each class. This is depicted in Figure 2. We used the hyperbolic tangent activation function in all of the layers, and stochastic gradient descent with a learning rate of 0.01 and a momentum of 0.5.

Two models were then devised. The difference in these models lies in the input supplied to the FC network. In the first model, this input is the concatenation of the vectors obtained by embedding phrases. In the second model, the input is the

Method	Accuracy	Precision	Recall	F1 score
Winning team	0.7347	0.6304	0.8006	0.7054
Our System β_1	0.6659	0.5527	0.6471	0.5962
Our System β_2	0.6390	0.5198	0.6941	0.5944
Our System α	0.6951	0.6197	0.5176	0.5641

Table 1: Results SemEval Task 3A

concatenation of the input in the first model along with a 2,304-dimensional vector representing the embedding of the tweet as a whole. The results we get from various experiments on these models are shown in Table 1.

System α is the first model. The best F1 score for this model was achieved after four epochs, as shown in Table 1. System β_1 and β_2 are the second model running for five and four epochs respectively.

4 Results and Discussions

We participated only in the shared task 3A as the team Binarizer. We came ninth as per accuracy and seventeenth as per F1 score among the forty-three participating systems. Due to a glitch on

our side during submission the results are based on 446 out of 784 instances in the test data.

The models perform better than the baseline system as per the competition leaderboard. This reinforces the notion that separate phrases in a tweet carry information required for irony detection. System α has greater precision whereas System β has higher recall. So an application which demands urgent detection of ironic tweets would profit more from System β . This demonstrates that the sentiment information of the context provided from the whole tweet is also important.

5 Conclusion and Future works

We have shown how using the sentiments of different segments of tweets can enable irony detection. From the results of our experiments, we conclude that the segments have sufficient sentiment information in them for the identification of irony. In future research, we aim to improve the algorithm for parsing these chunks by replacing the dependency parser. Also, more experimentation can be performed for the last part of the pipeline. As the phrases from the tweets are sequences themselves, we can apply sequence modelling with LSTMs or CNNs.

Abstract

Sentiment analysis plays an important role in E-commerce. Identifying ironic and sarcastic content in text plays a vital role in inferring the actual intention of the user, and is necessary to increase the accuracy of sentiment analysis. This paper describes the work on identifying the irony level in twitter texts. The system developed by the SSN MLRG1 team in SemEval-2018 for task 3 (irony detection) uses rule based approach for feature selection and MultiLayer Perceptron (MLP) technique to build the model for multiclass irony classification subtask, which classifies the given text into one of the four class labels.

1 Introduction

Humans have the natural ability to identify the sentiment or the irony intended in a review or comment. However, identifying the intention of the user is a difficult task for the machine. Detecting irony present in a text is critical to sentiment analysis since it will inverse the polarity of the sentiment inferred (Hernandez-Farias et al., 2015).

Choice of shops, books, movies, hotels and various other services and products is influenced by comments and reviews in social media to a large extent. Huge amount of data is available in the Internet about the choices people make and their reviews about it.

Irony in texts affects the polarity of the sentiment inferred from them. Since it gives the text a meaning that is just the opposite to what is actually said, it is called as a *polarity reverser* (Farias et al., 2016). Irony is studied in various disciplines such as linguistics, philosophy and psychology. Due to the frequent use of irony in social media, its detection has gained importance in natural language processing, which faces difficulty in achieving a high performance (Liu, 2012; Wallace, 2015). The potential applications of irony

detection include text mining, author profiling, detecting online harassment and sentiment analysis (Van Hee et al., June 2018). SSN MLRG1 team has already worked in sentiment analysis tasks conducted in SemEval 2017 (Angel Deborah et al., 2017a,b).

We can identify three types irony namely *verbal* irony, *situational* irony and *dramatic* irony. Sub-task B in task 3 is a multiclass classification task for classifying a given tweet to one of these four classes:

1. verbal irony realized through a polarity contrast,
2. verbal irony without such a polarity contrast,
3. situational irony, and
4. non-irony.

2 Related Work

Unlike factual information, sentiment analysis and opinion mining have to deal with subjective information. Consequently, for any problem, it is important to analyze opinions collected from many people and summarize them. Social and political discussions are much harder due to complex topic and sentiment expressions, instances of sarcasm and irony (Liu, 2012). Maynard and Greenwood (2014) discusses the need for analyzing sarcasm in social media. They have developed a hashtag tokenizer for GATE (General Architecture for Text Engineering) tool and detected the sentiments and sarcasm in hashtags. Ghosh and Veale (2016) have found deep neural networks to perform better compared to Support Vector Machines (SVM) for sarcasm detection. Hernandez-Farias et al. (2015) have used MLP for automatic irony detection using the basic features from sentiment analysis and observed that MLP yields better results, compared to Naive Bayes, decision trees, maximum entropy and SVM. Barbieri and Saggion (2014) have used

random forest and decision tree for analyzing the irony and humour content in twitter dataset using Weka tool. They have used seven features for detecting imbalance, unexpectedness and common patterns.

3 System Overview

The system consists of the following modules: data extraction, preprocessing, rule based feature selection, feature vector generation and multilayer perceptron for classification.

3.1 Feature Engineering and Implementation

The dataset is cleaned and processed using functions from NLTK toolkit. We identified the keywords for irony detection using rule based feature selection. The selected features are formed into a Bag of Words (BoW) dictionary. For each sentence, feature vectors are generated by one-hot encoding method, using the sentence keywords and BoW dictionary. The feature vectors are given to the MLP and output class label is predicted. Error is calculated and backpropagated to update the weight vectors. Nadam (Nesterov-accelerated Adaptive Moment Estimation) algorithm is used for optimization.

The procedure for data preprocessing is outlined in Algorithm 2:

Algorithm 2: Data preprocessing.

Input: Input dataset.

Output: Tokenized words and their parts of speech.

begin

1. Separate labels and sentences.
2. Perform tokenization using `word_tokenize` function of the NLTK toolkit.
3. Perform Parts of Speech tagging using `pos_tag` function from the NLTK toolkit.
4. Return the tokenized words and their parts of speech which will be given as inputs to rule based feature selection.

end

The procedure for rule based feature selection and feature vector generation is outlined in Algorithm 3:

Algorithm 3: Rule based feature selection and feature vector generation

Input: Tokenized words and their parts of speech.

Output: BoW feature representation with labels.

begin

For each of the tokenized words, falling under one of the categories listed in Table 1, do the following steps.

1. Lemmatize the word using `WordNetLemmatizer` from the NLTK toolkit.
2. Insert the lemmatized word into the dictionary.
3. Represent each sentence as a feature vector using one-hot encoding by looking up the dictionary.
4. Store the corresponding label in target vector using one-hot encoding.
5. Return the feature vector generated as the input to build the model.

end

Abbreviation	Parts of Speech
VB	verb, base form
VBZ	verb, 3rd person sing. present
VBP	verb, non 3rd sing. present
VBD	verb, past tense
VBG	verb, gerund/present participle
VBN	verb, past participle
JJ	adjective
JJR	adjective, comparative
JJS	adjective, superlative
RB	adverb
RBR	adverb, comparative
RBS	adverb, superlative
NN	noun, singular
NNP	proper noun, singular
NNS	noun plural
NNPS	proper noun, plural

Table 1: Parts of speech categories.

The procedure for building Multilayer Perceptron is outlined in Algorithm 4:

Algorithm 4: Build a Multilayer Perceptron model.

Input: BoW feature representation with labels.

Output: Learned model.

begin

1. Prepare the training dataset. `XTrain` contains the feature vectors and `YTrain` contains the target labels for irony class.
2. Build the classification model which comprises an input layer, two hidden layers and an output layer with `relu` activation function in the hidden layers and `softmax` activation function in the output layer.

3. Optimize the classification model using nadam optimizer of keras package for some n iterations.
4. Return the learned model.

end

For the test dataset, preprocessing is done and the feature vectors are generated from the training data BoW representation. The feature vectors are given as input to the learned model and the predicted output labels are stored.

3.2 MultiLayer Perceptron

MLP is a feedforward artificial neural network for supervised learning. MLP can be used for both classification and regression tasks. It consists of an input layer, one or more hidden layers and an output layer. Each neuron in one layer is fully connected to the neurons in next layer. Number of neurons in the output layer depends on the number of class labels in the given problem.

Each connection has a weight assigned to it. Output of each neuron is calculated by applying an activation function on the weighted sum of the inputs. Some of the common activation functions are linear, sigmoid, tanh, elu, softplus, softmax, relu, relu6, crelu, selu and relu_x.

Error value is calculated from the value predicted by the output layer and the actual class label. This error value is backpropagated and the weights and biases are updated. This procedure is repeated for the feature vectors of each input sentence. The whole procedure is repeated for some n iterations or until the error value converges to a value below a threshold.

Figure 1 depicts a simple MLP model, consisting of a single hidden layer. It takes four inputs and produces one output.

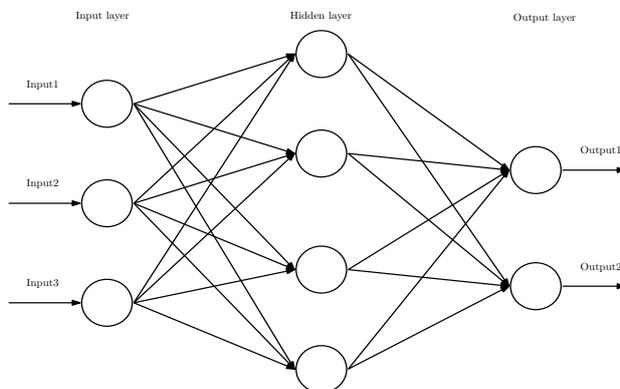

Figure 1: Multilayer Perceptron.

The working of Multilayer Perceptron model is outlined in Algorithm 1:

Algorithm 1: Multilayer Perceptron.

Input: Feature vectors and targets.

Output: Learned model.

begin

1. Initialize the weights with random values and choose a learning rate η .
2. Repeat steps 3 to 6 until the neural network is trained.
3. For each input example (feature_vector, target), do steps 4 to 6.
4. Forward Pass
 - (a) For each neuron of a layer, find the weighted sum of the input vectors. Apply the activation function and pass the outputs as inputs to the next layer.
 - (b) Predict the value in the output layer.
5. Backward Pass
 - (a) Compute the error ∇ between the actual target and the predicted class.
 - (b) Backpropagate the error and compute the error in all hidden layer neurons.
6. Update all the weights Δw_{ij} and biases b_{ij} by gradient descent technique.
7. Return the learned model.

end

4 Dataset

The dataset consists of 4792 English tweets that are collected between 01/12/2014 and 04/01/2015 from 2676 unique users. The entire corpus is split into training (80%) and test (20%) sets. The tweets are manually labeled using a fine grained annotation scheme for irony (Van Hee et al., 2016). The training dataset is further divided into training set and development test set for system building.

5 Performance Evaluation

The performance of the system is measured using accuracy, precision, recall and F1-score, using formulas shown in Equations 1 to 4.

$$\text{Accuracy (A)} = \frac{\text{TP} + \text{TN}}{\text{N}} \quad (1)$$

$$\text{Precision (P)} = \frac{\text{TP}}{\text{TP} + \text{FP}} \quad (2)$$

$$\text{Recall (R)} = \frac{\text{TP}}{\text{TP} + \text{FN}} \quad (3)$$

$$F_1 \text{ score} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \quad (4)$$

where TP denotes True Positive, TN denotes True Negative, FP denotes False Positive, FN denotes False Negative and N denotes total number of tweets.

The optimization of the model was performed using different gradient descent algorithms such as SGD, adam, adaGrad, RMSProp and nadam. Adam and nadam are the widely used optimizers. Adam (Adaptive Moment Estimation) computes the adaptive learning rates using momentum and RMSProp. Momentum points the model in the best direction, while RMSProp adapts how far the model goes in that direction on parameter basis. Nadam combines Nesterov momentum with Adam which is superior to momentum. (Dozat, 2016).

We split the training set into training set (80%) and development test set (20%). The different optimization algorithms were used with the model and nadam optimizer produced better results compared to other algorithms for the development test set.

There are 32 submissions for this particular task. The model has achieved the following values for the various measures as listed in Table 2.

Measure	Value	Ranking
Accuracy	0.5727	15
Precision	0.3484	21
Recall	0.3609	19
F1-Score	0.3337	20

Table 2: Performance.

From the result, it appears as if the basic text features selected by rule based approach is not enough to detect the irony level in the given text. Additional features like emoticons and hashtags

can be added to the feature set to enhance the performance.

6 Conclusion

We built a basic MLP to detect the irony level in twitter text, which has an input layer, two hidden layers with 128 and 64 neurons, and an output layer with 4 neurons for the four class labels. Relu activation function was used in both hidden layers and softmax activation function in output layer. The various optimizers such as SGD, RMSprop, adam, adagrad, and nadam were tried. Nadam optimizer performed better than others.

The text features were taken into consideration for BoW representation. Since irony renders an opposite meaning to the text, it is difficult to detect the irony from the text features alone. The system performance can be enhanced with the emoticon and hashtag information. The performance can also be improved by doing tweet normalization before the feature selection. The accuracy of system can be increased by using deep neural networks such as Convolutional Neural Network (CNN) or Recurrent Neural Network (RNN). Feature selection techniques can be enhanced with semantics and lexicon information.

Abstract

This paper describes our participation in SemEval 2018 Task 3 on Irony Detection in Tweets. We combine linguistic features with pre-trained activations of a neural network. The CNN is trained on the emoji prediction task. We combine the two feature sets and feed them into an XGBoost Classifier for classification. Subtask-A involves classification of tweets into ironic and non-ironic instances, whereas Subtask-B involves classification of tweets into *non-ironic*, *verbal irony*, *situational irony* or *other verbal irony*. It is observed that combining features from these two different feature spaces improves our system results. We leverage the SMOTE algorithm to handle the problem of class imbalance in Subtask-B. Our final model achieves an F1-score of 0.65 and 0.47 on Subtask-A and Subtask-B respectively. Our system ranks 4th on both tasks, respectively, outperforming the baseline by 6% on Subtask-A and 14% on Subtask-B.

1 Introduction

According to the Merriam-Webster dictionary¹, one of the meanings of irony is defined as ‘the use of words to express something other than and especially the opposite of the literal meaning’ (e.g. *I love getting spam emails.*). Irony can have different forms, such as verbal, situational, dramatic etc. Sarcasm is also categorized as a form of verbal irony. Various attempts have been made in the past for detection of sarcasm (Joshi et al., 2017). Sarcastic texts are characterized by the presence of humor and ridicule, which are not always present in the case of ironic texts (Kreuz and Glucksberg, 1989). The absence of these characteristics makes automatic irony detection a more difficult problem than sarcasm detection.

¹<https://www.merriam-webster.com/dictionary/irony>

Irony detection is a problem that is important for the working of many Natural Language Understanding Systems. For example, people often use irony to express their opinions on social media like Twitter (Buschmeier et al., 2014). Detecting irony in social texts can aid in improving opinion analysis.

The SemEval 2018 task 3 (Van Hee et al., 2018) consists of two subtasks. Subtask-A involves predicting whether a tweet is ironic or not and Subtask-B involves categorizing a tweet into Non-Ironic, Verbal Irony (by means of a polarity contrast), Situational Irony and Other Forms of Verbal Irony. The task organizers use macro averaged F1, rather than accuracy to force systems to optimize to work well on all the four classes of tweets, as described in Section 3.1.

Systems built in the past primarily used hand-crafted linguistic features for classification of ironic texts (Buschmeier et al. 2014; Farías et al. 2016). In our system, we try to combine them with the pre-trained activations of a neural network. Our results show that both types of features complement each other, as the results produced by the combination of them surpass the results of using either the linguistic or the pre-trained activation features individually by a large margin. We use XGBoost Classifier (Chen and Guestrin, 2016), as it performs at par with neural networks when the provided training data is of small size.

Our results indicate that oversampling techniques like SMOTE (Chawla et al., 2002) can also be used to oversample the representations generated using neural networks to improve performance on imbalanced datasets.

The rest of the paper is organized as follows: Section 2 gives a detailed description of how our system was built, Section 3 then describes the experimental setup and the results obtained and Section 4 concludes the paper.

2 Proposed Approach

For modeling irony in tweets, our system makes use of a combination of features. These features can be classified into two broad groups:

- Linguistic (Structure and User Behavior)
- Pre-trained Activations of a Neural Network.

These features were concatenated and the XG-Boost classifier (Chen and Guestrin, 2016) was used to perform the classification.

For subtask B, to counter the imbalance in the dataset, which might lead classifiers to favor the majority class in classification, we used SMOTE for oversampling the data (Chawla et al., 2002). Then we used XGBoost Classifier again for classification into various classes.

The details of the classifier parameters are provided in Section 2.2. Basic preprocessing of tweets was performed before feature extraction, which involved removing hash symbols ('#'), converting contractions ('doesn't' to 'does not'), removing links and quotations and normalizing the text into lower case. We will explicitly mention those features whose extraction require the original tweets.

2.1 Feature Extraction

Our system generates a 72-dimensional hand-crafted feature vector, based on the linguistic structure and user behavior. We then combine this with a 2304 dimensional feature vector generated using activations of a pre-trained CNN. The combined features are categorized into 11 broad classes:

Contrast Based Features: Contrast of sentiments is a feature that has been observed in sarcastic and ironic texts (Rajadesingan et al., 2015), e.g. *I love being ignored #not*. For capturing contrast, we use the affect score of lemmas (Warriner et al., 2013) and the sentiment score of words based on **SentiStrength** (Thelwall et al., 2010). The final feature vector consists of:

- The difference between the highest and lowest sentiment values of the words present in the tweet. (1 feature)
- The difference between the highest and lowest affect scores of the words present in the tweet. (1 feature)

- Longest unimodal sequence size and the number of transitions of sentiment polarity. (2 features)
- Sum of sentiment scores and counts of positive and negative n-grams. (4 features)

Readability Based Features: Ironic texts are usually complex, and hence we use the total number of syllables in the tweet, along with number of words that contain polysyllables as features. According to Automated Readability Index (Senter and Smith, 1967), the standard deviation, the average and the median of the word length serve as indicators of the complexity of the text (Rajadesingan et al., 2015).

Incongruity of Context: Ironic similes are common in literature (e.g. *as clear as mud* in which both *clear* and *mud* are sentiment neutral words.). Due to this neutrality, the lexicon based methods are unable to capture the incongruity present. Therefore, maximum and minimum GloVe (Pennington et al., 2014) cosine similarity between any two words in a tweet are used as features in our system (Joshi et al., 2016).

Repetition-based Features: Users often change their writing style to depict sarcasm and irony, which is analogous to the change of tone in speech while expressing sarcasm, e.g. *Looovvveeeeeee when my phone gets wiped*. We use the count of words with repetitive characters and the count of 'senti words' (sentiment score ≥ 2 and sentiment score ≤ -2) with repetitive characters as our features (Rajadesingan et al., 2015).

Punctuation-based Features: Punctuation counts can sometimes serve as an indicator of ironic texts (Kreuz and Caucci, 2007). We use the counts of characters like hashtag (#), ellipsis (...), exclamation mark (!), question mark (?), colon (:), quote (") and apostrophe (') in a tweet as features.

Presence of Markers: Discourse markers are certain words that help in expressing ideas and performing specific functions (Farías et al., 2016). Our system uses a curated list of discourse markers. Similar to the list of discourse markers, we also use a list of intensifiers (e.g. *heck*), laughter words (e.g. *lmao, lol etc.*), interjections (e.g. *oops*) and swear words (e.g. *shit*) as their appearance in a tweet indicates the presence of unexpectedness, which can, in turn, serve as an indicator of irony. We use counts of these different types of words separately as features.

Word Count Features: According to (2016), ironic tweets depict their content in fewer words compared to normal tweets. Hence we use the word count of tweets as a feature. Apart from the word count, (Kreuz and Caucci, 2007) suggest that the counts of adjectives and adverbs can also be used as markers of ironic content. We also use the preposition count as a separate feature.

Semantic Similarity: Ironic tweets that span multiple lines are often found to have lines that are very much semantically dissimilar to each other (Farías et al., 2016). We use the **WordNet** based similarity function (Mihalcea et al., 2006) available online² to obtain a similarity score, which is used as a feature.

Polarity and Subjectivity: Ironic texts are usually subjective and often convey something negative (or positive) about the target (Wallace et al., 2015). We use the Polarity and Subjectivity Scores (Sentiment Score) generated using **TextBlob** as features in our model (Loria et al., 2014).

URL Counts: We observed in the training set that users often used irony to express their opinion about online content, e.g. blogs, images, tweets, etc. For specifying the context of a comment (tweet), they often add a URL to the original content. So we used the counts of URLs in a tweet as a feature. Our system requires raw tweets for extracting this feature.

Apart from the above features, we also experimented with Named Entity Count and occurrence of popular hashtags like (*#hypocrisy*), using a curated list, as our features (Van Hee, 2017).

2.1.1 Pre-trained CNN Features

Apart from extracting linguistic features from tweets, we leverage the activations of a Convolutional Neural Network (CNN) pre-trained on emoji prediction task. We use DeepMoji³ (Felbo et al., 2017), a model trained on 1.2 billion tweets with emojis, and tested on eight benchmark datasets within sentiment, emotion and sarcasm detection. Since sarcasm is a form of verbal irony that expresses ridicule or contempt (Long and Graesser, 1988), we believe transferring the knowledge of CNN trained on sarcasm can improve the results of Irony Detection task.

Each tweet is converted into a 2304-dimensional feature vector by feeding into

²<http://nlpforhackers.io/wordnet-sentence-similarity/>

³<https://github.com/bfelbo/DeepMoji>

DeepMoji-CNN and extracting activations of the last hidden layer.

2.2 Classifiers

We construct XGBoost (Chen and Guestrin, 2016) feature-based classifiers for irony detection using the above features. Based on the 10-fold cross validation performance, the best performing parameters prove to be the default parameters used by the XGBoost Classifier Package⁴.

2.3 Handling Class Imbalance

The data provided for subtask-B is highly skewed. To perform well on every class of irony, we used an oversampling technique (SMOTE (Chawla et al., 2002)). In SMOTE, for generating a new synthetic sample, from the k -nearest neighbors of an instance, one is chosen at random, and a new sample is generated on the line joining the instance and the chosen neighbor. We use the SMOTE implementation available in *imblearn* (Lemaître et al., 2017) package for our system, with k -neighbors equal to 5.

3 Experiments and Evaluation

3.1 Dataset and Metrics

The annotated tweet corpus provided for training consists of 1390 instances of Verbal Irony due to polarity contrast, 205 instances of Other Types of Verbal Irony, 316 Situational Ironic instances, and 1923 Non Ironic instances. Our system only uses the training data provided by the organizers and no other annotated data is used (Constrained System).

The test dataset for Subtask-A contains 473 non-ironical tweets and 311 ironical tweets. For Subtask-B, the 311 ironical tweets are further classified into Verbal Irony by means of Polarity Contrast (164), Situational Irony (85) and Other Forms Of Verbal Irony (62).

The evaluation metric used for ranking teams in Sub-task A is the F1 score of the positive (Ironic) class whereas in Subtask-B, the organizers use macro averaged F1 (average of F1 for each class) as an evaluation metric for ranking teams.

3.2 Results and Discussion

We present the results achieved by our approaches, as well as the combination of our methods in Table 1. Our final submitted systems are: (Linguistic

⁴<http://xgboost.readthedocs.io/en/latest/parameter.html>

Approach	Task-A			Task-B		
	Precision	Recall	F1-score	Precision	Recall	F1-score
Linguistic	0.48	0.78	0.59	0.32	0.36	0.30
Pretrained CNN	0.60	0.63	0.62	0.51	0.44	0.42
Linguistic + Pretrained CNN	0.55	0.79	0.65	0.53	0.44	0.42
Linguistic + Pretrained CNN + SMOTE	-	-	-	0.46	0.51	0.47
Baseline (Linear SVC over BoW)	0.56	0.63	0.59	0.48	0.36	0.33

Table 1: F1 scores in Task A and Macro F1 in Task B on test set.

+ Pretrained CNN) for Task-A and (Linguistic + Pretrained CNN + SMOTE) for Task-B. We discuss the major takeaways from the results below.

- Our submitted models achieve 4th position in public leaderboard ⁵ on both Task-A and Task-B and beat the task baselines by about 6% and 14%, respectively, on both tasks on the test set.
- Leveraging DeepMoji model for Irony detection domain yields a considerable improvement over purely linguistic features (0.03 and 0.12). This is because the model is trained on over a *billion* tweets on sarcasm and four other domains. As stated earlier, sarcasm is a verbal form of irony (Long and Graesser, 1988), and transfer learning works as domains are quite similar.
- Our combination of linguistic features with pre-trained CNN achieves an F-score of 0.65 and 0.42, with an improvement of at least 0.03 on Task-A and significant improvement in Task-B, compared to linguistic features. The higher accuracy points to the power of ensemble learning by combining different feature spaces, as both feature sets specialize in different types of tweets.
- The use of SMOTE oversampling technique leads to an F-score of 0.47 in Task-B, which is an improvement of 0.05 over (Linguistic + Pretrained CNN) model.
- The improvement in scores due to linguistic features are not as pronounced in Subtask-B, as compared to Subtask-A. One of the possible reasons for this is that linguistic features are not able to capture the fine grained differences between different forms of irony.

⁵<https://competitions.codalab.org/competitions/17468#results>

4 Conclusion

We reported the use of handcrafted features and pre-trained CNN activations for predicting the irony in tweets. We implemented a variety of features based on user behavior as well as the linguistic structure in a tweet. We further exploit the SMOTE oversampling technique to handle the class imbalance problem in Subtask-B, which involves categorizing a tweet into Non Ironic, Verbal Irony, Situational Irony and Other Verbal Irony. We then feed the features into XGBoost classifier for both the tasks. The benefit of using CNN models pre-trained on sarcasm, sentiment, and emotion domains can be clearly seen, yielding an improvement of 3% and 9% over task baselines. Our final submitted system stood 4th in both the subtasks in the SemEval 2018 shared task on “Irony Detection in English Tweets”.

Abstract

In this paper we describe the system used by the ValenTO team in the shared task on *Irony Detection in English Tweets* at SemEval 2018. The system takes as starting point *emotIDM*, an irony detection model that explores the use of affective features based on a wide range of lexical resources available for English, reflecting different facets of affect. We experimented with different settings, by exploiting different classifiers and features, and participated both to the binary irony detection task and to the task devoted to distinguish among different types of irony. We report on the results obtained by our system both in a constrained setting and unconstrained setting, where we explored the impact of using additional data in the training phase, such as corpora annotated for the presence of irony or sarcasm from the state of the art. Overall, the performance of our system seems to validate the important role that affective information has for identifying ironic content in Twitter.

1 Introduction

People use social media platforms as a forum to share and express themselves by using the language in creative ways and employing figurative language devices such as *irony* to achieve different communication purposes. Irony is closely associated with the indirect expression of feelings, emotions and evaluations, and detecting the presence of irony in social media texts is considered a challenge for research in computational linguistics, also for the impact on sentiment analysis, where irony detection is important to avoid misinterpreting the polarity of ironic statements.

Broadly speaking, under the umbrella term of *irony* two main concepts are covered: *verbal irony* and *situational irony*. Verbal irony is commonly defined as a figure of speech where the speaker intends to communicate the opposite of what is liter-

ally said (Sperber and Wilson, 1986). Situational irony, instead refers to a contradictory or unexpected outcome of events (Lucariello, 2014). In Twitter we can find many examples both of verbal irony and of posts where users describe aspects of an ironic situation. Most of the proposed approaches to the automatic detection of irony in social media (Riloff et al., 2013; Buschmeier et al., 2014; Ptáček et al., 2014) take advantage of lexical factors such as n-grams, punctuation marks, among others. Information related to affect has been also exploited (Reyes et al., 2013; Barbieri et al., 2014; Hernández Farías et al., 2015). Other scholars proposed methods exploiting the context surrounding an ironic utterance (Wallace et al., 2015; Karoui et al., 2015). Recently, also deep learning techniques have been applied (Nozza et al., 2016; Poria et al., 2016).

This paper describes our participation in the SemEval-2018 Task 3. The aim of this task is to identify ironic tweets. ValenTO exploited an extended version of *emotIDM* (Hernández Farías et al., 2016), an irony detection model based mainly on affective information. In particular, we experimented the use of a wide range of affect-related features for characterizing the presence of ironic content, covering different facets of affect, from sentiment to finer-grained emotions. Most theorist (Grice, 1975; Wilson and Sperber, 1992; Alba-Juez and Attardo, 2014) recognized, indeed, the important role of affective information for irony communication-comprehension.

2 The emotIDM model

Irony is a very subjective language device that involves the expression of affective contents such as emotions, attitudes, or evaluations towards a particular target. Attempting to take advantage of the emotionally-laden characteristics of ironic expressions, we relied on *emotIDM*, an irony detection

model that, taking advantage of several affective resources available for English (Nissim and Patti, 2016), exploits various facets of affective information from sentiment to finer-grained emotions for characterizing the presence of irony in Twitter (Hernández Farías et al., 2016).

In (Hernández Farías and Rosso, 2016) the robustness of *emotIDM* was assessed over different Twitter state-of-the-art corpora for irony detection (Reyes et al., 2013; Barbieri et al., 2014; Mohammad et al., 2015; Ptáček et al., 2014; Riloff et al., 2013). The obtained results outperform those in the previous works confirming the significance of affective features for irony detection. An additional aspect to be mentioned about *emotIDM* is that it was designed to identify ironic content in a general sense, i.e. considering irony as a broad term covering different types of irony in tweets.

emotIDM comprises two main groups of features that are described below:

Structural Features (Str). This group includes different markers that could help to identify ironic intention in tweets: punctuation marks (colon, exclamation, question marks), Part-Of-Speech labels (verbs, adverbs, nouns, adjectives), emoticons, uppercase characters, among others.

Affective Features. They are organized in three sub-groups representing different facets of affect:

Sentiment-Related Features (*Sent*). Hu&Liu (Hu and Liu, 2004), General Inquirer (Stone and Hunt, 1963), EffectWordNet (Choi and Wiebe, 2014), Subjectivity lexicon (Wilson et al., 2005), and EmoLex (Mohammad and Turney, 2013), AFINN, SWN, Semantic Orientation lexicon (Taboada and Grieve, 2004), and SenticNet (SN) (Cambria et al., 2014).

Emotional Categories (*eCat*). EmoLex, EmoSenticNet (Poria et al., 2013), SentiSense (Carrillo de Albornoz et al., 2012), and the Linguistic Inquiry and Word Count dictionary (Pennebaker et al., 2001).

Dimensional Models of Emotions (*eDim*). ANEW (Bradley and Lang, 1999), DAL (Whissell, 2009), and SN.

3 emotIDM at SemEval-2018 Task 3: Irony Detection in English Tweets

3.1 Task Description and Datasets

In the framework of SemEval-2018 was organized the *Task 3 on Irony detection in English tweets* (Van Hee et al., 2018). The main objective of this

task is to identify the presence of irony in Twitter. It was divided in two different subtasks:

1. **Task A: Ironic vs. non-ironic:** to determine whether a tweet is ironic or not.
2. **Task B: Different types of irony:** to predict one out of four labels: 0) *non-irony* (*nI*), 1) *verbal_irony_by_polarity_contrast* (*vI*), 2) *other_verbal_irony* (*oI*), 3) *situational_irony* (*sI*).

Organizers provided datasets for training and test labeled according the objectives of each subtask. The whole dataset was collected by exploiting a set of hashtags (#irony, #sarcasm and #not). Therefore, a manual annotation process was applied in order to minimize the noise in the data. For Task A, 1,911 ironic and 1,923 non-ironic tweets were provided. While for Task B, the distribution was: 1923 for *nI*, 1393 for *vI*, 213 for *oI* and 328 for *sI*. Participants were allowed to submit systems trained under two settings: *constrained* (*C*), where only the training data provided for the task should be used; *unconstrained* (*U*), where the use of additional data was permitted.

3.2 Our Proposal

We decided to participate to the shared task by using *emotIDM*. By analyzing the training data, an interesting characteristic was found: 857 out of 3,834 tweets contain an URL. From these tweets, 265 were belonging to the ironic class, while 592 were labeled as non-ironic. Notice that, in (Hernández-Farías et al., 2014), the authors found a similar behavior regarding URL information in the dataset provided by the organizers of SentiPOLC-2014 (Basile et al., 2014). Furthermore, Barbieri et al. (2014) exploited a feature for alerting the existence of an URL in a tweet; such feature was ranked among the most discriminative ones according to an information gain analysis. Since, information regarding to the presence of URL in a tweet has proven to be useful for detecting irony in Twitter, we decided to enrich *emotIDM* by adding a binary feature for reflecting the presence of URL in a tweet.

Below, we describe our participation in the task.

Task A: Ironic vs. non-ironic

We addressed this task as a binary classification by taking advantage of two of the most widely applied classifiers in irony detection: Decision Tree (DT) and Support Vector Machine

(SVM)¹. Moreover, we also included Random Forest (RF) as a classifier in our experiments². We carried out a set of experiments for assessing the performance of the original version of *emotIDM* and the one including information concerning URL (*emotIDM+URL*). Besides, to investigate the contribution of the different sets of features in *emotIDM* further experiments were performed. Several classifiers were used in order to identify the most promising setting.

As mentioned before, exploiting external data was allowed in the *unconstrained* setting. We took advantage of a set of corpora previously used in the state of the art in irony detection. We exploited data from a set of corpora collected exploiting different approaches: *self-tagging* or *manual annotation* or *crowd-sourcing*³. We exploited the corpora developed by (Reyes et al., 2013), (Barbieri et al., 2014), (Mohammad et al., 2015), (Ptáček et al., 2014), (Riloff et al., 2013), (Ghosh et al., 2015), (Karoui et al., 2017), and (Sulis et al., 2016). Besides, we also take advantage of an in-house collection of tweets containing the hashtags #irony and #sarcasm⁴.

Table 1 shows the obtained results during the developing phase for Task A. We experimented with different sets of features and classifiers considering a five fold-cross validation setting.

Features	Classifiers					
	DT		RF		SVM	
	C	U	C	U	C	U
<i>emotIDM</i>	0.57	0.70	0.64	0.71	0.64	0.79
<i>emotIDM</i> + URL	0.56	0.74	0.62	0.70	0.64	0.81
Str + Sent	0.59	0.69	0.60	0.70	0.63	0.78
Str+eCat+eDim	0.58	0.69	0.62	0.70	0.65	0.77
Sent+eCat+eDim	0.52	0.61	0.54	0.62	0.57	0.70

Table 1: Training phase: results for Task A with different experimental settings in *C* and *U* scenarios.

SVM emerges as the classifier with the best performance in both *C* and *U* scenarios. We noticed that, when using SVM, adding the URL feature

¹For experimental purposes we used Scikit-learn: <http://scikit-learn.org/>. The default configuration of parameters in the classifiers was applied.

²This was motivated by the fact that it demonstrated a competitive performance for classifying tweets with #irony, #sarcasm, and #not hashtags in (Sulis et al., 2016).

³Further details on the approaches for collecting corpora for irony detection can be found in (Hernández Farías and Rosso, 2016).

⁴The tweets were retrieved during the 2016 US Elections period from 8th up to 18th November 2016.

to *emotIDM* helps to improve the overall performance of our system. When we experimented by removing a set of features in *emotIDM*, a drop in the performance (in most of the cases) is observed. The results of the experiments with external data are higher than those using only the training data. The last row in Table 1 shows the obtained results when only affect-related features were used; even though there is a drop in the performance respect to the experiments using structural features, it seems that affective features on their own provide useful information for irony detection.

We participated in the subtask A by submitting two runs (constrained and unconstrained) exploiting the experimental setting with the best performance: *emotIDM+URL* with a SVM as classifier.

Task B: Different types of irony

Distinguishing between different kinds of ironic devices is still a controversial issue. In computational linguistics, only few research works have attempted to address such a difficult task (Wang, 2013; Barbieri et al., 2014; Sulis et al., 2016; Van Hee et al., 2016). We are interested in assessing the performance of *emotIDM* when it deals with different types of irony, in order to test if a wide variety of affective features can help in discriminating also in the finer-grained classification task here proposed. This could give some insights on the role of affective content among ironic devices having different communication purposes.

emotIDM+URL was trained with the dataset provided for Task B (constrained setting) to test the effectiveness of affective features in such finer-grained task. We exploited the same classifiers than in Task A attempting to evaluate their performance when different classes of irony should be classified. Overall, the best performance was achieved by SVM (see Table 2). However, when the performance of each single class was considered, the best results were those obtained with DT. For this reason, we decided to combine two classifiers with the following criterion: the *sI* and *oI* classes are assigned by the DT; while *irony* and *non-irony* are assigned by SVM or RF. Table 2 shows the obtained results of the experiments carried out over the dataset for Task B. A five fold cross-validation was applied. From the results in Table 2, it can be noticed that when two classifiers are combined the performance of our model improves. The DT + SVM was selected as the system for participating in the Task B.

Classifier (s)	Macro F-measure
DT	0.31
RF	0.30
SVM	0.31
DT + RF	0.33
DT + SVM	0.34

Table 2: Training phase: obtained results for Task B.

3.3 Results

The results of ValenTO participation in the shared task are summarized in Table 3. In Task A, on the official CodaLab ranking, we ranked in the 16th position with the unconstrained version of our submission. When comparing our official result with the one obtained by the best-ranked system (0.7054), it can be noticed that the difference is lower than 0.1 in F-score terms. It is an interesting result considering that our system relies mainly on features covering different facets of affect in ironic tweets, and confirms the key role that such kind of affective information plays for detecting irony in Twitter. In addition, the organizers also provided separate rankings for constrained and unconstrained submissions. Our system ranked in the 17th position in the constrained setting, while in the unconstrained one we ranked as 4th. Moreover, the performance of our system seems to be stable in the two C and U settings. Concerning Task B, our system performed relatively well, considering that we did not apply further tuning to capture different ironic devices. We ranked in the 17th position of 31 submissions in the Official ranking at CodaLab.

Run	Accuracy	Precision	Recall	F1-score
Task A				
C	0.6709	0.5764	0.6431	0.6079
U	0.5982	0.4959	0.7814	0.6067
Task B				
C	0.5599	0.3534	0.3521	0.3520

Table 3: Official results of ValenTO team in both tasks

3.4 Discussion and Error Analysis

Data provided for the task were retrieved by exploiting hashtags #irony, #sarcasm and #not, which according to (Sulis et al., 2016) seems to label different kinds of ironic phenomena. We analyzed the gold standard labels provided by the organizers (where the ironic hashtags were also included in the tweets) in order to see the performance of our model for recognizing tweets labeled with distinct hashtags. Considering the results in Task A, we noticed that our system was able to identify all the three kinds of tweets without any kind of skew towards a particular hashtag.

It somehow confirms the robustness of emotIDM for recognizing irony in a broad sense.

Our system was able to correctly identify instances expressing an apparent positive emotional distress with an ironic intention, such as: *Sunday is such a fun day to study #ew #saywhat* and *Yay I just love this time of the month...!*. A special mention is for tweets labeled with #not. This hashtag is not always used for highlighting a figurative meaning. Our system was able to correctly identify instances containing #not when it was used for figurative meaning such as: *Yay for Fire Alarms at 3AM #not*, and also when it was used as part of the text in a tweet: *#Myanmar #men #plead #not #guilty to #murder of #British #tourists. http://t.co/flrKr3H6Kl via @reuters*.

For what concerns the performance of *emotIDM* in Task B, Table 4⁵ shows that our model performed better in identifying tweets where verbal irony was expressed by means of a polarity contrast. Moreover, it was recognizing better “situational irony” than “other irony”.

	<i>vI</i>	<i>oI</i>	<i>sI</i>	<i>nI</i>	tT	Correct (%)
<i>vI</i>	75	10	14	66	166	45
<i>oI</i>	6	4	11	25	62	9.2
<i>sI</i>	16	9	13	35	85	40
<i>nI</i>	67	39	47	347	473	79

Table 4: Confusion Matrix: Task B.

Since our model relies mainly on affective information, ironic instances lacking of subjective-related content are hard to recognize, as in: *Being a hipster now is so mainstream. Oh, the irony. #hipster #irony*. Moreover, we found some tweets where context information is crucial for capturing the ironic sense, like in: *So there used to be a crossfit place here.... #irony #pizzawins http://t.co/9BDkxT9GFJ*; or where the hashtag is the only signal for ironic intention.

4 Conclusions

In this paper, we described our participation at SemEval-2018 Task 3. We exploited an enhanced version of *emotIDM*. In our experiments, SVM emerges as the classifier with the best performance. The obtained results serve to validate the usefulness of affect-related features for distinguishing ironic tweets. As future work, it could be interesting to enrich *emotIDM* with features for capturing other kinds of information such as common-knowledge and semantic incongruity.

⁵The column “tT” refers to the amount of tweets in the test set. The column “Correct” refers to the percentage of instances correctly classified per class.

#NonDicevoSulSerio at SemEval-2018 Task 3: Exploiting Emojis and Affective Content for Irony Detection in English Tweets

Endang Wahyu Pamungkas, Viviana Patti
Dipartimento di Informatica, University of Turin
{pamungka,patti}@di.unito.it

Abstract

This paper describes the participation of the #NonDicevoSulSerio team at SemEval2018-Task3, which focused on *Irony Detection in English Tweets* and was articulated in two tasks addressing the identification of irony at different levels of granularity. We participated in both tasks proposed: Task A is a classical binary classification task to determine whether a tweet is ironic or not, while Task B is a multi-class classification task devoted to distinguish different types of irony, where systems have to predict one out of four labels describing verbal irony by clash, other verbal irony, situational irony, and non-irony. We addressed both tasks by proposing a model built upon a well-engineered features set involving both syntactic and lexical features, and a wide range of affective-based features, covering different facets of sentiment and emotions. The use of new features for taking advantage of the affective information conveyed by emojis has been analyzed. On this line, we also tried to exploit the possible incongruity between sentiment expressed in the text and in the emojis included in a tweet. We used a Support Vector Machine classifier, and obtained promising results. We also carried on experiments in an unconstrained setting.

1 Introduction

The use of creative language and figurative language devices such as irony has been proven to be pervasive in social media (Ghosh et al., 2015). The presence of these devices makes the process of mining social media texts challenging, especially because they can influence and twist the sentiment polarity of an utterance in different ways. Glossing over differences across different theoretical accounts proposed in the context of various disciplines (Gibbs and Colston, 2007; Grice, 1975; Wilson and Sperber, 1992; Attardo, 2007; Giora,

2003), irony can be defined as an incongruity between the literal meaning of an utterance and its intended meaning (Karoui et al., 2017). The term irony covers mainly two phenomena: verbal and situational irony (Attardo, 2006). Situational irony refers to events or situations which fail to meet expectations, such as for instance “warnings the dangerous effect of smoking on the cigarette advertisement”, while verbal irony occurs when the speaker intend to communicate a different meaning w.r.t what he/she is literally saying. Most of the time it involves the intention of communicating an *opposite meaning*, and this kind of opposition can be expressed by polarity contrast. However this is not the only possibility, and social media messages well reflect such variety, including different expressions of verbal irony and descriptions of situational irony (Van Hee et al., 2016a; Sulis et al., 2016). Automatic irony detection is an important task to improve sentiment analysis (Reyes et al., 2013; Maynard and Greenwood, 2014). However, detecting irony automatically from textual messages is still a challenging task for scholars (Joshi et al., 2017). The linguistic and social factors which impact on the perception of irony contribute to make the task complex.

In this paper, we will describe the irony detection systems we developed for participating in SemEval2018-Task3: *Irony Detection in English Tweets* (Van Hee et al., 2018). Our systems used a support vector classifier model by exploiting some novel and well-handcrafted features including lexical, syntactical and affective based features. We participated in 3 different scenarios (Task A constrained, Task A unconstrained, and Task B unconstrained). The official results show that our system outperformed all systems in the unconstrained setting on both tasks and was able to achieve a reasonable score in Task A constrained, ranking in the top ten out of 44 submissions.

2 The #NonDicevoSulSerio System

We performed our experiments using a support vector machine classifier, with *radial basis function* kernel. We exploited different kind of features (lexical, syntactical and affective-based), which has been proven effective in literature to identify ironic phenomena. In addition, we also investigated the use of novel features aimed at exploiting information conveyed by emojis, studying in particular sentiment incongruity between sentiment expressed in the text and in the emojis of a tweet.

2.1 Structural Features

Structural features consist of lexical and syntactical features which characterize Twitter data. Such kind of features has been proven beneficial in several tasks dealing with Twitter data, and we selected the most relevant ones for irony detection.

Hashtag Presence: binary value 0 (if no hashtag in tweet) and 1 (if hashtag contained in tweet).

Hashtag Count: number of hashtags contained in tweet.

Mention Count: number of mentions contained in tweet.

Exclamation Mark Count: number of exclamation marks contained in tweet.

Upper Case Count: number of upper case characters in tweet.

Link Count: number of links (http) contained in tweet.

Link Presence: binary value 0 (if no link in tweet) and 1 (if at least one link found in tweet).

Has Quote: binary value 0 (if quote (“ ” or ’ ’) not found in tweet) and 1 (if at least one pair of quote (“ ” or ’ ’) found in tweet).

Intensifiers & Overstatement Words Count: number of intensifiers and words typically used in ironic overstatements¹ found in tweet.

Emoji Presence: binary value 0 (if no emoji found in tweet) and 1 (if at least one emoji found in tweet).

Repeated Character: binary value 0 (if there is no repeated character found in tweet) and 1 (if at least three characters repeated consequently in one word found in tweet).

Text Length: the length of characters in each tweet.

Conjunction Count: the number of conjunctions found in tweet.

Verb Count: the number of verbs found in tweet.

Noun Count: the number of nouns found in tweet.

Adjective Count: the number of adjectives found in tweet. We use Stanford PoS-Tagger² to get the count of conjunctions, verbs, nouns, and adjectives.

¹love, really, lovely, like, great, brilliant, perfect, thank, glad.

²<https://nlp.stanford.edu/software/tagger.shtml>

2.2 Affective-Based Features

Affective features were proven effective in prior work to detect irony in tweets (Fariás et al., 2016). We exploited available affective resources to extract affective information trying to capture multiple facets of affects -sentiment polarity and emotions- by selecting a few resources developed for English, which refers to both categorical and dimensional models of emotions.

AFINN.: AFINN is a sentiment lexicon consisting of English words labeled with valence score between -5 and 5. We used the normalized version of AFINN in (Fariás et al., 2016), where the valence score was already normalized to the range between 0 and 1.

Emolex. Emolex (Mohammad and Turney, 2013) was developed by using crowdsourcing. Emolex contains 14,182 words associated with eight primary emotion based on (Plutchik, 2001).

EmoSenticNet. EmoSenticNet(EmoSN) (Poría et al., 2013) is an enriched version of SenticNet, where emotion labels were added by mapping WordNet-Affect labels to the SenticNet concepts. WordNet-Affect labels refers to six Ekman’s basic emotions.

Linguistic Inquiry and Word Count (LIWC). LIWC dictionary (Pennebaker et al., 2001) has 4,500 words distributed into 64 different emotional categories including positive and negative. Here we only use the positive (PosEMO) and negative emotion (NegEMO) categories.

Dictionary of Affect in Language (DAL). DAL was developed by (Whissell, 2009) and composed of 8,742 English words. These words were labeled by three scores representing the emotion dimensions *Pleasantness*, *Activation*, and *Imagery*.

Emoji Sentiment Ranking. Since we observed the presence of a lot of emojis in Twitter data, we used the emoji sentiment ranking lexicon by (Novak et al., 2015) to get the sentiment score of each emoji in the tweet. We also tried to detect *sentiment incongruity* between text and emoji in the same tweet. We used VADER (Hutto and Gilbert, 2014) to extract the polarity score of the text.

3 Experiment and Results

3.1 Task Description and Dataset

SemEval2018-Task3’s organizers proposed two subtasks related to the topic of detecting irony in Twitter automatically (Van Hee et al., 2018). Sub-Task A is a binary classification task, where every

		SubTask A	
		Irony	Not Irony
Training		1911	1923
Testing		311	473

		SubTask B			
		0	1	2	3
Training		1923	1390	316	205
Testing		473	164	85	62

Table 1: Dataset Distribution on Both Tasks.

- 0 : Not irony
- 1 : Verbal irony by polarity contrast
- 2 : Others irony
- 3 : Situational irony

system should determine whether a tweet is ironic or not ironic. Meanwhile, SubTask B is defined as a multi-class classification problem, where the aim is to classify each tweet into four different categories including: verbal irony by polarity contrast, other verbal irony, situational irony, and not irony. In both tasks, organizers allowed submissions in two scenarios: constrained and unconstrained. In unconstrained settings, participants were allowed to exploit external data from other corpora annotated with irony labels in the training phase. Standard evaluation metrics were proposed for the task, including, precision, recall, accuracy, and F_1 -score.

Dataset The organizers provided 3,834 training data and 784 test data for both tasks. Table 1 shows the dataset distribution. Data were collected by using three irony-related hashtags: #irony, #sarcasm, and #not. Datasets for both tasks were manually labeled by using the fine-grained annotation scheme in (Van Hee et al., 2016b). A two-layer annotation has been applied on the same tweets, one concerning the presence and absence of irony, the second one identifying different types of irony, when irony is present. As a consequence, as Table 1 shows, there is a class imbalance on SubTask B dataset in favor of non-ironic class (50%), verbal irony by polarity contrast (25%), other verbal irony (13%) and situational irony (12%). The irony-related hashtags were removed from the final dataset release.

3.2 Experimental Setup

We built our supervised systems based on available training data. In this phase performances

SubTask A		
Amt.	HashTag	Source
500	#irony	(Barbieri et al., 2014)
400	#sarcasm	(Riloff et al., 2013)
100	#sarcasm	(Barbieri et al., 2014)
500	#not	(Sulis et al., 2016)
500	non-irony	(Mohammad et al., 2015)
500	non-irony	(Ptáček et al., 2014)
500	non-irony	(Riloff et al., 2013)

SubTask B		
Amt.	HashTag	Source
867	#irony	(Barbieri et al., 2014)

Table 2: Additional data on Unconstrained Scenario.

were evaluated based on the mean of F_1 -score, by using 10-fold cross validation. We chose an SVM classifier with radial basis function kernel³. Our system implementation is free available for research purpose in GitHub page⁴. Therefore, we lean on feature selection process to improve the system performance. We carried on an ablation test on our feature sets to get the highest F_1 -score. We decided to participate in three different scenarios: SubTask A constrained, SubTask A unconstrained, and SubTask B unconstrained.

For unconstrained scenario in SubTask A, we used the available corpora from previous work. We tried to add new data with balance proportion (1500 ironic and 1500 non-ironic). We also added a balance proportion of ironic data based on different hashtag (500 #irony, 500 #sarcasm, and 500 #not) from three different corpora, with the aim of enriching the training data with ironic samples of various provenance and trying to avoid biases. The distribution and source of our additional data can be seen in Table 2.

In SubTask B, we proposed to use a pipeline approach in three-steps classification scenario. First, we classify the ironic and non-ironic (similar configuration with SubTask A). Second, we classify the ironic data from step one into two categories, *verbal_irony_by_polarity_contrast* and the rest (*other_verbal_irony+situational_irony*). In the second step, we add more training data on the *other_verbal_irony+situational_irony class* to

³SVM good performances for similar tasks were recognized (Joshi et al., 2017). We built our system by using scikit-learn Python Library <http://scikit-learn.org/>.

Table 3: Feature Selection on each System.

overcome the imbalance issue. We decided to use only additional tweets marked with #irony hashtags, relying on the analysis in (Sulis et al., 2016) suggesting that the polarity reversal phenomenon seems to be relevant in messages marked with #sarcasm and #not, but less relevant for messages tagged with #irony. In the last step, we classify between *other_verbal_irony* and *situational_irony*. Table 3 shows selected features on each submitted system based on our ablation test.

3.3 Result and Analysis

Table 4 shows our experimental results based on four different metrics including accuracy, precision, recall, and F_1 -score. For experiments on the training set we used 10-fold cross validation, and we report the score for each metric. However, F_1 -score has been used as the criterion to tune the configuration. Official Codalab results show that our system ranked 10th out of 44 submissions on Sub-

Task A and 9th out of 32 on SubTask B. We obtained F_1 -score 0.6216 (Best system: 0.7054) on SubTask A and 0.4131 (Best system: 0.5074) on SubTask B. However, our system outperformed all systems in the unconstrained setting on both tasks.

Based on our analysis, several stylistic features were very effective in Task A (both in constrained and unconstrained settings). Especially, Twitter specific symbols such as hashtags, mentions, and URLs were very useful to discriminate non ironic tweets. In addition, we found that affective resource were very helpful in the Step 2 and Step 3 of Task B, especially Emolex (Step 2) and EmoSenticNet (Step 3). Another important finding is that additional data on Task A did not improve the classifier performance. Instead, additional tweets marked with #irony on Task B were very useful to handle the imbalance dataset in Step-2 (*verbal_irony_by_polarity_contrast* vs *other_verbal_irony+situational_irony*). Our clas-

SubTask A Constrained				
	Acc	Prec	Rec	F_1

Training-3	0.689	0.651	0.488	0.544
Testing	0.555	0.409	0.441	0.413

Table 4: Results on Training and Test sets.

sifier was able to achieve a high F_1 score on the training phase in this case. Furthermore, we also found that our new features for capturing affective information in emojis (e.g. emoji incongruity) were very helpful in classifying between ironic and not ironic data.

Table 5 shows the confusion matrix of our classification result on SubTask B. Our system performed quite well in Step 1 (*irony vs non-irony*) and Step 2 (*verbal_irony_by_polarity_contrast vs other_verbal_irony+situational_irony*). However, our system was struggling in distinguishing between *other_verbal_irony* and *situational_irony* (Step 3). Our system got very low precision in detecting situational irony, and this has a huge impact on macro average F-score. The difficulties to find an important feature to discriminate other verbal and situational irony was, indeed, for us the main challenge in Task B. A qualitative error analysis was conducted. We found a lot of tweets which were difficult to understand without the context), like:

(tw1) "Produce Mobile Apps
<http://t.co/3OV57ZhqcH>
<http://t.co/wX1DbI8W9M>"

(tw2) "#Consensus of Absolute Hilarious -
 #MichaelMann to lecture on #Professional
 #Ethics for #Climate #Scientists?
<http://t.co/pD0TEMq1Z0>"

The first tweet is featured by situational irony and was originally including a #not hashtag before the link. Also for humans it is very difficult to get the

	0	1	2	3
0	285	80	75	33
1	19	96	31	18
2	29	7	38	11
3	29	13	12	8

Table 5: Confusion Matrix SubTask B.

0 : Not irony
 1 : Verbal irony by polarity contrast
 2 : Others irony
 3 : Situational irony

ironic intention behind the tweet when the #not hashtag is removed and without having access to the information in the URL, which was anyway inactive. The second example was labelled as *other_verbal_irony*. Although it is very difficult to resolve the context of this tweet, accessing to the URL contained was helpful in understanding the ironic intent.

4 Conclusion

This paper described the participation of the #NonDicevoSulSerio⁵ team at SemEval2018-Task3: *Irony Detection of English Tweets*. We proposed to use several stylistic features and exploited several affective resources to deal with this task. Based on our evaluation and analysis, classifying irony into its several types (verbal irony by polarity contrast, other verbal irony, and situational irony) is a very challenging task. Especially, getting relevant features to discriminate between other verbal irony and situational irony will become our main focus on the future research direction. In this case, capturing semantic incongruity by exploiting word embedding semantic similarity is an issue worth to be explored (Joshi et al., 2015).

Abstract

Character identification is an entity-linking task that finds words referring to the same person among the nouns mentioned in a conversation and turns them into one entity. In this paper, we define a sequence-labeling problem to solve character identification, and propose an attention-based recurrent neural network (RNN) encoder–decoder model. The input document for character identification on multiparty dialogues consists of several conversations, which increase the length of the input sequence. The RNN encoder–decoder model suffers from poor performance when the length of the input sequence is long. To solve this problem, we propose applying position encoding and the self-matching network to the RNN encoder–decoder model. Our experimental results demonstrate that of the four models proposed, Model 2 showed an F1 score of 86.00% and a label accuracy of 85.10% at the scene-level.

1 Introduction

In this paper, we define character identification (CI) (Chen et al., 2017) as a sequence-labeling problem and use a recurrent neural network (RNN) encoder–decoder (Enc–Dec) model (Cho et al., 2014) based on the attention mechanism (Bahdanau et al., 2015) to solve it. An Enc–Dec is an extension of the RNN model; it generates an encoding vector using an RNN in the encoder when an input sequence is given and performs decoding using the encoding vector. The attention mechanism calculates the alignment score for the two sequences and

performs the input sequence and weighted sum so that they can focus more on the position that affects the output result. The self-matching network (Wang et al., 2017) is used to calculate an attention weight for itself and a context vector by using a weighted sum, after which the weights of similar words in the RNN sequence can be applied to aid in coreference resolution. Position encoding (PE) (Sukhbaatar et al., 2015, Park and Lee, 2017, Vaswani et al., 2017) is a method of applying weights differently, according to the positions of words appearing in a sequence. Training and prediction are performed by multiplying a weight vector by a vector of positions to be identified in a given input sequence.

In an Enc–Dec model, a long input sequence results in performance degradation due to loss of information in the front portion of the input sequence when encoding is performed. In this paper, we propose four models that apply PE, attention mechanism, and self-matching network to Enc–Dec models to solve the problem of performance degradation due to long input sequences.

To summarize, the main contributions of this paper are as follows:

1. In this paper, we define CI task as sequence-labeling problem, and perform training and prediction in end-to-end model.
2. We propose four models using Enc–Dec based on attention mechanism and achieve high performance.

2 System Description

An Enc–Dec model maximizes $P(y|x)$ using an RNN. The encoder generates an encoder hidden

state by encoding the input sequence, and the decoder generates an output sequence that maximizes $P(y|x)$ using the hidden state of the decoder, which was generated until this time step, with the encoder hidden state. The attention mechanism is a method of determining which part of the target class should be focused using the hidden state of the decoder and the hidden state of the encoder when performing decoding.

2.1 Model 1: Attention-based Enc-Dec model

The first model proposed in this paper is a general attention mechanism-based Enc-Dec model, as shown in Figure 1.

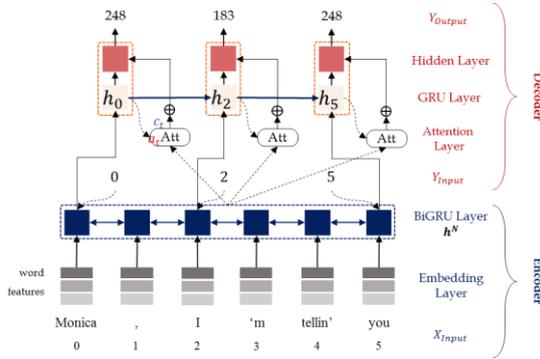

Figure 1: Attention-based Enc-Dec.

The input of the encoder is one document that contains S sentences (multiparty dialogue). Each sentence S consists of n_S words, and the input sequence X_{input} is $X_{input} = \{x_1, x_2, \dots, x_{n_S}\}$. The input to the decoder is $Y_{input} = \{y_{i_0}, y_{i_1}, \dots, y_{i_m}\}$ consisting of the positions of the words given in the gold mentions, and the output sequence accordingly becomes $Y_{output} = \{y_{o_0}, y_{o_1}, \dots, y_{o_m}\}$ consisting of the character number, which is corresponded with the decoder’s input mentions.

We use word embedding and adopt the K -dimensional word embedding $e_i^k, k \in [1, K]$ for all input words, where i is the word index in the input sequence. We perform feature embedding for three features — speaker, named entity recognition (NER) tags, and capitalization — and concatenate them to make \tilde{x}_i .

- The uppercase feature is a binary feature (1 or 0) that verifies whether the uppercase is included in the word.
- 10-dimensional speaker embedding for a total of 205 different types of speakers included by “unknown”.

- 19-dimensional NER embedding for a total of 19 different types of NER tags.

We use bidirectional gated recurrent unit (BiGRU) (Cho et al., 2014) for the encoder. The hidden state of the encoder for the input (word) sequence is defined as h_i^N .

$$e_i = W_e x_i \quad (1)$$

$$\tilde{x}_i = [e_i; uc_i; spk_i; NER_i] \quad (2)$$

$$h_i = biGRU(\tilde{x}_i, h_{i-1}) \quad (3)$$

where \vec{h}_i and \overleftarrow{h}_i are forward and backward networks, respectively, and h_i^N concatenates \vec{h}_i and \overleftarrow{h}_i .

The decoder of our model uses the GRU as follows.

$$h_t = GRU(h_{y_t}^N, h_{t-1}) \quad (4)$$

The input of the decoder is the hidden state h_i^N generated by the encoder corresponding to each position of Y_{input} which is the gold mention sequence. The hidden state h_t of the current decoder receives the hidden state h_i^N of the encoder corresponding to the output position of the previous decoder and the previous hidden state of the decoder.

$$\alpha_i^t = \frac{\exp(\text{score}_a(h_t, h_{y_i}^N))}{\sum_j \exp(\text{score}_a(h_t, h_{y_j}^N))} \quad (5)$$

$$\text{score}_a(h_t, h_{y_i}^N) = v_t^T \tanh(W_a [h_t; h_{y_i}^N; h_{y_i}^N]) \quad (6)$$

$$y_t = \text{argmax}_i(\alpha_i^t) \quad (7)$$

$$c_t = \begin{cases} \sum_i \alpha_i^t h_i^N, & \text{soft attention} \\ h_{y_t}^N, & \text{hard attention} \end{cases} \quad (8)$$

At the attention layer of the decoder, we use the attention weight α_i^t to compute the alignment score for the gold mention input into the decoder and the encoder hidden state h_i^N input. The attention layer acts as a coreference resolution for each gold mention and input sequence. After calculating the attention weights, we create the context vector c_t . We use soft attention and hard attention in Eq. (8). Soft attention $c_t = \sum_i \alpha_i^t h_i^N$ is an attention-pooling vector of the whole input sentence of the encoder (h^N). The other attention-pooling vector is hard attention $c_t = h_{y_t}^N$, which is based on the argmax function Eq. (7) for attention weight α_i^t to choose the position with high score for the decoder input as the gold mention.

$$\text{score}_z(h_t, c_t, h_{y_t}^N) = W_{z2}^T \text{ReLU}(W_z [h_t; c_t; h_{y_t}^N]) \quad (9)$$

$$y_{o_t} = \operatorname{argmax}_t \left(\operatorname{softmax} \left(\operatorname{score}_z(h_t, c_t, h_{y_{it}}^N) \right) \right) \quad (10)$$

After calculating the context vector between the input of the encoder and the input of the decoder, we calculate score_z , using which the context vector c_t , decode hidden state h_t and encoder hidden state h^N are concatenated in the decoder hidden layer. Next, the softmax function is used to calculate the alignment score for score_z , and then the character index (Y_{output}) for the CI task corresponding to the input of the decoder is obtained using the argmax function.

2.2 Model 2: Attention-based Enc-Dec w/ model with PE

The second model is based on the first model but uses PE which is a method of applying a weight to an input sequence of an RNN according to the word order. Among the words in the coreference resolution, the antecedent has a feature that appears mainly in the preceding context. In this paper, we apply PE with a feature to the encoder input sequence, and use the weight according to the word order as the feature. As shown in Eq. (11), PE information is concatenated to Eq. (2) to produce \tilde{x}_i , and PE is calculated as shown in Eq. (12).

$$\tilde{x}_i = [e_i; PE_i; uc_i; spk_i; NER_i] \quad (11)$$

$$PE_i = (1 - i/n_s) - (s/k)(1 - 2i/n_s) \quad (12)$$

In PE, i is the index of the word, n_s is the total length of the input sequence, s is the position of the sentence, and k is the number of dimensions of the word expression. The weight of PE is calculated as a real value that gradually decreases between 1 and 0, and is applied to the input of the encoder to take advantage of the feature that the predecessor precedes the current mention. In Eq. (12), $(1 - 2i/n_s)$ denotes the order of words. If it is a front word, it has a higher value than the next word. (s/k) is a weight based on the sentence order, and when the sentence is different, the weight reduction rate difference is calculated to be higher than the value decreasing in the sentence. The expression for the encoder and decoder are the same as for model 1.

2.3 Model 3: Self-matching Network-based Enc-Dec model

The third model is also based on the first model, but performs encoding by using the self-matching

network in the encoder without using PE, as shown in Figure 2. The self-matching network is used for calculating the alignment score for a given RNN sequence and itself, and then for performing a weighting sum with itself to create a context vector. While using the self-matching network for encoding, attention weights are weighted with high alignment scores between similar words. For example, if ‘‘Rachel’s child-hood best friend’’ and ‘‘Monica’’ appear in a sentence, a high alignment score between them is calculated by the self-matching network.

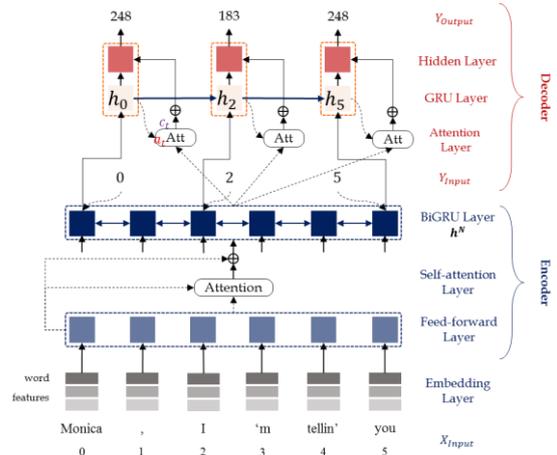

Figure 2: Self-matching-Network-based Enc-Dec.

The input sequence of the encoder becomes \tilde{x}_i in Eq. (2), and a feed-forward neural network is used, as in Eq. (13). Next, we use the self-matching network to compute the attention weight for the t sequence and create a context vector c_i^{self} that reflects the self-attention (Eqs. 14–16).

$$h_i^{src} = W_{src} \tilde{x}_i + b_{src} \quad (13)$$

$$\alpha_j^i = \frac{\exp(\operatorname{score}_{self}(h_j^{src}, h_i^{src}))}{\sum_t \exp(\operatorname{score}_{self}(h_t^{src}, h_i^{src}))} \quad (14)$$

$$\operatorname{score}_{self}(h_j^{src}, h_i^{src}) = v_i^T \tanh(W_a^{src} [h_j^{src}; h_i^{src}]) \quad (15)$$

$$c_i^{self} = \sum_j \alpha_j^i h_j^{src} \quad (16)$$

Subsequently, we construct $[h_i^{src}; c_i^{self}]$ by concatenating the context vector c_i^{self} , created using the self-matching network, and the hidden state h_i^{src} ; it is then fed to the input of the hidden layer of the encoder to perform BiGRU.

We apply $[h_i^{src}; c_i^{self}]$ to the additional gate to make $[h_i^{src}; c_i^{self}]^*$, this determines whether or not

the information of $[h_i^{src}; c_i^{self}]$ is transmitted to the encoder hidden layer input. The equation is as follows:

$$g_t = \text{sigmoid}(W_g[h_i^{src}; c_i^{self}]) \quad (17)$$

$$[h_i^{src}; c_i^{self}]^* = g_t \odot [h_i^{src}; c_i^{self}] \quad (18)$$

The decoder of model 3 performs training and prediction using a decoder such as the one used in model 1 (Eqs. 4–8) based on the hidden state where encoding is performed as above.

2.4 Model 4: Self-matching Network-based RNN Enc-Dec model with PE

Model 4 is based on model 3 using the self-matching network; it additionally uses PE, which was also used for model 2, as a feature to confirm the word order.

3 Experimental Results

We evaluate the entity linking performance of the models using label accuracy and macro-F1 (Chen et al., 2017), and the coreference resolution performance using CoNLL F1 (Rahman and Ng, 2009).

The word representation used in this paper is a data-set provided by LDC, which is learned by a neural network language model (Bengio et al., 2003, Lee et al., 2014), and is set to 50 dimensions. The experiments were performed with cross validation. The hyper parameters used in the experiment are as follows. We used tanh for the encoder and decoder, and ReLU for the attention layer. The hidden layers had 150 dimension, and the dropout of all layers was set to 0.3. The learning was done

using RMSprop (Hinton et al., 2012) and the learning rate was reduced by 50% for every 5 epochs without performance improvement starting at 0.1. The decoder attention functions of the models used in the experiments are all based on hard attention, and are compared with soft attention in Table 1.

	Episode-Level		Scene-Level	
	Main F1	All F1	Main F1	All F1
M 1	85.57	23.33	83.45	21.13
M 2	82.91	23.15	85.58	22.40
M 2'	82.46	22.04	83.56	19.67
M 3	86.30	22.93	84.10	21.84
M 4	83.65	22.13	87.41	22.06
M 4'	85.48	19.46	86.23	23.92

Table 1: Entity-linking results on the trial set (in %). Main and All in column mean main and other characters, and all characters.

Table 1 shows a comparison between the CI performances of the models on the trial set. M 2' is a model in which PE proposed by Vaswani et al. (2017) is applied, and M 4' is a model in which soft attention is applied to M 4. At the episode-level, M 3 showed the best Main F1 performance (86.30%) and M 1 showed the best All F1 performance (23.33%). At the scene-level, M 4 showed the highest Main F1 performance (87.41%), and M 4 showed the highest All F1 performance (23.92%). In the case of M 2 and M 2', we can see that the proposed PE method resulted in a better overall performance.

At the episode-level, M 4' showed a better Main F1 performance (1.83%) than M 4, whereas M 4 showed a better All F1 performance (by 2.67%). At the scene-level, M 4 showed a better Main F1 performance (by 1.18%) than M 4', whereas M 4'

Model		Characters						Main + Other		All		
		Chandler	Joey	Monica	Phoebe	Rachel	Ross	Others	F1	Acc	F1	Acc

	M 2	85.77	81.59	85.19	87.67	59.64	84.79	80.42	85.01	84.36	16.47	68.42
	M 3	82.76	82.06	86.36	84.21	88.76	81.78	77.40	83.33	82.38	17.02	66.65
	M 4	83.52	79.92	87.17	86.43	86.72	83.73	78.46	83.71	82.96	15.19	65.83
S	M 1	83.55	79.19	90.99	86.43	90.01	84.11	76.08	84.34	83.08	15.93	68.59
	M 2	84.94	79.67	91.16	88.09	92.49	85.86	79.79	86.00	85.10	16.98	69.49
	M 3	83.87	84.30	88.24	86.10	88.79	79.65	76.23	83.88	82.34	16.99	67.31
	M 4	78.21	83.06	84.42	84.30	89.94	79.08	90.41	85.33	84.64	15.43	67.68
Amore		-	-	-	-	-	-	-	79.36	77.23	41.05	74.72
Kamp.		-	-	-	-	-	-	-	73.51	73.36	37.37	59.45
zuma		-	-	-	-	-	-	-	43.15	46.07	14.42	25.81

Table 2: Entity-linking results on the evaluation set (in %). The F1 score is reported for each character. E/S: episode/scene level. F1 is macro-average F1 score. Acc is character label accuracy.

showed a better All F1 performance (by 1.86%). Thus, it can be seen that the use of hard attention results in a better performance.

Table 2 presents the experimental results of the test set (episode- and scene-level) for the method proposed in this paper, and the performance comparison with other competing models, namely AMORE UPF (Amore), Kampfpudding (Kamp.), and zuma. In the Main + Other character evaluations at episode-level, M 2 showed the best performance among all models (F1 of 85.01%, Acc of 84.36%), whereas in the All character evaluations, M 3 showed the best F1 performance (17.02%) and M 2 showed the best Acc performance (68.42%). At the scene-level, M 2 showed the best performance in both the Main + Other and the All character evaluation. The proposed method showed a lower overall performance in the All character evaluation compared with other competing models, but showed a higher performance in the Main + Other character evaluations. The reason for the lower performance in the All character evaluation is that the number of data points is smaller than that of the main characters.

4 Conclusion

In this paper, we defined the entity-linking problem of SemEval-2018 Task 4 as a sequence-labeling problem and proposed four models to solve it. Experimental results showed that M 2 shows the best performance in the test set scene-level (Main + Other characters), with an F1 of 86.00% and Acc of 85.10%. In the Main entities + Others evaluation of SemEval-2018 Task 4, it ranked 1st with an F1 of 83.37% and Acc of 82.13%. In All Entities + Others, it ranked 2nd with an F1 of 13.53% and Acc of 68.55%.

In future work, we will apply character CNN to solve the unknown word problem, and we will add word expressions such as GloVe (Pennington et al., 2014) and ELMo (Peters et al., 2018). We will also enhance the performance by tightening the model with less data by adding the features used in the task 4-based model.

NewsReader at SemEval-2018 Task 5: Counting events by reasoning over event-centric-knowledge-graphs

Piek Vossen

VU University Amsterdam / De Boelelaan 1105, 1081HV Amsterdam, Netherlands

piek.vossen@vu.nl

Abstract

In this paper, we describe the participation of the NewsReader system in the SemEval-2018 Task 5 on *Counting Events and Participants in the Long Tail*. NewsReader is a generic unsupervised text processing system that detects events with participants, time and place to generate Event Centric Knowledge Graphs (ECKGs). We minimally adapted these ECKGs to establish a baseline performance for the task. We first use the ECKGs to establish which documents report on the same incident and what event mentions are coreferential. Next, we aggregate ECKGs across coreferential mentions and use the aggregated knowledge to answer the questions of the task. Our participation tests the quality of NewsReader to create ECKGs, as well as the potential of ECKGs to establish event identity and reason over the result to answer the task queries.

1 Introduction

This paper describes the NewsReader system participating in the SemEval 2018 Task 5 *Counting Events and Participants in the Long Tail* (Postma et al., 2018). Task 5 requires detection of certain events (cases of gun violence, dismissal of employees, and burning fire incidents) with participants, as well as extraction of their location and time in a set of documents and reasoning over their identity, in order to answer queries over the data set. A typical query in the task is *How many people were killed in 2016 in Columbus, MS?*. Participants were given a collection of news articles in CoNLL format to distill the answer to the queries. The task consists of 3 subtasks: subtask 1 asks for all documents from the data set that report on a single incident that fits the question constraints; subtask 2 is to provide the number of incidents (zero or more) and the documents that report on these

incidents given the constraints of a query; subtask 3 asks for the number of affected (injured, dead, or fired) people in the incidents that match the query constraints, and the supporting documents for these incidents. In addition to answering the subtask queries, participants were asked to mark the (cross-document) coreferential event mentions in the CoNLL file according to a specific event schema for gun violence.

Since we also organized the task, we decided to participate out-of-competition. Our system is a version of the NewsReader system (Vossen et al., 2016) as it was delivered at the end of the project, with as little adaptation as possible to the processing of the text to answer the queries of the task. The generic NewsReader system created the semantic output by applying a deep reading approach to the text, and the tasks were addressed by loading that output and reasoning over the results.

We participated in all three subtasks by first resolving the event coreference (or identity) and next answering the questions for each task using event representations that are the results of resolving the coreference. Our approach consists of three steps: 1. the event mentions in the input documents are represented as Event-Centric Knowledge Graphs (ECKGs) using the NewsReader system as is. 2. the ECKGs of all documents are compared to each other to decide which documents refer to the same incident, resulting in an incident-document index and in cross-document event-coreference relations. 3. the constraints of each question (its event type, time, participant names, and location) are matched with the stored ECKGs, resulting in a number of incidents and source documents for each question.

Our approach is fully unsupervised and follows compositional semantic principles to 1) define the semantics of events and participants, 2) establish their identity, and 3) reason over the results.

The remainder of this paper is structured as follows. In Section 2, we briefly describe the NewsReader system and the preprocessing steps. In Section 3, we explain how we establish event identity and cross-document coreference starting from the NewsReader output. The aggregated event representations are used to answer the queries for the tasks, which we describe in Section 4.

Finally in Section 5, we discuss the results. For further details on the NewsReader system, we point to the NewsReader website and its Github repository.¹ The specific wrapper for this task that takes the Newsreader output as a starting point is available in a separate Github.²

2 The NewsReader system

NewsReader processes text by applying a wide range of NLP modules, among which named entity recognition, classification and disambiguation (NERCD), semantic role labeling (SRL), word sense disambiguation (WSD), and temporal expressions detection and normalization (TIMEX). The NLP modules store their output as separate layers in the Natural language processing Annotation Format (NAF) (Fokkens et al., 2014). For example, events are detected by the SRL system as PropBank predicates (Kingsbury and Palmer, 2002), while FrameNet frames (Baker, 2008) and Wordnet synsets (Fellbaum, 1998) are attached to these predicates on the basis of the WSD output. Similarly, NERCD will annotate the text with entities and entity classes and it will annotate some of them with DBpedia URIs. From these entities, we derive participant names and locations for the predicates in the SRL output, while TIMEX anchors these predicates to dates.

In a second step, NewsReader derives so-called Event-Centric-Knowledge-Graphs (ECKGs) by combining the results of the NLP module. The ECKGs follow the Simple Event Model (SEM) (Van Hage et al., 2011), which represents events as instances through URIs with relations to their participants, location, and time. The same event instance and participants can be mentioned several times throughout a text and across different documents. Identity across mentions is then modeled through the Grounded Annotation Framework (GAF) (Fokkens et al., 2013), by giving

¹www.newsreader-project.eu and <https://github.com/newsreader>

²<https://github.com/cltl/nwr-semeval2018-5>

event instances the same unique URI in SEM and pointing to the different mentions in the source text via a *denotedBy* relation to mention URIs based on their offsets. Assigning unique URIs to coreferential event mentions results in ECKGs with all the knowledge and information aggregated across mentions in the form of RDF properties for this subject URI.

Figure 1 shows two examples of ECKGs with the event URIs 094fe5921b642e30a00cd52ece7b0157#ev1 and 60ad5103290ae7aa16e39d3cd2695496#ev1. The ECKGs are derived from two mentions in two different documents. The triple representations capture the following properties for each event: subclass relations with WordNet synsets and FrameNet frames, *denotedBy* pointers to the offset positions in the original texts, the words or labels used to mention the event, PropBank roles filled by DBpedia URIs, or unresolved phrases that are not entities and finally, the date to which the events are anchored.

In this output of NewsReader, we did not apply any event coreference and we represent each mention as a separate event instance or ECKG. The WordNet synsets and FrameNet frames are associated through the WSD modules in NewsReader. We used the UKB (Agirre and Soroa, 2009) and IMS ((Zhong and Ng, 2010) to score the WordNet synsets for each predicate. Next, we take the highest scoring synsets and use the Predicate Matrix (Carreras et al., 2014) to obtain the associated FrameNet frames. The interpretation of the predicates as events for the task is thus derived from the SRL output in combination with the WSD output and the Predicate Matrix association.

We call the above output of NewsReader the **raw-ECKGs**. In the next sections, we describe how we post-process these to derive so-called **task-ECKGs** with only the information relevant for the task. We finally reason over these task-ECKGs to answer the queries. Both the raw-ECKGs and the task-ECKGs are available in the Github repository, including the scripts to extract the latter from the former.

3 Event coreference

As a first step for the task, we read the raw-ECKGs and filter out only those events that are relevant for the task: see section 3.2 for details. Next, we establish event identity across the different event

Figure 1: ECKG representation of events extracted by NewsReader for two different mentions in two different documents, showing the type of event, the mentions linked through the *denotedBy* property, the PropBank roles, the date and the actual words used to make reference. The denotedBy links are simplified to reduce space.

mentions: see subsections 3.3 and 3.4. For this, we assume that each document reports on a single incident and mentions within a document are coreferential. We carried out the following steps for this:

1. We build an index of all documents that report on the same incident as follows:
 - (a) We determine the incident time for a document.
 - (b) We determine the overall incident type for a document: killing, injuring, job firing, or fire burning.
 - (c) We compare all documents with the same incident time and incident type to further match the locations and participants.
 - (d) If there are sufficient matching locations and participants across documents, we store them relative to the same incident.
2. Iterating over the incident-document index, we determine the mentions of incidents and their subevents over all documents that report on the same incident. We establish coreference relations among these mentions:
 - (a) All mentions of the incident as a whole, e.g. *accident, shooting, this*, receive the same URI that represents the incident.
 - (b) All further subevents of an incident (*hit, injure, death*) are identified by their subevent type and the victims associated within and across documents related to

the same incident. Incident subevents of the same type and with the same victims become coreferential and receive the same URI.

In the next subsections, we explain these steps in more detail.

3.1 Incident time

The document-creation-time is given by the organizers for each document but it does not necessarily correspond with the date of the incident. We therefore extract the mostly mentioned year and month throughout the document and select the most frequently mentioned date for that year/month. We experimented with selecting different proportions of the text, as we assumed that the actual incident data is most likely mentioned in the beginning and other incidents from the past may be mentioned later in the text. We tested these approaches on the trial data and found that restricting the date references to the first two sentences gave the best results. If there are no time expressions in the first two sentences, we use the document-creation-time as the incident date as a fall-back.³

3.2 Incident type

For each document, we classify all the predicates for the event types of the task: *shooting, burning, and dismissal of employees* and count which type is most dominant. To classify the predicates, we

³We also experimented with other granularities e.g. by lumping incidents by the week of the month but these did not give better results.

collected all FrameNet frames that NewsReader assigned to the trial data and ordered the frames by frequency. We manually selected the following frames for each event type:

incident fn:Attack,fn:Catastrophe,fn:Cause_harm,
fn:Destroying

kill fn:Cause_to_end,fn:Death,fn:Killing

injured fn:Cause_harm,fn:Cause_impact,
fn:Experience_bodily_harm,
fn:Hit_target,fn:Recovery,fn:Resurrection

hit fn:Cause_impact,fn:Hit_target

shoot fn:Shoot_projectiles,fn:Use_firearm

burn fn:Absorb_heat,fn:Apply_heat,
fn:Setting_fire,fn:Fire_burning,fn:Fire_going_out

dismiss fn:Firing,fn:Quitting_a_place,
fn:Quitting,fn:Get_a_job,fn:Hiring,fn:Employing,
fn:Being_employed

We further noticed that some task-relevant words in the trial data were not matched with WordNet synsets or FrameNet frames by our system. After analysing the output of the trial data, we manually selected 84 predicates that were sometimes missed by the system (due to upper case, part-of-speech errors, out-of-vocabulary) to ensure higher coverage. We used this word list together with the FrameNet mappings to select only those events that are relevant for the tasks and derive the dominant event type of the document.

3.3 Incident-document index

After determining the dominant date and the type of incident, we compare documents with the same incident date and the same incident type to determine which documents report on the same incident. For this we compare the locations and the participants. If there is a sufficient degree of matching, we assume that documents report on the same incident.⁴ For participants, we first check the names of the entities detected by the NERC module. If there was no match, we check all other phrases with PropBank A0 or A1 role, such as *person*, *child*, *girl* that denote persons, but are not classified as entities by NERC.⁵ For locations, we assume that the entity linking software⁶ found a

⁴In our experiments, matching a single participant and a single location was sufficient.

⁵In NewsReader, these phrases are typed as non-entities because they can refer to generic or role instantiations, e.g. *victim*, *mother*

⁶mendes2011dbpedia

match to DBpedia. We directly compare the DBpedia URIs for locations across the documents to find a match. Eventually when documents match in terms of all properties: same incident date, same incident type, one participant and one location, we assume they report on the same incident and we store them together in an incident-document index.

3.4 Coreference across incident mentions

The second step in this process establishes the event coreference relations across all event mentions in all the documents related to the same incident. All references to the incident as a whole will receive a unique URI that identifies that incident. For example, if a document has *shooting* as the dominant incident type, then we consider all references to *shooting* as a mention of the incident as a whole. We consider abstract incident mentions such as *catastrophe*, *accident*, and even pronouns such as *it* and *this*, as coreferential with the incident as a whole. Next, we extract all references to subevents, e.g. *hit*, *injured*, *death* as separate event instances relative to the incident to which they are associated. Subevents are separated by their subtype in combination with the participants or victims. Each subevent receives a URI that is composed of the incident URI, the subevent type, and the participant string. An example of such a subevent URI is shown in Figure 2. It starts with a document reference⁷ followed by #incident, #INJURED and the words that make up all linked participant phrases: 6-year+old+girl+child+little+girl+person+young+girl. These participant phrases are aggregated across various mentions. In the case of phrases such as this one, it is difficult to reason over the participant identity; how many participants are injured? In this approach, we assume that the URI and therefore their identity was resolved by the generic processing of NewsReader. No specific matching strategy was implemented to establish coreference across participants. We see in Figure 2 the resulting list of distinct participant URIs based on their surface forms. In case of entity names, it is more likely to match participants across mentions directly through their URIs or their first name or surname. For example in Figure 2, the second ECKG shows

⁷We arbitrarily take the name of the first document used in comparison just to get a unique URI

an incident reference with the participant name *Tewalt* that needs to match a participant in another document with the same name to find a match.

3.5 Aggregating properties

Establishing coreference through the same URI, results in further aggregation of all properties that were initially expressed for separate event mentions. We also normalised the properties by lumping all PropBank A0 and A1 roles to *sem:hasActor* for participants and *sem:hasPlace* for location. Figure 2 shows two examples of **task-ECKG** resulting after aggregating data from mentions from the **raw-ECKGs**. The first ECKG shows a subevent of the type INJURED based on the raw-ECKGs shown in Figure 1. The second ECKG shows an event at the incident level, aggregated over various mentions in the same document and their corresponding properties. We also include all subevents for the incident as links. There are subevents both for being injured and for death although the participants detected are linked only to injured subevents. This has consequences for answering subtask 3 questions for number of people injured or died.

After aggregating the properties, we store these task-ECKGs to an output file named after the incident date inside a subfolder that corresponds with each incident event type: (*BURN*, *DISMISS* and *SHOOT*). For example for the test data, the software created a BURN subfolder with 6 ECKGs files in TRiG-RDF format: 20071026.trig, 20071022.trig, 20151027.trig, 20151024.trig, 20070207.trig, 20070201.trig, each representing the incident date. Each of these TRiG files contains all incidents of the same type that are associated with the same date. For SHOOT and DISMISS the number of RDF files with incidents on the same date is far larger: 1,367 and 43 respectively.

In addition to storing the task-ECKGs, we also read the CoNLL file and annotate its tokens with numeric event identifiers by taking the checksum of each URI in the ECKGs and assign the checksum to each *denotedBy* match with a token. The annotated CoNLL file is submitted for the task.

4 Counting incidents and victims

Given the ECKG representations of incident instances and their subevents, it is straightforward to answer the task questions. To achieve this, we pro-

cess all the questions and match their constraints with the knowledge on the task-ECKGs: the incident type, the date, the participant name, and location (if any). This results in a number of matching incidents and their associated source documents. For subtask 3, we additionally extract the victims for the specified subevents *killing* and *injuring*.

To obtain the answers, we first check the type of event in the query (*killing*, *injuring*, *fire_burning*, and *job_firing*) and match it with the subfolders of the adapted-ECKGs. We only consider the ECKGs files for a matching type. For *shooting* events that are differentiated into *killing* and *injuring* incidents, we additionally filter the ECKGs for the occurrence of the corresponding subevents. From each subfolder, we only load the ECKGs with matching dates. If there is no date constraint, we load all ECKGs. In case of a date constraint, we check if the constraint specifies a day or only a year or month. If no specific day is specified, we check if the ECKG files start with the corresponding year and/or month. Else if a specific day is asked for, we match the full date with the incident time.

We load all ECKG files that match the above constraints and consider each incident and its properties for further matching with other constraints on location or participant names. In the case of location, we first directly match the DBpedia URI for each incident against the *sem:hasPlace* properties. If there is no match, we expand the location in the query to DBpedia URIs that are related using spatial properties: north, east, west, south, northeast, southeast, northwest, and southwest of the specified location. For participants, we first check all participants of the incident that are classified as an entity of type PERSON by the NERCD module. We check the beginning of the name in case of a first name constraint and the ending of the name in case of a surname constraint.

After selecting incidents that match the query constraints, we derive the answers. In the case of subtask 1, we only provide the document ids for matched incidents and the numeric answer 1 (if any document was recovered). In the case of subtask 2, we count the unique number of incidents within the selected ECKGs and the associated documents of their mentions. If there are none, the answer is zero. If there is one or more, we provide the number of incidents and the associated document identifiers for their mentions. In the case of

Figure 2: task-ECKG representation of an *injure* event resulting from establishing event-coreference and aggregating the event properties across different mentions. The denotedBy and subevent links are adapted to save space.

subtask 3, we additionally extract all victims from the ECKGs as being *injured* or *killed*. If the victims in the ECKG are entities of the type PERSON, we count the unique list of names. If there are no entities of the type PERSON associated with the subevents, we simply count the unique strings of the non-entities associated with *injuring* or *death*. The victim count is then used to answer subtask 3 queries numerically.

5 Results and discussion

Our system answers the task queries using ECKGs in which event and participant identity is established by the unsupervised NewsReader system. Next, we reason over the properties of the ECKGs in relation to the query constraints. We did minimal adaptations for the task and the performance heavily relies on the quality of the ECKGs. The adaptations mainly involved detecting the relevant event types among all events detected by NewsReader, reasoning over the incident date and matching the location in the query with locations in the ECKGs using spatial relations from DBpedia. Furthermore, we relied on the one-document-one-incident heuristic. We expect that the system can be improved considerably by: 1) improving the incident-document index using state-of-the-art clustering techniques ((Li et al., 2005; Nicholls and Bright, 2018; Wei et al., 2018)), 2) improving the detection of predicates and the associated

event type on the basis of WSD, 3) improve the detection and reasoning over locations, 4) establishing coreference relations and identity of the participants of the events.

Except for subtask 1, our system ranked 2nd in all tasks. This suggests that it is relatively stable and can be used to obtain detailed interpretations such as the victim counts for subtask 3. Also for the event coreference, our system ranks 2nd. Given the low performance on the document-incident clustering in subtask 1, where we have an F1 of 23.82, we can expect that this performance can be substantially higher if we use a state-of-the-art document-incident clustering technique. Currently, we used a very simple semantic comparison over the event properties and do not use most of the textual data in the documents. We also noticed that the NewsReader raw-ECKG output is noisy with respect to the event participants and the location detection. There is room for improvement to better associate frames to events, interpret locations in the documents and the victims and their names.

Abstract

We present the approach developed at the Faculty of Engineering of the University of Porto to participate in SemEval-2018 Task 5: *Counting Events and Participants within Highly Ambiguous Data covering a very long tail*.¹ The work described here presents the experimental system developed to extract entities from news articles for the sake of Question Answering. We propose a supervised learning approach to enable the recognition of two different types of entities: *Locations* and *Participants*. We also discuss the use of distance-based algorithms (using Levenshtein distance and Q-grams) for the detection of documents' closeness based on the entities extracted. For the experiments, we also used a multi-agent system that improved the performance.

1 Introduction

Thousands of news articles are published every day on several media outlets. Representing and reasoning over all events in these articles is a challenging task. For instance, if we would like to answer questions about these articles like: *How many people died on the shootings in Philippi in 30th September, 2017?* or *How many people died last year on Birmingham?* or *How many people were killed by John List?*, a deep understanding is needed of many phenomena in the articles. For example, news story updates and duplicate news need to be considered in the answer processing. We can simplify the problem by identifying relevant elements from the news entities and create a structured representation to store these data.

Named Entity Recognition (NER) is a task that aims at identifying and classifying entity mentions in free text. Message Understanding Conference (MUC) defines the entities as belonging to three

categories:² 1. *Enamex*: names, such as Locations, Persons, Organizations, and others 2. *Timex*: temporal expressions 3. *Numex*: numerical elements, such as numbers and percentages.

In this paper, we present an experimental study to extract entities from news articles to answer questions. We make use of a supervised learning approach to deal with the recognition of two different kind of entities: Locations (e.g. *Philippi, Birmingham*) and Participants (e.g. *John List*). We also have studied the use of distance algorithms (Levenshtein and Q-grams) for the near document detection based on entities extracted.

The remainder of the paper is organized as follows. In Section 2, we describe SemEval-2018 Task 5, followed by an overview of the state of the art in Named Entity Recognition in Section 3. In Section 4, we present the state of the art in the Near Document Detection task, followed by the description of the system architecture in Section 5. In Section 6, we presents the approach, followed by the experimental setup in Section 7. The results are discussed in Section 8.

2 Task Description

The main goal of SemEval-2018 Task 5 (Postma et al., 2018) is to answer questions based on a set of provided news articles, e.g. *How many killing incidents happened in 2016 in Columbus, Mississippi?*. Each question has three components: an event type and two event properties. Each question contains one out of four event types: *killing, injuring, fire burning, and job firing*. Event Properties are all the related characteristics associated with the event. They can include *Locations* (City or State), *Participants* (First Name, Last Name, Full Name), and *Time* (Day (e.g. 1/1/2015), Month (e.g. 1/2015) or Year (e.g. 2015)). There are three

¹<https://competitions.codalab.org/competitions/17285>

²<http://afner.sourceforge.net/what.html>

subtasks:

- Subtask 1 (S1): Find the single event that answers the question
- Subtask 2 (S2): Find all events (if any) that answer the question
- Subtask 3 (S3): Find all participant-role relations that answer the question

3 Named Entity Recognition

A wide range of approaches have been developed to tackle NER. Early systems deal with this issue by making use of handcrafted rule-based algorithms (Hearst, 1992). More recently, systems focus on machine learning techniques (supervised learning (Florian et al., 2003), semi-supervised (Collins and Singer, 1999; Mikheev et al., 1999), and unsupervised learning). However, the major drawback of supervised learning is its dependence on annotated data. In the case of unavailability of training examples, handcrafted rules remain the practical technique (Riaz, 2010).

4 Near Document Detection

In the large amount of news articles that are published every day, the same information can be repeated in many different articles. The identification of similar or near-duplicate documents is applied in: plagiarized documents detection (Hoad and Zobel, 2003), similar web pages detection (Henzinger, 2006), and similar news articles detection (Abreu et al., 2015).

Identification of similar or near-duplicate pairs of documents in a large collection is a significant problem with wide-spread applications. Kumar and Govindarajulu (2009) present approaches used to solve this issue. For those kind of problems, three main approaches are proposed: based on URLs, on lexicon and, the third and more sophisticated, on semantics (Abreu et al., 2015).

In the work presented here, we are using the semantics-based approach applied to the information previously extracted from the news articles.

5 Architecture

The system consists of the following main components:

Creating a Structured News Representation.

Table 1: Journalistic Patterns

D	M	Y	Regular Expression
x	x	x	(Jan. [1-9]+[1-9]*, [1-2][0-9][0-9][0-9])
	x	x	(December [1-2][0-9][0-9][0-9])
		x	[1-2][0-9][0-9][0-9]

Table 2: Temporal Regular Expressions

Figure 1 presents the architecture used to parse the news article. After converting CoNLL to plain text, journalistic patterns are removed as demonstrated in Table 5. Journalistic patterns could be relevant for the reader, but not for the entity recognition task. The output of this system is a structured news representation with a list of Event Types, Locations, Participants, and Temporal Expressions. Additionally, the following sources of information are also extracted: the news identifier, publication date, and news title. To result in this representation, the following four extractions are performed:

Extract list of Event Types. We use WordNet (Fellbaum, 1998) to create a list of words that can be used to describe an event type. Our approach uses the news article title and body for the event type recognition. For each one of these elements, the English Snowball Stemmer is applied. We consider a document to have a certain event type if at least one term that describes an event type is present in the news title or body.

Extract Locations and Participants. For the Locations and Participants recognition, a supervised approach is used. The approach proposed is described in Section 6.

Extract Temporal Expressions. Our approach to finding temporal information in the news article is based on the application of regular expressions. Table 2 presents some of the regular expressions used.

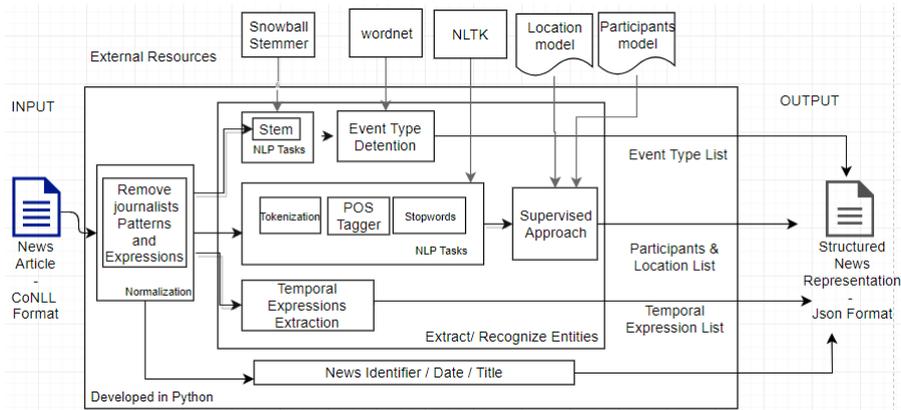

Figure 1: Create a structured news representation approach

Extract Auxiliar Information. The title, publication date, and news identifier are also extracted from the news article to create the structured news representation.

Search all the news that answer a question

When the system receives a question, an answer will be retrieved based on the structured news representation. Firstly, for each element (Event Type and Event Properties) a list of news articles that has some relation with the element under analysis is composed. In the end, the news or set of news articles that address all the items under analysis are extracted.

Near document detection

The near document detection was done based on the set of news that answers a question. The approach is explained in Section 6.

Counting participants

Similarly to what happened in the case of previously mentioned events' extraction, this one only uses a news article or a set of news articles that answer a question. For this set of news articles, we only process the information given by the news article title. For each Event Type we manually define the variation trend (increase/ decrease/ stable) - e.g. the number of death can increase with the decrease of the number of injured - in a killing event. We started this process by normalizing and removing temporal expressions from the news article title. After, we applied the POS-tagger and split the sentence into subsentences separated by comas. We started to recognize the event type for each subsentence. When we found it, we checked if

the subsentence also includes a numerical element ('CD' - Post tagger) - this element is considered as a number of participants associated with the event type. Once extracted the number of participants associated with each news article, we connect this information with news article's date. Finally, we try to find the maximum or the minimum of participants depending on the temporal event type trend.

The system we are presenting here was developed in Python 2.7. It uses some python libraries: Natural Language Toolkit (NLTK) - Wordnet, English Snowball Stemmer, Stopwords, POSTagger; Python multi-Agent Development Environment (SPADE); Scikit-Learn - tree, RandomForestClassifier, ExtraTreesClassifier, LinearSVC; Json; and, Regular Expressions (re).

6 The proposed approach

6.1 NER Supervised Approach

In this subsection, we describe the implementation details of the proposed approach for recognizing Locations and Participants.

Natural Language Processing Tasks:

The data was preprocessed with two NLP tasks: part of speech tagging and stop word recognition.

Features

Supervised learning techniques require their input to be categorized. When extracting information from news documents, it is common to label each word with a set of features. These features allow the SL approach to recognize an entity in a given document. We extracted the following features: 1. CAP (Capitalized) indicates whether a word: contains no capital characters,

	shooting	at	a	west	Phoenix	apartment	that	left	one	man	dead
CAP	0	0	0	0	1	0	0	0	0	0	0
PT	D	NN	IN	DT	NNP	NN	WDT	VBD	CD	NN	NN
SWI	0	1	1	0	0	0	1	0	0	0	0
SWA		at	a				that				

Table 3: Categorizing each word on a sentence

Exp	Current			Previous				Next				Loc	
	Cap	SW	Pos	Cap	SW	Pos	Sw	Cap	SW	Pos	Sw	NP	P
S1	x	x	x	x	x	x	x	x	x	x	x	x	x
S2	x	x	x	x	x	x	x	x	x	x	x		
S3	x	x	x	x	x	x	x						
S4	x	x	x					x	x	x	x		

Figure 2: Features used in each scenario

has only its first letter capitalized, or all its characters are capitalized; 2. PT (POS Tagger Association)³ identifies the part of speech tag of a word, such as noun, verb, adjective, etc.; 3. SWI (Stop-Words Identification) indicates whether a word is a stop-word; 4. SWA (Stop-Words Association) associates a corresponding stop-word; 5. NP - Paragraph records a numeric identifier of the paragraph in which the word appears.

Table 3 presents example of features computed for each word in the phrase “shooting at a west Phoenix apartment that left one man dead”. For instance, the word “Phoenix” is capitalized ($CAP = 1$), corresponds to a noun ($PT = NNP$), and is not a stop-word ($SWI = 0$). Note that we aggregate all sequential capitalized words as one, e.g. “Salt Lake City” will be combined in a single word to be classified.

We believe that a simple association as illustrated in Table 3 is not enough to categorize a word for the Named Entity Recognition task. For this reason, we also consider the word context in the document, i.e., the current word (C), the previous word (P), and the next word (N). Here we indicate the word position following the feature abbreviation, e.g., “C CAP” indicates whether the current word is capitalized or not.

Data Cleaning and Transformation

Data quality is the main challenge of information management. To guarantee data quality, two processes were executed: data cleaning and data transformation. Tables 4 and 5 present the data transformation for POS tags and stop-words.

³(POSTagger - All Tags) - <http://www.nltk.org/book/ch05.html> visited on 2017, November

Stop-words have no value for SWA. To fix this, we replace an empty value by the character “X” and we encode this value as demonstrated in Table 5.

PostTagger	Rep
DT	0
NN	1
NNP	2
VBD	3
...	...

Table 4: POSTagger

Stop-Word	Rep
X	0
a	1
that	2
and	3
...	...

Table 5: Stop Words

Classification Algorithms

Supervised learning techniques create a model that predicts the value of a target variable based on a set of input variables. One challenge is to select the most appropriate algorithm for the task of classifying Locations and Participants. We have compared the following algorithms: Support Vector Classifier (SVC); Decision Tree Classifier (Tree); Random Forest Classifier (Random); Extra Trees Classifier (Extra). As demonstrated on Table 6, different configurations were attempted for each algorithm. Implementations of these algorithms are provided by the Python library scikit-learn library⁴.

6.2 Near Document Detection

The answer to a question in this SemEval task consists of the following: question identifier, set of the news articles that help to answer the question, and a numerical answer.

The numerical answer of a question is dependent on the question task. Task 2 requires a number of unique events that correspond to a question. For this purpose, it is essential to detect similar news documents within the given set. To detect similar documents, we use the structured news representation described above. Each pair of news articles is compared based on: their titles, their lists of Participants, and their lists of Locations.

7 Experimental Setup

7.1 NER Approach

Data Resources

The SemEval 5 competition provides data for the purpose at stake. The data made available in this competition is a set of English news articles. To extract locations and participants from crime

news, additional annotations were done. A set of 10,580 individual words were annotated in three categories: Locations, Participants, and Others - where all the sequential capitalized words were aggregated as one, e.g., in "as she left Jackson Memorial Hospital", the annotated elements are: [as], [she], [left],[Jackson Memorial Hospital].

Evaluation

The evaluation metrics used to evaluate this approach are Precision (P), Recall (R), and F1 (F). Due to a large number of experiences and in order to correctly analyze the obtained results, we made use of a multi-agent architecture to find the best results. For this evaluation, we defined a utility function and we introduced an auction mechanism to enable some kind of negotiation. This mechanism is based on English auction, where each agent can propose their bids following the auction requirements. Our agents represent the different configuration of the classification algorithms and each bid reveals their result on a specific test scenario. We expect that in this experiment recall is the most important metric, thus it is assigned a higher weight than the other metrics. Our utility function was

defined as follows:

$$U = 0.5 * R + 0.25 * P + 0.25F1$$

In order to reduce the data to be analyzed we exclude all combinations with low performance, namely all combinations where either Recall, Precision, or F1 has a mean value below 60% or a standard deviation above 15%.

Experiments

A supervised learning system was needed to generate a model. The classification algorithms and the scenarios (S1, S2, S3, and S4) defining values of features are those described in section 6.1.

Our experiments were done taking cross-validation with $k = 7$ into account. We divided the annotated data into partitions of training data (75%) and testing data (15%).

7.2 Near Document Detection

Data Resources

Near document detection approach was studied with the dataset provided at the end of the competition. Each intended answer includes a list of similar documents identified in the given dataset and aggregated according to the corresponding question. For each answer, we created a script to aggregate all news articles in pairs. Additionally, a label indicating whether a pair is similar or not (pairs that are contained in the same set are similar) was added. In total, this resulted in 61,931 pairs of news articles.

Evaluation

We evaluate the performance of various thresholds on near document detection by applying the metrics: Precision, Recall, and Accuracy.

Experiments:

For each pair of news articles, we have calculated the similarity between their elements: title (T), list of participants (Part), and list of locations (Loc). For the sake of comparison, we have used two distance algorithms: Levenshtein (L) (Levenshtein, 1966) and Qgrams (Q) (Ullmann, 1977). We defined two scenarios (SS1, SS2), differing in the weights of the document elements as follows:

$$SS1 = 0.50T + 0.25Loc + 0.25Part$$

$$SS2 = 0.34T + 0.33Loc + 0.33Part$$

Exp	Alg	P	R	F	U
S3	Tree 6	66.47	70.94	68.34	69.17
S1	Extra 8	71.67	67.63	69.13	69.02
S1	Tree 2	71.28	67.53	69.08	68.85
S1	Tree 3	70.53	67.79	68.90	68.75
S2	Tree 4	70.35	67.55	68.54	68.50

S1	Extra 2	68.28	64.84	66.41	66.09

Table 8: Recognizing Location - Results

8 Analysis and Results

8.1 NER Approach

Due to the large volume of combinations and their corresponding results, we used a multi-agent system to simplify the analysis. Tables 7 and 8 present the best 5 results achieved on extracting Participants and Locations respectively. We considered the results only from two algorithms: Decision Tree and Extra Tree Classifier. Both approaches show that context helps the recognition task.

8.2 Near Document detection

Table 9 presents the results achieved for various threshold values. Changing the threshold value causes small variations in the performance of the Qgrams algorithm, but large variation in the performance of the Levenshtein distance algorithm. The scenarios presented here are not sufficient to determine if two news articles are similar or not. These results indicate that in cases where news articles refer to the same subject, a reduced news article representations is not sufficient to distinguish different events.

Alg	Function	Threshold	P	R	A
L	SS1	75	12.24	12.86	86.56
L	SS1	80	6.97	60.86	36.22

Table 9: Near Document Detection Results by Threshold

8.3 SemEval Results

SemEval-2018 Task 5 contains 3 subtasks, on which we achieved F1 score of 24.65, 30.51, 26.79 respectively.

9 Conclusion and Future Work

In this work, we presented an experimental study that addresses the Question Answering challenge in SemEval-2018 task 5. We have used Named Entity Recognition approaches to identify entities such as Location, Participants, Temporal Expressions, and Event Types. We used a structured news representation to perform the required tasks: 1. to answer questions on counting events 2. to detect which distinct documents provide an answer to a question; and 3. to answer questions by counting event participants.

The use of multi-agent system was crucial in order to find the best performing algorithm. Our utility function allowed us to have a previous definition of the influence of each evaluation metric on the overall evaluation. The resulting system can be applied to other scenarios by adapting the utility function according to their requirements. In the future, our system can be improved to include multiple combinations (e.g., on the near document detection we can use a different combination of elements and algorithms).

Task 2 has been solved with extracting information. Future work for this task could include another study of a supervised learning approach that is based on the entire information available in a news article. However, such a requires a corresponding annotated corpus. Our approach to Task 3 was relatively naive, since it does not consider the relationships between entities (participants and event type). Future work should investigate a more elaborate approach.

Event type behavior should also be studied, as we believe that some events could present temporal trends. For instance, we expect to observe an increase of the number of deaths/injuries described in crime news documents over time.

Abstract

In this paper, we describe Alibaba's participating system in the semEval-2018 Task5: Counting Events and Participants in the Long Tail. We designed and implemented a pipeline system that consists of components to extract question properties and document features, document event category classifications, document retrieval and document clustering. To retrieve the majority of the relevant documents, we carefully designed our system to extract key information from each question and document pair. After retrieval, we perform further document clustering to count the number of events. The task contains 3 subtasks, on which we achieved F1 score of 78.33, 50.52, 63.59, respectively, for document level retrieval. Our system ranks first in all the three subtasks on document level retrieval, and it also ranks first in incident-level evaluation by RSME measure in subtask 3.

1 Introduction

In this paper we present our system developed for participating in the semEval-2018 Task5: Counting Events and Participants in the Long Tail. Given a set of questions and a corpus of documents mainly from news articles, the system needs to provide a numeric answer together with the supporting documents that directly relate to the answer (Postma et al., 2018). According to the official task rule, participants can also optionally provide the text mentions of events in the documents, but we did not participate this year. The task contains 3 subtasks. Subtask 1 is to retrieve all the relevant documents related to one single event asked in the question. Subtask 2 and subtask 3 require the system not only retrieve relevant documents, but also count the number of events or number of participants. Event detection and extraction has been intensively

studied (Choubey and Huang, 2017; Nguyen et al., 2016a,b; Nguyen and Grishman, 2016; Feng et al., 2016; Ji and Grishman, 2008). Most of those research used a corpus of annotated documents for training. In this task, annotated documents were not provided, but the key factors to retrieve relevant documents are provided by the questions. Therefore, our system starts from a document retrieval system via key information extraction and matching and follows a document clustering component.

2 System Description

We developed a pipeline system for the task, including question parsing, document feature generation, document event type classifications, document retrieval and document clustering.

2.1 Question Properties

In this task, each question contains three components: the event type and two event properties. The two event properties provided are either the time, the location or the participant of the event. And specifications for these properties can vary in granularity (e.g. day/month/year, city/state, first/last/full name). Details can refer to official task description (Postma et al., 2018). In this task, we consider four event types (i.e. killing, injuring, fire_burning, job_firing). But in training data, only killing and injuring events are provided. Our system first processes each question to extract the question event type and properties. Later each question and document will be paired (q-d pair) and assigned question properties as binary features. For instance, if a question asks for killing event(s) that happened at specific location and time, the features related to the asked event type and properties (i.e. ask_killing, ask_time, ask_location) will be 1 and others

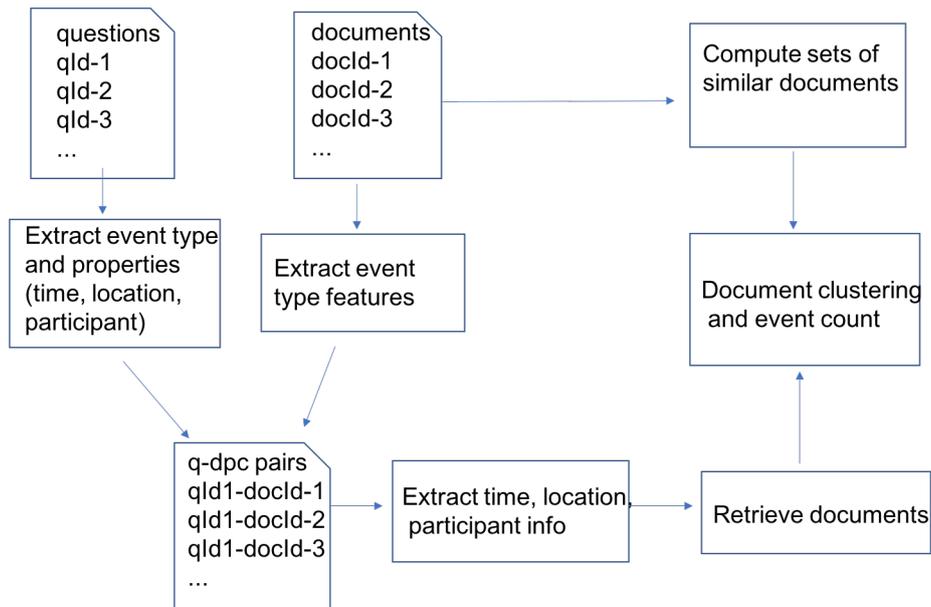

Figure 1: System Overview.

(i.e. `ask_injuring`, `ask_fire_burning`, `ask_job_firing`, `ask_participant`) will be 0.

2.2 Document Features

2.2.1 Event Type Feature

Event type is a feature which can be defined by the document itself. To decide if a document is one of the four types defined in this task, we utilized both word count feature and classification results. Given the root event trigger keywords for an event type, we first made a synonym word list by including the top similar words from `word2vec`, based on a cosine similarity score threshold (Mikolov et al., 2013a,b), and adding a couple of missing common words associated with the event. Then we scanned through all documents and count total number of words from the event word list in the document. These counts are then used as word count feature for each event type.

To prepare the training data for the classifier, we selected the killing and injuring documents according to the answer document in trial data. And we used a keyword list to select `fire_burning` (“firefighter”, “fire department”, “wildfire”, “burn”) and `job_firing` (“employee”, “employment”, “fired for”) related documents. To remove confusing documents that are actually gun violence related, a short list of gun violence keywords (“gun”, “shot”, “bullet”, “shoot”) were used when selecting `fire_burning` and `job_firing` documents. Two SVM models were trained

for event classification. One for classification between gun violence and non-gun violence. Another one is to determine if an event is an injuring event (not killing-only).

2.2.2 Location Feature

If a question asks for a specific location, the system will extract a location feature from each document according to such location. For instance, if a question asks for an event that occurred in Phoenix, Arizona, it will scan each token in the document and decide if “Phoenix” and “Arizona” are in the document. Based on the granularity of the location asked, a score is assigned to the q-d pair as document location feature. As the states in the U.S. are often abbreviated, a dictionary of the U.S. states with their abbreviations¹ is used for better recall. Additionally, a database of cities in states of the U.S.² is used to retrieve a document in the case that a state is asked but the document only mentions the city in that state. In the current system, a partial score is assigned to such a document. And one problem raised by this method is the possibility to retrieve the false positive documents which contain the city with the same name that is in a different state. This issue has not been resolved in the current system, although

	S1	S2	S3
F1	78.33	50.52	63.59

Table 2: Document-Retrieval Performance.

attempts with using additional county information are tried.

2.2.3 Participant Feature

If a question asks for a specific participant name, the system will extract a participant feature based on the match of the name and the granularity of the name that is asked. For example, if a name “Michael Farrow” is asked in the question, it will assign a max score to this participant feature when “Michael Farrow” is found, or partial score when only first or last name is found. To avoid the case that partial name matches to a wrong entity, we used named entity recognition tool from Stanford CoreNLP ³ to extract all named entities, and if the partial name is found in the named entities other than a person, a relatively low score will be assigned as the feature. In addition, in real life a location name (e.g. a street, a mountain or a station etc.) may sometimes be named after a person (e.g. Franklin Street). The system combines these partial names with the common location words and their abbreviations (e.g. street and st.), and use regular expression to check if the documents contain such combination. If so, a relative low score is given.

³<https://nlp.stanford.edu/software/CRF-NER.html>

2.2.4 Time Feature

In case a question asks about a specific time, the system extracts potential times via word level matching and Stanford named entity recognition tool. And all the extracted time phrase are normlized to the format as ‘DD/MM/YYYY’. Each document has a creation time, i.e. DCT. Because errors may occur during time extraction, it select a potential time only if it is before the DCT, and then such time is compared with the question’s time.

2.3 Document Retrieval

To decide the event type, we considered both event keywords and classification results. For violence events (killing and injuring), whether the document contains killing keywords is the only factor to decide if it is killing event, but for injuring event the classification result is used to decide if it is an injuring incidence. For the other two events, both the keyword count and gun violence classification results are considered. With all the features prepared for each q-d pair, a threshold is set for each feature and only q-d pairs with all the feature scores above their thresholds are considered as one corret q-d pair, which means the document is considered as an correct answer for the corresponding question.

2.4 Document Clustering

In subtask 2, after we identify documents that meet the requirements of the question, we need to group the documents that talk about the same event into the same cluster. We used the features listed in Table 1 to train a classifier, to determine

	Time	Location	Participant
questions	892	734	438
non-recalled correct documents	70	86	265

Table 3: Number of questions asked for each properties and number of correct documents missing the corresponding key information.

if two documents are talking about the same event. It is a binary classifier, with two classes: Yes and No. Based on the classification result, we used 1NN for clustering. The trial data of subtask 1 and 2 are used as the training data to train the classifier. In total, there are 599 positive samples (document pairs that talk about the same event), and we randomly generated 1000 document pairs as the negative samples. The classification algorithm used is Random Forest. Based on 10-fold validation, the F measure of the classifier is 0.96. This classifier was also used in subtask 1 and 3 for expanding the root documents for improving recall.

3 Evaluation

Document retrieval performance for all the three subtasks are shown in Table 2.

To understand the loss of the recall, we counted the numbers of questions that ask for time, participant, and location, respectively, and the numbers of documents our system did not retrieve due to the property (e.g. time, participant, and location) was not found, which is shown in Table 3. We use the following two documents as examples:

1. *“Probable cause hearing being held for 3 accused in fatal shooting of 3-year-old DETROIT (AP MODIFIED)- Three men charged in the shooting of a 3-year-old Detroit girl were in court today for a probable cause hearing. The Wayne County prosecutor’s office said the three are charged in the death of Makanzee Oldham, who died after she was shot while in a car with her father after a fight erupted and someone poured juice on a woman getting ready for prom. Thirty - year - old Cleveland Smelley is accused of firing the shot that killed Makanzee. He and two other men, Deonta Bennett and Antoine Smelley, are also charged with attempted murder because there were oth-ers in the car ”*, and

2. *“Suspect arrested in Detroit shooting, 2-year-old girl still in critical condition DETROIT (WXYZ)- A 2-year-old girl remains in critical*

condition after she was shot in the head on Detroit’s east side on Wednesday One of the men is the father of the little girl , the other is the suspected shooter , Cleveland Smelley Police say Smelley pulled out a gun and fired one shot at the other man , missing him and hitting the little girl in the head She was sitting in her car seat when she was shot Police confirmed they arrested Cleveland Smelley on Thursday afternoon ”

The above two documents are correct answer to this question, *“Which [‘killing’] event happened in 05/2016 (month) that involve the name Deonta (first)?”*

Document 1 was created on 06/09/2016, but there is no indication in it showing that the event happened in 05/2016, though it has the correct person name “Deonta”. In contrast, document 2 does not have the name “Deonta”. Therefore, neither of the two documents were retrieved via our current system. The document clustering method described in Section 2.4 does help in retrieving documents missing certain question properties, but there are still documents we cannot retrieve, especially for questions that we cannot find any document containing both required properties as the root document for document expansion using the clustering method.

As shown in Table 3, missing participants information in the documents is most common. We did not participant in the coreference competition and our system cannot correctly retrieve such documents without the key information that is asked in the question. Recent works on event nuget detection and coreference have proposed neural networks models (Nguyen et al., 2016a,b; Nguyen and Grishman, 2016; Choubey and Huang, 2017). Those works could be studied in the future, where one can elaborate the coreference information across the document to boost the recall of correct documents without key information.

Abstract

This paper describes the first task on semantic relation extraction and classification in scientific paper abstracts at SemEval 2018. The challenge focuses on domain-specific semantic relations and includes three different sub-tasks. The subtasks were designed so as to compare and quantify the effect of different pre-processing steps on the relation classification results. We expect the task to be relevant for a broad range of researchers working on extracting specialized knowledge from domain corpora, for example but not limited to scientific or bio-medical information extraction. The task attracted a total of 32 participants, with 158 submissions across different scenarios.

1 Introduction

One of the emerging trends of natural language technologies is their use for the humanities and sciences. Recent works in the semantic web (Osborne and Motta, 2015; Wolfram, 2016) and natural language processing (Tsai et al., 2013; Luan et al., 2017; Augenstein and Søgaard, 2017; Kim et al., 2010) aimed to improve the access to scientific literature, and in particular to respond to information needs that are currently beyond the capabilities of standard search engines. Such queries include finding all papers that address a problem in a specific way, or discovering the roots of a certain idea. This ambition involves the identification and classification of concepts, and the relations connecting them.

The purpose of the task is to automatically identify relevant domain-specific semantic relations in a corpus of scientific publications. In particular, we search for and classify relations that provide snippets of information such as "a (new) method is proposed for a task", or "a phenomenon is found

in a certain context", or "results of different experiments are compared to each other". Identifying such semantic relations between domain-specific concepts allows us to detect research papers which deal with the same problem, or to track the evolution of results on a certain task.

2 Related Work

SemEval 2010 Task 8 (Hendrickx et al., 2010) proposed a discrete classification of word pairs into 9 semantic relations, however, this task was not tailored to the needs of scientific text analysis as neither relation types nor the vocabulary were domain-specific. SemEval 2012 Task 2 (Jurgens et al., 2012) proposed a gradual notion of relational similarity: the task was to quantify the similarity between examples of relation instances. The data set was aimed at evaluating specific semantic representations for relational similarity, but does not fit our task: in this task, entity pairs were treated as static class instances; in particular, they were presented without any context. However, the relation types we deal with are contextual: e.g., a specific *machine learning method* is trained on a specific *data set* to perform an *NLP task* in the context of a given experiment reported by a paper. Finally, the most closely related to our task is SemEval 2017 Task 10 (Augenstein et al., 2017), which responds to the growing interest towards the semantic analysis of scientific corpora. This task focuses mostly on keyword extraction and categorization. The subtask concerned with relation classification proposes 3 categories of taxonomic relations (synonym, hypernym, unrelated). Our task goes a step further by proposing a more fine-grained and, thus, more informative set of semantic relations (see Table 1). The relation types were selected and annotated based on a careful corpus study and are intended to represent the major re-

lations that define the information content of the abstract of a scientific paper.

3 Task description

The task consists in identifying and classifying instances of semantic relations between concepts in a set of 6 discrete categories. The relations are specific to the science domain and their instances can frequently be found in the abstract/introduction of scientific papers. The task is split into three subtasks. This is done to provide a framework for the systematic evaluation of the steps that are necessary for full information extraction from scientific text, i. e. relation extraction and relation classification. Two of the subtasks focus solely on the *classification* of relation instances into 6 relation categories. Another subtask includes both the *extraction* of relation instances and their *classification*. The data we provide is presented as complete abstracts of scientific papers. An abstract contains about 100 words on average. Entities are annotated in both the training and the test data. Furthermore, in the classification subtasks, the relation instances (entity pairs that belong to one of the relation classes) as well as the directionality of the relation (argument1, argument2) are given in the training and test data. In the extraction subtask, relation instances are not provided in the test data. The training data for each subtask contains 350 annotated abstracts with the corresponding relation instances and their categories¹. The test data consists of 150 abstracts². Participants were allowed three submissions/subtask/team.

3.1 Relation classification scenario

Given a pair of entities in an abstract, the task consists in classifying the semantic relation between them. A pre-defined list of relations is given (see Table 1), together with training examples for each relation.

- **Subtask 1.1 : Relation classification on clean data.**

Entity occurrences are *manually* annotated in both the training and the test data. In the training data, semantic relations are manually annotated between entities. In the test data, only

¹The training data for subtask 1.1 and subtask 2 were identical.

²After the end of the competition, the complete dataset was published at <https://lipn.univ-paris13.fr/~gabor/semEval2018task7/>

entity annotations and unlabeled relation instances are given. The task is to predict the semantic relation between the entities. The following example shows a text snippet with the information provided in the test data :

```
Korean, a <entity id="H01-1041.10">verb final language</entity>with <entity id="H01-1041.11">overt case markers</entity>(...)
```

A relation instance is identified by the unique identifier of the entities in the pair, e.g. (H01-1041.10, H01-1041.11). The information to be predicted is the relation class label: MODEL-FEATURE(H01-1041.10, H01-1041.11).

- **Subtask 1.2 : Relation classification on noisy data.**

Entity occurrences are *automatically* annotated in both the training and the test data. Delimitation errors may occur in the entity annotation. In the training data, semantic relations are manually annotated between the entities. In the test data, only automatic entity annotations and unlabeled relation instances are given. The task is to predict the semantic relation between the entities. The following example shows a text snippet with the information provided in the test data:

```
This <entity id="L08-1203.8"> paper </entity> introduces a new <entity id="L08-1203.9">architecture</entity>(...)
```

The relation instance is (L08-1203.8, L08-1203.9). The information to be predicted is the relation class label: TOPIC(L08-1203.8, L08-1203.9)

3.2 Relation extraction and classification scenario

Given an abstract with annotated entities, the subtask consists in:

- identifying instances of semantic relations between entities in the same sentence,
- assigning class labels, i.e. one of six pre-defined relation types (see Table 1), to the relation instances.

RELATION TYPE	Explanation	Example
USAGE	<i>Methods, tasks, and data are linked by usage relations.</i>	
used_by	ARG1: <i>method, system</i> ARG2: <i>other method</i>	approach – model
used_for_task	ARG1: <i>method/system</i> ARG2: <i>task</i>	approach – parsing
used_on_data	ARG1: <i>method</i> applied to ARG2: <i>data</i>	MT system – Japanese
task_on_data	ARG1: <i>task</i> performed on ARG2: <i>data</i>	parse – sentence
RESULT	<i>An entity affects or yields a result.</i>	
affects	ARG1: <i>specific property of data</i> ARG2: <i>results</i>	order – performance
problem	ARG1: <i>phenomenon</i> is a problem in a ARG2: <i>field/task</i>	ambiguity – sentence
yields	ARG1: <i>experiment/method</i> ARG2: <i>result</i>	parser – performance
MODEL	<i>An entity is a analytic characteristic or abstract model of another entity.</i>	
char	ARG1: <i>observed characteristics</i> of an observed ARG2: <i>entity</i>	order – constituents
model	ARG1: <i>abstract representation</i> of an ARG2: <i>observed entity</i>	interpretation – utterance
tag	ARG1: <i>tag/meta-information</i> associated to an ARG2: <i>entity</i>	categories – words
PART_WHOLE	<i>Entities are in a part-whole relationship.</i>	
composed_of	ARG2: <i>database/resource</i> ARG1: <i>data</i>	ontology – concepts
datasource	ARG1: <i>information</i> extracted from ARG2: <i>kind of data</i>	knowledge – domain
phenomenon	ARG1: <i>entity, a phenomenon</i> found in ARG2: <i>context</i>	expressions – text
TOPIC	<i>This category relates a scientific work with its topic.</i>	
propose	ARG1: <i>paper/author</i> presents ARG2: <i>an idea</i>	paper – method
study	ARG1: <i>analysis</i> of a ARG2: <i>phenomenon</i>	research – speech
COMPARISON	<i>An entity is compared to another entity.</i>	
compare	ARG1: <i>result, experiment</i> compared to ARG2: <i>result, experiment</i>	result – standard

Table 1: Semantic relation typology. The six major relation types result from a finer grained classification which was used in manual annotation.

The training data we provide contains the same information as in the classification scenario, i.e. manually annotated entities, and labeled semantic relations holding between entities. The test data contains only abstracts with annotated entities: both the entity pairs and their relation type are to be predicted.

3.3 Evaluation

Submissions are evaluated differently for the individual subtasks. A dedicated gold standard containing entity and relation annotations is used.

3.3.1 Metrics for the classification scenario (subtasks 1.1 and 1.2)

Submissions for scenario 1 are assessed by means of standard metrics:

- **Class-wise evaluation:** Precision, recall, and F1 ($\beta = 1$) for each relation type.
- **Global evaluation:**
 - Macro-average of the F1 scores obtained for every relation type.
 - Micro-average of the F1 scores obtained for every relation type.

The official ranking of submissions is performed according to the **macro-average F1 score**.

3.3.2 Metrics for the extraction and classification scenario (Subtask 2)

Evaluation of submissions for scenario 2 is carried out in two steps:

- **Evaluation of relation extraction:** Extraction evaluation assesses the quality of identified relation instances. Relation labels and directionality are ignored in this step. *Precision* is calculated as the percentage of correctly connected entity pairs. *Recall* is calculated as the percentage of gold entity pairs found by the system. The official **F1 score** is calculated as the harmonic mean of precision and recall.
- **Evaluation of relation classification:** Classification evaluation considers only correctly identified relation instances as per step 1. For these instances, the same evaluation metrics are calculated as for task 1. The official score for this task is **macro-average F1**.

4 Data Preparation

The task is carried out on abstracts from published research papers in computational linguistics. Two existing high-quality corpora were used as starting points for data creation, namely ACL RD-TEC 2.0 (QasemiZadeh and Schumann, 2016) and ACL-RelAcS (Gábor et al., 2016a). Both resources are based on the ACL Anthology Reference Corpus (Bird et al., 2008). In ACL RD-TEC 2.0 entities were annotated manually, and it was used for the "clean" subtasks (subtasks 1.1 and 2). In ACL-RelAcS, entities were annotated fully automatically, and it was used for the "noisy" subtask (1.2).

4.1 Entity annotation

Manual ("clean") entity annotations were carried out in accordance with the ACL RD-TEC annotation guidelines (Schumann and QasemiZadeh, 2015). Thus, for subtasks 1.1 and 2 (training data) termhood is defined by a combination of semantic, linguistic, and formal criteria. The formal criteria, for instance, aim at making the annotations maximally useful for real-world extraction scenarios by accounting for various contextual usage patterns of terminological units in scientific prose. Therefore, annotators are instructed to annotate maximal noun phrases, abbreviations, and their contextual variants, including variants with incorrect spelling. Still, entity annotation proves to be a non-trivial task even for human expert annotators: QasemiZadeh and Schumann (2016) show that agreement scores are satisfactory (e.g., $\kappa > 0.7$) only after a thorough annotation training phase and the subsequent refinement of the annotation guidelines.

To extend the set of abstracts that were already available in ACL RD-TEC with double entity annotations, expert annotators were recruited from amongst the task organizers. Annotators were asked to read the ACL RD-TEC annotation guidelines. A training phase was carried out, during which each annotator carried out test annotations on unseen data. To facilitate annotations, abstracts were pre-annotated automatically using the automatic entity annotator of the ACL-RelAcS corpus (see below). Annotators were asked to correct the automatic annotations, in particular, to correct the boundary of the identified entity. Individual feedback was provided to novice annotators and annotation difficulties were clarified. Annotations were consistently monitored and potential causes for disagreement discussed and corrected.

The ACL RD-TEC already provided 171 double-annotated and 129 single-annotated abstracts. While double-annotations could directly be passed over to manual relation annotation, more single-pass annotations had to be performed to create a fully double-annotated training set. The remaining 150 abstracts for the test set of subtask 1.1 were single-annotated. It should be noted that, due to their origin from ACL RD-TEC, abstracts for subtask 1.1 contain not only entity annotations, but also information about the semantic class of the annotated entity. This information was not explicitly included in the provided data, but was accessible to participants through the original ACL

RD-TEC corpus.

The "noisy" subtask (1.2) was carried out on data coming from the ACL-RelAcS corpus 1.0 (Gábor et al., 2016a). The corpus consists of 4.2 million words from the abstract and introduction sections of papers in the ACL Anthology Corpus, with an automatic annotation of entities. This automatic annotation is based on a gazetteer which, in turn, was created using a combination of terminology extraction tools and ontological resources. As a domain specific resource, the domain models and topic hierarchies in the NLP domain from Saffron Knowledge Extraction Framework³ (Bordea, 2013; Bordea et al., 2013) were included. Terminology extraction was performed with TermSuite (Daille et al., 2013) and the resulting list of terms was filtered by part of speech and looked up in BabelNet (Navigli and Ponzetto, 2012). The extracted terms that were found in BabelNet were added to the gazetteer and used for automatic annotation.

4.2 Relation annotation

The work was divided as 1) defining the typology of semantic relations, 2) validation of the typology and of the annotation guidelines and 3) annotation. A data-driven approach was adopted to identify the relation types and define a typology (Gábor et al., 2016b). Domain experts studied the abstracts with entity annotation and were instructed to read the text and indicate the semantic relations that are explicit and relevant for the understanding of the abstract. They annotated entity pairs and the text span between them which explicitly indicates the relation.

Instances of explicit relations were thus discovered and manually annotated in a sample of 100 abstracts from ACL-RelAcS. A fine-grained typology of domain-specific relations was set up. The fine-grained relation types (see Table 1) were defined very precisely and specifically, e.g. using strict constraints on which types of entities the relations take as argument. The manual annotation used this typology; the relations were then automatically converted to the 6 types used in the classification tasks.

Only explicit relations were annotated, between already annotated entities. Entity annotation itself is never modified or corrected manually during the relation annotation phase. On the textual level, a semantic relation is conceived as a text span link-

³<http://saffron.insight-centre.org/>

ing two annotated instances of concepts within the same sentence. On the semantic level, relation types need to be specific enough to be easily distinguished from each other by a domain expert. Annotation was carried out by one of the organizers and two NLP student annotators who were subjected to a training of three weeks during which they annotated 100 abstracts under supervision. This training material was not included in the future dataset. Weekly feedback was given and difficult instances were discussed. If the annotation quality in the 100 abstracts was judged satisfactory, the annotator was allowed to carry on, and their subsequent annotations were included in the dataset (two out of three annotator candidates passed this phase).

Inter-annotator agreement was calculated using a double annotation on a sample of 150 abstracts from subtask 1.1 by two annotators. The overall class label agreement rate on these annotations was 90.8%. We also calculated the macro-averaged F1 score across classes, taking one of the annotators as "gold standard". The result was 0.91 (the performance of the best ranking system on this task is 0.81). When comparing agreement for individual relations, it turns out that the relation with the lowest agreement (F1=0.83) is PART_WHOLE, followed by RESULT (F1=0.89).

5 Results

5.1 Baseline system

As a baseline, we created a simple memory-based k -nearest neighbor (k -nn) search (Daelemans and van den Bosch, 2005) which relies on a small set of hand-crafted features.

Given a sentence s annotated with an ordered set of $e_1 \dots e_n$ entities appearing in it, we first pull out all tuples (e_i, e_j) , in which $j - i \leq 2$. For each tuple (e_i, e_j) , we encode their co-occurrence context using a set of 5 vectors of low dimensionality ($n = 100$). These vectors encode information about (a) tokens that appear before e_i in s (we use simple white-space tokenization), (b) tokens that appear between e_i and e_j , (c) tokens appearing after e_j , as well as (d) two additional vectors that capture the context of e_i and e_j occurrences in the ACL Anthology Reference Corpus (Bird et al., 2008). To encode information about these context-token occurrences into low-dimensional vectors, we use positive-only random projections (Qasemi-Zadeh and Kallmeyer, 2016). Additionally, feature vectors in each of the above-mentioned categories

are weighted using positive pointwise mutual information with respect to the collected co-occurrence information in vectors for each category for all the tuples in the training and test data (for each subtask). Finally, the weighted vectors are concatenated to form a 500 dimensional feature vector for each entity pair.

For each subtask, all the (e_i, e_j) extracted from the sentences in the training set are added to the k -nn's training instance memory T : if (e_i, e_j) is annotated with a relation, then the fetched label is assigned to it, otherwise it is marked as a negative example. Given the feature vector \vec{v} for a tuple (e_x, e_y) in the test set, the similarity between \vec{v} and all the training instances $t_i \in T$ is computed using the Pearson's correlation to find the k most similar t_i . Finally, we assign (e_x, e_y) to the relation category l_y using a majority voting.

Results obtained from this baseline system are listed in Tables 5, 7, 6, and 8 in the Appendix. We choose $k = 5$ based on the observed performances over the development dataset.

5.2 Summary of participating systems and results

The task attracted 32 participants altogether who took part in at least one subtask. The most popular subtask was the classification on clean data (subtask 1.1) with 28 participants; 19 of them also participated in the classification on noisy data (subtask 1.2). One participant chose to compete only in subtask 1.2. Subtask 2 attracted 11 teams. The scenario allowed to compete only in relation extraction, without classifying the extracted instances; only one team used this opportunity. The complete results and rankings are available in the Appendix section. Most participants opted for the use of deep learning methods, with a clear preference for Convolutional Neural Networks (CNN) which were used by 10 systems, and Long Short Term Memory (LSTM) networks, used by 5 systems. Support Vector Machines (SVM) were the preferred non-DL method, used by 5 systems. One participant (Bf3R) opted for a combination of existing tools in Subtask 2. In Figure 1 and 2 we show an overview of the number of methods chosen by participants and the average results obtained by each family of methods for each subtask. The average was calculated on all submissions. The number of systems doesn't necessarily match the number of participants (some participants tested different methods). Most par-

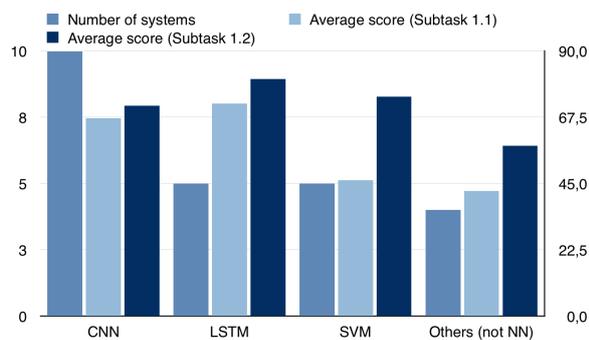

Figure 1: Popularity of methods chosen by participants (as number of systems that used the method, left) and average F1 score obtained for each method (right) in Subtask 1.1 and 1.2.

Participants exploited the possibility of aggregating training data from subtask 1.1 and subtask 1.2.

Word embeddings were used as features by the majority of systems (13 systems). Some participants chose to calculate the embeddings on domain-specific corpora, such as ACL (4 systems) and arXiv (3 systems), sometimes in combination with pre-trained embeddings. Pre-trained embeddings alone were used by a minority of participants, with TakeLab highlighting some problems in dealing with out-of-vocabulary words. Apart from the corpora dedicated to training the embeddings, participants didn't use external resources, with the exception of one system which employed VerbNet and two systems that used WordNet synonyms and hypernyms.

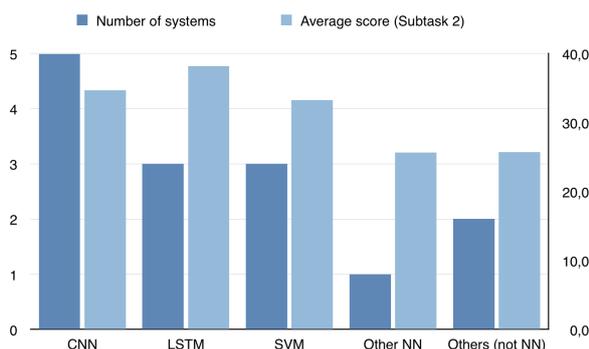

Figure 2: Popularity of methods chosen by participants (as number of systems that used the method, left) and average F1 score obtained for each method (right) in Subtask 2.

Among the chosen features, positional embeddings were quite popular (5 systems), to account for the relative position of the left and right entities.

Only three participants resorted to syntactic features, in particular dependency trees, despite their apparent relevance for the task.

SpaCy⁴ and CoreNLP⁵ were the most popular tools to analyze and preprocess text, with a slight preference for the first one (4 participants vs. 2).

6 Analysis of Results

6.1 Which processing step is the most difficult?

From the overall task results provided in the Appendix (Tables 5 – 8), it seems straightforward to conclude that the reliable identification of semantic relation instances is by far the most difficult step in the complete processing pipeline: Whereas systems reached an average F1 score of 47.28 in subtask 1.1 and 62.51 in subtask 1.2, performance scores drop rather sharply in scenario 2, namely to an average F1 of 30.8 for the extraction task and 20.34 for the extraction+classification task.

6.2 Which relation types are the most difficult to classify?

We examined whether there were relation types that were more difficult for the systems to classify, and whether it is possible to relate this to the semantics of the relations. For instance, the class MODEL-FEATURE is broad because it encompasses relatively different sub-classes: models, parts of models (such as a representation, a tag used for a word), or attributes (frequency of a phenomenon). To analyze this, we calculated the average recall by relation type over a sample of submissions to subtask 1.1 (70 submissions) and 1.2 (42 submissions) and the characteristic prediction error types by relation, if any (Table 2). We also calculated the average F1 score by relation type of the five top scoring systems from different participants (Tables 3 and 4).

Our analysis suggests that rather than the semantics of the relation types, it is their distribution in the data that poses difficulties. Class distribution is very imbalanced. Moreover, the distribution of classes in training and test data of subtask 1.1 and 1.2 is different. This difference is due to the nature of entities annotated automatically and those annotated manually. Because of the terminology extraction process and the resources that were used

MODEL-FEATURE	52%	USAGE, PART_WHOLE	175	75

Table 2: Relations: results and distribution.

for annotation, entities in subtask 1.2 are typically shorter terms with an intermediate level of specificity. On the other hand, entities in the clean scenario are more complex and more specific to the NLP domain. For instance, the TOPIC relation is more frequent in 1.2 than in 1.1 because entities like "paper" or "article" were annotated by the automated process, but not in the manual annotation.

Another aspect is that certain classes are lexically less varied than others and this might well affect the "difficulty" of the classification task. For instance, the TOPIC class has the lowest type-token ratio of all classes in subtask 1.2⁶. This does not seem surprising. Neither does it seem surprising that in subtask 1.2, TOPIC has gained the best average recall (2) and the highest F1 score among the top-5 systems (4). TOPIC is also much more frequent in subtask 1.2 than in subtask 1.1 and this effect is one likely cause for the difference in performance achieved over subtasks 1.1 and 1.2.

Relation	Top 5 Average F1
USAGE	0.85
RESULT	0.75
PART_WHOLE	0.73
TOPIC	0.71
MODEL-FEATURE	0.69
COMPARE	0.59

Table 3: Relations: Task 1.1 average results top 5 systems.

6.3 The effects of entity annotation

Entity annotation has a demonstrable effect on system performance. As stated earlier, annotation decisions have direct consequences for the distribution of certain types in the data and thus influence measurable system performance.

⁶In this analysis, a tuple of two entities pertaining to a certain relation class was counted as a "type".

Relation	Top 5 Average F1
TOPIC	0.97
RESULT	0.91
USAGE	0.87
COMPARE	0.80
PART_WHOLE	0.80
MODEL-FEATURE	0.79

Table 4: Relations: Task 1.2 average results top 5 systems.

A maybe rather surprising result of this task is the difference in system performance for subtasks 1.1 and 1.2. While "clean" entities can, with some plausibility, be considered more useful for a potential human user of the extracted information, "noisy" entity annotations seem to be more machine-friendly. The difference in the distribution of the TOPIC relation between subtasks 1.1 and 1.2 has already been pointed out as one potential cause for this effect. Moreover, the complexity of clean entities in subtask 1.1 could also have contributed to the performance gap. Manually annotated entities, in most cases, are long noun phrases, whereas automatically annotated entities in subtask 1.2 are generally shorter, partial (and therefore less specific!) entity matches. This also means that more training examples are likely to be found for automatically annotated entities. Moreover, some instances of automatic annotations in subtask 1.2 included explicit verbal relation cues. These cues sometimes explicitly state the type of the semantic relation, but they were not annotated in subtask 1.1. Verbal cues (e. g. the well-known Hearst patterns (Hearst, 1992)) have typically been used in earlier work on relation classification and, in fact, several teams participating in the task describe recurrent verbal elements between relation arguments.

The role of the specialized lexicon in relation extraction and classification is a topic that de-

serves further exploration for the following reasons: Firstly, highly specialized, complex terminological units are the main units of knowledge representation in specialized domains. Secondly, task results clearly show that a careful handling of lexical information improves performance: many successful systems in the task used domain-specific training data. The only system that treated complete specialized entities as semantic units, UWNLP, ranked first in the relation extraction task. None of the systems participating in subtasks 1.1 or 2 used semantic class information available for annotated entities from ACL RD-TEC, although it may be hypothesized that this feature helps to generalize lexical instance information.

7 Conclusion and Future Work

We presented the setup and results of SemEval 2018 Task 7: Semantic relation extraction and classification in scientific papers. The task is divided into three subtasks: classification on clean data, classification on noisy data, and a combined extraction and classification scenario. We also presented the dataset used for the challenge: a subset of abstracts of published papers in the ACL Anthology Reference Corpus, annotated for domain specific entities and semantic relations.

32 participants submitted to one or more subtasks. The most popular methods include Convolutional Neural Networks and Long Short Term Memory networks, with word embedding based features, often calculated on domain-specific corpora. Although it was allowed, only a minority of the participants used external knowledge resources. The results show that while good results can be obtained on the supervised multi-class classification of relation instances, the extraction of such instances remains very challenging. Moreover, the quality and type of entity annotation also plays an important role in determining relation extraction and classification results.

Knowledge extraction from a special domain poses specific challenges, such as working with a smaller corpus, dealing with specialized vocabularies, and the scarcity of annotated data and available domain-specific resources. One of the important future directions is to explore domain adaptation techniques to address these issues.

Abstract

Reliably detecting relevant relations between entities in unstructured text is a valuable resource for knowledge extraction, which is why it has awakened significant interest in the field of Natural Language Processing. In this paper, we present a system for relation classification and extraction based on an ensemble of convolutional and recurrent neural networks that ranked first in 3 out of the 4 subtasks at SemEval 2018 Task 7. We provide detailed explanations and grounds for the design choices behind the most relevant features and analyze their importance.

1 Introduction and related work

One of the current challenges in analyzing unstructured data is to extract valuable knowledge by detecting the relevant entities and relations between them. The focus of SemEval 2018 Task 7 is on relation classification (assigning a type of relation to an entity pair - *Subtask 1*) and relation extraction (detecting the existence of a relation between two entities and determining its type - *Subtask 2*).

Moreover, the task distinguishes between relation classification on clean data (i.e.: manually annotated entities - *Subtask 1.1*) and noisy data (automatically annotated entities - *Subtask 1.2*). It addresses semantic relations from 6 categories, all of them specific to scientific literature. Relation instances are to be classified into one of the following classes: USAGE, RESULT, MODEL-FEATURE, PART-WHOLE, TOPIC, COMPARE, where the first five are asymmetrical relations and the last is order-independent (see Gábor et al. (2018) for a more detailed description of the task). Since the training data was provided by the task organizers, we focused on supervised methods for relation classification and extraction. Similar systems in the past have been based on Support Vector Machines (Uzuner et al., 2011; Minard et al.,

2011), Naïve Bayes (Zayaraz et al., 2015) and Conditional Random Fields (Sutton and McCallum, 2006). More recent approaches have experimented with neural network architectures (Socher et al., 2012; Fu et al., 2017), especially convolutional neural networks (CNNs) (Nguyen and Grishman, 2015; Lee et al., 2017) and recurrent neural networks (RNNs) based on LSTMs (Zheng et al., 2017; Peng et al., 2017). The system presented in this article builds upon the latest improvements in employing neural networks for relation classification and extraction. An overview of the most relevant features is shown on Figure 1.

2 Method

2.1 Neural architecture

Figure 2 shows the full architecture of our system. Its main component is an ensemble of CNNs and RNNs. The CNN architecture follows closely on (Kim, 2014; Collobert et al., 2011). It consists of

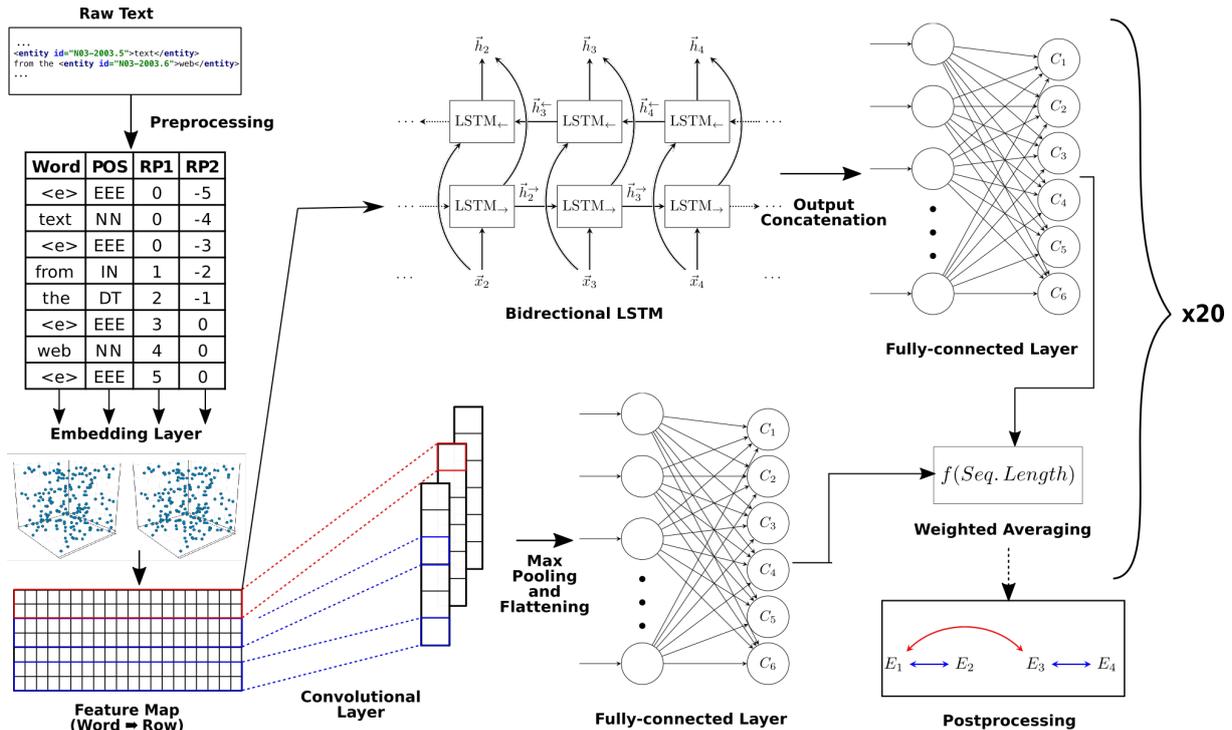

Figure 2: Full pipeline architecture

an initial embedding layer, which is followed by a convolutional layer with multiple filter widths and feature maps with a ReLU activation function, a max-pooling layer (applied over time) and a fully-connected layer, that is trained with dropout, and produces the output as logits, to which a softmax function is applied to obtain probabilities. The RNN consists of the same initial embedding layer, followed two LSTM-based sequence models (Hochreiter and Schmidhuber, 1997), one in the forward and one in the backward direction of the sequence, which are dynamic (i.e.: work seamlessly for varying sequence lengths). The output and final hidden states of the forward and backward networks are then concatenated to a single vector. Finally, a fully-connected layer, trained with dropout, connects this vector to the logit outputs, to which a softmax function is applied analogously to obtain probabilities.

The complete architecture was replicated and trained independently several times (see Table 2) using different random seeds that ensured distinct initial values, sample ordering, etc. in order to form an ensemble of classifiers, whose output probabilities were averaged to obtain the final probabilities for each class. We analyzed and tried several deeper and more complex neural architectures, such as multiple stacked LSTMs (up to 4)

and models with 2 to 4 hidden layers, but they didn't achieve any significant improvements over the simpler models. Conclusively, the strategy that produced the best results consisted of adequately combining the individual predictions of the single models (see section 4).

2.2 Domain-specific word embeddings

We collected additional domain-specific data from scientific NLP papers to train word embeddings. All *ArXiv cs.CL* abstracts since 2010 (1 million tokens) and the *ACL ARC corpus* (90 million tokens; Bird et al. (2008)) were downloaded and preprocessed. We used *gensim* (Řehůřek and Sojka, 2010) to train word2vec embeddings on these two data sources, and additionally the sentences provided as training data for the SemEval task (in total: 91,304,581 tokens). We experimented with embeddings of 100, 200 and 300 dimensions, where 200 dimensions yielded the best performance for the task as shown in Figure 3.

2.3 Preprocessing

Cropping sentences Since the most relevant portion of text to determine the relation type is generally the one contained between and including the entities (Lee et al., 2017), we solely analyzed that part of the sentences and disregarded the surrounding words. For Subtask 2, we initially con-

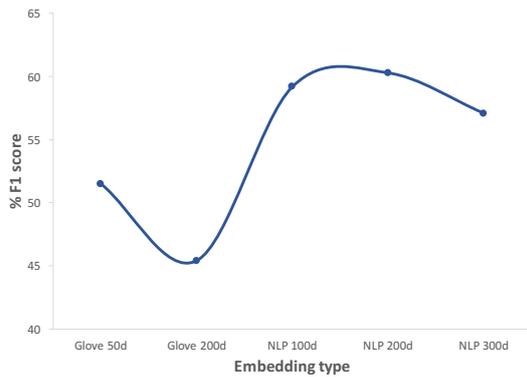

Figure 3: Effect of different word embedding types based on a simple CNN classifier for Subtask 1.1

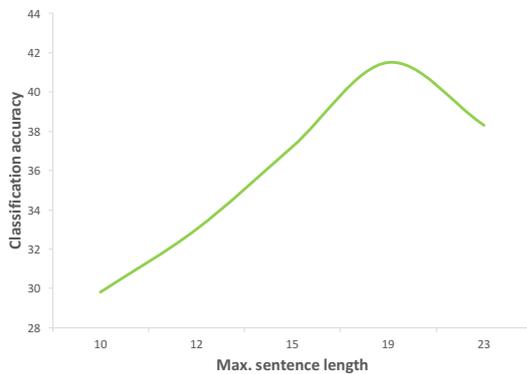

Figure 4: Effect of max. length threshold on accuracy for a preliminary RNN-based classifier

sidered every entity pair contained within a single sentence as having a potential relation. Since the probability that a relation between two entities exists drops very rapidly with increasing word distance between them (see Figure 5), we only considered sentences that didn't exceed a maximum length threshold (see Table 2) between entities to diminish the chances of predicting false positives in long sentences.

Various experiments with different thresholds between 7 and 23 words on the training set showed that the best results on sentences from scientific papers are achieved with a threshold of 19 words, as shown in Figure 4.

Cleaning sentences Some of the automatically annotated samples contained nested entities such as `<entity id="L08-1220.16"> signal <entity id="L08-1220.17"> processing </entity></entity>`. We flattened these structures into simple entities and considered all the entities separately for each train and test instance. Moreover, all tokens between brackets [] and parentheses () were deleted, and

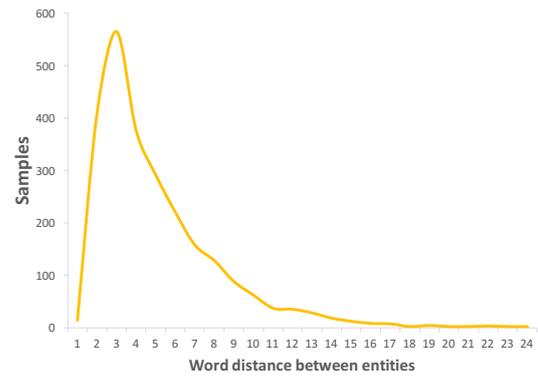

Figure 5: Word distance between entities in a relation for training data in Subtask 1.1

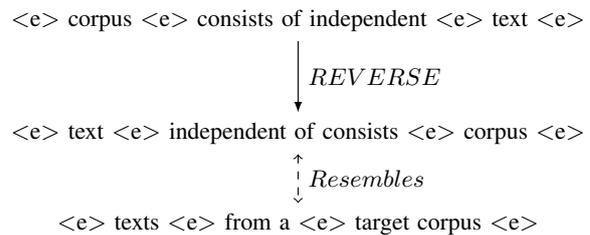

Figure 6: Example of a reversed sentence

the numbers that were not part of a proper noun replaced with a single wildcard token.

Using entity tags In order to provide the neural networks with explicit cues of where an entity started and ended, we used a single symbol, represented as an XML tag `<e>` before and after the entity, to indicate it (Dligach et al., 2017).

Relative order strategy & number of classes As mentioned in Section 1, 5 out of the 6 relation types are asymmetrical and the tagging is always done by using the same order for the entities as the one found in the abstracts' text/title. For that reason, it was important to carefully devise a schema that allowed generalization by exploiting the information from both ordered and reversed (words that will be treated here as antonyms) relations. Apart from using the relative position embeddings presented by Lee et al. (2017), for Subtask 1, we incorporated a full text reversal of those sentences in which a reverse relation was present, both at training and testing time. The result were instances that, although not corresponding to a valid English grammar, frequently resembled more in structure to their ordered counterparts. This has been illustrated by an example of two instances belonging to the *PART-WHOLE* class in Figure 6.

Thus, the system could operate by using only the 6 originally specified relation types and merely learn how to identify ordered relations, rather than having to handle the two different types of patterns or to add extra classes to describe both the ordered and the reversed versions of each class, which helped improve the overall accuracy of the classifier (+2.0% F_1).

For Subtask 2, since no information regarding the ordering of the arguments was available (the extraction and the ordering were part of the task), we opted for a 12-class strategy: one for each of the 5 ordered and reversed relations, plus the symmetrical relation (COMPARE) and a NONE class for the negative instances, i.e.: those that didn't contain any relation at all. An alternative 6-class approach based on presenting the sentences both ordered and reversed to the network, computing two predictions for each and afterwards consolidating both did not produce good results (-3.4% F_1).

Part-of-speech tags We used the Stanford CoreNLP tagger (Manning et al., 2014) to obtain POS tags for each word in every sentence in the dataset and trained high-dimensional embeddings for the 36 possible tags defined by the Penn Treebank Project (Marcus et al., 1993). Moreover, the XML tags to identify the entities and the number wildcard received their own corresponding artificial POS tag embedding (see Figure 2 for a detailed example).

3 Experiments

3.1 Exploiting provided data

One of the main challenges of the task was the limited size of the training set, which is a common drawback for many supervised novel machine learning tasks. To overcome it, we combined the provided datasets¹ for Subtask 1.1 and 1.2 to train the models for both Subtasks (+6.2% F_1). Furthermore, we leveraged the predictions of our system for Subtasks 1.1 and 1.2 and added them as training data for Subtask 2 (+3.6% F_1).

3.2 Generating additional data

Due to the limited number of training sentences provided, we explored the following approach to augment the data: We generated automatically-tagged artificial training samples for Subtask 1 by combining the entities that appeared in the test

data with the text between entities and relation labels of those from the training set (see Table 1). To evaluate the quality of the sentences and augment our data only with sensible instances, we estimated an NLP language model using the KenLM Language Model Toolkit (Heafield, 2011) on the corpus of NLP-related text described in Section 2.2 and evaluated the generated sentences with it. Furthermore, we set a minimum threshold of 5 words for the length of the text between entities, limited the number of sentences generated from each of them to a single instance in order to promote variety, and only kept those sentences that score a very high probability (-21 in log scale) against the language model. This process yielded 61 additional samples on the development set (+0.7% F_1).

3.3 Parameter optimization

To determine the optimal tuning for our richly parameterized models, we ran a grid search over the parameter space for those parameters that were part of our automatic pipeline. The final values and evaluated ranges are specified in Table 2.

3.4 Defining the objective

The cross-entropy loss, defined as the cross-entropy between the probability distribution outputted by the classifier and the one implied by the correct prediction is one of the most widely used objectives for training neural networks for classification problems (Janocha and Czarnecki, 2017). A shortcoming of this approach is that the cross-entropy loss usually only constitutes a conveniently decomposable proxy for what the ultimate goal of the optimization is (Eban et al., 2017): in this case, the macro-averaged F_1 score. Motivated by the fact that individual instances of infrequent classes have a bigger impact on the final F_1 score than those of more frequent ones (Manning et al., 2008), we opted for a weighted version of the cross-entropy as loss function, where each class had a weight w that was inversely proportional to their frequency in the training set:

$$w_{class\ i} = \frac{\sum_j \#_{class\ j}}{N_{classes} * \#_{class\ i}}$$

where $\#$ indicates the count for a certain class and $N_{classes}$ is the total number of classes.

The weights are scaled as to preserve the expected value of the factor k_i that accompanies the logarithm in the mathematical expression of the loss

Number of epochs (Subtask 2)	10	5-40
Ensemble size	20	1-30
Training batch size	64	32-192
Upsampling ratio (only Subtask 2)	1.0	0.0-5.0
Max. sentence length (only subtask 2)	19	7-23

Table 2: Final parameter values and their explored ranges

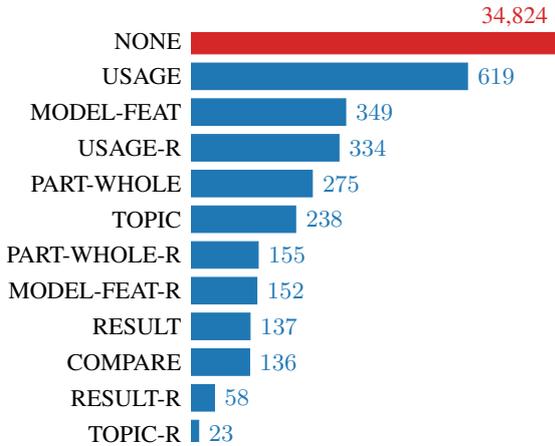

Figure 7: Class frequencies for Subtask 2

formula: $L = -\sum k_i \log(y_i)$, which is equal to wy'_i for the weighted cross-entropy and y'_i for the unweighted version, where $y'_i = 1$ for the correct class and y_i is the predicted probability for that class. Illustrating this concept, it can be observed that a single instance of class *TOPIC* (support of only 6 instances) could account for up to 2.8% of the final score on the test set. This function proved to be a better surrogate for the global final score than the standard cross-entropy (+1.6% F_1).

3.5 Upsampling

One of the challenges of our approach for Subtask 2 was the existence of a large imbalance between the target classes. Namely, the NONE class constituted the clear majority (Figure 7). To overcome it, we resorted to an upsampling scheme for which we defined an arbitrary ratio of positive to negative examples to present to the networks for the combination of all positive classes (+12.2% F_1).

4 Training and validating the model

The neural networks were trained using an Adam optimizer with parameter values $\beta_2 = 0.9$, $\beta_1 = 0.999$, $\epsilon = 1e - 08$ (suggested default values in the TensorFlow library (Abadi et al., 2015)) with a step learning rate decay scheme on top of it. This consisted in halving the learning rate every 25 and 1 iterations through the whole dataset for Subtasks 1 and 2 respectively (note: the size of the upsampled dataset for Subtask 2 was about 25 times that of Subtask 1), starting from the initial value determined in Section 3.3. In order to avoid overfitting the development set of each Subtask, we evaluated the quality of our models by applying a 5-fold cross-validation on the combined training data of Subtasks 1.1 and 1.2 and on the training data of Subtask 2.

Combining predictions During the development, we observed that similar F_1 scores could be achieved by using either a convolutional neural network or a recurrent one separately, but the combination of both outperformed the individual models. Moreover, since the RNN-based architecture had a tendency to obtain better results than its CNN-based counterpart for long sequences, we combined both predictions in such a way that a higher weight was assigned to the RNN predictions for longer sentences by applying:

$w_{rnn,i} = 0.5 + \text{sign}(s_i) \cdot s_i^2$, where

$$s_i = \frac{\text{length}_i - \min_j(\text{length}_j)}{\max_j(\text{length}_j) - \min_j(\text{length}_j)} - 0.5$$

and length_i is the length of the i -th sentence.

Post-processing To enforce consistency with the text annotation scheme, some rules that were not built into the system had to be applied ex-post. First, predictions of reversed relations should not be of type COMPARE, since it is the only symmetrical relation. When this condition occurred, we simply predicted the class that had the 2nd highest probability. Second, each entity could only be part of one relation. To address this for Subtask 2, we run a conflict-solving algorithm that, in case of overlaps, always preferred short relations (cf. Figure 3)) and broke ties by choosing the relation with the most frequent class in the training data and at random when it persisted.

5 Results

5.1 Feature analysis

We conducted a feature addition study to evaluate the impact of the most relevant features on the F_1 score of the 5-fold cross-validated training/development set of Subtasks 1.1 and 1.2.

The results have been previously shown in Figure 1. It can be observed from the plot that substantial gains can be obtained by applying standalone data manipulation techniques that are independent of the type of classifier used, such as combining the data of subtask 1.1 and 1.2 (*CSD* in Figure 1), reversing the sentences (*RS*), generating additional data (*GD*) and the pre-processing techniques from Section 2.3. Moreover, as in most machine learning problems, appropriately tuning the model hyperparameters also has a significant impact on the final score.

Subtask	P	R	F ₁
1.1	79.2	84.4	81.7
1.2	93.3	87.7	90.4
2.E	40.9	55.3	48.8
2.C	41.9	60.0	49.3

Table 3: Precision (P), recall (R) and F_1 -score (F₁) in % on the test set by Subtask

Relation type	P	R	F ₁
COMPARE	100.00	95.24	97.56
MODEL-FEATURE	71.01	74.24	72.59
PART-WHOLE	78.87	80.00	79.43
RESULT	87.50	70.00	77.78
TOPIC	50.00	100.00	66.67
USAGE	87.86	86.86	87.36
Micro-averaged total	82.82	82.82	82.82
Macro-averaged total	79.21	84.39	81.72

Table 4: Detailed results (Precision (P), recall (R) and F_1 -score (F₁)) in % for each relation type on the test set for Subtask 1.1

5.2 Final results

After presenting and analyzing the impact of each system feature separately, we show the overall results in this section. The final results on the official test set are presented on Table 3, ranking 1st in Subtasks 1.1, 1.2 and Subtask 2.C (joint result of classification and extraction) and 2nd for 2.E (relation extraction only). Furthermore, Table 4 shows the differences in performance between relation types for Subtask 1.1.

6 Conclusion

In this article we presented the winning system of SemEval 2018 Task 7 for relation classification, which also achieved the 2nd place for the relation extraction scenario. Our system, based on an ensemble of CNNs and RNNs, ranked first on 3 out of the 4 Subtasks (relation classification on clean and noisy data, and relation extraction and classification on clean data combined). We have tested various approaches to improve the system such as generating more additional training samples and experimenting with different order strategies for asymmetrical relation types. We demonstrated the effectiveness of preprocessing the samples by taking into account their length, marking the entities with explicit tags, defining an adequate surrogate optimization objective and combining effectively the outputs of several different models.

Abstract

This paper describes the SemEval 2018 shared task on semantic extraction from cybersecurity reports, which is introduced for the first time as a shared task on SemEval. This task comprises four SubTasks done incrementally to predict the characteristics of a specific malware using cybersecurity reports. To the best of our knowledge, we introduce the world's largest publicly available dataset of annotated malware reports in this task. This task received in total 18 submissions from 9 participating teams.

1 Introduction

As a result of the world getting more connected and digitized, cyber attacks become increasingly common and pose serious issues for the society. More recently in 2017, a ransomware called WannaCry, which has the capability to lock down the data files using strong encryption, spread around the world targeting public utilities and large corporations (Mohurle and Patil, 2017). Another example is the botnet known as Mirai, which used infected Internet of Things (IoT) devices to disable Internet access for millions of users in the US West Coast (US-CERT, 2016) through large-scale Distributed Denial of Service (DDoS) attacks. The impact levels of these attacks is ranging from simple ransomware on personal laptops (Andronio et al., 2015) to taking over the control of moving cars (Checkoway et al., 2011).

Along with the importance of cybersecurity in today's context, there is an increasing potential for substantial contribution in cybersecurity using natural language processing (NLP) techniques, even though this has not been significantly addressed. We introduced this task as a shared task on SemEval for the first time with the intention of motivating NLP researchers for this critical research

Figure 1: Annotated sentence and sentence fragment from MalwareTextDB. Such annotations provide semantic-level information to the text.

area. Even though there exists a large repository of malware related texts online, the sheer volume and diversity of these texts make it difficult for NLP researchers to quickly move to this research field. Another challenge is that most of the data is unannotated. Lim et al. (2017) has introduced a dataset of annotated malware reports for facilitating future NLP work in cybersecurity. In the light of that, we improved Lim's malware dataset to create, to the best of our knowledge, the world's largest publicly available dataset of annotated malware reports. The aim of our annotation is to mark the words and phrases in malware reports that describe the behaviour and capabilities of the malware and assign them to some certain categories.

Most of the machine learning efforts in the task of malware detection were based on the system calls. Rieck et al. (2011) and Alazab et al. (2010) proposed models using machine learning techniques for detecting and classifying malware through system calls. Previously, our group has proposed models to predict a malware's signatures based on the text describing the malware (Lim et al., 2017). We defined the same SubTasks mentioned in this paper and used the proposed models as the standard baselines for the shared task. This shared task is hosted on CodaLab¹.

The remainder of this paper is organized as

¹<https://competitions.codalab.org/competitions/17262>

follows: the information regarding the annotated dataset and its statistics, together with the Sub-Tasks are described in Section 2. Information about the evaluation measures and the baselines is described in Section 3. Different approaches used by the participants are described in Section 4. The evaluation scores of the participating systems and rankings are presented and discussed in Section 5. Finally, the paper concludes with an overall assessment of the task.

2 Data description and Task Definition

In this shared task we expanded upon our previous work, MalwareTextDB (Lim et al., 2017), which was published in ACL 2017. In this paper, we initiated a framework for annotating malware reports and annotated 39 Advanced Persistent Threat (APT) reports (containing 6,819 sentences) with attribute labels from the Malware Attribute Enumeration and Characterization (MAEC) vocabulary (Kirillov et al., 2010). An example of such annotation is shown in Figure 1. During this shared task, we have further annotated 46 APT reports (6,099 sentences), bringing the total number of annotated APT reports to 85 (12,918 sentences). We continue to follow our annotation procedure from the paper, which we will describe in the following subsection.

2.1 Annotation Procedure

This subsection contains the explanation of our annotation procedure.

2.1.1 Data Collection

The APT reports in our dataset are taken from APTnotes, a GitHub repository of publicly-released reports related to APT groups (Blanda, 2016). It provides a constant source of APT reports for annotations with consistent updates. At the time this paper was written, the repository contains 488 reports. We have chosen 85 reports from year 2014 and 2015 for annotation.

We consulted the cybersecurity team from DSO National Laboratories² when selecting the APT reports in order to ensure that the preliminary dataset will be relevant for the cybersecurity community.

2.1.2 Preprocessing

The APT reports from APTnotes are in PDF format, hence we used the PDFMiner tool

²<https://www.dso.org.sg/>

(Shinyama, 2004) to convert the PDF files into plaintext format. We also manually removed the non-sentences, such as the cover page or document header and footer, before the annotation. Hence only complete sentences were considered for subsequent steps.

2.1.3 Annotation

The annotation was performed using the Brat Rapid Annotation Tool (Stenetorp et al., 2012). In this annotation, our aim is to mark the words and phrases that describe malware behaviors and map them to the relevant *attribute labels*, which are the labels we extracted from the MAEC vocabulary. There are a total of 444 attribute labels, consisting of 211 *ActionName* labels, 20 *Capability* labels, 65 *StrategicObjectives* labels and 148 *TacticalObjectives* labels. The annotation was performed by a team of research assistants and student interns. The annotation work done by the student interns was further reviewed by the research assistants to ensure the quality.

The annotation was performed in three main stages:

2.1.4 Stage 1 - Token Labels

The first stage involves annotating the text with the following *token labels*, illustrated in Figure 2:

Action This refers to an event, such as “*implements*”, “*deploy*”, and “*transferred*”.

Subject This refers to the initiator of the Action such as “*Babar*” and “*they*”.

Object This refers to the recipient of the Action such as “*an obfuscation technique*”, “*the data*”, and “*privilege escalation tools*”; it also refers to word phrases that provide elaboration on the Action such as “*hide certain API names*” and “*external FTP servers*”.

Modifier This refers to the tokens that link to other word phrases that provide elaboration on the Action such as “*to*”.

This stage helps to identify word phrases that are relevant to the MAEC vocabulary.

2.1.5 Stage 2 - Relation Labels

The second stage involves annotating the text with the following *relation labels*:

SubjAction links an Action with its relevant Subject.

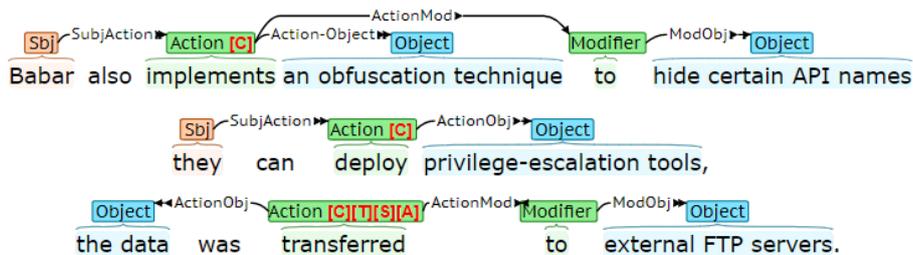

Figure 2: Examples of annotated sentences.

The myth of Babar has been around for a while in the intelligence community.

The drawing of personal educated conclusions is left as an exercise for the interested reader.

Figure 3: Examples of irrelevant sentences.

ActionObj links an Action with its relevant Object.

ActionMod links an Action with its relevant Modifier.

ModObj links a Modifier with the Object that provides elaboration.

This stage indicates the links between the labeled tokens. Such annotations are important in cases where an Action has more than one Subjects, Objects or Modifiers. The illustration on how the relation label links token labels is shown in Figure 2.

2.1.6 Stage 3 - Attribute Labels

The third stage involves annotating the text with the *attribute labels* extracted from the MAEC vocabulary. We decided to annotate the attribute labels onto the Action tokens tagged in the first stage. This is because Action is usually the main indicator of the malware's behaviour. This scheme requires each Action token to be annotated with at least one attribute label.

The attribute labels are categorized into four classes: ActionName, Capability, StrategicObjectives and TacticalObjectives. These classes describe different kinds of actions and capabilities of the malware.

2.1.7 Irrelevant Sentences

The document also contains sentences that provide no indication of malware action or capability. We call these sentences *irrelevant sentences* and do not annotate them. Examples of such sentences

can be seen in Figure 3.

2.1.8 Annotation Challenges

We took a portion of the dataset and calculated the agreement for the token labels annotation based on Cohen's kappa (Cohen, 1960). The agreement between annotators is quite low at 0.36, suggesting that this is a difficult task. The main challenges the annotators faced are:

Multiple ways of annotating the same sentence

There might be multiple ways of annotating the same sentence that are equally valid. An example of this is demonstrated in Figure 4. Both annotations highlight the malware ability to *conduct profiling*.

Large amount of annotation labels

There are 444 attribute labels and it is very challenging for the annotators to remember all of them. There are also some attribute labels that are very similar to each other, such as *ActionName 084: load library* and *ActionName 119: map library into process*.

Required special domain knowledge

The annotation requires the annotator to have some cybersecurity domain knowledge. For example, given the phrase "*conduct profiling*", the annotator must be able to classify it as *Capability 015: probing*.

2.2 SubTask Description

We focus on the evaluations for the following 4 different SubTasks, which are formulated as follows:

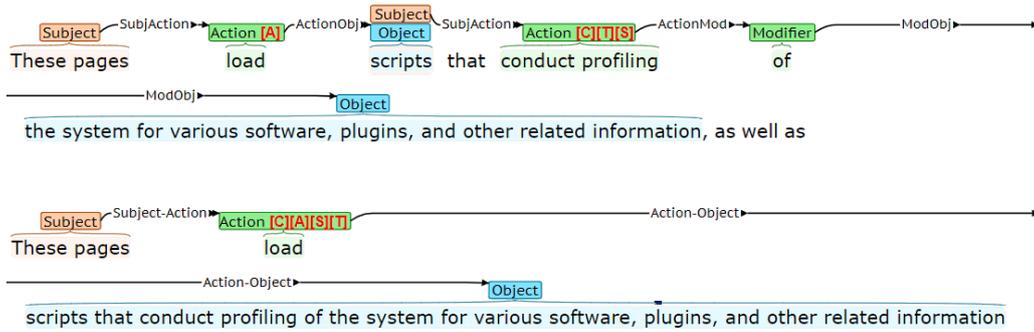

Figure 4: Two different ways of annotating an example sentence.

- SubTask 1: Classify relevant sentences for inferring malware actions and capabilities
- SubTask 2: Predict token labels for a malware related text
- SubTask 3: Predict relation labels between tokens for a malware-related text
- SubTask 4: Predict attribute labels for a malware-related text

In SubTask 1, participants were asked to solve the challenge of sifting out critical sentences from lengthy malware reports and articles. This is modeled as a binary classification task, where each sentence had to be labeled as either relevant or irrelevant. The participants are provided with a list of sentences.

In SubTask2, special tokens in a relevant sentence had to be identified and labeled with one of the following *token labels* (examples are taken from Figure 2):

- **Action** This refers to an event, such as “implements”, “deploys”, and “transferred”.
- **Entity** This refers to the initiator of the Action such as “Babar” and “They” or the recipient of the Action such as “an obfuscation technique”, “privilege-escalation tools”, and “the data”; it also refers to word phrases that provide elaboration on the Action such as “hide certain API names” and “external FTP servers”.
- **Modifier** This refers to tokens that link to other word phrases that provide elaboration on the Action such as “to”.

	#Documents	#Sentences
Train	65	9,424
Dev	5	1,213
SubTask1,2 test	5	618
SubTask3 test	5	668
SubTask4 test	5	995
Total	85	12,918

Table 1: Statistics of the MalwareTextDBv2.0.

The formulation is similar to the *token labels* in section 2.1.4. The only difference is the Entity label, which is a combination of the Subject and Object labels. This is to accommodate cases where a single word-phrase is annotated as both the initiator and the recipient of an Action (as seen in Figure 5). This SubTask uses the same list of sentences used in SubTask 1.

In SubTask 3, participants were asked to identify the relation between the tokens. We decided to provide the gold labels for the tokens here due to the low performance of our initial models on SubTask 2. The relation labels are as we described in section 2.1.5.

In SubTask 4, participants were asked to label each action token with the corresponding attribute label(s). In our ACL paper, we did the evaluation on token groups (a set of token labels connected by relation labels) instead of action tokens. However, we decided to evaluate on action tokens in order to encourage the participants to make use of the surrounding context, not limiting themselves just to the tokens in the token group. We also provided the gold labels for the token and relation labels here, following the same consideration as we described for SubTask 3.

In our ACL paper, we also had the experiments

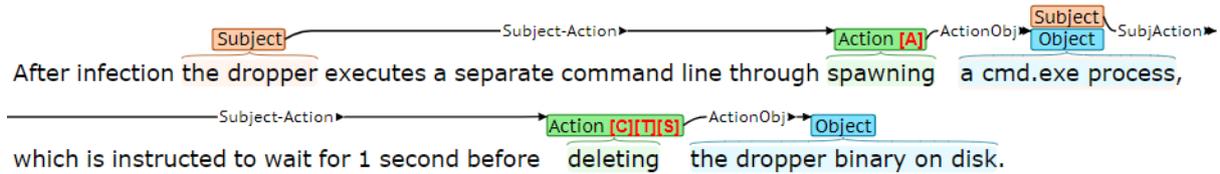

Figure 5: An example of a token (a cmd.exe process) labelled as both Subject and Object. In the first case, it is the recipient of the Action spawning, while in the latter case, it is the initiator of the Action deleting.

	#Relevant	#Irrelevant	#Sentences
Train	2,204	7,220	9,424
Dev	79	1,134	1,213
Test	90	528	618

Table 2: Data distribution of SubTask 1.

on predicting the malware signatures for each document. The list of malware signatures are taken from Cuckoo Sandbox³. We excluded such an evaluation at this stage as precise information like malware signatures might be easily obtained from external resources such as malware information websites.

2.3 Data Statistics

We decided to call the dataset we used for this shared task MalwareTextDBv2.0⁴, which has twice the number of documents compared to MalwareTextDB. The total statistics are shown in Table 1. The training data for this shared task contains 9,424 sentences, the dev set contains 1,213 sentences, and each test set has various amount of sentences. SubTask 1 and 2 share the same test set, while SubTask 3 and 4 use different test sets. This is because the gold labels from the previous annotation stages are provided for SubTask 3 and 4.

The data distribution for SubTask 1, 2, 3, and 4 can be seen in Table 2, 3, 4, and 5 respectively.

We can see from the distribution of SubTask 1 that the dataset mostly contains *irrelevant* sentences. This shows the importance of SubTask 1 in which the participants filter out the *irrelevant* sentences. Our preliminary result in the ACL paper also shows that removing the *irrelevant* sentences can improve the score for SubTask 2.

From the distribution of SubTask 2, an interesting observation is that the number of *Entity* tokens is roughly double the number of *Action* tokens.

³<https://cuckoosandbox.org/>

⁴<http://www.statnlp.org/research/resources>

This is quite intuitive since *Entity* token refers to either *Subject* or *Object* token and an *Action* usually has one *Subject* and one *Object*.

In the distribution table for SubTask 3, we can observe that the number of *ActionMod* is roughly the same as the number of *ModObj*. This is in-line with our observation that a *Modifier* is usually connected to an *Action* and an *Object*.

For SubTask 4, we can see that the *Capability* attribute class has the highest count in the dataset. This is also the category that has the least amount of unique labels (with only 20 different labels). On the other hand, *ActionName* class appears the least in the dataset but has the highest number of unique labels (with 211 different labels).

3 Evaluation Measures and Baselines

Our baseline and evaluation measures follow our ACL paper (Lim et al., 2017). We used F1 score for the evaluation metric for all the SubTasks. Simple baselines were utilized, such as linear support vector machines (SVM) and multinomial Naive Bayes (NB) implementation from the scikit-learn library (Pedregosa et al., 2011). For the conditional random fields (CRF) (Lafferty et al., 2001) models, we used the CRF++ implementation (Kudo, 2005). For the feature extraction, we used spaCy⁵ to extract the part-of-speech (POS) features and a C++ implementation (Liang, 2005) of the Brown clustering algorithm.

For SubTask 1, our baseline models are the SVM and NB baselines with bag-of-words features. We also performed some hyper-parameter tuning based on the development set. Other simple baselines, such as random uniform and stratified, are also included as a comparison.

For SubTask 2, we used the CRF baseline with unigrams, bigrams, POS, and Brown clustering features (Brown et al., 1992). CRF model was trained only on the malware related sentences in

⁵<https://spacy.io/>

Test	34	88	70	64	256

Table 5: Data distribution of SubTask 4.

the training set. The Brown clustering features for words were trained on the 84 additional unannotated APT reports provided with the training materials.

For SubTask 3, a simple rule-based model was utilized. The rules are listed in the Appendix section of our ACL paper. They consist of simple rules, such as connecting a *Modifier* token to the nearest *Action* token with *ActionMod* relation.

Finally, for SubTask 4, we trained SVM and NB model with bag-of-words features. The features for SubTask 4 are extracted from token groups, which are the set of tokens connected via relation labels. In creating the token groups, we only traverse the direction of Action \rightarrow Subj, Action \rightarrow Mod, Action \rightarrow Obj, and Mod \rightarrow Obj. This will prevent multiple *Action* tokens from having the same token group when they are connected to a common *Subject* or *Modifier*.

4 Participants

We received 18 submissions from 9 different teams; 9 submissions to SubTask 1, 8 submissions to SubTask 2, and 1 submission to SubTask 4. Unfortunately, none of the teams submitted to SubTask 3. Participants generally submitted to both SubTask 1 and 2. Here is the list of the participants who submitted a system description paper together with a brief summary of the method they used:

Villani (Loyola et al., 2018) submitted only to SubTask 1. They used word-embeddings initialized using Glove vectors (Pennington et al., 2014) trained on Wikipedia text to represent the tokens. In addition to that, they also used an LSTM to get another token representation from the characters. After that, they trained a binary classifier using Bi-directional Long Short-Term Memory network (BiLSTM) (Graves et al., 2013). They made use of attention mechanism (Luong et al., 2015) to weigh the importance of the tokens.

Flytxt_NTNU (Sikdar et al., 2018) submitted to both SubTask 1 and SubTask 2. They constructed an ensemble of CRF and NB classifiers for SubTask 1. The CRF model used lexical-based and context-based features. The same CRF model was also used to predict the answers for SubTask 2. If the CRF predicts any token labels for the sentence, the sentence is considered relevant in SubTask 1. They did SubTask 2 in 2 steps. First, they detect whether a token is either an *Action*, *Entity*, or *Modifier* (Mention identification). After that, they classify the tokens into one of the three types (Token identification).

DM_NLP (Ma et al., 2018) also submitted to

SubTask 1 and 2, but focuses on SubTask 2 and just used the predicted output labels from SubTask 2 to get the predictions for SubTask 1. They model this task as a sequence labeling task and used a hybrid approach with BiLSTM-CNN-CRF following the method of [Ma and Hovy \(2016\)](#). The CNN layer was used to extract char-level feature representation. They then added other features, such as POS, dependency labels, chunk labels, NER labels, and brown clustering labels as the input to BiLSTM layer. They also made use of word-embeddings, pre-trained using unlabeled data. The output of the BiLSTM layer is then fed into a CRF layer that makes the entity label prediction.

HCCL ([Fu et al., 2018](#)) submitted to SubTask 1 and 2. They performed a very similar approach to team DM_NLP using the same BiLSTM-CNN-CRF architecture. The main difference is that they just used POS features, instead of the more complicated linguistic features used by team DM_NLP. They aim to build an end-to-end system that does not require any feature engineering or data preprocessing. Their output for SubTask 1 was also generated from their predictions for SubTask 2.

Digital Operatives ([Brew, 2018](#)) participated in SubTask 1 and 2. They utilized a passive aggressive classifier ([Crammer et al., 2006](#)), which has similar cost and performance with the linear SVM classifier, for SubTask 1. The features they used include POS, lemma, dependency links, and bigrams. For SubTask 2, they implemented a linear CRF approach using a window of words and POS tags surrounding the focus token as features.

TeamDL ([R et al., 2018](#)) made the submissions for SubTask 1 and 2. For SubTask 1, they built a convolutional neural network with original glove embeddings. Their model followed the work of [Kim \(2014\)](#). They also used a CRF for SubTask 2 with features like N-grams ($N \in \{1, 2, \dots, 6\}$), POS tags, word lemmas, word shape features, etc. In order to tackle unknown malware entities, they used additional set of features taken from malware

documents from the web and the training corpus.

UMBC ([Padia et al., 2018](#)) participated in SubTask 1, 2 and 4. They are the only team participated in SubTask 4. They used a Multi-Layer Perceptron model for the submission of SubTask 1. After the submission deadline, they have explored other methods for SubTask 1 like LSTM. For SubTask 2, they used a CRF model with features similar to TeamDL. The main difference is that their model had less features compared to TeamDL's model. For SubTask 4, they mainly focused on learning better word embedding features. They developed an Annotation Word Embedding (AWE) model that is capable of incorporating domain-specific knowledge to the embeddings.

5 Results and Discussion

5.1 SubTask 1 Results

Table 6 shows the scores of the submissions to SubTask 1. We also added the precision, recall, and accuracy scores as additional metrics. All 9 participating teams submitted to SubTask 1. This might be because SubTask 1 is the simplest and can be done as a by-product of doing SubTask 2. We can see that by guessing randomly we get an F1 score of 25.06%. However, this does not mean that this SubTask is not challenging as we can see that the scores of top systems are far from perfect. We submitted the NB baseline result in the competition page since it achieved a better performance compared to the SVM baseline in the development data.

Most of the teams used neural network models to tackle this task, which were shown to perform quite well. However, approaches using classifiers such as naive Bayes are still competitive. Team Villani achieved the best F1 score of 57.14% using a neural approach and Flytxt_NTNU reached the second place with an F1 score of 56.87% using an ensemble of naive Bayes and CRF approach.

Some of the teams utilized their results from SubTask 2 to generate predictions for SubTask 1. This method seems to have performed quite well too, with 3 of the top-5 teams using it. Flytxt_NTNU is notable for combining this method with a naive Bayes approach as an ensemble system.

	Prec	Recall	F1	Acc
<i>Our baselines</i>				
Our SVM baseline	49.55	62.22	55.17	80.58
Our NB baseline	38.17	78.89	51.45	78.32
Random uniform baseline	16.09	56.67	25.06	50.65
Random stratified baseline	11.45	16.67	13.57	69.09
<i>Participants Outputs</i>				
Villani	47.76	71.11	57.14	84.47
Flytxt_NTNU	49.59	66.67	56.87	85.28
DM_NLP	39.43	76.67	52.08	79.45
HCCL	53.57	50.00	51.72	86.41
Digital Operatives	39.31	75.56	51.71	79.45
TeamDL	38.46	72.22	50.19	79.13
NLP_Foundation	36.13	76.67	49.11	76.86
UMBC	11.14	43.33	17.73	41.42
NanshanNLP	13.56	17.78	15.38	71.52

Table 6: SubTask 1 results sorted by F1 score, the highest score in each column from the baselines and the participants outputs are marked in **bold**.

5.2 SubTask 2 Results

The scores of the submissions for SubTask 2 are shown in Table 7. This task attracted 8 teams and 4 teams were able to outperform our baseline which is a CRF model with unigrams, bigrams, POS, and Brown clustering features. Though all participants have used the CRF model as the final layer of their models, 3 teams used neural architectures like Bi-LSTM and CNN-BiRNN architectures to generate better embeddings for the features.

Team DM_NLP achieved the best F1 score of 29.23%. In addition, we considered a relaxed scoring scheme where predictions are scored at token level instead of phrase level to give credit to the model when the span for a predicted label intersects with the span for the actual label. The model from team DM_NLP still achieved the highest F1 score of 39.18% under this scoring scheme. Team HCCL showed significant improvement in their scores for the relaxed scoring schemes for their model based on CNN-BiRNN-CRF architecture.

5.3 SubTask 3 Results

The results of our baselines for SubTask 3 can be seen in Table 8. As we mentioned in an earlier section, no participant submitted to this SubTask. From our baselines, we can see that this task cannot be done using random prediction. However, our rule-based method still works well on this new test set.

5.4 SubTask 4 Results

We summarized the results for SubTask 4 in Table 9. The main challenges to this SubTask are the data sparsity and the number of attribute labels. The only participant who submitted to this SubTask is from team UMBC. They used a domain-specific word embedding model trained on APT reports and their automatically generated text annotations to train an SVM classifier.

6 Conclusion and Future Work

In this work, we have presented the results of SemEval 2018 shared task on Semantic Extraction from CybersecUrity REports using Natural Language Processing (SecureNLP). This new SemEval task attracted 9 participating teams with 18 submissions. We have provided a new dataset on annotated malware report and also the evaluation criteria for the 4 SubTasks that we proposed. We also described the methods that the participants used to tackle this shared task. We hope that this shared task can spark the interest of the research community to use NLP techniques for cybersecurity purposes.

The participants have improved the state-of-the-art results for SubTask 1 and 2. They explored many interesting methods to tackle the SubTasks that we proposed. Since the post evaluation phase is still ongoing on the competition website, hopefully other people will be interested in testing their models.

Acknowledgments

We would like to thank all the teams who participated in this shared task. Special mention to Chris Brew and Arpita Roy for their valuable feedback. We also thank the authors of the ACL 2017 paper: Swee Kiat Lim, Aldrian Obaja Muis for doing the initial work, and Chen Hui Ong from DSO for her feedback during the annotation.

Abstract

This paper describes our submissions for SemEval-2018 Task 8: Semantic Extraction from CybersecUrity REports using NLP. The DM_NLP participated in two subtasks: SubTask 1 classifies if a sentence is useful for inferring malware actions and capabilities, and SubTask 2 predicts token labels ("Action", "Entity", "Modifier" and "Others") for a given malware-related sentence. Since we leverage results of Subtask 2 directly to infer the result of Subtask 1, the paper focus on the system solving Subtask 2. By taking Subtask 2 as a sequence labeling task, our system relies on a recurrent neural network named BiLSTM-CNN-CRF with rich linguistic features, such as POS tags, dependency parsing labels, chunking labels, NER labels, Brown clustering. Our system achieved the highest F1 score in both token level and phrase level.

1 Introduction

As a growing number of mobile devices and facilities are getting connected and digitized, malware attacks become increasingly rampant and dangerous. CybersecUrity attracts more public attention but few NLP research and efforts. A large number of malware-related texts is available online, such as malware reports and relevant blogs (DiMaggio, 2015). However due to the sheer volume and diversity of these texts, NLP researchers encounter problems to obtain valuable information, such as the specific actions taken by a certain malware and the capabilities described. Therefore, automatic screening malware-related contents and labeling every token of the contents become potential applications of NLP and have drawn growing research interests.

In order to create a database in CybersecUrity domain which helps researchers to parse malware-related texts, the organizers of SemEval 2018 Task

8 (Phandi et al., 2018) (Lim et al., 2017) proposed the follow tasks:

1. **SubTask1:** Classify if a sentence is relevant for inferring malware actions and capabilities.
2. **SubTask2:** Predict token labels for a given malware-related text.
3. **SubTask3:** Predict relation labels for a given malware-related text.
4. **SubTask4:** Predict attribute labels for a given malware-related text.

However, due to lack of time, we decided to address only SubTask 1 and SubTask 2. In this paper, we describe the system that we submitted for the SemEval 2018 shared task. Our system is based on RNN network and ranked first in both token level and phrase level.

Most existing high performance sequence labeling methods are linear statistical models, such as HMM (Hidden Markov Models) (Eddy, 1996) and CRF (Conditional Random Fields) (Lafferty et al., 2001). In the past few years, neural networks have been widely used to solve NLP problems. Specially, several RNN-based neural networks have been proposed to handle sequence labeling tasks including Chinese word segmentation (Yao and Huang, 2016), POS tagging (Huang et al., 2015), NER (Chiu and Nichols, 2015) (Lample et al., 2016), which achieved outstanding performance against traditional methods.

In this paper, we simple derive the result of SubTask1 from SubTask2 and regard SubTask 2 as the preorder. Namely, our system firstly outputs sequence labels of a given sentence, and then checks whether some target labels turn out, such as Action, Entity, Modifier. Sentences which have

those target labels will be classified as malware-related one. Focusing on SubTask1, We propose a neural network architecture using a hybrid bidirectional LSTM and CNN architecture which takes character-level and word-level representations combined with rich linguistic features as input. Instead of decoding each label independently, we feed the output vectors of BiLSTM to a CRF layer. Experiments show the significant improvement of our system compared with baselines.

The remainder of this paper includes a detail description of our system in Section 2. Experiments and analysis of results are presented in Section 3. Finally, Section 4 draws a conclusion and Section 5 describes our future work.

2 System Overview

We treat Subtask 2 as a sequence labeling problem and design a neural network architecture with some hand-crafted features. Our system is mainly based on the BiLSTM-CNN-CRF model and apply model average strategy to avoid over-fitting problem.

2.1 Data Preprocessing

In order to exclude the noise from data provided by the organizers, we use a python program to correct spelling mistakes and unreadable characters. After that, in order to avoid data distribution problem, we mix the training set development set, and then shuffle and split them into five parts randomly. We take four parts as training set and the rest as development set.

2.2 Feature Extraction

Based upon many previous work on sequence labeling, our system incorporates 5 types of features: POS tags, dependency parsing, NER labels, Chunking labels and Brown clustering. All features are generated automatically. In detail, we use Stanford CoreNLP (Manning et al., 2014)¹ to annotate POS tags, dependency parsing, NER labels, and use Apache OpenNLP² to annotate Chunking labels. Brown clustering labels are generated by an open source implementation.

2.2.1 POS Tags

POS Tagging (part-of-speech Tagging), which attaches each word of a sentence a part of speech tag

based on both its definition and its context, produces a generalization of words and is a fundamental procedure of other NLP tasks such as syntactic parsing and information extraction.

2.2.2 Dependency Labels

Dependency parsing describes the syntactic structure of a sentence in terms of the words (or lemmas) in a sentence and an associated set of directed binary grammatical relations that hold among the words. For a given word, our system takes the concatenation the dependency edge and its syntactic head as its dependency label, or 'ROOT' if the word has no syntactic head.

2.2.3 NER Labels

Named Entity Recognition (NER) labels sequences of words in a text which are the names of things, such as person and company names, or gene and protein names. We utilize NER labels as significant information to detect named token labels, such as Subject and Object.

2.2.4 Chunking Labels

Text chunking divides a text into phrases in such a way that syntactically related words become member of the same phrase. For instance, "technology organizations" is a noun phrase, our system annotates "technology" as "B-NP" and "organizations" as "I-NP".

2.2.5 Brown Clustering Labels

Similar words have similar distributions of words to their immediate left and right. Motivated by this intuition, Brown Clustering algorithm (Brown et al., 1992) gives an unsupervised class label to a word. Our system uses a C++ implementation³ of the Brown clustering algorithm (Liang, 2005) and sets cluster number as 50. The Brown clusters was trained on a large corpus of APT reports⁴ provided by the organizer.

2.3 Model Introduction

Similar to (Ma and Hovy, 2016), as shown in Figure 1, before feeding into the BiLSTM network, the model concatenates character-level representations obtained from CNN (LeCun et al., 1989), word-level representations and linguistic feature representations to acquire the final representation of the word. At the end, the model feeds the output

¹<https://stanfordnlp.github.io/CoreNLP/>

²<https://opennlp.apache.org/>

³<https://github.com/percyliang/brown-cluster>

⁴<https://www.atp.dk>

vectors of BiLSTM into a CRF layer, using sentence level tag information to jointly decode sequence labels.

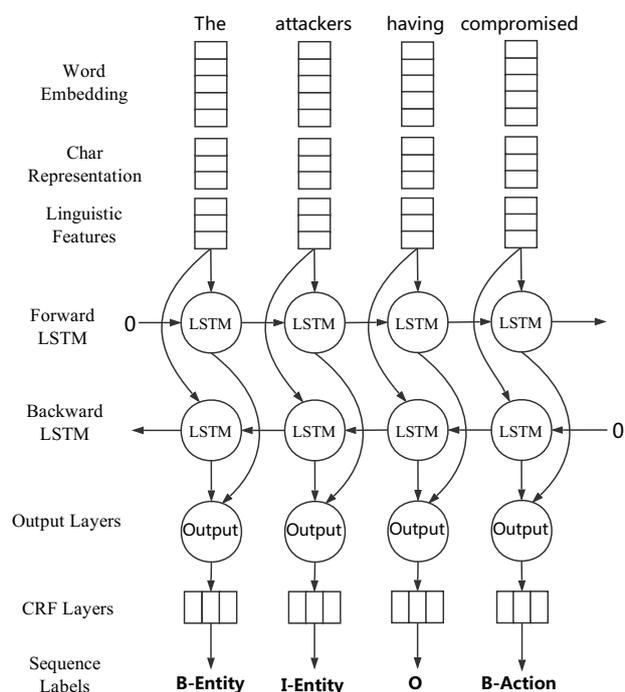

Figure 1: BiLSTM + CRF network architecture

Designing a neural network architecture with character representation as input is appealing for several reasons. First, words which have the same morphological properties (like the prefix or suffix of a word) often share the same grammatical function or meaning. Second, a character-level analysis can help to deal with the OOV (out-of-vocabulary) problem and the word starts with a capital letter may provide additional information. Previous studies (Santos and Zadrozny, 2014) (Chiu and Nichols, 2015) have shown that CNN is an effective approach to extract morphological information from characters of words, and consequently help to improve the performance of NER and POS tagging. As shown in Figure 2, we employ a max-pooling and a convolution layer to extract a new feature vector from character embeddings for each word. Then words are padded with a number of PADDING characters on both sides depending on the window size of the CNN.

2.3.1 BiLSTM for Word Representation

RNNs are well-studied solutions for a neural network to process variable length input and have

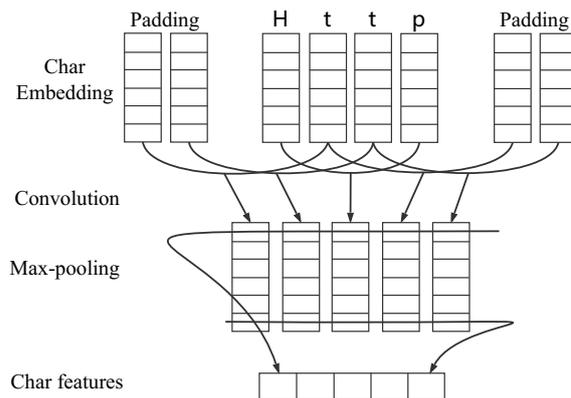

Figure 2: CNN feature extraction

long term memory. As a variant of RNNs, the long-short term memory (LSTM) unit with three multiplicative gates allows highly non-trivial long-distance dependencies to be easily learned. For sequence labeling tasks, we use a bidirectional LSTM network proposed in (Graves et al., 2013) in order to efficiently utilize both past features (via forward states) and future features (via backward states) for a specific time frame. Furthermore, pre-trained word embeddings learned from large unlabeled data are used.

2.3.2 Neural Network with Features

Before feeding into the BiLSTM network, we concatenate the char embedding, word embedding, POS embedding, NER embedding, Chunking labels embedding, Brown Clustering labels embedding as input.

2.3.3 CRF Layer

For sequence labeling task, such as POS tagging or NER, the output labels adjacent are often strongly related (e.g. I-ORG cannot follow B-PER or I-LOC in NER task of CoNLL2003). Therefore, we model BiLSTM networks jointly using a CRF layer to decode each label.

2.3.4 Model Average

Random initialization and shuffling order of training sentences introduce randomization into model training. During experiments, we found that model predictions vary considerably even when the same pre-trained data and parameters are used. In order to utilize the power of models ensembling and avoid over-fitting problem, we use a script provided by tensor2tensor to average values

Model	Phrase Level			Token Level		
	Precision	Recall	F1-score	Precision	Recall	F1-score
CRF	0.4867	0.2374	0.3191	0.5766	0.2739	0.3714
CRF with Linguistic Features	0.4971	0.2627	0.3438	0.5839	0.2911	0.3885
BiLSTM-CRF	0.5082	0.4305	0.4661	0.6273	0.4296	0.5100
BiLSTM-CRF with Linguistic Features	0.5265	0.4410	0.4799	0.6354	0.4437	0.5225
BiLSTM-CNN-CRF	0.5289	0.4461	0.4840	0.6370	0.4456	0.5243
BiLSTM-CNN-CRF with Linguistic Features	0.5436	0.4623	0.4997	0.6428	0.4531	0.5315

Table 1: Experiment results in phrase level and token level.

of variables in a list of checkpoint files generated by BiLSTM-CNN-CRF networks⁵.

3 Experiments and Analysis

3.1 Experiment Settings

We found that in the original dataset provided by organizers, the average percentage of positive samples dropped from 23% in training set to less than 6.6% in development set, which suggests that a model may be strongly biased if trained on the training set and fine-tuned on the development set without randomization. Therefore we combined the training data and development data after spelling correction and removal of unreadable characters. In order to avoid over-fitting problem, we adopted 5-fold cross validation by randomly splitting the combined data into five folds. Each time we took four folds as training data and the rest as development data.

We downloaded GloVe (Pennington et al., 2014) data as the source of pre-trained word embeddings. For char and feature embeddings, we randomly initialized them with values drawn from the standard normal distribution.

The evaluation metrics were calculated by the CoNLL2000 Perl script at token level and phrase level. For each level, precision, recall and F1-score were calculated. Based on the highest F1-score we selected the best hyper-parameters (CNN output size, LSTM State size, learning rate, dropout, etc.) for single model in 5-fold cross validation. Besides, for the submission generated by the BiLSTM-CNN-CRF, we adopted model average strategy by averaging values of variables of 5 checkpoint files from 5 independent experiments sharing the same experiment settings.

3.2 Experiment Results

Our experiments focus on improving the performance in phrase level because of two motivations: phrase level is more meaningful than token level

and the model superior in phrase level also outperforms the others in token level.

The comparison of models in Table 1 shows that neural networks models significantly outperform the traditional model based on CRF. Meanwhile models including character-level features in pre-trained word embeddings show better result. Last but not least, models with additional linguistic features improve the performance in both phrase level and token level significantly.

4 Conclusion

This paper describes our system for Subtask 1 and Subtask 2 of SemEval-2018 Task 8. For Subtask 2 we design a BiLSTM-CNN-CRF model combining several hand-crafted features, such as POS tagging, NER labels, Chunking labels, etc. For Subtask 1 we simply use the output labels generated by Subtask 2 to classify where a sentence is relevant to malware. It can be observed that rich linguistic features and pre-trained word embeddings for large unlabeled data benefit the task. The system is proven valid and effective to achieve the highest F1-score in Subtask 2.

5 Future Work

The fact is our system is not good enough to help semantic extraction from CybersecUurity reports. In the future, we will design a multi-task network to solve Subtask 1 and Subtask 2 simultaneously since they are highly related. Besides, more features, e.g., stemming and lemmatization, can be utilized in predicting token labels.

Acknowledgments

We thank the task organizers for providing malware corpus and organizing the shared task 8. Furthermore, we also appreciate the peer reviewers for their helpful comments on our first draft. We are especially grateful to Li Xiaoning for his insightful advice on the understanding of CybersecUurity reports.

Abstract

This paper describes the SemEval 2018 Shared Task on Hypernym Discovery. We put forward this task as a complementary benchmark for modeling hypernymy, a problem which has traditionally been cast as a binary classification task, taking a pair of candidate words as input. Instead, our reformulated task is defined as follows: given an input term, retrieve (or discover) its suitable hypernyms from a target corpus. We proposed five different subtasks covering three languages (English, Spanish, and Italian), and two specific domains of knowledge in English (Medical and Music). Participants were allowed to compete in any or all of the subtasks. Overall, a total of 11 teams participated, with a total of 39 different systems submitted through all subtasks. Data, results and further information about the task can be found at <https://competitions.codalab.org/competitions/17119>.

1 Introduction

Hypernymy, i.e. the capability to relate generic terms or classes to their specific instances, lies at the core of human cognition. It is not surprising, therefore, that identifying hypernymic (*is-a*) relations has been pursued in NLP for more than two decades (Shwartz et al., 2016): indeed, successfully identifying this lexical relation substantially improves Question Answering applications (Prager et al., 2008; Yahya et al., 2013), Textual Entailment and Semantic Search systems (Hoffart et al., 2014; Roller et al., 2014; Roller and Erk, 2016). In addition, hypernymic relations are the backbone of almost every ontology, semantic network and taxonomy (Yu et al., 2015), which are in turn useful resources for downstream tasks such as

web retrieval, website navigation or records management (Bordea et al., 2015).

Generally, evaluation benchmarks for modeling hypernymy have been designed such that in most cases they are reduced to binary classification (Baroni and Lenci, 2011; Snow et al., 2004; Boleda et al., 2017; Vyas and Carpuat, 2017), where a system has to decide whether a hypernymic relation holds between a given candidate pair of terms. Criticisms to this experimental setting point out that supervised systems tend to benefit from the inherent modeling of the datasets in the hypernym detection task, leading to lexical memorization phenomena (Levy et al., 2015; Santus et al., 2016a; Shwartz et al., 2017). In this respect, recent work has attempted to alleviate this issue by including a graded scale for evaluating the degree of hypernymy on a given pair (Vulić et al., 2017).

Crucially, Espinosa-Anke et al. (2016) proposed to frame the problem as *Hypernym Discovery*, i.e. given the search space of a domain’s vocabulary, and given an input term, discover its best (list of) candidate hypernyms. This formulation addresses one of the main drawbacks of the evaluation criterion described above, and better frames the evaluated systems within downstream real-world applications (Camacho-Collados, 2017). In fact, lessons learned from these studies have motivated the construction of a full-fledged benchmarking dataset for the shared task we present here, which covers multiple languages and knowledge domains. The main goal of this task is that of complementing current research in hypernymy modeling with this novel discovery setting.

	Term	Hypernym(s)	Source
1A: English	sorrow	sadness, unhappiness	WordNet
1B: Italian	Nina Simone	musicista, pianista, persona	MultiWiki
1C: Spanish	guacamole	salsa para mojar, salsa, alimento	Wikidata (via BabelNet)
2A: Medical	pulmonary embolism	pulmonary artery finding, trunk arterial embolus, embolism	SnomedCT
2B: Music	Green Day	artist, rock band, band	MusicBrainz

Table 1: Some example terms and hypernyms extracted from different sources (see Section 4.1.4), for each of the subtasks and languages considered in the task.

2 Related Work

Traditionally, identifying hypernymic relations from text corpora has been addressed with two main approaches: pattern-based and distributional (Wang et al., 2017). Pattern-based (path-based) methods, which provide higher precision at the price of lower coverage, exploit the co-occurrence of a hyponym and its hypernym in a textual corpus (Hearst, 1992; Navigli and Velardi, 2010; Boella and Di Caro, 2013; Flati et al., 2016; Gupta et al., 2016; Pavlick and Pasca, 2017). Conversely, distributional models rely on a distributional representation for each observed word, and are capable of identifying hypernymic relations between concepts even when they do not co-occur explicitly in text. Earlier work on hypernym modeling was unsupervised, and leveraged various interpretations of the distributional hypothesis.¹ Most of the recent work on the subject is however supervised, and in the main based on using word embeddings as input for classification or prediction (e.g Baroni et al., 2012; Santus et al., 2014; Fu et al., 2014; Weeds et al., 2014; Espinosa-Anke et al., 2016; Sanchez Carmona and Riedel, 2017; Nguyen et al., 2017). As shown by Shwartz et al. (2016), pattern-based and distributional evidences can be effectively combined within a neural architecture. In this shared task we have actually received systems of both natures, including a combination of pattern-based and distributional cues, similar to the one mentioned above, which also proved to be highly effective (see Section 5).

3 Task Description

We define Hypernym Discovery operatively as the task of finding and extracting the appropriate hypernym(s) for a target input term. As input for

¹See Shwartz et al. (2017) for a detailed review on unsupervised distributional hypernymy detection.

the task, together with the target term,² a large textual corpus (*source corpus* henceforth) is provided, and participating systems are intended to exploit this large source of textual data to retrieve (i.e. “discover”) as many suitable hypernyms as possible for the target term. A different source corpus, as well as the corresponding vocabulary, is specified for each subtask and language (cf. Section 4) in order to set a level playing field for competing systems, and constrain their search space.

For each input term (or *hyponym*) the expected output is a ranked list of *candidate hypernyms* (up to 15) drawn from the provided vocabulary. Some example input-output pairs (i.e. terms and corresponding hypernym lists) are shown in Table 1 for each subtask and language. Table 1 also reports the sources of hypernymy information beside each pair, which vary depending on the subtask and language, as detailed in Section 4.1.4.

The structure of our Hypernym Discovery task consists of five independent but related subtasks, split into two larger groups: *general-purpose* hypernym discovery and *domain-specific* hypernym discovery. Participants were allowed to submit systems for any individual subtask. Along with a specific source corpus and vocabulary, each subtask features its specific training and testing data, consisting of input terms and corresponding gold hypernym lists, obtained as described throughout Section 4.

General-Purpose Hypernym Discovery consists in discovering hypernyms in a large corpus of general-purpose textual data, gathered from different and heterogeneous sources. A system operating in this setting requires the flexibility to provide hypernyms for terms in a wide range of domains. In this shared task we consider three different lan-

²A valid input term is any word or multi-word expression drawn from the predefined vocabulary (cf. Section 4.1.2) up to trigrams.

guages for general-purpose hypernym discovery:

- **English (subtask 1A)**, with a gold standard of 3,000 labeled terms;
- **Italian (subtask 1B) and Spanish (subtask 1C)**, each with a gold standard of 2,000 labeled terms;

All the gold standards provide a balanced set of input terms, with different degrees of frequency and for different domains. The corresponding gold hypernyms have been extracted from multiple resources and manually validated (cf. Sections 4.1.4-4.1.5). Training and testing data are split evenly (50% training - 50% testing).

Domain-Specific Hypernym Discovery deals with the same problem, but constrains it to a specific domain of knowledge. As a consequence, in this case participants test their systems (which might be general or specifically tailored to the target domain) in a much more focused and reduced environment. In this shared task we focus on English and consider two different domains of knowledge:

- **Medical (subtask 2A)**, with a gold standard of 1,000 labeled terms;
- **Music (subtask 2B)**, also with a gold standard of 1,000 labeled terms;

As in the previous subtask, we provide a balanced set of terms and gold hypernyms, with different degrees of frequency and for different subdomains. Again, training and testing data are split evenly (50% training - 50% testing).

Subclass vs. Instance. Although many hypernym detection approaches tend to overlook this distinction, it is customary to consider two different varieties of the “is-a” relation: a subclass-of variety (e.g. a dog *is a* mammal), and an instance-of variety (e.g. Rome *is a* city).³ From a practical standpoint, the former occurs between two concepts, while the latter connects a named entity with a concept. We make this distinction explicit in our shared task by hand-labeling each input term as either a concept or a

³In fact, WordNet encodes hypernym and instance as two separate semantic relations. Instances are always leaf (terminal) nodes in their hierarchies.

named entity. This strategy serves a double purpose: on one hand, it helps reducing lexical ambiguity, and narrowing the search space of potential hypernyms even further;⁴ on the other hand, it enables participants to study and develop models specifically tailored to one of the two varieties, and possibly submit them separately. In this respect, Boleda et al. (2017) has indeed shown how systems tend to perform differently on these two kinds of hypernymy relation.

4 Task Data

In this section we present the data collection process carried out for each source corpus and gold standard featured in the task (Section 4.1). We then summarize and provide some global statistics on all these datasets (Section 4.2).

4.1 Data Collection Process

The process of collecting data for each subtask and language comprised five successive steps: compilation of the source corpus (Section 4.1.1), creation of the vocabulary (Section 4.1.2), collection and selection of the input terms (Section 4.1.3), extraction of the gold hypernyms (Section 4.1.4), and final filtering and validation of such hypernyms (Section 4.1.5).

4.1.1 Corpus Compilation

First, we selected and compiled a source corpus for each dataset, which was also considered in the vocabulary creation step (Section 4.1.2). Naturally, we considered three corpora as general and as large as possible for the general-purpose track, whereas for the domain-specific datasets we opted for more targeted and specific text collections.

General-purpose corpora. As source corpus for the English subtask (1A) we used the 3-billion-word UMBC corpus⁵ (Han et al., 2013), which is a resource composed of paragraphs extracted from the web as part of the Stanford WebBase Project⁶ (Hirai et al. 2000). The UMBC corpus is considerably large and contains information from many and diverse domains. This corpus presents additional challenges and different

⁴As an example, the term *apple* could either refer to a fruit (if labeled as concept) or to a company (if labeled as named entity).

sources of information with respect to the corpora used in previous tasks, such as Wikipedia in the SemEval 2016 task on taxonomy extraction (Bordea et al., 2016). In fact, the encyclopedic nature of Wikipedia has been exploited in a wide variety of works (Ponzetto and Strube, 2007; Flati et al., 2016; Gupta et al., 2016), and differs substantially from the web-based corpus we put forward here. As source corpus for the Italian subtask (1B) we instead used the 1.3-billion-word itWac corpus⁷ (Baroni et al., 2009), extracted from different sources of the web within the .it domain. Finally, as source corpus for the Spanish subtask (1C) we considered the 1.8-billion-word Spanish corpus⁸ (Cardellino, 2016), which also contains heterogeneous documents from different sources.

Domain-specific corpora. As source corpus for the medical domain (subtask 2A) we provided a combination of texts drawn from the MEDLINE⁹ (Medical Literature Analysis and Retrieval System) repository, which contains academic documents such as scientific publications and paper abstracts. This corpus contains 130 million words. As regards the music domain (subtask 2B), instead, the source corpus we compiled is a concatenation of several music-specific corpora, i.e. music biographies from Last.fm contained in ELMD 2.0 (Oramas et al., 2016), articles from the music branch of Wikipedia, and a corpus of album customer reviews from Amazon (Oramas et al., 2017). The resulting corpus reaches 100 million words in total.

4.1.2 Vocabulary Creation

With the aim of simplifying the task for participants by providing a unified hypernym search space, we built a series of vocabulary files including all the possible hypernyms on each dataset. Each vocabulary was constructed by considering all the words occurring at least N times across the source corpus of the corresponding subtask. We set N to five and three in the general-purpose and domain-specific subtasks, respectively. We also included bigrams and trigrams, by considering all the instances present in any of the resources that we leveraged as part of the hypernym extraction

⁷<http://wacky.sslmit.unibo.it/doku.php?id=corpora>

⁸<http://crscardellino.me/SBWCE/>

⁹https://www.nlm.nih.gov/databases/download/pubmed_medline.html

process (see Section 4.1.4), provided that they also surpassed the corresponding frequency thresholds.

In order to reduce the high granularity of some hypernymy relations (for example, *dog* is an *entity*) we created an additional blacklist of very general terms not considered in the vocabulary files. This list was obtained semi-automatically. We first extracted the most common hypernyms from the lexical sources we used for creating the datasets. Then, we filtered the resulting blacklist by removing manually a number of suitable hypernyms that, despite being general, provided useful information worthy to be taken into account (e.g. *animal*).

4.1.3 Term Collection

After compiling a source corpus and a corresponding vocabulary, we selected a suitable collection of input terms (i.e. hyponyms) to construct the gold standard for each subtask. Term selection was based on three key constraints. First, as in vocabulary creation step (Section 4.1.2), input terms were required to occur five and three times in the general-purpose and domain-specific datasets, respectively. Second, only terms up to trigrams were considered. Finally, we only allowed terms with at least one extracted hypernym (see Section 4.1.4) present in the corresponding vocabulary file.

We carried out the term collection process with a semi-automatic two-pass procedure, which we applied to the source corpus of each subtask. First, candidate terms were extracted automatically from the source corpus, taking into account frequency, type (i.e. concept and entity) and knowledge domain¹⁰ in order to produce a list as balanced and representative as possible. After a preliminary list of input terms was obtained, we carried out an extensive validation and refinement step by manually normalizing each item (e.g. changing plurals to singulars, capitalizing named entities and lower-casing concepts), and by pruning all the terms that appeared too vague or general, as well as terms with mis-attributed domains.

4.1.4 Automatic Hypernym Extraction

Once the terms were collected we proceeded to extract a set of candidate hypernyms from a number of heterogeneous taxonomies. We drew taxonomic information from the following lexical resources: WordNet (Miller, 1995), Wikidata

¹⁰We leveraged the domains from the Wikipedia featured articles pages available in BabelDomains (Camacho-Collados and Navigli, 2017).

(Vrandečić and Krötzsch, 2014), MultiWiBi (Flati et al., 2016), and Yago (Suchanek et al., 2007). In order to be able to use seamlessly all hypernymy information for languages other than English, we exploited the inter-resource mappings provided by BabelNet (Navigli and Ponzetto, 2012).¹¹ For the domain-specific datasets we additionally used SnomedCT (Spackman et al., 1997) and MusicBrainz (Swartz, 2002) for the medical and music datasets, respectively.

The hypernym extraction process was carried out as follows: given a term (hyponym), we first retrieved all the BabelNet synsets which included the given term as lexicalization; then, starting from that synset, we iteratively visited the father nodes across all the reference taxonomies up to five levels¹² and selected all the lexicalizations of the traversed synsets (i.e. concepts) as given by BabelNet, provided that they appeared in the corresponding vocabulary files (see Section 4.1.2).

4.1.5 Hypernym Validation

Starting from the candidate gold hypernyms extracted in the previous step, we carried out a validation step using human annotators. We leveraged crowdsourcing for the English data in subtask 1A (which featured the largest dataset), and then expert verification in all subtasks (including English).

Crowdsourcing. We validated the English gold standard (both training and test set) by using crowdsourcing workers from Amazon Mechanical Turk. To ensure the quality of workers, we required workers to have answered at least 500 prior HITs with an approval rate of at least 95%, and applied a qualification test. For each target term, we showed the workers multiple candidate hypernyms, extracted in the previous step (Section 4.1.4), and asked them to select all the correct hypernyms. We also added 20% of random false candidates to prevent bias towards a positive answer. Finally, we assigned each HIT to 3 workers and determined the gold label with majority voting. The resulting annotations yielded an inter-annotator agreement of 73%.

¹¹Yago is the only resource which is not mapped to BabelNet. For the mapping we simply relied on the WordNet and Wikipedia identifiers provided in Yago.

¹²We decided to consider only five levels for two reasons: first, to avoid very general hypernyms; and second, to avoid errors which would propagate to other levels and make the validation task much harder. To this aim, five levels seemed to provide a fine balance between precision and recall.

	1A	1B	1C	2A	2B
Trial	50	25	25	15	15
Training	1,500	1,000	1,000	500	500
Test	1,500	1,000	1,000	500	500

Table 2: Number of terms (hyponyms) for each dataset in trial, training and test sets.

Expert verification. Expert verification comprised two steps. First, all the extracted data was verified by an expert human annotator. In this first step, the annotator was focused on removing the incorrect hypernyms, or normalizing them if required (e.g. plural to singular). This first verification was performed in all dataset except English, which underwent the crowdsourcing validation explained earlier. Then, all datasets (including the English one) were again verified by other experts. However, in this case the annotators were given different guidelines: in particular, they were asked to fix clear hypernym errors (which may have been missed in the previous step) and to add obvious hypernyms which they found to be missing.

4.2 Statistics

Table 2 shows the number of input terms in each dataset. The dataset was split equally in training and testing, while the trial data provided a fewer examples and could also be used as development set. English (subtask 1A) was the largest dataset with 1,500 terms (hyponyms) and for training and other 1,500 for testing. Then, for the Italian (subtask 1B) and Spanish (subtask 1C) datasets, 2,000 terms were given overall between training and testing. Finally, both domain-specific datasets (i.e. medical, subtask 2A, and music, subtask 2B) contained half of this quantity, with 1,000 terms each.

Note that each term may be associated with one or (in most cases) more than one hypernym. Therefore, counting all the term-hypernym pairs per dataset, as it is done in hypernymy detection datasets, would provide much larger figures. As an example, the number of term-hypernym pairs in the test gold standard is 7,048 for English, 4,770 for Italian, 6,070 for Spanish, 4,116 for the medical dataset, and 5,233 for the music dataset.

5 Evaluation

Parting ways from the classic precision-recall- F_1 metrics used so far in hypernym detection/extraction, we decided to evaluate this shared

task as a soft ranking problem. Systems were evaluated over the top 15 (at most) hypernyms retrieved for each input term, which let us assess their performance through Information Retrieval metrics. Let us briefly introduce each of them.

Mean Average Precision (MAP). We use MAP as the main evaluation metric of this task. Intuitively, this metric should give a fine estimate on the capability of a system to retrieve a sizable number of hypernyms from textual data, as well as considering the precision of each of them. Formally:

$$\text{MAP} = \frac{1}{|Q|} \sum_{q \in Q} \text{AP}(q)$$

where Q is a sample of experiment runs, $\text{AP}(\cdot)$ refers to *average precision*, i.e. an average of the correctness of each individual obtained hypernym from the search space.

Mean Reciprocal Rank (MRR). MRR rewards the position of the first correct result in a ranked list of outcomes, and is defined as:

$$\text{MRR} = \frac{1}{|Q|} \sum_{i=1}^{|Q|} \frac{1}{\text{rank}_i}$$

where rank_i refers to the rank position of the *first* relevant outcome for the i th run. While its main field of application is Information Retrieval, it has also been used in NLP tasks such as collocation recognition (Wu et al., 2010; Rodríguez-Fernández et al., 2016).

In addition to the above, we also provide results according to $\mathbf{P@k}$, i.e. the number of correctly retrieved hypernyms at different cut-off thresholds, specifically $k \in \{1, 3, 5, 15\}$.¹³

5.1 Baselines

We compared the participating systems with both supervised and unsupervised baselines for each subtask, inspired by recent work on hypernym detection and discovery. In this section we briefly describe each of them.

5.1.1 Supervised Baselines

We first used a naïve *most frequent hypernym (MFH)* baseline, which simply returns, for each input term, the 15 most frequent hypernyms found

¹³Although only $\mathbf{P@5}$ is displayed in the tables due to lack of space, the other thresholds were used in the official evaluation as well.

in the training data. As a less naïve baseline, we also trained a *transformation matrix* (Mikolov et al., 2013; Fu et al., 2014), using the same optimization described by Espinosa-Anke et al. (2016). For this baseline the hypernyms in the vocabulary which are among the fifteen closest vectors by applying the transformation matrix are retrieved. However, unlike in the original implementation, in this case we did not perform any a priori domain clustering of the embeddings space, and thus used the same matrix for all input terms.¹⁴ This second supervised baseline is referred to as **vTE** (*vanilla Taxoembed*).

5.1.2 Unsupervised Baselines

We developed an unsupervised baseline by reducing hypernymy discovery to hypernymy detection. We generated a list of candidate hypernyms for each target word, and then employed unsupervised hypernymy detection measures to decide whether a hypernymy relation holds. We used the open-source code by Shwartz et al. (2017).¹⁵

Our baseline starts by creating a distributional semantic model (DSM) for each domain/language (English, Spanish, Italian, Music and Medical). We used a non-directional window of size 5 as context type, and PPMI as feature weighting. Similarly to the hyponym selection step (Section 4.1.3), all the terms with frequency of at least 3 occurrences in the source corpus are considered as valid targets. For the context words, instead, we required a minimum of 100 occurrences, as in Shwartz et al. (2017). To generate candidates, we took the 50 most similar terms for each target word via cosine similarity in the DSM.

We chose the hypernymy detection measures as representative algorithms from each “family” of unsupervised measures: **APSyn** (Santus et al., 2016b) as similarity measure, **balAPInc** (Kotlerman et al., 2010) as measure based on the distributional inclusion hypothesis, and **SLQS** (Santus et al., 2014) as measure based on informativeness.¹⁶ Finally, we tuned the thresholds for the above measures by maximizing the average of the performance metrics on the training set, separately for each subtask and measure.

¹⁴We used the open-source code available at <https://bitbucket.org/luisespinoza/taxoembed>

¹⁵<https://github.com/vered1986/UnsupervisedHypernymy>

¹⁶Following the conclusions from Shwartz et al. (2017), we set the hyper-parameters to: SLQS: median, PLMI, $N = 100$ and APSyn: $N = 500$.

5.2 Participant Systems

Table 3 shows a summary of all participant systems, displaying their main features with respect to supervision and external resources used, if any.

5.3 Results

A summary of the results is provided in tables 3 to 7, respectively describing results for English, Italian, Spanish and Music and Medical domains. Almost all systems performed better than the unsupervised baselines, while the supervised ones showed to be more challenging, with few systems outperforming them. For English, Music and Medical domains, **CRIM** (Bernier-Colborne and Barriere, 2018) obtained the best results, with a large margin on the other systems and baselines. This system is based on learning a projection between hyponym-hypernym pairs in terms of their corresponding embeddings, and combines this module with an unsupervised system which uses Hearst-style patterns. Moreover, in Italian, the best system was **300-sparsans_r1** (Berend et al., 2018), a logistic regression model informed mostly with information coming from word embeddings; whereas for Spanish, the best performing team was **NLP_HZ** (Qiu et al., 2018), who approached the task with a nearest neighbors algorithm trained with the provided training data.

From the summary tables we can also appreciate the difference in performance of the systems on concepts and entities. Such difference is due to several factors, including the quantity and type of hypernyms that needed to be identified for the two subclasses. Except for the Music domain, systems tended to perform better with entities than with concepts. This is probably due to the fact that entities contain many hypernyms which appear often (e.g. *person*, *company*), which in principle favor the inherent lexical memorization (Levy et al., 2015) of supervised systems. Hence, as expected, systems performed better in the specialized domains (i.e. medical and music) than in the general-domain dataset (34.05% and 40.97% MAP performance by the best systems in the medical and music domains, respectively, compared to the 19.78% result of the best system in the English dataset).

Finally, the results also show the clear superiority of supervised systems over unsupervised approaches in all languages and domains. As far as fully unsupervised systems are concerned, they achieved a diverse degree of success. While

in general they were outperformed by supervised systems, in some cases their performance came close, especially for concepts. For instance, the **ADAPT** (Maldonado and Klubika, 2018) system, which is based on a simple similarity measure applied to word embeddings, achieved a very decent 8.13 MAP percentage performance on the medical dataset, using neither supervision nor external resources. Supervised systems produced a larger gap for entities, probably due, as mentioned above, to the lower diversity of possible hypernyms.

Cross-evaluation. In addition to the normal setting on which supervised systems trained their system on the same dataset training data, we ask participants to train systems on the English general-purpose data and trained on the domain-specific datasets. This experiment could enable us to test how a system could perform on a particular dataset when training data is not available. A few teams provided results on this setting and the results showed that even though trained on general data, they are still competitive with respect to other approaches. In fact, they tend to equally outperform unsupervised systems and in the medical dataset, for example, CRIM trained on the general English corpora outperformed all remaining participant systems trained on the medical training data.

6 Analysis

Inspired by previous tasks in taxonomy learning (Bordea et al., 2015), we sampled for each system 50 incorrect hypernyms (25 entities, 25 concepts) which were retrieved as first choice, and manually assessed their correctness. This evaluation of false positives is intended to account for the inevitable scenario in which not all possible correct hypernyms according to human judgement were included in the gold standard. The results in false positives were measured by accuracy (i.e. percentage of correct false positives on the given sample) and are displayed in Tables 4-8 under *FPS*.

In general, we observe that the systems' performances in this false positives experiment are correlated with the figures they obtained with the other automatic evaluation measures. Nonetheless, according to this false positives evaluation, most systems (both supervised and unsupervised) were able to retrieve some hypernyms which were not present in the gold standard. This result is encouraging, as not only hypernym discovery sys-

tems can be used to speed up the hypernym discovery process, but they can also provide new hypernyms not considered beforehand.

Unsupervised distributional methods (e.g. the unsupervised baselines) seemed to perform poorly overall, as these systems tended to retrieve similar words which are not necessarily hypernyms. For example, false positives for APSyn and balAPInc are characterized by a large number of co-hyponyms (e.g. *Exodus* and *Genesis*) and syntag-

matically related words (e.g. *orange* and *juice*).

As regards the top performing systems, it is worth noting that they often tended to retrieve correct or near-correct hypernyms. The hypernyms that were retrieved on the gold standard were of several kinds: first, some hypernyms were present in the gold standard but normalized differently (for example, for *About.com* the gold standard contained *website* but not *web site* retrieved by CRIM_r1); second, they retrieved hy-

but retrieved by the 300-sparsans_r2 system). Perhaps surprisingly, this latter case also extends to baselines such as MFH: in fact, many named entities have very skewed sense distributions, with less popular senses corresponding to people, cities, or companies often unbeknownst to most human annotators.¹⁷ In addition to these three common patterns, there are also other correct false positives which do not clearly correspond to any of these three.

7 Conclusion

In this paper we have presented the SemEval 2018 task on *Hypernym Discovery*. We provided a large, reliable framework to evaluate hypernym discovery system in various languages (English, Italian, and Spanish) and domains (medical and music). This evaluation framework aims at going beyond the common practice of seeing hypernymy detection as a binary classification task, and provides a more challenging setting, inherently closer to how the task should be modeled within downstream applications. We hope this framework will contribute to the development of hypernym discovery systems in several languages and, more

¹⁷As an example, *Cervantes* is universally known as the famous Spanish writer who authored ‘*Don Quixote*’, but the word might also refer to a town in Western Australia.

generally, to a wider understanding of hypernymy from a computational perspective.

As far as the results are concerned, this newly-proposed task proved to be challenging for all participating systems, leaving considerable room for improvement. It is clear from the figures that supervised systems perform considerably better than unsupervised systems. This might suggest that, given a well-defined downstream task, it could be more valuable to annotate hypernyms manually or semi-automatically (whenever possible) and then train a supervised system, than proposing unsupervised solutions with suboptimal performances. On the other hand, it is also noteworthy that the best system across three of the subtasks (i.e. CRIM) combined a supervised neural network architecture with the output of an unsupervised system using Hearst-style patterns (Hearst, 1992).

Acknowledgements

The authors gratefully acknowledge the economic support in the construction of the datasets from the Maria de Maeztu-UPF Grant provided to Horacio Saggion, Luis Espinosa-Anke and Sergio Oramas; Google Research through the Google Doctoral Fellowship in Natural Language Processing to Jose Camacho-Collados; and Bar-Ilan University through Vered Shwartz. This work is partially supported by the TUNER project (TIN2015-65308-C5-5-R, MINECO/FEDER, UE), Spanish Ministry of Economy and Competitiveness.

We would also like to thank the task participants who provided helpful inputs to improve the task through their comments in the Google Group.

CRIM at SemEval-2018 Task 9: A Hybrid Approach to Hypernym Discovery

Gabriel Bernier-Colborne

g.b.colborne@gmail.com

Caroline Barrière

caroline_barriere@yahoo.ca

Abstract

This report describes the system developed by the CRIM team for the hypernym discovery task at SemEval 2018. This system exploits a combination of supervised projection learning and unsupervised pattern-based hypernym discovery. It was ranked first on the 3 sub-tasks for which we submitted results.

1 Introduction

The goal of the hypernym discovery task at SemEval 2018 is to predict the hypernyms of a query given a large vocabulary of candidate hypernyms. A query can be either a concept (e.g. *cocktail* or *epistemology*) or a named entity (e.g. *Craig Anderson* or *City of Whitehorse*). Two types of data were provided to train the systems: a large unlabeled text corpus and a small training set of examples comprising a query and its hypernyms. More details on this task may be found in the task description paper (Camacho-Collados et al., 2018).

The system developed by the CRIM team for the task of hypernym discovery exploits a combination of two approaches: an unsupervised, pattern-based approach and a supervised, projection learning approach. These two approaches are described in Sections 2 and 3, then Section 4 describes our hybrid system and Section 5 presents our results.

2 Pattern-Based Hypernym Discovery

Pattern-based approaches to relation extraction have been discussed in the literature for quite some time (see surveys by Auger and Barrière (2008) and Nastase et al. (2013)). They can be used to discover various relations, including domain-specific ones (Halskov and Barrière, 2008) and more general ones, such as hypernymy. The pattern-based approach to hypernym discovery was pioneered by Hearst (1992), who defined specific

textual patterns (e.g. *Y such as X*) to mine hyponym/hypernym pairs from corpora.

This approach is known to suffer from low recall because it assumes that hyponym/hypernym pairs will occur together in one of these patterns, which is often not the case. For instance, using the training data of sub-task 1A, we found that the majority of training pairs never co-occur within the same paragraph in corpus 1A, let alone within a pattern that suggests hypernymy.

To increase recall, we extend the basic pattern-based approach to hypernym discovery in two ways. First, we identify co-hyponyms for each query and add the hypernyms discovered for these terms to those found for the query. These co-hyponyms are identified using patterns, and filtered based on distributional similarity using the embeddings described in Section 3.3. Furthermore, we discover additional hypernyms using a method based on the following assumptions: most multi-word expressions are compositional, and the prevailing head-modifier relation is hypernymy.

The co-hyponym patterns we use are limited to enumeration patterns (e.g. X_1, X_2 and X_3). For hypernyms, we use an extended set of Hearst-like patterns which we selected empirically (e.g. *Y such as X*, *Y other than X*, *not all Y are X*, *Y including X*, *Y especially X*, *Y like X*, *Y for example X*, *Y which includes X*, *X are also Y*, *X are all Y*, *not Y so much as X*).

Our pattern-based hypernym discovery algorithm can be defined as follows: given a query q ,

1. Create the empty set Q , which will contain an extended set of queries.
2. Search for the co-hyponym patterns in the corpus to discover co-hyponyms of q . Add these to Q and store their frequency (number of times a given co-hyponym was found using these patterns).

3. Score each co-hyponym $q' \in Q$ by multiplying the frequency of q' by the cosine similarity of the embeddings of q and q' . Rank the co-hyponyms in Q according to this score, keep the top n ,¹ and discard the rest.
4. Add the original query q to Q .
5. Create the empty set of hypernyms H_q .
6. For each query $q' \in Q$, search for the hypernym patterns in the corpus to discover hypernyms of q' . Add these to H_q .
7. Add the head of each term in H_q to this set, as well as the head of the original query q .
8. Score each candidate $c \in H_q$ by multiplying its normalized frequency² by the cosine similarity between the embeddings of c and q , and rank the candidates according to this score.

Although the pattern-based search for both co-hyponyms and hypernyms can find terms not included in the provided vocabulary (which could also be useful), we discarded out-of-vocabulary terms because we had not learned embeddings for them.

3 Learning Projections for Hypernym Discovery

Several supervised learning approaches based on word embeddings have recently been developed for the task of hypernym detection and the related task of hypernym discovery (Camacho-Collados, 2017). The general idea is to learn a function that takes as input the word embeddings of a query q and a candidate hypernym h and outputs the likelihood that there is a hypernymy relationship between q and h . To discover hypernyms for a given query q (rather than classify a given pair of words), we apply this decision function to all candidate hypernyms, and select the most likely candidates (or all those classified as hypernyms).

This decision function can be learned in a supervised fashion using examples of pairs of words that are related by hypernymy and pairs that are not. The supervised model can take as input a combination of the embeddings of q and h , and different ways of combining the embeddings for this purpose have been used (Baroni et al., 2012;

¹We set $n = 5$ empirically.

²Frequencies were normalized in the range $[0.05, 1.0]$.

Roller et al., 2014; Weeds et al., 2014). In related work, models have been proposed that learn to project the embedding of q such that its projection is close to that of its hypernym h (Fu et al., 2014; Yamane et al., 2016; Espinosa-Anke et al., 2016). This has been termed *projection learning* (Ustalov et al., 2017). The decision function is then based on how close the projection of q is to a given candidate h .

Fu et al. (2014) introduced a model that learns multiple projection matrices representing different kinds of hypernymy relationships. In this model, each (q, h) pair is first assigned to a cluster based on their vector offsets, then projection matrices are learned for each cluster. Based on this work, Yamane et al. (2016) proposed a model that jointly learns the clusters and projection matrices.

We use a similar method to learn projections for hypernym discovery, but our approach differs from that of Yamane et al. (2016) in several ways: our model performs a soft clustering of query-hypernym pairs rather than a hard clustering, and we modified the training algorithm in several ways.

3.1 The Model

Given a query q and a candidate hypernym h , the model retrieves their embeddings $e_q, e_h \in \mathbb{R}^{d \times 1}$ using a lookup table. These embeddings were learned beforehand on a large unlabeled text corpus (i.e. the corpora provided for this task). The embedding e_q is then multiplied by a 3-D tensor containing k square projection matrices $\phi_i \in \mathbb{R}^{d \times d}$ for $i \in \{1, \dots, k\}$, producing a matrix $P \in \mathbb{R}^{k \times d}$ containing the projections of e_q :

$$P_i = (\phi_i \cdot e_q)^T \quad (1)$$

The model then checks how close each of the k projections of e_q are to e_h by taking the dot product:

$$s = P \cdot e_h \quad (2)$$

The column vector $s \in \mathbb{R}^{k \times 1}$ is then fed to an affine transformation and a sigmoid activation function (in other words, a logistic regression classifier) to obtain an estimate of the likelihood that q and h are related by hypernymy:

$$y = \sigma(W \cdot s + b) \quad (3)$$

To discover the hypernyms of a given query, we compute the likelihood y for all candidates and select the top-ranked ones.

3.2 The Training Algorithm

We train the model using negative sampling: for each positive example of a (query, hypernym) pair in the training data, we generate a fixed number m of negative examples by replacing the hypernym with a word randomly drawn from the vocabulary.³ We then train the model to output a likelihood (y) close to 1 for positive examples and close to 0 for negative examples. This is accomplished by minimizing the binary cross-entropy of the positive and negative training examples. For a particular example, this is computed as follows:

$$H(q, h, t) = t \times \log(y) + (1 - t) \times \log(1 - y)$$

where q is a query, h is a candidate hypernym, t is the target (1 for positive examples, 0 for negative), and y is the likelihood predicted by the model. If we sum H for every example in the training set D (containing both the positive and negative examples), we obtain the cost function $J = \sum_{(q,h,t) \in D} H(q, h, t)$. This function is minimized by gradient descent, using the Adam optimizer⁴ (Kingma and Ba, 2014).

A few details of the setup we use for training are worth mentioning:

- We use a fixed number of projections (k) rather than the dynamic clustering algorithm of Yamane et al. (2016). For our official runs, we used $k = 24$.
- The word embeddings are normalized to unit-length before training.
- For the initialization of the projection matrices, we add random noise to an identity matrix, which means that at first, the projections of a query are simply k randomly corrupted copies of the query’s embedding.
- We train the model on random mini-batches containing 32 positive examples and $32 \times m$ negative examples (m being the number of negative examples).
- Dropout is applied to the embeddings e_q and e_h and the query projections P . For regularization, we also use gradient clipping, as well as early stopping.

³Different ways of selecting the negative examples for this purpose have been proposed. See Ustalov et al. (2017).

⁴We use $\beta_1 = \beta_2 = 0.9$.

- We sample positive examples using a function based on the frequency of the hypernyms in the training data, such that we subsample (q, h) pairs where h occurs often in the training data. The probability of sampling (q, h) is given by:

$$P(q, h) = \sqrt{\frac{\min_{h' \in D}(\text{freq}(h'))}{\text{freq}(h)}}$$

where $\text{freq}(h)$ returns the frequency of h in the training data.⁵

- The word embeddings are optimized (or “fine-tuned”) during training.
- We use a multi-task learning setup whereby we train two separate logistic regression classifiers, each with their own parameters W and b , and use one for queries that are named entities, and the other for queries that are concepts.⁶ The rest of the parameters (i.e. the projection matrices ϕ) are shared.

The various hyperparameters mentioned above were tuned on the trial set (i.e. development set) provided for sub-task 1A.

3.3 The Word Embeddings

We learned term embeddings for all queries and candidates using the pre-tokenized corpora provided for sub-tasks 1A, 2A, and 2B. We pre-processed the corpora by converting all characters to lower case and replacing multi-word terms found in the vocabulary (candidates and lower-cased queries) with a single token, starting with trigrams, then bigrams.⁷ We then used the skip-gram algorithm with negative sampling (Mikolov et al., 2013) to learn the embeddings.

3.4 Data Augmentation

For one of our 2 runs, we experimented with a method to add synthetic examples to the positive examples in the training set provided (D). This

⁵On the training data of subtask 1A, this produces a sampling probability of 0.06 for the most frequent hypernym (*person*), while the least frequent hypernyms have a sampling probability of 1.

⁶Multi-task learning was not used on subtask 2A, because all queries were concepts.

⁷It is worth noting that a small number of candidates (e.g. less than 0.1% of candidates on corpus 1A) had a frequency of 0 in this preprocessed corpus, so we could not train an embedding for these candidates. These appear to be terms that always occur within a longer candidate.

was meant to provide additional training data and avoid overfitting the embeddings of the words in the training set. We use 2 heuristics to generate these synthetic examples:

1. Given a positive example $(q, h) \in D$, add (q', h) to the positive examples, where q' is the nearest neighbour of q , based on the cosine similarity of the embeddings of all the words in the vocabulary. This was motivated by the observation that nearest neighbours were often co-hyponyms.
2. Given a query q and the set H_q containing the hypernyms of q according to the training data, compute the α nearest neighbours of each hypernym in H_q , and for each neighbour that is shared by at least 2 of the hypernyms in H_q , add that neighbour to H_q .⁸

Negative examples are generated for each of the synthetic examples, as with the actual positive examples in the training set.

4 Hybrid Hypernym Discovery

Our hybrid approach to hypernym discovery combines supervised projection learning and unsupervised pattern-based hypernym discovery (see Sections 2 and 3). To combine the outputs of the 2 systems, we take the top 100 candidates according to each,⁹ normalize their scores and sum them, then rerank the candidates according to this new score. This reranking function favours candidates found by both systems, but also gives a chance to strong candidates found by a single system.

5 Experiments and Results

We submitted 2 runs on 3 of the 5 sub-tasks: 1A (general), 2A (medical), and 2B (music). The system outputs its top 15 predictions in all cases. The difference between the 2 runs is that for run 1, we used data augmentation (see Section 3.4) to train the supervised system – the same unsupervised output was used for both runs. We also submitted one run for cross-evaluation (training on 1A, but testing on 2A or 2B). First, we added the queries and candidates of 2A or 2B to those of 1A be-

⁸We use $\alpha = 2$.

⁹Analyzing the individual and combined recall of the two systems at various ranks indicated that using more than 100 candidates would not increase recall.

fore training embeddings on the corpus of 1A.¹⁰ These embeddings were used to train the supervised model on the 1A training data. We then combined the predictions of the supervised and unsupervised models on test set 2A/2B.¹¹

A summary of our system’s results is shown in Table 1. This table shows the mean average precision (MAP), mean reciprocal rank (MRR) and precision at rank 1 (P@1) of our system and those of the 2 strongest baselines which were computed by the task organizers. The first is a supervised baseline¹² and the second is based on the most frequent hypernyms in the training data. For more details, see (Camacho-Collados et al., 2018).

Our hybrid system was ranked 1st on all three sub-tasks for which we submitted runs. As shown in Table 1, the scores obtained using this system are much higher than the strongest baselines for this task. Furthermore, it is likely that we could improve our scores on 2A and 2B, since we only tuned the system on 1A.

If we compare runs 1 and 2 of our hybrid system, we see that data augmentation improved our scores slightly on 1A and 2B, and increased them by several points on 2A.

Our cross-evaluation results are better than the supervised baseline computed using the normal evaluation setup, so training our system on general-purpose data produced better results on a domain-specific test set than a strong, supervised baseline trained on the domain-specific data.

Table 1 also shows the scores we would have obtained on the test set if we had used only the unsupervised (pattern-based) or supervised (projection learning) parts of our system. Note that the unsupervised system outperformed all other unsupervised systems evaluated on this task, and even outperformed the supervised baseline on 2A.

Combining the outputs of the 2 systems improves the best score of either system on all test sets, sometimes by as much as 10 points.

Notice also that the results obtained using only the supervised system indicate that data augmentation had a positive effect on our 2A scores only (compare runs 1 and 2), although our tests on the

¹⁰Several of the domain-specific queries that were added to the vocab were not found in corpus 1A. We decided to only use the output of the unsupervised system in these cases.

¹¹Note that the unsupervised system used the corpora of 2A/2B, but no supervised learning was carried out on the training data of 2A/2B.

¹²This is a “vanilla” version of TaxoEmbed (Espinosa-Anke et al., 2016).

	Test set 1A			Test set 2A			Test set 2B		
	MAP	MRR	P@1	MAP	MRR	P@1	MAP	MRR	P@1
Hybrid run 1	19.78	36.10	29.67	34.05	54.64	49.20	40.97	60.93	48.20
Hybrid run 2	19.54	35.94	29.67	31.54	46.19	41.40	40.88	60.18	47.60

Supervised cross-eval	N/A	N/A	N/A	22.89	38.30	30.60	16.80	29.28	19.20
BaselineSUP cross-eval	N/A	N/A	N/A	11.66	23.83	17.20	6.31	16.54	9.60

Table 1: Our system’s results on test sets 1A, 2A, and 2B. The runs we submitted are the hybrid runs. The supervised and unsupervised runs were produced by using our 2 sub-systems separately. BaselineSUP is a strong, supervised baseline and BaselineMFH is the most-frequent-hypernym baseline. Cross-evaluation results were obtained by training the supervised system on 1A and evaluating on 2A or 2B.

trial set suggested it would also have a positive effect on our 1A scores. Given this observation, we find it somewhat surprising that run 1 is the best on all 3 test sets when we use the hybrid system. One possible explanation is that adding the synthetic examples makes the errors of the supervised system *more different* from those of the unsupervised system, and that this in turn makes the ensemble method more beneficial, but we haven’t looked into this.

5.1 Ablation Tests

To assess the influence of different aspects of the supervised system and its training algorithm, we carried out a few simple ablation tests on sub-task 1A. The baseline for these tests is our supervised projection learning system – we did not apply pattern-based hypernym discovery for any of these tests. We used the setup of run 1 (with data augmentation) and used the trial set for early stopping. We conducted the following tests (one by one, without combining any of the ablations):

1. No subsampling: we sample positive examples uniformly from the training set.
2. No MTL: instead of multi-task learning (MTL), we use a single classifier for both named entities and concepts.
3. Random init: the weights of ϕ are initialized randomly, instead of adding random noise to an identity matrix.
4. Single projection: $k = 1$ instead of 24.

5. Single neg. example: $m = 1$ instead of 10.
6. Frozen embeddings: the word embeddings are not fine-tuned during training.

The results obtained on test set 1A are shown in Table 2.¹³ These results show that 2 of the techniques we used, namely subsampling and multi-task learning, actually harmed our system’s performance on test set 1A, although our experiments on the trial set suggested that they would be beneficial. This may be due to the small size of the trial set (i.e. 50 queries) or some difference in the underlying distributions of the trial and test sets.

	MAP	MRR	P@1
Baseline	19.05	34.36	27.93
No subsampling	19.47	35.56	29.33
No MTL	19.22	35.09	28.67
Random init	16.54	30.60	24.93
Single projection	12.88	26.50	23.33
Single neg. example	11.58	21.75	15.20
Frozen embeddings	8.01	17.15	11.67

Table 2: Results of ablation tests on test set 1A. The baseline is our supervised system (run 1).

On the other hand, fine-tuning the word embeddings during training seems to be one of the keys to the success of this approach, as are the use of multiple projection matrices, and the sampling of

¹³Note that the baseline results are slightly different than those shown in Table 1 for run 1 (supervised), because we re-trained the model to get the results on the trial set, and a random number generator used during training was not seeded with a fixed value.

Query	Predictions
Suzy Favor Hamilton	athlete, sportsperson, person , competitor, sport, olympic sport, ...
wicketkeeper	cricketer, sportsperson, athlete, competitor , footballer, person , ...
aquamarine	stone , crystal, precious stone, pebble , gem, rock, gemstone , ...
tenpence	monetary unit, metal money, note of hand , person, silver coin, coin , ...
vegetarian	dessert, dish, recipe, veggie, food product, organic food, meal, salad, ...

Swarthmore	university, college, educational institution, school, student, ...
hypostasis	figure of speech, intellection, philosophy, ordinary language, ...

Table 3: Examples of predictions made by our system (run 1) on the test queries of 1A. Correct predictions are in bold. Midline separates high-accuracy examples from low-accuracy examples.

multiple negative examples for each positive example. The way we initialize ϕ also seems to have helped quite a bit.

It is important to remember that a more thorough exploration of hyperparameter space would produce results very different from those of simple ablation tests such as these.

It is worth noting that our supervised model outperforms the supervised baseline provided for this task (see Table 1) even when it exploits a single projection matrix, however the difference in scores between these 2 systems is only 2 or 3 points, depending on the evaluation metric.

We should also note that the supervised model is prone to overfitting, and we found early stopping to be particularly important.

5.2 Qualitative Analysis

We manually inspected the results of run 1 on some of the 1A test queries to get a better idea of the ability of the model to discover hypernyms, and to identify potential sources of errors. Table 3 shows a few of these test cases. Below we will outline a few of our observations, and will refer repeatedly to examples in Table 3.

The model is indeed able to discover valid hypernyms for both concepts and named entities. It seems that it can even handle very low-frequency queries in some cases (*Suzy Favor Hamilton* occurs only 5 times in the corpus), but we have not had the chance to investigate how sensitive the model is to term frequency.

Lexical memorization (Levy et al., 2015) can sometimes be observed. For example, *person* is the most frequent hypernym in the 1A training data, and the model often predicts this candidate incorrectly, even when its other top predictions are completely unrelated (e.g. *tenpence*).

The model can discover hypernyms of different

senses of the same query (e.g. *aquamarine*, for which the top 15 predictions contain the valid hypernyms *spectral color* and *primary color*), and it sometimes discovers hypernyms for senses that are not represented in the gold standard (e.g. there is a college named *Swarthmore*, and *hypostasis* has senses related to linguistics and philosophy). It is likely that the senses that dominate the model’s top predictions for a given query are its most frequent senses in the corpus.

The case of *vegetarian* suggests that syntactic ambiguity is a source of errors: the predicted hypernyms include some that might be considered valid for the query *vegetarian food*, where *vegetarian* is an adjective, but not for the noun *vegetarian*.

Lastly, the model sometimes confuses concepts and named entities (e.g. *Local Group*, which refers to a group of galaxies). Preserving the true case of the characters in the corpus would mitigate this issue.

6 Concluding Remarks

Our approach to hypernym discovery combines a novel supervised projection learning algorithm and an unsupervised pattern-based algorithm which exploits co-hyponyms in its search for hypernyms. This hybrid approach produced very good results on the hypernym discovery task, and was ranked first on all 3 sub-tasks for which we submitted results.

Acknowledgments

This research was conducted while both authors were affiliated with the Computer Research Institute of Montréal (CRIM), and was supported by the Natural Sciences and Engineering Research Council of Canada.

Abstract

This paper describes the SemEval 2018 Task 10 on Capturing Discriminative Attributes. Participants were asked to identify whether an attribute could help discriminate between two concepts. For example, a successful system should determine that *urine* is a discriminating feature in the word pair *kidney, bone*. The aim of the task is to better evaluate the capabilities of state of the art semantic models, beyond pure semantic similarity. The task attracted submissions from 21 teams, and the best system achieved a 0.75 F1 score.

1 Introduction

State of the art semantic models do an excellent job at detecting semantic similarity, a traditional semantic task; for example, they can tell us that cappuccino, espresso and americano are similar to each other. It is obvious, however, that no model can claim to capture semantic competence if it does not, in addition to similarity, predict semantic differences between words. If one can tell that americano is similar to cappuccino and espresso but cannot tell the difference between them, one only has a very approximate idea of the meaning of these words. As a step beyond similarity, one should at the very least recognize that americano is bigger than espresso, and that capuccino contains milk foam. In this spirit, we present Semeval 2018 Task 10 (Capturing Discriminative Attributes) as a new challenge for lexical semantic models.

1.1 Task description

A semantic model that has only been evaluated on similarity detection may very well fail to be of practical use for specific applications. For example, word sense disambiguation could benefit greatly from representations that can model complex semantic relations. This means that the evaluation of word representation models should not

only be centered on semantic similarity and relatedness, and should include different, complementary tasks. To fill this gap, we proposed a novel task of semantic difference detection as Task 10 of the SemEval 2018 workshop. The goal of the systems in this case was to predict whether a word is a discriminative attribute between two other words. For example, given the words *apple* and *banana*, is the word *red* a discriminative attribute?

Semantic difference is a ternary relation between two concepts (*apple*, *banana*) and a discriminative attribute (*red*) that characterizes the first concept but not the other. By its nature, semantic difference detection is a binary classification task: given a triple *apple, banana, red*, the task is to determine whether it exemplifies a semantic difference or not.

In practice, when preparing the task, we started out with defining potential discriminative attributes as semantic features in the sense of (McRae et al., 2005): properties that people tend to think are important for a given concept. McRae et al.’s features are expressed as phrases, but these phrases can usually be reconstructed from a single word (e.g. *red* as a feature of *apple* stands for the phrase *is red*, *carpentry* as a feature of *hammer* can be used as a shorthand of *used for carpentry*, etc.) Given this general reconstructability, we have for simplicity used single words rather than phrases to represent features. The same solution was also adopted in the feature norming studies by (Vinson and Vigliocco, 2008) and (Lenci et al., 2013).

Following McRae et al., we did not define discriminative features in purely logical but rather in psychological terms. Accordingly, features are prototypical properties that subjects tend to associate to a certain concept. For example, not all apples are red and some bananas are, but *red* tends to be judged as an important feature of apples and not of bananas. We therefore fully trust human anno-

tators in deciding what counts as a distinguishing attribute and what does not.

1.2 Motivation

Exploring semantic differences between words can allow us to grasp subtle aspects of meaning: while it is relatively easy to train a model to recognize that *apple* and *banana* are somewhat similar, it is less straightforward to learn that, contrary to an apple, a typical banana is not red. This task is therefore more challenging than, and complementary to, the traditional similarity task, and we expect it to contribute to the progress in computational modeling of meaning.

While semantic similarity and relatedness measures have been used extensively to evaluate semantic representations, they may not be sufficient as a method for evaluating lexical semantic models (Faruqui et al., 2016; Batchkarov et al., 2016). Firstly, it has been noted that the relevant notions of similarity and relatedness can vary depending on the linguistic context, on the downstream application, etc. The difference task resolves this concern by effectively providing a context. In our example, comparison with bananas determines the relevance of the redness attribute for apples, which, out of context, might not necessarily be a salient attribute of apples.

Existing similarity and relatedness datasets have also been criticized for low inter-annotator agreement. The semantic difference detection task alleviates this issue, too. Binary choice is easier for human annotators than rating on a continuous scale, and produces more consistent patterns of answers. In our pilot study, the agreement between annotators was over 0.80. To further ensure the quality of our data, we discarded any items that caused disagreement.

1.3 Expected impact

The semantic difference task can enable further progress in the field of word representation learning. Indeed, state of art models have reached ceiling performance in the tasks of semantic similarity and relatedness (in part because the ceiling, as determined by the agreement of human subjects, is relatively low). Another commonly employed task, analogy, has its own issues (Linzen, 2016) and effectively boils down to similarity optimization (Levy and Goldberg, 2014). A new general evaluation task for lexical semantics is long due,

and we hope that the semantic difference task is capable of filling this gap.

In the future, solving the discriminative attributes task could help in a range of applications, from conversational agents (choosing lexical items with contextually relevant differential features can help create more pragmatically appropriate, human-like dialogues), to coreference resolution (differentiating features of concepts mentioned or alluded to in text could help in reference disambiguation), to machine translation and text generation, where explicitly taking into account semantic differences between competing translation variants can improve the quality of the output.

2 Data and resources

2.1 Overview

One can express semantic differences between concepts by referring to attributes of those concepts. A difference can usually be expressed as presence or absence of a specific attribute. For instance, one of the differences between a *narwhal* and a *dolphin* is the presence of a tusk.

The task dataset includes 5062 manually verified triples of the form $\langle \text{word}_1, \text{word}_2, \text{attribute} \rangle$. The set is built in such a way that the attribute in each positive example characterizes the first word of the triple. For example, in Table 1, *wings* is an attribute of *airplane*. The word pair $[\text{airplane}, \text{helicopter}]$ is included in the order $[\text{helicopter}, \text{airplane}]$ if *helicopter* has a feature that *airplane* does not have. We thereby assume, in contrast to the standard formalization of similarity, that semantic difference is not symmetric: the triple *apple, banana, red* is a semantic difference but *banana, apple, red* is not since *red* is not an attribute of bananas.¹

We supplemented positive data (as described above) with negative examples. Two types of negative examples were added: examples where the attribute is shared between word_1 and word_2 (both concepts have the attribute in question), and examples where the attribute is neither an attribute of word_1 nor word_2 (both concepts lack the attribute). For that last type of attributes, since their

¹This is a somewhat arbitrary choice. One could experiment with a symmetric notion of a discriminative attribute, whereby both *apple, banana, red* and *banana, apple, red* are considered examples of semantic difference, but in our opinion such an approach would only make the task more challenging.

$word_1$	$word_2$	$attribute$
airplane	helicopter	wings
bagpipe	accordion	pipes
dolphin	seal	fins
gorilla	crocodile	bananas
oak	pine	leaves
octopus	lobster	tentacles
pajamas	necklace	silk
skirt	jacket	pleats
subway	train	dirty

Table 1: Sample data: Word pairs and their distinguishing features (positive examples)

number is potentially huge, the examples were selected randomly so that the number of negative examples matches the number of positive examples. Presence of both positive and negative examples makes it possible to train a binary classifier that, for a given triple, predicts whether the attribute is a difference between $word_1$ and $word_2$.

$word_1$	$word_2$	$attribute$
tractor	scooter	wheels
crow	owl	black
squirrel	leopard	fur
pillow	jacket	white
dresser	cupboard	large
spider	elephant	legs
gloves	pants	wool
gorilla	panther	long
scarf	slippers	colours
lion	zebra	large

Table 2: Sample data: Word pairs and non-distinguishing features (negative examples)

Approximately half of the manually checked triples was given to participants as a validation set for parameter tuning of their systems, the rest was used for testing (cf. Section 2.4 for detailed statistics about the dataset composition). A larger training set of almost 18K examples (automatically constructed by the procedure described below, without manual filtering) was provided for training parameter-rich systems.

2.2 Data collection and annotation

When creating the dataset, we started from the approach that Lazaridou et al. (2016) used for visual discriminating attribute identification, followed by manual filtering for the test and validation data. Dataset creation consisted of three phases:

1. Semi-automatically created triples (section 2.2.1)
2. Manually created triples (section 2.2.2)
3. Automatically created triples (section 2.2.3)

As an initial source of data, we used the feature norms collected by McRae et al. (2005) and created a pilot dataset (Krebs and Paperno, 2016). This set was then reverified and manually extended to improve the quality and the variety of the data. Finally, a large number of triples were automatically generated for training purposes.

2.2.1 Triples from Mcrae norms

The first part of the dataset was created semi-automatically by identifying discriminative attributes of the concepts in the McRae norms, which consist of a list of features for 541 concepts (living and non-living entities), collected by asking 725 participants to produce features for each concept. Production frequencies of these attributes indicate how salient they are. Concepts that have different meanings had been disambiguated before being shown to participants. For example, there are two entries for *bow*, *bow_(weapon)* and *bow_(ribbon)*.

Because our task is not intended to test word sense models, we did not differentiate between entries that have multiple senses and ignored the disambiguating phrase. In our dataset, the concept *bow* has the attributes of both the weapon and the ribbon. This is not problematic because we do not refer to more than one attribute at a time, so senses of a word do not mix.² The McRae dataset uses the brain region taxonomy (Cree and McRae, 2003) to classify attributes into different types, such as *function*, *sound* or *taxonomic*. For the construction of our dataset, we decided to only work with visual attributes, which exist for all concrete concepts, while attributes such as *sound* or *taste* are only relevant for some classes of concepts.

Any one word concept that has at least one visual attribute was considered a candidate. Each

²An anonymous reviewer points out that the presence or absence of a feature in w_1 can be influenced by the context of w_2 : e.g. *tail* could be considered a distinguishing feature for the pair *mouse,cheese* but not for *mouse, keyboard*, because *keyboard* primes the device sense of the word *mouse* as opposed to the animal sense. Such strong contextualization effects could make our task even more interesting, but we believe that these cases are too rare to strongly influence the outcomes.

candidate concept was paired with another candidate concept from the list of its 100 closest neighbours in a PPMI-based distributional vector space (using the best settings from Baroni et al. (2014)). The motivation for this step is that finding non-trivial semantic differences only makes sense in the context of related words; detecting the difference between two unrelated concepts, such as a narwhal and a tractor, is rather trivial and would not constitute a very interesting task.

For each word pair, if there was an attribute in McRae feature norms that the first word has but the second doesn't, the word pair – attribute triple was added to the list of candidate positive examples. For simplicity, multi-word attributes were processed so that only the last word is taken into account (e.g. `has_wings` becomes `wings`). At this point, we had 512 unique concepts, 1645 unique attributes, 6355 unique word pairs, and 41723 triples (word pair-concept combinations). A random sample of triples was selected for manual annotation.

For candidate positive examples, two annotators agreed to keep 45.2% of items, agreed to discard 33% of items, and disagreed on 21.8% of items. A total of 54.8% of candidate positive examples were discarded. Among the negative examples, 12.5% of items were discarded. Annotators agreed to keep 87.5% of items, agreed to discard 0.8% of items, and disagreed on 11.6% of items. The examples that both annotators agreed to discard from the positive examples were added to the negative examples. Finally, the third author manually filtered the data removing dubious examples.

2.2.2 Manual triples

In the second phase, we extended the dataset by adding new concepts and attributes. Our intention was to make the dataset more diverse and more representative of the noun lexicon by including words and features that are not part of the McRae feature norms (e.g., human nouns such as *doctor* or *student*).

To select new nouns, we used SimLex-999 (Hill et al., 2015), one of the largest and most popular datasets for semantic similarity. We extracted from SimLex all the nouns with a concreteness rating above the median, and identified 204 candidate items that were not included in the McRae Norms. Each selected noun was paired with candidate concepts from the list of its 20 closest neighbours in the distributional vector space. We then

filtered the neighbors by frequency, keeping the neighbors that belong to the frequency range of the original McRae and SimLex vocabulary. We also made sure at this step that candidate word pairs belong to the same WordNet supersense. This latter constraint was added because distributional models often return neighbors that are only loosely related to the target, while finding non-trivial semantic differences makes sense only for words that are taxonomically similar. We also discarded grammatical number pairs like *seed/seeds* and hypernym/hyponym pairs like *doctor/surgeon*, since by definition there is no feature that a hypernym has but its hyponym does not have.

Each of the three task organizers was given a third of the resulting 1851 candidate noun pairs to annotate, generating discriminative and non-discriminative attributes for each pair. The suggested triples were then manually filtered by the other two authors.

2.2.3 Random triples

Finally, to further ensure the diversity of examples and to alleviate any biases unintentionally introduced in the annotation pipeline, we generated 500 additional triples by randomly matching words and features produced at earlier stages. Each of the three authors annotated these random triples, which contained mainly negative (*motorbike, rifle, liquor*) and some positive examples (e.g. *maid, evening, help*). Again, only those examples for which a full consensus of the three authors existed were kept.

2.3 Training, test and validation partitions

The manually validated dataset of semantic differences consists of examples from three sources described above: combinations of nouns with McRae features, triples with manually suggested attributes, and random triples. All of these examples have been verified by the three authors and were then randomly split into a validation partition and a test partition, making sure that no feature occurs in both.

	McRae	manual	random
positive	897	1477	37
negative	634	1656	361
total	1531	3133	398

Table 3: Composition of the manually validated part of the dataset

To enable development of systems that require more training data, we also created a distinct, bigger training set that was not manually curated. The training set was derived from McRae feature norms using automatically matched examples as described in 2.1.1, but without manual validation. We have to note that this training partition is very noisy, its main advantage being its size. In fact, the best performing system in our task was trained directly on validation data.

We further filtered the training set to minimize lexical overlap between partitions, making sure that no attribute present in the test set or the validation set is also present in the training set. For example, if the attribute “red” appears in some triple in the test partition, you will not find it anywhere in the training set. This was done to ensure that models cannot rely on attribute memorization from training data but are forced to transfer lexical knowledge from other sources.

2.4 Dataset composition

The final dataset consists of 22884 items, divided into:

1. A training set of 17782 examples with 515 distinct concepts and 1292 distinct features.
2. A validation set of 2722 examples with 1283 concepts and 576 distinct features.
3. A test set of 2340 triples with 1272 distinct concepts and 577 distinct features.

The proportion of positive and negative examples is reported in Table 2.4.

	training	validation	testing
positive	6591	1364	1047
negative	11191	1358	1293
total	17782	2722	2340

Table 4: Total size of the final dataset.

All data used in this task can be accessed from the competition’s github repository.³

3 Evaluation

3.1 Metrics

The submitted systems were evaluated on F1 measure, as is standard in binary classification tasks.

³<https://github.com/dpaperno/DiscriminAtt/>

The evaluation script can be found in the competition’s github repository. The competition results can be seen at the corresponding Codalab page.⁴ Participants were allowed to make up to 2 submissions, resulting in 47 total submissions from 28 different teams (but only 21 teams submitted papers). Only the better of the two submissions of each team is included in final results.

3.2 Baselines

Since our task is formalized as binary classification, the random baseline has 0.50 accuracy. As our test set is not perfectly balanced, a most frequent class baseline would get 0.517 F1.

We also computed an unsupervised distributional vector cosine baseline based on the idea that a discriminative attribute is close to the word it characterizes and further away from the other member of the pair. In the cosine method, each item is classified as a semantic difference if the cosine similarity of $word_1$ and the attribute is greater than the cosine similarity of $word_2$ and the attribute. To compute the cosine baseline, we used a PPMI-based vector space with the best settings from Baroni et al. (2014).

The cosine baseline correctly classifies 0.691 of positive items and 0.539 of negative items in the test data, which corresponds to an average F1 measure of 0.607.

3.3 Human upper bound

In order to obtain a performance upper bound for our task, we measured how complex it is for expert human annotators to identify discriminative attributes. We asked three PhD and post-doc computational linguists to classify a batch of 100 items randomly sampled from the test set. The annotators received two rounds of training on the task by classifying a batch of 100 triples from the validation and test sets. The triples used at annotator training and testing stages were all distinct. Various questions and doubts about the annotation were clarified before passing to the test annotation phase. The agreement between aggregated human judgments (majority vote) and the gold standard was very high, with an accuracy of 0.9, an F1 of 0.89 for the positive class, and an F1 of 0.91 for the negative class.

	correct	incorrect
positive	724	323
negative	697	596

Table 8: Average F1 score per resource type (KB = Knowledge Base, WE = Word Embeddings).

ity or co-occurrence frequency thresholds (Meaning Space, Sommerauer et al.; ELiRF-UPV, Gonzalez et al.; CitiusNLP Gamallo; UNAM Arroyo-Fernandez et al.; Discriminator, Kulmizev et al.; UNBNLP, King et al.; ABDN, Mao et al.; Igevorse, Grishin).

Some of the most successful systems employed traditional machine learning algorithms such as SVMs (SUNNYNLP, Lai et al.; ALB, Dumitru et al.; Wolves, Taslimipoor et al.; ECNU, Zhou et al.; UMD, Zhang and Carpuat), SVC (Luminoso, Speer and Lowry-Duda) and Maximum Entropy Classifiers (UWB, Brychen et al.).

Other teams chose to build their systems using deep learning systems such as neural networks (GHH, Attia et al.; Shiue et al.), CNNs (THU NGN, Wu et al.; AmritaNLP, Vinayan et al.) and XGB classifiers (BomJi, Santus et al.; ECNU, Zhou et al.).

Participants made use of a large number of resources. Such resources can be divided into word embeddings (e.g., Word2Vec, GloVe, fastText) and knowledge base type resources (e.g., WordNet, ConceptNet, Probase). Participants’ analyses of their results indicate that although using knowledge bases can yield high precision results, they cannot easily cover all cases. When employing pre-trained word embeddings, participants noted that out-of-vocabulary items become a challenge. But most importantly, a shortcoming of word embeddings with regard to our task is their inability to distinguish between different types of semantic relatedness. As noted by the GHH team (Attia et al.), *garlic* is related to *wings* not because garlic has the ability to fly but because garlic chicken wings are a popular dish choice; a shallow cooccurrence-based model will fail to recognize that wings characterize chicken but not garlic.

On average, systems which combined word embeddings and knowledge bases outperformed systems that only used word embeddings (Table 8).

Subset	Accuracy	F1 pos	F1 neg
Easy	0.98	0.97	0.98
Hard	0.56	0.61	0.66
Hardest	0.38	0.35	0.39

Table 9: Results of human annotation of the Easy, Hard and Hardest subsets of the test data.

5 Results analysis

We have carried out an in-depth exploration of the systems results in order to get a better insight on the relationship between their performance and the dataset structure and complexity. We ranked all the test triples by the number of systems that annotated them correctly and we selected the 50 top triples that were scored correctly by the most systems and the 50 top triples that were failed by most systems. We called these two subsets the **Easy** and the **Hard** data, respectively. Then, we focused on the results produced by the top 5 systems in Table 6, with an overall performance greater than 70%. Out of the 1340 triples that were failed by at least one of these top systems, we selected the 112 triples (8.3%) that were failed by all 5 systems. We called this subset the **Hardest** data. These datasets were annotated by the same three expert annotators used to compute the human upper bound (cf. Section 3.3). The accuracy and F1 of the aggregated human judgments (majority vote) with respect to the gold standard are reported in Table 9.

The annotation results show an interesting correlation between the system and human performances. The “easy” triples for the systems are easy for humans too, and conversely the harder a triple is for a system the harder it is for humans. The lowest annotation accuracy is on the Hardest subset, less than 40%. However, since this set contains the triples that were failed by all top systems, the human accuracy also proves that there is still plenty of room for improvement even for the best performing models.

Table 9 shows that the F1 on the negative class is usually higher than the one on the positive class. This is again similar to systems behavior. In fact, 70% of the top 100 triples scored correctly by most systems are negative cases, while 67% of the top 100 triples failed by most systems are positive cases. The 112 triples failed by all top file systems contain 54% positive cases. This suggests that for systems and humans alike it is usually harder to

	McRae		manual		random	
label	pos	neg	pos	neg	pos	neg
Easy	1	9	20	7	13	0
Hard	8	2	12	26	0	2

Table 10: Example label and source distribution for the Easy and Hard subsets of the test data.

identify a discriminative attribute, rather than a non-discriminative one. Finally, out of the 1340 triples that were failed by at least one of the top 5 systems, 502 (37%) were failed by just one model. This shows that a great variance exists in the behavior and in the weaknesses of these systems, despite their very close performance.

Types of attributes seem to vary in how difficult they are to differentiate in the context of our task. For example, attributes that stand in the whole-part relation with the word, as in *door, gate, handle*, lean on the hard side (9 examples in the **Hard** sample vs. 2 in the **Easy** one). Attributes that are adjectives, as in *rods, wire, hard*, also tend to be hard (25 examples in the **Hard** sample vs. 13 in the **Easy** one), presumably because of the gradient and context-dependent meaning of adjectives; indeed, 9 of the 13 “easy” examples with adjective attributes involve colours, which are relatively context-independent (as opposed to 4 colour out of the 25 “hard” adjective examples).

Further analysis reveals an unequal distribution of positive and negative examples in the Easy and Hard subsets across different types of data, as shown in Table 10. While overall easy examples tend to be the positive ones and hard examples tend to be negative, among the examples derived from McRae feature norms the pattern is reversed.

Lastly, it is an important issue to understand the causes of the low human performance on the Hard and especially on the Hardest subset. By looking at the wrongly annotated triples in this dataset, we can identify various possible reasons. The first one are mistakes in the gold standard annotation. For instance, *peel* was marked as a discriminative attribute of *banana* from *onion*, but actually peeling is a possible action for both entities. Other cases are instead related to the inherent vagueness of the notion of prototypical attribute. For example, the feature *acts* was marked as non-discriminative of *actress* from *artist*, because any artist can in principle act. Conversely, humans annotators have identified acting as a truly specific attribute for *ac-*

tress, but not for *artist*. The former type of problems prompt for a further revision of the gold standard, while the latter type reveals the complexity of the notion of discriminative attribute and its difficult applications in some cases, which will require a deeper specification of annotation guidelines.

6 Conclusion

Discriminative attribute detection is an intuitively simple and appealing yet challenging new task for lexical semantic systems. For the SemEval competition, we created a high quality dataset of semantic differences, with estimated ceiling performance of human annotators of 0.90. While the task is far from being solved, participating systems showed promising results, most of them beating the cosine baseline.

It is clear that learning to discriminate differentiating features is not trivial and requires training, both for human annotators and for computational systems; all of the top performing systems used machine learning techniques of some kind.

While different teams employed different linguistic resources, the results of the competition do not allow us to conclude that a particular resource gives one's system an edge. On the one hand, exploiting information from knowledge base resources like WordNet does improve the performance on average. On the other hand, traditional machine learning systems that entered our competition were much more likely to make use of knowledge bases. Therefore, combining neural approaches with knowledge bases may very well lead to improved performances.

As we mentioned above, ceiling performance has already been achieved in traditional tasks such as word similarity, causing a stagnation of lexical semantic modeling. As the best systems in our competition showed very promising results, we hope to see novel semantic models demonstrate their full potential on our task.

Abstract

We present SUNNYNLP, our system for solving SemEval 2018 Task 10: “Capturing Discriminative Attributes”. Our Support-Vector-Machine(SVM)-based system combines features extracted from pre-trained embeddings and statistical information from *Is-A* taxonomy to detect semantic difference of concepts pairs. Our system is demonstrated to be effective in detecting semantic difference and is ranked 1st in the competition in terms of F1 measure. The open source of our code is coined SUNNYNLP¹.

1 Introduction

Measuring semantic similarity between words has been a fundamental issue in Natural Language Processing (NLP). Semantic similarity measurements are used to improve downstream applications including paraphrase detection (Xu et al., 2014), question answering (Lin, 2007), taxonomy enrichment (Jurgens and Pilehvar, 2016) and dialogue state tracking (Mrksic et al., 2016).

Despite the current success in using semantic model to measure semantic similarity, lesser attention is paid to teaching machines to make reference (Searle, 1969; Abbott, 2010) to the real world in detecting semantic difference. The semantic difference detection problem can be formalized as a binary classification task: given a triplet (*concept1*, *concept2*, *attribute*) which comprises two concepts (e.g. *apple*, *banana*) and one attribute (e.g. *red*), determine whether the attribute characterizes the former concept but not the latter. Compared to pairwise semantic similarity detection, this problem is more complex than measuring similarity in general because of its underlying asymmetric property and the extra attribute involved. The SemEval 2018 Task 10 (Krebs et al., 2018) is

therefore posed to attract attention to solving this problem.

Although the task of semantic difference detection is novel, similar tasks like referring expression generation (REG) have been studied in the literature. Resources such as ontologies, knowledge bases (Krahmer and Van Deemter, 2012) and images (Kazemzadeh et al., 2014; Lazaridou et al., 2016) are used to learn referring expressions. The major difference between the present task and referring expression is that REG systems can choose salient attributes for making successful reference to objects, while our system is required to decide whether a given attribute can be used to differentiate two similar objects.

The rest of the paper is organized as follows: Section 2 explains our motivation and approach. Section 3 describes the official and external data used. Section 4 details our system implementation. We analyze and discuss the result in Section 5 and conclude our work in Section 6.

2 General Approach

Our approach to this problem is to divide the ternary concept-concept-attribute relationship (*concept1*, *concept2*, *attribute*) into two concept-attribute relationships (*concept*, *attribute*)². The ternary relationship will hold only when the first pair of concept-attribute relation is true and the second false. This approach allows us to use well developed pairwise similarity measurements to extract semantic information from the two concept-attribute pairs, and aggregate the features to train a support vector machine (Cortes and Vapnik, 1995) to detect semantic difference of the triplet, *i.e.* identifying whether a concept contains a specific attribute is a key task of our system.

²For instance, dividing the concept-concept-attribute relationship (*apple*, *banana*, *red*) into two concept-attribute relationships: (*apple*, *red*) and (*banana*, *red*).

¹<https://github.com/Yermouth/sunnynlp>

Concept-instance example (<i>Is-A</i>) from Probase
(<i>yellow</i> food, <i>lemon</i>)
Possible concept-attribute (<i>Has-A</i>) pairs
(yellow, food), (food, yellow), (yellow, lemon), (<i>lemon</i> , <i>yellow</i>), (food, lemon), (lemon, food)
Useful concept-attribute (<i>Has-A</i>) pairs
(<i>lemon</i> , <i>yellow</i>)
Semantic difference triplet in official test cases
(<i>lemon</i> , <i>cranberry</i> , <i>yellow</i>)

Table 1: Concept-attribute pairs (*Has-A*) can be inferred from concept-instance (*Is-A*) entries in taxonomy, and used to determine whether a semantic difference relationship (*concept1*, *concept2*, *attribute*) holds in official test cases.

By observation, we draw similarities between concept-attribute relationship and meronymy (*Has-A*). They are similar in a sense that both describe subtype relationships. Although linguistics resources constructed by human subjects including norms and priming effect data can help us detect and verify these relationships effectively, they are not allowed to be used in this SemEval Task.

This SemEval Task also limits the scope of concepts and attributes to concrete concepts and visual attributes only. As instances of the same concept are likely to share common attributes from our intuitive perspective³, we would like to experiment on extracting meronymy (*Has-A*) information from hypernymy (*Is-A*) pairs. Taxonomies and ontologies which contain rich *Is-A* information in terms of concept-instance pairs are therefore the key external linguistic resources which we rely on to extract concept-attribute relationships.

Another intuition that guides our research direction is that modifiers such as adjectives, adverbs and noun modifiers are useful for capturing salient attribute of a specific class of objects⁴. As modifiers are used to describe the scope of concepts or specify context of instances, we can leverage on

³As both apple and banana are hypernyms of fruit, i.e. apple *Is-A* fruit and banana *Is-A* fruit. If we know apple is “edible”, then banana may have a higher chance of being “edible” by intuition because “edible” can be a common attribute for most fruits.

⁴When we want to differentiate one object from another, we usually use a salient and outstanding attribute to describe the object instead of using a common or similar attribute. Similar viewpoint is previously raised in (Pechmann, 1989; Dale and Haddock, 1991), which states that human beings prefer using efficient and sufficiently distinguishing description when they are constructing referring expressions.

the co-occurrence probability of modifiers to analyze their dependence/independence relationships with different concepts, and hence, to determine whether a concept-attribute relationship holds.

As the SemEval Task limits the word length of the concept and attribute to be 1, we can enumerate all possible pairs of modifiers and concepts from large scale taxonomy and ontology and use them as features to train our system. Table 1 shows an *Is-A* entry in taxonomies which we find instructive for learning semantic difference relationship. For instance, verifying whether semantic difference relationship holds for the triplet (*lemon*, *cranberry*, *yellow*) would require the information of “*lemon* has the attribute *yellow*?” and “*cranberry* does not have the attribute *yellow*?”. With the *Is-A* pair (*yellow* food, *lemon*) from Probase, we can extract possible concept-attribute pairs and their frequency to train our system, such that our system knows with high probability that *lemon* has the attribute *yellow* while *cranberry* does not.

3 Data

We use the official dataset together with two external linguistic resources, GloVe (Pennington et al., 2014) and Probase (Wu et al., 2012; Cheng et al., 2015), to train our system.

3.1 Official Dataset

Official datasets⁵ are split into three parts – training, validation and testing, where the testing holds a disjoint attribute sets apart from training and validation. This further increases the difficulty of the task as it prevents *lexical memorization* (Roller et al., 2014; Levy et al., 2015; Weeds et al., 2014) and tests for generalization.

3.2 Probase

Probase is a web scale open domain taxonomy which uses Hearst patterns (Hearst, 1992) to extract *Is-A* relationship from web documents. Each *Is-A* entry in Probase is represented as a triplet form: super-concept, sub-concept and number of co-occurrence. We choose Probase for two main reasons:

1. Large number of concepts covered: The number of concepts covered in Probase (Wu et al., 2012) exceeds other publicly available

⁵in the form of concept-concept-attribute triplet with human annotated label indicating whether semantic difference exists.

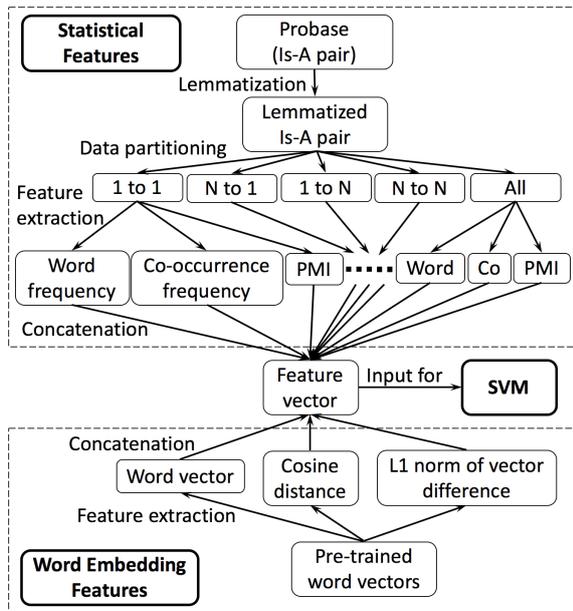

Figure 1: System architecture pipeline diagram.

taxonomies and ontologies including WordNet (Miller, 1995) and YAGO (Suchanek et al., 2007)⁶.

2. Rich in semantic features: Probase provides *Is-A* relationship pairs with concepts of different senses and abstraction levels, which allows our system to extract rich statistical information for training. For instance, *Is-A* pairs in Table 2 are extracted from Probase.

3.3 GloVe

Pre-trained embeddings such as Word2Vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014) and FastText (Bojanowski et al., 2016) encode syntactic and semantic relationships of words in low-dimension space, which is crucial to the capturing of semantic difference. We use the GloVe embedding pre-trained on both Gigaword corpus and 2014 Wikipedia dump in our final submission system.

4 System Description

Our system architecture pipeline (Figure 1) includes the process of data preprocessing, feature extraction and classifier selection.

4.1 Data Preprocessing

Preprocessing procedure is applied to Probase including:

⁶Probase includes 2,653,872 concepts while WordNet and YAGO contain 25,229 and 352,297, respectively.

Partition	Concept-Instance(<i>Is-A</i>) example	Size
1 to 1	(fruit, banana)	2.12M
N to 1	(high sugar fruit, banana)	7.91M
1 to N	(plant, banana tree)	9.32M
N to N	(dried fruit, banana chip)	14.01M
Total		33.37M

Table 2: Partitioning of dataset into 4 subsets with an example entrand partition size provided.

Frequency Type	Feature Extracted
Individual word	(dried), (fruit), (banana), (chip)
Concept-Concept	(dried, fruit)
Instance-Instance	(banana, chip)
Concept-Instance	(dried, banana), (dried, chip), (fruit, banana), (fruit, chip)

Table 3: Example of how individual word frequency (the first row) and three types of co-occurrences (the last three rows) are counted for the *Is-A* pair (dried fruit, banana chip) in Probase.

- Lemmatization: As Probase is crawled using a rule-based system, we lemmatize the data using stanford CoreNLP (Manning et al., 2014) to reduce words of different forms and allow better matching between *Is-A* entries in taxonomy and official dataset.
- Data partitioning: To give our system additional information regarding the adjectives, adverbs and modifiers of both concepts and instances, we partition Probase into 4 sub datasets, according to the word length of the concept and instance pair. For instance, partition “1 to 1” indicates that both concept and instance are of word length 1. Partition “N to 1” indicates concepts of arbitrary word length (more than 1) and instances of word length 1. Example of each partition are given in Table 2.

4.2 Feature Extraction

4.2.1 Statistical Features

As for statistical features, we consider the statistical features of the individual words, *i.e.* *concept1*, *concept2*, *attribute*, and the two concept-attribute relationship pairs, *i.e.* (*concept1*, *attribute*), (*concept2*, *attribute*) using individual or co-occurrence frequency in Probase.

Word frequency is extracted from individual words, and the following features are extracted from the *Is-A* pairs:

- Co-occurrence frequency

Model (Features)	Valid(cv=5)	Train/Test	Train+Valid/Test	Valid/Test
SVM(GloVe, Probase)	0.790	0.644	0.714	0.754
SVM(FastText, Probase)	0.764	0.649	0.709	0.757
SVM(Word2Vec, Probase)	0.757	0.636	0.721	0.732
Logistic Regression(Probase)	0.698	0.602	0.644	0.717
SVM(Probase)	0.730	0.553	0.637	0.691
Logistic Regression(GloVe, Probase)	0.753	0.607	0.674	0.674
SVM(GloVe)	0.712	0.597	0.652	0.668
SVM(FastText)	0.689	0.563	0.593	0.650
SVM(Word2Vec)	0.667	0.556	0.581	0.634

Table 4: Result (F1-score) obtained by our system. The underlined value represents the score of our official submission. Best scores for each partition are denoted in boldface.

- Pointwise Mutual Information(PMI) (Fano, 1961; Church and Hanks, 1990)
- Asymmetric Pointwise Mutual Information(APMI)

There are three types of pairwise word co-occurrence frequencies, including Concept-Concept, Instance-Instance and Concept-Instance. All types of frequencies are calculated for all partitions as distinct features. Table 3 gives an example of how occurrence and co-occurrence are counted. We apply logarithm to the statistical features to reduce the scale of frequently occurring words.

4.2.2 Word Embedding Features

We use the Python package Gensim (Rehurek and Sojka, 2010) to match each word in the triplet (*concept1*, *concept2*, *attribute*) in the official dataset with their corresponding pre-trained vectors v_{con1} , v_{con2} , v_{attr} , each of 300 dimensions. We then divide the triplet into three pairwise relationships *i.e.* (v_{con1} , v_{con2}), (v_{con1} , v_{attr}), and (v_{con2} , v_{attr}), and calculate the cosine similarity and L1-norm of the vector difference of these pairs as features. Dot-product is considered initially but removed as it adversely affects the performance of our system.

4.3 Classifiers

Using the same set of word embedding and statistical features, we compared the performance of four off-the-shelf classifiers including SVM (Cortes and Vapnik, 1995), Logistic Regression Classifier, Decision Tree Classifier and Random Forest Classifier. SVM classifier with RBF kernel (Vert et al., 2004) is used in our system as it outperforms other classifiers in terms of precision and F1-score.

5 Results and Discussion

5.1 Results

We provide the results of our system with different combinations of features and datasets in Table 4. Column *Train+Valid/Test* represents the F1-score obtained by training our system with both the training partition and validation partition, while column *Train/Test* and *Valid/Test* are F1-score obtained by training our system on the training partition and validation partition individually. Training our SVM system with Probase and GloVe (or FastText) gives the best result in terms of F1-score for official evaluation (column *Valid/Test*). Our system achieves a F1-score of 0.754 and outperforms those of the other teams.

5.2 Discussion

During the competition phase, we noticed that our system performs better when we did not use training partition together with validation partition. As the entries in the training partition are automatically generated, there may be false entries or noise which can adversely affect our system. Since the validation partition comprises manually curated examples, we evaluate our models using 5-fold cross validation on the clean validation partition only (indicated by column *Valid(cv=5)*).

6 Conclusion

In this paper, we have discussed how our simple yet effective SVM system leverages on hyponymy (*Is-A*) relationships and word embeddings to detect single word semantic difference relationship. SVM has been shown useful especially in performing semantic relationship detection tasks (Filice et al., 2016; Panchenko et al., 2016). We would like to extend our system for detecting multiple-words semantic difference relationship, and to broaden the scope of concepts

and attributes from visual only to sound and taxonomic.

As our system separates a concept-concept-instance relationship into two concept-instance relationships, our system is relatively weak in capturing attributes that are comparative or fuzzy, for instance, *young* and *tall*. It would be interesting to explore how semantic difference relationship can be embedded into taxonomies, ontologies and vector representations, so that comparative attributes can be comprehensively and directly captured.

Saarbrücken, Germany

{simono|mroth|ashutosh|stth|pinkal}@coli.uni-saarland.de

Abstract

This report summarizes the results of the SemEval 2018 task on machine comprehension using commonsense knowledge. For this machine comprehension task, we created a new corpus, *MCScript*. It contains a high number of questions that require commonsense knowledge for finding the correct answer. 11 teams from 4 different countries participated in this shared task, most of them used neural approaches. The best performing system achieves an accuracy of 83.95%, outperforming the baselines by a large margin, but still far from the human upper bound, which was found to be at 98%.

1 Introduction

Developing algorithms for understanding natural language is not trivial. Natural language comes with its own complexity and inherent ambiguities. Ambiguities can occur, for example, at the level of word meaning, syntactic structure, or semantic interpretation. Traditionally, Natural Language Understanding (NLU) systems have resolved ambiguities using information from the textual context (e.g. neighboring words and sentences), for example via distributional methods (Lenci, 2008). However, many times context may be absent or may lack sufficient information to resolve the ambiguity. In such cases, it would be beneficial to include commonsense knowledge about the world in an NLU system. For example, consider example (1).

- (1) The waitress brought Rachel's order. She ate the food with great pleasure.

Looking at the example in isolation, the person eating the food could be either Rachel or the waitress. Using commonsense knowledge, or, more specifically, script knowledge about the RESTAURANT scenario, helps to resolve the referent of the pronoun: Rachel ordered the food. The person who

orders the food is the customer. So Rachel should eat the food, *she* thus refers to Rachel.

This shared task assesses how the inclusion of commonsense knowledge benefits natural language understanding systems. In particular, we focus on commonsense knowledge about everyday activities, referred to as *scripts*. Scripts are sequences of events describing stereotypical human activities (also called *scenarios*), for example baking a cake, taking a bus, etc. (Schank and Abelson, 1975). The concept of scripts has its underpinnings in cognitive psychology and has been shown to be an important component of the human cognitive system (Bower et al., 1979; Schank, 1982; Modi et al., 2017). From an application perspective, scripts have been shown to be useful for a variety of tasks, including story understanding (Schank, 1990), information extraction (Rau et al., 1989), and drawing inferences from texts (Miikkulainen, 1993).

Factual knowledge is mentioned explicitly in texts from sources such as Wikipedia and news papers. On the contrary, script knowledge is often implicit in the texts as it is assumed to be known to the comprehender. Because of this implicitness, learning script knowledge from texts is very challenging. There are few exceptions of corpora containing narrative texts that explicitly instantiate script knowledge. An example is the *InScript* (Modi et al., 2016), which contains short and simple narratives, that very explicitly mention script events and participants. The *Dinners from Hell* corpus (Rudinger et al., 2015a) is a similar dataset centered around the EATING IN A RESTAURANT scenario.

In the past, script modeling systems have been evaluated using intrinsic tasks such as event ordering (Modi and Titov, 2014), paraphrasing (Regneri et al., 2010; Wanzare et al., 2017), event prediction (namely, the narrative cloze task) (Chambers and Jurafsky, 2008, 2009; Rudinger et al., 2015b; Modi, 2016) or story completion (e.g. the story cloze task

T It was a long day at work and I decided to stop at the gym before going home. I ran on the treadmill and lifted some weights. I decided I would also swim a few laps in the pool. Once I was done working out, I went in the locker room and stripped down and wrapped myself in a towel. I went into the sauna and turned on the heat. I let it get nice and steamy. I sat down and relaxed. I let my mind think about nothing but peaceful, happy thoughts. I stayed in there for only about ten minutes because it was so hot and steamy. When I got out, I turned the sauna off to save energy and took a cool shower. I got out of the shower and dried off. After that, I put on my extra set of clean clothes I brought with me, and got in my car and drove home.

Q1 Where did they sit inside the sauna?
a. on the floor b. on a bench

Q2 How long did they stay in the sauna?
a. about ten minutes b. over thirty minutes

Figure 1: An example for a text from MCScript with 2 reading comprehension questions.

(Mostafazadeh et al., 2016)). These tasks test a system’s ability to learn script knowledge from a text but they do not provide a mechanism to evaluate how useful script knowledge is in natural language understanding tasks.

Our shared task bridges this gap by directly relating commonsense knowledge and language comprehension. The task has a machine comprehension setting: A machine is given a text document and asked questions based on the text. In addition to what is mentioned in the text, answering the questions requires knowledge beyond the facts mentioned in the text. In particular, a substantial subset of questions requires inference over commonsense knowledge via scripts. For example, consider the short narrative in (1). For the first question, the correct choice for an answer requires commonsense knowledge about the activity of going to the sauna, which goes beyond what is mentioned in the text: Usually, people sit on benches inside a sauna, an

information that is not given in the text. The dataset also comprises questions that can just be answered from the text, as the second question: The information about the duration of the stay is given literally in the text.

The paper is organized as follows: In Section 2, we give an overview of other machine comprehension datasets. In Section 3, we describe the dataset used for our shared task. Section 4.2 gives details about the setup of our task. In Section 5, information about participating systems is given. Results are presented and discussed in Sections 6 and 8, respectively.

2 Related Work

Recently, a number of datasets have been proposed for machine comprehension. One example is *MCTest* (Richardson et al., 2013), a small curated dataset of 660 stories, with 4 multiple choice questions per story. The stories are crowdsourced and not limited to a domain. Answering questions in *MCTest* requires drawing inferences from multiple sentences from the text passage. In our dataset, in contrast, answering requires drawing inferences using knowledge not explicit in the text. Another recently published multiple choice dataset is RACE (Lai et al., 2017), which contains 100,000 questions on reading examination data.

Rajpurkar et al. (2016) have proposed the *Stanford Question Answering Dataset (SQuAD)*, a data set of 100,000 questions on Wikipedia articles collected via crowdsourcing. In that dataset, the answer to a question corresponds to a segment/span from the reading passage. Since Wikipedia articles mostly contain factual knowledge, *SQuAD* does not assess how in practice, language comprehension relies on implicit and underrepresented knowledge about everyday activities i.e. script knowledge.

Weston et al. (2015) have created the *BAbI* dataset. *BAbI* is a synthetic reading comprehension data set testing different types of reasoning to solve different tasks. In contrast to our dataset, the artificial texts in *BAbI* are not reflective of a typically occurring narrative text.

Two recently published datasets that also have a larger focus on commonsense reasoning are *NewsQA* and *TriviaQA*. *NewsQA* (Trischler et al., 2017) contains newswire texts from CNN with crowdsourced questions and answers. During the question collection, workers were only presented with the title of the text, and a short summary. This

method ensures that literal repetitions of the text are avoided and the generation of non-trivial questions requiring background knowledge is supported. The NewsQA text collection differs from MCScript in domain and genre (newswire texts vs. narrative stories about everyday events). Knowledge required to answer the questions is mostly factual knowledge and script knowledge is only marginally relevant.

TriviaQA (Joshi et al., 2017) contains automatically collected question-answer pairs from 14 trivia and quiz-league websites, together with web-crawled evidence documents from *Wikipedia* and *Bing*. While a majority of questions require world knowledge for finding the correct answer, it is mostly factual knowledge.

3 Data

In 3.1, we now briefly describe the machine comprehension dataset used for the shared task, *MCScript*. Parts of the following Section are taken from Ostermann et al. (2018). For a more detailed description of the resource collection and a more thorough discussion of the dataset, we refer to the original paper. Section 3.2 gives details about script data collections that were made available to the participants.

3.1 Machine Comprehension Data - MCScript

For our shared task, we use the *MCScript* data set (Ostermann et al., 2018). It is a collection of narrative texts, questions of various types referring to these texts, and pairs of answer candidates for each question. It comprises 2,119 such texts and a total of 13,939 questions. The texts in the data set talk about everyday activities and cover 110 script scenarios of differing complexity. For the text collection, we followed Modi et al. (2016): All texts are simple and explicit in the description of script events and script participants.

The data set was crowdsourced via Amazon Mechanical turk¹. In the crowdsourcing experiments, participants were asked to write questions independent of a concrete narrative, but only based on short descriptions of a scenario. By doing so, the collected questions were related to the scenario only and could be answered from different texts, independent of story details.

The scenario-based questions were paired randomly with texts from the same scenario. The

¹www.mturk.com

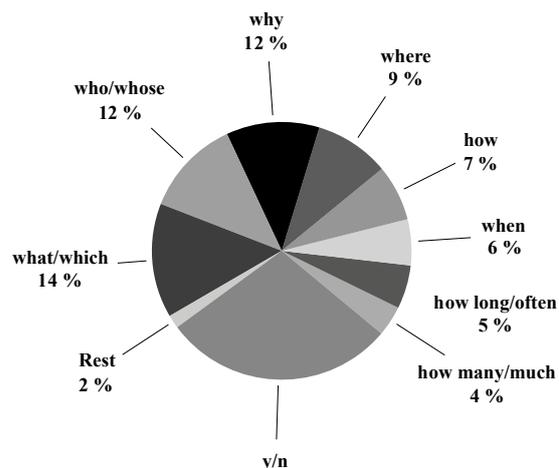

Figure 2: Distribution of question types in MCScript, from Ostermann et al. (2018).

subsequent answer collection was divided up into two steps: First, crowdsourcing workers had to annotate whether a question could be answered based on the given text. If it could be answered, they had to explicitly mark whether it could be answered from the text directly or based on commonsense knowledge. Second, they had to write a plausible correct and incorrect answer, if the question was answerable. Afterwards, all texts, questions and answers were manually validated by trained annotators, and corrected, if necessary.

Due to the design of the data acquisition process, a substantial subset of questions (27.4%) require commonsense inference about everyday activities. Figure 2 gives an overview of the distribution of question types on the data. *Yes/No* questions form the largest group, with 29%, followed by questions asking for details of a narration or scenario (*what/which* and *who*).

For the task, the corpus was split into training (9,731 questions on 1,470 texts), development (1,411 questions on 219 texts), and test set (2,797 questions on 430 texts). For 5 scenarios, all texts were held out for the test set, in order to avoid that models overfit and memorize the scenarios in the training data. Texts, questions, and answers contain on average 196.0 words, 7.8 words, and 3.6 words, respectively. There are 6.7 questions per text on average.

3.2 Script and Commonsense Knowledge Data

We also encouraged participants to make use of existing script data collections. Thus, we provided several existing collections of script data together with the machine comprehension corpus: DeScript (Wanzare et al., 2016), RKP (Regneri et al., 2010) and the OMCS stories (Singh et al., 2002). The three datasets contain sequences of short, telegraph-styled descriptions of all events that need to be conducted in a scenario (*event sequence descriptions, ESDs*). The data sets contain ESDs for different numbers of scenarios, with a total coverage of over 200 scenarios. The complexity of scenarios varies from simple activities, such as *opening a window*, to more complex ones, such as *attending a wedding*.

For 90 of the 110 scenarios in MCScript, there exist multiple ESDs per scenario in at least one of the 3 script data collections.

We also advised participants to make use of other representations for script knowledge, such as narrative chains (Chambers and Jurafsky, 2008), or event embeddings (Modi and Titov, 2014).

Some participants also made use of *ConceptNet* (Speer et al., 2017) as a resource for commonsense knowledge. ConceptNet is a large-scale knowledge graph that is built from several handcrafted and crowdsourced sources, and that encodes various types of commonsense knowledge.

4 Shared Task Setup

4.1 Evaluation Method

In our evaluation, we measured how well a system was capable of correctly answering questions that may involve commonsense knowledge. As evaluation metric, we used accuracy, calculated as the ratio between correctly answered questions and all questions in our evaluation data. We also evaluated systems with regard to specific question types and based on whether a question is directly answerable, or only inferable from the text.

4.2 Baselines

We provide results of two baseline systems as lower bounds for comparison: a rule-based baseline (*Sliding Window*) and a neural end-to-end system (*Attentive Reader*). Both baselines are described in

²IUCM cluster MCScript texts and try to find answers also in other texts, that are topically similar. In that sense, MCScript itself is used to represent commonsense knowledge.

more detail below. For details about the tuning of hyperparameters, we refer to Ostermann et al. (2018).

Sliding Window

The sliding window baseline is a simple rule-based method that answers a question on a text by predicting the answer option with the highest similarity to the text. The intuition underlying this method is that answers similar to a text should be more plausible than answer options that are different from the text (independent of the question). In our baseline implementation, we compute similarity using a sliding window that compares each answer option to any possible “window” of w tokens of the text. For comparison, each window and each answer is represented by an average vector, computed over the components of word embeddings corresponding to the words in the window and answer, respectively. For each possible window, we compute similarity as the cosine similarity between the window and the answer representation. The answer with the higher maximum similarity (over possible windows) is predicted to be the correct answer.

Attentive Reader

The attentive reader is an established machine comprehension model that reaches good performance e.g. on the *CNN/Daily Mail* corpus (Hermann et al., 2015; Chen et al., 2016). It is a neural network-based approach, which scores answers to a question on a text by finding (“paying attention to”) and scoring relevant passages in the text. The scoring and attention mechanisms are learned directly (“end-to-end”) from text–question–answer triples, without the need for manual rule writing or feature engineering. As a baseline for the shared task, we use the model formulation by Chen et al. (2016) and Lai et al. (2017), who employ bilinear weight functions to compute both attention and answer-text fit. Bi-directional gated recurrent units (GRUs) are used to encode questions, texts and answers into hidden representations. For a question q and an answer a , the last state of the GRU, \mathbf{q} and \mathbf{a} , are used as representations, while the text is encoded as a sequence of hidden states $\mathbf{t}_1 \dots \mathbf{t}_n$. We compute an attention score s_j for each hidden state \mathbf{t}_j using the question representation \mathbf{q} , a weight matrix \mathbf{W}_a , and an attention bias b . The text representation \mathbf{t} is computed as a weighted average of hidden

Rank	Team name	Main model	Commonsense	Other resources	Acc.

representations:

$$s_j = \text{softmax}_j(\mathbf{t}_j^\top \mathbf{W}_a \mathbf{q} + b)$$

$$\mathbf{t} = \sum_j s_j \mathbf{t}_j \quad (1)$$

The probability p of answer a being correct is predicted using another bilinear weight matrix \mathbf{W}_s , followed by an application of the softmax function over both answer options for the question:

$$p(a|t, q) = \text{softmax}(\mathbf{t}^\top \mathbf{W}_s \mathbf{a}) \quad (2)$$

5 Participants

We ran our shared task through the CodaLab platform³. 24 teams submitted results during the evaluation period, out of which 11 teams provided system descriptions: 8 teams from China, and one team each from Spain, Russia and the US. The full leader board containing all 24 submissions can be found on the shared task website.

Except for one team, all participating models rely on recurrent neural network techniques to encode texts, questions and/or answers. The one team that did not apply neural methods proposed an alternative approach based on clustering techniques and scoring word overlap. Only 3 of the 11 teams made explicit use of commonsense knowledge: Two approaches used ConceptNet, either in the form of features extracted from ConceptNet relations or in the form of pretrained *Numberbatch*

³<https://competitions.codalab.org/competitions/17184>

embeddings (Speer et al., 2017). One participating system made use of script knowledge in the form of event sequence descriptions. Resources commonly used by participants include pretrained word embeddings such as GloVe (Pennington et al., 2014) or word2vec (Mikolov et al., 2013), and preprocessing pipelines such as NLTK⁴. In the following, we provide short summaries of the participants’ systems and we give an overview of models and resources used by them (Table 1).

Non-neural methods *IUCM* (Reznikova and Derczynski, 2018) applied an unsupervised approach that assigns the correct answer to a question based on text overlap. Text overlap is computed based on the given passage and text sources of the same topic. Different clustering and topic modeling techniques are used to identify such text sources in MCScript and DeScript.

Neural-network based models Apart from *IUCM*, all participating systems are neural end-to-end models that employ recurrent and/or convolutional neural network architectures. Systems mainly differ with respect to details of the architecture and the form of how words are represented.

Yuanfudao (Liang Wang, 2018) applies a three-way attention mechanism to model interactions between the text, question and answers, on top of BiLSTMs. Each word in a text, question, and answer is represented by a vector of GloVe embeddings and additional information from part-of-speech tagging, name entity recognition, and relation extraction

Table 2: The accuracy of participating systems and the two baselines in total, on commonsense-based questions (CS), text-based questions (TXT) and on out-of-domain questions (from the 5 held-out testing scenarios). The best performance for each column is marked in **bold print**. Significant differences in results between two adjacent lines are marked by an asterisk (* $p < 0.05$) in the upper line. The last line shows the human upper bound (Ostermann et al., 2018) as comparison.

(based on ConceptNet). The model is pretrained on another large machine comprehension dataset, namely the RACE corpus.

MITRE (Merkhofer et al., 2018) use a combination of 3 systems - two LSTMs with attention mechanisms, and one logistic regression model using patterns based on the vocabulary of the training set. The two neural models use different word embeddings - one trained on GoogleNews, another one trained on Twitter, which were enriched with word overlap features. Interestingly, the simple logistic regression model achieves competitive performance and would have ranked 4th as an individual system.

Jiangnan (Xia, 2018) applies a BiLSTM over GloVe and CoVe embeddings (McCann et al., 2017) with an additional attention mechanism. The attention mechanism computes soft word alignment between words in the question and the text or answer. Manual features, including part-of-speech tags, named entity types, and term frequencies, are employed to enrich word token representations.

ELiRF-UPV (José -Ángel González et al., 2018) employs a BiLSTM with attention to find similarities between texts, questions, and answers. Each word is represented based on Numberbatch embeddings, which encode information from ConceptNet.

YNU_Deep (Ding and Zhou, 2018) test different LSTMs and BiLSTMs variants to encode questions, answers and texts. A simple attention mechanism is applied between question-answer and text-answer pairs. The final submission is an ensemble of five model instances.

ZMU (Li and Zhou, 2018) consider a wide variety of neural models, ranging from CNNs, LSTMs and BiLSTMs with attention, together with pretrained Word2Vec and GloVe embeddings. They also employ data augmentation methods typically used in image processing. Their best performing model is a BiLSTM with attention mechanism and combined GloVe and Word2Vec embeddings.

ECNU (Sheng et al., 2018) use BiGRUs and BiLSTMs to encode questions, answers and texts. They implement a multi-hop attention mechanism from question to text (a Gated Attention Reader (Dhingra et al., 2017)).

YNU_AII799 (Liu et al., 2018) submitted an ensemble of neural network models based on LSTMs, RNNs, and BiLSTM/CNN combinations, with attention mechanisms. In addition to word2vec embeddings, positional embeddings are used that are generated based on word embeddings.

Table 3: Accuracy of participating systems and the baselines on the six most frequent question types. The best performance for each column is marked in **bold print**. Significant differences in results between two adjacent lines are marked by an asterisk (* $p < 0.05$) in the upper line.

YNU-HPCC (Yuan et al., 2018) use an ensemble of neural networks with stacked CNN and LSTM layers and attention.

CSReader (Jiang and Sun, 2018) use GRUs to encode questions and texts. Answer and text are combined by using an attention mechanism that models soft word alignments, inspired by work on Natural Language Inference (Bowman et al., 2015). Two answer classifiers based on these representations are ensembled for prediction.

6 Results

Tables 2 and 3 give detailed results for all participating systems. We performed pairwise significance tests using an approximate randomization test (Yeh, 2000) over texts. At an accuracy of 84%, the best participating team Yuanfudao performed significantly better ($p < 0.05$) than the second best system, MITRE (82%).

Except for *when* questions, Yuanfudao also achieved the best performance at each question type. However, individual differences in results over the 2nd place system were not found to be significant. The top three participating teams, Yuanfudao, MITRE and Jiangnan, all significantly outperform the remaining teams on text-based questions (>80% vs. <74%) as well as on *yes/no*, *what*, *where* and *when* questions.

In comparison to our baselines, all teams but Innopolis significantly outperform Sliding Window. Results of the Attentive Reader are in line

with those of the participating systems ranked 7–9: ECNU, YNU_AI1799 and YNU_HPCC. The six top-ranked systems all significantly outperform both of our baselines. On out-of-domain questions, only the top 3 performing models significantly outperform the Attentive Reader baseline, while all models significantly outperform the Sliding Window approach.

For commonsense-based questions as well as for questions on *why* and *who*, results are considerably less consistent: while the top ranked system significantly outperforms teams ranked 7th or lower, most pairwise differences between the top teams are not statistically significant. This implies that the set of correctly answered questions considerably varies between systems, either due to randomness or because they excel at different inference problems.

We found that 19.3 % of the questions in the test set were answered correctly by each participating system. These questions mainly contain text-based questions with an answer that is literally given in the text. Also, there are many commonsense-based questions with a standardized correct answer, as shown in Example 2. Only few of the stories in MCScript cover a long timespan, so the answer to such questions is always similar.

- (2) **Q:** How long did it take to pump up the tires?
a. just a few minutes b. a few hours

In contrast, only 1% of questions could not be answered by any of the participating models. Answer-

ing these questions mainly requires complicated inference steps, such as counting or plausibility judgements.

7 Discussion

We briefly highlight some of the findings by the shared task participants.

External knowledge sources. One of the main goals of this shared task was to provide an extrinsic evaluation framework for models of commonsense knowledge. However, only three participants actually made use of resources of commonsense knowledge.

Most prominent is the use of ConceptNet, a large-scale knowledge graph that is built from several handcrafted and crowdsourced sources. It was employed by two of the top 5 scoring models: Yuanfudao use it to learn their own ConceptNet-based relation embeddings. ELiRF-UPV make use of Numberbatch word embeddings, which are learned based on ConceptNet data. Ablation analyses conducted by Yuanfudao indicate that the addition of ConceptNet increases overall accuracy by almost 1% absolute. In contrast, only one participant used crowdsourced script data from the DeScript corpus in their final submission, IUCM. They found that the use of script data, instead of or in addition to texts, improved performance by up to 0.3% absolute.

CSReader tried to extend their neural model with script data from OMCS, but report that it did not result in an improvement.

No participant made use of narrative chains or other forms of structured/learned representations of scripts or events (such as event embeddings).

Pretraining. Most participants made use of pretraining in the form of word embeddings such as word2vec or GloVe, that were build on large data collections. Yuanfudao used the RACE dataset, which is the largest available multiple-choice machine comprehension corpus, for pretraining the complete model for several epochs. In their ablation analysis, they found pretraining to have the largest effect on model performance, with improvements in accuracy of up to 1.4% absolute. This result underlines that the comparably small size of MCScript naturally restricts how much neural approaches can learn from the data without overfitting.

Word representations. For representing tokens, most participants used word2vec embeddings, GloVe embeddings, or combinations thereof. The participating teams used different dimensionality sizes, and some of them refitted the vectors while others did not, leading to differing outcomes for both embedding types. In summary, none of both representations seems to clearly outperform the other.

In contrast, participants consistently found that extending word representations with additional features improves results: For example, Yuanfudao and Jiangnan use predicted part-of-speech tags and named entity information, as well as term frequency, and report improvements of up to 1% absolute in accuracy. Also, some participants report the use of word overlap features. Most notably, MITRE found that a logistic regression classifier based on overlap features can achieve performance competitive with neural approaches.

In general, additional features seem to be beneficial, since they provide more explicit or additional information that can be leveraged by neural networks and other classifiers.

Preprocessing. Several participants reported that lemmatizing and stop word removal further improved their results. A prominent example is the submission by MITRE, who use a stemmer to derive root forms for all words, in order to compute overlap and co-occurrence statistics between answers and text/questions.

8 Conclusions

This shared task provides an evaluation framework for commonsense knowledge in a machine comprehension setting. We create the MCScript corpus, which provides 2,119 stories and 13,939 answers for 110 everyday activities of different complexity. In contrast to previous datasets, MCScript was created in a way that results in a relatively large amount of *common sense questions*, i.e. questions which can not be answered directly from the text but require some form of common-sense knowledge about the scenario under consideration to be answered correctly.

24 teams submitted systems during the the evaluation period of the shared task, of which 11 teams submitted task description papers. The best-performing system achieves an overall accuracy of 84%, which outperforms the two baselines by a

large margin; yet, there gap to the human upper bound (98%) is still relative large.

Although participants were explicitly encouraged to use additional common-sense knowledge resources like DeScript or OMCS, only 3 systems (including the best-performing system) actually used such additional resources. The evaluation results suggest that additional common-sense knowledge is in fact beneficial for overall accuracy. However, the positive effect is relatively small, which might be due to the fact that our dataset has been created in a way that leads to relatively “easy” stories, and that the systems are able to learn a certain amount of common sense knowledge directly from the stories. In future work, it would be interesting to see if the results of our shared task carry over to other, presumably more complex stories like for instance personal blog stories from the Spinn3r corpus (Burton et al., 2011).

Acknowledgments

We thank the reviewers for their helpful comments. Also, we thank all teams for their participation and the effort they put into their submissions and the discussions, making this shared task a success.

This research was funded by the German Research Foundation (DFG) as part of SFB 1102 Information Density and Linguistic Encoding and EXC 284 Multimodal Computing and Interaction.

Abstract

This paper describes our system for *SemEval-2018 Task 11: Machine Comprehension using Commonsense Knowledge* (Ostermann et al., 2018b). We use **Three-way Attentive Networks (TriAN)** to model interactions between the passage, question and answers. To incorporate commonsense knowledge, we augment the input with relation embedding from the graph of general knowledge *ConceptNet* (Speer et al., 2017). As a result, our system achieves state-of-the-art performance with 83.95% accuracy on the official test data. Code is publicly available at <https://github.com/intfloat/commonsense-rc>.

1 Introduction

It is well known that humans have a vast amount of commonsense knowledge acquired from everyday life. For machine reading comprehension, natural language inference and many other NLP tasks, commonsense reasoning is one of the major obstacles to make machines as intelligent as humans.

A large portion of previous work focus on commonsense knowledge acquisition with unsupervised learning (Chambers and Jurafsky, 2008; Tandon et al., 2017) or crowdsourcing approach (Singh et al., 2002; Wanzare et al., 2016). *ConceptNet* (Speer et al., 2017), *WebChild* (Tandon et al., 2017) and *DeScript* (Wanzare et al., 2016) etc are all publicly available knowledge resources. However, resources based on unsupervised learning tend to be noisy, while crowdsourcing approach has scalability issues. There is also some research on incorporating knowledge into NLP tasks such as reading comprehension (Lin et al., 2017; Yang and Mitchell, 2017) neural machine translation (Zhang et al., 2017a) and text classification (Zhang et al., 2017b) etc. Though

experiments show performance gains over baselines, these gains are often quite marginal over the state-of-the-art system without external knowledge.

In this paper, we present **Three-way Attentive Networks (TriAN)** for multiple-choice commonsense reading comprehension. The given task requires modeling interactions between the passage, question and answers. Different questions need to focus on different parts of the passage, attention mechanism is a natural choice and turns out to be effective for reading comprehension. Due to the relatively small size of training data, *TriAN* use word-level attention and consists of only one layer of LSTM (Hochreiter and Schmidhuber, 1997). Deeper models result in serious overfitting and poor generalization empirically.

To explicitly model commonsense knowledge, relation embeddings based on *ConceptNet* (Speer et al., 2017) are used as additional features. *ConceptNet* is a large-scale graph of general knowledge from both crowdsourced resources and expert-created resources. It consists of over 21 million edges and 8 million nodes. *ConceptNet* shows state-of-the-art performance on tasks like word analogy and word relatedness.

Besides, we also find that pretraining our network on other datasets helps to improve the overall performance. There are some existing multiple-choice English reading comprehension datasets contributed by NLP community such as *MCTest* (Richardson et al., 2013) and *RACE* (Lai et al., 2017). Although those datasets don't focus specifically on commonsense comprehension, they provide a convenient way for data augmentation. Augmented data can be used to learn shared regularities of reading comprehension tasks.

Combining all of the aforementioned techniques, our system achieves competitive performance on the official test set.

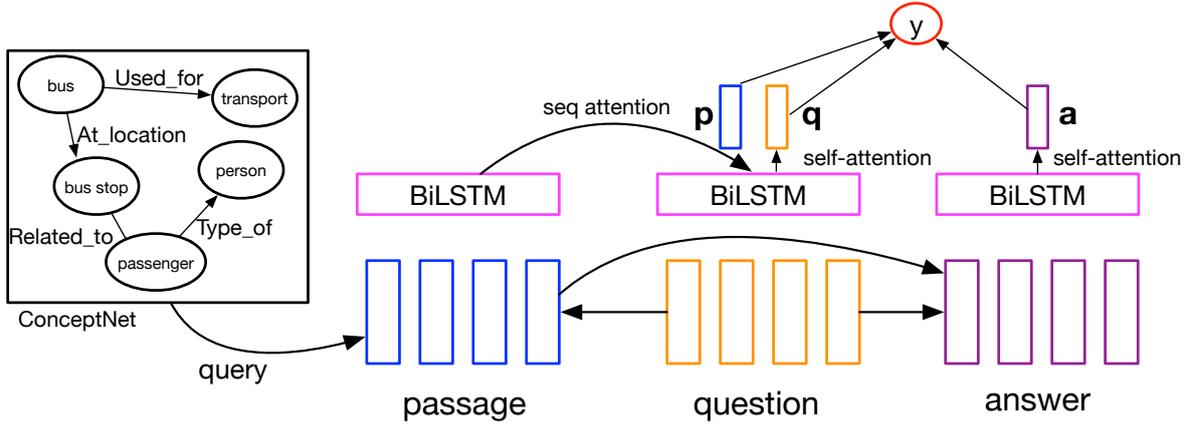

Figure 1: *TriAN* Model Architecture.

2 Model

The overall architecture of *TriAN* is shown in Figure 1. It consists of an input layer, an attention layer and an output layer.

Input Layer. A training example consists of a passage $\{P_i\}_{i=1}^{|P|}$, a question $\{Q_i\}_{i=1}^{|Q|}$, an answer $\{A_i\}_{i=1}^{|A|}$ and a label $y^* \in \{0, 1\}$ as input. P , Q and A are all sequences of word indices. For a word P_i in the given passage, the input representation of P_i is the concatenation of several vectors:

- **GloVe embeddings.** Pretrained 300-dimensional *GloVe* vector $\mathbf{E}_{P_i}^{glove}$.
- **Part-of-speech and named-entity embeddings.** Randomly initialized 12-dimensional part-of-speech embedding $\mathbf{E}_{P_i}^{pos}$ and 8-dimensional named-entity embedding $\mathbf{E}_{P_i}^{ner}$.
- **Relation embeddings.** Randomly initialized 10-dimensional relation embedding $\mathbf{E}_{P_i}^{rel}$. The relation is determined by querying ConceptNet whether there is an edge between P_i and any word in question $\{Q_i\}_{i=1}^{|Q|}$ or answer $\{A_i\}_{i=1}^{|A|}$. If there exist multiple different relations, just randomly choose one.
- **Handcrafted features.** We also add logarithmic term frequency feature and co-occurrence feature \mathbf{f}_{P_i} . Term frequency is calculated based on English Wikipedia. Co-occurrence feature is a binary feature which is true if P_i appears in question $\{Q_i\}_{i=1}^{|Q|}$ or answer $\{A_i\}_{i=1}^{|A|}$.

The input representation for P_i is \mathbf{w}_{P_i} :

$$\mathbf{w}_{P_i} = [\mathbf{E}_{P_i}^{glove}; \mathbf{E}_{P_i}^{pos}; \mathbf{E}_{P_i}^{ner}; \mathbf{E}_{P_i}^{rel}; \mathbf{f}_{P_i}] \quad (1)$$

In a similar way, we can get input representation for question \mathbf{w}_{Q_i} and answer \mathbf{w}_{A_i} .

Attention Layer. We use word-level attention to model interactions between the given passage $\{P_i\}_{i=1}^{|P|}$, the question $\{Q_i\}_{i=1}^{|Q|}$ and the answer $\{A_i\}_{i=1}^{|A|}$. First, let's define a sequence attention function (Chen et al., 2017):

$$Att_{seq}(\mathbf{u}, \{\mathbf{v}_i\}_{i=1}^n) = \sum_{i=1}^n \alpha_i \mathbf{v}_i \quad (2)$$

$$\alpha_i = \text{softmax}_i(f(\mathbf{W}_1 \mathbf{u})^T f(\mathbf{W}_1 \mathbf{v}_i))$$

\mathbf{u} and \mathbf{v}_i are vectors and \mathbf{W}_1 is a matrix. f is a non-linear activation function and is set to *ReLU*.

Question-aware passage representation $\{\mathbf{w}_{P_i}^q\}_{i=1}^{|P|}$ can be calculated as: $\mathbf{w}_{P_i}^q = Att_{seq}(\mathbf{E}_{P_i}^{glove}, \{\mathbf{E}_{Q_i}^{glove}\}_{i=1}^{|Q|})$. Similarly, we can get passage-aware answer representation $\{\mathbf{w}_{A_i}^p\}_{i=1}^{|A|}$ and question-aware answer representation $\{\mathbf{w}_{A_i}^q\}_{i=1}^{|A|}$. Then three BiLSTMs are applied to the concatenation of those vectors to model the temporal dependency:

$$\mathbf{h}^q = \text{BiLSTM}(\{\mathbf{w}_{Q_i}\}_{i=1}^{|Q|})$$

$$\mathbf{h}^p = \text{BiLSTM}(\{[\mathbf{w}_{P_i}; \mathbf{w}_{P_i}^q]\}_{i=1}^{|P|}) \quad (3)$$

$$\mathbf{h}^a = \text{BiLSTM}(\{[\mathbf{w}_{A_i}; \mathbf{w}_{A_i}^p; \mathbf{w}_{A_i}^q]\}_{i=1}^{|A|})$$

\mathbf{h}^p , \mathbf{h}^q , \mathbf{h}^a are the new representation vectors that incorporates more context information.

Output Layer. Question sequence and answer sequence representation \mathbf{h}^q , \mathbf{h}^a are summarized into fixed-length vectors with self-attention (Yang et al., 2016). Self-attention function is defined as

follows:

$$Att_{self}(\{\mathbf{u}_i\}_{i=1}^n) = \sum_{i=1}^n \alpha_i \mathbf{u}_i \quad (4)$$

$$\alpha_i = \text{softmax}_i(\mathbf{W}_2^T \mathbf{u}_i)$$

Then we have question representation $\mathbf{q} = Att_{self}(\{\mathbf{h}_i^q\}_{i=1}^{|Q|})$, answer representation $\mathbf{a} = Att_{self}(\{\mathbf{h}_i^a\}_{i=1}^{|A|})$ and passage representation $\mathbf{p} = Att_{seq}(\mathbf{q}, \{\mathbf{h}_i^p\}_{i=1}^{|P|})$. The final output y is based on their bilinear interactions:

$$y = \sigma(\mathbf{p}^T \mathbf{W}_3 \mathbf{a} + \mathbf{q}^T \mathbf{W}_4 \mathbf{a}) \quad (5)$$

Model Learning. We first pretrain *TriAN* on *RACE* dataset for 10 epochs. Then our model is fine-tuned on official training data. Standard cross entropy function is used as the loss function to minimize.

3 Experiments

3.1 Setup

Data. For data preprocessing, we use *spaCy*¹ for tokenization, part-of-speech tagging and named-entity recognition. Statistics for official dataset *MCScript* (Ostermann et al., 2018a) are shown in Table 1. *RACE*² dataset is used for network pretraining. English stop words are ignored when computing handcrafted features. Input word embeddings are initialized with 300-dimensional *GloVe* (Pennington et al., 2014) vectors³.

	train	dev	test
# of examples	9731	1411	2797

Table 1: Official dataset statistics.

Hyperparameters. Our model *TriAN* is implemented based on *PyTorch*⁴. Models are trained on a single GPU (Tesla P40) and each epoch takes about 80 seconds. Only the word embeddings of top 10 frequent words are fine-tuned during training. The dimension of both forward and backward LSTM hidden state is set to 96. Dropout rate is set to 0.4 for both input embeddings and BiLSTM outputs (Srivastava et al., 2014). For parameter optimization, we use *Adamax* (Kingma and

¹<https://github.com/explosion/spaCy>

²<http://www.cs.cmu.edu/~glail/data/race/>

³<http://nlp.stanford.edu/data/glove.840B.300d.zip>

⁴<http://pytorch.org/>

Ba, 2014) with an initial learning rate 2×10^{-3} . Learning rate is then halved after 10 and 15 training epochs. The model converges after 50 epochs. Gradients are clipped to have a maximum L2 norm of 10. Minibatch with batch size 32 is used. Hyperparameters are optimized by random search strategy (Bergstra and Bengio, 2012). Our model is quite robust over a wide range of hyperparameter configurations.

3.2 Main Results

The experimental results are shown in Table 2. Human performance is shared by task organizers. For *TriAN-ensemble*, we average the output probabilities of 9 models trained with the same datasets and network architecture but different random seeds. *TriAN-ensemble* is the model that we used for official submission.

model	dev	test
Random	50.00%	50.00%
TriAN-RACE	64.78%	64.28%
TriAN-single	83.84%	81.94%
TriAN-ensemble	85.27%	83.95%
HFL	–	84.13%
Human	–	98.00%

Table 2: Main results. *TriAN-RACE* only use *RACE* dataset for training; *HFL* is the 1st place team for *SemEval-2018 Task 11*. The evaluation metric is accuracy.

From Table 2, we can see that even though *RACE* dataset contains nearly 100k questions, *TriAN-RACE* achieves quite poor results. The accuracy on development set is only 64.78%, which is worse than most participants’ systems. However, pretraining acts as a way of implicit knowledge transfer and is beneficial for overall performance, as will be seen in Section 3.3. The accuracy of our system *TriAN-ensemble* is very close to the 1st place team *HFL* with 0.18% difference. Yet there is still a large gap between machine learning models and human.

We also compared the performances of shallow and deep *TriAN* models. On datasets such as *SQuAD* (Rajpurkar et al., 2016), deep models typically works better than shallow ones. Notice that the attention layer in our proposed *TriAN* model can be stacked multiple times if we treat the output vectors of BiLSTMs as new input representations.

Maybe a little bit surprising, Table 3 shows that *2-layer TriAN* model performs worse than *1-layer*

model	dev	test
1-layer TriAN-single	83.84%	81.94%
2-layer TriAN-single	82.71%	80.55%

Table 3: Accuracy comparison of shallow and deep TriAN models.

TriAN. One possible explanation is that the labeled dataset is relatively small and deeper models tend to easily overfit.

3.3 Ablation Study

The input representation consists of several components: part-of-speech embedding, relation embedding and handcrafted features etc. We conduct an ablation study to investigate the effects of each component. The results are in Table 4.

model	dev	test
TriAN-single	83.84%	81.94%
w/o pretraining	82.71%	80.51%
w/o ConceptNet	82.78%	81.08%
w/o POS	82.84%	81.27%
w/o features	82.92%	81.35%
w/o NER	83.60%	81.87%

Table 4: Ablation study for input representation.

Pretraining on *RACE* dataset turns out to be the most important factor. Without pretraining, the accuracy drops by more than 1% on both development and test set. Relation embeddings based on ConceptNet make approximately 1% difference. Part-of-speech and named-entity embeddings are also helpful. In fact, combining input representations from multiple sources has been a standard practice for reading comprehension tasks.

At attention layer, our proposed *TriAN* involves applying several attention functions to model interactions between different text sequences. It would be interesting to examine the importance of each attention function, as shown in Table 5.

model	dev	test
TriAN-single	83.84%	81.94%
w/o passage-question attention	83.51%	82.20%
w/o passage-answer attention	83.07%	81.39%
w/o question-answer attention	83.23%	81.84%
w/o attention	81.93%	80.65%

Table 5: Ablation study for attention. The last one “w/o attention” removes all word-level attentions.

Interestingly, removing any of the three word-

level sequence attentions does not seem to hurt the performance much. In fact, removing passage-question attention even results in higher accuracy on test set than *TriAN-single*. However, if we remove all word-level attentions, the performance drastically drops by 1.9% on development set and 1.3% on test set.

3.4 Discussion

Even though our system is built for commonsense reading comprehension, it doesn’t have any explicit knowledge reasoning component. Relation embeddings based on ConceptNet only serve as additional input features. Methods like event calculus (Mueller, 2014) are more rigorous mathematically and resemble the way of how human brain works. The problem of event calculus is that it requires large amounts of domain-specific axioms and therefore doesn’t scale well.

Another limitation is that our system relies on hard-coded commonsense knowledge bases, just like most systems for commonsense reasoning. For humans, commonsense knowledge comes from constant interactions with the real-world environment. From our point of view, it is quite hopeless to enumerate all of them.

There are a lot of reading comprehension datasets available. When the size of training data is relatively small like this *SemEval-2018 task*, transfer learning among different datasets is a useful technique. This paper shows that pretraining is a simple and effective method. However, it still remains to be seen whether there is a better alternative approach.

4 Conclusion

In this paper, we present the core ideas and design philosophy for our system *TriAN* at *SemEval-2018 Task 11: Machine Comprehension using Commonsense Knowledge*. We build upon recent progress on neural models for reading comprehension and incorporate commonsense knowledge from ConceptNet. Pretraining and handcrafted features are also proved to be helpful. As a result, our proposed model *TriAN* achieves near state-of-the-art performance.

Abstract

A natural language argument is composed of a claim as well as reasons given as premises for the claim. The *warrant* explaining the reasoning is usually left implicit, as it is clear from the context and common sense. This makes a comprehension of arguments easy for humans but hard for machines. This paper summarizes the first shared task on *argument reasoning comprehension*. Given a premise and a claim along with some topic information, the goal is to automatically identify the correct warrant among two candidates that are plausible and lexically close, but in fact imply opposite claims. We describe the dataset with 1970 instances that we built for the task, and we outline the 21 computational approaches that participated, most of which used neural networks. The results reveal the complexity of the task, with many approaches hardly improving over the random accuracy of ≈ 0.5 . Still, the best observed accuracy (0.712) underlines the principle feasibility of identifying warrants. Our analysis indicates that an inclusion of external knowledge is key to reasoning comprehension.

1 Introduction

When we argue in natural language, we give reasons as premises for our claims. A fundamental pragmatic instrument in this regard is to leave those parts of an argument unstated that can be presupposed. This is particularly common for the reasoning between an argument's premises and its claim, called implicit *warrants* there (Toulmin, 1958). A warrant takes the role of an inference rule, i.e., the abstract structure of an argument is *reason* \rightarrow (since) *warrant* \rightarrow (therefore) *claim*. In principle, this structure applies to deductive arguments, which allows us to validate arguments properly formalized in propositional logic. However, most natural language arguments are in fact inductive (Govier, 2010) or defeasible (Walton, 2007).

Topic: Tax Break for Sports.

Additional Information: Should pro sports leagues enjoy nonprofit status?

Premise (Reason): Government is already struggling to pay for basic needs.

And since

✓ **Warrant 0:** the government isn't required to pay for all the country's needs

✗ **Warrant 1:** the government is required to pay for the country's needs

Claim: Sport leagues should not enjoy nonprofit.

Figure 1: Instance of the argument reasoning comprehension task. The correct warrant has to be classified.

Now, when we comprehend an argument, we reconstruct its warrant driven by the cognitive principle of relevance (Wilson and Sperber, 2004). What is easy for humans in many cases, however, turns out to be hard for machines, because reasoning usually depends on context and common sense. In (Habernal et al., 2018), we have thus introduced the *argument reasoning comprehension task* in order to study the construction and identification of implicit warrants for natural language arguments. It forms the basis of the shared task presented here:

Task Given an argument with a *reason* serving as a premise for a *claim*, along with the *topic* and some *additional information* of the discussion they occur in, identify the correct warrant among two opposing candidates, *warrant0* and *warrant1*.

With opposing, we here mean that the two candidate warrants actually imply contradicting claims, the correct one and its opposite. An instance of the task is shown in Figure 1. Being a binary classification task, the main evaluation measure of argument reasoning comprehension is accuracy.

To our knowledge, this is the first shared NLP task directly targeting argumentation; others tasks have only been sketched so far (Kiesel et al., 2015).

A solution to our task will represent a substantial step towards automatic warrant reconstruction, which in turn is important for the general long-term goal of automatic argument evaluation. So far, most research on computational argumentation focused on mining claims and premises from text and assessing their properties. In contrast, filling the gap between claims and premises computationally remains an open issue, due to the inherent difficulty of reconstructing the world knowledge and reasoning patterns in arguments (Feng and Hirst, 2011; Green, 2014; Boltužić and Šnajder, 2016). Previous tasks have dealt with the textual entailment of a hypothesis from a proposition (Dagan et al., 2009) or with semantic inference (Bowman et al., 2015). While understanding semantics is important in the given task, argumentation also reasoning beyond what is understood, i.e., pragmatics.

As a basis for the shared task, we built a new dataset with 1970 instances based on authentic English arguments, whose concept and construction process is detailed in Section 2. We outline the systems that participated in the task in Section 3. Most systems implement a computational approach that employs one or more neural networks (often LSTMs, often with attention) based on different pre-trained embedding models. We then present the results of all systems on the test set of the shared task in Section 4 and analyze specific cases in Section 5, before we finally conclude (Section 6).

2 Dataset

This section presents the dataset with all instances used in the shared task. We summarize the main points from its construction process, which is described in detail in (Habernal et al., 2018).

2.1 Task Instances

Let R be the reason for the claim C in a natural language argument. Then there is a warrant W that explains why R supports C , but W is left implicit. For example, if C is “It should be illegal to declaw your cat” and R is “They need to use their claws for defense and instinct”, then W could be specified as ‘If cat needs claws for instincts, declawing would be against nature’ or similar.

The question is how to find a warrant W for a given reason R and claim C . To obtain candidate warrants systematically for our dataset, we propose a trick. In particular, we first construct an *alternative warrant* AW that explains why R may serve as

Unit	Text
Reason	Cooperating with Russia on terrorism ignores Russia’s overall objectives.
Claim	Russia cannot be a partner.
Warrant0	Russia has the same objectives of the US.
Warrant1	Russia has the opposite objectives of the US.
Reason	Economic growth needs innovation.
Claim	3-D printing will change the world.
Warrant0	There is no innovation in 3-d printing since it’s unsustainable.
Warrant1	There is much innovation in 3-d printing and it is sustainable.
Reason	College students have the best chance of knowing history.
Claim	College students’ votes do matter in an election.
Warrant0	Knowing history doesn’t mean that we will repeat it.
Warrant1	Knowing history means that we won’t repeat it.

Table 1: Three example task instances from the dataset. In all cases, *warrant1* is the alternative warrant. For brevity, we omit the topic and additional information.

support for the opposite $\neg C$ of the claim C . For the example above, we invert C to “It should be *legal* to declaw your cat” ($\neg C$). $\neg C$ may be explained based on R quite plausibly with the alternative warrant “Most house cats don’t face enemies” (AW). Analog to C and $\neg C$, we then invert AW to “Most house cats face enemies”, which is a plausible warrant W for the original reason-claim pair (R, C) .

Constructing a plausible alternative warrant is not always possible, as many reasons already convey the arguer’s stance. If it is, however, W and AW usually capture the core of a reason’s relevance and reveal the implicit presuppositions, due to the trick we performed for construction. For such as cases, we define an instance of our task as a 6-tuple:

Instance (*reason, claim, warrant0, warrant1, topic, additional information*)

The question to be answered is whether *warrant0* is W and *warrant1* is AW , or vice versa. As context, we provide a short *topic* specification and some *additional information* describing the topic. Figure 1 has already shown an example. Further are given in Table 1. They all result from the following process.

2.2 Data Acquisition and Annotation

To obtain a dataset with a permissive license, we decided to build a new dataset from scratch. As source data, we used user-generated web comments from the well-moderated *Room for Debate* of the New York Times, which covers arguments on a variety of contemporary controversial issues.¹

¹<https://www.nytimes.com/roomfordebate>

We manually selected 188 debates with polar questions in the title from a six-year span (2011–2017). We converted each question into a claim C (e.g., “It should be illegal to declaw your cat”) and derived a directly opposing claim $\neg C$ (“It should be legal to declaw your cat”). Then, we crawled all comments from the debates and sampled about 11,000 high-ranked, root-level comments² from which 5,000 were selected randomly as a basis for the dataset construction. Each comment was split into elementary discourse units using SistaNLP (Surdeanu et al., 2015). To obtain task instances, we then performed the following eight-step crowdsourcing process using Amazon Mechanical Turk:

1. *Stance Annotation.* For each comment, the crowdworkers first classified what stance it takes, if it remains neutral, or if it does not take any stance.

2. *Reason Span Annotation.* In all 2,884 comments taking a stance, the workers then marked sequences of discourse units that give a reason for the claim.

3. *Reason Gist Summarization.* In this step, the workers rewrote all 5,119 marked reasons (2,026 within arguments), such that their gist remains the same but the clutter is removed. The result is a reason R for the claim C .

4. *Reason Disambiguation.* In order to ensure that R implies C really holds, the workers next decided whether C or $\neg C$ is more plausible for R , or whether both are similarly (im)plausible. We kept only those 1,955 reason-claim pairs where workers agreed that C is most plausible.

5. *Alternative Warrant.* This step was the trickiest. As in the example above, the workers had to specify a plausible alternative warrant AW , explaining why R implies $\neg C$, or declare that impossible.

6. *Alternative Warrant Validation.* Afterwards, other workers validated each of the 5,342 specified alternative warrants AW as to whether it actually relates to R , by identifying R among two alternatives: R itself and the lexically most similar reason from the same debate topic. For the 3,791 correctly validated cases, we let workers score how logical AW is (0–2) and only kept those 2,613 that had a mean score of at least 0.68. This threshold was chosen based on a manual examination of the scores.

²We removed ‘noisy’ candidates based on several indicators, such as the absence of quotations or URLs and certain lengths. We did not check any quality criteria of arguments, though, because this was not our focus; see, for instance, (Wachsmuth et al., 2017) for argumentation quality.

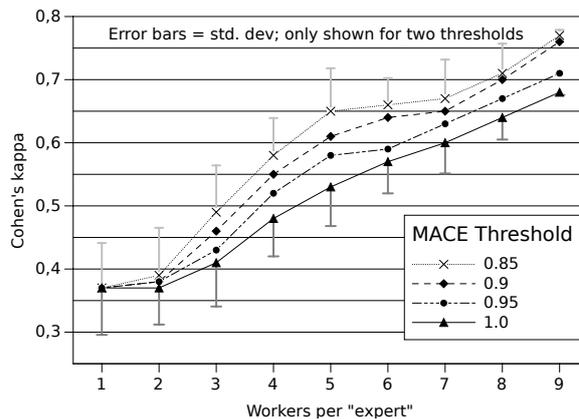

Figure 2: Cohen’s κ agreement for stance annotation on 98 comments. As a trade-off between the number of kept instances and their reliability, we chose five annotators and a threshold of 0.95 for this task, which resulted in $\kappa = 0.58$ (moderate to substantial agreement).

7. *Warrant For Original Claim.* Given R and C , workers then should create a minimally modified version of each AW that may serve as an actual warrant W for C (as in the second half of the example above). They succeeded to do so in 2,447 cases.

8. *Warrant Validation.* To ensure that only W is correct for R and C , all tuples (R, C, W, AW) were validated again. Unclear cases were resolved by an expert. We obtained 1,970 instances of the argument reasoning comprehension task, so 1,970 pairs of *warrant0* and *warrant1* for a reason and a claim, along with a topic and the additional information.

2.3 Agreement

To assess quality in the crowdsourcing process, we relied on MACE (Hovy et al., 2013), which estimates gold labels for a set of workers, outperforming simple majority votes. Given the number of the different crowdsourcing tasks and their variety, here we only demonstrate the first step, namely stance annotation. We collected 18 assignments per item and split them into two groups (9+9) based on their submission time. We then considered each group as an independent experiment and estimated gold labels for each group. Having two independent “experts from the crowd” allowed us to compute standard agreement scores. We also varied the size of each group from 1 to 9 by repeated random sampling of assignments, and we tuned the MACE threshold for keeping only the most confident predictions. Figure 2 shows the Cohen’s κ agreement for stance annotation with respect to the crowd size computed by our method. The decision what number of workers per task to take (five in case of

stance annotation) implies a trade-off between the number of instances and their reliability. We performed similar quality measures with reasonable agreement for the other crowdsourcing steps too. Details are given in (Habernal et al., 2018).

2.4 Datasets in the Shared Task

For the shared task, we split the 1,970 instances into three sets based on the year of the debate they were taken from: 2011–2015 became the training set (1,210 instances), 2016 the development set (316 instances), and 2017 the test set (444 instances). This follows the paradigm of learning on past data and predicting on new ones. In addition, it removes much lexical and topical overlap. The same split has been used by Habernal et al. (2018).

The shared task had two phases, trial and test. In the trial phase, the training and development set were given, both with gold labels stating the correct warrant for all instances. In the test phase, all three datasets were available. Naturally, no labels were given for the test set instances. All provided data is licensed under Creative Commons-family license.

3 Approaches

This section briefly summarizes the computational approaches of the systems that participated in the shared task as well as baselines. Intuitions and detailed explanations are given in the system description papers associated to the shared task.

3.1 Participating Systems

The following 20 systems participated in the shared task, sorted alphabetically. In addition, a 21st system called *Joker* took part, but the team behind did not provide any description. For many of the systems, many more details are given in the respective SemEval-2018 system description papers.

ArcNet uses GloVe embeddings and an LSTM encoder to get the semantic representation of each input (*reason*, *claim*, and both *warrants*). Then an attention mechanism aligns the *reason* and the *warrant* so that the reason-aware warrant representation is generated. Finally, a bilinear function matches the claim with the reason-aware warrant. The network is trained to minimize margin loss. The submission was based on an ensemble model of 10 training runs with the identical architecture.

ArgEns-GRU votes a majority on an ensemble of the following three systems: First, a shared GRU

network that learns one representation of the *reason*, *claim*, and both *warrants* each, initialized with 100-dimensional GloVe embeddings. Its output is concatenated and passed through a softmax layer for the final predictions. Second, an extension of the GRU with an attention on the *reason*, *claim*, and both *warrants* each. And third, another GRU model extended with negation and polarity features.

ART uses a bi-directional LSTM with an attention mechanism on top, followed by a multi-layer perceptron network.

blcu_nlp not only pays attention to the consensual part between each warrant and other information, but also to the contradictory part between two warrants. On the model’s input (GloVe embeddings), *warrant0*, *claim*, *reason*, and *debate info* are concatenated in order to put attention on *warrant1*. An analog structure is used for the attention on *warrant0*. After obtaining two vectors ‘attented_w0’ and ‘attented_w1’ — referring to the ESIM model (Chen et al., 2017) — the two warrants are aligned. A similarity matrix helps to highlight the consensual and the contradictory part. The decision is then drawn after passing through feed-forward layers. A majority voting strategy is used in the final ensemble, which is based on five models performing best on the development data.

Deepfinder shares one LSTM layer for *warrant0*, *warrant1*, *claim*, and *reason*, while the *topic* part uses one LSTM alone. All of them share the same word embedding layer before LSTM layers. After that, one individual dot product is computed for the output of the *warrant0* LSTM and each of the *claim*, *reason* and *claim* (the same is done for the *warrant1* LSTM). The resulting dot products are concatenated and fed into a softmax layer.

ECNU modifies the baseline intra-warrant attention (Habernal et al., 2018) by using a CNN and an LSTM for representing each sentence (*claim*, *reason*, *debate*, *warrant0*, and *warrant1*). Different parts of *warrant0* and *warrant1* are used as an attention vector to obtain representations of the warrants. Similarly, different parts of *claim* and the opposite *claim* serve as attention for the final representation. The final decision is then given by a vote from three networks.

GIST uses pretrained word2vec embeddings as well as the ESIM model (Chen et al., 2017), trained on the SNLI (Bowman et al., 2015) and MultiNLI

(Nangia et al., 2017) datasets. The parameters have been frozen afterwards. Then, pairs of sentences are fed into the the ESIM model. For *warrant0*, for example, these pairs are (*claim*, *warrant0*), (*warrant0*, *reason*), and (*warrant0*, *warrant1*). Also, another bi-LSTM module encoding *claim*, *warrant*, and *reason* is added. The output vectors of each pair and the bi-LSTM are concatenated after averaging and max pooling, and the final prediction is made through feed-forward layers.

HHU encodes *reason*, *claim*, and *warrants* using a bi-directional LSTM. Next, *warrant0*, *reason*, and *claim* are fed into another LSTM; similarly, *warrant1*, *reason*, and *claim* to another LSTM in parallel. Both branches are followed by a dropout and two common dense layers. Embeddings have been pre-trained in four different flavors: fasttext-embeddings trained on the entire Wikipedia corpus, two embeddings trained on the task’s dataset using the word2vec skip-gram model with different dimensionalities, and another word2vec model based on the tasks vocabulary but augmented with related articles from Wikipedia. For all embeddings, different parameter combinations and seeds were used to train an ensemble of 623 models in total.

ITNLP-ARC first encodes sentences (*warrant*, *reason*, *claim*) using LSTMs. Attention is used to merge the *reason* vector with the *claim* vector. A shared weight matrix then holds the relationship between the *warrant* and the attention vector, from which the maximum is chosen as the answer. An ensemble method is used for the final vote.

lyb3b encodes sentences using word2vec or GloVe embeddings and a bi-directional LSTM. The instances are treated as positive or negative, depending on the correct training *warrant*. The network then combines the *warrant* with the *reason*, *claim*, and *additional info*. Finally, a fully-connected layer is used to decide whether the instance is correct.

mingyan performs a word-by-word attention that is fused with the original representation then. Self-attention pooling produces a single vector fed into a sigmoid function, trained with cross-entropy loss.

NLITrans attempts to leverage the transfer of semantic knowledge from a bi-directional LSTM encoder with max pooling trained on the MultiNLI corpus (Nangia et al., 2017). This yields a small performance boost on the development set. All sentences (*claim*, *reason*, *warrant0*, and *warrant1*) are

encoded with this a transferred encoder. Then, task-specific representations of two ‘arguments’, one for each *warrant*, are learned via fully-connected layers. A final linear layer generates an independent score representing the fit of each *warrant* to the argument. These are concatenated and passed through softmax to generate a probability distribution over the two *warrants*.

RW2C uses two neural networks. The first one classifies each *warrant* as true or false separately and chooses the one with higher confidence as the right one. The second model makes a decision given two *warrant* candidates. The final prediction is an ensemble over the previous predictions. Both models represent sentences using a CNN.

SNU_IDS decides whether a logic built on a set of given sentences (*claim*, *reason*, and *warrant*) is plausible. It accepts only one *warrant* at a time and outputs a score on the *warrant*’s validity. The intuition is that the model can learn what has more meaningful semantics of natural language when it judges whether the logic of the given sequence is correct, instead of just selecting the more probable *warrant* among two candidates. The model consists of an encoding layer with GloVe embeddings (Pennington et al., 2014) and a CoVe sentence encoder (McCann et al., 2017), a ‘localization’ layer (a set of fully connected layers), and output layers that combine calculating several arithmetic measures over the input representation and compute a final score using a logistic layer on top.

TakeLab preprocesses sentences from the dataset, applies some arithmetic, converts them to SkipThought vectors, and feeds them into an SVM classifier with fine-tuned hyperparameters. The SkipThought vectors are sentence representation vectors whose encoder and decoder (with an identical structure to RNN encoder-decoders used for neural machine translation) are trained on a large corpus of books unbiased in domain (Kiros et al., 2015).

TRANSRW learns the semantic representation of sentences (*reason*, *warrants*, *claim*) using a convolutional neural network. The assumption behind is that a composition of the *reason* and the *warrant* is close to the representation of the *claim*.

UniMelb combines 3 stacked LSTMs, one for the *reason*, one for the *claim*, and one shared Siamese Network for the two *warrants* under investigation. It generates semantic feature vectors that

serve as input to a shared compressed feature space by using simple vector operations and semantic similarity classification to enforce the interrelationships between them. In doing so, the aim is to learn a form of “generative implication” through the semantic feature vectors. The vectors are able to correctly encode the interrelationships between a reason, a claim, and both the correct and incorrect warrants. The given data is augmented by utilizing WordNet synonym fuzzing.

YNU-HPCC uses a bi-directional LSTM with attention whose input is divided into three parts (*claim*, *reason*, and both *warrants*). To prevent overfitting, dropout is added before the final layer.

YNU_Deep combines the *reason* and the *claim* with a so-called ‘story’ feature. The story feature is merged with the *warrant*. The network is a bi-directional LSTM with attention and uses GloVe embeddings. Ensemble technology is put on top to mitigate the small size of the data.

ztangfdu first concatenates the *claim* and the *reason* as one sentence named ‘sent1’, and denotes the correct *warrant* as ‘sent2’ and the wrong *warrant* as ‘sent3’, respectively. The output of an LSTM layer with non-trained embeddings then represents each of the sentences. After applying mean pooling to transform the output matrices to vectors, two fully connected layers cater for obtaining the difference score between ‘sent2’ and ‘sent3’, whose minimization is the core of the loss function.

3.2 Baselines

For the official task, we provided only a simple naïve random baseline. The outcome (*warrant0* or *warrant1*) is drawn from a Bernoulli distribution ($\theta = 0.5$) resulting in a theoretical accuracy of 0.5. The reported baseline was a single random draw.

Further computational baseline approaches, such as a language model, are evaluated in (Habernal et al., 2018), but we did not consider them within the official competition. There, we also report human bounds for argument reasoning comprehension based on a crowdsourcing study, where each of 173 participants had to solve 10 instances. The mean accuracy was 0.798, but varied depending on the participants’ prior knowledge of reasoning, logic, and argumentation. Those with extensive prior knowledge achieved 0.909, and 30 participants solved all instances correctly. We conclude that the task is reasonably solvable for humans.

Rank	System	Accuracy

Table 2: Final results of the competition. For the star-denoted system, no description has been provided.

4 Results

The final accuracies of all participating systems are ranked in Table 2. Due to the limited size of the test set (444 instances) and the subtle accuracy differences of many systems, we also measured significance using the approximate randomization test, as described in (Riezler and Maxwell, 2005).³ Table 3 shows p -values of all system pairs, including the random baseline. As p -values lower than 0.05 are usually considered statistically significant, only three systems outperform the random baseline. However, we would like to emphasize that drawing a strong conclusion about superiority of a particular neural-based system given only one benchmark value might be misleading, as Reimers and Gurevych (2017) showed for several NLP tasks.

We see that the winning system GIST significantly outperforms all other systems on this particular test data ($p \ll 0.05$). For future SemEval tasks, however, we encourage task organizers to solicit multiple submissions of the same system trained with different random initializations, and perform a proper Bayesian system comparison. The machine learning community has already abandoned the controversial p -value and replaced it with Bayesian methods that are easily interpretable and account well for uncertainty (Benavoli et al., 2017).

³The implementation of the complete task evaluation is available at <https://github.com/habernal/semEval2018-task12-results>.

Table 3: p -values obtained by running the approximate randomization test among all systems. For convenience, the diagonal (bold values) shows the accuracy of each system as in Table 2 but rounded to two decimal numbers. Only the three top systems (GIST, blcu_nlp, and ECNU) are significantly better than the random baseline (p -values < 0.05). The first system (GIST) also significantly outperforms the second system (blcu_nlp) (p -value $\ll 0.05$).

5 Analysis

First, we show a quantitative analysis of the results on the test instances. Figure 3 displays the distribution of all instances over the number of systems that classified each of them correctly. The shape of this rather bi-modal distribution reveals that there are both easy and hard cases. In particular, there are 13 instances completely unsolved and about 90 instances solved by fewer than five participating systems. On the other hand, 32 instances were solved by all systems.

5.1 Easy instances

We qualitatively investigated instances that were classified correctly by all participating systems. It turned out that systems needed to learn only one single property common to all of them: *negation*. Correct warrants in these instances contain negating words (“not”, “don’t”) or negated modals (“can’t”, “wouldn’t”), as shown in Figure 4. This artifact originates from the process of intentionally creating the dichotomy between the alternative warrant and warrant (see Section 2) that in many cases consist of an assertion firstly created for the alternative warrant, and its negation for the correct warrant.

Distribution of correctly classified instances among all systems

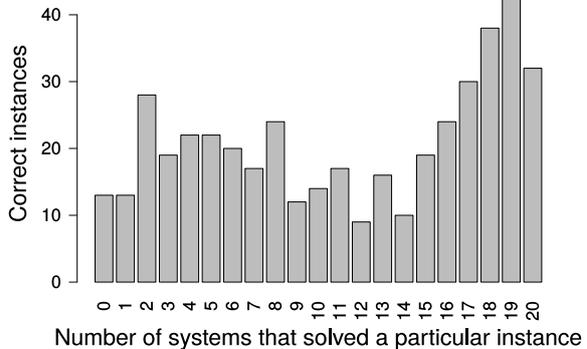

Figure 3: Despite many solvable instances (centered around the right mode), there are hard cases that most systems were not able to cope with (the left mode).

5.2 Difficult instances

A similar problem arises for the difficult instances, such as those not solved by any system. We manually analyzed them and found that the opposite of the easy instances caused misclassification here, namely *misleading negation*. In these instances, the correct warrant is a positive assertion while the alternative warrant is negated. It seems that the

Topic: Have Comment Sections Failed?

Additional Information: In recent years, many media companies have disabled them because of widespread abuse and obscenity.

Premise (Reason): Comment sections are just a propaganda device.

And since

- ✗ **Warrant 0:** propaganda is the grease of the democratic wheels
- ✓ **Warrant 1:** propaganda is not the grease of the democratic wheels

Claim: Comment sections have failed.

Topic: Does Turkey Still Belong in NATO?

Additional Information: Given President Erdogan’s record on human rights and how his focus on the Kurdish minority has interfered with his fight against ISIS, is he a reliable ally?

Premise (Reason): Turkey does not have much in common with the rest of the countries in NATO.

And since

- ✓ **Warrant 0:** diversity wouldn’t be good for NATO
- ✗ **Warrant 1:** diversity would be good for NATO

Claim: Turkey doesn’t belong to NATO

Figure 4: Examples of “easy” instances from the test data solved by all systems, revealing that relying solely on the negation artifact in the correct warrant gives the right answer (IDs: 18247022_132_A104V8NZIQFN2F, 18068301_176_A3TKD7EJ6BM0M5).

learned negation “feature” then makes the systems fall into the trap; see examples in Figure 5.

This data analysis clearly shows that it is possible to guess some answers right only given their surface or syntactic form, perhaps because such “features” are prevalent in the training data. However, they do not really help to find any underlying connections between the reasons, warrants, and claims. One solution to test for such cases would be to double the test set simply by adding to each instance another one with an opposite claim and switched warrants. From the reasoning perspective, such an instance still makes sense (which is actually a backbone principle of creating our data), but would clearly penalize systems relying on simple features, such as negation.

6 Conclusion

This paper has overviewed the first shared task on argument reasoning comprehension, one of the tasks at SemEval-2018. Being able to identify the correct warrant connecting an argument’s reason to its claim automatically, which is the goal of the task, is the first step of understanding the argu-

Topic: Have Christians Created a Harmful Atmosphere for Gays?

Additional Information: Church-backed efforts to fight L.G.B.T. rights have been blamed for feeding a hateful atmosphere that accommodates attacks on gays.

Premise (Reason): The Bible is not consistent in it’s treatment of sex and marriage.

And since

- ✓ **Warrant 0:** many Christians take the Bible literally
- ✗ **Warrant 1:** many Christians do not take the Bible literally

Claim: Christians have created a harmful atmosphere for gays

Topic: Is Google a Harmful Monopoly?

Additional Information: European regulators say the company’s Android phone blocks rival services.

Premise (Reason): People can choose not to use Google.

And since

- ✓ **Warrant 0:** they can opt-out from being indexed by their search engine
- ✗ **Warrant 1:** they cannot opt-out from being indexed by their search engine

Claim: Google is not a harmful monopoly

Figure 5: Examples of “difficult” instances from the test data on which all systems failed. One possibly explanation is the misleading negation contained in these instances (IDs: 18865357_593_A1CF6U3GF7DZEJ, 18362833_247_A1CF6U3GF7DZEJ).

ment’s reasoning. We have outlined the dataset used in the task, the participating system, and the performance they achieved. The results have revealed how challenging the task is: Many systems improved only little over the random baseline. At the same time, the accuracy of GIST, the best system in the evaluation, suggests that it is possible in principle to identify warrants computationally.

Our analysis of the results showed that the participating systems were capable to solve cases with discriminative surface features, but failed where exactly these were misleading. The strongest systems relied on models trained on natural language inference corpora, which suggests that external knowledge may be key to argument reasoning comprehension. Still, more research needs to be done in the future to further investigate this hypothesis.

Abstract

This paper describes our GIST team system that participated in SemEval-2018 Argument Reasoning Comprehension task (Task 12). Here, we address two challenging factors: unstated common senses and two lexically close warrants that lead to contradicting claims. A key idea for our system is full use of transfer learning from the Natural Language Inference (NLI) task to this task. We used Enhanced Sequential Inference Model (ESIM) to learn the NLI dataset. We describe how to use ESIM for transfer learning to choose correct warrant through a proposed system. We show comparable results through ablation experiments. Our system ranked 1st among 22 systems, outperforming all the systems more than 10%.

1 Introduction

Argument Reasoning Comprehension is a task that choose correct warrant from two options given a claim and a reason. The Argument Reasoning Comprehension is a very important task because “*argument comprehension requires not only language understanding and logic skills, but it also heavily depends on common sense*”, as mentioned by Habernal et al. (2018). There are two challenging factors. One is a certain part of an argument is left unstated (Habernal et al., 2018). Because of the unstated part, humans or machines need reasoning ability about that part. Human can reconstruct the unstated part depending on common knowledge. However, it has still remained difficult to machines. Another is that “*both options are plausible and lexically very close while leading to contradicting claims*”, as mentioned by Habernal et al. (2018). To address these factors, we have two assumptions. One is that similar and large datasets may help to address the unstated common sense by learning various cases. Another is that an in-

ference model to distinguish semantic differences between two sentences may help to choose one of two lexically close warrants that lead to contradicting claims. There are two suitable datasets in the Natural Language Inference (NLI) task, Stanford NLI (SNLI) (Bowman et al., 2015) and Multi NLI (MNLI) (Williams et al., 2017) datasets. NLI is a task choosing one of relationships (*Entailment, Contradiction, Neutral*) between two sentences. Both SNLI and MNLI are very large corpus (each 0.5M sentence pairs). In addition, there is a good performance model for the task, Enhanced Sequential Inference Model (ESIM) (Chen et al., 2017). To make use of other datasets for our task, we use transfer learning. About transfer learning, Conneau et al. (2017) showed a good precedent, using SNLI dataset. By learning the NLI task, the model can obtain inference knowledge. Therefore, we propose a network transferring inference knowledge to argument reasoning comprehension task. We summarize our system with 5 main components.

1. ESIM is trained on SNLI and MNLI datasets. Then, parameters are frozen and used to transfer the inference knowledge.
2. As inputs of the ESIM, we make sentence pairs such as (*claim, warrant*), (*warrant, reason*) and (*warrant, other warrant*).
3. To add flexibility, we added biLSTM module encoding *claim, reason* and *warrant*.
4. To make a fixed length vector from variable one, we used average and max pooling.
5. Finally, all the fixed length vectors from ESIM and biLSTM are concatenated and fed into a fully-connected neural network to determine whether the warrant is correct or not.

The detail process is described in Section 2.

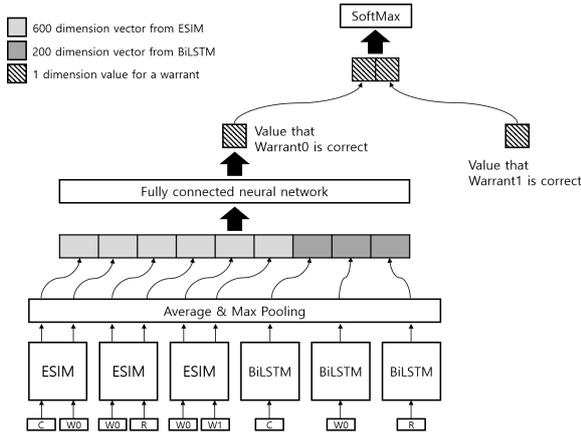

Figure 1: Overview of our system

2 System Description

Figure 1 shows an overview of our system. The preprocessing is described in subsection 2.1. ESIM is described in subsection 2.2. Then, to apply transfer learning, we describe how to compose the inputs of the ESIM in subsection 2.3. In the subsection 2.4, we describe a simple biLSTM module added to our model. Pooling is described in subsection 2.5. Finally, the fully-connected neural network is described in subsection 2.6 to determine whether the warrant is correct or not. We introduce our notations for following sections. A sentence is notated as $S = (w_1^S, \dots, w_{len(S)}^S)$. $len(S)$ denotes the length of the sentence S . The $w_i^S \in \mathbb{R}^d$ is a d -dimensional word embeddings. Also C , R , $W0$ and $W1$ denote the sentence of *Claim*, *Reason*, *Warrant0* and *Warrant1* respectively. Our goal is to predict which warrant ($W0$ or $W1$) is more correct given a claim (C) and a reason (R).

2.1 Preprocessing

First, we initialize all words that exist in the vocabulary with pre-trained 300 dimension `word2vec` (Mikolov et al., 2013). When the word does not exist in the vocabulary, we use following several preprocessing rules.

1. All [’s] are removed. (ex. He’ s, something’s)
2. All words with number are split into number and word. (ex. 17th \rightarrow 17, th)
3. All abbreviations are replaced with <abbreviation> token.

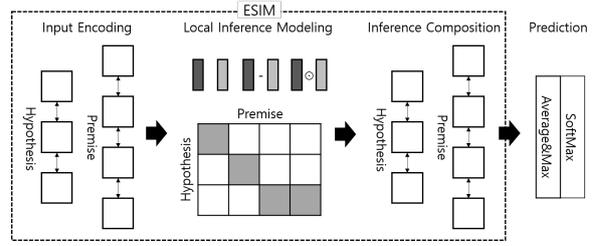

Figure 2: A high-level view of ESIM with prediction part. The prediction part is used when training on the NLI task, and two sentence vectors generated after inference composition are used in our system. This picture is taken from the author (Chen et al., 2017) with a few modifications.

4. All number is replaced with <number> token.

After this preprocessing, if the preprocessed word exists in the vocabulary, we initialized it with the `word2vec` again. Otherwise, we replaced it with <unknown> token. Each token is randomly initialized.

2.2 Pre-trained ESIM on NLI dataset

Because of page limit, we briefly explain this part. Chen et al. (2017) described that ESIM is composed of the following major components: input encoding, local inference modeling, and inference composition. Figure 2 shows a high-level view of the architecture. For more details, refer to the paper (Chen et al., 2017). ESIM generates two sentence vectors after comparing two input sentences with each other. We notate it as follows.

$$\mathbf{sv}_{S_1}^{(S_1, S_2)}, \mathbf{sv}_{S_2}^{(S_1, S_2)} = ESIM(S_1, S_2) \quad (1)$$

The \mathbf{sv} consists of vectors of l dimension, the number of which correspond to the length of each sentence. The \mathbf{sv} is the output of the inference composition part. We implemented it as 300 dimensions. The ESIM was trained on SNLI and MNLI datasets. The training was stopped when the average of development set accuracies was maximum. Then, the parameters were frozen so as to be not updated.

2.3 Input sentence pair for transfer learning

To exploit transfer learning, the sentence pairs are composed of $(C, W0)$, $(W0, R)$ and $(W0, W1)$ for Warrant0. In the case of Warrant1, the pairs are composed of $(C, W1)$, $(W1, R)$ and $(W1, W0)$. Then, these sentence pairs are fed into the ESIM.

2.4 BiLSTM for Flexibility

LSTM (Hochreiter and Schmidhuber, 1997) is a building block well-suited to learn long and short information in a sequence. We employed bidirectional LSTM, where forward and backward directional LSTMs are concatenated. For more details, refer to the paper (Hochreiter and Schmidhuber, 1997).

$$\mathbf{sv}_S = \text{biLSTM}(S) \quad (2)$$

We add 100 dimension biLSTMs to our model. Since the ESIM is only trained on NLI dataset, it may be over-fitted to the NLI task. By adding a new module that is not trained on the NLI task, our system may have a chance to learn new knowledge about the target task. We feed *Claim*, *Warrants* and *Reason* into the biLSTM. The biLSTMs for Warrant0 and Warrant1 share the parameters.

2.5 Pooling Layer

To generate a fixed length sentence vector, we use both average and max pooling per one sentence. The equations are as follow:

$$\mathbf{sv}_{S,ave} = \frac{1}{\text{len}(S)} \sum_{i=1}^{\text{len}(S)} \mathbf{sv}_{S,i} \quad (3)$$

$$\mathbf{sv}_{S,max} = \max_{i=1}^{\text{len}(S)} (\mathbf{sv}_{S,i}) \quad (4)$$

After pooling, the vector of average pooling and max pooling are concatenated. We notate it as $\mathbf{sv}_{S,pool} = [\mathbf{sv}_{S,ave}; \mathbf{sv}_{S,max}]$.

2.6 Fully-connected neural network

To determine whether the warrant is correct or not, a fully-connected neural network (FCNN) is used. Finally, all the vectors from ESIM and biLSTM are concatenated. For Warrant0, the vectors are concatenated as follow: $[\mathbf{sv}_{C,pool}^{(C,W0)}; \mathbf{sv}_{W0,pool}^{(C,W0)}; \mathbf{sv}_{W0,pool}^{(W0,R)}; \mathbf{sv}_{R,pool}^{(W0,R)}; \mathbf{sv}_{W0,pool}^{(W0,W1)}; \mathbf{sv}_{W1,pool}^{(W0,W1)}; \mathbf{sv}_{C,pool}; \mathbf{sv}_{W0,pool}; \mathbf{sv}_{R,pool}]$. The Warrant1 is also composed as the same way. The concatenated vector is fed into FCNN. We build two layers of FCNN. The first layer has 600 dimension with the ReLu function. The second layer has only 1 dimension without any activation function. Then, the 1 dimension value for Warrant0 and Warrant1 are concatenated with the softmax function.

3 Experimental setup

Pre-training First, to learn the inference knowledge, we implemented ESIM and trained on NLI training dataset. Our implemented ESIM dimension is 300. Except for the ESIM dimension, we used the same hyperparameter values as those in Chen et al. (2017). The preprocessing process is implemented in the same way with subsection 2.1. The word embeddings are not updated during training. The training was stopped when the average of development set accuracies is maximum. We got development accuracy of 86.58%, 74.09%, 74.67% on SNLI, MNLi match, MNLi mismatch datasets, respectively.

Training We used the ADAM (Kingma and Ba, 2014) optimizer for updating weight parameters. The parameters of ADAM set to be as follow: $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 10^{-8}$. The initial learning rate is 0.0002 and is decayed with 0.9 rate per one epoch. We did not use dropout but added L2 regularization on the first FCNN layer. The regularization parameter λ was set to be 5×10^{-4} . The word embeddings were not updated during training. We randomly shuffled training data during training. The minibatch size was 25. We trained 10 epochs and chose our model when the development set reached the max accuracy. We implemented our system by using lasagne (Dieleman et al., 2015) and theano (Theano Development Team, 2016) library. Our code is available at here¹.

4 Results and Discussion

To get more reliable results, all accuracies were calculated by averaging after repeating ten experiments. In this competition, the official accuracy of our system recorded 0.712 on test set. Table 1 shows accuracies of other approaches and ours on Argument Reasoning Comprehension task. Our approach showed best performance except human, outperforming all the systems more than 10%. Table 2 shows the results of ablation experiments. Model (a) is our proposed system. Model (d) indicates a model that is same as the model (a), except that the inference knowledge is not transferred. This model is directly trained on our task. Models (b) and (e) indicate that the modules including warrant pair inputs ($W0, W1$) and ($W1, W0$) are removed from model (a) and (d), respectively.

¹<https://github.com/hongking9/SemEval-2018-task12>

Approach	Dev	Test
Human average	-	0.798
Human w/ training in reasoning	-	0.909
Our system	0.716 ± 0.006	0.711 ± 0.007
Random baseline	0.473	0.491
2nd ranked system	-	0.606
Attention [†]	0.488	0.513
Attention w/ context [†]	0.502	0.512
Intra-warrant attention [†]	0.638	0.556
Intra-warrant attent. w/ context [†]	0.637	0.560

Table 1: Accuracy of each approach. The human and baseline results are taken from Habernal et al. (2018). Our approach ranked 1st among 22 systems, outperforming all the systems more than 10%. [†] indicates approaches implemented by Habernal et al. (2018). Readers can check all system results at here².

Model	Dev	Test
(a) Our system	0.716	0.711
(b) – warrants pair input	0.685	0.696
(c) – biLSTM	0.726	0.706
(d) No Transferring	0.652	0.599
(e) – warrants pair input	0.653	0.605
(f) – biLSTM	0.656	0.608

Table 2: Ablation experiments.

Models (c) and (f) indicate that the biLSTM module is removed from model (a) and (d), respectively.

As we mentioned above introduction section, our proposed model addresses two challenging factors. The one is about common sense and the other is about the two lexically close warrants that lead to contradicting claims.

Transfer learning First, by comparing models (a) and (d), we can observe that the inference knowledge of the NLI task is very helpful to the argument reasoning comprehension task. We may assume that machine can accommodate common sense by learning similar tasks and large corpus.

Warrants pair input Second, by comparing models (a) and (b), we can observe that the warrants pair input result in improved performance. We may infer that the model can distinguish fine difference of the two warrants well by directly feeding the warrant pair. However, in the case of model (d) and (e), there is no sufficient difference of the performance. We think this is because the model

²<https://github.com/habernal/semEval2018-task12-results>

did not learn to infer the relationship between two sentences.

Adding biLSTM Finally, by comparing (a) and (c), we can observe that adding biLSTM results in a little improved performance on the test set. Also, the performance on the test set was nearly similar with those in development set in model (a) whereas there was 2% difference in model (c). We carefully infer that the performance on the development set was more reliable and the model becomes flexible to the target task when adding not-trained module to pre-trained and frozen model. However, since the data is not large enough to prove it, we leave it as future work.

5 Conclusion

To address argument reasoning comprehension task, we proposed a network transferring inference knowledge to the Argument Reasoning Comprehension task. First, we implemented ESIM and trained it on a large NLI task corpus. We took full advantage of the model to transfer inference knowledge of NLI task, appropriately building the network. Our approach showed robustness on this task. Through ablation experiment, we showed the following effects: transfer learning, warrants pair input, and adding biLSTM. Also, we showed our system can address the factors about common sense and two lexically close warrants that lead to contradicting claims.

LIGHTREL at SemEval-2018 Task 7: Lightweight and Fast Relation Classification

Tyler Renslow

DFKI, Saarbrücken, Germany
tdrenslow@gmail.com

Günter Neumann

DFKI, Saarbrücken, Germany
neumann@dfki.de

Abstract

We present LIGHTREL, a lightweight and fast relation classifier. Our goal is to develop a high baseline for different relation extraction tasks. By defining only very few data-internal, word-level features and external knowledge sources in the form of word clusters and word embeddings, we train a fast and simple linear classifier.

1 Introduction

The main motivation for our participation at SemEval-2018 (Gábor et al., 2018) was the ideal opportunity to test and improve our relation extraction system LIGHTREL. The system design and development was inspired by the work described in (Nguyen and Grishman, 2015). Their goal was to depart from traditional relation extraction approaches with complicated feature engineering by exploring a deep neural network that would minimize its dependence on external toolkits and resources, e.g. external word embeddings. That allowed them to design a rather lightweight relation extraction approach that would basically only require supervised training data, external word embeddings and a few hyperparameters. Their "end-to-end" relation extraction approach produced competitive results.

Since tuning hyperparameters for neural networks can be a intricate process, we considered whether it would be possible to define an even simpler system and use it as a baseline for our future research. Thus, we adopted some of the design decisions made by (Nguyen and Grishman, 2015) and combined them with a well-known, fast linear classifier, viz. LibLinear (Fan et al., 2008).

Following Nguyen and Grishman (2015), we represent a relation mention as a sequence of tokens. The core idea of our approach consists of transforming this sequence into a a vector of fixed

length, such that each token (or word) is represented only by: 1) the word itself, 2) its shape (a small, fixed amount of character-based features), 3) the word's cluster id, and 4) the word's embedding of fixed size.

For this competition, we introduce a new relation-level feature, namely the ID of the word directly following and preceding entities one and two, respectively. Furthermore, we ignore all tokens to the left of the first entity and to the right of second entity. The size of the whole vector therefore hinges on the maximum number of elements between the two entities found in the training set.

These representations are then used to train a LibLinear model. Note that this reduces manual feature engineering to defining the shape features, finding an appropriate number of clusters and word embedding dimensions, and hyperparameters for LibLinear. All other information is automatically computed from the training data. In this sense, we consider our system lightweight.

We initially developed and tested our approach on the previous and widely-used SemEval-2010 Task 8 data set (Hendrickx et al., 2010), and obtained as our best result an F1 measure of 79.78% on the test-data using the standard evaluation script from SemEval-2010 (see also Sec. 3). Although this result is behind the best reported ones (the majority between 83%-85%, and the best 88.0%, cf. (Wang et al., 2016)), we think it provides a strong baseline compared to the manually-engineered, feature-heavy approaches or complex neural architectures. Thus, when the SemEval-2018 Task 7 challenge was announced, it was a natural decision to use it as an additional testing ground for LIGHTREL.

2 Approach

LIGHTREL can be divided into three major steps:

1) extracting information from the training data and external sources and storing it in an internal representation; 2) converting the internal representation into feature vectors; 3) using feature vectors to train a logistic regression classification model to predict classes.

In the first step of the system, pertinent information is extracted from the training data. Each relation instance (the two entities and the text between them) is collected. Along with the relation instance, the ID of the abstract, the IDs of the entities, the relation type and the length of the sentence are all gathered into one internal representation to facilitate vector computation later. We do not include additional data in our training set, e.g. from other tasks or subtasks, previous SemEval years, etc. For example, the following relation:

```
<entity id="E89-1006.1">French tenses
</entity> in the framework of <entity
id="E89-1006.2">Discourse
Representation Theory</entity>
```

would be represented in our system as:

```
('E89-1006', ['French_tenses', 'in',
'the', 'framework', 'of',
'Discourse_Representation_Theory'],
'E89-1006.1', 'E89-1006.2',
'MODEL-FEATURE REVERSE', 6)
```

The only processing done on the text is: 1) merging any punctuation and the word before it into a single string and 2) joining multi-word entities into a single string with an underscore. Using the words from these instances, we index a unique vocabulary and the single word immediately following or preceding entity one or entity two, respectively, provided that the word isn't the other entity. The unique relation types are also indexed later so that their unique identifiers can be used as a feature in the training vectors for LibLinear. In the case of the competition, the test data is used to expand the unique vocabulary and entity context words. Once this information is collected, it can be converted into vector representations to train a LibLinear model.

The next step involves converting our relation instances into feature vectors. In addition to the information gleaned from the training data, we use features that are independent of our training data. For instance, we include a word-shape feature, a unique vector representing certain character-level features found in a word. In particular the features are based on whether: any character is capitalized; a comma is present; the first character is capitalized and the word is the first in the relation (representing the beginning of a sentence); the first character is lower-case; there is an underscore present (representing a multi-word entity); and if quotes are present in the token. These features were left unchanged from the ones that achieved the best results on SemEval-2010 Task 8.

We also incorporate our own word embeddings into our feature vectors. Our previous system developed for the SemEval-2010 task used Numberbatch embeddings from ConceptNet (Speer et al., 2017) to yield the best results, but development was slower than desired due to the size of the embedding file. We therefore hand-pick the data used to calculate the new, smaller embeddings in order to experiment with domain-specific word embeddings better tuned to the task at hand.

We pre-compute two word embedding files: one based on the ACM-Citation-network V9 corpus of abstracts and the other on the DBLP-Citation-network V5 corpus.¹ The embeddings are calculated using the word2vec² tool with the following constraints: the continuous bag-of-words model, 300-dimension vectors (chosen for portability from the old system that used 300-d Numberbatch vectors) and leaving out tokens occurring fewer than five times. The DBLP corpus embedding file used for the final system was around half the size of the Numberbatch embeddings.

Cluster-membership features are also included in our feature vectors. We used the MarLin (Müller and Schuetze, 2015) clustering tool to pre-compute word clusters for the aforementioned two corpora based on their bigram context. In particular, we ran five training epochs to cluster the words into 1000 classes. MarLin was chosen over the Brown clustering algorithm (Brown et al., 1992), as these clusters produced better results for SemEval-2010 Task 8. Using all of our features, we convert our internal representation into the proper input format for training a LibLinear model. All features are binary besides the word embeddings. The test data is converted into the same format for predicting, albeit without relation IDs in the case of the competition run.

Cluster-membership features are also included in our feature vectors. We used the MarLin (Müller and Schuetze, 2015) clustering tool to pre-compute word clusters for the aforementioned two corpora based on their bigram context. In particular, we ran five training epochs to cluster the words into 1000 classes. MarLin was chosen over the Brown clustering algorithm (Brown et al., 1992), as these clusters produced better results for SemEval-2010 Task 8. Using all of our features, we convert our internal representation into the proper input format for training a LibLinear model. All features are binary besides the word embeddings. The test data is converted into the same format for predicting, albeit without relation IDs in the case of the competition run.

In the same way as (Nguyen and Grishman, 2015), we represent a relation mention x of length n as a sequence of tokens $x = [x_1, x_2, \dots, x_n]$, where x_i is the i -th word in the mention. Further-

¹Corpora available at <https://aminer.org/citation>.

²<https://code.google.com/archive/p/word2vec/>

more, let x_{i_1} and x_{i_2} be the head of the two entity mentions of interest. Now, we transform this into a vector of fixed length l , whose size is determined by the relation mention with highest number of tokens k between its entity head tokens, and by using L tokens left to the entity token x_{i_1} , and R tokens to the right of x_{i_2} . In all experiments described below, L and R are set to 0, which is also done by (Nguyen and Grishman, 2015). If a relation mention has fewer than k elements between entities, we add padding elements (i.e. dummy word tokens). One of the system parameters we tuned was the padding strategy employed: in the end, we got better results when padding after entity one as opposed to padding before entity two. Thus, initially, all relation mentions are represented by a fixed length vector $x' = [x'_1, x'_2, \dots, x'_{k+2}]$, where $x'_1 = x_{i_1}$ and $x'_{k+2} = x_{i_2}$, with words plus the necessary number of padding elements between.

Once we have a fixed-length vector for each relation, we append the word-context feature to the vector. The motivation behind this feature is to provide some distributional information to the model regarding the syntactic contexts in which entities occur. In the case where there are no words between entities, we use no word context in our feature vector. If a single word occurs between entities, they share the same context. Otherwise, word context is represented by the word directly to the right and left of entity one and two, respectively. The context features are calculated based on the original, non-normalized sentence, so that padding elements are not involved.

The last step involves training a model to predict classes based on our vector representations of the training data. We employ LibLinear’s default classifier (version 2.11), cf. also Sec. 3. Once the model is trained, it can then make predictions on the vectors that represent test relation instances. The predictions are then converted back into the format necessary for evaluating our system using the scorer script provided by SemEval.

3 Experiments

As mentioned before, our system was an adaptation to the one that produced the optimal result on SemEval-2010 Task 8. Through cross-validation, we tuned our system parameters to produce the best results on SemEval-2018 training data, bearing in mind the goal of keeping our system as lightweight as possible. It is important to note that

hyperparameter tuning was only done according to system performance on task 1.1’s training data; we simply used the optimal parameters from this task while participating in task 1.2 for the competition.

Through experimentation, we found a LibLinear classifier that performed better on the current task than the one that we used for the SemEval-2010 task. We also developed a novel word-context feature for the 2018 task, which modestly improved our cross-validation results (anywhere from a 1% to 3% increase in F1 score, depending on the different parameters used). We will display the parameters that produced optimal results in cross-validation, as well as the results obtained using these same parameters in the competition phase in tabular form below.

For the SemEval-2010 task, we obtained the best results using LibLinear’s support vector classifier by Crammer and Singer (Crammer and Singer, 2000) with a cost of 0.1 and a stopping tolerance of 0.3. Given the fewer relation types and smaller training vectors in the SemEval-2018 task, we experimented with different classifiers. In development, we achieved the best performance in using LibLinear’s default classifier, which performs dual L2-regularized L2-loss support vector classification, cf. (Fan et al., 2008). We set cost and stopping tolerance parameters equal to 0.1, using default settings for all other parameters.

The total competition data was made up of $1228 + 355 = 1583$ relation instances ($\#training + \#test$), corresponding to an approximate train-test split of $\approx 78\%-22\%$. Because of this, we developed our system using 5-fold cross-validation on the training set, which entails an even 80%-20% split of data, i.e. $982 + 246 = 1228$ instances. Even though a subset of the training data was provided by the organizers for system development, we opted to split the data in accordance with the proportion of training and test instances, in order to get the best estimate of system performance in the competition phase.

We obtained the best average F1 score for tasks 1.1 and 1.2 when using all features but the shape feature (word, embeddings, clusters, entity one context, entity two context); the second best score was obtained when using all features and the third best by removing the entity two context feature from the entire feature set. These feature sets represent a modest approach to the task at hand compared to more complex systems in-

corporating knowledge from sources like part-of-speech tagging or dependency parsing. An exception to these feature sets was cross-validation on task 1.2’s training data, where an average F1 score of 61.83% was obtained when using neither context-related feature. However, since removing a context-related feature (no e2 context) already produced the best results in development, we decided to hedge our bets in the competition with a feature set composed of all features but the shape feature, i.e. of no manually engineered features.

The results from cross-validation on task 1.1 and task 1.2 are shown in Table 1 below. Based on these results, we expected our system to perform similarly in the competition.

feature set	task 1.1	task 1.2
all features	45.4%	62.0%
w/o shape	46.4%	61.7%
w/o e2 context	45.5%	62.1%

Table 1: Average F1 scores from 5-fold cross-validation.

The actual results of the competition can be seen below in Table 2. These results placed us in 18th out of 28 groups in subtask 1.1 and 12th out of 20 in subtask 1.2.

feature set	task 1.1	task 1.2
all features	39.3%	67.5%
w/o shape	39.9%	68.2%
w/o e2 context	39.2%	67.5%

Table 2: Competition F1 scores.

The best result was obtained when using all features except the shape feature. This points to evidence that there is overlap in the information gained from the shape feature and the word feature. The same token, differing only in punctuation (e.g. the strings 'IR' and 'IR,'), is represented with both different word and different shape IDs in our system. However, for the shape feature to provide extra information to the model, the word feature would have to remain the same, since the shape feature changed.

The results on the first task were worse than the cross-validation results suggested. Since we incorporated the words from the test data into our word and context features, there was no information that the model could have missed in the competition phase. Therefore, we attribute the slight decrease

in performance to the fact that more training and less test data were used in development, meaning that our models were overfitting in training.

Surprisingly, our system performed better on noisily annotated data, given no extra development in relation to the task. It is difficult to say with conviction why these results occurred, as our features do not incorporate the entity markup. Another difference in this task is the data itself; it could be that more tokens were found in the embedding and cluster features, providing more information to the model. However, this fact alone hardly explains an almost 30% increase in F1.

Finally, we assessed our system’s speed. The final system which produced the best results for subtask 1.1 needed a total of 35 seconds to run on a 2012 MacBook Pro with 16GB of RAM and a 2.6 GHz quad-core Intel Core i7 processor³. The bottleneck occurred in the creating of vectors (80% of total time), which can be attributed to the simple way we stored and accessed the embeddings. Training lasted 5 seconds, while testing/prediction only required a fraction of a second. These results demonstrate our system’s agility in relation to complex neural architectures, which typically need hours, or even days, to train.

4 Conclusion

We believe our system has established a useful baseline for relation classification. Our approach is simple in that it involves few features. These few features yield remarkable results given the amount of time required to deploy the system, allowing for quicker development and prototyping of models compared to more cumbersome neural networks. The performance on task 1.2 as opposed to task 1.1 demonstrates our system’s flexibility, as we obtained fair results with no extra development. However, further research is needed to explain the jump in performance between the tasks.

OhioState at SemEval-2018 Task 7: Exploiting Data Augmentation for Relation Classification in Scientific Papers Using Piecewise Convolutional Neural Networks

Dushyanta Dhyani

The Ohio State University OH, USA

dhyani.2@osu.edu

Abstract

We describe our system for SemEval-2018 Shared Task on Semantic Relation Extraction and Classification in Scientific Papers where we focus on the Classification task. Our simple piecewise convolution neural network (PCNN) performs decently in an end to end manner. A simple inter-task data augmentation significantly boosts the performance of the model. Our best-performing systems stood 8th out of 20 teams on the classification task on noisy data and 12th out of 28 teams on the classification task on clean data.

1 Introduction

Relation extraction (RE) and Classification (RC) is an integral component of information extraction systems which aim to extract all the entity pairs and their relation $\langle e_1, r, e_2 \rangle$ from a given text corpora. An alternate formulation of relation extraction task focuses on identifying if a relation exists between a predefined pair of entities, and if yes classify from a given set of class relations. RE finds applications in a variety of domains, ranging from knowledge base construction to semantic parsing and question answering. However, the applicability of existing efforts in relation extraction to scientific text calls for a quantitative and qualitative analysis which is the aim of this shared task.

2 Related Work

Existing efforts for RE range from traditional strategies (Qian et al., 2008; Bunescu and Mooney, 2006, 2005; Mintz et al., 2009; Riedel et al., 2010) to more recent end to end deep learning based methods (Zeng et al., 2014, 2015; Lin et al., 2016; Wu et al., 2017) that are more suitable in situations where a lot of training data is available. While a majority of efforts in the RE community are specifically focused towards using

distantly supervised data and reduce the associated noise, their discussion is not relevant to the current scenario. The most relevant work is that of (Zeng et al., 2014) who demonstrated the efficacy of convolution neural networks for relation classification and (Zeng et al., 2015) who further enhanced the architecture by proposing the piecewise max-pooling strategy.

3 Task Description

The semantic relation extraction and classification in scientific papers task (Gábor et al., 2018) aims at identifying semantic relations expressed by entity pairs in scientific literature. The contest is further divided into three subtasks, where the first two focus on classification of varying nature of data and the third focuses on extraction task. Since our submitted systems focused only on the classification task, we would from here on discuss mostly about the classification sub-tasks.

3.1 Dataset

The data contains titles and abstracts of papers from ACL Anthology Corpus where entity mentions are either manually annotated (Subtask 1.1 and Subtask 2) or heuristically (Subtask 1.2) determined. However, the relations are manually annotated across all subtasks. For the classification scenario, we are provided with relevant entities and the directionality of their relation. There are 6 class labels: USAGE, RESULT, MODEL, PART_WHOLE, TOPIC, COMPARISON. The classes are highly imbalanced in nature as shown in Fig. 2

3.2 Evaluation

For both Task 1.1 and 1.2, given that the classes are imbalanced, macro-f1 score is used as the official evaluation metric and thus the metric we use for hyperparameter tuning. For more details, we

would refer the reader to the task description paper (Gábor et al., 2018)

4 Methodology

As shown in Fig. 1, we use the piecewise convolutional encoder proposed by (Zeng et al., 2015) which encodes the sentence into an embedding space taking into account the context of text around the entities in an end to end manner. The various components of the encoder are described below

4.1 Preprocessing

Since the original training dataset provided is annotated using XML tags which can be utilized in a variety of ways, we briefly describe our preprocessing steps. Each text item contains a title of a paper and its abstract. Both the entities for a particular training/testing instance could only either be in the title or in the abstract. While it would be interesting to see the impact of incorporating the effect of paper titles on the entities in abstracts and vice versa, to simplify the architecture, we simply treat titles and abstracts as separate and independent sentences. For the representation of entities, the two most obvious options are to either combine sub-words in an entity using a

special character (e.g. *word sense disambiguation* becomes *word_sense_disambiguation*) or to simply use entity head words to represent the starting position of the entity as proposed by (Nguyen and Grishman, 2015). We chose the latter approach for two reasons: 1) The amount of data is relatively small to learn word embeddings on the data itself 2) The conjoined entity representation as in the former approach would probably not exist in the pre-trained word embeddings and thus would have to be replaced by an unknown token. Finally, we used common text cleaning techniques like removing non-alphanumeric characters, replacing all numbers by a unique token, etc.

4.2 Word Representation

Each word in the input is transformed to a static, dense feature representation by looking up a pre-trained word embedding dictionary. We use dependency based word embeddings (Levy and Goldberg, 2014) which incorporate long-range dependencies between words and thus generate embeddings that are more functional in nature (than the traditional bag of words based embeddings) which is presumably more suitable to the current task as dependency based features have been shown to be useful for relation extraction (Xu et al., 2015; Bunescu and Mooney, 2005). All words that do not exist in the dictionary are replaced by *UNK* token and initialized randomly.

4.3 Position Embedding

Since convolved representations are position invariant, incorporating positional information using embeddings has been shown to be useful for a variety of task (Zeng et al., 2014; Gehring et al., 2017) when using a convolutional encoder. We evaluate the distance of each word in the sentence with respect to both *entity 1* and *entity 2* (we limit the values to a maximum distance of *position_window_size*). These position values are then projected into a relatively small embedding space using a trainable embedding layer.

4.4 Directionality Embedding

Since the relations are directional in nature, it is important to incorporate the available directionality information in the sentence representation. While this can be implicitly done when using dependency tree base input representation, to incorporate the directionality of the relation exhibited by the two entities ($\langle e_1, r, e_2 \rangle$ or $\langle e_2, r, e_1 \rangle$)

we also project the direction information into the embedding space by another embedding layer that is trained along with the entire network.

4.5 Convolution and Piecewise Max-Pooling

CNN's have been shown to be good at encoding sentences into vector representations for text classification tasks (Kim, 2014; Zhang et al., 2015; Hu et al., 2014; Kim et al., 2016) and at the same time also speed up the training and inference time. The word representations and position embeddings are concatenated and fed into a convolution encoder which generates features using varying width of filters. To take into account the context of text around and between the entities in consideration, we then perform a piecewise max-pooling operation as shown in Fig. 1. The input representations (word-embedding \oplus position-embedding) are appropriately padded before the convolution operation to ensure that the convolved features have the same length as the input sentence in order to correctly use entity positions for piecewise max-pooling. These features generated by the PCNN are finally concatenated with the directionality embeddings discussed above to generate the sentence level representation.

4.6 Regularization, Output and Training

We use dropout (Srivastava et al., 2014) on the sentence representations with a keep probability of 0.5 as a simple regularization strategy. This is followed by a fully connected layer and a softmax operation for the classification task. We use the standard multi-class cross-entropy loss as our training objective and Adam (Kingma and Ba, 2014) for optimization.

Parameter	Values
Number of Epochs	100,200,400
Maximum Sequence Length	100,200
Batch Size	32,64
Number of Filters	32,64,128
Learning Rate	0.001, 0.0005

Table 1: Hyperparameter Values.

5 Experiments

5.1 Data Augmentation

Deep neural models require significant amount of training data to extract relevant features. While

Task	Data	Epoch	Batch Size	No. of Filters	Macro-F1 Score
1.1	1.1	200	32	64	35.3
1.1	1.1 + 1.2	200	64	32	48.1
1.2	1.2	200	32	64	64.4
1.2	1.1 + 1.2	100	64	128	74.7

Table 2: Results of our best performing systems on the official test set with/without data augmentation.

our neural model is relatively shallow, the data size for each of the subtask is also small. As a workaround, we simply mix the data from subtask 1.1 with data from subtask 1.2 which hopefully helps in improving the model’s generalizability.

5.2 Experimental Settings

While the final training and prediction was performed on the entire training dataset, we use the official validation split provided by contest organizers to perform hyper-parameter tuning. For the data augmentation scenario, however, we also make use of the validation data from the other task. Given that CNN’s are fast to train, we easily use grid search to find the optimal combination of a subset of parameters for each task and each data configuration (with or without augmentation) which are listed in Table 1. For the remaining parameters, we used standard values as recommended by prior literature as follows: convolution filters of width 3,4 and 5; position and directionality embeddings of size 5; windows size for relative positions from entities was set to 30.

6 Results

We report our performance on the classification tasks (Subtask 1.1 and 1.2) according to the official evaluation. While all task settings perform best for a maximum sequence length of 200 and learning rate of 0.001, the rest of the parameters and their corresponding results are listed in Table 2. Even a simple mixing of the two datasets which differ significantly in the nature of tagged entities lead to a significant improvement. Surprisingly though, adding the noisy data to the clean dataset also leads to a 36% increase in performance. This could be attributed to the fact that while heuristically annotated entities are high-level concepts thus sharing a lot of context with similar concepts, most of the manually annotated entities are full noun phrases, thus adding to the complexity of the

task. These results also falsify our initial assumption/expectation of Task 1.1 to be easier.

7 Conclusion

We presented a simple end to end model that is fast to train and though does not perform competitively well, makes effective use of additional data for a significant improvement in performance. These results show the effectiveness of mixing/transferring supervision from data coming from a different distribution and thus invites further exploration in semi-supervised/supervised domain adaptation scenarios.

The UWNLP system at SemEval-2018 Task 7: Neural Relation Extraction Model with Selectively Incorporated Concept Embeddings

Yi Luan Mari Ostendorf Hannaneh Hajishirzi

University of Washington
{luanyi, ostendor, hannaneh}@uw.edu

Abstract

This paper describes our submission for the SemEval 2018 Task 7 shared task on semantic relation extraction and classification in scientific papers. We extend the end-to-end relation extraction model of (Miwa and Bansal, 2016) with enhancements such as a character-level encoding attention mechanism on selecting pretrained concept candidate embeddings. Our official submission ranked the second in relation classification task (Subtask 1.1 and Subtask 2 Senerio 2), and the first in the relation extraction task (Subtask 2 Scenario 1).

1 Task Overview

The SemEval 2018 Task 7 Shared Task (Gábor et al., 2018) focuses on the task of recognizing the semantic relation that holds between scientific concepts. The task involves semantic relation extraction and classification into six categories specific to scientific literature: USAGE, RESULT, MODEL-FEATURE, PART-WHOLE, TOPIC, COMPARE. Two types of tasks are proposed: 1) identifying pairs of entities that are instances of any of the six semantic relations (extraction task), and 2) classifying instances into one of the specific relation types (classification task).

Consider the following input sentence: “[*Unsupervised training*] is first used to train a [*phone n-gram model*] for a particular domain.” Given the concept pair [*Unsupervised training*] and [*phone n-gram model*], the relation extraction task is to identify whether there is a relation between the concepts, while the relation classification task is to identify the relation as USAGE. Relation directionality is not taken into account for the evaluation of the extraction task. Directionality is taken into account when relevant for the classification task (5 out of the 6 semantic relations are asymmetrical). We will use this example throughout the paper to illustrate various parts of our system.

The SemEval 2018 Task 7 dataset contains 350 abstracts from the ACL Anthology for training and validation, and 150 abstracts for testing each sub-task. Since the scale of the data is small for supervised training of neural systems, we introduce several strategies to leverage a large quantity of unlabeled scientific articles. In addition to initializing a neural system with pre-trained word embeddings, as in (Luan et al., 2017), we also try to incorporate embeddings of concepts that span multiple words. In neural models such as (Miwa and Bansal, 2016), phrases are often represented by an average (or weighted average) of the token’s sequential LSTM representation. The intuition behind explicit modeling of multi-word concept embeddings is that the concept use may be different from that of its individual words. Due to the size of the dataset and the nature of scientific literature, a large number of the scientific terms in the test set have never appeared in the training set, so supervised learning of the phrase embeddings is not feasible. Therefore, we pre-trained scientific term embeddings on a large scientific corpus and provide a strategy to selectively incorporate the pre-trained embeddings into the relation extraction system.

2 System Description

2.1 Neural Architecture Model

Our system is an extension of (Luan et al., 2017) and (Miwa and Bansal, 2016) with LSTM RNNs that represent both word sequences and dependency tree structures, and perform relation extraction between concepts on top of these RNNs. As illustrated in Figure 1, it is composed of a 5 types of layers in a hierarchical neural model to encode context information. The first two layers (token, token LSTM) use the neural modeling framework in (Luan et al., 2017). The forward and backward dependency layers and the relation classification

layer are based on (Miwa and Bansal, 2016). The concept selection layer is novel, to the best of our knowledge. The different layers are described in more detail below.

Token Layer. The token layer concatenates three types of vector space embeddings. *Word embeddings* are learned for words from a fixed vocabulary (plus the unknown word token), initialized using Word2vec pre-training with large scholarly corpora. The *character-based embedding* for a token is derived from its characters as the concatenation of forward and backward representations from a bidirectional LSTM. The character look-up table is initialized at random. The advantage of building a character-based embedding layer is that it can handle out-of-vocabulary words and equations, which are frequent in this data, all of which are mapped to “UNK” tokens in the Word Embedding Layer. *Word embeddings* are learned for words from a fixed vocabulary (plus the unknown word token), initialized using Word2vec pre-training with large scholarly corpora. A *feature embedding* is learned as a mapping from features associated with capitalization (all capital, first capital, all lower, any capital but first letter) and part-of-speech tags. The embeddings are randomly initialized and trained jointly with other parameters during supervised training.

Token LSTM Layer We apply a bidirectional LSTM at the token level taking the concatenated character-word-feature embedding as input. An LSTM hidden state generated in this layer is denoted as h^S .

Forward & Backward Dependency Layers Given the concept pair (C_l, C_r) , the Forward Dependency Layer (generating h^F) traces from the closest common ancestor w_a (for example the word “used” in Fig. 1) to the headword w_j (word “model”) of the right target concept C_r (“phone n-gram model”). The Backward Dependency Layer (generating h^B) traces from the ancestor to the headword w_i of the left concept C_l . We map the dependency relation into vector space and concatenate the resulting embedding to the embedding (h^S) of the headword of the concepts C_l or C_r for the backward and forward dependency layers, respectively. We concatenate the resulting bi-directional LSTM vector for the headwords together with the common ancestor in both Forward & Backward Dependency Layer as input to Relation Classification Layer

$$h^{DP} = [\overleftarrow{h_{w_i}^B}; \overrightarrow{h_{w_i}^B}; \overleftarrow{h_{w_j}^F}; \overrightarrow{h_{w_j}^F}; \overleftarrow{h_{w_a}^B}; \overrightarrow{h_{w_a}^B}; \overleftarrow{h_{w_a}^F}; \overrightarrow{h_{w_a}^F}].$$

Concept Selection Layer The concepts in the task are mostly phrases rather than single words, in the SemEval Task 7. We therefore seek ways to obtain prior knowledge for those terms. We train a scientific concept extraction model using the state-of-the-art scientific neural tagging technique in (Luan et al., 2017), given the scientific concept annotation in the SemEval 2018 Task7 training data. We were able to achieve 79.8% F1 score (span level) to identify the scientific concepts. We then use the model to extract all scientific concepts in the ACL anthology and AI2 dataset (refer to Sec. 3). We keep all the concepts that occur more than 10 times in the whole corpus, which results in around 15k concepts. We treat each of the 15k concepts as an individual token and retrain word2vec embeddings v_k together with all other single words. At training time, given a scientific concept pair (C_l, C_r) , we search through the 15k concepts to get all the concept candidates that have n-gram string match with C_l and C_r respectively (n is from 1 to the length of the target concept C). For example, for the concept *phone n-gram model*, the candidate concepts we get are $\{\textit{phone n-gram}, \textit{n-gram model}, \textit{n-gram}, \textit{model}, \textit{phone}\}$. Since there may exist cases where no match could be found in the 15k concepts, we introduce a null vector v_\emptyset . v_\emptyset is learned with other neural network parameters. Assume there are K concept candidates in the candidate list, we denote the embeddings for the concept candidates to be $V = \{v_1 \dots v_K, v_\emptyset\}$. The attention weights are calculated by $\alpha_{lk} \propto \exp(h_{C_l}^S W_{ATT} v_k)$, where $v_k \in V$. $h_{C_l}^S$ is the concatenation of bidirectional LSTM hidden states of the first and last word in C_l .¹ W_{ATT} is a parameter matrix for the bilinear score for $h_{C_l}^S$ and v_k . The final concept embedding v_{C_l} is $v_{C_l} = \sum_{v_k \in V} \alpha_{lk} v_k$. For a target concept C, if exact match exists in the 15K concepts, we set the pre-trained concept embedding to be v_{C_l} . We concatenate the resulting embedding for both concepts in the concept pair as input to the final classification layer ($v_C = [v_{C_l}; v_{C_r}]$).

Relation Classification Layer We concatenate the output of Forward & Backward Dependency Layer h^{DP} and Concept Embedding Selection Layer v_C as input to Relation Classification Layer.

¹We also tried using the weighted average of all LSTM word embeddings in the span to calculate $h_{C_l}^S$; this yields a slightly worse result.

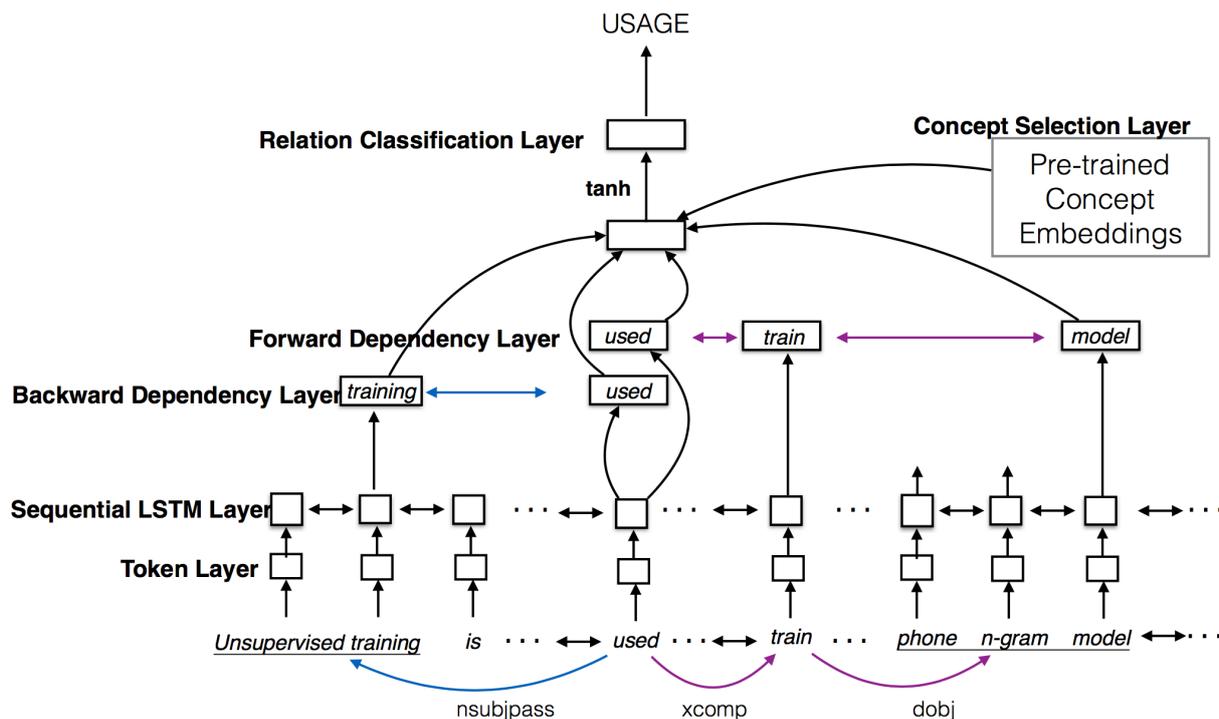

Figure 1: Neural relation extraction model with bidirectional sequential and dependency path LSTMs.

Besides, we also introduce a distance feature between the two concepts which indicates how many other concepts there are in between the target concept pairs. We concatenate the distance embedding with all the other features. The concatenated features are then projected down to a lower dimension through *tanh* function and make the final prediction through a *softmax* function.

3 Experimental Setup

External Data We use two external resources for pretraining word embeddings: i) the Semantic Scholar Corpus,² a collection of over 20 million research papers from which we extract a subset of 110k abstracts of publications in the artificial intelligence area; and ii) the ACL Anthology Reference Corpus, which contains 22k full papers published in the ACL Anthology (Bird et al., 2008).

Baseline We compare our model with a baseline that removes the Concept Selection Layer and replaces it with a weighted sum (using attention) of hidden states (from the Sequential LSTM Layer) for all words in a concept.

Implementation details All parameters are tuned based on dev set performance; the best parameters are selected and used for final evaluation.

²<http://labs.semanticscholar.org/corpus/>

For all experiments, we explore tuning with two different evaluation metrics: macro-F1 score and micro-F1 score.³ We keep the pre-trained concept embedding fixed as additional input feature. The word embedding dimension is 250; the LSTM hidden dimension is 100 (for both sequential and dependency layer); the character-level hidden dimension is 25; and the optimization algorithm is SGD with a learning rate of 0.05. For Subtask 2, since 5 out of 6 relation types have directionality, we add relation label “_REVERSE” to all the 5 directional relations together with a “NONE” type, which result in 12 labels in total. For each epoch, we also randomly filter out some “NONE” samples with probability p during training, since the “NONE” type relation dominates the training set and would bias the model towards predicting “NONE” types. We tune p according to dev set, and use $p = 0.4$ for the final evaluation.

4 Experimental Results

Ablation Study Table 1 provides the results of an ablation study on the dev set showing the impact of removing different components of our system.

³The official evaluation is macro-F1, but since the number of instances in each class is highly unbalanced, the observed macro-F1 scores were unstable. We therefore introduce micro-F1 score for tuning and evaluation as well.

Model	Macro			Micro		
	P	R	F1	P	R	F1
Our system	49.4	36.7	42.1	46.2	42.2	44.1
-DepFeat	38.2	39.6	39.0	45.2	41.9	43.0
-DistFeat	43.4	37.8	40.4	38.7	47.8	42.7
-DepLSTM	51.5	30.0	37.9	48.6	32.6	39.0
-Concept	36.2	41.8	38.8	37.6	46.5	41.6
Baseline	40.9	32.5	36.2	41.9	38.0	39.9

Table 1: Ablation study showing the impact of neural network configurations on system performance on the dev set for the relation classification task (Subtask 2, senerio 2). -DepFeat removes the input dependency relation embeddings from the Backward & Forward Dependency Layers. -DistFeat and -Concept omit the distance and concept selection features, respectively, from the final classification layer. -DepLSTM removes the Backward & Forward Dependency Layers entirely (using the LSTM embeddings in the weighted token average).

Looking at micro F1 scores, dependency path information is very important (performance dropped 11.5% without it), and the Concept Selection Layer is also important as it gives 2.5 absolute improvement. The Dependency relation feature and the distance feature also show 1-2 points gain. It is worth noticing that removing the Concept Layer (-Concept) does better than replacing it with the weighted sequential LSTM sum (Baseline). With the small amount of training data, it is difficult for the baseline system to learn a good transformation from word to phrase.

Competition Result The results of our system is in Table 2. We submit two sets of results, one tuned with micro F1 and the other with macro F1. It turns out that even though the official evaluation metric is macro F1 score, our model tuned by micro F1 gets better results in the final competition. In Subtask 1.1 and Subtask 2 scenario 2, we were the second place team with F1 score of 78.9% and 39.1% respectively. We were the first place in Subtask 2 scenario 1 with 50.0% F1.

5 Related Work

There has been growing interest in research on automatic methods to help researchers search and extract information from scientific literature. Past research has addressed citation sentiment (Athar and Teufel, 2012b,a), citation networks (Kas, 2011; Gabor et al., 2016; Sim et al., 2012; Do et al., 2013; Jaidka et al., 2014), summarization (Abu-Jbara and

Model	T1.1	T2-E	T2-C
Our system (Micro)	78.9	50.0	39.1
Our system (Macro)	78.4	49.3	37.0
Team-1	81.7	48.8	49.3
Team-2	76.7	37.4	33.6

Table 2: Competition result for the top 3 teams. The official evaluation metric is macro F1 score. T1.1 means Subtask 1.1, T2-E means Subtask 2 senerio 1 (extraction task), T2-C means Subtask 2 senerio 2 (classification task).

Radev, 2011) and some analysis of research community (Vogel and Jurafsky, 2012; Anderson et al., 2012). However, due to scarce hand-annotated data resources, previous work on information extraction (IE) for scientific literature is very limited. Most previous work focuses on unsupervised methods for extracting scientific terms such as bootstrapping Gupta and Manning (2011); Tsai et al. (2013), or extracting relations (Gábor et al., 2016). Luan et al. (2017); Augenstein and Søgaard (2017) applied semi-supervised learning and multi-task learning to neural based models to leverage large unannotated scholarly datasets for a scientific term extraction task (Augenstein and Søgaard, 2017).

Although not much supervised relation extraction work has been done on scientific literature, neural network techniques have obtained the state of the art for general domain relation extraction. Both convolutional (Santos et al., 2015) and RNN-based architectures (Xu et al., 2016; Miwa and Bansal, 2016; Peng et al., 2017; Quirk and Poon, 2017) have been successfully applied to the task and significantly improve performance.

6 Conclusion

This paper describes the system of the UWNLP team submitted to SemEval 2018 Task 7. We extend state-of-the-art neural models for information extraction by proposing a Concept Selection module which can leverage the semantic information of concepts pre-trained from a large scholarly dataset. Our system ranked second in the relation classification task (subtask 1.1 and subtask 2 senerio 2), and first in the relation extraction task (subtask 2 scenario 1).

Abstract

This paper reports our participation for SemEval-2018 Task 7 on extraction and classification of relationships between entities in scientific papers. Our approach is based on the use of a Convolutional Neural Network (CNN) trained on 350 abstract with manually annotated entities and relations. Our hypothesis is that this deep learning model can be applied to extract and classify relations between entities for scientific papers at the same time. We use the Part-of-Speech and the distances to the target entities as part of the embedding for each word and we blind all the entities by marker names. In addition, we use sampling techniques to overcome the imbalance issues of this dataset. Our architecture obtained an F1-score of 35.4% for the relation extraction task and 18.5% for the relation classification task with a basic configuration of the one step CNN.

1 Introduction

Nowadays, there is a high increase in the publication of scientific articles every year, which demonstrates that we are living in an emerging knowledge era. Experts cannot deal with this explosion of information and it is very hard to be up to date about the state-of-the-art techniques in a given field. This arduous task could be reduced if we automatically identify concepts from scientific articles and recognize the semantic relations between them with Natural Language Processing (NLP) techniques.

The Semantic Relation Extraction and Classification in Scientific Papers task at SemEval-2018 task 7 (Gábor et al., 2018) provides a framework for measuring the automatic annotation performance by models which are trained on scientific publications abstracts. The task defines six categories of relations between concepts and two tasks

are proposed: (1) the classification of the relations between two entities in the predefined categories, which is divided in two scenarios according to the data used: clean or noisy; and (2) the extraction of the relations given the entities from the clean data, which also could involve their subsequent classification.

In this paper, we describe our participation for SemEval-2018 Task 7 on the extraction of relationships between entities in scientific papers and also the subsequent classification in the predefined classes of this relations with one step classifier. The model is based on the Convolutional Neural Network (CNN) proposed in (Kim, 2014), which was the first work to exploit this architecture for the task of sentence classification. CNN is a robust deep-learning architecture which has exhibited good performance in others NLP tasks such as semantic clustering (Wang et al., 2016), sentiment analysis (Dos Santos and Gatti, 2014) and event detection (Nguyen and Grishman, 2015). The model uses as the input of each instance the transformation into real value vectors of the words of the sentence, the distances to the target entities of each word and the Part-of-Speech types. Furthermore, we carry out a sampling technique to alleviate the imbalance issues of the dataset equalizing the number of the instances for all the classes.

2 Dataset

An annotated corpus for training and testing the participating systems was provided in the SemEval-2018 Task 7. The dataset contains 350 and 150 abstract from scientific articles for training and testing set, respectively.

The relation instances are divided into the following classes: *USAGE*, *RESULT*, *MODEL*, *PART WHOLE*, *TOPIC* and *COMPARISON*. All of them are asymmetrical except *COMPARISON*, where

both entities are involved in the same bidirectional relation. A detailed description and analysis of the corpus and its methodology used to collect and process the scientific abstracts can be found in (Gábor et al., 2018).

2.1 Pre-processing phase

The relations between scientific concepts are annotated pair by pair in the abstracts. All annotated relations span within one sentence, thus, we split the paragraphs of the abstracts into sentences with NLTK tool¹ to generate all the possible instances in the corpus.

After that, each instance was tokenized, all words were converted to lower-case and special character were removed in order to clean the sentences as the approach described in (Kim, 2014). In addition, we used entity blinding for each relation to generalize the model, in which the two target entities of the relations were replaced by entity markers as "entity1" and "entity2", and "entity0" for the remaining entities. Since relations can be asymmetrical, we considered both directions. In other words, for each pair of candidates entities, we generated two different instances. For the *COMPARISON* class, which is a bidirectional relationship, we annotated both instances with the same class label. For example, the sentence: 'We suggest a method that mimics the behaviour of the oracle using a neural network or a decision tree.' should be transformed to the relation instances showed in Table 1.

Instances after entity blinding (entity1, entity2)
(oracle, neural network) 'We suggest a method that mimics the behaviour of the entity1 using a entity2 or a entity0.'
(neural network, oracle) 'We suggest a method that mimics the behaviour of the entity2 using a entity1 or a entity0.'
(oracle, decision tree) 'We suggest a method that mimics the behaviour of the entity1 using a entity0 or a entity2.'
(decision tree, oracle) 'We suggest a method that mimics the behaviour of the entity2 using a entity0 or a entity1.'
(neural network, decision tree) 'We suggest a method that mimics the behaviour of the entity0 using a entity1 or a entity2.'
(decision tree, neural network) 'We suggest a method that mimics the behaviour of the entity0 using a entity2 or a entity1.'

Table 1: Instances of a sentence in the corpus after applying the pre-processing phase with entity blinding.

¹<http://www.nltk.org>

Table 2 shows the number of the instances extracted in the training set per each class. The *None* class represents the number of pairs of entities that are not related (negative instances). The number of positive instances is very low compared to the negative ones, 1323 over 19210 (around 7%), mainly because most classes are unidirectional and we annotated the reverse instance as *None*.

We followed a similar sampling technique described in (Wang et al., 2017) to adjust the same numbers of instances per each class. Therefore, we randomly discard 60% of the negative instances and we duplicate the instances in each class until having the same number as the more representative class, 483 corresponding to *US-AGE*. Thus, we try to solve possible issues associated with the imbalanced dataset.

<i>TOPIC</i>	18
<i>USAGE</i>	483
<i>None</i>	17887
Total	19210

Table 2: Number of instances in the dataset.

3 Method

In this section, we present a CNN model to detect and classify relationships between scientific concepts. Figure 1 shows the whole process from its input, which is a sentence with blinded entities, until the output, which is the classification of the instance into one of the relation types defined by the task.

3.1 Word table layer

Firstly, we determined n as the maximum sentence length in the training dataset. Those sentences with lengths shorter than n are padded with an auxiliary token "0". After that, we assigned a randomly initialized vector for each different word, creating thus a word embedding matrix: $\mathbf{W}_e \in \mathbb{R}^{|V| \times m_e}$ where V is the vocabulary size and m_e is the word embedding dimension. Finally, we obtained a matrix $\mathbf{x} = [x_1; x_2; \dots; x_n]$ for each instance where the words are represented by their corresponding word embedding vectors.

In addition, we used the word position embedding described in (Zeng et al., 2014), which

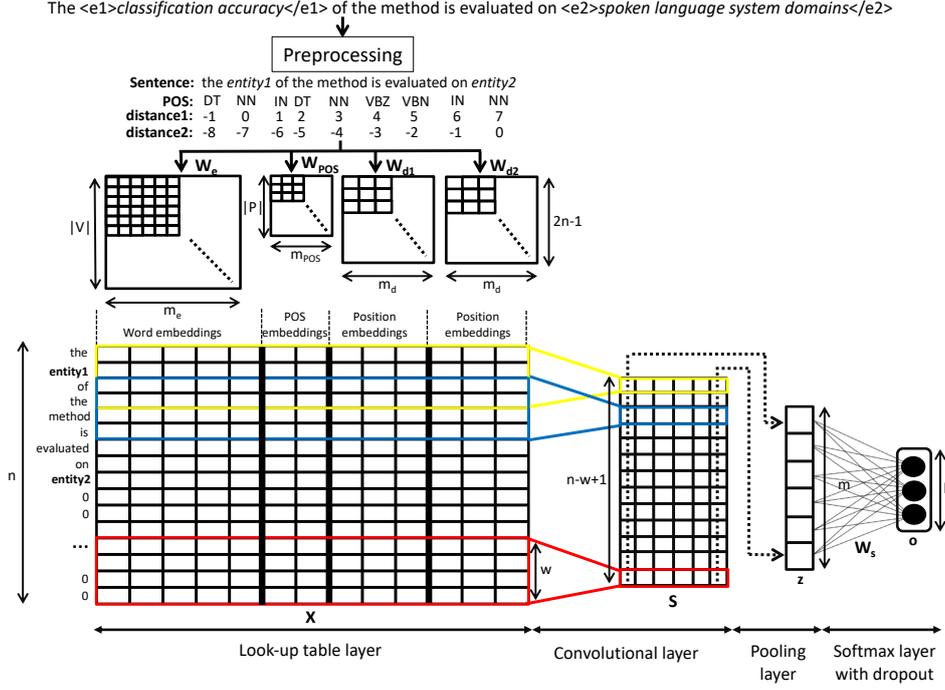

Figure 1: CNN model for the semantic relation classification in scientific papers of SemEval-2018 Task 7.

maps the distances of each word with respect to the two candidate entities into a real value vector using two position embedding matrices $\mathbf{W}_{d1} \in \mathbb{R}^{(2n-1) \times m_d}$ and $\mathbf{W}_{d2} \in \mathbb{R}^{(2n-1) \times m_d}$ where m_d is the position embedding dimension. Moreover, we extracted the Part-of-Speech (POS) feature of each word (entities are marked as common nouns) and create a POS embedding matrix as (Zhao et al., 2016) $\mathbf{W}_{POS} \in \mathbb{R}^{|P| \times m_{POS}}$ where P is the POS types vocabulary size and m_{POS} is the POS embedding dimension.

Finally, we created an input matrix $\mathbf{X} \in \mathbb{R}^{n \times (m_e + m_{POS} + 2m_d)}$ which is represented by the concatenation of the word embedding, the POS embedding and the two position embeddings for each word in the instance.

3.2 Convolutional layer

Once we obtained the input matrix, we applied the convolutional operation with a context window of size w to create higher level features. For each filter in $\mathbf{f} = [f_1; f_2; \dots; f_w]$, we created a score matrix for the whole sentence as

$$s_i = g\left(\sum_{j=1}^w f_j x_{i+j-1}^T + b\right)$$

where b is a bias term and g is a non-linear function (such as tangent or sigmoid) of m number of filters.

3.3 Pooling layer

We extracted the most relevant features of each filter using the max function, which produces a single value in each filter as $z_f = \max\{\mathbf{s}\} = \max\{s_1; s_2; \dots; s_{n-w+1}\}$. Thus, we created a vector $\mathbf{z} = [z_1, z_2, \dots, z_m]$, whose dimension is the total number of filters m representing the relation instance. In the end, we concatenated the output values of the different filters in this layer.

3.4 Softmax layer

In this layer, we performed a dropout to prevent over-fitting obtaining a reduced vector \mathbf{z}_d randomly dropping elements in \mathbf{z} . After that, we fed this vector into a fully connected softmax layer with weights $\mathbf{W}_s \in \mathbb{R}^{m \times k}$ to compute the output prediction values for the classification as

$$\mathbf{o} = \mathbf{z}_d \mathbf{W}_s + d$$

where d is a bias term. At test time, the vector \mathbf{z} of a new instance is directly classified by the softmax layer without a dropout.

3.5 Learning

We defined the CNN parameter set to be learned in the training phase as $\theta = (\mathbf{W}_e, \mathbf{W}_{POS}, \mathbf{W}_{d1}, \mathbf{W}_{d2}, \mathbf{W}_s, \mathbf{F}_m)$, where \mathbf{F}_m are all of the m filters \mathbf{f} . For this purpose, we used the conditional probability

of a relation r obtained by the softmax operation as

$$p(r|\mathbf{x}, \theta) = \frac{\exp(\mathbf{o}_r)}{\sum_{l=1}^k \exp(\mathbf{o}_l)}$$

to minimize the cross-entropy function for all instances (\mathbf{x}_i, y_i) in the training set T as follows

$$J(\theta) = \sum_{i=1}^T \log p(y_i|\mathbf{x}_i, \theta)$$

In addition, we minimized the objective function by using stochastic gradient descent over shuffled mini-batches and the Adam update rule (Kingma and Ba, 2014) to learn the parameters.

4 Results and Discussion

We define the CNN parameters for the experiments using the values described in Table 3. The number of epochs was fine-tuned in the validation set using the stopping criteria.

Parameter	Value
Maximal length in the dataset, n	152
Word embeddings dimension, M_e	300
POS embeddings dimension, M_{POS}	10
Position embeddings dimension, M_d	5
Filters for each window size, m	200
Filter sizes, w	(3, 4, 5)
Dropout rate, p	50%
Mini-batch size	50
Non-linear function, g	ReLU

Table 3: The CNN model parameters and their values used for the results.

Our CNN system obtained an F1-score of 35.4% for the relation extraction task in which only the detection of relation is taken into consideration. The official results obtained for the relation classification task are showed in Table 4. Our model reaches an F1-score in Macro-average of 18.5% with one step classifier, which means that the extraction and classification are considered at the same time. This performance was expected because we reached the similar results with a validation set created from the training set. Furthermore, we correctly predicted 147 instances with correct directionality over 367 (i.e. 40.05% in coverage).

The main problem is the high number of FP in the majority of classes, which are the *None* instances classified as a class. In some classes such as *PART WHOLE* and *USAGE* we have also a high number of FN compared to the total number of instances. We consider that the main reason is that

the representation of the two directions of each relation is very similar, only the position distances and the target entity names are inverted, and the CNN cannot distinguish between them.

Classes	TP	FP	FN	P	R	F1
<i>COMPARE</i>	8	116	11	6.45%	42.11%	11.19%
<i>MODEL-FEATURE</i>	36	185	37	16.29%	49.32%	24.49%
<i>PART WHOLE</i>	22	66	60	25%	26.83%	25.88%
<i>RESULT</i>	2	21	14	8.7%	12.5%	10.26%
<i>TOPIC</i>	0	0	3	0%	0%	0%
<i>USAGE</i>	41	96	133	29.93%	23.56%	26.37%
Micro-averaged	-	-	-	18.38%	29.7%	22.71%
Macro-averaged	-	-	-	14.39%	25.72%	18.46%

Table 4: Results over the dataset using a CNN model measured by True Positives, False Positives, False Negatives, Precision, Recall and F1-measure, respectively.

5 Conclusions and Future work

A CNN model is used for the Relation Classification task of SemEval 2018 by UC3M-NII Team. Moreover, we balanced the dataset using sampling techniques, blinded the entities in the sentence and aggregated position embedding and POS embedding to the word embedding of each word to have more representation of each instance. This architecture obtained an F1-score of 35.4% and 18.5% for the relation extraction and classification task, respectively.

As future work, we proposed to use a two steps model to overcome the extraction of the relationships between two concepts and subsequently classify them in the different semantic classes. In addition, we also plan to rule out the reverse instances of each class as *None* in order to avoid having very similar representation with different labels. We plan to tackle the directionality problem with post-processing rules after the classification. Furthermore, we will train a CNN with different pre-trained word embedding models instead of using a random initialization.

Funding

This work was supported by the Research Program of the Ministry of Economy and Competitiveness - Government of Spain, (DeepEMR project TIN2017-87548-C2-1-R) and the TEAM project (Erasmus Mundus Action 2-Strand 2 Programme) funded by the European Commission.

Abstract

SemEval 2018 Task 7 tasked participants to build a system to classify two entities within a sentence into one of the 6 possible relation types. We tested 3 classes of models: Linear classifiers, Long Short-Term Memory (LSTM) models, and Convolutional Neural Network (CNN) models. Ultimately, the CNN model class proved most performant, so we specialized to this model for our final submissions.

We improved performance beyond a vanilla CNN by including a variant of negative sampling, using custom word embeddings learned over a corpus of ACL articles, training over corpora of both tasks 1.1 and 1.2, using reversed feature, using part of context words beyond the entity pairs and using ensemble methods to improve our final predictions. We also tested attention based pooling, up-sampling, and data augmentation, but none improved performance. Our model achieved rank 6 out of 28 (macro-averaged F1-score: **72.7**) in subtask 1.1, and rank 4 out of 20 (macro F1: **80.6**) in subtask 1.2.

1 Introduction

SemEval 2018 Task 7 (Gbor et al., 2018) focuses on relation classification and extraction on a corpus of 350 scientific paper abstracts consisting of 1228 and 1248 annotated sentences for subtasks 1.1 and 1.2, respectively. There are six possible relations: *USAGE*, *RESULT*, *MODEL-FEATURE*, *PART-WHOLE*, *TOPIC*, and *COMPARE*.

Given this data, our task is to take an example sentence, as well as the left and right entities within that sentence, and an indicator as to whether the relation is reversed, and predict the relation type for that sentence. In subtasks 1.1 and 1.2, all presented sentences have a relation.

We submitted predictions based on a self-ensembled convolutional neural network (CNN) model trained with a negative sampling augmented loss using ACL-specific embeddings as input features. We achieved rank 6 out of 28 (macro-averaged F1-score: 72.7) in subtask 1.1, and rank 4 out of 20 (macro F1 80.6) in subtask 1.2.

2 Related Work

Previous SemEval challenges have explored relation identification and extraction. The 2010 SemEval Task 8 (Hendrickx et al., 2010) explored classification of natural language relations, such as *CONTENT-CONTAINER* or *ENTITY-ORIGIN*. This challenge differs from ours in its generalizability; our relations are specific to ACL papers (e.g. *MODEL-FEATURE*) whereas the 2010 relations are more general, and may necessitate more common-sense knowledge than the 2018 relations. The 2010 data has been extensively studied and has offered significant opportunity for other researchers to test their model. Rink and Harabagiu (2010) produced a strong SVM/LR model to attack this challenge. Several deep architectures have also been proposed for this task, including the work of Cai et al. (2016), which demonstrated a novel approach merging ideas from recurrent networks and convolutional networks based on shortest dependency path (SDP). Xu et al. (2015a) and Santos et al. (2015) both used convolutional architectures along with negative sampling to pursue this task. More recently, Wang et al. (2016) used two levels of attention, one for input selection and the other for output pooling, to boost the performance of their model to state of the art.

The 2017 SemEval Task 10 (Augenstein et al., 2017) also featured relation extraction within

Model	Acc. (%)
SVM	64.0 ± 5.3
LR	65.3 ± 4.3
DEEP RF	63.1 ± 4.1
LSTM	61.4 ± 5.5
CNN	66.3 ± 4.4

Table 1: Comparison of best performance of different model types in our initial experimentation.

scientific publications. Here, however, there were only 2 relation types, *HYPONYM-OF* and *SYNONYM-OF*. One successful model on this task utilized a convolutional network operating on word, tag, position, and part-of-speech features (Lee et al., 2017), and found that restricting network focus to only the words between the requisite entities offered a notable performance improvement.

3 Methods

3.1 Pre-processing

Data was tokenized using the SpaCy tokenizer¹. Part of speech (POS) tags were extracted using SpaCy, while lemmas and hypernyms were extracted via WordNet (Miller et al., 1990), inspired by Rink and Harabagiu (2010).

3.2 Initial Experiments

We tested several machine learning methods on these data, including a logistic regression classifier over `tf-idf` features extracted from words, lemmas, hypernyms, and POS. Additionally, we tested deep random forests with multi-grain sequence scanning over word embeddings sequences (Zhou and Feng, 2017) and LSTM with attention (Zhou et al., 2016) over both word/lemma/hypernym embeddings, character sequence embeddings, and position indicators. Lastly, we tested a CNN model over these data, using word/lemma embeddings, position embeddings, and a variant of negative sampling. After optimizing all model configurations and doing preliminary hyperparameter optimization via automatic grid search, early comparisons between the differing model classes yielded the results in Table 1. These results were measured in accuracy over 15-fold cross validation on the 1.1 train set.

Given these initial results, we focused principally on the CNN model.

3.3 CNN Model Details

Figure 1 presents the architecture of the CNN model. The model first takes the tokenized sentence, as well as the targeted entities, and transforms it to a sequence of continuous embedding vectors (Subsection 3.3.1). Next, the model uses a convolution layer to transform the embedded sentence to a fixed-size representation of the whole sentence (Subsection 3.3.2). Finally, it computes the score for each relation class via a linear transformation (Subsection 3.3.3). The overall system is trained end-to-end via a cross entropy loss augmented with a variant of negative sampling (Subsection 3.3.4).

3.3.1 Feature Embeddings

Given a sentence $\mathbf{x} = [x_1, \dots, x_n]$, the tokens x_i are featurized into continuous embedding vectors via concatenated word embeddings (e^{w_i}) and word position embeddings (e^{wp_i}): $e_i = [e^{w_i}, e^{wp_i}]$.

Word Embeddings Word representations are encoded by the column vector in the embedding matrix $W^{word} \in \mathbb{R}^{d^w \times |V|}$, where V is the vocabulary of the dataset. Each column $W_i^{word} \in \mathbb{R}^{d^w}$ is the word embedding vector for the i^{th} word in the vocabulary. This matrix is trainable during the optimization process and initialized by pre-trained embedding vectors described in Section 3.4.

Word Position Embeddings (WPEs) In general, the information needed to determine the sentence’s relations mostly comes from the words close to the two entities. In addition, some information needs to be input into the model to indicate which words are entities. We use the word’s relative position to either entity as a feature to fulfill the above-mentioned two functions. For instance, in the sentence “the **probabilistic model** used in the **alignment**” shown in Figure 1, the relative distance of all the words to the left entity “probabilistic model” is $-1, 0, 0, 1, 2, 3, 4$ and that to the right entity “alignment” is $-6, -5, -4, -3, -2, -1, 0$. Each relative distance is mapped into a vector of dimension d^{wp} , which is randomly initialized then updated during training. Each word w has two relative distances wp_1 and wp_2 with respect to two entities $entity_1$ and $entity_2$, and each distance is mapped to corresponding embedding vector and the position embedding e^{wp} of word w is the concatenation of these two vectors: $e^{wp} = [e^{wp_1}, e^{wp_2}]$.

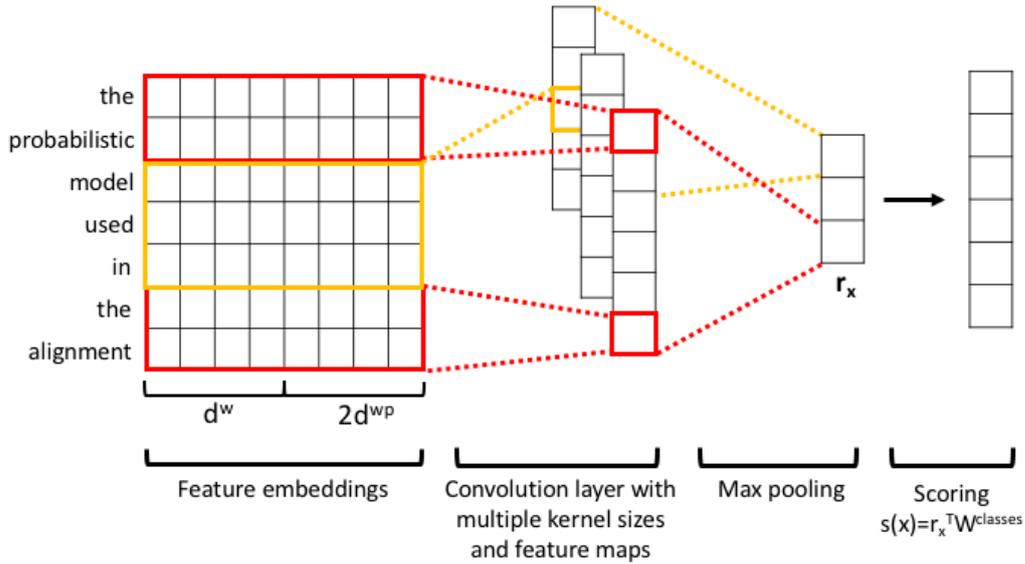

Figure 1: Illustration of CNN model architecture.

3.3.2 Sentence Representation

After featurization, a sentence \mathbf{x} of length N is represented as $\mathbf{e} = [e_1, e_2, \dots, e_N]$. We denote $e_{i:i+j}$ as the concatenation of featurized tokens: $e_{i:i+j} = [e_i, e_{i+1}, \dots, e_{i+j}]$. A convolution operation involves a filter weight matrix $W \in \mathbb{R}^{(d^w + 2d^{wp}) \times k}$, which is applied to a window of k words to produce a new feature c_i , as represented by:

$$c_i = \tanh(W \cdot e_{i:i+k-1} + b),$$

where $b \in \mathbb{R}$ is a bias term. This filter is applied to each possible window of words in the sentence $e_{1:h}, e_{2:h+1}, \dots, e_{N-h+1:N}$ to produce a feature map vector $\mathbf{c} = [c_1, c_2, \dots, c_{N-k+1}]$. We then apply a max pooling operation to this feature map to obtain the maximum value $\hat{c} = \max\{\mathbf{c}\}$ as the feature corresponding to this particular filter. This is how we extract one feature by one filter. And the model can use multiple filters with varying window sizes and filter parameters to produce multiple features. We concatenate all the obtained features to form the fixed size sentence representation $r_{\mathbf{x}}$.

3.3.3 Inference Scoring

Given the vector representation $r_{\mathbf{x}}$ of the sentence \mathbf{x} , class scores are computed via a linear transfor-

mation mediated by a trainable matrix $W^{classes}$:

$$s(\mathbf{x}) = W^{classes} r_{\mathbf{x}}.$$

At prediction time, the relation class is inferred by taking the index of maximum score.

3.3.4 Loss with Negative Sampling

After obtaining the score vector $s(\mathbf{x})$ for the sentence \mathbf{x} , we use a loss function motivated by ideas in negative sampling as follows. Let y be the correct label for sentence \mathbf{x} , and $I = \mathcal{Y} \setminus \{y\}$ be the set of all incorrect labels for \mathbf{x} . Then, we compute the loss:

$$L = \log \left(1 + e^{\gamma(m^+ - s(\mathbf{x})_y)} \right) + \log \left(1 + e^{\gamma(m^- + \max_{y' \in I} (s(\mathbf{x})_{y'}))} \right),$$

where m^+ and m^- are margins, γ is the penalty scale factor. Minimizing this loss function will both increase the score of the correct label and decrease that of the wrong label. We used Adam optimizer (Kingma and Ba, 2014) to minimize the loss function.

3.4 ACL Corpus Embeddings

We pretrained 50-dimensional word embeddings on the ACL anthology corpus (Radev et al., 2013) using word2vec (Mikolov et al., 2013a,b) (we

have also tried 100-dimensional word embeddings pre-trained in the same way but it performed worse in this small dataset). The corpus was derived by downloading all ACL anthology articles in PDF format, then converting them into text via some imperfect optical character recognition (OCR). The corpus contains 25,938 papers totaling 136,772,370 tokens, with 49,600 unique tokens. We used the following parameters for word2vec: skip-gram model, maximum skip length between words of 10, negative sampling with 10 negative examples, discard words that appear less than 5 times, and 5 training iterations².

4 Results

4.1 Model Tuning

We first optimized the CNN model hyperparameters via random search with 90 samples; final hyperparameters are shown in Table 2.

Beyond traditional hyperparameter optimization, a number of modifications with this model incurred performance gains during our final stages of experimentation, as determined by cross validation over either the 1.1 or 1.2 data. We detail the types of these changes below, then show the performance results obtained on the *test set* (not the cross validation results which motivated their use in our system) in Table 3.

Merged Training Sets Merging the 1.1 & 1.2 training datasets as a new training set had a large impact on the macro F1 score of our models. Both training datasets are relatively small, containing only approximately 1200 examples. Merging the 1.1 and 1.2 training

sets helps equalize class imbalance and expand the dataset size, at the cost of introducing a biased distribution of relation types for either class alone.

Reversal Indicator Features Each entity pair was given the information whether the relation of it is reversed or not. We added this binary feature, which proved performant.

Custom ACL Embeddings Specializing our word vector embeddings pre-training source to an ACL-specific corpus (described in section 3.4) offered notable gains.

Context words We explored using a context window of varying sizes around the entity-enclosed text within the sentence. Our pre-submission cross validation experiments suggested a context window of ± 50 words was optimal, but post-submission evaluation on the provided test set yielded better results with a ± 20 word window. Empirically, the number of context words to be included needs to be optimized on the specific dataset.

Ensembling We trained 50 copies of our network, using different random initializations and dev sets (for early stopping), then averaged their scores for prediction. This reduced variance of our predictions and improved performance.

Besides the above successful strategies, we also tested some settings that, in reality had a negative effect. We experimented with attention based pooling as suggested by (Wang et al., 2016), but it hurt performance in our cross validation experiments so we discarded that mechanism. Additionally, we also tried replacing the original words with their corresponding lemmas—this increased performance in our cross validation results, however, (post-submission evaluation revealed) harmed our results on the SemEval test set, where it yielded average macro-F1 scores of 71.48% and 77.01% for subtasks 1.1 and 1.2, respectively, after 10 runs. The potential reason for this degradation could be that the word embeddings are all trained on original words instead of lemmas so the embeddings of lemmas cannot be as well initialized as original words. Additionally, we tried data augmentation (via synonym substitution), and up-sampling (via duplication to equalize

²-cbow 0 -window 10 -negative 10 -hs 0 -sample 1e-3 -threads 15 -binary 0 -iter 5 -min-count 5 -size 50

1.2 Train Set	N/A	66.5 ± 3.2
Merged Train Sets	68.5 ± 3.8	74.4 ± 3.2
Reversed Feature	69.0 ± 1.2	78.0 ± 3.6
ACL Embeddings	71.7 ± 0.7	80.5 ± 1.5
Context Words	71.3 ± 1.0	82.5 ± 1.6
Ensemble	72.7	85.0

Table 3: CNN Improvements over a series of modifications. Each row includes the modifications of the previous rows. All numbers are macro-F1 scores on test set after 10 runs in the form of {average}±{standard deviation} (the “Ensemble” row lacks deviation numbers as it, being a variance reduction technique, does not have the same sources of variation as the other models). We report ±20 context words here, which was found to be optimal in post-submission experimentation, but our submitted models used ±50 context words, which was preferred under initial cross validation.

data size of each label), but all proved ineffective at the cross validation level and were not included in our final submission.

4.2 Submission Results

We entered 6 submissions in total, 3 for subtask 1.1, and 3 for subtask 1.2. Their final performances are listed in Table 4. All the submissions were based on the ensemble model listed in Table 3 except that the lemmas were used instead of original words and we used ±50 context words. The major difference between submissions was the strategy for early stopping. Detailed settings for each submission of subtask 1.1 are:

Submission 1 We randomly extracted 10% training data as validation set and made test set predictions when the highest validation accuracy was reached.

Submission 2 We randomly extracted 10% training data as validation set with stratification (stratification is based on the proportion of labels in the train set) and made test set predictions when the highest validation accuracy was reached.

Submission 3 No validation set was used. Test set predictions were made at fixed number of training epochs, chosen by cross validation using training data.

Detailed settings for each submission of subtask 1.2 are:

Subtask	Submission	Macro-F1 (%)
1.1	1	71.5
	2	72.3
	3	72.7
1.2	1	80.6
	2	76.4
	3	79.8

Table 4: Final submission performance.

Submission 1 We randomly extracted 10% training data as validation set and made test set predictions when the highest validation accuracy was reached.

Submission 2 No validation set was used. Test set predictions were made at fixed number of training epochs, chosen by cross validation using training data.

Submission 3 Settings are the same as submission 2 except that we added the embeddings of the two entities (max pooled) to the sentence representation vector extracted by CNN model as additional features prior to scoring and inference.

In summary, early stopping made based on the validation set accuracy does not guarantee better test set performance than that using a fixed number of training epochs. Stratifying the label ratio of validation set according to the training set does help improve the test set performance. The benefit of adding embeddings of entities as extra features is not clear.

5 Future Work

Our custom ACL embeddings offered significant performance boosts over embeddings pre-trained on the corpus in the general domain such as wikipedia, but the corpus we obtained for pre-training is noisy due to the imperfect OCR. Cleaning up the input ACL dataset may result in better embeddings, offering even larger performance gains. Additionally, we could try restricting the ACL dataset to only those papers published more recently, in hopes to further specify the embedding space to a relevant subset—of course, this would also have reduced the embedding dataset size, so it may have cost more than it gained and experimentation would be warranted.

We also never explored any dependency tree-based featurizations of our data, though those were

found to be helpful in prior works (Cai et al., 2016; Xu et al., 2015b).

The class imbalance of the training dataset is one of the greatest obstacles, where performance of common classes is a lot better than the rare classes. To tackle this problem, adversarial generative network (GAN) models (Goodfellow et al., 2014) could be used for data augmentation so that the data size of all labels can be equalized.

6 Conclusion

We tested linear classifiers, sequential random forests, LSTM models, and CNN models on these data. Within each model, we explored many variations, including two models of attention, negative sampling, entity embedding or sentence-only embeddings, among others. The most performant combination found was a CNN model trained over ACL-specific embeddings and a negative sampling augmented loss, without attention. We submitted self-ensembled predictions from this model both with and without early stop—ultimately early stop proved efficacious only on task 2. This model achieved rank 6 out of 28 (macro F1 72.7) in subtask 1.1, and rank 4 out of 20 (macro F1 80.6) in subtask 1.2.

SIRIUS-LTG-UiO at SemEval-2018 Task 7: Convolutional Neural Networks with Shortest Dependency Paths for Semantic Relation Extraction and Classification in Scientific Papers

Farhad Nooralahzadeh, Lilja Øvrelid, Jan Tore Lønning

Department of Informatics

University of Oslo, Norway

{farhadno, liljao, jtl}@ifi.uio.no

Abstract

This article presents the SIRIUS-LTG-UiO system for the SemEval 2018 Task 7 on Semantic Relation Extraction and Classification in Scientific Papers. First we extract the shortest dependency path (sdp) between two entities, then we introduce a convolutional neural network (CNN) which takes the shortest dependency path embeddings as input and performs relation classification with differing objectives for each subtask of the shared task. This approach achieved overall F1 scores of 76.7 and 83.2 for relation classification on clean and noisy data, respectively. Furthermore, for combined relation extraction and classification on clean data, it obtained F1 scores of 37.4 and 33.6 for each phase. Our system ranks 3rd in all three sub-tasks of the shared task.

1 Introduction

Relation extraction and classification can be defined as follows: given a sentence where entities are manually annotated, we aim to identify the pairs of entities that are instances of the semantic relations of interest and classify them based on a pre-defined set of relation types. A range of different approaches have been applied to solve this task in previous work. Conventional classification approaches have made use of contextual, lexical and syntactic features combined with richer linguistic and background knowledge such as WordNet and FrameNet (Hendrickx et al., 2010; Rink and Harabagiu, 2010).

Recently, the re-emergence of deep neural networks provides a way to develop highly automatic features and representations to handle complex interpretation tasks. These approaches have yielded impressive results for many different NLP tasks. The use of deep neural networks for relation classification has been investigated in several recent studies (Socher et al., 2012; Lin et al.,

2016; Zhou et al., 2016). Convolutional neural networks (CNNs) have been effectively applied to extract lexical and sentence level features for relation classification (Zhang and Wang, 2015; Lee et al., 2017; Nguyen and Grishman, 2015). However, these works consider whole sentences or the context between two target entities as input for the CNN. Such representations suffer from irrelevant sub-sequences or clauses when target entities occur far from each other or there are other target entities in the same sentence. To avoid negative effects from irrelevant chunks or clauses and capture the relation between two entities, Xu et al. (2015a); Liu et al. (2015) and Xu et al. (2015b) employ a CNN to learn more robust and effective relation representations from the shortest dependency path (sdp) between two entities. The sdp between two entities in the dependency graph captures a condensed representation of the information required to assert a relationship between two entities (Bunescu and Mooney, 2005). In this work, we continue this line of work and present a system based on a CNN architecture over shortest dependency paths combined with domain-specific word embeddings to extract and classify semantic relations in scientific papers.

2 System description

In this section, we describe the various components of our system.

Text pre-processing. For each relation instance in the training data set, we assign a sentence that contains the participant entities. Sentence and token boundaries are detected using the Stanford CoreNLP tool (Manning et al., 2014). Since most of the entities are multi-word units, in order to obtain a precise dependency path between entities, we replace the entities with their codes. The example sentence in (1) below is thus transformed to

- (2).
- (1) Syntax-based statistical machine translation (MT) aims at applying statistical models to structured data .
 - (2) P05-1067.1 aims at applying P05-1067.2 to P05-1067.3 .

Given an encoded sentence, we find the sdp connecting two target entities for each relation instance using a syntactic parser, see below.

For syntactic parsing we employ the parser described in Bohnet and Nivre (2012), a transition-based parser which performs joint PoS-tagging and parsing. We train the parser on the standard training sections 02-21 of the Wall Street Journal (WSJ) portion of the Penn Treebank (Marcus et al., 1993). The constituency-based treebank is converted to dependencies using two different conversion tools: (i) the pennconverter software¹ (Johansson and Nugues, 2007), which produces the so-called CoNLL-style dependencies employed in the CoNLL08 shared task on dependency parsing (Surdeanu et al., 2008)², and (ii) the Stanford parser using the option to produce basic Stanford dependencies (de Marneffe et al., 2014)³. The parser achieves a labeled accuracy score of 91.23 when trained on the CoNLL08 representation and 91.31 for the Stanford basic model, when evaluated against the standard evaluation set (section 23) of the WSJ. We also experimented with the pre-trained parsing model for English included in the Stanford CoreNLP toolkit (Manning et al., 2014), which outputs Universal Dependencies. However, it was clearly outperformed by our version of the Bohnet and Nivre (2012) parser in the initial development experiments.

Based on the dependency graphs output by the parser, we extract the shortest dependency path connecting two entities. The path records the direction of arc traversal using left and right arrows (i.e. \leftarrow and \rightarrow) as well as the dependency relation of the traversed arcs and the predicates involved, following Xu et al. (2015a). The entity codes in the final sdp are replaced with the corresponding word tokens at the end of the pre-processing step.

¹<http://nlp.cs.lth.se/software/treebank-converter/>

²The pennconverter tool is run using the rightBranching=false flag.

³The Stanford parser is run using the -basic flag to produce the basic version of Stanford dependencies.

For the sentence in (1) and the two entities *statistical models* and *structured data* we thus extract the path in (3) below.

(3) statistical models \leftarrow OBJ \leftarrow
 applying \rightarrow DIR \rightarrow to \rightarrow PMOD
 \rightarrow structured data

Label encoding. The classification sub-tasks contain five asymmetric relations (USAGE, RESULT, MODEL-FEATURE, PART-WHOLE, TOPIC) and one symmetric relation (COMPARE). The relation instance along with its directionality are provided in both the training and the test data sets. For these sub-tasks we therefore use the same labels in our system. For sub-task 2 which combines the extraction and classification tasks, however, we construct an extra set of relation types. First, we collect every pair of entities within a single sentence that are not included in the annotated relation set. To minimize the noise, we retain only the entity pairs which are not further away than 6 tokens. From these entity pairs we generate negative instances with the NONE class and extract the corresponding sdp. Second, to preserve the directionality in the asymmetric relations, we add the \neg symbol to the instances with reverse directionality (e.g., USAGE(e1,e2,REVERSE) becomes \neg USAGE(e1,e2)). The final label set for sub-task 2 thus consists of 12 relations.

Word embeddings. In our system, two different sets of pre-trained word embeddings are used for initialization. One is the 300-d pre-trained embeddings provided by the NLPL repository⁴ (Fares et al., 2017), trained on English Wikipedia data with word2vec (Mikolov et al., 2013), here dubbed wiki-w2v. In addition, we train a second set of domain-specific embeddings on the ACL Anthology corpus. We obtain the XML versions of 22,878 articles from ACL Anthology⁵. After extracting the raw texts, for training of the 300-d word embeddings (acl-w2v), we exploit the available word2vec (Mikolov et al., 2013) implementation gensim (Řehůřek and Sojka, 2010) for training.

Classification Model Our system is based on a Convolutional Neural Network (CNN) architecture similar to the one used for sentence classification in Kim (2014). Figure 1 provides an overview

⁴<http://vectors.nlpl.eu/repository/>

⁵<https://acl-arc.comp.nus.edu.sg/>

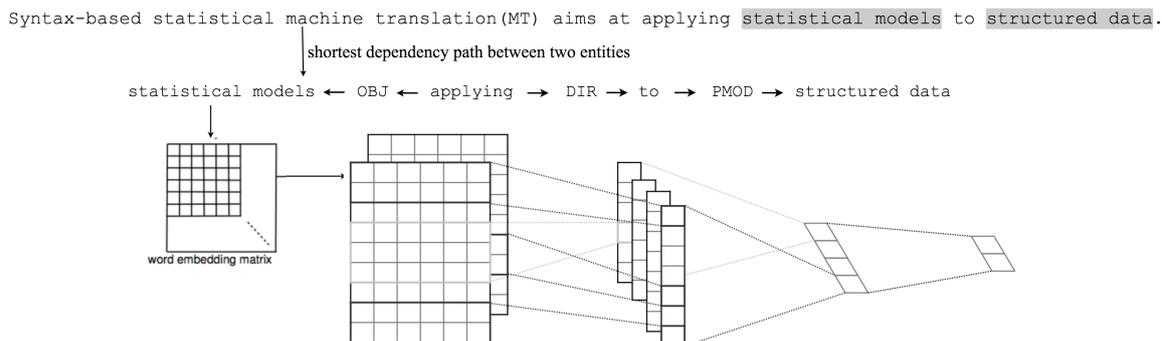

Figure 1: Model architecture with two channels for an example shortest dependency path (CNN model from Kim (2014)).

of the proposed model. It consists of 4 main layers as follows:

Look-up Table and Embedding layer: In the first step, the model takes a dependency path, as in (3) as input and transforms it into a matrix representation by looking up the pre-trained word embeddings.

Convolutional Layer: The next layer performs convolutions with the ReLU activation to the embedding layer using multiple filter sizes ($filter_sizes \in [3, 4, 5]$) and extracts feature maps over the tokens.

Max pooling Layer: By applying the *max* operator, the most effective local features are generated from each feature map.

Fully connected Layer: Finally, the higher level syntactic features are fed to a fully connected *softmax* layer which outputs the probability distribution over each relation.

3 Experiments

Dataset For each sub-task, the training data includes abstracts of papers from the ACL Anthology corpus with pre-annotated entities. For sub-task 1.1 and 2, the training datasets are the same. It contains entities that are manually annotated and they represent domain concepts specific to Natural Language Processing (NLP). In sub-task 1.2 the entities are automatically assigned and therefore contain a fair amount of noise (verbs, irrelevant words). The terms include high-level terms (e.g. "algorithm", "paper", "method") and are not always full NPs (Gábor et al., 2018). Since the related entity pairs and the relation types are provided for the full dataset, we extend the dataset for sub-task 1.1 and 2 by extracting the related entities and their corresponding sdp from the sub-task 1.2

Relation	Subtask		Reverse		Total
	1.1 & 2	1.2	False	True	
USAGE	483	464	615	332	947
MODEL-FEATURE	326	172	346	152	498
RESULT	72	121	135	58	193
TOPIC	18	240	235	23	258
PART-WHOLE	233	192	273	152	425
COMPARE	95	41	136	-	136
NONE	2315	-	2315	-	2315

Table 1: Number of instances for each relation in the final dataset.

dataset. In order to train a model for sub-task 2, we also augment the dataset by extracting NONE relation instances (see Section 2), extracted from the corresponding dataset. Table 1 shows the number of instances for each relation class. As we can see, the class distribution is clearly unbalanced.

Model settings We keep the value of hyperparameters equal to the ones that are reported in the original work (Kim, 2014), i.e., 128 filters for each window size, a dropout rate of $\rho = 0.5$ and l_2 regularization of 3. To deal with the effects of class imbalance, we weight the cost by the ratio of class instances, thus each observation receives a weight, depending on the class it belongs to. The effect of the minority class observations is thereby increased simply by a higher weight of these instances and is decreased for majority class observations. Furthermore, to guarantee that each fold in n -fold cross validation will have the proportion of same classes during training, evaluation and test, we apply the stratification technique proposed by Sechidis et al. (2011). We use the validation set to detect when overfitting starts during the training of our model; using *early stopping*, training is

Sub-task	Model	Representation	F1	
			Ext.	Class.
1.1	cnn.multi.acl-w2v.rand	Stanford Basic	-	74.16
1.2			-	77.70
2	cnn.acl-w2v	CoNLL08	74.26	60.31

Table 2: F1 (macro-average) scores for selected configurations during training.

then stopped before convergence to avoid overfitting (Prechelt, 1998). The official evaluation metric is the macro-averaged F1-score, therefore we implement early-stopping (*patience*= 20) based on macro-F1 score in the development set.

Model variants We run experiments with several variants of the model as follows: `cnn.rand`: A baseline model, where all elements in the embedding layer are randomly initialized and updated in the training process. `cnn.wiki-w2v`: The embedding layer is initialized with the pre-trained Wikipeda word embeddings and fine-tuned for the target task. `cnn.acl-w2v`: The embedding layer is initialized with the pre-trained ACL Anthology word embeddings and fine-tuned for the target task. `cnn.multi.rand`: There are two embedding layers as a 'channel' in the CNN architecture. Both channels are initialized randomly and only one of them is updated during training while the other remains static. `cnn.multi.wiki-w2v`: Same as before, but the channels are initialized with Wikipedia embedding vectors. `cnn.multi.acl-w2v`: The two channels are initialized with ACL embedding vectors. `cnn.multi.wiki-w2v.rand`: First channel is initialized with Wikipedia embeddings in static mode and the second initialized randomly with a non-static mode. `cnn.multi.acl-w2v.rand`: Same as previous setting, but the first channel makes use of ACL embeddings.

Results During development, we investigate the performance of different configurations; different dependency representations (CoNLL08 and Stanford basic) and model variants (see above); by running 5-fold cross validation (i.e. 3 folds for training, 1 fold for evaluation and 1 fold for test). The experiments show that, the multi-channel mode performs better only in the classification sub-tasks compared to the single channel setting. The results suggest that having a significant amount of

instances per relation assists the model to classify better. The use of the pre-trained embeddings helps the model in class assignment. Particularly, the domain-specific embeddings (i.e. `acl-w2v`) provide higher performance gains when used in the model. Table 2 presents the F1-score of the best performing model for each sub-task via 5-fold cross validation on the training data. In the evaluation period, we re-run 5-fold cross validation using selected model for each sub-task. However, in this setting we use 4 folds as training and 1 fold as development set, and we apply the output model to the evaluation dataset. We select the 1st and 2nd best performing models on the development datasets as well as the majority vote (mv) of 5 models for the final submission. The final results are shown in Table 3.

Sub-task	1st		2nd		mv	
	Ext.	Class.	Ext.	Class.	Ext.	Class.
1.1	-	72.1	-	74.7	-	76.7
1.2	-	83.2	-	82.9	-	80.1
2	37.4	33.6	36.5	28.8	35.6	28.3

Table 3: Official evaluation results of the submitted runs on the test set.

4 Conclusion

We present a CNN model over shortest dependency paths between entity pairs for relation extraction and classification. We examine various architectures for the proposed model. The experiments demonstrate the effectiveness of domain-specific word embeddings for all sub-tasks as well as sensitivity to the specific dependency representation employed in the input layer. Our future work includes: 1) to perform error analysis for the different sub-tasks, and 2) to investigate the effects of different dependency representations in relation extraction and classification.

Abstract

This paper presents our participation for sub-task1 (1.1 and 1.2) in SemEval 2018 task 7: Semantic Relation Extraction and Classification in Scientific Papers (Gábor et al., 2018). We experimented on this task with two methods: CNN method and traditional pipeline method. We use the context between two entities (included) as input information for both methods, which extremely reduce the noise effect. For the CNN method, we construct a simple convolution neural network to automatically learn features from raw texts without any manual processing. Moreover, we use the softmax function to classify the entity pair into a specific relation category. For the traditional pipeline method, we use the Hackabout method as a representation which is described in section3.5. The CNN method's result is much better than traditional pipeline method (49.1% vs. 42.3% and 71.1% vs. 54.6%).

1 Introduction

Scientific paper, as a major source of new technology, is a common way for tracing the dynamics of a research domain. With lots of papers published every year, scholars can't read all of them to extract useful aspects for our research domain. Information extraction (IE) is a main NLP aspects for analyzing scientific papers, which includes named entity recognition (NER) and relation extraction (RE). Scientific papers' information extraction is identify concepts or semantic relation between these concepts. This paper focuses on the relation classification between relative concepts in scientific paper.

Relation classification is one of the most important topics for analyzing scientific papers. Most of the traditional relation classification methods

are influenced by the handcrafted features or extra NLP tools to derive lexical features (Surdeanu et al., 2012; Kozareva, 2012). However, these methods are time consuming and there is a problem of error propagation. Additionally, the traditional semantic textual similarity measuring approaches are using a large number of pairwise similarity features to represent the text. It is difficult for these features to represent the syntactic information.

To address these problems, DNN methods have been proposed and made remarkable achievement (Qin et al., 2016a; Guo et al., 2016). This paper is based on the work of (Qin et al., 2016b) which uses a CNN architecture to control feature learning automatically. As a result, Qin et al. (2016b) minimize the application of external toolkits and resources, which is used for part of speech (POS) or other basic pretreatment. Additionally, Zeng et al. (2014) proposes position feature to locate the entity pair, so as to highlight its promotion for the semantic relation. Owing to this position feature is mapped to several (e.g. 5) dimension followed each word's vector (e.g. 100 dimension), which represents the relative distances of current word to first and second entity. This position feature will disappear because of the excessive training times or error propagation during the training procedure. Thus we use the Qin et al. (2016b)'s entity tag features to strengthen the entity pair information, which use the tag words ($\langle e1s \rangle$, $\langle e1e \rangle$, $\langle e2s \rangle$, $\langle e2e \rangle$) to represent start and end position features of entities. What's more, these tag features are represented as independent vector so as to avoid position feature's disappeared defect in Zeng et al. (2014).

As far as we know, most of the pervious DNN methods used entire sentence's words embedding as the input information for DNN to extracting features for relation classification such as (Xu et al.,

*Corresponding author

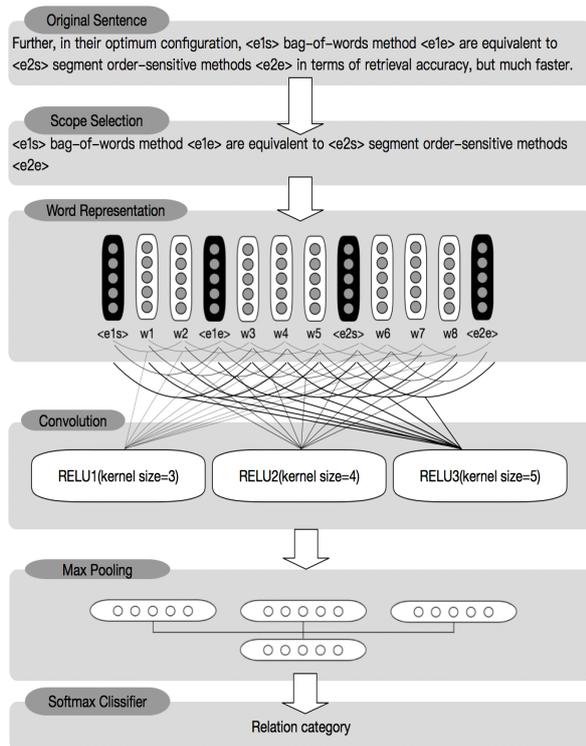

Figure 1: The architecture of CNN

2015; Liu et al., 2015). However, our goal is to achieve relation classification instead of sentence classification. Even though we use the position feature or entity tag feature to highlight the entity effect, it still suffers from that the long sentences have lots of noise words which is useless for relation classification. In pervious working, Qin et al. (2016b) just use the context between two entities, which got a remarkable performance promotion. Thus, we use Qin et al. (2016b)’s context scope as our CNN’s input information.

The contributions of this paper can be summarized as follows: Firstly, we construct a simple convolution neural network architecture for relation classification without sophisticated NLP preprocessing. Secondly, we use a more effective context input for convolution neural network, which extremely reduce the useless context’s noise effect. Then, we use entity tag feature to replace the entity position feature. Finally, we conduct experiments on subtasks 1.1 and 1.2 datasets, and the experiment results reveal that the proposed approaches is helpful to improve the performance.

2 Methodology

Our relation classification architecture is depicted as Figure 1. First, we select the scope of context

words and convert them to word embeddings. In the word representation step, the entity tag feature ($\langle e1s \rangle$, $\langle e1e \rangle$, $\langle e2s \rangle$, $\langle e2e \rangle$) will also be encoded into embeddings. Then, all the embeddings will be transmitted to three convolution network whose kernel size is 3, 4 and 5. Finally, these three convolution outputs are pooled into the same dimensional vector which will be concatenated as a input of a softmax classifier.

2.1 Context Scope for Convolution Neural Network

Most of the existing DNN relation classification methods use entire sentence’s words embedding as context information. As the following sentence, the entity *bag-of-words method* and *segment order-sensitive methods* have a **Compare** relation. However, the sub sentence *Further, in their optimum configuration and in terms of retrieval accuracy, but much faster* have little relevance to the target relation category. However, the sub sentence $\langle e1s \rangle$ *bag-of-words method* $\langle e1e \rangle$ *are equivalent to* $\langle e2s \rangle$ *segment order-sensitive methods* $\langle e2e \rangle$ have more relevant information to the target relation. As a result, we extract the context between two entities for relation classification. As for the no-words between entities’ condition, only two entities’ names have been extracted.

Further, in their optimum configuration, <e1s> bag-of-words method <e1e> are equivalent to <e2s> segment order-sensitive methods <e2e> in terms of retrieval accuracy, but much faster.

2.2 Convolution Neural Network Architecture

As the Convolution part in Figure 1, the input embedding is delivered to three convolution neural networks whose kernel size is 3, 4 and 5 respectively. It means that all the 3-grams, 4-grams and 5-grams features will be considered. Since each input sentence has a different length, the convolution output will be pooled into the same dimensional vector space. Finally, we use the multi-class classifier softmax to classify the relation into a specific category.

3 Experiment

3.1 Dataset

We use the SemEval-2018 Task 7.1.1 & 7.1.2 datasets Gábor et al. (2018) in experiment, which is in computational linguistic domain. This task

Embedding dim	Batch size	Dropout	Learning rate	Filter num	Epoch num	Activation
300	30	0.5	1e-4	100	30	Softmax

Table 1: CNN Parameters

Description	Macro-F1	
	sub1.1	sub1.2
CNN input: all words in the sentence (scope1)	47.2	67.8
+ Zeng et al. (2014)’s position feature	47.5	67.9
+Qin et al. (2016b)’s position feature	48.1	69.1
CNN input: entity pair and words between them (scope2)	48.2	68.9
+ Zeng et al. (2014)’s position feature	48.6	69.6
+Qin et al. (2016b)’s position feature	49.1	71.1
rules filtering before CNN	48.1	69.6
traditional pipeline method	42.3	54.6

Table 2: Experiment Results

addresses 6 semantic relation categories (5 relationships with bi-directions and an undirected *Compare* class) in scientific papers. We use datasets of subtasks 1.1 and 1.2 that contain titles and abstracts of papers in computational linguistic domain where entity mentions are either manually annotated (Subtask 1.1) or automatically annotated (Subtask 1.2). The relations are manually annotated and belong to 6 semantic relation categories (5 relationships with bi-directions and an undirected *Compare* class). There are 1228/1248 training examples and 355/255 testing examples in dataset 1.1/1.2. These relation instances are classified into one of the following relations: USAGE, RESULT, MODEL, PART-WHOLE, TOPIC, COMPARISON. The official evaluation metric is macro-F1 score.

3.2 Parameter Settings

The experiment settings are listed in Table 2.2, we use the Wikipedia general English 300 dimensional embeddings which have 408 million words¹. After testing, we find the parameters in the Table 2.2 achieve the most effective performance. As there are lots of parameters in CNN, we list some primary data in Table 2.2. For more detailed, we will share the whole project in our Github².

²https://github.com/zhongboyin/SemEval2018_task7

Rule	Category
”than” between entity pair	Compare
”used” between entity pair	Usage
”propose” between entity pair	Topic
”contain” between entity pair	Part-Whole
”precision” in entity name	Result
”model” in entity name	Model-Feature

Table 3: Filtering Rules.

3.3 Effect of Position Feature

As described in previous sections, position feature is helpful to promote the classification’s performance. Moreover, results in table 2.2 (first 3 lines or 4th to 6th lines) proved that Qin et al. (2016b)’s position features have a better performance than Zeng et al. (2014)’s features.

3.4 Effect of New Context Scope

By comparing 1st and 4th lines’ result, we could conclude that the entity names and words between them contain more accurate and cleaner semantic relation information.

By analyzing the predicted relation of the two experiments, we find that many wrong predicted long sentence instances in entire scope (scope1) experiment have been corrected in words between entity pair scope (scope2) as Table 4.

3.5 Result of Rule-based Experiment

In our early research, we explored lots of heuristic rules (as in Table 3.5) for each category by ob-

Sentence	Scope	Prediction	True/False
We present an implementation of the model based on finite-state models, demonstrate the $\langle e1s \rangle$ model's $\langle e1e \rangle$ ability to significantly reduce $\langle e2s \rangle$ character and word error rate $\langle e2e \rangle$, and provide evaluation results involving extraction of translation.	scope1	Compare	False
	scope2	Result	True

Table 4: Input Scope Experiment Result Analyzing.

servicing the provided training set manually. However, most of sentences' category couldn't be determined by these rules. Thus, we divided this task into two-steps method. For the first step, we use the heuristic rules to classify some sentences into a specific category. Then, for the second step, we use our CNN method to classify the remaining sentence into a specific category. Before the testing set published, the heuristic rules achieved remarkable improvement in development set. On the contrary, the heuristic rules' filtering step drops the performance in the testing set as the 7th line result in Table 2. After analyzing the result, we noticed that the rules are overfitting, since all of them are explored by training set and promoted by development set. As a result, it causes the decrease of the final evolution performance in the testing set.

3.6 Results of Comparison Experiment

To further prove the better performance of our CNN's relation classification method, we also evaluated the same dataset using a more traditional NLP method which is based on the Multinomial Naive Bayes Classifier³. First the data from the training text file is extracted. The labels are extracted and encoded using a LabelEncoder. All the words from e1 to e2 in a sentence are considered for training the Multinomial Naive Bayes classifier. These words are also lemmatized and stemmed for better prediction. However, traditional pipeline method not only excises the error propagation problem, but also can't detect some complicated semantic information such as hyponymy or synonymy. As a result, CNN method has a better performance than traditional method. The 8th line's result in Table 2 shows that our CNN method is better than the general NLP processing method.

³<https://github.com/shouryay98/Hackabout-2017-Round-1>

4 Conclusion and Future Work

In this paper, we propose a new convolution neural network architecture for relation classification in scientific paper. We showed that the words between entity pairs are the most important for relation classification. Finally, our proposed method gets the macro-f1 value of 49.1 for subtask 1.1 and 71.1 for subtask 1.2.

For the future work, we will explore more features which are helpful for relation classification such as entity type and preposition features. Moreover, we will explore a more flexible sub-sentence scope as the context information for relation classification.

Abstract

Automatic extraction of semantic relations from text can support finding relevant information from scientific publications. We describe our participation in Task 7 of SemEval-2018 for which we experimented with two relations extraction tools - jSRE and TEES - for the extraction and classification of six relation types. The results we obtained with TEES were significantly superior than those with jSRE (33.4% vs. 30.09% and 20.3% vs. 16%). Additionally, we utilized the model trained with TEES for extracting semantic relations from biomedical abstracts, for which we present a preliminary evaluation.

1 Introduction

Finding relevant publications for a certain topic is an important task daily carried out by most researchers in various domains, such as computer science or biomedicine. However, most information retrieval methods usually consider only words and terms (named entities) and do not usually profit from semantic relationships between these entities (Lu, 2011). Many approaches frequently consider words and entities as bags of words but do not take advantage from intrinsic properties of scientific texts, such as subsections (e.g., introduction, methods, results), common concepts (e.g., task, material) and relations between these concepts (e.g., model-feature, part-whole). However, extracting semantic relations from scientific text can potentially support finding relevant information for a certain topic by focusing on particular terms which participate in those relations. In addition, the relation type and the corresponding arguments provide further information regarding the role that a certain entity plays in the text.

We describe the experiments that we carried out during our participation in Subtask

2 of SemEval-2018 Task 7¹ (Gábor et al., 2018). The task consisted on the extraction of six semantic relations from scientific abstracts, namely: “USAGE”, “RESULT”, “MODEL”, “PART-WHOLE”, “TOPIC” and “COMPARISON”. While the entities were given (and all belong to the general type “ENTITY”), participants of subtask 2 were required to identify the relations and classify these into one of the six types. All relations were asymmetrical (regarding their direction), except for “COMPARISON”, and the identification of the direction of the relations was mandatory. The documents came from the ACL Anthology², thus belonged to the domain of computational linguistic, and were derived from a more comprehensive corpus which includes more relations than the ones under evaluation in the challenge (Gábor et al., 2016).

Our contribution in this work is two-fold: (a) we experimented with two available relation extraction (RE) tools in the context of the Subtask 2 of SemEval-2018 Task 7; and (b) we evaluated the models trained on the task data for the extraction of the relations mentioned above from biomedical abstracts. In the next section, we present a short overview of related work, followed by a detailed description of our methods in section 3, the results that we obtained both during the development and official evaluation phases (section 4) and the discussion of our results and the preliminary experiments with biomedical publications.

2 Related Work

Despite the importance of the task, few previous work has focused on the identification of semantic elements in publications. Document zoning is probably the task that more attention received in

¹<https://competitions.codalab.org/competitions/17422>

²<http://aclweb.org/anthology/>

the last years and covered the identification of sections both in abstracts (Hirohata et al., 2008) and full text (Liakata et al., 2012). A more comprehensive study and comparison of different schemes for zoning was carried out in (Guo et al., 2010).

Regarding automatic extraction of scientific relations, many researchers have proposed various scheme based on either (or both) concepts or relations. For instance, (Gupta and Manning, 2011) proposed the annotation of the focus, technique and domain in scientific publications. A more comprehensive schema was proposed by (Tateisi et al., 2016), who developed an ontology of semantic structures in research articles. More recently, the ScienceIE task in SemEval-2017 (Augenstein et al., 2017) proposed the automatic extraction of both entities (Task, Process and Material) and relations from scientific abstracts. Finally, (Gábor et al., 2016) recently proposed a schema of about 20 relations, some of which are considered in the challenge.

The current task focuses on relation extraction and classification, for which many approaches have been proposed in the past years and for which some tools are readily available, including the ones we describe here. Similar to other natural language processing (NLP) tasks, recent work has shifted to the use of neural networks, as reported in (Nguyen and Grishman, 2015) and (Sorokin and Gurevych, 2017).

3 Methods

We evaluated the performance of two existing tools for relation extraction, namely, jsRE (Giuliano et al., 2006) and TEES (Björne et al., 2012). Both tools can be trained for any RE task, provided that a corpus in the appropriate format is available. The methods behind jsRE utilize kernel methods, features derived from shallow linguistic information and both global (sentence level) and local (regarding the relations) contexts (Giuliano et al., 2006). TEES trains support vector machines algorithms using a variety of features derived from the sentence, tokens and dependency chains (Björne et al., 2012).

The workflow of our experiments is shown in Figure 1. After parsing the corpus provided by the organizers, we performed standard NLP pre-processing, followed by preparing input files in the appropriate format required by the two RE tools. This included the generation of negative examples,

which are necessary for the jsRE tool. After training the models with each tool and classifying the test documents, we merged predictions (only for jsRE) and printed the predicted relations in the format required by the challenge.

Corpus reader. The main corpus was provided in two files: (a) one XML file which includes the text and entities (all belonging to the general format “ENTITY”); and (b) one file in plain text format with the list of the positive relations and one of the corresponding types listed above. For reading the data, we utilized the BioC format (Comeau et al., 2013). Our model also includes the identification of the direction of the relation (which is necessary for the task).

Pre-processing. We processed all documents using the Stanford CoreNLP library³ (Manning et al., 2014), including sentence splitting, tokenization, part-of-speech (POS) tagging, chunking, constituency parsing and dependency parsing. While jsRE is based on shallow parsing, TEES relies on both dependency and constituency parsing.

Corpus preparation. We prepared the input format required by each RE tool as specified in their documentation. For jsRE, we generated plain text files for each relation type. These included the original tokens, lemma, POS tagging, indicative of participation in the relation (T or O, otherwise) and the relation category. For multi-token entities, the corresponding tokens should be merged into one, e.g., “storage_media_and_networks” instead of the four individual tokens. The relation category were the following: -1 (unknown), 1 (positive), (2 positive reverse) and 0 (negative). For TEES, we generated a combined XML file which included complete pre-processing analysis (sentences, tokens, full parse tree, constituents and dependency parsing), as well as entities and relations (including their types). The indicative for the direction of the relation is provided as an attribute.

Negative examples generation. We automatically generated negative examples for jsRE. We produced negative examples for each pair of entities following the following guidelines: (a) the entities should belong to the same sentence (according to the sentence splitting analysis); (b) just one

³<https://stanfordnlp.github.io/CoreNLP/>

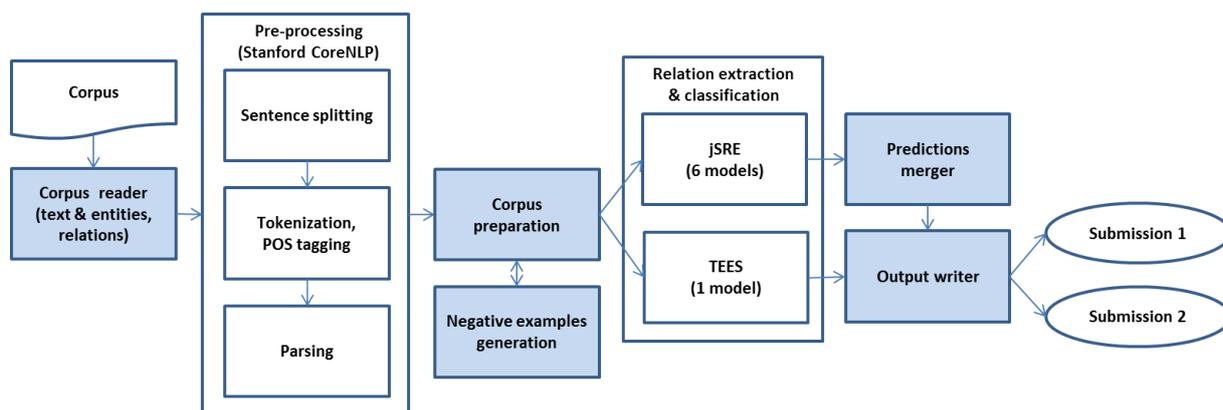

Figure 1: Workflow of the components in our approach. The components that we developed are displayed in blue.

training example (negative or positive) for each pair (always in the order that these appear in the sentence). We generated negatives examples also for sentences which contain no positive example at all. This step was not necessary for TEES, as the tool includes it in its training procedure.

Relation extraction and classification. Provided the training and development files in the format required by each tool, we trained the system according to their documentation. In the case of jSRE, we build six models, one for each relation type. Each model from jSRE calculates scores for one of the categories: 1 (positive), 2 (positive reverse) and 0 (negative). We tried the three kernels included in jSRE (LC - Local Context, GC - Global Context and SL - Shallow Linguistic), and we obtained best results with the later. In the case of TEES, we only trained one model, which performs the both the automatic extraction and classification into a category.

Predictions merger. This component is only necessary for jSRE and it consisted on reading the prediction for each of the categories (0, 1 or 2) from each of the six models and choosing the one that scored higher.

Output writer. We converted the output from both tools to the output (submission) format required by the challenge. We also checked whether a reverse relation was predicted for the “COMPARISON” type and avoided printing it, given that this is a symmetrical relation.

4 Data and Results

The training set released by the organizers consisted of 350 documents which we split in the

following datasets: 250 for training, 50 for tuning (only for TEES) and 50 for development test. The whole dataset contained the following distribution of relation types which appear in 342 (out of 350) documents: 483 for “USAGE”, 326 for “MODEL”, 234 for “PART-WHOLE”, 95 for “COMPARE”, 72 for “RESULT” and only 18 for “TOPIC”. Our evaluation during the development of the system (over the development test dataset) is shown in Table 1. We did not obtain predictions for the “TOPIC” from none of the RE tools, given the low frequency of this relation in the training set. Indeed, only three instances of this relation type are present in the development set.

Regarding the official test set, the organizers released 152 documents for this aim. All our submissions were based on models trained only on the 250 documents, i.e., we did not train models based on the totality of the 350 documents. Our official results for Subtask 2 is shown in Table 2.

5 Discussion

Relation extraction and classification. We tried two available RE tools for extracting semantic relations from scientific publications. TEES performed significantly superior to jSRE and we chose to use this tool for our further experiments with biomedical publications (cf. below). However, the performance of TEES is rather low in comparison to the best results in the challenge (cf. Table 4). Finally, we did experiment with a simple union of predictions generated by both tools, but adding the predictions from jSRE only harmed the performance of TEES (cf. Table 1).

With respect to both tools, we found TEES easier to use and run, also given our previous experience with it (Thomas et al., 2013). Addition-

Tool	USAGE	RESULT	MODEL	PART_WHOLE	COMPARISON	TOPIC
TEES (t)	29.63%	38.10%	26.23%	26.32%	28.57%	0.00%
jSRE (j)	16.67%	12.50%	24.56%	6.67%	20.00%	0.00%
(t) + (j)	19.58%	28.57%	24.62%	20.00%	28.57%	0.00%

Table 1: Results for each category for the development set (50 documents).

Tool	Extraction		Classification	
	D	T	D	T
TEES (t)	44.69%	33.4%	25.45%	20.3%
jSRE (j)	22.32%	30.9%	15.03%	16.0%
(t) + (j)	37.63%	-	20.88%	-

Table 2: Results for Sub-task 2 of SemEval-2018 Task 7, for the extraction and classification tasks, for both development (D) and official test (T) sets. The highest F1 in the official test set were 50% and 49.3% for the extraction and classification tasks, respectively.

ally, we found the input format from jSRE harder to process. On the other hand, TEES requires full parsing while jSRE is based on shallow parsing. Finally, TEES is readily available for download while we needed to contact the developers of jSRE in order to get a copy of it and needed to do some changes on the code in order to run it. Changes on the code were also necessary in order to obtain scores (probabilities) for the various categories and thus, obtain the predicted relation type. TEES, on the other hand, supports both relation extraction and classification by default.

Semantic relations in biomedical abstracts. We experimented with the model trained on TEES to extract the same semantic relations from biomedical abstracts. Our aim was to evaluate whether the predicted relations is part of either the research goal or the methods in the publication. In particular, we were interested in assessing whether the relations could potentially support the automatic extraction of either an animal experiment or an alternative method to animal experiment (e.g., in vitro or in silico experiments) (Liebsch et al., 2011). This information could later support the automatic identification of abstracts which describe either of the two experiments (animal or alternative to animal).

We processed a set of 161 abstracts retrieved from PubMed⁴. We followed the same workflow showed on Figure 1 only that we performed NER on the abstracts using the Metamap tool (Aronson

⁴<http://www.ncbi.nlm.nih.gov/pubmed/>

and Lang, 2010). We used exactly the same model (from TEES) that we used to predict relations for the official test set of the challenge. We obtained a total of 241 relations from 108 abstracts (out of a total of 161). The number of relations detected for each type were the following: 99 for “MODEL”, 87 for “USAGE”, 30 for “PART_WHOLE”, 22 for “RESULT”, two for “COMPARISON” and one for “TOPIC”.

We manually checked 28 relations detected from a sample of 13 abstracts. During these attempts, the definitions of the semantic relations as provided by the organizers gave much room for individual interpretations by the evaluating researcher. Being aware of this possible pitfall, however, we judged 9 out of 28 suggested relations as correct.

6 Conclusions

During our participation in the SemEval-2018 Task 7, we experimented with two available relation extraction tools - jSRE and TEES. As future work, we plan to run additional experiments with the current tools, such as using the totality of the training data as well as combination of the systems, as carried out in (Thomas et al., 2013). Additionally, we plan to use additional tools, such as ones based on neural networks (Nguyen and Grishman, 2015).

We applied the generated model from TEES for extraction of semantic relations from biomedical abstracts. Our manual evaluation of some of those relations shows that these have the potential to support the identification of the methods that are part of the research goal. We now plan to run a comprehensive evaluation based on a larger collection of biomedical abstracts as well as a task-specific assessment.

Acknowledgments

We would like to thank Jari Björne for support with TEES, Alberto Lavelli for providing a copy of jSRE and Roland Roller for fruitful discussions on the generation of negative examples.

Abstract

In this work we evaluate applicability of entity pair models and neural network architectures for relation extraction and classification in scientific papers at SemEval-2018. We carry out experiments with representing entity pairs through sentence tokens and through shortest path in dependency tree, comparing approaches based on convolutional and recurrent neural networks. With convolutional network applied to shortest path in dependency tree we managed to be ranked eighth in subtask 1.1 (“clean data”), ninth in 1.2 (“noisy data”). Similar model applied to separate parts of the shortest path was mounted to ninth (extraction track) and seventh (classification track) positions in subtask 2 ranking.

1 Introduction

Information extraction is an important part of natural language processing. During SemEval-2018 an evaluation devoted to extraction and classification of relations in scientific papers was held (Gábor et al., 2018). The task is described as follows: given abstracts of scientific articles with detected entities, the goal is to choose correct relations for provided $\langle source, target \rangle$ entity pairs (subtask 1 - relation classification) and to determine correct relations among all entity pairs (subtask 2 - relation extraction and classification). The target quality metric in classification is macro-average of F1-scores of every class; for extraction scenario the target metric is F1-score.

Our method is based on multinomial classification of entity pairs and their sentences with neural networks. We experiment with representing entity pairs through all sentence tokens and through tokens along the shortest path between entities in dependency tree (Bunescu and Mooney, 2005). We employ convolutional (CNN) (LeCun et al., 1989)

and bidirectional Long Short-Term Memory (biLSTM) (Hochreiter and Schmidhuber, 1997; Tan et al., 2015) neural network based approaches to encode sentences and dependency tree paths.

In this work we mainly focus on relation classification, so most of analysis and experiments are carried out for this task. Slightly modified models which achieve the best results on subtask 1 are adapted for solving relation extraction and classification problem.

The rest of the paper is organized as follows: in section 2 we describe some known approaches for relation extraction and classification. In section 3 our approach is presented in details. Section 4 outlines results of described approach evaluation on official SemEval-2018 task 7 test set. We wrap up with some final thoughts in section 5.

2 Related Work

The relation extraction and classification problem has a long history. Early approaches were based on manually constructed patterns, used to detect entities in the relation under consideration (Blaschke and Valencia, 2001). Further approaches utilized machine learning algorithms (Zelenko et al., 2003) with various hand-crafted features (GuoDong et al., 2005) - syntactic labels, part of speech tags, morphological properties and so on. A brief overview of such methods is presented in (Bach and Badaskar, 2007). Significant part of recent approaches is based on neural networks, trying to eliminate dependency on natural language processing tools: (dos Santos et al., 2015; Lin et al., 2016) use CNNs to extract and classify relations; (Zeng et al., 2014) adapts deep CNNs for the same task. (Socher et al., 2012) introduces recursive neural networks which capture information from phrases and sentences and applies it to relation classification task.

In this work we try to inject extra - syntactic - information gained from natural language processing tools into neural networks based approaches.

3 System Description

Our method is based on multinomial classification with neural networks. The decision about the relation being held is made by analysing sentence, which contains examined entities. Each sentence is represented as a sequence of tokens or as a dependency tree.

3.1 Modelling Tokens

Tokens are encoded with fasttext (Bojanowski et al., 2017). Each token embedding also contains binary indicators of its belonging to source or target entity or other part of the sentence.

3.2 Modelling Entity Pair

The basic way to model entity pair is just to take all tokens of the sentence containing these entities and to encode them with described embedding (section 3.1). Binary indicators of token belonging to entities allow us to distinguish several relations in a single sentence.

Another idea is to use path from source to target entity tokens in dependency tree. In our approach the shortest path is considered: it rises up from source entity directly to the lowest common ancestor and then immediately goes down to target entity tokens (Figure 1). Note that dependency trees are built automatically and are sometimes inconsistent with layout of entities, which may be represented differently in the tree.

When using shortest path in dependency tree, each token embedding is extended with additional information - fasttext of the parent token, syntactic label and direction indicator (whether token is on path from source or target entity to lowest common ancestor).

3.3 Neural Network Architectures

General architecture can be described as follows: some method is utilized to encode sequence of input embeddings into a vector, which is then passed through fully-connected layer L and finally fed into softmax to output predicted label. We experiment with two well-known approaches to encode sequences of input embeddings - biLSTM and CNN.

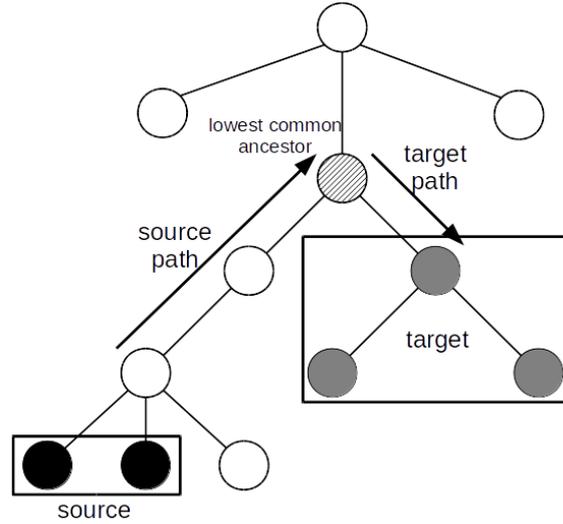

Figure 1: Modelling $\langle source, target \rangle$ entity pair in dependency tree with shortest path.

3.3.1 BiLSTM

BiLSTM-based method is hugely inspired by (Yang et al., 2016). For each sequence item w_k^0 we analyse its nearest context - two items to the left (w_k^{-2}, w_k^{-1}) and to the right (w_k^1, w_k^2). Instead of using w_k^0 directly, its "attentioned" version ω_k is used:

$$\omega_k = \sum_{i=-2}^2 \alpha_k^i w_k^i, \quad \alpha_k^i = \tanh(W w_k^i + b)^T u,$$

where w_k^i are D -dimensional embedding vectors; b and u are A -dimensional attention vectors; W is an $A \times D$ -dimensional attention matrix.

Computed ω_k are further fed into biLSTM network (hidden layer size B). Its final cells output and hidden state together with attention vector (computed similarly to what has been described earlier, but on all biLSTM outputs) are concatenated to form final sequence coding vector.

3.3.2 CNN

Another method is based on CNN. All input sequences are trimmed or padded to fit the same size. Then a number of filters F are applied. Each filter application yields a vector of dimensionality $sequence_length - filter_height + 1$; a single maximum value is pulled from each such vector. These values are finally concatenated to form final sequence encoding.

3.3.3 Separate CNNs for Shortest Path Parts

The final method is a modification of CNN one, which is specifically designed to be used when

modelling entity pairs with shortest paths. Instead of merging different parts of the path into a single sequence, we use four individual sequences by analogy with (Zeng et al., 2015) - source entity tokens, tokens on path from source to lowest common ancestor, tokens on path from lowest common ancestor to target and target entity tokens - and four separate CNNs for them (sCNN). Outputs of all networks are merged into a single final vector.

3.4 Relation Extraction

We adapt classification approach to relation extraction subtask. The first idea is to apply the same model for seven-class classification (six known relations and absence of relation). Secondly we try two-step approach with successive classifiers of the same architecture: extraction classifier detects entity pairs associated with any relation and then another classifier assigns relation labels for extracted pairs of entities.

For negative examples generation the following strategies are examined: *reflection* - reversed correct asymmetric (all except *COMPARE*) relations are supposed to be negative examples; *in-sentence* - some random portion of entity pairs which co-occur in the same sentence is treated as negative examples.

Finally an attempt to filter out excess relations is made (according to guidelines each entity is allowed to participate in not more than a single relation). We employ greedy method that chooses the most confident relation being held using classifier output weights.

4 Evaluation

We took part in both relation classification and relation extraction subtasks. All results reported in this section are gained on official SemEval-2018 task 7 test data developed by organizers and released after the evaluation phase. Official scores for corresponding submissions are specified in Tables 2 and 3 after the slash sign. The difference is explained by minor parameter variations, typically randomness in variables initialization and number of training epochs.

Relation classification (subtask 1) has two datasets - with manually annotated entities (subtask 1.1 - "clean data") and with automatically detected entities (subtask 1.2 - "noisy data"). We decided to construct a single model merging

Relation	1.1	1.2	1.1+1.2
COMPARE	95	41	136
MODEL-FEATURE	326	175	501
PART-WHOLE	234	196	430
RESULT	72	123	195
TOPIC	18	243	261
USAGE	483	470	953

Table 1: Number of relations in subtask datasets.

both datasets into one in order to increase the amount of training examples and to diminish skew in number of sample relations for different types (Table 1).

To encode tokens fasttext (skipgram; minimum length of character n-gram is 1, maximum - 5) is used. We build two separate models with different embedding dimensions - 100 and 300 - using the English Wikipedia.

Evaluation results are presented in Table 2. The target metric is F1. The first part of method name specifies whether all sentence tokens or tokens from shortest path in dependency tree are used. The second part specifies neural network architecture being utilized. We report results for the following neural network parameter values: attention size A is 400; biLSTM hidden layer size B is 1000; CNN filters F - 200 with height 3, 50 with heights 2 and 4, width matches the embedding dimensionality; size of fully-connected layer L is 1000 for biLSTM and 900 for CNN. Specified values are selected during experiments, which are out of this paper scope.

As for subtask 1.1, we conclude that: context attention tends to be beneficial (the only counterexample is sentence biLSTM with fasttext size 300); larger token embeddings are typically better (the only counterexample is sentence biLSTM); syntactic information is helpful for relation classification with neural networks.

For subtask 1.2 the results are more controversial: smaller embeddings sometimes surpass larger ones; utilizing syntactic information seems still beneficial, but the results are not as convincing as in 1.1; in contrast to subtask 1.1 context attention does not tend to improve quality of the approach. From our point of view, such strange behaviour on subtask 1.2 dataset requires further investigation.

Quality evaluations for subtask 2 solutions are presented in Table 3. Target metrics are extrac-

Method	Context attention	Fasttext size	1.1			1.2

Table 3: Final quality results for subtask 2.

tion and evaluation F1. All experiments are performed with the same input vector size (fasttext dimensionality equals to 300); entity pairs are modelled with shortest path in dependency tree. The second column specifies negative examples generation strategy: reflection with some portion (0-100%) of in-sentence negative examples is always used. For training purposes both subtask 1.1 and 1.2 data is utilized.

When reflection strategy for negative examples generation is used seven-class approach performs better. With utilization of both strategies two-step approach breaks forward. Post-processing im-

proves quality for both approaches, however it is still rather low compared with the results of other participants.

5 Conclusion

In this work we tried to study how utilization of syntactic information influences the quality of relation extraction and classification in scientific papers. According to our experiments the approach based on shortest path in dependency tree yields the best results. The actual network architecture delivering the best result depends on the subtask being solved.

Abstract

Large repositories of scientific literature call for the development of robust methods to extract information from scholarly papers. This problem is addressed by the SemEval 2018 Task 7 on extracting and classifying relations found within scientific publications. In this paper, we present a feature-based and a deep learning-based approach to the task and discuss the results of the system runs that we submitted for evaluation.

1 Introduction

Nowadays, the exploding amount of scientific literature makes it ever more problematic for researchers and scholars to get focused access to the state-of-the-art in a certain field of science. Therefore, it is getting increasingly important to develop effective computational approaches for extracting information from large scholarly corpora. SemEval 2018 Task 7 (Gábor et al., 2018) addresses this problem with a shared task on extracting and classifying semantic relations in scientific papers. The task is divided into two subtasks:

1. **Relation Classification.** Given an existing relation between two entities and their context, the task is to predict the label of the relation out of the set of possible classes, namely USAGE, RESULT, MODEL-FEATURE, PART-WHOLE, TOPIC, COMPARISON. The task is decomposed into two different scenarios according to the data used, namely with either manually annotated entities (1.1) or noisy data with automatically extracted entities (1.2).
2. **Relation Extraction and Classification.** This subtask addresses the whole end-to-end pipeline of relation extraction. Given abstracts

of scientific papers annotated with entities, systems are required to extract pairs of entities in a semantic relation, as well as assign a label and directionality to the extracted relation.

We participated in the subtask 1.1, relation classification on clean data, and subtask 2 (relation extraction only). Our approach relies on supervised learning using Support Vector Machines (SVMs), k-Nearest Neighbors (kNNs), and Convolutional Neural Networks (CNNs). We were ranked 16th on task 1.1 with an F1 score 44.0% and 7th on task 2 with an F1 of 28.4%.

2 Related Work

A series of supervised systems for extracting keyphrases and relations in scientific publications was presented in the context of the SemEval task 10 in 2017 (Augenstein et al., 2017). In contrast to the present task formulation, the set of relations consisted only of two, namely hyponymy and synonymy. For this task, the best systems were those based on neural approaches.

Lee et al. (2017) obtained the highest score by employing a convolutional neural network with a specific embedding layer encoding manually crafted features such as the word, the position of the word and the part-of-speech (POS) tag. The second best system was a neural end-to-end model by Ammar et al. (2017). It predicted the relation types based on a context-sensitive representation of the keyphrases which they obtained by using a variety of information, e.g., entity type embeddings and syntactic and sequential path information generated by a bidirectional Long Short-Term Memory (LSTM) layer. As opposed to the former systems, the approach of Barik and Marsi (2017), ranked third, was based on manually crafted features and more traditional classifiers such as decision trees and SVMs.

Outside SemEval, Zelenko et al. (2003) proposed different kernel methods combined with the SVM and Voted Perceptron learning algorithms for extracting person-affiliation and organization-location relations. Another kernel-based approach using different sources of syntactic information was presented by Zhao and Grishman (2005).

Our neural approach is inspired by the work of Nguyen and Grishman (2015), who employ a CNN with word embedding and position embedding lookup. Embeddings are concatenated for obtaining positionally and semantically sensitive token representations and then fed into a convolutional layer, followed by a maximum pooling layer and a fully connected feed-forward network with a softmax classifier.

3 Methodology

3.1 Feature-based Approach

Feature Engineering. For our feature-based approach we explored the following pool of features.

1. **Structural Features.** We compute for each entity the distance to the last and next entity and the relative position of the entity in the sentence. Furthermore, assuming that verb phrases are a strong indicator for the specific type of relationship, we also add the distance to the next verb.
2. **Lexical features.** We include the first and last five letters of the given surface form of each entity. Furthermore, for each word we add the last and next three words in the surrounding context window and the word length. Again emphasizing the relative importance of verbs, we specifically encode the last and the next verb. Manual exploration of the training data revealed patterns such as the preposition ‘of’ and the verb ‘use’ being a strong indicator of the relations PART_WHOLE and USAGE respectively. Therefore, we add two binary features `hasOf` and `hasUse`. The last lexical feature we employ is the Tf-Idf representation of the sentence.
3. **Syntactic features.** We use the POS tag of each word as shallow syntactic feature.
4. **Semantic features.** In order to add semantic information we employ an embedding representation of the sentence by averaging the GloVe

word embeddings pretrained on Wikipedia 2014 and Gigaword 5.¹

Experimental Setup. We experimented with two classifiers, namely linear SVM and kNN. Both models were wrapped in a 5-fold cross validation in order to obtain performance estimates on the whole training set. Furthermore, we tuned the hyperparameters of the models by nesting the cross validation in a grid search, optimizing the penalty term c of the linear SVM given the search space $c \in \{0, 001, 0.01, 0.1, 1, 10\}$ and weighting the penalty term either balanced according to the distribution of the classes or leaving all classes with equal penalty. In the relation classification, we also experimented with one-vs-rest and Crammer-Singer as multi-class classification strategies.

Similarly, for the kNN we optimized the number of neighbors in the search space $k \in \{3, 5, 7, 9\}$ and tried uniform weighting and weighting neighbors based on their inverse distance. All other parameters were left to the default values provided by scikit-learn,² which we used as implementation framework.

To find suitable subsets of our heuristically extracted pool of features, a forward feature selection was employed.

3.2 Deep Learning-based Approach

Model Architecture. We employ a CNN (LeCun and Bengio, 1998) for the relation extraction task, which was first introduced to the natural language processing community by Collobert and Weston (2008). Our CNN architecture is inspired by Nguyen and Grishman (2015) and consists of four main layers: (1) embedding layer, (2) convolutional layer, (3) maximum pooling layer, and (4) fully connected output layer.

In a first step, given a word and its relative position in the sentence, we lookup the accompanying vector representations and concatenate them in order to obtain a position-sensitive semantic representation of the token. Next, the model convolutes, i.e., slides, over the embeddings to capture the context of the token in a window of size k , which is followed by subsampling the obtained matrices using maximum pooling, e.g., preserving the N maximal values. This allows the model to recognize the most informative k-grams for the task. In a last step, the representations are fed into a fully

subtree	8	0	C08-1105.3

Table 1: Example of how we assign relative position to training and test instances.

connected layer followed by a softmax classifier predicting the label.

Experimental Setup. As input to the model we feed pairs of candidate entities together with the textual content between them. As the CNN expects fixed-size vector representations, we pad the texts to the length of the longest sequence using a special token to which we assign a random embedding vector. We compute the relative position for each word w_i as distance vector $d_i = [d_{i1}, d_{i2}]$. Table 1 shows an example of how we assign relative distances to each word in our instances. The word embedding matrix is initialized with 300-dimensional domain-specific word embeddings from Lauscher et al. (2017), which showed during prototyping superior performance when compared with standard domain-independent ones. Finally, we obtain a position-sensitive representation of the word w_i by concatenating its embedding e_i as well as the position embedding into a single vector $v_i = [e_i, d_{i1}, d_{i2}]$.

Since the data for the relation extraction task is highly skewed towards the number of negative instances (i.e., only 1,228 out of 8,768 are positive), we decided to experiment with data balancing techniques. More specifically, we tried upsampling the positive instances applying an upsampling rate $r_u \in [1, 5]$ and similarly, downsampling the negative instances with a rate $r_d \in [0.1, 1]$.

Optimizing the hyperparameters of our model, we experimented with the numbers of CNN filters in range $f \in [50, 500]$ and with a filter size $s \in [3, 15]$. For the regularization of our model we apply dropout before the fully connected layer and experimented with a dropout keep probabil-

ity of $d \in [0, 1]$. For all other hyperparameters we use the values from Nguyen and Grishman (2015). Last, in order to make our models comparable among each other, we nested the CNN in a 5-fold cross validation.

4 Evaluation

Here, we briefly give an overview of the data provided by the organizers of the shared task as well as our submitted runs. We also present and discuss the final results achieved.

Data. The training data provided by the task organizers for subtask 1.1 and subtask 2 is composed of 350 abstracts of scientific publications with manually annotated entities and relations. In total, the number of relation instances amounts to 1,228 samples. Table 2 shows the distribution of the labels for the relation classification.

For the relation extraction task, entity pairs for all semantic relations appear in the very same sentence. Therefore, we generate relation candidates by pairing all entity mentions found within the same sentence boundary. This way we end up with 8,386 candidate entity pairs among which 1,228 are positive instances.

The test data for task 1.1 and 2 was provided in the same format as training data, containing 150 abstracts and 355 relation instances (for subtask 1.1 only).

Submitted runs. We selected two models for the relation classification and three models for the relation extraction task for the final submission according to their scores on the development data using the official scoring script. The model configurations are summarized in Table 3 and Table 4, respectively.

Final Results. The official scores for the submitted models are listed in Tables 5 and 6.

Model	Hyperparameter	Choice	Features
SVM	c	1	tfidf
	multi class	one-vs-rest	isReverse
	class weight	balanced	nextEntityDist(x) position(y) POStag(x)
kNN	k	5	tfidf
	weights	distance	isReverse hasOf

Table 3: Submitted models for task 1.1 (relation classification). In the features listed, x represents the first entity while y represents the second entity of a candidate pair.

Model	Hyperparameter	Choice	Features
SVM	c	0.1	position(x,y)
	class weight	balanced	lastEntityDist(y) nextEntityDist(x) tokenLength(y) POStag(x,y) firstLetter(y)
kNN	k	3	relativePosition(x,y)
	weights	distance	lastEntityDist(y) position(y) avgEmbedding hasUse POStag(x,y)
CNN	dropout	0.5	word embedding
	upsampling rate	3	relative position
	number of filters	200	
	filter size	3-8	

Table 4: Submitted models for task 2 (relation extraction). In the features listed, x represents the first entity while y represents the second entity of a candidate pair.

In the relation classification task, SVM achieves better performance than kNN by a large margin, while in the relation extraction task, it is the deep learning models that perform best. Within the scope of the traditional models, SVM consistently outperforms kNN for both the classification (on every relation type, cf. Table 5), as well as the extraction task (Table 6). Furthermore, for task 1.1, SVM performed better than kNN, in every relation type. The reason could be that the vector-like features we used, such as Tf-Idf and the binary POS-tags, suit better for SVM, while kNN was not able to handle the high-dimensional dataset.

For task 2 the linear SVM model results in a relatively high recall but considerably low precision. This result could be related to the following reasons. First, since the training data is highly skewed towards negative examples as described in subsection 4, more false positive cases are predicted. Second, the data is likely to be nonlin-

Class	SVM	kNN
Usage	73.68%	63.04%

Topic	22.22%	00.00%
Result	37.50%	37.50%
Compare	26.32%	12.12%
Macro F1	44.00%	32.49%

Table 5: Results (F1) on relation classification (task 1.1).

	Precision	Recall	F1
SVM	15.67%	90.19%	26.70%
kNN	9.93%	11.44%	10.63%
CNN	18.84%	57.49%	28.38%

Table 6: Results on relation extraction (task 2).

early distributed. As a result, the linear SVM is not able to perform better even when increasing feature dimensionality. In addition to a better feature engineering, we explored the use of an Radial Basis Function (RBF) kernel and Gradient Boosting Tree to increase the precision without hurting the recall. Another interesting point is that the improvement of precision contributed more to the overall F1-score in this official evaluation method. This can be inferred from the results listed in Table 6, where the CNN has higher F1-score, with a higher precision but much lower recall compared to the SVM.

5 Conclusion

In this paper we have presented our approach to the SemEval 2018 Task 7 on extracting and classifying semantic relations from scientific publications. We experimented with feature-based versus neural models. For the classification task, SVM performed better than kNN, although both show problems in predicting minority classes with few examples. For the extraction task, the deep learning method outperformed SVM by a narrow margin. The overall comparable results across methods seem to indicate that, in the future, more work should turn to devising better features or architectures that are able to capture the nuances of semantic relations in the domain of scientific texts.

Information Retrieval Lab

Department of Computer Science

Georgetown University

{firstname}@ir.cs.georgetown.edu

Abstract

SemEval 2018 Task 7 focuses on relation extraction and classification in scientific literature. In this work, we present our tree-based LSTM network for this shared task. Our approach placed 9th (of 28) for subtask 1.1 (relation classification), and 5th (of 20) for subtask 1.2 (relation classification with noisy entities). We also provide an ablation study of features included as input to the network.

1 Introduction

Information Extraction (IE) has applications in a variety of domains, including in scientific literature. Extracted entities and relations from scientific articles could be used for a variety of tasks, including abstractive summarization, identification of articles that make similar or contrastive claims, and filtering based on article topics. While ontological resources can be leveraged for entity extraction (Gábor et al., 2016), relation extraction and classification still remains a challenging task. Relations are particularly valuable because (unlike simple entity occurrences) relations between entities capture lexical semantics. SemEval 2018 Task 7 (Semantic Relation Extraction and Classification in Scientific Papers) encourages research in relation extraction in scientific literature by providing common training and evaluation datasets (Gábor et al., 2018). In this work, we describe our approach using a tree-structured recursive neural network, and provide an analysis of its performance.

There has been considerable previous work with scientific literature due to its availability and interest to the research community. A previous shared task (SemEval 2017 Task 10) investigated the extraction of both keyphrases (entities) and relations in scientific literature (Augenstein et al., 2017). However, the relation set for this shared task was limited to just synonym and hypernym relation-

ships. The top three approaches used for relation-only extraction included convolutional neural networks (Lee et al., 2017a), bi-directional recurrent neural networks with Long Short-Term Memory (LSTM, Hochreiter and Schmidhuber, 1997) cells (Ammar et al., 2017), and conditional random fields (Lee et al., 2017b).

There are several challenges related to scientific relation extraction. One is the extraction of the entities themselves. Luan et al. (2017) produce the best published results on the 2017 ScienceIE shared task for entity extraction using a semi-supervised approach with a bidirectional LSTM and a CRF tagger. Zheng et al. (2014) provide an unsupervised technique for entity linking scientific entities in the biomedical domain to an ontology.

Contribution. Our approach employs a tree-based LSTM network using a variety of syntactic features to perform relation label classification. We rank 9th (of 28) when manual entities are used for training, and 5th (of 20) when noisy entities are used for training. Furthermore, we provide an ablation analysis of the features used by our model. Code for our model and experiments is available.¹

2 Methodology

Syntactic information between entities plays an important role in relation extraction and classification (Mintz et al., 2009; MacAvaney et al., 2017). Similarly, sequential neural models, such as LSTM, have shown promising results on scientific literature (Ammar et al., 2017). Therefore, in our approach, we leverage both syntactic structures and neural sequential models by employing a tree-based long-short term memory cell (tree-LSTM). Tree-LSTMs, originally introduced by Tai et al. (2015), have been successfully used to

¹<https://github.com/Georgetown-IR-Lab/semEval2018-task7>

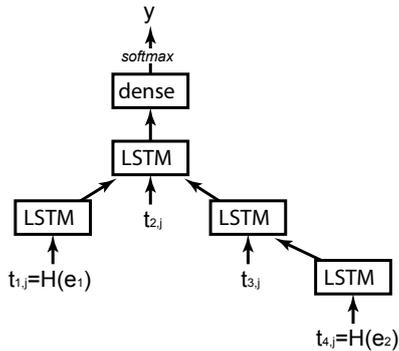

Figure 1: Our tree LSTM network.

capture relation information in other domains (Xu et al., 2015; Miwa and Bansal, 2016). On a high level, tree-LSTMs operate very similarly to sequential models; however, rather than processing tokens sequentially, they follow syntactic dependencies; once the model reaches the root of the tree, the output is used to compute a prediction, usually through a dense layer. We use the child-sum variant of tree-LSTM (Tai et al., 2015).

Formally, let $S_j = \{t_{1,j}, \dots, t_{n,j}\}$ be a sentence of length n , $e_1 = \{t_i, \dots, t_k\}$ and $e_2 = \{t_p, \dots, t_q\}$ two entities whose relationship we intend to classify; let $H(e_1)$, $H(e_2)$ be the root of the syntactic subtree spanning over entities e_1 and e_2 . Finally, let $T(e_1, e_2)$ be the syntactic sub-tree spanning from $H(e_1)$ to $H(e_2)$. For the first example in Table 1, $e_1 = \{\text{'Oral', 'communication'}\}$, $e_2 = \{\text{'indices'}\}$, $H(e_1) = \{\text{'communication'}\}$, $T(e_1, e_2) = \{\text{'communication', 'offer', 'indices'}\}$. The proposed model uses word embeddings of terms in $T(e_1, e_2)$ as inputs; the output of the tree-LSTM cell on the root of the syntactic tree is used to predict one of the six relation types (y) using a softmax layer. A diagram of our tree LSTM network is shown in Figure 1.

In order to overcome the limitation imposed by the small amount of training data available for this task, we modify the general architecture proposed in (Miwa and Bansal, 2016) in two crucial ways. First, rather than using the representation of entities as input, we only consider the syntactic head of each entity. This approach improves the generalizability of the model, as it prevents overfitting on very specific entities in the corpus. For example, by reducing *'Bag-of-words methods'* to *'methods'* and *'segment order-sensitive models'* to *'models'*, the model is able to recognize the COM-

Relation (abbr.)	Example
USAGE (U)	<u>Oral communication</u> may offer additional <u>indices</u> ...
MODEL-FEATURE (M-F)	We look at the <u>intelligibility</u> of <u>MT output</u> ...
PART-WHOLE (P-W)	As the operational semantics of <u>natural language applications</u> improve...

RESULT (R)	We find that <u>interpolation methods</u> improve the <u>performance</u> ...
TOPIC (T)	A formal analysis for a large class of words called <u>alternative markers</u> ...

Table 1: Example relations for each type. Entities are underlined, and all relations are from the first entity to the second entity (non-reversed).

PARE relation between these two entities (see Table 1). Second, we experimented with augmenting each term representation with the following features:

- Dependency labels (DEP): we append to each term embedding the label representing the dependency between the term and its parent.
- PoS tags (POS): the part-of-speech tag for each term is append to its embedding.
- Entity length (ENTLEN): we concatenate the number of tokens in e_1 and e_2 to embeddings representation of heads $H(e_1)$ to $H(e_2)$. For terms that are not entity heads, the entity length feature is replaced by '0'.
- Height: the height of each term in the syntactic subtree connecting two entities.

3 Experimental Setup

SemEval 2018 Task 7 focuses on relation extraction, assuming a gold set of entities. This allows participants to focus on specific issues related to relation extraction with a rich set of semantic relations. These include relations for USAGE, MODEL-FEATURE, PART-WHOLE, COMPARE, RESULT, and TOPIC. Examples of each type of relation are given in Table 1.

The shared task evaluates three separate sub-tasks (1.1, 1.2, and 2). We tuned and submitted

Dataset	U	M-F	P-W	C	R	T
Subtask 1.1

our system for subtasks 1.1 and 1.2. In both of these subtasks, participants are given scientific abstracts with entities and candidate relation pairs, and are asked to determine the relation label of each pair. For subtask 1.1, both the entities and relations are manually annotated. For subtask 1.2, the entities are automatically generated using the procedure described in Gábor et al. (2016). This procedure introduces noise, but represents a more realistic evaluation environment than subtask 1.1. In both cases, relations and gold labels are produced by human annotators. All abstracts are from the ACL Anthology Reference Corpus (Bird et al., 2008). We randomly select 50 texts from the training datasets for validation of our system. We provide a summary of the datasets for training, validation, and testing in Table 2. Notice how the proportions of each relation label vary considerably among the datasets.

We experiment with two sets of word embeddings: Wiki News and arXiv. The Wiki News embeddings benefit from the large amount of general language, and the arXiv embeddings capture specialized domain language. The Wiki News embeddings are pretrained using fastText with a dimension of 300 (Mikolov et al., 2018). The arXiv embeddings are trained on a corpus of text from the cs section of arXiv.org² using a window of 8 (to capture adequate term context) and a dimension of 100 (Cohan et al., 2018). A third variation of the embeddings simply concatenates the Wiki News and arXiv embeddings, yielding a dimension of 400; for words that appear in only one of

the two embedding sources, the available embeddings are concatenated with a vector of appropriate size sampled from $\mathcal{N}(0, 10^{-8})$.

For our official SemEval submission, we train our model using the concatenated embeddings and one-hot encoded dependency label features. We use a hidden layer of 200 nodes, a 0.2 dropout rate, and a training batch size of 16. Syntactic trees were extracted using SpaCy³, and the neural model was implemented using MxNet⁴.

The official evaluation metric is the macro-averaged F1 score of all relation labels. For additional analysis, we use the macro precision and recall, and the F1 score for each relation label.

4 Results and Discussion

In Table 3, we provide our official SemEval results in the context of other task participants. In both subtasks, we ranked above both the median and mean team scores, treating the top-ranking approach for each team as the team’s score. For Subtask 1.1, we ranked 9 out of 28, and for Subtask 1.2, we ranked 5 out of 20. This indicates

Wiki News	59.2	57.3	57.6
arXiv	58.5	55.1	56.4
Wiki News + arXiv	59.4	64.1	60.9
Subtask 1.2			
Wiki News	73.1	76.2	72.7
arXiv	65.4	67.4	65.9
Wiki News + arXiv	78.2	79.7	78.0

Table 5: Performance comparison for subtasks 1.1 and 1.2 when using Wiki News and arXiv embeddings. The concatenated embeddings outperform the individual methods.

that our approach is generally more tolerant to the noisy entities given in Subtask 1.2 than most other approaches. Figure 2 is a confusion matrix for the official submission for subtask 1.1. The three most frequent labels in the training data (USAGE, MODEL-FEATURE, and PART-WHOLE) are also the most frequently confused relation labels. This behavior can be partially attributed to the class imbalance.

In Table 4, we examine the effects of various feature combinations on the model. Specifically, we check the macro averaged precision, recall, and F1 scores for both subtask 1.1 and 1.2 with various sets of features on the test set. Of the combinations we investigated, including the dependency labels, part of speech tags, and the token length of entities

yielded the best results in terms of overall F1 score for both subtasks. The results by individual relation label are more mixed, with the overall best combination simply yielding better performance on average, not on each label individually. Interestingly, the entity height feature reduces performance, perhaps indicating that it is easy to overfit the model using this feature.

Table 5 examines the effect of the choice of word embeddings on performance. In both subtasks, concatenating the Wiki News and arXiv embeddings yields better performance than using a single type of embedding. This suggests that the two types of embeddings are useful in different cases; perhaps Wiki News better captures the general language linking the entities, whereas the arXiv embeddings capture the specialized language of the entities themselves.

5 Conclusion

In this work, we investigated the use of a tree LSTM-based approach for relation classification in scientific literature. Our results at SemEval 2018 were encouraging, placing 9th (of 28) at subtask 1.1 (relation classification with manually-annotated entities), and 5th (of 20) at subtask 1.2 (relation classification using automatically-generated entities). Furthermore, we conducted an analysis of our system by varying the system parameters and features.

Abstract

In this paper we describe our system for SemEval-2018 Task 7 on classification of semantic relations in scientific literature for clean (subtask 1.1) and noisy data (subtask 1.2). We compare two models for classification, a C-LSTM which utilizes only word embeddings and an SVM that also takes hand-crafted features into account. To adapt to the domain of science we train word embeddings on scientific papers collected from arXiv.org. The hand-crafted features consist of lexical features to model the semantic relations as well as the entities between which the relation holds. **Classification of Relations using Embeddings (ClaiRE)** achieved an F1 score of 74.89 % for the first subtask and 78.39 % for the second.

1 Introduction

The goal of SemEval-2018 Task 7 is to extract and classify semantic relations between entities into six categories that are specific to scientific literature (Gábor et al., 2018). In this work, we focus on the subtask of classifying relations between entities in manually (subtask 1.1) and automatically annotated and therefore noisy data (subtask 1.2). Given a pair of related entities, the task is to classify the type of their relation among the following options: `Compare`, `Model-Feature`, `Part-Whole`, `Result`, `Topic` or `Usage`. Relation types are explained in detail in the task description paper (Gábor et al., 2018). The following sentence shows an example of a `Result` relation between the two entities **combination methods** and **system performance**:

Combination methods are an effective way of improving **system performance**.

This sentence is a good example for two challenges we face in this task. First, almost half of

all entities consist of noun phrases which has to be considered when constructing features. Secondly, the vocabulary is domain dependent and therefore background knowledge should be adopted.

Previous approaches for semantic relation classification tasks mainly employed two strategies. Either they made use of a lot of hand-crafted features or they utilized a neural network with as few background knowledge as possible. The winning system of an earlier SemEval challenge on relation classification (Hendrickx et al., 2009) adopted the first approach and achieved an F1 score of 82.2% (Rink and Harabagiu, 2010). Later, other works outperformed this approach by using CNNs with and without hand-crafted features (Santos et al., 2015; Xu et al., 2015) as well as RNNs (Miwa and Bansal, 2016).

Approach We present two approaches that use different levels of preliminary information. Our first approach is inspired by the winning method of the SemEval-2010 challenge (Rink and Harabagiu, 2010). It models semantic relations by describing the two *entities*, between which the semantic relation holds, as well as the words between those entities. We call those in-between words the *context* of the semantic relation. We classify relations by using an SVM on lexical features, such as part-of-speech tags. Additionally we make use of semantic background knowledge and add pre-trained word embeddings to the SVM, as word embeddings have been shown to improve performance in a series of NLP tasks, such as sentiment analysis (Kim, 2014), question answering (Chen et al., 2017) or relation extraction (Dligach et al., 2017). Besides using existing word embeddings generated from a general corpus, we also train embeddings on scientific articles that better reflect scientific vocabulary.

In contrast, our second approach relies on word

embeddings only, which are fed into a convolutional long-short term memory (C-LSTM) network, a model that combines convolutional and recurrent neural networks (Zhou et al., 2015). Therefore no hand-crafted features are used. Because both CNN and RNN models have shown good performance for this task, we assume that a combination of them will positively impact classification performance compared to the individual models.

By combining lexical information and domain-adapted scientific word embeddings, our system ClaiRE achieved an F1 score of 74.89% for the first subtask with manually annotated data and 78.39% for the second subtask with automatically annotated data.

2 Features

In this section, we describe the features which are used in our two approaches. All sentences are first preprocessed before constructing boolean lexical features on the one hand and word embedding vectors on the other. Both feature groups are based on the entities of relations as well as the context in which those entities appear.

Apart from the `Compare` relation, all relation types are asymmetric, and therefore the distinction between start and end entity of a relation is important. If entities appear in reverse order, that means the end entity of a relation appears first in the sentence, this is marked by a *direction* feature which is part of the data set.

In our entrance example, **combination methods** denotes the start entity, **system performance** the end entity, and **are an effective way of improving** the context.

2.1 Preprocessing

Early experiments showed that it is beneficial to filter the vocabulary of our data and reduce noise by leaving out infrequent context words. The best setting was found to be a frequency threshold of 5 on lemmatized words. Therefore we discard a context word if its lemma appears less than 5 times in the corpus of the respective subtask.

2.2 Context features

First we will explain feature construction based on the context of a relation. Abbreviations for feature names are denoted in brackets. Context is defined as the words between two entities. Early

tests showed that using those words described the relation better than the words surrounding the relation entities.

Lexical We construct several lexical boolean features which are illustrated in Table 1. First we apply a bag of words (*bow*) approach where each lemmatized word forms one boolean feature, which for example takes 1 as value if the lemma *improve* is present and 0 if it is not. Second we determine whether the context words contain certain part-of-speech (POS) tags (*pos*), such as *VERB*. POS-tagging was done with the help of SpaCy¹ (v. 2.0.2). To represent the structure of the context phrase we add a path of POS tags feature, which contains the order in which POS tags appear (*pospath*). The distance feature depicts whether the POS-path and therefore the context phrase has a certain length (*dist*).

Additionally we add background knowledge by extracting the top-level Levin classes of intermediary verbs from VerbNet² (*lc*), a verb lexicon compatible with WordNet. It contains explicitly stated syntactic and semantic information, using Levin verb classes to systematically construct lexical entries (Schuler, 2005). For example the verb *improve* belongs to class 45.4, which is described by Levin as consisting of “alternating change of state” verbs.³

Embeddings Aside from lexical features we also use word embedding vectors to leverage information from the context of entities (*c*). For each filtered context word we extract its word embedding from a pre-trained corpus, where out-of-vocabulary words (OOV) are represented by the zero vector. The individual word vectors are later applied to train a C-LSTM.

In contrast, for use in an SVM we found it beneficial to represent the context embedding features as the average over all context word embeddings.

2.3 Entity features

In the second set of features, we model the relation entities themselves as they may be connected to a certain relation class. For example, the token *performance* or one form of it mostly appears as an end entity of a `Result` relation, and in the rare

Start entity (<i>startEnt</i>)	combination methods, methods
End entity (<i>endEnt</i>)	system performance, performance
Similarity (<i>sim100</i>)	0.43
Similarity bucket (<i>simb</i>)	q50

Table 1: Examples for lexical context and entity features.

case when it represents a start entity, it is almost always part of a `Compare` relation. Therefore we leverage information about entity position for the creation of lexical and embedding entity features.

Lexical For the creation of boolean lexical features, we first take the lowercased string of each entity and construct up to three distinct features from it. One feature which marks its general appearance in the corpus without order (*ents*) and one each if it occurs as start (*startEnt*) or end (*endEnt*) entity of a relation, taking its direction into account. Additionally we add the head noun to the respective feature set if the entity consists of a nominal phrase to create greater overlap between instances.

Furthermore we measure the semantic similarity of the relation entities using the cosine of the corresponding word embedding vectors (*sim100*). While the cosine takes every value from $[-1, 1]$ in theory, we cut off after two digits to reduce the feature space and get 99 boolean similarity features for our corpus. To again enable learning across instances we additionally discretize the similarity range and form another five boolean similarity features (*simb*) that capture into which of the following buckets the similarity score falls: $q0 = [-1, 0)$, $q25 = [0, 0.25)$, $q50 = [0.25, 0.5)$, $q75 = [0.5, 0.75)$, $q100 = [0.75, 1]$ (values below zero are very rare in this corpus).

Embeddings Similar to the context features we also want to add word embeddings of entities to our entity feature set. This is not straightforward as more than 44% of all entities consist of nominal phrases, while a word embedding usually corresponds to a single word. By way of comparison, the proportion of nominals in the relation classification corpus of the SemEval-2010 challenge was

only 5%. Thus we tested different strategies to obtain a word embedding for nominal phrases and found that averaging over the individual word vectors of the phrase yielded the best results for this task. These word embeddings for start (e_s) and end (e_e) entities of relations were then presented to our two classification methods, which will be described in detail in the following section.

3 Classification Methods

We utilize two different models for classifying semantic relations: an SVM which incorporates both the lexical and embedding features described in Section 2 and a Convolutional Long Short Term Memory (C-LSTM) neural network that only uses word embedding vectors

To fully exploit our hand-crafted lexical features we employ a traditional classifier. In comparison to Naive Bayes, Decision Trees and Random Forests we found a Support Vector Machine to perform best for this task. Instead of utilizing the decision function of the SVM to predict test labels we decided to make use of the probability estimates according to Wu et al. (2004) as this proved to be more successful. As mentioned before, the lexical features are fed into the SVM as boolean features whereas the word embeddings are normalized using MinMax-Scaling to the range $[0, 1]$ to make it easier for the SVM to handle both feature groups.

In contrast to SVM, neural network models do not necessarily rely on handcrafted features and are therefore faster to implement. We experiment with standard C-LSTM (Zhou et al., 2015) which extracts a sentence representation by combining one-dimensional convolution and an LSTM network and uses the representation to perform a classification.

label	subtask 1.1	subtask 1.2	total
COMPARE	95 (8%)	41 (3%)	136 (5%)
MODEL-F.	326 (27%)	174 (14%)	500 (20%)
PART.W.	234 (19%)	196 (16%)	430 (17%)
RESULT	72 (6%)	123 (10%)	195 (8%)
TOPIC	18 (1%)	243 (20%)	261 (11%)
USAGE	483 (39%)	468 (38%)	951 (38%)

4 Evaluation

After describing the two models we employ for relation classification, we now portray the data set we use and present results for both SVM and C-LSTM as micro-F1 and macro-F1. The latter is the official evaluation score of the SemEval Challenge. We describe the experimental setup for both models and compare different feature sets and pre-trained embeddings.

4.1 Data and Background Knowledge

We evaluate our approach on a set of scientific abstracts, D_{test} . It consists of 355 semantic relations for each subtask which are similarly distributed as its respective training data set. As training data we received 350 abstracts of scientific articles per subtask, which resulted in 1228 labeled training relations for subtask 1.1 and 1245 training instances for subtask 1.2 (c.f. Table 2). We combine data sets of both subtasks for training, resulting in 2473 training examples in total (D_{train}).

Background Knowledge In our experiments, we compare different pre-trained word embeddings as a source of background knowledge. As a baseline, we employ a publicly available set of 300-dimensional word embeddings trained with GloVe (Pennington et al., 2014) on the Common Crawl data⁴ (CC). To better reflect the semantics of scientific language, we trained our own scientific embeddings using word2vec (Mikolov et al., 2013) on a large corpus of papers collected from arXiv.org⁵ (arXiv).

In order to create the scientific embeddings, we downloaded L^AT_EX sources for all papers published in 2016 on arXiv.org using the provided dumps.⁶ After originally trying to extract the plain text from the sources, we found that it was more feasible to first compile the sources to pdf (exclud-

ing all graphics etc.) and then use pdftotext⁷ to convert the documents to plain text. This resulted in a dataset of about 166 000 papers. Using gensim (Řehůřek and Sojka, 2010), for each document we extracted tokens of minimum length 1 with the wikicorpus tokenizer and used word2vec to train 300-dimensional word embeddings on the data. We kept most hyper-parameters at their default values, but limited the vocabulary to words occurring at least 100 times in the dataset, reducing for example the noise introduced by artifacts from equations.

4.2 Parameters and Results

After an extensive grid search per cross validation the best parameters for the SVM were found to be a rbf-kernel with $C = 100$ and $\gamma = 0.001$ for both tasks.

Results of the SVM for subtask 1.1. are shown in Table 3. Adding entity features proves to be very beneficial compared to using only context features, as we could improve macro-F1 by 12 points on average. Results are further improved by enlarging the data set with the training samples of subtask 1.2 and by adding word embeddings to the feature set. While adding the CC embeddings enhances the micro-F1 by more than 4 points, our domain-adapted arXiv embeddings prove to perform even better and deliver the best result with a macro-F1 score of 74.89% and a micro-F1 of 76.90%.

Similar observations can be made for subtask 1.2., as is pictured in Table 4.

Due to space limitations we publish parameter

⁷<https://poppler.freedesktop.org>

details and elaborate results for the C-LSTM on arXiv.org (Hettinger et al., 2018). In comparison to the SVM, which additionally uses hand-crafted features, the C-LSTM achieves lower scores. For arXiv embeddings it reaches a macro-F1 of 63.3% for the first subtask and 68.0% for the second.

5 Discussion

We briefly discuss our approach during the training phase of the SemEval-Challenge and how label distribution and evaluation measure influences our results. Ahead of the final evaluation phase where the concealed test data D_{test} was presented to the participants we were given a preliminary test partition D_{pre} as part of the training data D_{train} . To be able to estimate our performance we evaluated it on D_{pre} as well as for a 10-fold stratified cross validation setting. We chose this procedure to be sure to pick the best system for submission at the challenge.

As some classes were strongly underrepresented in the training corpus and D_{pre} , we assumed that this is also true for the final test set D_{test} . When in doubt we therefore chose to optimize according to D_{pre} as cross validation is based on a slightly more balanced data set (of train data for subtask 1.1 + 1.2). The best system we submitted for subtask 1.1 of the challenge achieved a macro-F1 of 75.05% on D_{pre} during the training phase which shows that we were able to estimate our final result pretty closely.

During training we also noticed that for heavily skewed class distributions as in this case, macro-F1 as an evaluation measure strongly depends on a good prediction of very small classes. For example, macro-F1 of subtask 1.1 increases by 5 points if we correctly predict one `Topic` instance out of three instead of none. Thus we pick a configuration that optimizes the small classes.

We also omitted some lexical feature sets from our system as performance on the temporary and final test set showed that they did not improve results. These features were hypernyms of context and entity tokens from WordNet and dependency paths between entities. Using tf-idf normalization instead of boolean for lexical features also worsened our results.

6 Conclusion

In this paper, we described our SemEval-2018 Task 7 system to classify semantic relations in sci-

entific literature for clean (subtask 1.1) and noisy (subtask 1.2) data. We constructed features based on relation entities and their context by means of hand-crafted lexical features as well as word embeddings. To better adapt to the scientific domain, we trained scientific word embeddings on a large corpus of scientific papers obtained from arXiv.org. We used an SVM to classify relations and additionally contrasted these results with those obtained from training a C-LSTM model on the scientific embeddings. We were able to obtain a macro-F1 score of 74.89% on clean data and rank 4th out of 28 and 78.39% on noisy data, which resulted in a 6th place out of 20.

In future work, we will improve the tokenization of the scientific word embeddings and also take noun compounds into account, as they make up a large part of the scientific vocabulary. We will also investigate more complex neural network based models, that can leverage additional information, for example relation direction and POS tags. Some minor changes we applied to the feature generation during the post-evaluation phase and which further improved our results by more than 2% are published on arXiv.org together with more detailed evaluation (Hettinger et al., 2018).

Abstract

We describe two systems for semantic relation classification with which we participated in the SemEval 2018 Task 7, subtask 1 on semantic relation classification: an SVM model and a CNN model. Both models combine dense pretrained word2vec features and handcrafted sparse features. For training the models, we combine the two datasets provided for the subtasks in order to balance the under-represented classes. The SVM model performed better than CNN, achieving an F1-macro score of 69.98% on subtask 1.1 and 75.69% on subtask 1.2. The system ranked 7th among 28 submissions on subtask 1.1 and 7th among 20 submissions on subtask 1.2.

1 Introduction

Relation extraction is a traditional information extraction task which aims at detecting and classifying semantic relations between entities in text (Pawar et al., 2017). The task essentially induces structure from unstructured textual information, allowing us to obtain valuable information about the way in which entities interact, thus improving human capacity to analyze (often large) quantities of textual data. Relation extraction is typically framed as a classification task: pairs of entities from a document are inspected and the type of relation is predicted by means of local linguistic cues (Culotta et al., 2006).

Relation extraction has been extensively studied in the literature; see (Konstantinova, 2014) for a comprehensive overview. Etzioni et al. (2008) group the relation extraction approaches into three classes: (1) knowledge-based methods, (2) supervised methods, and (3) self-supervised methods. Traditional approaches mostly relied on shallow machine learning models with handcrafted features (GuoDong et al., 2005) and specific kernel methods (Zelenko et al., 2003). Some systems

leverage unlabeled data to improve classification and use semi-supervised or unsupervised learning (Chen et al., 2006; Hasegawa et al., 2004). The current state of the art is a deep recurrent neural network model by Xu et al. (2016). Most research on relation extraction has leveraged standard benchmark datasets from the ACE (Dodington et al.) and SemEval-2010 Task 8 (Hendrickx et al., 2009).

This paper describes the systems with which we participated in the SemEval 2018 task 7 on Semantic relation extraction and classification in scientific papers. We focused on the subtask 1 (relation classification), which featured two scenarios: 1.1 Relation classification on clean (i.e., manually annotated) data and 1.2 Relation classification on noisy (i.e., automatically annotated) data. Both scenarios start out with pre-extracted entity pairs, which makes the task simpler than relation extraction proper. On the other hand, the task remains challenging because of the choice of the domain: scientific publications abound with complex syntactic structures and rely on specialist terminology, which makes it more difficult to predict the correct relation type. We framed the problem as a supervised classification task and devised two models: a support vector machine (SVM) model, which utilizes a rich set of features combining dense pretrained word2vec features and handcrafted sparse features, and a convolutional neural network (CNN) model. The best result was achieved with the SVM model, which ranked 7th in both scenarios of subtask 1.

2 Dataset

The organizers have provided different training datasets for scenarios 1.1 and 1.2 of subtask 1, each consisting of 350 abstracts of scientific papers from the Natural Language Processing (NLP)

domain (Gábor et al., 2018) to be used for training the models. All entities representing domain concepts (e.g., *word sense disambiguation* and *translation*) are already annotated and listed in pairs according to one of the relations that holds between them. For example, in the sentence “High quality *translation* via *word sense disambiguation* and accurate word order generation of the target language”, the entity *word sense disambiguation* is used for *translation*, hence it is annotated as an instance of the USAGE relation type. There are six distinct relation types: USAGE, TOPIC, COMPARE, MODEL-FEATURE, RESULT, PART-WHOLE. Except for COMPARE, all relations are asymmetric, which means that the direction of relation matters. For this reason, every asymmetrical relation instance has additionally been annotated with the direction of the relation using the “reverse” flag to indicate that the order of entities should be flipped.

The total number of training instances is 1228 and 1248 for subtask 1.1 and subtask 1.2 datasets, respectively. Each instance contains exactly two entities and both appear in the same sentence. The subtask 1.2 dataset uses the same annotation scheme as the first subtask, but the entities are automatically extracted rather than manually annotated, thus introducing noise.

Table 1 shows the breakdown of relation types for the two datasets. In general, the class distribution is rather imbalanced, especially the TOPIC relation, which is heavily under-represented in the dataset for subtask 1.1.

3 System Description

We devised two supervised machine learning models: an SVM with a rich set of features and a CNN model. We next describe these models in more detail.

3.1 SVM Model

Our best-performing model uses an SVM classifier with a combination of sparse and dense features.

Sparse feature encoding. To encode the sparse features, we adopt the method of Chen et al. (2006) who divide the sentence into contexts. In a nutshell, the method consists in describing the context in which the entities occur by dividing the sentence into five contexts around the entity mentions. Two of these five contexts are related to the

entities involved in the relation, while the remaining three contexts represent the words before, between, and after the entity mention pair. Every feature describing a word contains the information about which context it is located in. It also additionally contains the position of the word relative to the start of that context. While this increases the total number of parameters, it also provides information about the word ordering in the context independently of the size of other contexts.

This encoding scheme is used to create features of word tokens, part-of-speech tags, and named entities. Similarly as Chen et al. (2006), who in turn followed Charniak (2000) and Zhang (2004), we experimented with additional constituency parse features describing grammatical functions and chunk tag information for all five contexts, and IOB-chains of the heads of the two entities. However, as preliminary experiments showed that these additional features do not provide any performance gains, we decided not to include them in our final models, intending to evaluate these results in future work.

Word windows. In the scientific domain sentence structures may be very complex, increasing the distance between the two entity mentions. This presents a considerable problem for sparse feature encoding of the context between two entities: as there the features are encoded for each word separately, the increase in distance yields a proportional increase in the number of parameters, which may cause overfitting. To mitigate this problem, instead of representing the contexts for the whole sentence, we use word windows that focus on the words around the entity mentions. Based on preliminary experiments, we decided to use different sizes of word windows for before, between, and after contexts: the window size for the context in between the entities is a maximum of eight words (at most four on the side of each entity; for longer distance the middle words get ignored), while the window size of the before and after contexts is at most two words to the left and right, respectively. The rationale for this is the assumption that words indicative of relation type are more likely to lie in between and close to one of the two entities.

Dependency features. Many systems from the literature make use of dependency features (Nguyen and Grishman, 2015a; Xu et al., 2016, 2015), which, intuitively, should be useful for re-

Relation type	Subtask 1.1			Subtask 1.2			Combined
	Regular	Reversed	All	Regular	Reversed	All	
USAGE	296	187	483	323	147	470	953
TOPIC	8	10	18	230	13	243	261
COMPARE	95	–	95	41	–	41	136
MODEL-FEATURE	226	100	326	123	52	175	501
RESULT	52	20	72	85	38	123	195
PART-WHOLE	158	76	234	117	79	196	430
Total	835	393	1228	919	329	1248	2476

Table 1: Class distribution in subtask 1 training datasets for scenario 1.1 (clean annotation) and scenario 1.2 (noisy annotation). Last column shows the combined counts of both datasets.

lation extraction and classification. Specifically for the relation classification task, we are interested in the connection between the two entities involved in a relation within an instance. Thus, after performing a dependency parse of the whole sentence in which the relation appears, we find the shortest dependency path between the two entities. As demonstrated by Xu et al. (2016), the shortest dependency path between two entities is advantageous over a raw word sequence or a whole parse tree, because it reduces irrelevant information and because the shortest path dependency relations focus on the action and agents in a sentence and are thus naturally suitable for relation classification. The dependency parsing was done using the SpaCy parser.¹

Considering that the edges on the shortest dependency path also have directions, we split the path into two sub-paths based on the edge direction. Usually, the first path goes from the first entity node towards the lowest common ancestor in the dependency parse tree, while the other path goes downwards to the second entity from the ancestor node. Then, each sub-path is encoded into a series of one-hot sparse features that represent the edge dependency type and the distance of the edge from the starting point. Preliminary experiments showed that these features lead to substantial performance improvement.

Word embeddings and OOV words. To capture the semantic meaning of the words we used 300-dimensional pre-trained Google word2vec word embeddings.² In accordance with standard practice, which leverages the additive compositionality of word embeddings (Gittens et al., 2017), we represent each context as a sum of its word embeddings. As we divided the sentence

into five context, the result is five vectors, which are subsequently concatenated into a single 1500-dimensional vector.

Using a pre-trained word2vec model combined with a scientific domain dataset led to many out-of-vocabulary (OOV) words. After some very basic word preprocessing, e.g., handling of hyphens and underscores, 1108 out of 9319 unique words from the datasets (combined datasets of subtasks 1.1. and 1.2) remained uncovered by the word2vec model. To tackle the OOV problem, we experimented with a fallback mechanism based on the context2vec (Melamud et al., 2016), an off-the-shelf lexical substitution system. Our idea was to retrieve the lexical substitutes for each OOV word³ and retrieve their vectors instead – a technique akin to query expansion in information retrieval. We experimented with a number of variants of this method, however as none led to performance improvements, we decided not to include lexical substitution fallback in the final model.

Reversed relations. We use a boolean feature to indicate the reverse direction of a relation in an instance, as provided in the training datasets. With the addition of that feature the model can more easily differentiate between the regular and reversed instances of a class. We expand the number of classes from the initial six types of relations to include reversed relations as distinct classes, resulting in an 11-way classification model. The results obtained this way were better than using a 6-way classification model; while this appears counter-intuitive, we leave a more thorough investigation for future work. Once the predicted classes are obtained, we map regular and reversed relation types into one class, as in the original task.

Considering that COMPARE relation cannot be

¹<https://spacy.io/>

²<https://code.google.com/archive/p/word2vec/>

³A lexical substitute is a meaning-preserving replacement of a word in its context.

reversed, we perform a post-prediction correction if a relation instance has an active reverse flag in the test set but the model predicted the instance to be of the COMPARE class. In this case, we change the prediction for that instance to be the second most probable class according to the predicted class probabilities.

3.2 CNN model

Motivated by the high performance that deep learning techniques have achieved in this area (Kumar, 2017), we experimented with a convolutional neural network (CNN) model. This model outperforms traditional feature-engineered approaches on relation extraction benchmarks, as shown by Nguyen and Grishman (2015b).

Architecture. The idea behind the use of a CNN model is to use the convolutional layer to capture the local content and meaning of a few consecutive words, depending on the size of the convolution kernel. Our CNN model comprises a single convolution layer connected to a max-pooling layer. As proposed by Nguyen and Grishman (2015b), pooling is followed by a dropout layer, which has been shown to work well in fully-connected layers (Hinton et al., 2012; Wan et al., 2013; Krizhevsky et al., 2012). We use the softmax function at the output layer activation function. The model is implemented using TensorFlow.⁴

Features. The CNN model uses the same pre-trained word2vec embeddings as the SVM model. Since the training data is limited, the word embeddings are kept static and not adjusted during training. In addition to word embeddings, the model is fed as input the position of words relative to the entities. In this way, the model is provided with the information on the positions of entities and the distance of context words, which could affect their relevance for predicting the relation type (Nguyen and Grishman, 2015b). Thus, each word has two position features: (1) a relative distance to the closest word for the first entity and (2) a relative distance to the closest word for the second entity. Position embeddings are randomly initialized to 50-dimensional vectors and are shared for the two entities. Unlike with the word embeddings, the position embeddings are adjusted during training. The assumption is that this relative

distance from the entity mentions is inversely proportional to the importance of words. In line with this assumption, we capped the distance values at 15, as words at longer distances are likely not to have much effect on relation type.

Another feature that we added is the information about the shortest dependency path, as described by Nguyen and Grishman (2015a). Assuming that words from the shortest dependency path are more relevant than others, we add for each word a boolean value feature indicating whether that word belongs to the shortest dependency path. We also use an additional indicator feature to distinguish the relation instances with the REVERSE attribute, even though the CNN model has been trained as a 6-way classifier. All the features pertaining to a word are concatenated and considered as a single element when passed to the first layer of the network.

Lastly, we include word windows into the CNN model, in the same manner as we did for the SVM model, but this time increasing the window sizes of contexts around the entities, as this has less of an effect on the number of parameters than it was the case for the SVM model. Thus, we set the window size for between context to four words from each side, while the window size of before and after contexts has been set to the five words closest to the entities. For clarification, word windows simply decide the size of the sentence (not to be confused with position features, which embed previously discussed distances of each word inside the window).

4 Evaluation and Results

As subtask 1.1 and 1.2 are very similar and differ only in how the labeling was carried out (manual or automatic), we decided to combine the training sets of the two tasks in one training set. This allowed us to increase the number of instances for the TOPIC relation type, which was severely under-represented in subtask 1.1 training set (cf. Table 1).

The hyperparameters for the SVM model were selected using cross-validated grid search. The CNN model was trained using early stopping with batch size of 64. Kernel sizes of the convolution layers are 3, 4, and 5 words, each size having 32 kernels. Adam algorithm was used for the model optimization. A dropout rate of 0.5 was used during the training.

⁴<https://www.tensorflow.org/>

Test set	Model	P	R	F1
Subtask 1.1	SVM	64.64	75.57	69.68
	CNN	63.35	72.42	67.58
Subtask 1.2.	SVM	71.64	80.24	75.69
	CNN	14.78	15.81	15.28

Table 2: Relation classification results

The evaluation was performed on the test sets provided by the task organizers. Each test set is comprised of 150 scientific paper abstracts with 350 relation instances. Table 2 shows macro-averaged precision, recall, and F1 score for the two models on the two test sets.

Differently from previous findings (Nguyen and Grishman, 2015b), in our case the SVM outperformed the CNN model. This might be explained by the relatively small size of the training set. On subtask 1.1, the CNN performs slightly worse than the SVM model, while it fails completely on the second subtask. We presume this might be due to an implementation error, but we were unable to identify the problem. In the official SemEval competition, the SVM model ranked 7th among 28 submissions on subtask 1.1 and 7th among 20 submissions on subtask 1.2.

5 Conclusion

We described two models for relation classification with which participated in the SemEval-2018 Task 7, subtasks 1.1 and 1.2 on relation classification: an SVM model and a CNN model. Our models combine sparse, handcrafted features and dense features based on word embeddings. Although deep learning models currently excels at relation extraction tasks, in our case, probably due to the small relatively small training set available, SVM outperformed the CNN model, ranking 7th in both evaluation runs. Overall, the tasks proved to be very challenging, mainly due to the peculiarities of the domain.

For future work, we intend to retrain our models on a larger dataset using distant supervision based on publicly available scientific corpora, and also experiment with training domain-specific word2vec embeddings.

dragoni@fbk.eu

Abstract

Discovering semantic relations within textual documents is a timely topic worthy of investigation. Natural language processing strategies are generally used for linking chunks of text in order to extract information that can be exploited by semantic search engines for performing complex queries. The scientific domain is an interesting area where these techniques can be applied. In this paper, we describe a system based on neural networks applied to the SemEval 2018 Task 7. The system relies on the use of word embeddings for composing the vectorial representation of text chunks. Such representations are used for feeding a neural network aims to learn the structure of paths connecting chunks associated with a specific relation. Preliminary results demonstrated the suitability of the proposed approach encouraging the investigation of this research direction.

1 Introduction

One of the emerging trends of natural language technologies is their application to scientific literature. There is a constant increase in the production of scientific papers and experts are faced with an explosion of information that makes it difficult to have an overview of the state of the art in a given domain. Recent works from the semantic web, scientometry, and natural language processing (NLP) communities aimed to improve the access to scientific literature, in particular to answer queries that are currently beyond the capabilities of standard search engines. Examples of such queries include finding all papers that address a given problem in a specific way, or to discover the roots of a certain idea.

The NLP tasks that underlie intelligent processing of scientific documents are those of information extraction: identifying concepts and recognizing the semantic relation that holds between

them. Information extraction from corpora including relation extraction and classification normally involves a complicated multiple-step process.

In this paper, we present a neural network strategy for addressing the challenge of extracting informative entities from scientific papers and inferring their semantic relation among a set of six alternatives. This challenge is part of the SemEval 2018 Task 7 (Gábor et al., 2018). One of the pillars of the proposed approach is that the word embeddings used for representing the text within the neural network have been generated from a corpus containing only scientific papers instead of a general purpose one, like news repositories or Wikipedia.

2 System Implementation

NeuroSent has been entirely developed in Java with the support of the Deeplearning4j library¹ and it is composed by following two main phases:

- Generation of Word vectors (Section 2.1): raw text, appropriately tokenized using the Stanford CoreNLP Toolkit, is provided as input to a 2-layers neural network implementing the skip-gram approach with the aim of generating word vectors.
- Learning of Relations Model (Section 2.2): word vectors are used for training a recurrent neural network (RNN) (Gelenbe, 1993) with an output layer containing one node for each type of relation supported by the model. We decided to use RNN due to the necessity of working with input information provided through a sequence of input instances (i.e. the ordered arrays of embeddings corresponding to each word of the text to analyze).

¹<https://deeplearning4j.org/>

In the following subsections, we describe in more detail each phase by providing also the settings used for managing our data.

2.1 Generation of Word Vectors

The generation of the word vectors has been performed by applying the skip-gram algorithm on the raw natural language text extracted from a collection of 2,459,264 scientific papers collected from proceedings of past conferences and journals. In particular, we used the text extracted from the papers contained within the ACM Digital library, IEEE Xplore and Springer LNCS website. The rationale behind the choice of this dataset focuses on two reasons:

- the dataset contains only scientific documents. This way, we are able to build word embeddings focused on the scientific context.
- the dataset is smaller with respect to other corpora used in the literature for building other word embeddings that are currently freely available, like the Google News ones.² Indeed, as introduced in Section 1, one of our goal is to demonstrate how we can leverage the use of dedicated resources for generating word embeddings, instead of corpora's size, for improving the effectiveness of classification systems.

These two points represent the main original contributions of this work, in particular the aspect of considering only scientific information for generating word embeddings. While embeddings currently available are created from big corpora of general purpose texts (like news archives or Wikipedia pages), ours are generated by using a smaller corpus containing documents strongly related to the problem that the model will be thought for. On the one hand, this aspect may be considered a limitation of the proposed solution due to the requirement of training a new model in case of problem change. However, on the other hand, the usage of dedicated resources would lead to the construction of more effective models.

Word embeddings have been generated by the Word2Vec implementation integrated into the Deeplearning4j library. The algorithm has been set up with the following parameters: the size of

²<https://github.com/mmihaltz/word2vec-GoogleNews-vectors>

the vector to 64, the size of the window used as input of the skip-gram algorithm to 5, and the minimum word frequency was set to 1. The reason for which we kept the minimum word frequency set to 1 is to avoid the loss of rare but important words that can occur in specific documents.

2.2 Learning of The Relations Model

The relations model is built by starting from the word embeddings generated during the previous phase.

The first step consists in converting each textual sentence contained within the dataset into the corresponding numerical matrix \mathbf{S} . Given a sentence s , we extract all tokens t_i , with $i \in [0, n]$, and we replace each t_i with the corresponding embedding \mathbf{w} . During the conversion of each word in its corresponding embedding, if such embedding is not found, the word is discarded. At the end of this step, each sentence contained in the training set is converted in a matrix $\mathbf{S} = [\mathbf{w}^{(1)}, \dots, \mathbf{w}^{(n)}]$.

Before giving all matrices as input to the neural network, we need to include both padding and masking vectors in order to train our model correctly. Padding and masking allows us to support different training situations depending on the number of the input vectors and on the number of predictions that the network has to provide at each time step. In our scenario, we work in a many-to-one situation where our neural network has to provide one prediction as result of the analysis of many input vectors (word embeddings).

Padding vectors are required because we have to deal with the different length of sentences. Indeed, the neural network needs to know the number of time steps that the input layer has to import. This problem is solved by including, if necessary, into each matrix \mathbf{S}_k , with $k \in [0, z]$ and z the number of sentences contained in the training set, null word vectors that are used for filling empty word's slots. These null vectors are accompanied by a further vector telling to the neural network if data contained in a specific positions has to be considered as an informative embedding or not.

A final note concerns the back propagation of the error. Training recurrent neural networks can be quite computationally demanding in cases when each training instance is composed by many time steps. A possible optimization is the use of truncated back propagation through time (BPTT) (Werbos, 1990) that was developed for re-

ducing the computational complexity of each parameter update in a recurrent neural network. On the one hand, this strategy allows to reduce the time needed for training our model. However, on the other hand, there is the risk of not flowing backward the gradients for the full unrolled network. This prevents the full update of all network parameters. For this reason, even if we work with recurrent neural networks, we decided to do not implement a BPTT approach but to use the default backpropagation implemented into the DL4J library.

Concerning information about network structure, the input layer was composed by 64 neurons (i.e. embedding vector size), the hidden RNN layer was composed by 128 nodes, and the output layer contained 6 nodes, one for each relation (described in Section 3). The network has been trained by using the Stochastic Gradient Descent with 1000 epochs and a learning rate of 0.002.

3 The Tasks

The SemEval 2018 Task 7 is composed by two different subtasks concerning the identification and classification of semantic relations. For the first subtask the participants had to identify pairs of entities that are instances of any of the six semantic relations. This was an extraction task. While for the second subtask, participants had to classify extracted instances into one of the six semantic relation types. This was a classification task.

The six semantic relations subject of this task are the following.

- **USAGE**: this is an asymmetrical relation holds between two entities X and Y, where, for example: “X is used for Y”.
- **RESULT**: this is an asymmetrical relation holds between two entities X and Y, where, for example: “X gives as a result Y” (where Y is typically a measure of evaluation).
- **MODEL-FEATURE**: this is an asymmetrical relation holds between two entities X and Y, where, for example: “X is a feature/an observed characteristic of Y”.
- **PART-WHOLE**: this is an asymmetrical relation holds between two entities X and Y, where, for example: “X is a part, a component of Y”.

- **TOPIC**: this is an asymmetrical relation holds between two entities X and Y, where, for example: “X deals with topic Y” or “X (author, paper) puts forward Y” (an idea, an approach).
- **COMPARE**: this is a symmetrical relation holds between two entities X and Y, where “X is compared to Y” (e.g. two systems, two feature sets or two results).

Below, we briefly described the two subtasks composing the SemEval 2018 Task 7.

Subtask #1: Relation classification The subtask is decomposed into two scenarios according to the data used: classification on clean data and classification on noisy data.

For this subtask, instances with directionality are provided in both the training data and the test data and they are not to be modified or completed in the test data.

This subtask was then split in two separated activities.

1.1 *Relation classification on clean data.* The classification task is performed on data where entities were manually annotated following the ACL RD-TEC 2.0 guidelines³. Entities represent domain concepts specific to NLP, while high-level scientific terms (e.g. “hypothesis”, “experiment”) are not annotated.

1.2 *Relation classification on noisy data.* This activity is identical to the previous one with the difference is that the entities are annotated automatically and contain noise. The annotation comes from the ACL-RelAcS corpus⁴ (Gábor et al., 2016) and it is based on a combination of automatic terminology extraction and external ontologies. Entities are therefore terms specific to the given corpus, and include high-level terms (e.g. “algorithm”, “paper”, “method”). Relations were manually annotated in the training data and in the gold standard, between automatically annotated entities.

Subtask #2: Relation extraction and classification This subtask combines the extraction task and the classification task. The training data for

³<https://lipn.univ-paris13.fr/gabor/Relacs/>

⁴<http://pars.ie/publications/papers/pre-prints/acl-rd-tec-guidelines-ver2.pdf>

this scenario is the same that is used for the previous subtask, i.e. manually annotated entities, semantic relations with relation types between these entities. The test data contains different abstracts than the previous subtask and only entity annotations were provided. For the extraction task, participants need to identify pairs of entities in the abstracts that correspond to an instance of any of the six relations. While, for the classification task, relation labels of the extracted relations need to be predicted similarly to Subtask #1.

The NeuroSent system has been applied to both subtasks. In Section 4, we report the preliminary results obtained by NeuroSent on the training set compared with a set of baselines.

4 In-Vitro Evaluation

Approach	Task #1.1	Task #1.2
Support Vector Machine	0.4534	0.4551
Naive-Bayes	0.4788	0.4787
Maximum Entropy	0.4917	0.4892
CNN Architecture	0.5329	0.4918
NeuroSent	0.5572	0.5749

Table 1: Results obtained on the training set by NeuroSent and by the four baselines for the Task#1.

Approach	Task #2.1	Task #2.2
Support Vector Machine	0.3591	0.3498
Naive-Bayes	0.3842	0.3658
Maximum Entropy	0.3982	0.3755
CNN Architecture	0.4103	0.3814
NeuroSent	0.4274	0.4009

Table 2: Results obtained on the training set by NeuroSent and by the four baselines for the Task#2.

Approach	Task #1.1	Task #1.2
ETH-DS3Lab	0.817	0.904
NeuroSent	0.180	0.218

Table 3: Results obtained on the test set by NeuroSent and by the best system of Task#1.

The NeuroSent approach have been preliminarily evaluated by adopting the Dranziera protocol (Dragoni et al., 2016). This protocol, even if it was thought for the sentiment analysis task, can be easily adapted to any NLP task.

Approach	Task #2.1	Task #2.2
ETH-DS3Lab	0.488	0.493
UWNLP	0.500	0.391
NeuroSent	0.256	0.031

Table 4: Results obtained on the test set by NeuroSent and by the best systems of Task#2.

The validation procedure leverage on a five-fold cross evaluation setting in order to validate the robustness of the proposed solution. The approach has been compared with four baselines:

- Support Vector Machine (SVM): classification was run with a linear kernel type by using the Libsvm (Chang and Lin, 2011). Libsvm uses a sparse format so that zero values do not need to be captured for training files. This can cause training time to be longer, but keeps Libsvm flexible for sparse cases.
- Naive Bayes (NB) and Maximum Entropy (ME): the MALLET: MACHine Learning for Language Toolkit (McCallum, 2002) was used for classification by using both Naive Bayes and Maximum Entropy algorithms. For the experiments conducted in our evaluation, the Maximum Entropy classification has been performed by using a Gaussian prior variance of 1.0.
- Convolutional Neural Network (Chaturvedi et al., 2016) (CNN): we compared our architecture with a classic CNN. Models have been trained with the embeddings created from the Blitzer dataset.

Tables 1 and 2 show the results obtained on Tasks #1 and #2 respectively. In each table, we provide averaged F1-Score obtained on the five folds in which the training set has been split.

We performed a detailed error analysis concerning the performance of NeuroSent. In general, we observed how our strategy tends to provide false negative predictions. Unfortunately, on the test set our approach obtained significant worse results with respect to the other systems participated to the competition (Tables 3 and 4). We are investigating about the reasons of these low performance.

On the one hand, a possible action for improving the effectiveness our strategy is to increase the granularity of the embeddings (i.e. augmenting the size of the embedding vectors) in order

to increase the distance between the space regions of each kind of relation. On the other hand, by increasing the size of embedding vectors, the computational time for building, or updating, the model and for evaluating a single instance increases as well. Part of the future work, will be the analysis of more efficient neural network architectures able to manage augmented embedding vectors without negatively affecting the efficiency of the platform.

5 Conclusion

In this paper, we described the NeuroSent system presented at SemEval 2018 Task 7. Our system makes use of artificial neural networks to extract relevant text chunk from scientific documents and to label pairs of them with semantic relation tags. Obtained results demonstrated the suitability of NeuroSent with respect to the adopted baselines. We may also observed how solutions based on neural networks obtained a significant improvement with respect to the others for both tasks. Future work will focus on improving the system by exploring the integration of knowledge bases (Dragoni et al., 2015) in order to move toward a more cognitive approach.

SciREL at SemEval-2018 Task 7: A System for Semantic Relation Extraction and Classification

Darshini Mahendran Chathurika S. Wickramasinghe Bridget T. McInnes
Virginia Commonwealth University, Richmond, Virginia
{mahendrand, brahmanacsw, btmcinnes}@vcu.edu

Abstract

This paper describes our system, SciREL (Scientific abstract RELation extraction system), developed for the SemEval 2018 Task 7: Semantic Relation Extraction and Classification in Scientific Papers. We present a feature-vector based system to extract explicit semantic relation and classify them. Our system is trained in the ACL corpus (Bird et al., 2008) that contains annotated abstracts given by the task organizers. When an abstract with annotated entities is given as the input into our system, it extracts the semantic relations through a set of defined features and classifies them into one of the given six categories of relations through feature engineering and a learned model. For the best combination of features our system SciREL obtained an F-measure of 20.03 on the official test corpus in the relation classification Subtask 1.1. In this paper, we provide an in-depth error analysis of our results to prevent duplication of research efforts in the development of future systems.

1 Introduction

Automatic detection and extraction of semantic relations among the entities from unstructured text has received growing attention in the recent years (Konstantinova, 2014), (Augenstein et al., 2017), (Fundel et al., 2006), (Luo et al., 2016). Text mining is the process of automatically extracting knowledge from unstructured text documents and this idea of text mining is to link extracted information together which possibly results in new facts or hypothesis to be explored further through conventional scientific experimentations (Delen and Crossland, 2008), (Fleuren and Alkema, 2015).

SemEval 2018 Task 7 (Gábor et al., 2018) aims to extract and classify semantic relations to improve the access to scientific literature. Their tasks

focus on identifying pairs of entities that are instances of six semantic relation types and classifying those instances into one of the six semantic relation types. To address this challenge, we implemented a supervised machine learning based approach in order to extract explicit semantic relations from the ACL anthology corpus (Bird et al., 2008) for Subtask 1.1.

2 Methodology

In this section, we describe our relation extraction system (SciREL) which classifies the semantic relations into one of the given six categories of relations. The main steps of our approach can be summarized as follows. First, an abstract with annotated entities is given as the input into our system and all the sentences in the abstract are segmented, preprocessed, and the entity pairs are identified. Second, a set of features are defined and are combined into a feature vector which is used to train a machine learning model. This is the most crucial part of our system, as the idea is to decrease the size of the effective vocabulary which would in turn increase the classification accuracy by eliminating the noise in the features (GuoDong et al., 2005). Relations between entities are extracted and classified into one of the six relations through this learned model. Each step of our approach is discussed in detail in the following subsections.

2.1 Preprocessing Steps

All sentences in the abstracts are preprocessed to normalize the text so that the input text is guaranteed to be consistent and feature extraction/classification is simplified. Some of the existing NLP techniques and tools are used for preprocessing. Preprocessing is performed as follows ¹:

¹Natural Language Toolkit's (NLTK) Tokenizers, part-of-speech (POS) tagger and Porter Stemmer are used in text preprocessing.

1) tokenization; 2) convert text to lower case; 3) removal of special characters; and 4) lemmatization.

2.2 Feature selection

The most challenging part of our system is the feature selection and the feature vector generation (Sammons et al., 2016). After preprocessing the input text, a subset of words which contain the respective entity pair are selected from each sentences, a set of features are computed and a feature vector is created by combining the computed features.

After the initial text processing, a separate set of steps are followed where each feature is computed. Some features are extracted in two different scenarios: before removing the stop words and after removing the stop words. Stop words are the most common words of the language that do not contribute to the semantics of the documents or contain any significance but has a high frequency. Filtering out such words prevents from returning vast amount of unnecessary information.

Bigram is a sequence of words formed from two adjacent words, and bigram frequency of the word pairs between entities is calculated in some features. Collocations² are words that appear successively and the frequencies of such words appearing in the the context of other words are calculated in some features and the highest value of the bigram collocations is considered during the feature selection. The bag-of-words model which represents a text as the bag of its words, ignoring its grammar and word order is used in some features to group the words from the sentence for further processing (Peng et al., 2016).

Part-of-speech tagging (POS tagging) is applied on words in some features which assigns parts of speech to those words (Fundel et al., 2006). This helps in disambiguating homonyms and improving the efficiency of feature selection. Term frequency-inverse document frequency (TF-IDF) values are calculated for a set of selected words in some features to distinguish important words based on how frequently they appear across multiple documents (GuoDong et al., 2005). During the feature selection, a representative set of features is computed for each entity pair. Features used in building our system are listed below; E1 refers to

the first entity and E2 refers to the second entity.

1. Number of words before E1 with / without stop words
2. Number of words after E2 with / without stop words
3. Word before E1
4. Word after E2
5. POS of the words before E1 with / without stop words
6. POS of the words after E1 with / without stop words
7. POS of the words before E2 with / without stop words
8. POS of the words after E2 with / without stop words
9. Bigram of the first word before E1 with / without stop words
10. Bigram of the first word after E2 with / without stop words
11. Bigram of E1
12. Bigram of E2
13. Highest bigram value of words in between entities with / without stop words
14. Number of unique POS types in between the entities with / without stop words
15. Number of unique POS types before E1 with / without stop words
16. Number of unique POS types after E2 with / without stop words
17. POS type of the word with highest tf-idf score in between the entities
18. POS type of the word with highest tf-idf score in before E1
19. POS type of the word with highest tf-idf score in after E2

2.3 Multi-class classification

In the final step of our approach, a feature vector is generated for each sentence by incorporating the extracted features in the previous step. The generated feature vector is then used to train a classifier which classifies the relation into the given six categories. The following classifiers which represent three main classification algorithms are used to train and evaluate the data set in our approach:³ Decision Trees, Naive Bayes, and Support Vector Machines (SVMs). The resulting model is then used to classify the extracted semantic relations into one of the six categories below: Usage, Result, Model-feature, Part-whole, Topic, Compare.

²Natural Language Toolkit's (NLTK) bigramcollocation-finder is used.

³Natural Language Toolkit's (NLTK) scikit-learn library classifiers are used.

3 Dataset

We evaluated our system on the dataset provided by the SemEval 2018 - Task 7. The dataset contains abstracts from the ACL Anthology Corpus (Bird et al., 2008) with pre-annotated entities that represent concepts. The dataset provided for the evaluation is divided into two subsets: training set and test set. The training set includes 350 abstracts containing 5259 entities and 1228 annotated types of relations between entities. The test set includes 150 abstracts containing 2246 entities and 355 annotated types of relations between entities. During the development, the training set is split into 60/40 and k-fold cross validation was used to evaluate the performance.

4 Results

Our system was evaluated on both the development corpus and the official test corpus and the set of features are extracted for each entity pair from the training corpus which was used to compute the feature vector. The feature set of our model included 37 features in total which resulted in 2^{37} combinations of features. We conducted an ablation study to determine the efficacy of the different combinations of features when run with different classifiers and selected the feature combination that resulted in high performance. Consequently, it was found that the following features produce the best performance:

1. Lexical information

- Bigram of the first word after E1 with stop words
- Bigram of the first word before E2 without stop words
- Highest bigram value of words in between entities with stop words
- Highest bigram value of words in between entities without stop words

2. Syntactic information

- POS of the word before E2 with stop words
- Number of unique POS types in between the entities with stop words
- Number of unique POS types in between the entities without stop words

Validation was performed using 60/40 split evaluation. Performance of each classifier was

	Development	Test
Accuracy	48.07	
F1-measure	29.25	20.03
Precision	34.29	20.58
Recall	28.55	20.03

Table 2: Confusion matrix of the model trained on the official test corpus where the predicted tags are horizontal and the actual tags are vertical.

measured by the following commonly used evaluation metrics: Accuracy, F-measure, Precision, Recall. Our model was evaluated using three classifiers and it was found that SVMs is the most suitable classifier for our approach through a set of experiments. The results for our development corpus and the official test corpus are presented in the Table 1.

From the Table 1 we can see that our system (SciREL) achieves the accuracy of 48.07 and the F-measure of 29.25 on the development corpus which includes 350 abstracts and the F-measure of 20.03 on the official test corpus which includes 150 abstracts.

5 Error analysis

The performance of our system is quite low therefore, we performed an error analysis to identify some of the mistakes from our system output and find ways to improve it. Our classification model was trained to distinguish between six semantic relations and the confusion matrix displays the results of testing the model for further inspection. Table 2 shows the confusion matrix based on the performance of our classification model trained on the test corpus. We identified three main areas which affected the performance of our system: 1) feature selection; 2) vector representation; and 3) class imbalance.

Feature Selection. We compared the effects of different features and from this analysis, we found several reasons for their poor performance. First,

for the lexical information, we are only incorporating the word prior to each of the entities and a single bigram that exists between them. This misses information such as if there is only a single word in between the entities, and in the case where there are more than two words, we miss additional contextual information describing the relationship. Second the syntactic information does not contain an explicit representation of what was seen between the two entities. We focused on the number of unique types of POS tags rather than what type of tags were actually present. In conclusion, we believe that our feature set does contain enough contextual information from between the two entities.

Vector representation. Another major reason for the poor performance of our system is the way the feature vectors are representing the relationship. We generated a feature vector for each entity pair and for all the proposed features which resulted in a feature vector with only 37 features initially. Then, we selected the best set of features that gave the best performance with the model and eliminated the rest, which reduced the size of the feature vector further and we ended up with the feature vector that contained only 7 features. Each feature was represented numerically, therefore if there were more than one bigram, or POS tag sequence between the entities, we were not able to incorporate it into our representation. In addition, analysis of the test instances show that for 100 of the 355 instances, we do not have any contextual or syntactic information due to the stop word removal for three of the features. In conclusion, we believe that this feature vector representation is too compact and does not hold sufficient contextual information to identify patterns between the relationships.

Class Imbalance. From Table 2, we can see most of the instances of the USAGE class are correctly classified and most of the misclassified instances are classified under PART-WHOLE and RESULT. Most of the instances that should have been classified under PART-WHOLE are classified under USAGE and RESULT. None of the instances of the class COMPARE are classified correct and again most of them are classified under the class USAGE. A similar behavior is observed with TOPIC where almost all instances are classified under USAGE. Reason for this observation is mainly due to the imbalanced na-

	U	MF	PW	R	C	T
number of instances	175	66	70	20	21	3
F-measure	59.50	7.14	26.56	8.93	0	16.22

Table 3: Number of instances and the F-measure of the given six classes on the official test corpus where U - USAGE, MF- MODEL-FEATURE, PW- PART-WHOLE, R- RESULT, C- COMPARE, T- TOPIC.

ture of the dataset used to train our system. The number of instances belonging to the classes USAGE, MODEL-FEATURE and PART-WHOLE is approximately five times larger than the number of instances of the rest of the classes. For comparison purposes, we have provided the number of instances of each class and their individual F-measures in the Table 3. From the results, we can clearly see that USAGE which is the majority class shows high performance compared to other categories. In conclusion, we can say most of the misclassified instances belong to the category of USAGE indicating that the machine learning algorithm was unable to identify discriminating features between the classes and defaulted to the majority class.

6 Conclusions

Our goal is to design a system that identify pairs of entities that are instances of any of the given semantic relations. Our system (SciREL) is built to serve this purpose, so that when an input with annotated entities is fed into the model it identifies, extracts and classify the semantic relations. The model selects the set of features that shows the best performance with the classifier and combines the features to compute a feature vector. The classifier then classifies the instances into one of the six semantic relation types. Our system classifies the given ACL anthology corpus with the F-measure of 20.03 on the official test corpus with the SVM classifier. Due to the low results, we provide an in-depth error analysis of our results to prevent duplication of research efforts in the development of future systems. We identified three main areas which affected the performance of our system: 1) feature selection; 2) vector representation; and 3) class imbalance. In conclusion, we believe our feature set does contain enough contextual information from between the two entities and the feature vector representation is too compact to hold sufficient contextual information to discriminate between the classes.

Abstract

The paper presents NTNU's contribution to SemEval-2018 Task 7 on relation identification and classification. The class weights and parameters of five alternative supervised classifiers were optimized through grid search and cross-validation. The outputs of the classifiers were combined through voting for the final prediction. A wide variety of features were explored, with the most informative identified by feature selection. The best setting achieved F_1 scores of 47.4% and 66.0% in the relation classification subtasks 1.1 and 1.2. For relation identification and classification in subtask 2, it achieved F_1 scores of 33.9% and 17.0%,

(Gábor et al., 2016; Augenstein et al., 2017), quantitative variables (Marsi et al., 2014) or events (Barik et al., 2017), and are syntactically represented by noun phrases, clauses or larger complex structures. A semantic relation may be either symmetric (undirected) or asymmetric (hierarchical).

Supervised machine learning approaches have been successfully used for identifying semantic relations encoded in texts. Broadly, three types of supervised approaches to relation extraction have been investigated: *feature-based* (Kambhatla, 2004; Jiang and Zhai, 2007), *kernel-based* (Zelenko et al., 2003), and *neural network based* (Zeng et al., 2014; Miwa and Bansal, 2016).

In this work, various relation identification and classification subtasks of SemEval 2018 Task 7 (Gábor et al., 2018) were addressed using feature-based approaches. A wide variety of features was explored, including lexical (e.g., bag-of-words, lemmata, n-grams), syntactic (e.g., part-of-speech, parsing information), semantic (e.g., dependency information, WordNet (Miller, 1995)), and other binary indicators. A χ^2 -based feature selection technique was used to identify informative features. The class weights and parameters of five different classifiers—Support Vector Machines (SVM), Decision Trees (DT), Random Forests (RF), Multinomial Naïve Bayes (MNB), and k-Nearest Neighbor (kNN)—were optimized for each subtask through grid search and k -fold cross-validation. These classifiers were chosen as they are effective in identifying and classifying semantic relations in feature-based classification scenario (Barik and Marsi, 2017). The trained classifiers were ensembled using majority class labels (hard voting) for the final predictions. All classifier, feature selection and classifier ensembling modules used were implemented in the `scikit-learn` (Pedregosa et al., 2011) machine learning library.

1 Introduction

Scientific papers are valuable knowledge sources providing authentic insights about certain aspects of the research domains. With the advancement of scientific research, a massive growth of published articles are observed. As per the American Journal Experts (AJE) scholarly publishing report¹, approximately 2.2 million articles were added to the literature in 2016 only. The sheer volume of the ever increasing literature of any scientific discipline makes it hard for human capability and expertise to quickly process and identify information of interest. Therefore, there is a need to efficiently exploit automatic means of accessing this reliable unstructured knowledge repository.

Semantic relation extraction is one of the main information extraction tasks, and aims to identify a pair of arguments connected by certain predefined relation types based on a target application. The relation arguments are of different types such as Named Entities (Freitas et al., 2009), nominals (Hendrickx et al., 2009), general keyphrases

Table 1: Relation type statistics in datasets D_1 and D_2

The tasks and the datasets are described in Section 2, while Section 3 outlines the experimental setup, system architecture and parameter optimisation. Section 4 discusses the results of the final evaluation of SemEval 2018 Task 7, where the system achieved 47.4% and 66.0% F_1 scores on the relation classification subtasks 1.1 and 1.2. In subtask 2, the system reached 33.9% and 17.0% F_1 scores for relation identification and relation classification, respectively. These results are elaborated on in Section 5, before Section 6 concludes and points to future research.

2 Task and Dataset Description

SemEval 2018 Task 7 (Gábor et al., 2018) consisted of two main relation extraction subtasks:

- identifying entity mentions related with any predefined set of relation (Subtask 2), and
- classifying them into specific relation types (Subtasks 1.1, 1.2, and 2).

There are six relation types, among which USAGE, RESULT, MODEL-FEATURE, PART-WHOLE, and TOPIC are asymmetric, while COMPARE is the only symmetric relation. All the relations are intra-sentential and there are no referring expressions.

The training dataset consisted of two subsets:

D_1 : 350 abstracts of scientific papers that have been manually annotated with entity mentions and relation labels (*clean data*), and

D_2 : 350 abstracts with entity mentions automatically labelled, but with the relations labelled manually (*noisy data*).

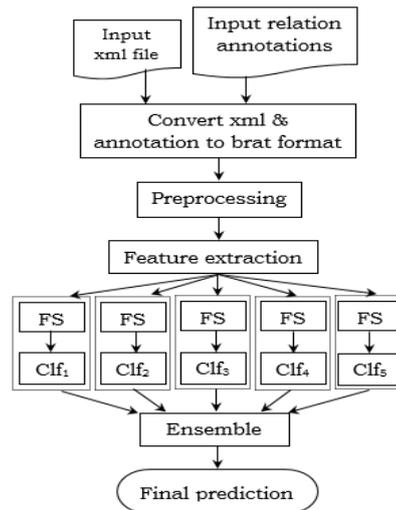

Figure 1: Relation detection and classification pipeline: 5 classifiers (Clf_n) work on extracted feature sets (FS)

Subtask 1.1 and subtask 2 are associated with the clean dataset D_1 , while subtask 1.2 is associated with the noisy D_2 dataset. The test data consisted of 150 abstracts each for subtask 1.1, 1.2 and 2.

Table 1 shows the distribution of relation instances into different relation types, and their forward (Fwd) and reverse (Rev) directionalities in datasets D_1 and D_2 . The highest number of instances are of the USAGE type in both datasets, whereas TOPIC is the least frequent relation type (1.46%) in D_1 , but significant (19.47%) in D_2 . The overall forward directionalities of relations are 68% in D_1 and 73.63% in D_2 . The directionalities of individual relation types are similar.

The most frequent lengths of the entity mentions are two and one word(s) in D_1 and D_2 , respectively, with maximum lengths of 13 and 4. The most frequent context lengths of the relation instances are two words, with a highest length of 31 words (RESULT(I05-3022.6, I05-3022.16)) in D_1 and 24 words (USAGE(E91-1004.30, E91-1004.37)) in D_2 . The average number of entities in the sentences are 3 and 6 in D_1 and D_2 , with highest number of entities being 17 and 29, respectively.

3 Experimental Setup

Figure 1 shows the processing pipeline common to both relation identification and classification. The processing steps are elaborated on below.

Inputs to brat annotation: The input training and test files are in xml format with the entity mentions marked. Each entity mention has an ID with two parts, abstract ID and entity number. For example, the entity ID `H91-1045.18` denotes abstract ID `H91-1045` and entity number 18. The relation labels are in a separate file with the format `TOPIC(A92-1023.7,A92-1023.8,REVERSE)`, where the first two arguments of the relation type are entity IDs and the last is the directionality of the relation. The xml and relation label files were converted into ‘brat’ (Stenetorp et al., 2012) format, with the text content of each abstract ID kept in a text file, and entity and relation information kept in an annotation file. Conversion to brat format helps to visualize and study the annotations of the training and test set output. Also, the text content (without entity tags) is used for preprocessing.

Text Processing: The text content of each abstract is analyzed with the Stanford CoreNLP toolkit (Manning et al., 2014) for sentence boundary detection, tokenization, lemmatization, part-of-speech (POS) tagging, and constituent and dependency parsing. Character offset-based brat entity annotations are mapped into word level indices using the tokens’ character offsets. Finally, the dependency heads of entity mentions, in between context and the text window representing the relation expression are identified.

Feature Extraction: Given a sentence with more than one entity mention, all possible entity pairs are considered in left to right order. For each entity pair, the text span containing the entities and their middle context is considered as the representation of the relation instance. As word features, unigrams and bigrams of the context and entity mentions (excluding articles, adjectives, cardinals, ordinals, pronouns, brackets and punctuations) are considered. Corresponding to word features, POS, word+POS, and lemma+POS combinations are included, as well as word and POS of entity dependency heads, context dependency heads, and their combinations.

As the shortest dependency path between the entity pair contains major information for relation identification (Bunescu and Mooney, 2005), dependency path features are added for the distance from left entity head to right entity head, words belonging to the dependency path and their rela-

tions to the parent node. WordNet synonyms and hyponyms of dependency head of entities and contexts are included. Also, other binary indicators such as adjacent or overlapping entities are included.

Parameters Optimization through Cross-Validation (CV): As there was no development data available for model parameter tuning, 20% of the training data was kept as development data, and the remaining training data was used for parameters optimization with 5-fold cross-validation. For relation labeling in subtask 1.1 and 1.2, the relation type is predicted against 11 classes (five directed and one undirected relation). Relation instance identification in subtask 2 is a binary classification problem, and the class weights of positive instances are optimized through CV. In the final system, the parameters are optimized on the entire training set.

Classifiers Ensembling and Final Prediction: The optimized parameters of the classifiers and class weights are set to the classifiers. For each classifier, the χ^2 -based `SelectKBest()` method selects the top k features from the input feature space, where the k for each classifier is determined through cross-validation. The predictions of the classifiers are then ensembled with (majority) voting where each participating classifier uses its own feature selection method.

4 Results

Three separate submissions were made on the test data. The first two submissions were on relation classification on clean (subtask 1.1) and noisy data (subtask 1.2). The third submission (subtask 2) consisted of relation identification followed by classification on clean data. In subtask 2, a separate system was created for the relation identification, while the relation classification system of subtask 1.1 was used for the classification.

Table 2 shows the performance (precision, recall and F_1 score) of individual classifiers, as well as their combinations in the relation classification subtask 1.1, where the scores are micro-averaged over all (11) classes. Among the individual classifiers, SVM gives the best result (56% F_1 score). Voting with the top-3 classifiers (SVM, DT & MNB) gave a slightly higher F_1 score of 58%.

Table 3 shows the scores of the relation classification subtask on noisy training data (subtask 1.2).

Classifier	#Features	P	R	F ₁
SVM	13,200	0.59	0.56	0.56
DT	3,400	0.58	0.53	0.54
RF	6,600	0.38	0.42	0.40
MNB	2,300	0.40	0.79	0.53
kNN	7,800	0.43	0.30	0.35
Ensemble-all	—	0.56	0.42	0.48
Ensemble-best	—	0.57	0.63	0.58

Table 2: Precision, recall and F-scores of individual and ensemble classifiers on subtask 1.1. The scores are micro-averaged over 11 classes. Ensemble-best is SVM+DT+MNB.

Classifier	#Features	P	R	F ₁
SVM	9,700	0.71	0.70	0.69
DT	7,200	0.72	0.66	0.65
RF	8,900	0.60	0.58	0.53
MNB	3,700	0.70	0.67	0.62
kNN	6,700	0.48	0.70	0.57
Ensemble-all	—	0.57	0.71	0.63
Ensemble-best	—	0.81	0.67	0.73

Table 3: Result of individual and ensemble classifiers on subtask 1.2. Scores are micro-averaged over 11 classes. Ensemble-best is SVM+RF+MNB.

As individual classifier, SVM gave the best performance with 69% F₁ score followed by Decision Trees (65%) and Multinomial Naïve Bayes (62%). The best performance of voting classifiers scored 73% using the classifiers SVM, RF and MNB.

Table 4 shows the results of the relation identification in subtask 2. Again SVM gave the best single classifier level performance.

5 Discussion

The total relation instances in the clean data and in the noisy data are almost the same (1228 and 1248, respectively). However, it is interesting to observe that the best performance in relation classification both at the single classifier level and in ensemble voting on noisy data (subtask 1.2) is significantly higher than on clean data (subtask 1.1). This behaviour is consistent also on the test data.

One explanation may be the differences in relation expressions in dataset D_1 and D_2 . In the clean data (D_1), 25.66% of the entity mentions have three or more words with a maximum length of 13 words, whereas in the noisy data (D_2) only 0.96%

Classifier	#Features	P	R	F ₁
SVM	18,100	0.39	0.46	0.42
DT	5,800	0.50	0.29	0.36
RF	6,300	0.33	0.26	0.29
MNB	4,900	0.43	0.30	0.35
KNN	8,100	0.14	0.25	0.18
Ensemble-all	—	0.31	0.26	0.28
Ensemble-best	—	0.44	0.31	0.36

Table 4: Performance of positive class in relation identification on clean data (subtask 2). Ensemble-best is SVM+DT+MNB.

of the mentions have more than three words. The feature-based approach with n-grams as major feature source might not be able to capture the semantics of entity mentions having very large text spans. Furthermore, the context length between entity pairs in the clean data is larger than in the noisy data. Therefore, the shortest dependency paths and context n-grams—which are the two major feature sources—generate many insignificant features. Modeling the relation instances through a neural network could be a better alternative in this scenario.

Feature selection has a positive impact on prediction both in relation identification and in classification. SVM gave the best results at the single classifier level on all subtasks, but needs a larger feature space, whereas MNB performed reasonably although needing the smallest number of features for training the classifier.

6 Conclusion

In this work, we experimented with the relation identification and classification subtasks of SemEval 2018 Task 7 using a feature-based approach. A wide variety of features are explored, including lexical, syntactic, semantic, and other binary features. Two relation classification systems are developed on clean and noisy data and the third system is developed to identify relations in clean data. Five classifiers are trained for each subtask, with the final predictions made through voting based on the corresponding predictions of the individual classifiers. Experimental results shows that the lengths of the entity mentions and the lengths of the context in-between a pair of entities have significant impact on the relation identification and relation classification.

Abstract

This paper describes our approach to SemEval-2018 Task 7 – given an entity-tagged text from the ACL Anthology corpus, identify and classify pairs of entities that have one of six possible semantic relationships. Our model consists of a convolutional neural network leveraging pre-trained word embeddings, unlabeled ACL-abstracts, and multiple window sizes to automatically learn useful features from entity-tagged sentences. We also experiment with a hybrid loss function, a combination of cross-entropy loss and ranking loss, to boost the separation in classification scores. Lastly, we include WordNet-based features to further improve the performance of our model. Our best model achieves an F1(macro) score of 74.2 and 84.8 on subtasks 1.1 and 1.2, respectively.

1 Introduction

Classifying the relationship between entities is an important natural language processing (NLP) task that serves as a building block for a variety of NLP applications such as knowledge base construction and question-answering tasks. SemEval-2018 Task 7 (Gábor et al., 2018) provided entity-tagged texts from the ACL Anthology corpus and asked participants to identify and classify entity pairs into one of six semantic relationships.

Our approach to this problem consisted of selecting two architectures shown to be successful (Zeng et al., 2014; Nguyen and Grishman, 2015) in this problem domain and adapting them to this particular task. We found that pre-trained word embeddings were effective for this problem, as well as a combined loss function, and using WordNet features at a later stage of our model.

Sentence: High quality $\langle e1 \rangle$ **translation** $\langle /e1 \rangle$ via $\langle e2 \rangle$ **word sense disambiguation** $\langle /e2 \rangle$ and accurate word order generation of the target language .

Relation: USAGE

Figure 1: An example of sentence-level relation Instance. Sentences marked with entity positions were the input to our model.

2 System Description

Convolutional neural networks (CNNs) have been proven to significantly outperform other methods for Relation Classification (Zeng et al., 2014; dos Santos et al., 2015; Nguyen and Grishman, 2015). Our approach was inspired by Nguyen and Grishman (2015) and dos Santos et al. (2015), both systems being minimally dependent on explicit feature engineering. While Nguyen and Grishman (2015) relied solely on their model architecture to automatically extract useful features, we also included additional features based on part-of-speech tags and WordNet hypernyms. Following dos Santos et al. (2015), we trained our model on a hybrid objective function, a combination of cross entropy loss and ranking loss. Finally, we also trained our model in two stages to utilize large amounts of unlabeled ACL corpus abstracts (Bird et al., 2008). We describe these stages in detail in section 4.1.

Each abstract is first tokenized into sentences. For each sentence, we then formed training examples by taking all combinations of pairs of entities annotated in the sentence. If a pair is annotated with a relation label, we labeled the sentence as this relation. Otherwise, we labeled the sentence as an artificial class called *OTHER*. Figure 1 shows an example of a training instance in our sentence-level dataset.

For an input sentence, each word was mapped to a word-vector to form a sentence matrix. These sentence matrices were provided as inputs to the

CNN. The output of this layer was then fed into a softmax layer to classify the relationship between two entities. Section 3 provides a detailed description of the underlying CNN.

3 Convolutional Neural Network for Relation Classification

Our model consists of a preprocessing feature generation step followed by a 2D convolutional layer with max pooling and then a fully connected layer with softmax output.

3.1 Preprocessing and Feature Generation

The input to our model was a raw sentence marked with entity positions. This raw sentence was first converted into a real-valued sentence matrix by tokenizing the sentence and then replacing each token with a corresponding word embedding. We used three different look-up tables: publicly available pre-trained word embeddings, randomly initialized word positions, and randomly initialized part-of-speech tags. Following Collobert et al. (2011), the final word embedding for each token in the sentence was a concatenation of these three embeddings.

For pre-trained word embeddings, we evaluated word2vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014), and Numberbatch (Speer and Chin, 2016), ultimately choosing word2vec as the best performer for this task.

The specific process used to generate the feature vector for a given token in a sentence is as follows. Let n be the number of tokens in a sentence $x = [x_1, x_2, \dots, x_n]$ with x_{i_1} and x_{i_2} being the two head words of the two entities in relationship r . Relative positions between a token x_i and two entities are given by $(i - i_1)$ and $(i - i_2)$. These positions are also mapped into real-valued vectors using a position embeddings look-up table W_p . Also, W_e , and W_t embeddings look-up tables are used to map each word and its part-of-speech tag into a real valued vector. Finally, x_i is transformed into a vector $v_i = [e_i; u_{i_1}; u_{i_2}; t_i]^T$, where v_i is the concatenation of vectors $e_i, u_{i_1}, u_{i_2}, t_i$, e_i is the word-vector mapped using the W_e look-up table, u_{i_1} and u_{i_2} are the word-position vectors mapped using the W_p look-up table, and t_i is the word-part-of-speech vector mapped using the W_t look-up table. Dimension d of the final input vector is given by $d = (d_e + 2 * d_p + d_t)$, where d_e, d_p and d_t are the dimensions of pre-

trained word-embeddings, word-position embeddings and word-part-of-speech tag embeddings. As a result of these look-up operations, the raw sentence $x = [x_1, x_2, \dots, x_n]$ is transformed into a real-valued sentence matrix $\mathbf{x} = [\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n]$ of size $d \times n$.

3.2 2D Convolution with Max Pooling

We used multiple window sizes to extract features corresponding to various n -grams. Let w be a window size and n_w be the number of unique window sizes, a filter $\mathbf{f} = [\mathbf{f}_1, \mathbf{f}_2, \dots, \mathbf{f}_w]$ is a weight matrix where \mathbf{f}_i is a column vector of size $d = (d_e + 2 * d_p + d_t)$. A convolutional operation is then performed using \mathbf{x} and \mathbf{f} to produce a feature map $s = [s_1, s_2, \dots, s_{n-w+1}]$ as:

$$s_i = g\left(\sum_{j=0}^{w-1} f_{j+1}^T x_{j+i}^T + b\right)$$

where b and g are bias and ReLU (Nair and Hinton, 2010) activation function respectively. This convolutional operation was repeated for different filters and window sizes, and then a max pooling strategy Zhang and Wallace (2017) was applied to extract only 1 feature (the one with highest activation) from each feature map. That is, for each feature map s , a max function was applied to produce a single value: $p_f = max(s)$.

3.3 Classification Layer

We took all the individually selected features from the max pooling operation and concatenated them together, producing $z = [p_1, p_2, \dots, p_m]$, where m is the number of feature maps and p_i is the pooled value for i^{th} feature map. A random proportion of input vector z was set to zero for regularization purposes to produce a drop-out version z_d of input vector z . The vector z_d was then fed into a dense layer followed by a softmax operation to produce the final classification probability for a relation class r as:

$$\mathbf{o} = \mathbf{C}z_d + \mathbf{b}$$

$$p(r|\theta) = \frac{e^{o_i}}{\sum_{k=1}^L e^{o_k}}$$

where \mathbf{o} is the output of the dense layer, \mathbf{b} is a bias term, L is the number of relation categories, and \mathbf{C} is a weight matrix of size $(n_w m \times L)$ with n_w being the number of unique window sizes and m being the number of filters.

3.4 Additional Features

In addition to the output of the CNN layer, we explored a variety of additional features derived from the input sentences.

Part-of-speech features, *pos* We randomly initialized embeddings for each part-of-speech tag and used these embeddings as additional input to our network. Part-of-speech tags for raw sentences were generated using *spaCy*¹.

WordNet hypernym features, *hyp* We incorporated WordNet hypernyms using the implementation² provided by Ciramita and Altun (2006).

Semantic Similarity between two entities, *sim* We computed the cosine similarity between the word-embeddings of the head-words of the two entities in a relation instance.

REVERSE flag feature, *rev* We applied an indicator function on the REVERSE flag of the relationship instance.

We fed *hyp*, *sim* and *rev* features as additional inputs to the classification layer. While *pos* features were provided as input to the convolution layer.

4 Training Methods

We evaluated three different loss functions for training our model: cross-entropy loss, ranking loss (dos Santos et al., 2015), and a weighted combination of the two, where

$$L_{combined} = \alpha L_{ranking} + (1 - \alpha) L_{cross\ entropy}$$

with α as a weighting parameter. The combined loss function was determined to be the most effective.

4.1 Two-Stage Training

To make use of unlabeled data for fine-tuning word-position and word-part-of-speech embeddings, we trained our model in two-stages following Severyn and Moschitti (2015): a *distant* training stage and a *supervised* training stage.

Distant Training We first created a distantly supervised training dataset using unlabeled ACL corpus abstracts (Bird et al., 2008) based on the naive assumption that *two entities have the same relationship across all aligned sentences*. By

aligned sentences, we mean all sentences which have exactly two entities. In order to create distantly supervised training data based on the above assumption, we performed the following operations:

i) All the sentences in the ACL-corpus were indexed in an IR system. Here we used *Whoosh*³.

ii) For each relation instance in the labeled training data, the top 40 sentences which contained both the entity texts in the relation were returned from the IR system.

iii) Result sentences in which the distance (number of characters) between the two entity texts was greater than 170 were removed. This number was derived from distance statistics from given labeled datasets.

iv) The remaining sentences were labeled with the same relationship as the relation instance in (ii).

Following above steps, we created distant-datasets of around 1600 and 11000 training instances for subtasks 1.1 and 1.2, respectively. We also verified that there is no overlap between these generated distant-datasets and the provided test datasets.

Once the distantly supervised training data is created, we train our model using these datasets to fine-tune only word-position and part-of-speech tag embeddings, while keeping word-embeddings fixed.

Supervised Training In the second stage, we initialized our model with the fine-tuned embeddings trained in the distantly supervised training stage and then train our model using the provided labeled training data. In this stage we also train word-embeddings but freeze them for first 10 epochs to prevent any large updates.

5 Experiments and Results

The class labels for subtasks 1.1 and 1.2 are highly imbalanced (Table 1). To compensate for this imbalance, we trained our models for subtasks 1.1 and 1.2 jointly on a combined dataset and used class-weights to weight our loss function.

5.1 Resources and Hyperparameters

We chose all the hyperparameters based on the model performance on our validation set. All experiments below use the hyperparameters as shown in Table 2.

Table 3 shows the results of our ablation studies using different feature sets on subtasks 1.1

⁴<https://www.tensorflow.org/>

and 1.2. It shows that the simple similarity (*sim*) feature helps in case of subtask 1.2, while it degrades the performance in case of subtask 1.1. Similarly, WordNet features with part-of-speech features boosted the performance only of subtask 1.1. Fine tuning using the two-staged training approach did not yield any performance gain in either the subtasks.

We also evaluated the effect of loss function choice. Table 4 shows the results of our final

Loss Function	F1-Macro Subtask 1.1	F1-Macro Subtask 1.2

Overall Best(UWNLP)	50.0

Table 5: Performance of our final model on Subtask 2(Relation Extraction).

sults of our experiments on subtask 2 (relation extraction). While this method did not outperform the top submissions, it still demonstrated competitive results.

6 Conclusion

Our experiments indicate that pre-training on an unlabeled corpus did not noticeably impact performance on our evaluation set. Our plain CNN model (without any external features) has comparable performance to the competition’s best submission. We also observed improved performance of our model on Subtask 1.1 when using the WordNet features as additional input to the final layer. Finally, when we combine the cross-entropy and ranking loss functions, performance of our model improved on both Subtasks 1.1 and 1.2.

Abstract

In this paper we present our participation to SemEval-2018 Task 8 subtasks 1 & 2 respectively. We developed Convolution Neural Network system for malware sentence classification (subtask 1) and Conditional Random Fields system for malware token label prediction (subtask 2). We experimented with couple of word embedding strategies, feature sets and achieved competitive performance across the two subtasks. Code is made available at <https://bitbucket.org/vishnumani2009/securenlp>

1 Introduction

Cybersecurity risks and malware threats are becoming common and increasingly dangerous requiring analysis of large repositories of malware related information in realtime to understand its capabilities and mount an effective defense. The sheer volume of data and its potential applications alone have increased traction in recent times among NLP researchers. In this line, SemEval 2018 Task-8 offers 4 subtasks addressing text classification and token, relation and attribute label prediction in cybersecurity domain using MalwareTextDB (Lim et al., 2017). While subtask 1 focuses on predicting sentences relevance to malware, subtasks 2, 3 and 4 focus on predicting token, relation and attribute labels for malware text from subtask 1. More details about the each of the subtasks can be found in Phandi et al. (2018).

Concerning subtask 1, which was inherently formulated as a text classification problem very few works are done till date in cybersecurity domain (Lim et al., 2017; Zhang et al., 2016). However, in general domain the problem of text classification is well addressed with extensive usage

^{*}Work performed during weekend part time assistantship at CAMMS

of deep learning approaches (Zhou et al., 2016; Liang and Zhang, 2016; Kim, 2014; Kalchbrenner et al., 2014; Zhang et al., 2015), Support vector machines, logistic regression (Genkin et al., 2007; Jiang et al., 2016) and Tree based approaches (Bouaziz et al., 2014). On the other hand, subtask 2 was formulated as sequence tagging problem which is addressed till date by CRF (Finkel et al., 2005; R. et al., 2016, 2017), deep learning approaches (Chiu and Nichols, 2016; Ma and Hovy, 2016; Lample et al., 2016) and SVM (Ekbal and Bandyopadhyay, 2012).

In this paper, we describe our system that addresses subtasks 1 and 2 involving malware sentence classification and malware token label prediction. We designed these systems by adapting various insights from previous works on text classification and sequence tagging. We submitted a Convolutional Neural Network(CNN) based system based system for subtask 1 and Conditional Random Field (CRF) based system for subtask 2.

The rest of the paper is organized as follows. In section section 2, we discuss datasets and preprocessing. In section 3, we describe the algorithms and features used in the process of model development. In section 4, we describe our results and some of our findings. Finally in section 5, we conclude with summary and possible implications on future work.

2 Dataset and Preprocessing

The MalwareTextDB corpus used for this work consists of APT reports describing malware reported information taken from APTnotes¹. We designed an end-to-end pipeline consisting on three module which process input text across multiple stages. In stage 1, the input sentence is fed to a preprocessing module which pre-processes the

Table 1: Tokens and placeholders used in stage 1

text for stage 2 where the sentence are subject to classification and finally stage 3 sequence tags the tokens of the input sentence. We used following preprocessing steps in stage 1.

1. All the words are lower-cased.
2. All the words that can be grouped under common category were replaced by a category placeholder as shown in table 1.

We used following opensource tools 1) Stanford Core-NLP (Manning et al., 2014) 2) Keras (Chollet et al., 2015) 3) CNTK (Seide and Agarwal, 2016) 4) Gensim (Řehůřek and Sojka, 2010) 5) NLTK for preprocessing (Loper and Bird, 2002) 6) Scikit-learn (Pedregosa et al., 2011) for grid search 7) Glove (Pennington et al., 2014).

3 Model

In this section, we explain the algorithms and hyperparameters used for system development. More specifically, in section 3.1 we explain our CNN architecture for subtask 1 and in section 3.2 we show our CRF architecture for subtask 2.

3.1 Algorithm - Subtask 1

For subtask 1, we focused more towards deep learning. Previous works (Yin et al., 2017) suggests that both Convolutional Neural Network (CNN) and Recurrent Neural Network (RNN) architectures has been successfully applied for various instances of text classification analysis at various level. With most of recent works (Zhang and Wallace, 2017) showing success of CNN, we developed a CNN architecture based on work of Kim (2014). The architecture developed in this work is as shown in figure 1.

3.1.1 Convolutional Neural Network

Our CNN architecture was derived from original works of Kim (2014) by using grid search over input channel size, number of convolution layers and number of filters. We use a multichannel model architecture with five input channels for processing

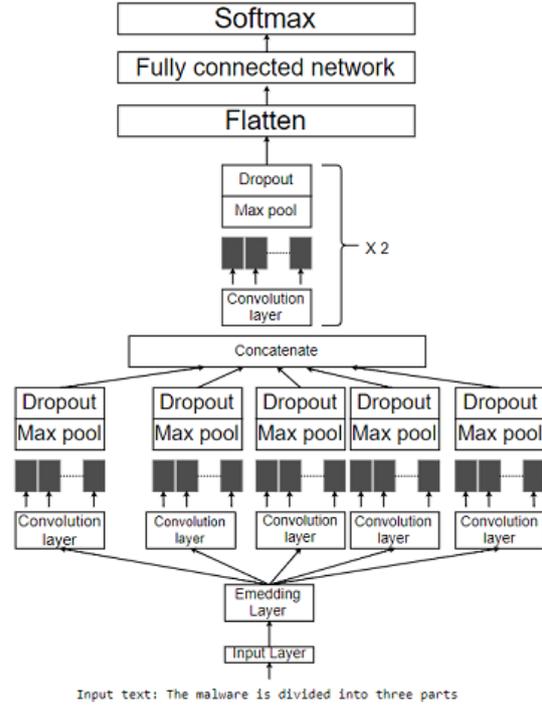

Figure 1: CNN Architecture

2-6 grams of input malware text. Each channel is comprised of the following elements:

1. Input layer that defines the length of input sequences.
2. Embedding layer set to the size of the vocabulary and 100-dimensional real-valued representations.
3. One-dimensional convolutional layer with 128 filters and a kernel size set to the number of words to read at once.
4. Channel wise Pooling layer with pool size of 5 to consolidate the output from the convolutional layer.

Following CNN, we use a Fully Connected Neural Network (FCNN) to transfer the the concatenated feature map (600 dimension) to a probability distribution over the two class labels. The number of layers in FCNN is set to be 2. The first layer uses 128 units with a tanh activation function. The second layer produces the classification probability distribution over 2 units combined with a softmax activation function.

Further to handle overfitting we use regularization via dropout (Srivastava et al., 2014) with

Feature	Value
Sentence pad length	1000
Dimensions of wordvectors	100
Number of CNN layers	8
Dimension of CNN layers	1
Number of CNN filters	128

Optimizer	Adam
Batch size	32
Max Epoch	10
Loss function	Cross Entropy

Table 2: Hyper parameters of CNN

threshold of 0.25. Additionally, we also apply cost sensitive learning (Zhou and Liu, 2006) in order to balance the effect of the larger negative samples present in the training dataset. For each class, we assigned weight proportional to class frequency. We implemented the neural network model using Keras. We trained our networks using Adam optimizer (Kingma and Ba, 2014). All the hyper parameters are listed in table 2.

3.1.2 Input Embeddings

We experimented with two category of word embeddings namely native embeddings and task specific embedding using Word2vec (Le and Mikolov, 2014) and Glove (Pennington et al., 2014) algorithms. Characteristics of each of the embedding is as explained below.

1. **Native Embeddings:** All words including the unknown ones that are randomly initialized use embeddings from original Word2vec/Glove models.
2. **Task specific :** The embeddings are generated by training Word2vec/Glove algorithms on sentences from MalwareTextDB.

3.2 Algorithm - Subtask 2

For subtask 2, we developed a Conditional Random Field (CRF) system (Finkel et al., 2005) based on previous works of Lim et al.(2017).

3.2.1 Conditional Random Fields

We used Conditional Random Fields with following features that is available as part of Stanford CoreNLP ToolKit.

Common Features: N-grams of size 6, previous, next tokens and labels, features giving disjunctions of words anywhere in the left or right,

	Word2vec			Glove

word shape features, word lemma of current, previous and next words, word-tag pair features, POS tags, prefix and suffixes. The description of the features are given in CoreNLP(2014).

Additional features: Based on analysis of corpus, to tackle unknown malware entities we used a gazette with token that describes malware entity. These tokens were taken from training corpus and internet².

4 Experiments and Results

In this section, we present results for each of the developed systems. The original dataset was split into **train17**, **test-17**³ released at the start of competition and **dev-18**, **test-18** released during the competition pre-evaluation period for tuning of parameters and final evaluation respectively . We submitted CNN system for subtask 1 and CRF system for subtask 2. Tables 3-5 show the results of subtasks 1 and 2 respectively across the datasets. Our systems achieve F-score of 0.5 for subtask 1 and 0.25, 0.36 for subtask 2 over strict, relaxed runs of subtask 2.

4.1 Discussion

In previous sections we described the system developed for malware text analysis using which we achieved competitive performance for subtask 1 and subtask 2.

For subtask 1, we developed a CNN system and experimented the same with different embedding strategies as explained in section 3.1.2. Across all

³(train/dev/test)-(17/18) is not an official naming convention , instead used here for ease of understanding

	CRF-Strict			CRF-Relaxed		
	P	R	F	P	R	F
test17	0.51	0.26	0.34	0.45	0.36	0.40
dev18	0.18	0.25	0.21	0.38	0.22	0.29
test18	0.29	0.23	0.25	0.42	0.30	0.36

Table 5: Results of subtask 2 on Conditional Random fields

the subset of datasets, glove embeddings consistently outperformed Word2Vec embeddings. This is in line with works of Kim (2014). We initially hypothesized that since "the context of the malware texts are different from normal English texts", task-specific embeddings would improve the results of subtask 1. However, we observe that task specific embeddings produced lower results compared to native embeddings. Observations of results revealed high false negative predictions of non-malware texts, we believe that this may attributed to limited dataset used for developing embeddings, unlike native embeddings which was created using very large corpus. This results also agrees the general observation, that the size of the training corpus has often a greater impact on results than its strict matching with the target domain(Tourille et al., 2017).

For subtask 1, we achieved an accuracy of 0.50 and were 7% behind the top performing systems. We identified three different sources of errors across the sentences in line with previous works(Lim et al., 2017) namely misclassification of i) Sentences consisting of malware related keywords without implication on actions; ii) Sentences describing attacker actions and additionally we also found iii) misclassification of sentences containing specific patterns like presence of `..PATH..` and `..EXE..`. Further, we had initially hoped that the multichannel architecture would prevent overfitting(Kim, 2014) and thus work better than the single channel model, especially on small datasets like MalwareTextDB. The results, however, are vice versa and hence further work on regularizing the training process and simpler single channel architecture is warranted.

For subtask 2, during analysis we found that there were multiple malware names which were previously unseen and felt only orthographic features would be insufficient. Hence in addition to commonly used features, we also included gazette features with words that quantify malware entity. However, during evaluation on development set

we found high drop in precision when we used gazette features owing to its deterministic nature. Hence, we submitted CRF only with common features described in section 3.2.1 for final evaluation. With this system we achieved a result of 0.25 and 0.36 in strict and relaxed evaluation respectively. Our accuracy is 3.5% (avg) behind the top performing system across the evaluations. We identified following sources of errors i) Tagging of tokens in sentences containing only actions but not entities - these are sentences with only attackers actions in line with error from subtask 1 ii) Lack of sensitivity to context - some tokens in test document are given same label from train irrespective of context iii) Miss tagging of some of the tokens with common suffixes. For subtask 2, we experimented with simple CRF architecture with basic features, hence we believe further exploration of future engineering is needed to reduce context related errors. As far as addressing rest of the errors, we plan to explore combination of rule based and deep learning approaches.

5 Conclusion

In this work, we developed CNN and CRF systems for malware text classification and token label prediction, achieving competitive results. For subtask 1, we experimented with couple of word embedding strategies and found native glove embedding to be useful. For subtask 2, we used CRF with simple features achieving results closer to top performing system and above the official benchmark. Further, we described various sources of errors identified in the due process of analysis. In future, we plan to further improve our system to show higher performance based on the above observations.

Acknowledgments

We thank the task organizers for providing access to MalwareTextDB corpus and organizing the shared task. Further, we would like to thank various authors for open sourcing the codes of various algorithms used in this work.

Abstract

This paper describes HCCL team systems that participated in SemEval 2018 Task 8: SecureNLP (Semantic Extraction from cybersecurity reports using NLP). To solve the problem, our team applied a neural network architecture that benefits from both word and character level representations automatically, by using combination of Bi-directional LSTM, CNN and CRF (Ma and Hovy, 2016). Our system is truly end-to-end, requiring no feature engineering or data preprocessing, and we ranked 4th in the subtask 1, 7th in the subtask 2 and 3rd in the SubTask2-relaxed.

1 Introduction

Recently, cybersecurity defense has also been recognized as one of the problem areas likely to be important both for advancing AI and for its long-run impact on society. In particular, natural language processing (NLP) has the potential for substantial contribution in cybersecurity and that this is a critical research area given the urgency and risks involved (Lim et al., 2017).

In SemEval 2018 Task 8 (Phandi et al., 2018), there are four subtask:

1. SubTask1: Classify if a sentence is useful for inferring malware actions and capabilities
2. SubTask2: predict the token labels in the sentences. The output needs to be in BIO format. There are 3 types of token labels: "Action", "Entity", and "Modifier".
3. SubTask3: predict the relations between the token labels
4. SubTask4: predict the attributes for each entity token

In this evaluation, our team submitted the results of Subtask 1 and Subtask 2. To tackle this

problem, we treat subtask 2 as a sequence labeling problem. Most traditional high performance sequence labeling models are linear statistical models, including Hidden Markov Models (HMM) and Conditional Random Fields (CRF) (Luo et al., 2015), which rely heavily on hand-crafted features and task-specific resources.

Recently, many neural network based methods have been successfully applied to sequence labeling task: Named Entity Recognition (Lample et al., 2016). In this paper, we present an end-to-end System (combined CNN, LSTM and CRF) for sequence labeling that uses no complicated handcrafted features or domain knowledge. LSTM is capable of learning long-term dependencies, which is beneficial to sequence modeling tasks. And character level CNN can get character-level representation. For sequence labeling (or general structured prediction) tasks, it is beneficial to consider the correlations between labels in neighborhoods and jointly decode the best chain of labels for a given input sentence. So we model label sequence jointly using a conditional random field (CRF), instead of decoding each label independently. Therefore, the system we proposed is based on CNN, Bi-directional LSTM and CRF. And in the SubTask2-relaxed our group ranked third. As for SubTask1, we proposed a ruled based method that if any token in the sentence is labeled "Action", "Entity", or "Modifier", the sentence would be considered relevant. Our team ranked 4th in the subtask 1.

2 System Description

In this section, we describe the components (layers) of our end-to-end system. We design our model with CNN-BiLSTM-CRF that combined word level representation, character level representation and POS representation as feature in-

put, and outperform than the baseline in subtask2-relaxed.

2.1 Feature Embedding

Feature representation as the meta input of neural network have received a great deal of attention, and there are many outstanding achievements. In our system, the word level embedding is trained by the Google’s Word2Vec (Mikolov et al., 2013) tool. Previous studies (Santos and Guimaraes, 2015; Chiu and Nichols, 2015) have shown that CNN is an effective approach to extract morphological information (like the prefix or suffix of a word) from characters of words and encode it into neural representations. To get more diverse information, our team decided to use Part-Of-Speech (POS) as extra feature input.

Word level Embeddings: Taking into account the particularity of the cybersecurity, we use the evaluation data to train our own word embeddings. Word level embeddings are trained by Word2Vec¹, and we set embedding dim = 300.

Character level Embeddings: Character level embeddings are random initialization(trainable), and we set embedding dim = 30.

POS Embeddings: POS embeddings are random initialization(trainable), and we set embedding dim = 30.

2.2 Model

We provide a brief description of CNN, LSTM and CRF, and present a hybrid sequence labeling architecture. This architecture is similar to the ones presented by (Ma and Hovy, 2016).

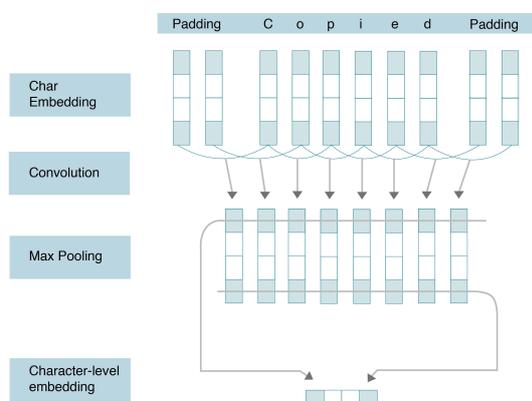

Figure 1: The CNN network for extracting character-level embedding of words.

¹<https://code.google.com/archive/p/word2vec/>

2.2.1 CNN

Figure 1 shows the CNN we use to extract character-level representation of a given word. The CNN is similar to the (Chiu and Nichols, 2015), except that we use only character embeddings as the inputs to CNN, without character type features. A dropout layer (Srivastava et al., 2014) is applied before character embeddings are input to CNN.

2.2.2 LSTM

Recurrent neural networks (RNNs) are a family of neural networks that operate on sequential data. Although RNN can, in theory, learn long dependencies, in practice they fail to do so and tend to be biased towards their most recent inputs in the sequence (Bengio et al., 1994). Long Short-term Memory Network (LSTM) have been designed to combat this issue by incorporating a memory-cell and have been shown to capture long-range dependencies. They do so using several gates that control the proportion of the input to give to the memory cell, and the proportion from the previous state to forget (Hochreiter and Schmidhuber, 1997). We use the following implementation:

We will refer to the former as the forward LSTM and the latter as the backward LSTM. This forward and backward LSTM pair is referred to as a bidirectional LSTM (Graves and Schmidhuber, 2005; Dyer et al., 2015). The basic idea is to present each sequence forwards and backwards to two separate hidden states to capture past and future information, respectively.

2.2.3 CRF

For sequence labeling (or general structured prediction) tasks, it is beneficial to consider the correlations between labels in neighborhoods and jointly decode the best chain of labels for a given input sentence. Therefore, we model label sequence jointly using a conditional random field (CRF) (Lafferty et al., 2001), instead of decoding each label independently.

For a sequence CRF model (only interactions between two successive labels are considered), training and decoding can be solved efficiently by adopting the Viterbi algorithm.

2.2.4 CNN-BiLSTM-CRF

Finally, we construct our neural network model by feeding the output vectors of BiLSTM into a

CRF layer. Figure 2 illustrates the architecture of our network in detail. For each word, the character-level is computed by the CNN in Figure 1 with character embeddings as inputs, and we use NLTK² to get POS information. Then the character-level representation vector the POS representation vector are concatenated with the word embedding vector to feed into the BiLSTM network. Finally, the output vectors of BiLSTM are fed to the CRF layer to jointly decode the best label sequence. As shown in Figure 2, dropout layers are applied on both the input and output vectors of BiLSTM. Experimental results show that using dropout significantly improve the performance of our model.

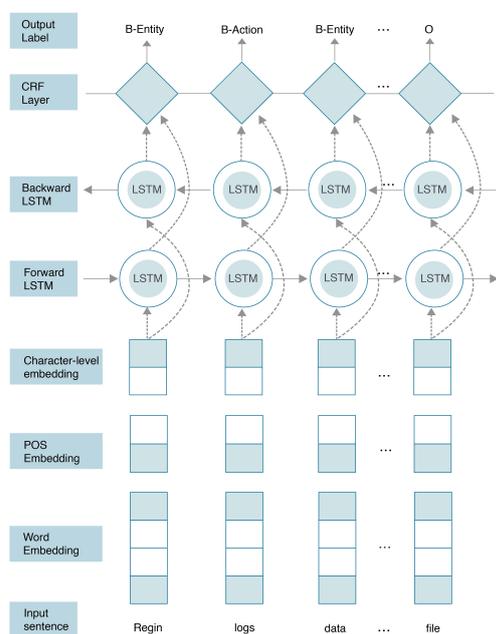

Figure 2: Main architecture of the network. Concatenated feature embeddings are given to BiLSTM.

3 Experiments and Results

3.1 Training

For model presented, we train our networks using the back-propagation algorithm updating our parameters on every training batch, using Adam with a learning rate of 0.001 and a gradient clipping of 5.0. Our CNN-BiLSTM-CRF model uses a single layer for the forward and backward LSTMs whose dimensions are set to 300. Tuning this dimension did not significantly impact model performance. We set the dropout rate to 0.5. Using

²<http://www.nltk.org/>

higher rates negatively impacted our results, while smaller rates led to longer training time. The models were implemented in TensorFlow³ and experiments were run on K80 GPU.

3.2 Result

In this work, our team submitted the subtask 1 and subtask 2 results. The results of all the teams are shown in Table 2.

For subtask1, its goal is to classify if a sentence is relevant for inferring malware actions and capabilities. We make use of the result in subtask2 for this subtask and consider a sentence to be relevant as long as it has an annotated token label. Table 2 shows that our system is ranked 4th and behave better than baseline for subtask1.

For subtask2, our CNN-BiLSTM-CRF model is then trained to predict token labels from cybersecurity reports. From Table 2 we can see that in subtask2, our system is slightly worse than the baseline. However, our system has a 22.5% improvement in subtask2-relaxed than baseline.

3.3 Error Analysis

For subTask1, a lot of non-malware sentences are regarded as malware sentences. May be due to the fact that we use the subTask2 output to estimate whether the current sentence is non-malware sentence or malware sentence, so the errors of subTask2 will affect subTask1. And both non-malware sentences and malware sentences contain annotated tokens.

For subTask2, we find that many unannotated tokens are labeled as annotated tokens and annotated tokens are not labeled. By analyzing the data, we found that the same words occurring as both unannotated and annotated tokens in the sentences, which might make our system achieve a low F-score.

4 Conclusion

In this paper we presented the system we used to compete in the SemEval-2018 Semantic Extraction from cybersecurity reports using NLP competition. Our goal is to implement a deep learning based end-to-end system that can solve cross domain sequence labeling issues without complicated feature engineering.

For future work, it would be interesting to explore systems that can solve the problem of self-

Abstract

We describe the systems developed by the UMBC team for 2018 SemEval Task 8, SecureNLP (Semantic Extraction from Cybersecurity REports using Natural Language Processing). We participated in three of the sub-tasks: (1) classifying sentences as being relevant or irrelevant to malware, (2) predicting token labels for sentences, and (4) predicting attribute labels from the Malware Attribute Enumeration and Characterization vocabulary for defining malware characteristics. We achieved F1 scores of 50.34/18.0 (dev/test), 22.23 (test-data), and 31.98 (test-data) for Task1, Task2 and Task2 respectively. We also make our cybersecurity embeddings publicly available at <https://bit.ly/cybr2vec>.

1 Introduction

Task 8 for SemEval 2018 asked participants to work on a set of related sub-tasks involving analyzing information from text about malware drawn from the Advanced Persistent Threats Notes collection (Blanda and Westcott, 2018) using the semantic framework found in the Malware Attribute Enumeration and Characterization language (Kirillov et al., 2011; Beck et al., 2014). The task was composed of four related sub-tasks that could be part of a processing pipeline for an information extraction system for cybersecurity related text (Phandi et al., 2018).

Subtask 1 required classifying a sentence as being relevant or irrelevant for inferring malware actions and capabilities. Subtask 2 involved predicting token labels for entities, actions and modifiers in sentences. Subtask 3, which we did not undertake, expanded on subtask 2 by asking participants to label relevant relations between the entities. Subtask 4 required predicting more detailed attribute labels, including ActionName, Capability,

StrategicObjectives and TacticalObjectives, drawn from the MAEC vocabulary.

One of our aims is to better understand the differences between cybersecurity text and general, non-cybersecurity text; another is to also better understand differences and variation within cybersecurity texts. To that end, we focus on learning and extracting better representations of the input reports. Specifically, for our approaches, we focus on approaches that incorporate additional, domain-specific knowledge into our system, and we use these enhanced representations and features in well-studied classification, representation, and sequence prediction models.

2 Subtask 1

In this section we describe our approaches to classify a given sentence as relevant or irrelevant to malware. We used logistic regression (LR), multi-layer perceptron (MLP), and Long-Short Term Memory (Hochreiter and Schmidhuber, 1997, LSTM) as classifiers, and we used multiple encoding schemes to represent features for the classification task.

2.1 Models

We experimented with and evaluated three different techniques for implementing the Subtask 1 relevance classifier. Each approach used similar features; we opted for bag-of-words or bag-of-embeddings due to their simplicity and competitive performance (Wang and Manning, 2012).

- **Logistic Regression:** We used logistic regression, as a baseline classifier with an L2 penalty of 10.
- **Multi-Layer Perceptron:** We used two architectures for MLP for two different kinds of input; one was bag-of-words, the other

	LR			MLP		
	ACC	AUC	F1	ACC	AUC	F1
Avg. Binary BOW	89.78	81.58	47.9	90.85	77.44	46.89
Binary BOW	78.9	79.29	32.98	65.05	77.77	25.61
Avg. Count BOW	89.94	79.31	46.49	91.01	75.76	45.77
Count BOW	78.4	81.38	33.84	83.35	75.2	33.99
Wiki embeddings	93.49	50	0	93.49	50	0
Cyber embeddings	88.38	79.65	43.82	83.51	82.35	39.02

Table 1: Performance on Task 1 (dev-data) for each of the model we implemented. We used the best MLP model for SemEval submission (test-data) and had F1 score of 18. We found LR and MLP to always label majority class resulting in zero F1 score using Wiki embeddings.

was dense embeddings. When the input representation was bag-of-words, we used one hidden layer of dimension 32 followed by a classification layer. When embeddings were used we used a network of three hidden layers followed by a classification layer; we found adding up to 3 layers to the network helped improving training accuracy. We used L2 regularization (Tibshirani, 1996) of 0.1 and dropout (Srivastava et al., 2014) of 0.1 to avoid overfitting. We fixed the value of dropout and experimented with multiple values of L2 and chose one giving the best performance on the development dataset. Performance decreased gradually when L2 penalty was either increased to {0.2, 0.25, 0.5} or decreased to {0.01, 0.001, 0.0001}. We set the size of the hidden layer to 100 when embeddings were used.

- **LSTM (for embeddings):** We applied an LSTM network with one hidden layer of size 128. We used dense, pre-trained embeddings (§2.2) for each word in the input sentence.

2.2 Features for the models

We experimented with the following four feature sets in order to determine the best performing representation for Task 1.

- **(Average) Count Bag-Of-Words:** We created standard bag-of-words features from the training dataset. We experimented with normalizing each vector via averaging.
- **(Average) Binary Bag-Of-Words:** We also considered binary bag-of-words features, by replacing each term frequency count with binary value where positive value is set to one and a negative value to zero. We also experi-

mented with normalizing each feature vector by averaging.

- **Cybersecurity embeddings:** The cybersecurity embeddings were generated using word2vec Skipgram model with negative samplings of 100 dimension and a window size of five (Mikolov et al., 2013b) on one million cybersecurity related documents.¹
- **Wikipedia embeddings:** We generated 400 dimensional word2vec skip-gram embeddings from a recent Wikipedia dump. We used a window size of 5.²

2.3 Datasets, embeddings & hyperparameters

For Subtask 1, we used all 65 files available as part of SemEval Task 8. We tuned and tested our model on development data available as part of SemEval. For logistic regression we swept the L2 regularization coefficient ({100, 10, 1, 0.1, 0.01, 0.001}) and chose the value that gave best performance on the development dataset. For neural approaches we used stochastic gradient descent with momentum of 0.4 for LSTM and 0.9 for MLP. We tried multiple learning rates and chose one which gave best performance on the development dataset. We chose starting learning rate of 0.2 for LSTM and 0.1 for MLP. We also tried using Adam optimizer (Kingma and Ba, 2014) with the same learning rate as MLP but found the resulting model labeled all test instances with the majority class.

For our implementation we used Keras (Chollet,

¹We used an embedding model produced by IBM Research trained on a collection of 1 million cybersecurity-related documents with a vocabulary size of 6.4 millions words and 100 dimensions.

²Reported models use the 20180220 English Wikipedia dump; we did not notice large differences in performance when using this vs. an earlier version for the competition.

	LSTM		
	ACC	AUC	F1
Wiki embeddings	80.21	82.35	35.83
Cyber embeddings	93.98	72.05	50.34

Table 2: LSTM Performance (dev data). We offer these as supplementary evaluations.

2015) with a Tensorflow backend to train neural network based models and Gensim (Řehůrek and Sojka, 2010) to train word embeddings. We used Scikit-learn (Pedregosa et al., 2011) for Logistic Regression. For the LSTM, we let the size of the input sequence be the maximum length of all sentences in the batch and padded shorter sentences with zero vectors.

The input was a matrix of dimension $l \times d$ where d is the size of embedding vector and l is the length of the longest sentence.

2.4 Discussion

As evident from Tables 1 and 2, the neural network based classifiers perform better compared to other methods depending on the features.

However, we find a considerable gap between the score from Table 1 and 2. As explained later, we believe that the models’ low scores are related to the scope of the task. Overall, the LSTM performs better compared to the MLP due its ability to capture subtle nuances.

We note the positive impact that domain-centered cybersecurity embeddings have. Nevertheless, not all cybersecurity texts may accurately reflect other cybersecurity texts, especially ones with the task-specific annotations as considered here. We posit that the performance of all our models, in particular the LSTM, may be improved with embeddings that are learned from documents more representative of those evaluated.³

Comparing the results of Wikipedia embeddings and embeddings trained on cybersecurity text we found Wikipedia based embeddings to consistently perform poorly. We believe one of the reasons Wikipedia embeddings performed poorly for this task is due to less overlap between the technicality of the task and content.

Moreover the F1 score is zero sometimes as the features are rich enough to classify positive instance and predicts only negative (as evident from

³The actual collection of APT notes included about 400 documents, vs. the 1 million documents trained on broader cybersecurity texts.

False Positive: Attackers always use this minimal effort approach in order to bypass a victim’s defenses.
False Negative: Trojan.Karagany first checks for a live Internet connection by visiting Microsoft or Adobe websites.
General Information: The group has used two main malware tools: Trojan.Karagany and Backdoor.Oldrea.

Table 3: Task 1 classification examples.

AUC). On the other hand, the cybersecurity embeddings performed better when compared with Wikipedia embeddings, due to the more focused corpus, but we believe there is scope to improve the quality of embeddings. Frequency based features tend to perform better than binary features; averaging the features improves the performance score across all classifiers.

2.5 Error analysis

Among the classifiers, the MLP makes mistakes by getting caught into to domain specific words that occur frequently, like *attack* and *attackers*, and skips less frequent but indicative words like *Trojan.Karagany*. Additionally we found the MLP incorrectly classifies general sentences as relevant. We demonstrate examples in Table 3.

Looking at the example sentences from 3, we see that whether or not a sentence is “relevant” is task-dependent. For example, the general information sentence above could be useful for identifying relationships among different malware instances or families. However, the sentence would be irrelevant in the context of action and capabilities of a particular malware mention.

3 Subtask 2

In this section we describe our approach for Task 2, which required participants to predict token labels for malware-related documents. The Task 2 system served as an automatic labeling tool using one of four labels:

- Action, referring to an malware-related event;
- Entities, referring to either Subjects or Objects in the malware-related sentence; or
- Modifiers, referring to prepositions that link between action and phrases.

Each label is represented by a tag using the inside, outside, beginning (IOB) format (Ramshaw and Marcus, 1999). The performance was measured using F1 score and the relaxed measurement by omitting the IOB tags.

3.1 Our Approach

We extended the previous work Lim et al. (2017), who trained a conditional random field (CRF) on unigram and bigram features of the surface words, part-of-speech tags and Brown clustering signatures (Brown et al., 1992). Like Lim et al. (2017), we also trained a CRF. Our features include:

- unigrams and bigrams of words in the dependency parse tree,
- unigrams and bigrams of the word lemmas,
- wordshape equivalence class analysis (Christopher, 2016), and
- Brown clustering signatures from a larger APT collection .

The word’s context, which are words in the window of size three, was included. These features were extracted using Stanford CoreNLP (Manning et al., 2014). We did not use the surface word as in development we found it yielded lower performance. The dependency function will help to recognize the similar sentence by comparing similar sentence’s structure. The wordshape features represent the classes of upper case, lower case, digits, and punctuations, and also groups the sequence of the same class. The wordshape features help to recognize named entities.⁴

We trained our own Brown clustering features (Liang, 2005) with our own APT corpus of 456 APT files from 2008 to 2017. We experimented with the Brown clustering hyperparameters: the Brown cluster size (1000,10000) and its prefix length (6,8,10,12,16). The best result from the experiment is the prefix of size 8 and cluster size 1000. We built our own Brown clustering for two reasons. First, we will not be able to identify Brown clustering feature when we encounter out of vocabulary word; we found the larger corpus to partially alleviate this concern. Second, we believed that the bigger size of the corpus, with an appropriate clustering size and prefix length, would yield better clustering features.

⁴ We use the ‘dan2’ wordshape classes from CoreNLP (Manning et al., 2014).

	P	R	F1

Modifier	29.92	48.10	36.89
Average	24.42	46.31	31.98

Table 5: Official Task 2 relaxed/token-level scores on Test set

3.2 Experimental Results

We used the CRF++ toolkit (Kudo, 2005) to develop our conditional random field (CRF) models. For the official evaluation, we ran our system on Test set provided by SemEval2018. The test set contains 13,080 tokens in total. The official scoring reported our F1 performance of 22 for strict scoring, and 32 for relaxed scoring. Our F1-score for subtask 2 are generally on par with the baselines (23 for the strict, and 31 for the relaxed, measures). Detailed performance analyses are shown in Tables 4 and 5.

3.3 Discussion

Table 4 demonstrates that our system performance of predicting Entity is lower than Action and Modifier. We believe this is because malware-related entities are different from other text; in particular, they can be quite long. For example, the following (gold test) entity is a long clause with complex syntactic structure: *‘method of leaving the encoded file on disk and only decoding it in memories.’* This entire clause is labeled as an Entity. Despite the dependency features, our system cannot identify these long spans as an entity. Another example of this limitation is shown in Figure 1. This is a rich area for future improvement.

4 Subtask 4

In this section we describe our approach for task 4. The task is to predict attribute labels (Action-Name, Capability, StrategicObjectives and TacticalObjectives) for a given malware-related text

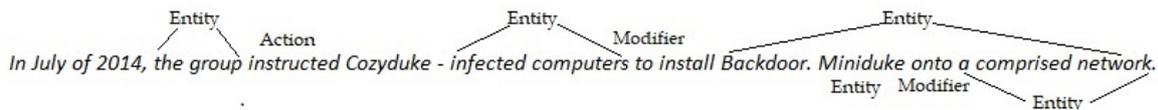

Figure 1: An example of wrong prediction of Task 2. Above the line is the gold standard annotation. Under the line is our predictions.

describing action of a malware.

4.1 Our Approach

For this task we focus on learning better quality word embedding features for a classifier, as classifier performance depends on the quality of its features. In addition to encoding semantics present in the text via embeddings, we want to encode domain specific knowledge in the embeddings. For this purpose, we developed an Annotation Word Embedding (AWE) model that is capable of incorporating diverse types of domain knowledge, such as metadata, keyword information, ontology knowledge, and manual annotation. The AWE model learns to predict this knowledge from the text, resulting in better quality embedding since domain knowledge can be incorporated in the embeddings. We then train a classifier with these high quality word embedding features to classify attribute labels.

4.1.1 Annotation Word Embedding

The AWE model’s learning task is to predict annotations and context words given a target word. A sliding window on the input text generates the training samples. In each sliding window the task is to use target word to predict its own annotation as well as the context words. Formally, we maximize the log probability of context words and annotations given target word.

Given a sequence of T training words ($W_1, W_2 \dots W_{t-1}, W_t, W_{t+1} \dots W_T$) and their annotations $((A_{1,1}, A_{1,2} \dots A_{1,M_1}), (A_{2,1} \dots A_{2,M_2}) \dots (A_{T,1}, \dots A_{T,M_T}))$, our objective is to maximize the average log probability shown in Equation 1:

$$\frac{1}{T} \sum_{t=1}^T \left(\sum_{-C \leq j \leq C, j \neq 0} \log P(W_{t+j} | W_t) + \sum_{0 \leq k \leq M_t} \log P(A_{t,k} | W_t) \right) \quad (1)$$

where C is the size of the context window, W_t is the target word, W_{t+j} is a context word, $A_{t,k}$ is

the k th annotation of target word W_t . In addition to using the target word to predict context words, like Mikolov et al. (2013a)’s skipgram model, the AWE embedding model predicts annotations of target word using target word itself.

4.2 Experiments

To train the AWE model we used all 456 APT reports as text corpus. In addition we used keywords for each attribute label described in MAEC vocabulary (Kirillov et al., 2011) and gold annotation given for 65 APT reports available as part of the SemEval task to create text annotation.

To create text annotation we collected keywords from attribute label descriptions and extracted the token groups from the gold annotations. Token groups consist of the subject, action and object linked to each other via relation labels. We used these token words and keywords to create text annotation; we deleted stop words.

For example, one token group extracted from gold annotation is “these configuration issued commands to attack following domain and IPs.” After deleting stop words this token group we get “configuration,” “issued,” “commands,” “attack,” “domain,” and “IPs.” In the gold annotation, this token group has label Capability12 in attribute category of Capability. In MAEC vocabulary (Kirillov et al., 2011) keywords given for this capability label are “machine access,” “control,” “execute,” “terminate,” and “create.” All these token words and keywords will have an annotation of Capability12 in our AWE model.

After creating the text annotation we train an AWE model with 100 dimension feature vectors, window size 5 and negative sampling. After training embeddings we use these embeddings to create features for classifier. We use average embeddings of all the words in each token group to create classifier instance. We use SVM as classifier. On the test dataset we get F-score of 0.19.

4.3 Discussion

This task is one of the most challenging tasks because of data sparsity and large number of attribute labels. In fact, out of the 444 attribute labels, 185 labels do not appear in dataset. For the remaining 259 attribute labels 169 labels occur less than five times. In addition, among 3348 instances there are 2298 instances without any ActionName attribute, 642 instances without a Capability attribute, 1244 instances without a StrategicObjective attribute and 1675 instances without a TacticalObjective attribute.

To improve classifier performance future work can try training a classifier that focuses on the common classes, with non frequent classes labeled as “other.” Applying other techniques like similarity score to classify infrequent classes may also be beneficial. Additionally, we noticed that in the gold annotation there are often missing relation labels. This missing relation labels result in incomplete token group as token groups are tokens linked by relation labels.

5 Conclusion

We described the systems developed by the UMBC team for 2018 SemEval Task 8, SecureNLP (Semantic Extraction from Cybersecurity REports using Natural Language Processing). We participated in three of the subtasks: (1) classifying sentences as relevant or irrelevant for further malware analysis, (2) predicting token labels for sentences about malware, and (4) adding detained attribute labels to sentences from the MAEC vocabulary for defining malware characteristics. Our cybersecurity embeddings are available at <https://bit.ly/cybr2vec>.

We plan to continue development our systems by getting additional annotations for training, exploring the application of different machine learning algorithms, making use of the knowledge in our Unified Cybersecurity Ontology (Syed et al., 2016) and associated data, and through our ongoing collaboration with colleagues at IBM as part of the AI Horizons Network.

Acknowledgments

The research described in this paper was partially supported by gifts from IBM and Northrop Grumman. We thank Agniva Banerjee, Sudip Mittal, Sandeep Narayanan, Maithilee Prabodh, Vishal

Rathod, and Arya Renjan for helping with annotations.

Abstract

In this paper, we describe our proposal for the task of Semantic Extraction from Cybersecurity Reports. The goal is to explore if natural language processing methods can provide relevant and actionable knowledge to contribute to better understand malicious behavior. Our method consists of an attention-based Bi-LSTM which achieved competitive performance of 0.57 for the Subtask 1. In the due process we also present ablation studies across multiple embeddings and their level of representation and also report the strategies we used to mitigate the extreme imbalance between classes.

1 Introduction

Cybersecurity represents one of the most comprehensive and challenging tasks to tackle from a data-driven perspective. It is inherently technical, covering field such as networking and programming languages, but at the same time, it considers human aspects, such as intent, trust and strategy among benign and malicious agents (Buczak and Guven, 2016).

This rich mixture makes it an ideal playground for machine learning, to extract patterns and characterize the interaction between the different set of actors involved. Moreover, as we can collect large amounts of data from security related sources, such as trace logs and reports, the level of generalization that machine learning methods could achieve could increase. Nevertheless, several challenges also emerge such as noise, lack structure, unavailability of annotated sources and a characteristic class imbalance when data is labeled. Therefore, for machine learning to be considered useful in a cybersecurity context, it must provide robust and reliable results, overcoming the aforementioned issues.

In that sense, how we represent the data plays a key role, as it is known that in any machine learning setting, different feature representations yield to different results, entangling different explanatory factors of variation on the data (Bengio et al., 2013). We are interested in study the tradeoff between the use of hand crafted features the process of automatically learning feature representations.

In that sense, the present SemEval Task 8 (Phandi et al., 2018) represents a relevant scenario to test several hypotheses in the context of a controlled semantic extraction competition. The dataset, provided by Lim et al. (2017), contains over 6,800 labeled sentences from 39 malware reports. From the subtasks, we focused on the first one, as it provides compact goal to assess a proof of concept.

Our approach consists on the use of an attention based LSTM-based recurrent architecture (Hochreiter and Schmidhuber, 1997; Luong et al., 2015) which is capable of learning sentence level feature representations at both character and token level. Additionally, we prepend an embedding layer from which pretrained feature vectors can be associated to the tokens. Given the natural class imbalance of the data, we tried several techniques to alleviate generalization issues.

Our results show that our approach can outperform the baselines, reaching up to 0.57 in the competition leaderboard for the Subtask 1. Nevertheless, the actual scores show that the task is far from being solved, illustrating the difficulty of the problem and the need for more powerful methods that allow us to obtain more expressive feature representations.

2 Data Pre-processing

We tried to keep the data as natural as possible in an attempt to retain most of the characteristics and

nuances from the original reports. Therefore, we did not perform any transformation or cleaning on the tokens extracted from each sentence.

Given the configuration of the contest, where the leaderboard on the test set was kept hidden to the public, the only way to obtain a reliable estimation of the performance of the experiments were to look at the validation set. While this is not usually a problem, in our exploratory study, we found that the set of sentences on the provided validation set differed in distributional terms from the sentences on the provided testing set.

To alleviate this issue we implemented an adjustment procedure that consisted of merging all the sources of data (training, validation and test) into one set while re-labeling each sentence as *part to the test set* or not.

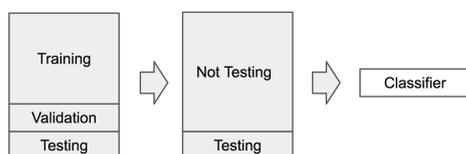

Figure 1: Data Re-classification process.

With this relabeled set, we trained a classifier to predict if a given sentence belonged to the test set or not. In this case, for feature extraction, we computed trigram based vectors for each sentence using Scikit-learn package¹, and a standard feed forward neural network was used. Figure 1 illustrates the approach.

We then considered the sentences that originally belonged to the training + validation set but that obtained the highest probability to be part of the test set by the trained model. This new set presented slightly more similar characteristics to the original test set than the original validation set, in both average sentence length and vocabulary overlap perspectives. For the empirical study, we experimented with both the original validation set and the proposed variation.

3 Proposed Approach

The problem we are trying to solve is, given a sentence from a report, estimates if it contains relevant information about malware characterization or not. Therefore, we can treat it as a binary classification.

¹<http://scikit-learn.org/>

3.1 Use of pretrained feature vectors

The use of pretrained feature vectors has shown positive effects when initializing recurrent architectures (Le et al., 2015). In that sense, we provide three initialization sources.

The first one is the use of an external source represented by Glove vectors (Pennington et al., 2014). The decision of incorporating such source is related to the fact that given that Glove vectors are trained on a Wikipedia corpus, in theory they can provide a considerable level of coverage. On the other hand, we are aware that, as the corpus for this competition is highly focused on security topics, there is a chance that a portion of the token may not have a corresponding feature vector from Glove source. For this cases, we decided to initialize such tokens with a vector computed as the average of the top 10 % less frequent words appearing in Glove set.

In the second place, we wanted to test if pre-training with the same sources used for the competition could have a positive outcome. This is natural decision as we are building an ad-hoc feature representation that is narrowed to the security context. To achieve that, we computed a feature vector based on i) bigrams and trigrams combination and ii) learning a continuous vector representation by means of a word2vec (Mikolov et al., 2013) configuration. We experimented with these three sources isolated as well as combined.

Finally, in addition to a token-level feature representation, we implemented a character level feature learning pretraining that consists of a single LSTM that passes through each token and from which we capture the last hidden state to use as a token representation.

3.2 Model Architecture

The resulting sequence of vectors associated to a given sentence is then passed to a BiSTM module. In this step, as we need to obtain a learned representation of the entire sequence, we explored three configurations. The first one consists of just take the last hidden state and treat it as the sentence level representation. The second one consists of performing a simple averaging on all the hidden states obtained from the sequence. This average can be further complemented by means of element wise operations, such as direct sum or the dot product, following a schema similar to (Mou et al., 2015). The third configuration was the use

the kernel sends commands to each module using its module id .

the victim is then redirected to a url which in turn determines the best exploit to use based on the information collected .

here also it uses hashes to look up apis .

pipe server is a special mode of the injected dll .

it appears this method makes sending sms easy .

the data is sent encrypted with rc4 , and base64-encoded .

the malicious content is stored inside the document in encoded form , and the shellcode decodes and writes this to disk .

it is designed as a survey tool .

its method of exfiltrating the logged keystrokes relied upon a hardcoded email address stored in the binary .

the communication between the attacker and the sockss is encoded using the rc4 key .

Table 2: Sample of false negatives from the custom validation set.

of an attention mechanism, as proposed by (Luong et al., 2015). In this case, a feedforward neural network is trained jointly with the recurrent module and it is in charge of learning the portions of the sentences that are more expressive for the classification.

The learned sentence representations are then passed to a binary classifier that estimates the likelihood of a sentence to be relevant or not by minimizing the categorical cross entropy loss. For all our experiments we use as optimizer Rmsprop (Tieleman and Hinton, 2012). For regularization, we added Dropout (Srivastava et al., 2014) both in the recurrent module as well as in the binary classifier.

4 Results and Discussion

The main results are shown on Table 3 and Table 4. From them, we can see that taking Glove as a baseline and incorporating n-grams vectors produce the best results. The addition of word2vec based vectors did not have a positive impact. We hypothesize this is due to the size of the training set used, the resulting vectors are based on a model that could not converge.

In the case of the configurations used to obtain a sentence representation, a clear improvement is obtained by using an attention mechanism, which outperforms both the selection of the last hidden state and all the averaging alternatives. These results are aligned with the current state of the art in language modeling, as attention is a robust way to prioritize the elements that conform a sentence. The use of a character level representation learning module slightly improved the results, while at the same time increased the time consumption of the model in approximately 15%. Therefore, it is not clear if such addition is cost effective in all cases.

Name	Accuracy
Glove	0.612
Glove+Ngrams	0.683
Glove+Ngrams+ w2v	0.681

Table 3: Classification results for different initializations.

We tried regularization via Dropout, from 0.2 to 0.7 but it did not show relevant improvements. Another technique we implemented was to re-weight the labels to mitigate the imbalance problem, but such addition decreased the overall performance of the model.

We repeated the experiments using the original train-validation schema, as well as with the variation proposed. On average using the proposed variation only increased the performance in around 2% (obtained once the test set was released) by the competition organizers.

From the results showed above, we can summarize the best configuration for the proposed task as follows:

- Initialize token vectors by means of a concatenation between Glove vectors and trigrams captured from the training set.
- The use of an BiLSTM module and an attention mechanism to efficiently weight the importance of the tokens in a sentence.

4.1 Misclassification Analysis

To obtain a better understanding of the performance of the model, we sampled a group of instances coming from both the false positive and false negative sets.

Table 1 shows a set of false positives, i.e., not relevant sentences misclassified as relevant by the

Name	Accuracy
Last hidden	0.692
Average hidden	0.694
Attention	0.822
Attention + char	0.828

Table 4: Classification results for different sentence level representation learning.

model. One of the main characteristics is the lack of specific details expressed on the sentences and the shallow descriptions of processes or tasks. On the other hand, on Table 2, the set of false negatives, i.e., relevant sentences classified as not relevant by the model, presents a denser population of specific terms, usually associated to tools or protocols used by the attackers. From this, we can hypothesize the model is not able to effectively understand the context of the token usage, especially when it is rare and probably has very low frequency. In that sense, this could represent the need for additional information the model requires treating this cases in a particular way (e.g. passing explicitly token dependencies). Further experiments are needed to find ways to operationalize such additions.

4.2 Parameter Sensibility Analysis

Given the considerable number of hyperparameters that can be configured, we decided to study how such tuning impact model performance. During training, we found that the learning rate was key factor. While it is known that a small learning rate is beneficial when working with recurrent architectures, we found that in this case, give the extreme class imbalance, it was required to search for learning rates in a considerable lower spectrum. Figure 2 and Figure 3 show different learning dynamics sampled from several learning rates configurations. Values higher than 0.0001 produce uniform increments in the validation loss, which means the model was not able to generalize (as seen on Figure 2, training loss rapidly converged in such cases, not giving the model enough space to learn efficiently). Learning rates around 0.0001 or below started providing a decreasing validation loss. This phenomenon provides some insights on the difficulty of the task and the challenges associated when trying to achieve generalization.

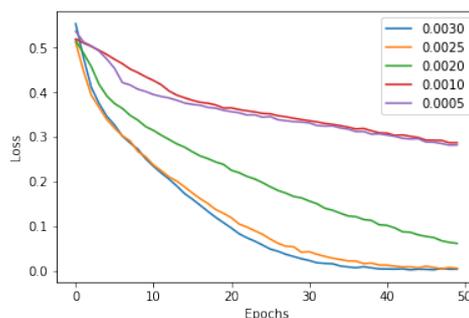

Figure 2: Impact of the learning rate on the training loss.

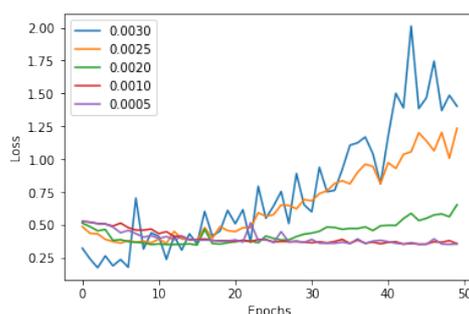

Figure 3: Impact of the learning rate on the validation loss.

5 Conclusion and Future work

In this work, we described our experience on the semantic extraction from cybersecurity reports. We were able to produce a model the generate feasible results for estimating the relevance of sentences in the context of security information. For future work, we consider that while keep improving the performance of the model is vital task, equally important is to explore ways to allow decision makers to have a clear understanding of the internals of the model to assess how much they can depend on it to support their actions. Therefore, we consider working towards incorporating an explanatory or interpretable layer in the design of a model.

Abstract

Cybersecurity risks such as malware threaten the personal safety of users, but to identify malware text is a major challenge. The paper proposes a supervised learning approach to identifying malware sentences given a document (subTask1 of SemEval 2018, Task 8), as well as to classifying malware tokens in the sentences (subTask2). The approach achieved good results, ranking second of twelve participants for both subtasks, with F-scores of 57% for subTask1 and 28% for subTask2.

1 Introduction

Malware is a major problem in the digital world. Recently, Lim et al. (2017) addressed the malware threat by creating a new database of malware texts. In addition, they constructed different models for identifying and classifying malware sentences, and discussed the outstanding challenges. Sutskever et al. (2016) also pointed to cybersecurity defense as a key area because of its long-term impact on society. Still, there have been very few efforts addressing the problem. Many cybersecurity agencies such as Cylance (Gross, 2016) and Symantec (DiMaggio, 2015) have collected large repositories of malware-related online texts. The diversity of those texts shows that identifying malware is quite challenging.

The organizers of SemEval 2018, Task 8 defined four subtasks for Semantic Extraction from CybersecUrity REports using NLP, SecureNLP (Phandi et al., 2018). The paper outlines a supervised approach to the first two subtasks, on malware sentence and token identification, respectively. In subTask1, given a sentence, the systems need to predict whether the sentence is relevant for inferring the malware’s actions and capabilities. For this subtask, two machine learning classifiers were used, Naïve Bayes (Rish, 2001) and

Data	Total		Malware	
	Sents	Tokens	Sents	Tokens
Train	9,435	231,180	2,204	12,165
Dev	1,213	32,029	79	459
Test	618	13,080	90	453

Table 1: Malware dataset statistics

Conditional Random Fields (CRF, Lafferty et al., 2001), as well as a combination of the two models.

In subTask2, the systems should predict and classify malware tokens in the sentences into three different categories, namely Action, Entity, and Modifier. A CRF-based classifier was used also for the second subtask.

The paper is organized as follows: The datasets are presented in Section 2. The malware sentence identification is described in Section 3, while the token label malware identification is described in Section 4. Results are presented in Section 5, with system comparison and error analysis reported in Sections 6 and 7, respectively. Section 8 addresses future work and concludes.

2 Datasets

The SecureNLP shared task organizers provided three different datasets: training, development and test sets. The statistics of the datasets are reported in Table 1, with the total number of sentences and tokens in each set as well as the number of those sentences and tokens containing malware.

3 Malware Sentence Identification

Two classifiers, CRF and Naïve Bayes were used for malware sentence identification. When both the classifiers identified a sentence as malware, the outputs of the classifiers were combined. The system architecture is shown in Figure 1.

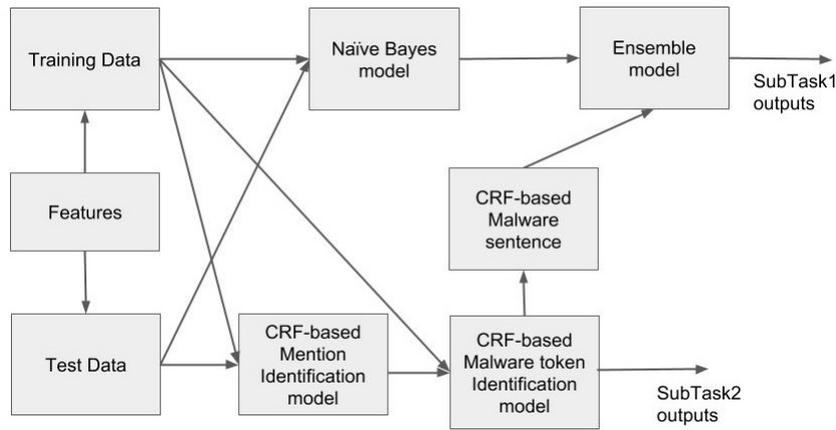

Figure 1: Overall system architecture

3.1 Conditional Random Fields

Token level malware words were identified in the texts described in Section 2. If a sentence contains malware token(s) as identified by the CRF classifier, the sentence is considered as a potential malware sentence. A range of features (further described in Section 4 below) were utilized to train the CRF classifier to predict malware tokens.

3.2 Naïve Bayes

A Naïve Bayes classifier is a probabilistic classifier based on Bayes' theorem an independence assumption between the features. As an initial step, a dictionary was created using the vocabulary found in all the sentences. In the next step, a term-document matrix was built for each sentence. Then Bayes' Theorem was applied to calculate the malware ($y = 1$) and non-malware ($y = 0$) probabilities for each sentence. Equation 1 represents the malware probability, P for each sentence.

$$P(y = 1|S) = \frac{P(S|y = 1) \times P(y = 1)}{P(S)} \quad (1)$$

Here S denotes the set of words in a particular sentence and $P(S) = P(S|y = 1) \times P(y = 1) + P(S|y = 0) \times P(y = 0)$. The non-malware probability for each sentence can be calculated in the same way. If $P(\text{malware}) > P(\text{non-malware})$, the sentence is considered to be a malware sentence, otherwise it is assumed to be non-malware.

3.3 Classifier Ensemble Prediction

An ensemble classifier was created by merging the outputs of the two classifiers described above. If both classifiers identify a sentence as malware,

it is considered to be malware, otherwise non-malware. Combining the two classifiers gave better accuracy than using each classifier individually.

4 CRF-based Malware Token Identification and Classification

To identify and classify each token from unstructured text into the three categories Action, Entity and Modifier, a supervised CRF-based approach was used. The task was divided into two steps. In the first step, each token (called a mention) was identified as belonging to one of the three categories or not. In the next step, the identified tokens were classified into one of the three categories.

The CRF token label malware identification model was implemented using the C++ CRF++ package¹, which allows for fast training by utilizing L-BFGS (Liu and Nocedal, 1989), a limited memory quasi-Newton algorithm for large scale numerical optimization. The classifier was trained with L2 regularization and the following features:

- local context (with a -1 to +2 window, i.e., from one preceding to two following tokens),
- part-of-speech information (-1 to +3 tokens),
- suffix (last two or three characters)
- prefix characters (three initial characters)
- starts-with-upper-case,
- stem (-3 to +2 tokens),
- is-a-stop-word,
- is-alphanumeric,
- is-sentence-initial,
- identified mention (-3 to +3 tokens),
- bi-gram: a combination of the current token output and previous token output.

System	Precision	Recall	F-score
CRF	0.30	0.80	0.43
Naïve Bayes	0.30	0.89	0.45
Ensemble	0.43	0.75	0.55

Table 2: SubTask1 Development Results

System	Precision	Recall	F-score
CRF	0.40	0.71	0.51
Naïve Bayes	0.32	0.88	0.47
Ensemble	0.49	0.67	0.57

Table 3: SubTask1 Test Results

To identifying the mentions, the above features (except the mention feature) were used together with the current word and a context consisting of the previous two and the next two words.

5 Results

The supervised learning approaches were applied to subTask1 and subTask2. The systems were learned from the training data and tested on the development data. Table 2 reports the precision, recall and F_1 -score on the subTask1 development data for the CRF approach, the Naïve Bayes, and the combined ensemble approach. The ensemble achieved 10% better F-score than the Naïve Bayes approach, which in turned slightly out-performed the CRF classifier. Before evaluating on the unseen test data, the development set was merged with the training set to build the classifiers. The combined approach also produced the best results on unseen test data, as reported in Table 3. Note that the enlarged training set helped to increase precision on the test set for all classifiers, while recall went down in all cases.

For subTask2, token label malware identification, we applied the Conditional Random Fields classifier using the features given in Section 4. The results are shown in Table 4. When tested on the development data, the classifier and achieved an F-score of 24.90%, with slightly higher recall than precision. Again, the unseen test data results were somewhat better, with an F-score of 28%. Tentatively since also here the development data was merged with the training data when learning the classifier used for the unseen test data.

Data	Precision	Recall	F-score
Dev	22.22	28.32	24.90
Test	26.00	29.40	28.00

Table 4: SubTask2 Results (%)

Team Name	T1	T2	T2-rel
Villani	0.57	0.23	0.31
Flytxt_NTNU	0.57	0.28	0.36
DM_NLP	0.52	0.29	0.39
HCCL	0.52	0.22	0.38
TeamDL	0.50	0.25	0.36
NLP_Found	0.49	0.28	0.39
ACL benchmark	0.51	0.23	0.31

Table 5: Top-7 results (F-score) for SubTask-1 (T1), SubTask-2 (T2), and SubTask2-relaxed (T2-rel)

6 Comparison with Other Systems

Comparing our system (‘Flytxt_NTNU’) with the other systems participating in the shared task, Table 5 reports the top 7 results and shows that in subTask1 (malware sentence identification) we secured second position, while achieving the same F-score (57%) as the top-rated system (Villani). Also for token label malware identification (subTask2), our system got second position with a 28% F-score. For both subtasks, we achieved clearly better scores than the baseline system (‘ACL benchmark’).

7 Error Analysis and Discussion

To analyze the outputs of the development data for subTask1 and subTask2, Tables 6 and 7 draws the confusion matrices for each subtask.

For subTask1, Table 6 shows that many non-malware sentences are identified as malware sentences by both classifiers, tentatively since many common words are shared by both malware and non-malware sentences. Both classifiers generate higher recall than precision values because the classifiers try to identify as many sentences as possible as malware. Once the outputs of the two classifiers were combined (when both classifiers agreed on a sentence being potential malware), about half of the non-malware sentence classification errors were removed, and the ensemble thus produced better F-scores than the Naïve Bayes and CRF models in isolation.

	CRF		Naïve Bayes		Ensemble	
	Non-Malware	Malware	Non-Malware	Malware	Non-Malware	Malware
Non-Malware	985	149	969	165	1057	77
Malware	16	63	9	70	20	59

Table 6: Confusion Matrix for SubTask1 on the development data

	B-Entity	I-Entity	B-Action	I-Action	B-Modifier	I-Modifier	O
B-Entity	51	68	1	0	1	0	135
I-Entity	8	122	1	0	7	0	383
B-Action	2	1	57	7	0	0	57
I-Action	0	0	0	0	0	0	6
B-Modifier	0	6	0	0	28	1	44
I-Modifier	0	0	0	0	0	0	0
O	277	537	107	12	46	3	30061

Table 7: Confusion Matrix for SubTask2 on the development data

The confusion matrix for subTask2 is reported in Table 7, in the BIO (beginning, inside, outside) format for each of the three classes (entity, action, modifier). We observe that many non-malware tokens (**O**) are identified as malware and vice versa. Again, this might be due to same words occurring as both malware and non-malware tokens in the sentences, which is why the system achieved low precision and recall values. Furthermore, two of the inside mention classes (**I-Action** and **I-Modifier**) are tiny, indicating that training machine learners on them will be difficult.

8 Conclusion and Future Work

The paper has proposed Naïve Bayes and CRF based approaches to identify malware sentences (subTask1). In the future, we will incorporate other features such as tf-idf and information gain to improve system performance. Furthermore, we aim to apply deep learning-based approaches such as LSTM (Long Short-Term Memory) and CNN (Convolution Neural Network) to malware sentence classification.

For subTask2, many features were developed to identify malware tokens using Conditional Random Fields. Most of the features were extracted directly from training data, but the features could have been further optimized using grid search and evolutionary approaches. Also for this subtask, we will in the future experiment with applying other approaches, such as LSTM and CNN, to identify the types of malware tokens in the sentences.

Digital Operatives at SemEval-2018 Task 8: Using dependency features for malware NLP

Chris Brew

Digital Operatives

chris.brew@digitaloperatives.com

Abstract

The four sub-tasks of SecureNLP build towards a capability for quickly highlighting critical information from malware reports, such as the specific actions taken by a malware sample. Digital Operatives (DO) submitted to sub-tasks 1 and 2, using standard text analysis technology (text classification for sub-task 1, and a CRF for sub-task 2). Performance is broadly competitive with other submitted systems on sub-task 1 and weak on sub-task 2. The annotation guidelines for the intermediate sub-tasks create a linkage to the final task, which is both an annotation challenge and a potentially useful feature of the task. The methods DO chose do not attempt to make use of this linkage, which may be a missed opportunity. This motivates a post-hoc error analysis. It appears that the annotation task is very hard, and that in some cases both deep conceptual knowledge and substantial surrounding context are needed in order to correctly classify sentences.

1 Introduction

The SecureNLP challenge is motivated by (Lim et al., 2017) and further described in (Phandi et al., 2018), it aims to provide automation for malware analysts who might otherwise be overwhelmed by the task of finding key data in long threat reports. The annotation guidelines used to create the task ask analysts to include actions carried out by the malware, but exclude actions carried out by the human designers of the malware. These actions are related to the MAEC cybersecurity ontology (Kirillov et al., 2010). The guidelines include one substantial caveat:

As a general guide [for a positive annotation], the sentence should imply a particular malware action or capability, with reference to the list of attribute labels. [i.e. the MAEC labels]

Sub-task 1 calls for a determination of relevance or irrelevance to malware activity on a per-sentence basis. However a number of issues make this difficult. See detail in (Lim et al., 2017). First, it is not obvious what to do when a sentence describes malware activity but does not fit in with any MAEC category. Second, the distinction between things done by the malware and things done (or intended) by its designers is not easy to maintain.

We describe the systems that we built for tasks 1 and 2 and use them to conduct ablation studies and error analyses.

2 Digital Operatives Systems

The Digital Operatives submission used spaCy (Honnibal and Johnson, 2015). to generate features for each token, then aggregated the features from the whole sentence. To estimate performance, we used 5-fold cross-validation on the combined training and development sets.

As an example, consider the word "ago" in the sentence:

"A few days ago we detected a watering hole campaign in a website owned by one big industrial company."

We extract:

- the word itself
- the lemmatized form provided by spaCy,
- the orthographic shape (all lower case, represented as "xxx")
- the part-of-speech ("ADV")
- the detailed part-of-speech ("RB")
- Brown cluster (6442) (Brown et al., 1992)
- the fact that it does or does not look like a URL

- the bigrams in which it participates (“days ago” and “ago we”)
- similar bigrams for lemma, Brown cluster and shape.
- extract features from dependency links. Each token has a head from which it depends, and the relation that it holds to the head has a name. The head of “ago” is the verb “detected”, and the relation is “advmod”. We package this up into the feature detected-ADVMOD-ago.
- features of the form X-advmod-Y where X and Y are either both cluster ids or both orthographic shapes.

The result is passed to a passive aggressive classifier (Crammer et al., 2006)¹. This learner, which is similar in cost and performance to a linear kernel SVM and to a number of other linear classifiers, seems to be close to the best choice from a large number of experiments. Grid search was used to choose the C regularization parameter for the classifier. On our 5 validation splits this method had a mean f1 of 0.60 with standard deviation 0.045. Performance on the actual test set was lower, at 0.52. This was rank 5 among the 11 submitted systems, well behind the top 2 systems and slightly ahead of the organizers’ benchmark.

Our system classifies each sentence in isolation. No attempt was made to establish the referents of pronouns.

For sub-task 2 we used CRFsuite (Okazaki, 2007) to implement a linear-chain conditional random field. Per-word features were: the lower-cased word and its part-of-speech tag; a two-letter prefix of the word; two- and three-letter character prefixes of the word; shape indicators for whether the word is numeric, title-case or upper-case; indicators for whether the word is beginning or end of sentence; the nltk part of speech of previous and subsequent words, if present; the shape indicators of previous and subsequent words, if present. We would have preferred to use features from spaCy, as in task 1, but did not overcome tokenization differences in time. This system was not competitive, with an F-score of 0.16 and a ranking of 9th. The best system had an F1 score of 0.39.

¹In scikit-learn’s implementation (Pedregosa et al., 2011)

	precision	recall	f1-score	sup
irrelevant	0.96	0.83	0.89	528
relevant	0.44	0.79	0.57	90
avg / total	0.88	0.83	0.84	618

Table 1: F1-scores using only lemmas and dependencies between lemmas.

2.1 Ablation study

The submitted system used all the features generated by spaCy. We augmented this with ablation studies in which only subsets of the features were used. The best performance came using only unigrams and bigrams derived from lemmas, along with dependency features derived from lemmas. Ablation actually improved performance over the submission, as shown in table 1. Presumably, these features give the sparse linear classifier an appropriate level of generality. There are 89 false positives in the complete test set and 19 false negatives. There are only 71 true positives.

3 Task analysis

MAEC labels classify malware along several dimensions. We focus on a tractable subset that can be assigned to Actions and that describe capabilities of malware. Table 2 lists these labels.

3.1 Error analysis

We carried out our own annotation of the 112 examples from the test set for which our system did not agree with the organizers annotations. To these we added a further 111 randomly chosen examples from the test set, for which our system did agree. We assessed each of these examples against the 20 categories from table 2, There were differences of judgment between our annotations and those of the organizers. Potential reasons for this include simple errors, misunderstandings, and consequences of the linkage between sub-task 1 and sub-task 4.

Table 4 shows performance when using the new annotations. There are now 72 false positives in the complete test set and 13 false negatives. True positives now slightly outnumber false positives, at 88. It is of course possible that some of our annotations are unintentionally biased in our favor. See table 3. In future work, it may be beneficial to apply the crowdsourcing methods and careful evaluation of annotation found in, for example, (Snow et al., 2008).

Number	Capability	Example	Frequency
000	anti-behavioral_analysis	avoid detection and frustrate analysis,	36
001	anti-code_analysis	XOR 0xAA applied on top of it,	36
002	anti-detection	making its open ports invisible to scanners.	240
003	anti-removal	block access to where the rootkit keeps its file	5
004	availability_violation	DDoS attacks were launched	28
005	command_and_control	C & C proxies talk to [other] proxies	580
006	data_exfiltration	exfiltrate data back to the C&C server	189
007	data_theft	extract Internet Explorer passwords	186
008	destruction	collects file names and overwrites them	63
009	fraud	smart meters could be manipulated	7
010	infection/propagation	infected via a multi-stage attack	525
011	integrity_violation	attacker can hijack the network	85
012	machine_access/control	control the keyboard and mouse.	245
013	persistence	the malware creates a registry key	57
014	privilege_escalation	achieve admin privileges	23
015	probing	malware checks if an old versn is installed	77
016	remote_machine_manipulation	the malware will access network shares	13
017	secondary_operation	The dropper installs a second file	280
018	security_degradation	bypass User Account Control (UAC)	33
019	spying	Babar is able to sniff all keystrokes	128

Table 2: Malware capability labels. Note that the frequency distribution is highly skewed. Examples are edited to fit.

Example	DO	SN	MAEC
A screenshot of the desktop is saved into the C:\ProgramData\Mail\MailAg\scs.jpg file .	0	1	spying?
As you can see this powershell script simply extracts another VBScript and executes it .',	0	1	
Cozyduke was used throughout these attacks to harvest and exfiltrate sensitive information to the attackers .	1	0	exfiltration
Cozyduke will periodically contact these websites to retrieve task information to be executed on the local machine .	0	1	C&C
Execute contents in unlabeled textbox1 as a SQL query and return binary data to adversary.	0	1	exfiltration
The malware hides behind numerous layers of encryption and obfuscation and is capable of quietly stealing and exfiltrating sensitive information such as email from the victim's computer	1	0	anti-detection,data_theft
To communicate with the C&C - server , the Trojan makes use of asymmetric encryption with a hardcoded pair of private and public keys .	1	0	c&c

Table 3: Sample annotation disagreements. The column labeled DO reflects our classification, SN represents that given by the SecureNLP organizers. The column labeled MAEC gives detail on the capability that DO thinks is being described. When we feel confident that one of the annotations for a sentence is clearly right, it is shown in bold. If not, neither is bold.

	P	R	F1	sup
irrelevant	0.97	0.86	0.91	517
relevant	0.55	0.87	0.67	101
avg / total	0.90	0.86	0.87	618

Table 4: Performance against DO’s (possibly unintentionally biased) annotations.

4 Discussion and conclusions

We suspected that the secure NLP task is difficult (Lim et al., 2017). Results bear this out:

- Our post-hoc annotation study suggests that it is indeed difficult to distinguish between things done by attackers and things done by malware.
- Often, the system described is distributed, consisting of downloaded malware, websites and C&C servers. The MAEC classification and the SecureNLP annotation guidelines emphasize measurable properties of malware samples. This puts tension into the annotation scheme and may well be a contributor to annotation errors.
- A more extensive effort using multiple annotators and reformulated guidelines could be beneficial.
- With the technology that we used, analysts relying on the classifier’s judgment as a filter will still need to read approximately double the number of sentences that actually contain relevant information, and will miss 10% to 20% of the relevant material, which the classifier regards as irrelevant.

Acknowledgments

Thanks to Nathan Landon and colleagues at Digital Operatives for resources, feedback and encouragement. Particular thanks to Jordan Bryant for detailed discussions. This work was funded, in part, by IARPA’s Cyber-attack Automated Unconventional Sensor Environment (CAUSE) program. Judgments and opinions are our own. Thanks to two anonymous reviewers for thoughtful suggestions on how to improve the paper.

Abstract

This paper presents the participation of Apollo’s team in the SemEval-2018 Task 9 “Hypernym Discovery”, Subtask 1: “General-Purpose Hypernym Discovery”, which tries to produce a ranked list of hypernyms for a specific term. We propose a novel approach for automatic extraction of hypernymy relations from a corpus by using dependency patterns. The results show that the application of these patterns leads to a higher score than using the traditional lexical patterns.

Keywords: hypernymy relations, semantic relations, corpus, taxonomy, syntactic dependencies.

1 Introduction

This paper presents the Apollo team’s system for hypernym discovery which participated in task 9 of Semeval 2018 (Camacho-Collados et al., 2018) based on unsupervised machine learning. It is a rule-based system that exploits syntactic dependency paths that generalize Hearst-style lexical patterns.

The paper is structured in 4 sections: this section presents existing approaches for automatic extraction of hypernymy relations, Section 2

contains the current system architecture. The next section presents the web interface of the project, and, finally, Section 4 briefly analyses the results and drafts some conclusions.

Since language is a “vital organ”, constantly evolving and changing over time, there are many words which lose one of their meanings or attach a new meaning. For instance, when searching the word “apple” in WordNet (Miller, 1995), it appears defined as “fruit with red or yellow or green skin and sweet to tart crisp whitish flesh” and “native Eurasian tree widely cultivated in many varieties for its firm rounded edible fruits” but searching in British National Corpus¹, we will remark that the term is used more frequently as a named entity (referring to a “company”).

From this point of view, we consider that developing a system for hypernym discovery that uses linguistic features from a corpus could be more useful for this task than using a manually-crafted taxonomy.

It is well known that in natural language processing (NLP), one of the biggest challenges is to understand the meaning of words. Also, detecting hypernymy relations is an important task in NLP, which has been pursued for over two decades, and it is addressed in the literature using two complementary approaches: rule-based and distributional

¹ <https://corpus.byu.edu/bnc/>

methods. Rule-based methods (Hearst, 1992; Snow et al., 2004) base the decision on the lexico-syntactic paths connecting the joint occurrences of two or more terms in a corpus. In the case of supervised distributional methods (Baroni et al., 2012; Roller et al., 2014, Weeds et al., 2014; Levy et al., 2015, Kruszewski et al., 2015), term-pair is represented using some combination of the terms' embedding vectors.

This challenge has been shown to directly help in downstream applications such automatic hypernymy detection is useful for NLP tasks such as: taxonomy creation, recognizing textual entailment, text generation, Question Answering systems, semantic search, Natural Language Inference, Coreference Resolution and many others.

Traditional procedures to evaluate taxonomies have focused on measuring the quality of the edges, i.e., assessing the quality of the *is-a* relations. This process typically consists of extracting a random sample of edges and manually labeling them by human judges. In addition to the manual effort required to perform this evaluation, this procedure is not easily replicable from taxonomy to taxonomy (which would most likely include different sets of concepts), and do not reflect the overall quality of a taxonomy. Moreover, some taxonomy learning approaches link their concepts to existing resources such as Wikipedia.

2 A new Approach to Detect Hypernymy Relation

The main purpose of this project was to identify the best (set of) candidate hypernyms for a certain term from the given corpus².

In our system, we considered the rule-based approach and, in order to extract the corresponding patterns, we used syntactic dependencies relations (Universal Dependencies Parser³).

Below, we present our method of extracting hypernyms from text:

² For this subtask, we used the 3-billion-word UMBC corpus, which consists of paragraphs extracted from the web as part of the Stanford WebBase Project. This is a very large corpus containing information from different domains.

³ Universal Dependencies (UD) is a framework for cross-linguistically consistent grammatical annotation and an open community effort with over 200 contributors producing more than 100 treebanks in over 60 languages.

- **Tokenization:** sentence boundaries are detected and punctuation signs are separated from words;
- **Part-of-speech tagging:** the process of assigning a part-of-speech or lexical class marker to each word in a corpus. Words in natural languages usually encode many pieces of information, such as: *what the word "means" in the real world, what categories, if any, the word belongs to, what is the function of the word in the sentence?* Many language processing applications need to extract the information encoded in the words. Parsers which analyze sentence structure need to know/check agreement between: subjects and verbs, adjectives and nouns, determiners and nouns, etc. Information retrieval systems benefit from know what the stem of a word is. Machine translation systems need to analyze words to their components and generate words with specific features in the target language.
- **Dependency parsing:** the syntactic parsing of a sentence consists of finding the correct syntactic structure of that sentence in a given formalism/grammar. Dependency parsing structure consists of lexical items, linked by binary asymmetric relations called dependencies. It is interested in grammatical relations between individual words (governing & dependent words), it does not propose a recursive structure, rather a network of relations. These relations can also have labels and the phrasal nodes are missing in the dependency structure, when compared to constituency structure.

One of the boosts for this approach was to develop new dependency patterns for identifying hypernymy relations from text that are based on dependency relations. The increased popularity and the universal inventory of categories and guidelines (which facilitate annotation across languages) of Universal Dependencies determined us to use this resource in order to automatically extract the hypernyms from the corpus.

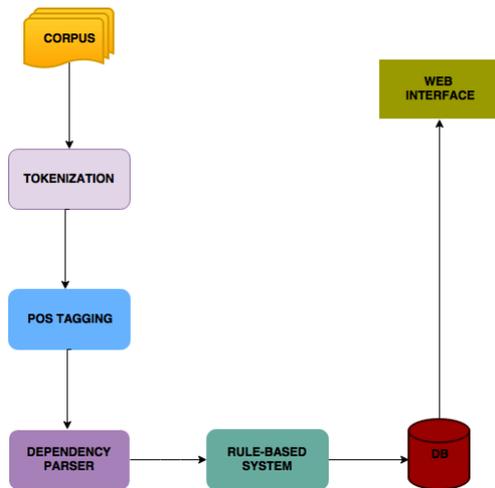

Figure1: Project's architecture

In this manner, we managed to compress a list of 44 lexico-syntactic patterns used for the hypernyms extraction⁴ in only 8 dependencies patterns. In the next lines, we present few examples of lexico-syntactic patterns that were replaced by dependencies patterns:

*{X and other Y; X or other Y; X and any other Y; X and some other Y; Y other than X; X like other Y; Y other than X} → replaced by **X "amod" Y;***

*{X is a Y; X was a Y; X are a Y; X are Y; X will be a Y; X is an adj Y; X was a adj. Y; X are a adj. Y; X was a adj. Y; X are examples of Y; X is example of Y; Y for example X; examples of Y is X; examples of Y are X; X which is named Y; X which is called Y; Y which are similar to X; Y which is similar to X} replaced by **X "nmod" Y.***

Because we used syntactic dependencies relations (no lexical patterns were involved), our system is language independent. Unfortunately, the limited hardware resources determined us to run

⁴ <http://webdatacommons.org/isadb/lrec2016.pdf>

our system only in English but we are looking forward to running it in both Spanish and Italian.

3 The Web Interface

The interface⁵ was implemented in the form of a website. The site is backed by a MongoDB database. When a user types in a query and hits enter a post request is sent and the backend will do some processing on the query (tokenizing, lemmatizing) and then search in the database. The results are then sent back to the user where they are rendered.

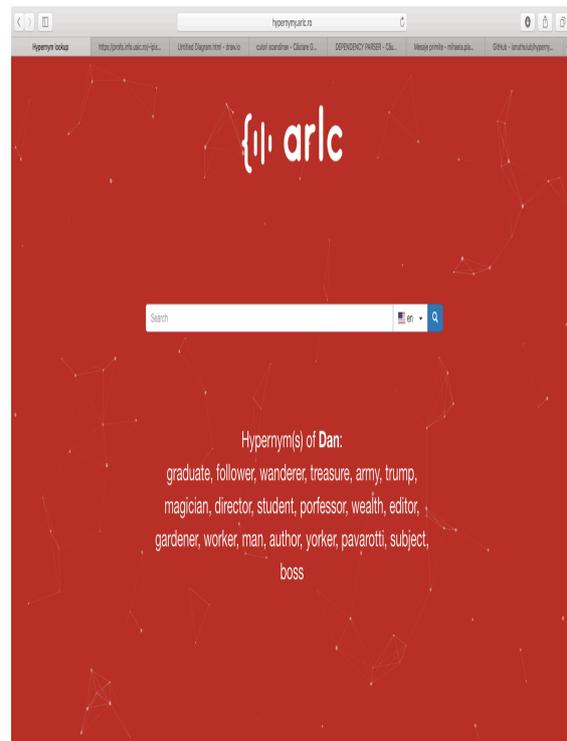

Figure 2: Project's interface

4 Results

We consider that a qualitative way of analyzing our system is to look at which relations are more productive. Table 1 presents the percentages of the most representative syntactic relations which we have identified. While some relations have not been very fruitful (such as *X "obj" Y*, for instance), others, instead, have been very productive, generating tens of thousands relations.

⁵ <http://hypernymy.arlc.ro>

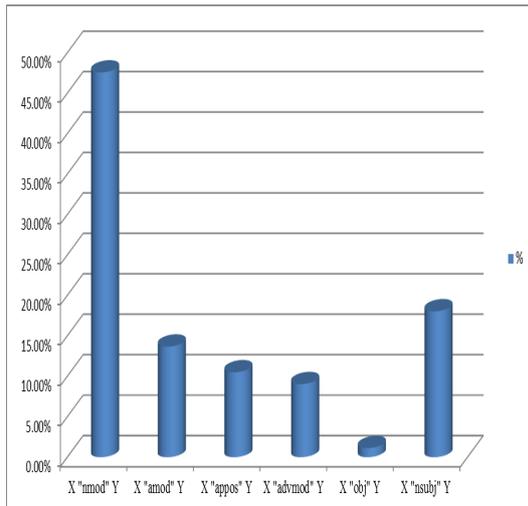

Table 1: Percentages of the identified syntactic relations

The project's results show that we have managed to accomplish the main objective of this project, to outperform the random strategy. The lower scores have been obtained for multiword expressions, for which we plan to add dedicated modules.

An issue that we have noticed was that the given vocabulary was quite restrictive, for instance, it contains words like "above-water", "artesian water", "bath water" etc., but it doesn't contain the word "water" (we had a case when our system identified the word "water" as a hypernym and it was a correct hypernym, but due to the fact that the vocabulary doesn't contain the word "water", it cannot be evaluated) and many other examples like this.

Abstract

This paper describes a hypernym discovery system for our participation in the SemEval-2018 Task 9, which aims to discover the best (set of) candidate hypernyms for input concepts or entities, given the search space of a pre-defined vocabulary. We introduce a neural network architecture for the concerned task and empirically study various neural network models to build the representations in latent space for words and phrases. The evaluated models include convolutional neural network, long-short term memory network, gated recurrent unit and recurrent convolutional neural network. We also explore different embedding methods, including word embedding and sense embedding for better performance.

1 Introduction

Hypernym-hyponym relationship is an *is-a* semantic relation between terms as shown in Table 1. Various natural language processing (NLP) tasks, especially those semantically intensive ones aiming for inference and reasoning with generalization capability, such as question answering (Harabagiu and Hickl, 2006; Yahya et al., 2013) and textual entailment (Dagan et al., 2013; Roller and Erk, 2016), can benefit from identifying semantic relations between words beyond synonymy.

The *hypernym discovery* task (Camacho-Collados et al., 2018) aims to discover the most appropriate hypernym(s) for input concepts or entities from a pre-defined corpus. A relevant well-known scenario is *hypernym detection*,

which is a binary task to decide whether a hypernymic relationship holds between a pair of words or not. A hypernym detection system should be capable of learning taxonomy and lexical semantics, including pattern-based methods (Boella and Caro, 2013; Espinosa-Anke et al., 2016b) and graph-based approaches (Fountain and Lapata, 2012; Velardi et al., 2013; Kang et al., 2016). However, our concerned task, hypernym discovery, is rather more challenging since it requires the systems to explore the semantic connection with all the exhausted candidates in the latent space and rank a candidate set instead of a binary classification in previous work. The other challenge is representation for terms, including words and phrases, where the phrase embedding could not be obtained by word embeddings directly. A simple method is to average the inner word embeddings to form the phrase embedding. However, this is too coarse since each word might share different weights. Current systems like (Espinosa-Anke et al., 2016a) commonly discover hypernymic relations by exploiting linear transformation matrix in embedding space, where the embedding should contain words and phrases, resulting to be parameter-exploded and hard to train. Besides, these systems might be insufficient to obtain the deep relationships between terms.

Hyponym	Hypernyms
Heming	actor, person, company
Kralendijk	town, city, provincial capital, capital
StarCraft	video game, pc game, computer game, videogaming, comic, electronic game, scientification

tures (Qin et al., 2016b; Pang et al., 2016; Qin et al., 2016a; Wang et al., 2016c; Zhao et al., 2017a; Wang et al., 2017; Qin et al., 2017; Cai and Zhao, 2017; Zhao et al., 2017b; Li et al., 2018). In this work, we introduce a neural network architecture for the concerned task and empirically study various neural networks to model the distributed representations for words and phrases.

In our system, we leverage an unambiguous vector representation via term embedding, and we take advantage of deep neural networks to discover the hypernym relationships between terms.

The rest of the paper is organized as follows: Section 2 briefly describes our system, Section 3 shows our experiments on the hypernym discovery task including the general-purpose and domain-specific one. Section 4 concludes this paper.

2 System Overview

Our hypernym discovery system can be roughly split into two parts, *Term Embedding* and *Hypernym Relationship Learning*. We first train term embeddings, either using word embedding or sense embedding to represent each word. Then, neural networks are used to discover and rank the hypernym candidates for given terms.

2.1 Embedding

To use deep neural networks, symbolic data needs to be transformed into distributed representations (Wang et al., 2016a; Qin et al., 2016b; Cai and Zhao, 2016; Zhang et al., 2016; Wang et al., 2016b, 2015; Cai et al., 2017). We use *Glove* toolkit to train the word embeddings using *UMBC* corpus (Han et al., 2013). Moreover, in order to perform word sense induction and disambiguation, the word embedding could be transformed to sense embedding, which is induced from existing word embeddings via clustering of ego-networks (Pelevina et al., 2016) of related words. Thus, each input word or phrase is embedded into vector sequence, $w = \{x_1, x_2, \dots, x_l\}$ where l denotes the sequence length. If the input term is a word, then $l = 1$ while for phrases, l means the number of words.

2.2 Hypernym Learning

Previous work like TAXOEMBED (Espinosa-Anke et al., 2016a) uses transformation matrix for hypernym relationship learning, which might be not optimal due to the lack of deeper nonlinear fea-

ture extraction. Thus, we empirically survey various neural networks to represent terms in latent space. After obtaining the representation for input term and all the candidate hypernyms, to give the ranked hypernym list, the cosine similarity between the term and the candidate hypernym is computed by,

$$\text{cosine} = \frac{\sum_{i=1}^n (x_i \times y_i)}{\sum_{i=1}^n x_i^2 \times \sum_{i=1}^n y_i^2}$$

where x_i and y_i denote the two concerned vectors. Our candidate neural networks include Convolutional Neural Network (CNN), Long-short Term Memory network (LSTM), Gated Recurrent Unit (GRU) and Recurrent Convolutional Neural Network (RCNN).

GRU The structure of GRU (Cho et al., 2014) used in this paper are described as follows.

$$\begin{aligned} r_t &= \sigma(W_r x_t + U_r h_{t-1} + b_r), \\ z_t &= \sigma(W_z x_t + U_z h_{t-1} + b_z), \\ \tilde{h}_t &= \tanh(W_h x_t + U_h (r_t \odot h_{t-1}) + b_h) \\ h_t &= (1 - z_t) \odot h_{t-1} + z_t \odot \tilde{h}_t \end{aligned}$$

where \odot denotes the element-wise multiplication. r_t and z_t are the reset and update gates respectively, and \tilde{h}_t the hidden states.

LSTM LSTM (Hochreiter and Schmidhuber, 1997) unit is defined as follows.

$$\begin{aligned} i_t &= \sigma(W_i x_t + W_h h_{t-1} + b_i), \\ f_t &= \sigma(W_f x_t + W_h h_{t-1} + b_f), \\ u_t &= \sigma(W_u x_t + W_h h_{t-1} + b_u), \\ c_t &= f_t \odot c_{t-1} + i_t \odot \tanh(W_c x_t + W_h h_{t-1} + b_c), \\ h_t &= \tanh(c_t) \odot u_t, \end{aligned}$$

where σ stands for the sigmoid function, \odot represents element-wise multiplication and $W_i, W_f, W_u, W_c, b_i, b_f, b_u, b_c$ are model parameters. i_t, f_t, u_t, c_t, h_t are the input gates, forget gates, memory cells, output gates and the current state, respectively.

CNN Convolutional neural networks have also been successfully applied to various NLP tasks, in which the temporal convolution operation and associated filters map local chunks (windows) of the input into a feature representation.

Concretely, let n denote the filter width, filter matrices $[W_1, W_2, \dots, W_k]$ with several variable sizes $[l_1, l_2, \dots, l_k]$ are utilized to perform the

convolution operations for input embeddings. For the sake of simplicity, we will explain the procedure for only one embedding sequence. The embedding will be transformed to sequences $c_j(j \in [1, k])$:

$$c_j = [\dots; \tanh(W_j \cdot x_{[i:i+l_j-1]} + b_j); \dots]$$

where $[i : i + l_j - 1]$ indexes the convolution window. Additionally, we apply wide convolution operation between embedding layer and filter matrices, because it ensures that all weights in the filters reach the entire sentence, including the words at the margins.

A *one-max-pooling* operation is adopted after convolution and the output vector s is obtained through concatenating all the mappings for those k filters.

$$s_j = \max(c_j)$$

$$s = [s_1 \oplus \dots \oplus s_j \oplus \dots \oplus s_k]$$

In this way, the model can capture the critical features in the sentence with different filters.

RCNN Since some input terms are phrases, whose member words share different weights. In RCNN, an adaptive gated decay mechanism is used to weight the words in the convolution layer. Following (Lei et al., 2016), we introduce neural gates similar λ to LSTMs to specify when and how to average the observed signals. The resulting architecture integrates recurrent networks with non-consecutive convolutions:

$$\lambda = \sigma(W^\lambda x_t + U^\lambda h_{t-1} + b^\lambda)$$

$$c_t^1 = \lambda_t \odot c_{t-1}^1 + (1 - \lambda_t) \odot W_1 x_t$$

$$c_t^2 = \lambda_t \odot c_{t-1}^2 + (1 - \lambda_t) \odot (c_{t-1}^1 + W_2 x_t)$$

$$\dots$$

$$c_t^n = \lambda_t \odot c_{t-1}^n + (1 - \lambda_t) \odot (c_{t-1}^{n-1} + W_n x_t)$$

$$h_t = \tanh(c_t^n + b)$$

where $c_t^1, c_t^2, \dots, c_t^n$ are accumulator vectors that store weighted averages of 1-gram to n -gram features.

For discriminative training, we use a max-margin framework for learning (or fine-tuning) parameters θ . Specifically, a scoring function $\varphi(\cdot, \cdot; \theta)$ is defined to measure the semantic similarity between the corresponding representations of input term and hypernym. Let $p = \{p_1, \dots, p_n\}$ denote the hypernym corpus and $h \in p$ is the

ground-truth hypernym to the term t_i , the optimal parameters θ are learned by minimizing the max-margin loss:

$$\max\{\varphi(t_i, p_i; \theta) - \varphi(t_i, a; \theta) + \delta(p_i, a)\}$$

where $\delta(\cdot, \cdot)$ denotes a non-negative margin and $\delta(p_i, a)$ is a small constant when $a \neq p_i$ and 0 otherwise.

3 Experiment

In the following experiments, besides the neural networks, we also simply average the embeddings of an input phrase as our baseline to discover the relationship of terms and their corresponding hypernyms for comparison (denoted as *term embedding averaging, TEA*).

3.1 Setting

Our hypernym discovery experiments include general-purpose subtask for English and domain-specific ones for medical and music. Our evaluation is based on the following information retrieval metrics: Mean Average Precision (MAP), Mean Reciprocal Rank (MRR), Precision at 1 (P@1), Precision at 3 (P@3), Precision at 5 (P@5), Precision at 15 (P@15).

For the sake of computational efficiency, we simply average the sense embedding if a word has more than one sense embedding (among various domains). Our model was implemented using the Theano¹. The diagonal variant of AdaGrad (Duchi et al., 2011) is used for neural network training. We tune the hyper-parameters with the following range of values: learning rate $\in \{1e-3, 1e-2\}$, dropout probability $\in \{0.1, 0.2\}$, CNN filter width $\in \{2, 3, 4\}$. The hidden dimension of all neural models are 200. The batch size is set to 20 and the word embedding and sense embedding sizes are set to 300. All of our models are trained on a single GPU (NVIDIA GTX 980Ti), with roughly 1.5h for general-purpose subtask for English and 0.5h domain-specific domain-specific ones for medical and music. We run all our models up to 50 epoch and select the best result in validation.

3.2 Result and analysis

Table 2 shows the result on general-domain subtask for English. All the neural models outperform term embedding averaging in terms of

Table 3: Gold standard evaluation on domain-specific subtask. “Embed” is short for “Embedding”.

all the metrics. This result indicates simply averaging the embedding of words in a phrase is not an appropriate solution to represent a phrase. Convolution or recurrent gated mechanisms in either CNN-based (CNN, RCNN) or RNN (GRU, LSTM) based neural networks could essentially be helpful of modeling the semantic connections between words in a phrase, and guide the networks to discover the hypernym relationships. We also observe CNN-based network performance is better than RNN-based, which indicates local features between words could be more important than long-term dependency in this task where the term length is up to trigrams.

To investigate the performance of neural models on specific domains, we conduct experiments on medical and medicine subtask. Table 3 shows the result. All the neural models outperform *term embedding averaging* in terms of all the metrics and CNN-based network also performs better than RNN-based ones in most of the metrics using word embedding, which verifies our hypothesis in the general-purpose task. Compared with word embedding, the sense embedding shows a much poorer result though they work closely in general-purpose subtask. The reason might be the simple averaging of sense embedding of various domains for a word, which may introduce too much noise

and bias the overall sense representation. This also discloses that modeling the sense embedding of specific domains could be quite important for further improvement.

4 Conclusion

In this paper, we introduce a neural network architecture for the hypernym discovery task and empirically study various neural network models to model the representations in latent space for words and phrases. Experiments on three subtasks show the neural models can yield satisfying results. We also evaluate the performance of word embedding and sense embedding, showing that in domain-specific tasks, sense embedding could be much more volatile.

Abstract

Hypernym discovery aims to discover the hypernym word sets given a hyponym word and proper corpus. This paper proposes a simple but effective method for the discovery of hypernym sets based on word embedding, which can be used to measure the contextual similarities between words. Given a test hyponym word, we get its hypernym lists by computing the similarities between the hyponym word and words in the training data, and fill the test word's hypernym lists with the hypernym list in the training set of the nearest similarity distance to the test word. In SemEval 2018 task9, our results, achieve 1st on Spanish, 2nd on Italian, 6th on English in the metric of MAP.

1 Introduction

Hypernymy relationship plays a critical role in language understanding because it enables generalization, which lies at the core of human cognition (Yu et al. (2015)). It has been widely used in various NLP applications (Espinosa Anke et al. (2016)), from word sense disambiguation (Agirre et al. (2014)) to information retrieval (Varelas et al. (2005)), question answering (Prager (2006)) and textual entailment (Glickman et al. (2005)). To date, the hypernymy relation also plays an important role in Knowledge Base Construction task.

In the past SemEval contest (SemEval-2015 task 17¹, SemEval-2016 task 13²), the “Hypernym Detection” task was treated as a classification task, i.e., given a (hyponym, hypernym) pair, deciding whether the pair is a true hypernymic relation or not. This has led to criticisms regarding its oversimplification (Levy et al., 2015). In the SemEval 2018 Task 9 (Camacho-Collados et al., 2018), the task has shifted to “Hypernym Discovery”, i.e.,

given the search space of a domain's vocabulary and an input hyponym, discover its best (set of) candidate hypernyms.

In this paper, the content is organized as follows: Section 2 gives an introduction to the related work; Section 3 describes our methods for this task, including word embedding projection learning as the baseline and the nearest-neighbour-based method as the submission result; The experimental results are presented in Section 4. We conclude the paper with Section 5.

2 Related Work

The work of identifying hypernymy relationship can be categorized from different aspects according to the learning methods and the task formalization. The earlier work (Hearst (1992)) formalized the task as an unsupervised hypernym discovery task, i.e., none hyponym-hypernyms pairs (x, y) are given as the training data. Hearst (1992) handcrafted a set of lexico-syntactic paths that connect the joint occurrences of x and y which indicate hypernymy in a large corpus. Snow et al. (2004) trained a logistic regression classifier using all dependency paths which connect a small number of known hyponym-hypernym pairs. Paths that were assigned high weights by the classifier are used to extract unseen hypernym pairs from a new corpus. Variations of Snow et al. (2004) were later used in tasks such as taxonomy construction (Snow et al. (2006); Kozareva and Hovy (2010); Carlson et al. (2010)), analogy identification (Turney (2006)), and definition extraction (Borg et al. (2009); Navigli and Velardi (2010)).

A major limitation in relying on lexico-syntactic paths is the requirement of the cooccurrence of the hypernym pairs. Distributional methods are developed to overcome this limitation. Lin (1998) developed symmetric similarity

¹<http://alt.qcri.org/semeval2015/task17/>

²<http://alt.qcri.org/semeval2016/task13/>

measures to detect hypernym in an unsupervised manner. Weeds and Weir (2003); Kotlerman et al. (2010) employed directional measures based on the distributional inclusion hypothesis. More recent work (Santus et al. (2014); Rimell (2014)) introduces new measures, based on the distributional informativeness hypothesis. Yu et al. (2015); Tuan and Ng (2016); Nguyen et al. (2017) learn directly the word embeddings which are optimized for capturing the hypernymy relationship.

The supervised methods include Baroni and Lenci (2011); Roller et al. (2014); Weeds and Weir (2003). These methods were originally word-count-based, but can be easily adapted using word embeddings (Mikolov et al. (2013a); Pennington et al. (2014)). However, it was criticized that the supervised methods only learn prototypical hypernymy (Levy et al. (2015)).

3 Hyponym-hypernym Discovery method

3.1 Preprocessing

For the corpus and the train/gold/test data, we have two preprocessing steps: 1) Lowercase all the words; 2) Concatenate the phrases (hyponym or hypernym composed with more than one word) which occur in the training set or the test set with underline, i.e., “executive president” is replaced by “executive_president”. It is quite useful for training word embedding models because we want to treat phrases as single words.

If there are multiple phrases in one sentence, we generate multiple sentences, one per phrase. For example, “executive president” and “vice executive president” both exist in the corpus sentence “Hoang Van Dung , vice executive president of the Vietnam Chamber of Commerce and Industry.”. After preprocessing, two more sentences are generated and included in the training corpus for word embeddings:

- Hoang Van Dung , vice executive_president of the Vietnam Chamber of Commerce and Industry.
- Hoang Van Dung , vice_executive_president of the Vietnam Chamber of Commerce and Industry.

The size of the original corpus has increased after the preprocessing step, e.g., The English corpus has increased from $\sim 18\text{G}$ to $\sim 32\text{G}$.

3.2 Word Embedding

We train our word embedding models using the Google word2vec (Mikolov et al. (2013a,b)) tool³ on the preprocessed corpus. We employ the skip-gram model since the skip-gram model is shown to perform best in identifying semantic relations among words. The trained word embeddings are used in the projection learning and nearest-neighbour based method.

3.3 Method based on Projection Learning

The intuition of this method is to assume that there is a linear transformation in the embedding space which maps hyponyms to their correspondent hypernyms. We first learn a projection matrix from the training data, then apply the matrix to the test data. Our method is similar to that described in Fu et al. (2014), the main idea can be summarized as follows:

1. Give a word x and its hypernym y , assuming there exists a linear projection matrix Φ to meet $y = \Phi x$. We need to learn an approximate Φ using the following equation to minimize the MSE loss:

$$\Phi^* = \arg \min_{\Phi} \frac{1}{N} \sum_{(x,y)} \|\Phi x - y\|^2 \quad (1)$$

2. Learn the piecewise linear projection by clustering the training data into different groups according to the vector offsets. The motivation for the clustering is two-fold: firstly, the hypernym-hyponym relation is diverse, e.g., offset from “carpenter” and “laborer” is distant from the one from “gold fish” to “fish”; Secondly, if a hyponym x has many hypernyms (or hierarchical hypernyms), we can’t use a single transition matrix Φ to project x to different hypernym y . So a piecewise projection learning is needed in each individual group. Thus, the optimization goal can be formalized as follows:

$$\Phi_k^* = \arg \min_{\Phi_k} \frac{1}{N_k} \sum_{(x,y \in C_k)} \|\Phi_k x - y\|^2 \quad (2)$$

Where N_k is the number of word pairs in the k^{th} cluster C_k .

³<https://code.google.com/archive/p/word2vec/>

- Learn the threshold δ_k for each cluster, by assuming that positive (hyponym-hypernym) pairs can locate in radius δ while negative pairs can not:

$$d(\Phi_k x - y) = \|\Phi_k x - y\|^2 < \delta_k \quad (3)$$

Where d stands for the euclidean distance.

- Once the piecewise projection and the threshold is learned, given a new hyponym x , all of the hypernym candidates y s from the vocabulary are paired with x . The pairs are assigned to the proper cluster by the vector offset ($y-x$). According to the threshold δ in that group, it can be decided whether (x, y) is a reasonable hyponym-hypernym pair.

3.4 Method Based on Nearest Neighbors

We noticed that the hypernyms are often very distant from the correspondent hyponyms in the embedding space. Meanwhile, hyponyms which are close to each other often share the same hypernyms. We propose a simple yet effective approach based on this observation.

Suppose the training set H consists of a number of hyponyms and their correspondent hypernyms

$$H : \{Hypo^k : Hyper_1^k \dots Hyper_i^k\}$$

During the test time, for an unseen hyponym x , the top K nearest hyponyms in the training set, i.e., $Hypo_i$ are found, and their hypernyms are used as the output, i.e., the hypernyms of x . The found hypernyms are sorted according to the distance between x and $Hypo_i$. This can be formalized as follows:

$$\begin{aligned} \text{HypoN} &= [Hypo_i].\text{sort.by}(\text{distance}(\text{Hypo}_i, x)) \\ \text{Hyper}(x) &= [\text{Hyper}(w) | w \text{ in HypoN}] \end{aligned}$$

where the *distance* function measures the similarity between $Hypo_i$ and x , HypoN is the list of words from the training set sorted according to their distances to x . Cosine similarity in the embedding space is used for the distance function in our setup. According to the requirements of Task 9, only the top 15 of $\text{Hyper}(x)$ are submitted for evaluation.

4 Evaluation

4.1 Experimental Setup

Word2vec is used to produce the word embeddings. The skip-gram model (**-cbow 0**) is used

with the embedding dimension set to 300 (**-size 300**). The other options are by default. We use 10-fold cross validation to evaluate both methods on the provided training data. The results are shown in Table 1⁴

4.2 Results Based on Projection Learning

For the projection learning method, we followed experimental settings described in Fu et al. (2014). The negative (hyponym, hypernym) pairs are randomly sampled from the vocabulary. The training set consists of the negative pairs and the positive pairs in 3:1 ratio.

By using the same evaluating metrics as PRF in the cited paper, our best F-value on the validation set is 0.68 (the paper result is 0.73) when the best cluster number is 2 and the threshold is (17.7, 17.3). We apply the learned projection matrices and thresholds on the validation data, extract out the candidate hypernyms from the given vocabulary and truncate the top 15 candidates by sorting them according to the $d(\Phi_k x, y)/\delta_k$ scores. The generated results are not very promising, see Table 1 for details.

This projection learning method performs not very well on task9, we think the most probable reason is that in Fu et al. (2014), the problem is formalized as a classification problem, in which the (**hyponym, hypernym**) pairs are given. However, our task is formalized as a hypernym discovery problem given only **hyponmys**. This task might be inherently much harder than the classification task; a second reason might be related to the relative small amount of training data, i.e., ~ 7500 training pairs in total.

4.3 Results Based on NN

The results are shown in Table 1 from row 2 to row 5. Table 2 shows the results evaluated on the test data. The performance evaluated using either cross validation or the test data is much worse than that of a typical hypernym prediction task reported by Weeds and Weir (2003). This illustrates that hypernym discovery is indeed a much harder task than the hypernym prediction task.

Although the method proposed by us is quite simple, our submissions are the 1st on Spanish, the 2nd on Italian, the 6th on English, ranked by the

⁴The PL based method is not evaluated on Italian or Spanish corpus due to its poor performance on English corpus. The result of PL method is not submitted for the task evaluation either.

System	Language	MAP	MRR	P@1	P@3	P@5	P@15
PL	English	2.8	7.6	7.5	3.3	2.6	2.0
NN	English	13.3	25.1	18.7	13.9	13.5	12.5
NN	Spanish	16.6	27.2	19.0	17.2	16.4	16.1
NN	Italian	19.3	32.4	25	19.8	18.6	18.6

Table 1: Cross validation results of the two methods on training set(%). PL stands for the projection-learning based system. NN stands for the nearest-neighbor based method.

Language	MAP	MRR	P@1	P@3	P@5	P@15
English	9.37	17.29	12	10.14	9.19	8.78
Spanish	20.04	28.27	21.4	20.95	20.39	19.38
Italian	11.37	19.19	13.1	12.08	11.23	10.9

Table 2: Results on the test data for our submissions(%).

metric of MAP. This proves the effectiveness of the method.

Compared with the results got by cross validation, the performance evaluated on the test data (Table 2) dropped significantly on English (MAP dropped by 4%) and Italian (MAP dropped by 8%), but increased by a margin on Spanish (MAP increased by 3.6%). We consider that it is due to the properties of provided data, i.e., the hypernyms in the test set are similar to those in the training set for Spanish, but dissimilar for English or Italian.

The performance drop for English and Italian exposes one of the main drawbacks of our method: the method can not discover the hypernyms that have never occurred in the training set. To overcome this shortcoming, using syntactic patterns to extract hyponym-hypernym with high confidence can be employed to enlarge the training set. We leave this to the future work.

5 Conclusion

In this paper we describe two methods we have tried out for the hypernym discovery task in SemEval 2018. We extended the method originally proposed for hypernym prediction by Fu et al. (2014) as a baseline system. However the performance of this method is poor. The nearest-neighbor-based method is relatively simple, yet quite effective. We analyzed the experimental results, reveal some shortcomings, and propose a potential extension to future improvement.

Abstract

Hypernym Discovery is the task of identifying potential hypernyms for a given term. A hypernym is a more generalized word that is super-ordinate to more specific words. This paper explores several approaches that rely on co-occurrence frequencies of word pairs, Hearst Patterns based on regular expressions, and word embeddings created from the UMBC corpus. Our system Babbage participated in Subtask 1A for English and placed 6th of 19 systems when identifying concept hypernyms, and 12th of 18 systems for entity hypernyms.

1 Introduction

Hypernym-hyponym pairs exhibit an *is-a* relationship where a hypernym is a generalization of a hyponym. The objective of SemEval-2018 Task 9 (Camacho-Collados et al., 2018) is to generate a ranked list of hypernyms when given an input hyponym and a vocabulary of candidate hypernyms. For example, the input hyponym *lemongrass* could yield the hypernyms [*grass*, *oil plant*, *herb*], where *herb* would be the best candidate. This scenario is illustrated in Figure 1, where the three leaf nodes are hyponyms and the root is a hypernym.

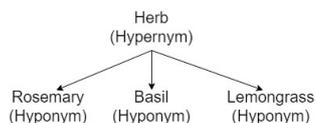

Figure 1: Hypernym-hyponym example

Note that hypernym discovery is distinct from hypernym detection, where the problem is to detect if a hyponym-hypernym relationship exists between a given pair, such as *lemongrass-grass*.

In our first module, we retrieve candidate hypernyms for an input term using a paragraph-length context-window and calculate their co-occurrence frequencies, which is later used for

ranking the candidates. Our second module uses Hearst Patterns (Hearst, 1992) to extract hyponym-hypernym pairs and ranks candidate hypernyms based on co-occurrence frequency of the pairs. Our final module employs word-embeddings created using word2vec (Mikolov et al., 2013). This paper continues with a more detailed discussion of each module, and then a review of our results.

2 Implementation

Babbage begins by pre-processing (2.2.1) the UMBC Corpus (2.1) and extracting candidate hypernyms using four different strategies (2.2.2). The first and second module calculates the co-occurrence frequencies between the input term and words in context using the pre-processed UMBC Corpus and the Hearst Pattern set extracted from the UMBC Corpus. The third module uses the IS-A Hearst Pattern set extracted from UMBC Corpus to obtain hypernyms. The final module constructs a word embedding over the UMBC corpus and uses a distance measure to fetch candidate hypernyms for a given input term.

2.1 UMBC Corpus

Our training corpus is the University of Maryland, Baltimore County (UMBC) WebBase Corpus (Han et al., 2013). It contains 3 billion words from paragraphs obtained from more than 100 million web pages over various domains. We use the 28 GB tokenized version of UMBC corpus which is part-of-speech tagged and divided among 408 files. There is also a vocabulary file with 218,755 unigram, bigram and trigram hypernym terms provided by task organizers. This file defines the set of possible candidate hypernyms.

2.2 Architecture of System Babbage

The following are the steps involved in constructing our system:

1. Pre-processing the input text corpus

[2.2.1]: Corpora obtained in this stage include:

- (a) Normalize the input corpus and store as *Normalized Corpus*
- (b) Fetch Hearst Patterns (see Figure 2) from input corpus and store as *Hearst Corpus*
- (c) Fetch IS-A Pattern from the input corpus and store as *IS-A Corpus*
- (d) Creating the word-embedding matrix *UMBC Embedding* using Normalized Corpus.

The Hearst Corpus and the IS-A Corpus patterns are extracted from the original text corpus which has been preprocessed to eliminate punctuation, prepositions, and conjunctions. All possible combinations of bigram and trigram noun phrases are retained in the Normalized Corpus. A Word-Embedding matrix is built over this Normalized Corpus.

2. Extracting candidate hypernyms [2.2.2]:

- (a) **Co-occurrence frequencies from Normalized Corpus:** A co-occurrence map is built for the input terms with the words in the context of the input term and the frequency of their co-occurrence using the Normalized Corpus. Words with co-occurrence frequency higher than 5 are listed as candidate hypernyms for an input term. This is considered the first module result.
- (b) **Co-occurrence frequencies from Hearst Corpus:** A co-occurrence map similar to the previous step is built by using the Hearst Corpus. All the words which occur at least once in context of the input term in the Hearst Patterns are listed as candidate hypernyms for this term. This is considered the second module result.
- (c) **Co-occurrence frequencies from IS-A Corpus:** All the words which occur at least once in the context of the input term in the IS-A Corpus are listed as

candidate hypernyms for this term. If the input term is a concept and is a bigram or trigram term, then part of it is considered as a hypernym for that term. This is considered the third module result.

- (d) **Applying word similarity to word embeddings:** A fixed distance value called *Phi* is used to extract words at this distance to the input term in the UMBC Embedding. These words are listed as the candidate hypernyms for an input term. This is considered our final module result.

3. Merging results from various modules

[2.3]: The order of merging these results is decided by the evaluation scores from these modules for training data. The same order is applied to the test data.

2.2.1 Pre-processing

The task description states that our system should predict candidate hypernyms for an input word which is either a concept or an entity. Hence, the part-of-speech tag for all candidate hypernyms is *noun*. This restricts our search space to words with *noun* part-of-speech tag and bigram or trigram phrases with a *noun* head word. Our system focuses on concepts, so we do not have any module specific for entities. To refine the input corpus as per these specifications, the input UMBC Corpus is processed through the following modules:

Normalized Corpus: The POS tagged input corpus is processed per paragraph. Each paragraph is converted to lower-case text. Then, bigram and trigram noun phrases from each paragraph are obtained using the POS tags given for each word. It is further filtered by removing punctuation marks and words with part-of-speech tags other than *noun*, *verb*, *adverb* or *adjective*. This filtered line is modified by appending it with bigram and trigram noun phrases obtained earlier.

Hearst Corpus: The original input paragraph is searched for the Hearst Patterns (shown in Figure 2) and all the possible matches are returned in the form of *hypernym* : *one or more hyponyms*. Figure 2 shows the extraction of Hearst Patterns, where NP represents a noun-phrase where the head word is tagged as a *noun*, *the loved-ones such as family and friends* is a match for Hearst Patterns (from

Figure 2) with noun phrases *the loved-ones, family and friends*.

IS-A Corpus: A pattern which is not used in the construction of the Hearst Corpus is used here: **Hyponym Noun Phrase is (a | an | the) Hypernym Noun Phrase**. Here the original input paragraph is searched against this pattern and all the possible matches are returned in the form of *hyponym : hypernym*. *a fennel is a plant* is a match for this pattern with noun phrases *a fennel* and *plant*.

UMBC Embedding: A word embedding matrix is created over the Normalized Corpus using word2vec (Mikolov et al., 2013). The specifications of the model are as follows:

(a) **Model : Continuous Bag of Words (CBOW)** - a term's embedding value is determined by its context words. The order of the words in the window size does not matter.

(b) **Window Size : 10**. The context window size for a term which determines its vector value.

(c) **Minimum Frequency Count : 5**. If the frequency of a word is less than this value, the word does not exist in the embedding.

(d) **Embedding Dimension Size : 300**. The number of dimensions for the embedding matrix.

2.2.2 Extracting candidate hypernyms:

Once the UMBC corpus is pre-processed and the three required corpora and an embedding matrix are derived, candidate hypernyms are acquired by applying the below processes.

Co-occurrence frequency from Normalized Corpus: With this module, we hypothesized that a hyponym and its possible hypernyms are more likely to co-occur within a context-window. The context window of a term is its own paragraph. We start by creating a map for all the input terms. If a normalized paragraph 2.2.1 contains any of the input terms, then all the words in the context are added to the map of this particular term which considers them to be hypernyms for this input hyponym term. Every time a hypernym-hyponym pair co-occurs in one line, their co-occurrence count is increased by one. Finally, the candidate hypernyms are ranked in descending order of their co-occurrence frequencies.

Co-occurrence frequency from Hearst Corpus: In the pre-processing step 2.2.1, we extracted possible hypernym-hyponym mapping data using

Hearst Patterns. Each line of the data is of the form *hypernym : hyponym-1 , hyponym-2 , , hyponym-n*. In this module, we created a map where each *hyponym* is a key mapped to *hypernyms* occurring with that *hyponym* and their co-occurrence frequencies. For example, values for keys *hyponym-1, hyponym-2, and hyponym-n* are updated with *hypernym* and the frequencies are increased by 1. Finally the top 15 *hyponyms* (based on frequencies) for each key are reported as the result hypernyms.

Co-occurrence frequencies from IS-A Corpus:

This module uses hypernym-hyponym pairs from the IS-A Corpus 2.2.1 which are in the form *hyponym : hypernym*. We use the same strategy as *Co-occurrence frequency from Hearst Corpus* to obtain the result.

Applying word similarity to word embeddings:

We need a general distance vector which represents a hypernym-hyponym distance in the UMBC Embedding. We use training data input term (x) and the gold data hypernyms (y) to calculate this distance(Φ^*) which is calculated by:

$$\Phi^* = \operatorname{argmin}_{\Phi} \frac{1}{N} \sum_{(x,y)} \Phi \|x - y\|^2 \quad (1)$$

Φ is used to get candidate hypernyms from the UMBC word embedding matrix for the input terms (test data).

2.3 Merging results from various modules

For this task, our system is required to report the 15 most probable hypernyms for each input term. We have four modules each reporting their top 15 candidate hypernyms. By looking at the training scores of these modules, we merge the co-occurrence frequencies from IS-A corpus that have higher ranks followed by the co-occurrence frequencies from Normalized corpus and Hearst Pattern corpus. Results from word embedding module are given the lowest ranks.

3 Experimental Results and Discussion

Output candidate hypernym lists are evaluated against gold hypernym lists using the following evaluation criteria : Mean Reciprocal Rank (MRR), Mean Average Precision (MAP) and Precision At k (P@k), where k is 1, 3, 5 and 15. We ran our model against two sets of data training data

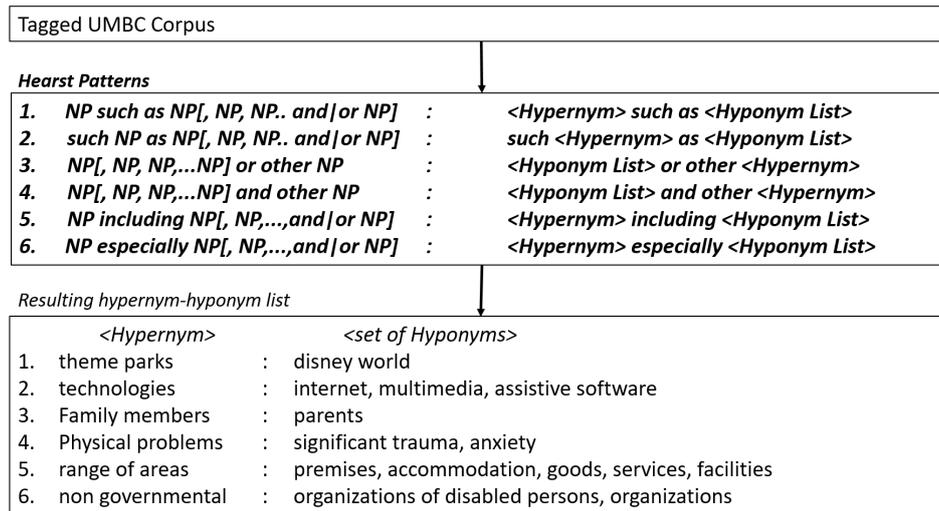

Figure 2: Creating Hearst Corpus using 6 Hearst Patterns

	Cooc	Hearst	Phi	Is-A	Merged
MRR	.103	.020	.025	.165	.188
MAP	.050	.008	.012	.071	.080
P@1	.061	.013	.012	.140	.152
P@3	.055	.008	.012	.076	.087
P@5	.048	.008	.012	.066	.075
P@15	.047	.007	.011	.062	.070

Table 1: Test Data 1A English - Concept Scores

	Cooc	Hearst	Phi	Is-A	Merged
MRR	.000	.000	.008	.090	.099
MAP	.000	.000	.003	.036	.037
P@1	.000	.000	.004	.069	.081
P@3	.000	.000	.003	.041	.045
P@5	.000	.000	.003	.035	.036
P@15	.000	.000	.003	.031	.030

Table 2: Test Data 1A English - Entity Scores

and test data with 1500 input terms each. These results are shown in Tables 1 and 2, where it can be clearly observed that our system performs much better for concepts. However, the IS-A module seemed to fetch good candidates for both entity and concept data.

The gold data provided with the task does not always consider all possible word senses or domains of an input term. As a result, we observed numerous candidate hypernyms that seem to be plausible solutions that are not considered correct when compared to the gold data.

For example, the input concept *navigator* has gold standard hypernyms of [*military branch, ex-*

plorer, military machine, travel, adventurer, seaman]. Our system finds candidate hypernyms [*browser, web browser, website, application*]. We also noticed that due to our normalization decisions (i.e., using all lower-case characters) and the contents of the corpus, Babbage performs poorly in some cases. For example, the gold hypernyms for input entity *Hurricane* are [*video game, software program, computer program*] but our system produced [*storm, windstorm, typhoon, tornado, cyclone*]. Clearly, our system did not differentiate between the named entity *Hurricane* and the common noun *hurricane* while training the word-embedding models.

On the positive side, our system produced promising results in some cases. Hyponym *liberalism* produced [*theory, philosophy, economic policy*] which is very similar to the gold data [*economic theory, theory*]. It also correctly generated the hyponym *person* for hypernyms such as collector, moderator, director, senior, and reporter. For input *reporter* it produced [*writer, person*] which matches the gold hypernym set.

Acknowledgments

This project was carried out as a part of CS 8761, Natural Language Processing, a graduate level class offered in Fall 2017 at the University of Minnesota, Duluth by Dr. Ted Pedersen. All authors of this paper have contributed equally and are listed in alphabetical order by first name.

Abstract

In this paper, we present our proposed system (EXPR) to participate in the hypernym discovery task of SemEval 2018. The task addresses the challenge of discovering hypernym relations from a text corpus. Our proposal is a combined approach of path-based technique and distributional technique. We use dependency parser on a corpus to extract candidate hypernyms and represent their dependency paths as a feature vector. The feature vector is concatenated with a feature vector obtained using Wikipedia pre-trained term embedding model. The concatenated feature vector fits a supervised machine learning method to learn a classifier model. This model is able to classify new candidate hypernyms as hypernym or not. Our system performs well to discover new hypernyms not defined in gold hypernyms.

1 Introduction

Hypernymy is an important lexical-semantic relation that is useful for many applications such as question answering, machine translation, information retrieval, and so on. In addition, hypernym relations are the backbone for building ontologies.

Various methods have been proposed to detect hypernym relation from text corpora. Most of these techniques are either path-based techniques or distributional techniques. In path-based methods, the detection of hypernym relations is based on the lexico-syntactic paths connecting a pair of terms in a corpus. Conversely, distributional methods are based on the distribution of term pair contexts. Most of these methods were unsupervised. Recently, focus shifted towards supervised methods.

This task inherits complexity and is far from being solved. The SemEval organizers address the same task but with a novel formulation (Camacho-Collados et al., 2018). They reformulate the task

from hypernym detection into hypernym discovery. This novel formulation makes the task more realistic in terms of actual downstream application, while also enabling the benefits of information retrieval evaluation metrics. Hypernym detection focuses on deciding whether a hypernymic relation holds between a given pair of terms or not. Hypernym discovery focuses on discovering a set containing the best hypernyms for a given term from a given vocabulary search space. The task is divided into two subtasks: General-Purpose Hypernym Discovery and Domain-Specific Hypernym Discovery. The first consists of discovering hypernym in a general-purpose corpus, thus the SemEval organizers provide the participants with data for three languages: English, Italian, and Spanish. The second consists of discovering hypernym in a domain-specific corpus, thus they provide the participants with data for two specific domains: Medical and Music. The data contains a list of training terms along with gold hypernyms, a list of testing terms, and a vocabulary search space. The term is either a concept or an entity.

To tackle this task, we propose an approach that combines a path-based technique and distributional technique via concatenating two feature vectors: a feature vector constructed using dependency parser output and a feature vector obtained using term embeddings. Then, by using the concatenated vector we create a binary supervised classifier model based on support vector machine (SVM) algorithm. The model predicts if a term and its candidate hypernym are hypernym related or not.

2 Related Work

Most of the previous approaches for hypernymy detection are either path-based (patterns) or distributional based. Recently, some approaches are taking advantages of the combination of path-based and distributional techniques.

2.1 Path-Based

Path-based approaches are heuristic methods that predict hypernymy between a pair of terms if they match a particular pattern in a sentence of the corpus. These patterns are either manually identified (Hearst, 1992) or automatically extracted (Snow et al., 2005; Navigli and Velardi, 2010; Sheena et al., 2016). Approaches based on handcrafted patterns yield a good precision, but their recall is very low (Buitelaar et al., 2005). Approaches based on automatic learning of patterns achieve better performance by a small improvement in terms of precision and a considerable improvement in terms of recall, but the main limitation of these approaches is the sparsity of the feature space (Shwartz et al., 2016).

2.2 Distributional

Distributional approaches predict hypernym relations between terms based on their distributional representation, by either unsupervised or supervised models. The early unsupervised distributional models are based on symmetric measures (Lin, 1998). Later, asymmetric measures are introduced based on the Distributional Inclusion Hypothesis (DIH) (Weeds and Weir, 2003; Kotlerman et al., 2010). More recent, Santus et al. (2014); Rimell (2014) introduce new measures based on assumption that DIH is not correct for all cases. While, most of the supervised models rely on term embedding (Mikolov et al., 2013; Pennington et al., 2014) to represent the feature vector between the terms x and y . Various vector representations have been used such as concatenation $\vec{x} \oplus \vec{y}$ (Baroni et al., 2012) and difference $\vec{y} - \vec{x}$ (Roller et al., 2014; Weeds et al., 2014). More recent, Yu et al. (2015); Luu et al. (2016) suggested that models rely on term embedding are useful to indicate similarity between words, not to indicate hypernymy relations. Consequently, they learn their own term embedding models that are more relevant to indicate hypernym relations.

2.3 Combined Approaches

Combined approaches of distributional and lexicosyntactic paths are proposed based on the assumption that distributional approaches and path-based approaches have certain complementary properties. To our best knowledge, there are little works on integrating them (Mirkin et al., 2006; Kaji and Katsuregawa, 2008). The recent work on integrat-

ing them is proposed by Shwartz et al. (2016). They use a long short-term memory (LSTM) network (Hochreiter and Schmidhuber, 1997) to encode dependency paths into a feature vector, then they concatenate the feature vector by the term embedding vectors of term x and term y .

3 System Description

As a preliminary step, we split each corpus into a training corpus and a testing corpus. Training corpus is a corpus of all sentences that contains training data terms (Concept/Entity), while testing corpus is a corpus of all sentences that contains testing data terms (Concept/Entity). Some sentences may contain training and testing data terms. These sentences will exist in both training and testing corpus.

3.1 Candidate Hypernyms

The first step in the system is to extract candidate hypernyms for the given training and testing data terms from a training corpus and a testing corpus respectively. We consider a term as a candidate hypernym if:

1. The term and its candidate occur in the same sentence.
2. The candidate exists in the vocabulary list.
3. The term and its candidate are noun phrases.
4. The term and its candidate are linked by short dependency path.

We consider a dependency path as short if it doesn't exceed two grammatical dependency relations. Using the short dependency path, we are capable representing paths similar to Hearst Patterns and other patterns. For example of short dependency paths, the dependency path between X and Y in the sentence S_1 “ X such as Y ” is $\{\text{nmod:such_as}(X, Y)\}$ and in the sentence S_2 “ X includes Y ” is $\{\text{nsubj}(includes, X), \text{dobj}(includes, Y)\}$. We use Stanford dependency parser¹ (Marneffe et al., 2006) to extract dependency paths.

3.2 Feature Vector

The feature vector used to learn a model capable of predicting hypernym relations between a term

¹<https://stanfordnlp.github.io/CoreNLP/>

and a candidate hypernym consists of the concatenation of two vectors: the first one is a vector extracted using a path-based technique while the second is extracted using a distributional technique.

The path-based vector consists of a set of features representing the short dependency path between a term y and its candidate hypernym x . The feature set is: $[Tag(x), GRel(x), HR, Freq, Tag(y), GRel(y)]$. $Tag(x)$ and $Tag(y)$ are the POS tag of x and y , $GRel(x)$ and $GRel(y)$ are the grammatical dependency relation of x and y , HR is the hypernym ratio of a dependency path and it is equal to the number of occurrences of a dependency path when indicating hypernym relation divided by the total occurrences of the same dependency path, and $Freq$ is the relative frequency of a dependency path and it is equal to the occurrence of a dependency path divided by the total occurrences of all dependency paths.

$$HR = \frac{\text{hypernym_DP_occurrences}}{\text{DP_occurrences}}$$

$$Freq = \frac{\text{DP_occurrences}}{\text{Total_DPs_occurrences}}$$

For a distributional based vector, We use pre-trained 300 dimensional Word2Vec² term embeddings, trained on Wikipedia (Mikolov et al., 2013). We apply the difference between the embedding vector of term y and the embedding vector of term x ($\vec{y} - \vec{x}$) (Roller et al., 2014; Weeds et al., 2014). The term is either a single word or a multi-word expression.

3.3 Model Learning and Hypernym Discovery

In each training corpus, we extract a set of candidate hypernyms for each training term and label them if they are hypernym related or not using the gold hypernym data. Next, we represent each term and its candidate hypernym by a concatenated feature vector. These concatenated vectors are used for training the model. The classification method we used is SVM³ with RBF kernel ($C = 1.0$, $\gamma = 1/FeatureSize$). The training dataset was unbalanced, the ratio of hypernym instances w.r.t. not hypernym is less than 0.05. To represent the two categories (hypernym and not hypernym)

²<https://radimrehurek.com/gensim/>

³We use a machine learning python library scikit-learn (<http://scikit-learn.org/stable/>)

in the training set, we improved this ratio to 0.2 by random elimination of not hypernym instances (20% hypernym instances and 80% not hypernym instances).

The classifier model is then used to discover hypernyms from a set of candidate hypernyms extracted from a testing corpus for each testing term by predicting if a term and its candidate hypernym are hypernym related or not. Each predicted hypernym is associated with a probability value. These values are used as ranking values to select the best fifteen hypernyms for each term (from higher to lower probability).

4 Results and Analysis

We submit our systems predictions for three corpora: English, Medical, and Music. The table 1 (a,b and c) below shows the result of our system and other supervised systems to discover hypernyms for Concept terms only. For the three corpora, our system performs better than STJU system, and it performs better than the MFH system on the English corpora. In addition, the result shows that our system performs well in discovering new hypernyms not defined in the gold hypernyms where it yields good False Positive values in the three corpora and we achieve the best False Positive value in Medical corpus (40) with a large difference to the second value (20) achieved by CRIM system.

(c) Music Corpus.

Table 1: The evaluation results of our system and other supervised systems.

Our system result was beneath the expectation. By a short look into the output result files, we notice a lot of empty lines, meaning that our system was unable to discover any hypernym for a lot of terms and unexpectedly these terms correspond to all entity terms. In other words, our system lacks the ability to discover hypernyms for entity terms.

The table 2 (a,b and c) below shows the coverage of Wikipedia pre-trained term embedding model (TEM) and the coverage of candidate hypernym extraction (CHE) for the training and testing terms of the three corpora (English, Medical, and Music). The table shows that our system is unable to discover hypernyms for a considerable number of terms due to two main reasons. The first reason is that Wikipedia pre-trained term embedding model is limited in coverage, where many terms (Concepts/Entities) are not covered by the pre-trained embeddings, which leads to failure to discover hypernyms for these terms. For example, the term embedding (TEM) coverage of Medical Testing terms is 249 (50%), which means the system is unable to discover hypernyms for 251 (50%) terms not covered by the pre-trained term embedding. The second reason is that some conditions used to extract candidate hypernyms restrict the number of candidate hypernyms. For instance, the condition of the existence of a short dependency link between the term and its candidate causes the system to miss many candidate hypernyms if they are not linked by a short dependency path with the terms. In addition, the term and its candidate hypernym must occur as noun phrases in the sentence. This condition leads to failure to extract candidate hypernyms for some entity terms that can't be identified as noun phrases in the corpus such as "Up All Night", "Someday Came Suddenly", "Now What", etc. As shown in the table 2, the candidate hypernym extraction (CHE) coverage for English testing terms is 950 (63%), that means our system is unable to extract any candidate hypernym for 550 (37%) terms (398 entities and 152 concepts).

Furthermore, our system suffers from a major computational issue when applied to a large corpus. Parsing the corpus took too long and failed to complete before the submission deadline. Approximately, we processed 50% sentences of English corpus and 80% sentences of Music corpus, while we processed all sentences of Medical corpus. This explains why the performance of our

system on Medical corpus is better than its performance on the two others corpora.

5 Conclusion

In this paper, we presented our proposed system (EXPR) that is a combination of path-based technique and distributional technique to participate in Hypernym Discovery task of SemEval 2018. In this work, two feature vectors were extracted and concatenated: the first one is obtained using dependency parser on sentences and the second vector is obtained using pre-trained term embedding. A supervised classifier model based on SVM is built using training dataset composed of concatenated vectors. This model is used to discover hypernyms for new terms. The result was good but didn't fulfill our ambition due to several issues.

Our future work is to improve our approach for hypernym discovery by solving several issues. We believe that relying on term embedding model learned from the corpus provided in this task may be a good choice. In addition, we will work on the definition of a new dependency links not only those defined in this paper. Also, we will work to propose an unsupervised approach by using sequential pattern mining technique to automatically extract frequent sequential pattern between hyponym terms and their given hypernyms from the corpus.

Abstract

This paper describes a simple but competitive unsupervised system for hypernym discovery. The system uses skip-gram word embeddings with negative sampling, trained on specialised corpora. Candidate hypernyms for an input word are predicted based on cosine similarity scores. Two sets of word embedding models were trained separately on two specialised corpora: a medical corpus and a music industry corpus. Our system scored highest in the medical domain among the competing unsupervised systems but performed poorly on the music industry domain. Our approach does not depend on any external data other than raw specialised corpora.

1 Introduction

The SemEval-2018 shared task on Hypernymy Discovery sought to study approaches for identifying words that hold a hypernymic relation (Camacho-Collados et al., 2018). Two words have a hypernymic relation if one of the words belongs to a taxonomical class that is more general than that of the other word. For example, the word *vehicle* belongs to a more general taxonomical class than *car* does, as *car* is a type of *vehicle*. Hypernymy can be seen as an *is-a* relationship. Hypernymy has been studied from different angles in the natural language processing literature as it is related to the human cognitive ability of generalisation.

This shared task differs from recent taxonomy evaluation tasks (Bordea et al., 2015, 2016) by concentrating on Hypernym Discovery: the task of predicting (discovering) n hypernym candidates for a given input word, within the vocabulary of a specific domain (Espinosa-Anke et al., 2016). This shared task provided a general language domain vocabulary and two specialised domain vocabularies in English: medical and music indus-

try. For each vocabulary, a reference corpus was also supplied. In addition to these English vocabularies, general language domain vocabularies for Spanish and Italian were also provided. The ADAPT team focused on the two specialised domain English subtasks by developing an unsupervised system that builds word embeddings from the supplied reference corpora for these domains.

Word embeddings trained on large corpora have been shown to capture semantic relations between words (Mikolov et al., 2013a,b), including hypernym-hyponym relations. The word embeddings built and used by the system presented here exploit this property. Although these word embeddings do not distinguish one semantic relation from another, we expect that true hypernyms will constitute a significant proportion of the predicted candidate hypernyms. Indeed, we show that for the medical domain subtask, our system beats the other unsupervised systems, although it still ranks behind the supervised systems.

Even though unsupervised systems tend to rank behind supervised systems in NLP tasks in general, our motivation to focus on an unsupervised approach is derived from the fact that they do not require explicit hand-annotated data, and from the expectation that they are able to generalise more easily to unseen hypernym-hyponym pairs.

The rest of this system description paper is organised as follows: Section 2 briefly surveys the relevant literature and explains the reasons for choosing to use a particular flavour of word embeddings. Section 3 describes the components of the system and its settings. Section 4 summarises the results and offers some insights behind the numbers. Section 5 concludes and proposes avenues for future work.

2 Related Work

Modern neural methods for natural language processing (NLP) use pre-trained word embeddings as fixed-sized vector representations of lexical units in running text as input data (Goldberg, 2017, ch. 10). However, as mentioned previously, word embedding vectors can be used on their own to measure semantic relations between words in an unsupervised manner by, for example, taking the cosine similarity of two word embedding vectors for which semantic similarity is to be measured.

There are several competing approaches for producing word embedding vectors. One such approach is skip-gram with negative sampling (SGNS), introduced by Mikolov et al. (2013a,b) as part of their Word2Vec software package. The skip-gram approach assumes that a focus word occurring in text depends on its context words (the words the focus word co-occurs with inside a fixed-sized window), but that those context words occur independently of each other. This conditional independence assumption in the context words makes computation more efficient and produces vectors that work well in practice. The negative sampling portion of the algorithm is a way of producing “negative” context words for the focus word by simply drawing random words from the corpus. These random words are assumed to be “bad” context words for the focus word. The positive and negative examples are used by an objective function that seeks to maximise the probability that the positive examples came from the corpus whilst the negative examples did not.

Cosine measures on word embeddings pairs (or even on other distributional lexical semantic representations) give an indication of the overall *semantic relatedness* of the word pairs they represent (Turney and Pantel, 2010), without specifying the type(s) of semantic relation(s) the two words hold. There have been endeavours to train word embeddings that emphasise one semantic relation over another. For example, Nguyen et al. (2016) modified the skip-gram objective function to train word embeddings that distinguished synonymy from antonymy. In a similar vein, Nguyen et al. (2017) developed an algorithm called Hypervec by adapting the skip-gram objective function to emphasise the non-symmetric hypernym-hyponym relations.

Our team indeed implemented a variant of the Hypervec method but failed to obtain better per-

formance scores on the training set than those obtained by using traditional SGNS (see Section 4). Whilst it is possible that a software bug in our implementation could be the cause of this lower performance, we decided to submit the SGNS results to the official shared task due to time constraints.

3 System Description

Our system consists of two components: a **trainer** that learns word vectors using an implementation of the Skip-Gram with Negative Sampling algorithm, and a **predictor** that outputs (predicts) the top 10 hypernyms of an input word based on the trained vectors. These two components and their settings are described here.

Trainer The trainer is a modification of PyTorch SGNS¹, a freely available implementation of the Skip-Gram with Negative Sampling algorithm. One set of vectors per specialised corpus (medicine and music industry) were trained on a vocabulary that consists of the 100,000 most frequent words in each corpus, using a word window of 5 words to the left and 5 words to the right of a sliding focus word. The windows do not cross sentence boundaries. For negative sampling, 20 words were randomly selected from the vocabulary based on their frequency². All vectors had a dimensionality of 300.

Predictor For each input word in the test file, the predictor attempts to produce 10 candidate hypernyms based on the vectors it learned during training. If there is no vector for an input word, no output for that word is given. If the input word is a multiword expression, then the learned vectors for the individual component words are retrieved and averaged together. This averaged vector is interpreted to represent the input multiword expression. After a vector is retrieved (or computed, in the case of averaged multiword expressions), pairwise cosine similarities are taken between this vector and all other vectors (i.e. the vectors corresponding to the other 99,999 most frequent words). The words represented by the 10 highest ranking cosine similarities are output as the 10 candidate hypernyms for the input word or multiword expression.

¹<https://github.com/theeluwin/pytorch-sgns>

²The frequencies were smoothed by raising them to the power of 0.75 before dividing by the total.

Domain	Approach	MAP	MRR	P@1	P@3	P@5	P@15
medical	SGNS	8.13	20.56	13.20	10.80	8.32	6.33
medical	HV	4.40	13.05	10.60	5.60	4.27	3.10
music	SGNS	1.88	5.34	4.00	2.40	1.89	1.35
music	HV	1.79	5.39	5.00	2.07	1.62	1.28

Table 1: Automatic evaluation results for the submitted system (SGNS) and a Hypervec variant (HV).

As can be seen, our system is completely unsupervised as it does not require corpora with tagged examples of words holding hypernym-hyponym relations or any external linguistic or taxonomical resources.

4 Results

Table 1 shows the results for our SGNS-based approach, which was submitted to the official shared task (SGNS), and for our Hypervec variant (HV), which was not submitted.

Our official submission ranked at eleven out of eighteen on the medical domain subtask with a Mean Average Precision (MAP) of 8.13. However, it ranked first place among all the unsupervised systems on this subtask. On the music industry domain subtask, our system ranked 13th out of 16 places with a MAP of 1.88, ranking 4th among the unsupervised systems. We believe that one reason why the music industry scores are so much lower than the medical results is due to our system not producing an output for 233 of the music industry input words (45% of the total), compared to the 128 medical input words (26%) it failed to predict.

Another aspect that seems to work against our system is its simplistic way of handling multiword expressions, namely by averaging together the individual word’s vectors. The total number of multiword expressions in the medical test set is 264, slightly higher than in the music test set, which contains 220 multiword expressions. Similarly, our system does not have a way of predicting multiword expressions as hypernym candidates, as it can only output the unigrams for which it has vector representations. 82% of the medical domain input words have at least one hypernym that is a multi-word expression, whilst 92% of the music industry domain input words have multi-word expression hypernyms.

5 Conclusions and Future Work

We presented a simple but competitive unsupervised system to predict hypernym candidates for input words, based on cosine similarity scores of word embedding vectors trained on specialised corpora.

Unsupervised systems in general tend to have lower performance than supervised systems as they lack explicit information to train on. So we are encouraged that our system beat other unsupervised systems on one corpus, as this gives us more avenues to explore.

One such avenue is to revisit our Hypervec implementation. We suspect that it might require more training epochs than the traditional SGNS method in order to achieve reasonable results. We also seek to experiment with refining pre-trained SGNS word embeddings with Hypervec, rather than training word embeddings from scratch using Hypervec directly.

Another avenue to explore involves incorporating taxonomical information into our word embeddings. One way to achieve this is by retrofitting pre-trained SGNS word embeddings with information derived from existing taxonomies like WordNet (Faruqui et al., 2015). Another way of incorporating taxonomical information is by generating a pseudo-corpus via a random walk over such a taxonomy and then learn SGNS word embeddings in the usual way (Goikoetxea et al., 2015).

These approaches (Hypervec, retrofitting and taxonomy random-walk) however, would relax the unsupervised constraint we followed in our implementation. So yet another avenue to explore is to instead apply different similarity functions that might be more sensitive to the one-way, general-specific nature of hypernymic relationships between words.

Abstract

This paper describes 300-sparsans' participation in SemEval-2018 Task 9: *Hypernym Discovery*, with a system based on sparse coding and a formal concept hierarchy obtained from word embeddings. Our system took first place in subtasks (1B) *Italian (all and entities)*, (1C) *Spanish entities*, and (2B) *music entities*.

1 Introduction

Natural language phenomena are extremely sparse by their nature, whereas continuous word embeddings employ dense representations of words. Turning these dense representations into a much sparser form can help in focusing on most salient parts of word representations (Faruqui et al., 2015; Berend, 2017; Subramanian et al., 2018).

Sparsity-based techniques often involve the coding of a large number of signals over the same dictionary (Rubinstein et al., 2008). Sparse, overcomplete representations have been motivated in various domains as a way to increase separability and interpretability (Olshausen and Field, 1997) and stability in the presence of noise.

Non-negativity has also been argued to be advantageous for interpretability (Faruqui et al., 2015; Fyshe et al., 2015; Arora et al., 2016). As Subramanian et al. (2018) illustrates this in the language domain, where sparse features are interpreted as lexical attributes, “to describe the city of Pittsburgh, one might talk about phenomena typical of the city, like erratic weather and large bridges. It is redundant and inefficient to list negative properties, like the absence of the Statue of Liberty”. Berend (2018) utilizes non-negative sparse coding for word translation by training

sparse word vectors for the two languages such that coding bases correspond to each other.

Here we apply sparse feature pairs to hypernym extraction. The role of an attribute pair $\langle i, j \rangle \in \phi(q) \times \phi(h)$ (where q is the query word, h is the hypernym candidate, and $\phi(w)$ is the index of a non-zero component in the sparse representations of w) is similar to *interaction terms* in regression, see section 2 for details.

Sparse representation is related to hypernymy in various natural ways. One of them is through *Formal concept Analysis (FCA)*. The idea of acquiring concept hierarchies from a text corpus with the tools of Formal concept Analysis (FCA) is relatively new (Cimiano et al., 2005). Our submissions experiment with formal concept analysis tool by Endres et al. (2010). See the next section for a description of formal concept lattices, and how hypernyms can be found in them.

Another natural formulation is related to *hierarchical sparse coding* (Zhao et al., 2009), where trees describe the order in which variables “enter the model” (i.e., take non-zero values). A node may take a non-zero value only if its ancestors also do: the dimensions that correspond to top level nodes should focus on “general” meaning components that are present in most words. Yogatama et al. (2015) offer an implementation that is efficient for gigaword corpora. Exploiting the correspondence between the variable tree and the hypernym hierarchy offers itself as a natural choice.

The task (Camacho-Collados et al., 2018) evaluated systems on their ability to extract hypernyms for query words in five subtasks (three languages, English, Italian, and Spanish, and two domains,

medical and music). Queries have been categorized as concepts or entities. Results were reported for each category separately as well as in combined form, thus resulting in 5×3 combinations. Our system took first place in subtasks (1B) *Italian (all and entities)*, (1C) *Spanish entities*, and (2B) *music entities*. Detailed results for our system appear in section 3. Our source code is available online¹.

1.1 Formal concept analysis

Formal concept Analysis (FCA) is the mathematization of *concept* and conceptual hierarchy (Ganter and Wille, 2012; Endres et al., 2010). In FCA terminology, a *context* is a set of *objects* \mathcal{O} , a set of *attributes* \mathcal{A} , and a binary incidence relation $\mathcal{I} \subseteq \mathcal{O} \times \mathcal{A}$ between members of \mathcal{O} and \mathcal{A} . In our application, \mathcal{I} associates a word $w \in \mathcal{O}$ to the indices of its non-zero sparse coding coordinates $i \in \mathcal{A}$. FCA finds formal *concepts*, pairs $\langle O, A \rangle$ of object sets and attribute sets ($O \subseteq \mathcal{O}, A \subseteq \mathcal{A}$) such that A consists of the shared attributes of objects in O (and no more), and O consists of the objects in \mathcal{O} that have all the attributes in A (and no more). (There is a closure-operator related to each FCA context, for which O and A are closed sets iff $\langle O, A \rangle$ is a concept.) O is called the extent and A is the intent of the concept.

There is an order defined in the context: if $\langle A_1, B_1 \rangle$ and $\langle A_2, B_2 \rangle$ are concepts in \mathcal{C} , $\langle A_1, B_1 \rangle$ is a *subconcept* of $\langle A_2, B_2 \rangle$ if $A_1 \subseteq A_2$ which is equivalent to $B_1 \supseteq B_2$. The concept order forms a lattice. The smallest concept whose extent contains a word is said to *introduce* the object. We expect that h will be a hypernym of q iff $n(q) \leq n(h)$ where $n(w)$ denotes the node in the concept lattice that introduces w .

The closedness of extents and intents has an important structural consequence. Adding attributes to \mathcal{A} (e.g. responses of additional neurons) will very probably grow the model. However, the original concepts will be embedded as a substructure in the larger lattice, with their ordering relationships preserved.

2 Our approach

Now we describe our system that is based on sparse non-negative word representations and FCA besides more traditional features.

¹https://github.com/begab/fca_hyponymy

We use the popular skip-gram (SG) approach (Mikolov et al., 2013) to train $d = 100$ dimensional dense distributed word representations for each sub-corpus. The word embeddings are trained over the text corpora provided by the shared task organizers with the default training parameters of `word2vec (w2v)`, i.e. a window size of 10 and 25 negative samples for each positive context.

We derived *multi-token units* by relying on the `word2phrase` software accompanying the `w2v` toolkit. An additional source for identifying multi-token units in the training corpora was the list of potential hypernyms released for each subtask by the shared task organizers.

Given the dense embedding matrix $W_x \in \mathbb{R}^{d \times |V_x|}$, for some subcorpus of the shared task $x \in \{1A, 1B, 1C, 2A, 2B\}$, where $|V_x|$ is the size of the vocabulary and d is set to 100. As a subsequent step, we turn W_x into *sparse word vectors* akin to Berend (2017) by solving for

$$\min_{D \in \mathcal{C}, \alpha \in \mathbb{R}_{\geq 0}} \|D\alpha - W_x\|_F + \lambda \|\alpha\|_1, \quad (1)$$

where \mathcal{C} refers to the convex set of $\mathbb{R}^{d \times k}$ matrices consisting of d -dimensional columns vectors with norm at most 1, and α contains the sparse coefficients for the elements of the vocabulary. The only difference compared to Berend (2017) is that here we ensure a non-negativity constraint over the elements of α .

For the elements of the vocabulary we ran the *formal concept analysis* tool of Endres et al. (2010)². In order to keep the size of the DAG outputted by the FCA algorithm manageable, we only included the query words and those hypernyms in the analysis which occur in the training dataset for the corpora. As we will see in the next section, this restriction turns out to be very useful.

Next, we determine a handful of features for a pair of expressions (q, h) consisting of a query q and its potential hypernym h . Table 1 provides an overview of the features employed for a pair (q, h) . We denote with \mathbf{q} and \mathbf{h} the 100-dimensional dense vectorial representations of q and h . Additionally, we denote with Q and H the sequence of tokens constituting the query and hypernym phrases. Finally, we refer to the set of basis vectors (in the FCA terminology, attributes)

queryBeginsWith	$Q[0] = h$
queryEndsWith	$Q[-1] = h$
hasCommonWord	$Q \cap H \neq \emptyset$
sameFirstWord	$Q[0] = H[0]$
sameLastWord	$Q[-1] = H[-1]$
logFrequencyRatio	$\log_{10} \frac{\text{count}(q)}{\text{count}(h)}$
isFrequentHypernym ³	$c \in MF_{50}(q.type)$
sameConcept	$n(h) = n(q)$
parent	$n(q) \prec n(h)$
child	$n(h) \prec n(q)$
overlappingBasis	$\phi(q) \cap \phi(h) \neq \emptyset$
sparseDifference _{q \setminus h}	$ \phi(q) - \phi(h) $
sparseDifference _{h \setminus q}	$ \phi(h) - \phi(q) $
attributePair _{ij}	$\langle i, j \rangle \in \phi(q) \times \phi(h)$

Table 1: The features employed in our classifier. $MF_{50}(q.type)$ refers to the set of top-50 most frequent hypernyms for a given query type.

which are assigned non-zero weights in the reconstruction of the vectorial representation of q and h as $\phi(q)$ and $\phi(h)$. It is also considered as a feature (`isFrequentHypernym`) whether a particular candidate hypernym h belongs to the top-50 most frequent hypernyms for the category of q (i.e. concept or entity). Modeling the two categories separately played an important role in the success of our systems.

Three additional features are defined for incorporating the concept lattice output by FCA. With $n(w)$ denoting the concept that introduces w , i.e. the most specific location within the DAG for w , our features indicate whether $n(q)$ (1) coincides with that of h , (2) is the parent (immediate successor) for that of h , or (3) is the child (immediate predictions) for that of h . Parents, and even the inverse relation, proved to be more predictive than the conceptually motivated $q \leq h$. In Table 1, $n_1 \prec n_2$ denotes that n_1 is an immediate predecessor of n_2 . We will see in post-evaluation ablation experiments, where we refer to the above three features as the *FCA* features, that they were not useful in our submissions.

³At submission time, this feature did not work properly.

The `attributePairij`s above, our most important features, are indicator features for every possible interaction term between the sparse coefficients in α . That means that for a pair of words (q, h) we defined $\phi(q) \times \phi(h)$, i.e. candidates get assigned with the Cartesian product derived from the indices of the non-zero coefficients in α . Note that this feature template induces k^2 features, with k being the number of basis vectors introduced in the dictionary matrix D according to Eq. 1.

In order to rank potential hypernym candidates over the test set we trained a *logistic regression* classifier for concepts and entities utilizing the `sklearn` package (Pedregosa et al., 2011)⁴ with the regularization parameter defaulting to 1.0.

For each appropriate (q, h) pair of words for which h is a hypernym of q , we generated a number of *negative samples* (q, h') , such that the training data does not include h' as a valid hypernym for q . For a given query q , belonging to either of the *concept* or *entity* category, we sampled h' from those hypernyms which were included as a valid hypernym in the training data with respect to some $q' \neq q$ query phrase.

When making predictions for the hypernyms of a query, we relied on our query type sensitive logistic regression model to determine the ranking of the hypernym candidates. In our official submission we treated such phrases to rank which were included in the training data for being a proper hypernym at least once.

After the appropriate model ranked the hypernym candidates, we selected the top 15 ranked candidates and applied a *post-ranking* heuristic over them, i.e. reordered them according to their background frequency from the training corpus. Our assumption here is that more frequent words tend to refer to more general concepts and more general hypernymy relations potentially tend to be more easily detectable than more specialized ones.

3 Results

3.1 Our submissions

Our submissions were based on $k = 200$ dimensional sparse vectors computed from unit-normed 100-dimensional dense vectors with $\lambda = .3$. The sum of the two dimensions motivates our group name. For training the regression model with negative samples, 50 false hypernyms were sampled for each query q in the training dataset. One of our

submissions involved attribute pairs, the other not. Both submissions used the conceptually motivated but practically harmful FCA-based features.

Table 2 shows submission results. The figures that can be reproduced with the code in the project repo (`reprd`) is slightly different from our official submissions (`offic`) for two reasons: because the implementation of `isFreqHyp` contained a bug, and because of the natural randomness in negative sampling. For reproducibility, we report result without the `isFreqHyp` feature. The randomness introduced by negative sampling is now factored out by random seeding.

(b) entity

Table 4: Number of in-vocabulary (and out-of-vocabulary, OOV) queries per query type. The ratio of the latter is also shown.

3.2 Query type sensitive baselining

Our submission with attribute pairs achieved first place in categories (1B) Italian (all and entities), (1C) Spanish entities, and (2B) music entities. This is in part due to our good choice of a fallback solution in the case of OOV queries: we applied a category-sensitive baseline returning the most frequent train hypernym in the corresponding query type (concept or entity). Table 4 shows how frequently we had to rely on this fallback, and Table 3 shows the corresponding pure baseline results.

Table 6: Ablation experiments, on the 1A dataset with $k = 200, ns = 50$ (and the implementation of `isFreqHyp` fixed). The first two columns indicate whether `attributePairij` and FCA-derived features are utilized, respectively.

3.3 Post-evaluation analysis

After the evaluation closed, we conducted ablation experiments the results of which are included in Table 6. In these experiments, we investigated the contribution of the features derived from sparse attribute pairs and FCA. These ablation experiments corroborate the importance of features derived from sparse attribute pairs and reveal that turning off FCA-based features does not hurt performance at all. For this reason – even though our official shared task submission included FCA-related features – we no longer employed them in our post-evaluation experiments.

Table 5 includes the detailed behavior of our model on subtask 1A with respect three distinct factors, that is

1. the number of basis vectors employed during sparse coding ($k \in \{200, 300, 1000\}$),
2. the number of negative training samples per positive sample ($ns \in \{50, all\}$),
3. candidate filtering being turned on/off.

In our original submission we generated 50 negative samples (ns) generated per query q during

Table 7: Test results of an oracle system which uses candidate filtering.

training. In our post evaluation experiments we investigated the effects of generating more negative samples, i.e. we regarded all the valid hypernyms over the training set – not being a proper hypernym for q – as h' upon the creation of the (q, h') negative training instances. This latter strategy is referenced as $ns = all$ in Table 5.

In our official submission we regarded only those hypernyms as potential candidates to rank during test time which occurred at least once as a correct hypernym in the training data. We call this strategy as candidate filtering. Historically, we applied this restriction to speed up the FCA algorithm because this way the size of the concept lattice could be made smaller. As there are valid hypernyms on the test set which never occurred in the training data, our official submission would not be able to obtain a perfect score even in theory. Table 7 contains the best possible metrics on the test set that we could achieve when candidate filtering is applied. In our post evaluation experiments we also investigated the effects of turning this kind of filtering step off. As Table 5 illustrates, however, our scores degrade after turning candidate filtering off.

Our post evaluation experiments in Table 5 sug-

	MAP	MRR	P@1	P@3	P@10	P@15

Table 8: Post evaluation results for the different subtasks using $k = 1000$, $ns = 50$ and hypernym candidate filtering. Upper: our system, lower: subtask winner.

gest that it is advantageous to apply sparse representation of more expressive power (i.e. a higher number of basis vectors). Generating more negative samples also provides some additional performance boost. These previous observations hold irrespective whether candidate filtering is employed or not, however, their effects are more pronounced when hypernym candidates are not filtered.

Finally, we report our post-evaluation results for all the subtasks and compare them to the official scores of the best performing systems in Table 8. It can be seen from these enhanced results for category “all” (concepts and entities mixed) that we would win (1B) Italian and (1C) Spanish. Our post-evaluation system – which only differs from our participating system that it fixes the calculation of a features, does not rely on FCA-based features and uses $k = 1000$ – would also place third in the rest of the subtasks.

4 Conclusion

In this paper we experimented with the integration of sparse word representations into the task of hypernymy discovery. We strived to utilize sparse word representations in two ways, i.e. via building concept lattices using formal concept analysis and modeling the hypernymy relation with the help of interaction terms. While our former approach for deriving formal concepts from sparse word representations was not successful, the interaction terms derived from sparse word representations proved to be highly beneficial.

Abstract

We present our UWB system for the task of capturing discriminative attributes at SemEval 2018. Given two words and an attribute, the system decides, whether this attribute is discriminative between the words or not. Assuming Distributional Hypothesis, i.e., a word meaning is related to the distribution across contexts, we introduce several approaches to compare word contextual information.

We experiment with state-of-the-art semantic spaces and with simple co-occurrence statistics. We show the word distribution in the corpus has potential for detecting discriminative attributes. Our system achieves F1 score 72.1% and is ranked #4 among 26 submitted systems.

1 Introduction

In this paper, we describe our UWB system participating in the pilot shared task on capturing discriminative attributes held at SemEval 2018. Given two words and an attribute, the goal of this task is to decide, whether the attribute is discriminative between them. For example, we can distinguish between the words *car* and *boat* by a discriminative feature (attribute) *wheels*. On the other hand, both *tennis* and *basketball* use a *ball*, so that the *ball* is not discriminative between them. By its nature, capturing discriminative attributes is a binary classification task. In general, there is no assumption on the input words and their attributes (e.g., part of speech, etc.).

While most related works focus on extracting discriminative features from images (Guo et al., 2015; Huang et al., 2016; Lazaridou et al., 2016), this shared task is oriented purely on textual level. The first experiments have been performed by Krebs and Paperno (2016) and have shown the promising potential of this task.

The fundamental assumption of our work is *Distributional Hypothesis*, i.e., two words are expected to be semantically similar if they occur in similar contexts (they are similarly distributed across the text). This hypothesis was formulated by Harris (1954) several decades ago. Today it is the basis of state-of-the-art distributional semantic models (Mikolov et al., 2013; Pennington et al., 2014; Bojanowski et al., 2017). We present several approaches, which rely on Distributional Hypothesis and employ the word contexts for statistical comparison of their meanings.

2 Proposed Approach

Given two words $w_1 \in \mathbf{V}$, $w_2 \in \mathbf{V}$ and the attribute $a \in \mathbf{V}$, where \mathbf{V} is a word vocabulary. The task is to predict, whether the attribute a is discriminative between the words w_1 and w_2 , which leads to a binary classification task.

We propose several metrics, which estimate the degree to which the attribute a is important for the word w . We denote this importance as $\varphi(w, a) \in \mathbb{R}$. Clearly, if the attribute is important for one word and not for the other, it is likely to be discriminative. In general, we do not place any assumption on the importance metric $\varphi(w, a)$. We transform this score onto the binary vector $\mathbf{b}_{w,a}$ containing exactly one non-zero element (*one-hot vector*). Let $\mathcal{T} : \mathbb{R} \mapsto \{0, 1\}^b$ be the transformation function so that $\mathbf{b}_{w,a} = \mathcal{T}(\varphi(w, a))$. In our case, we split the scores $\varphi(w, a)$ for all pairs (w, a) from training data into b bins according to $\frac{100}{b}\%$ quantiles. The bin, where the importance score belongs to, represents the value 1 in the vector $\mathbf{b}_{w,a}$.

Having the one-hot vectors $\mathbf{b}_{w_1,a}$ and $\mathbf{b}_{w_2,a}$ for the pair of words w_1 and w_2 , we represent the discriminativeness of the attribute a as a conjunction matrix $\mathbf{C}_{w_1,w_2,a} = \mathbf{b}_{w_1,a} \mathbf{b}_{w_2,a}^\top$ (note $\mathbf{b}_{w_1,a}$ is a column vector). The matrix $\mathbf{C}_{w_1,w_2,a} \in \{0, 1\}^{b \times b}$

has exactly one non-zero element at the coordinates given by the bins, onto which the scores $\varphi(w_1, a)$ and $\varphi(w_2, a)$ are mapped. Values in the matrix are used as binary features for the classifier. The main motivation behind this binarization is to allow combining different importance metrics on different scale.

In the following subsections, we introduce several approaches to estimate the importance score $\varphi(w, a)$.

2.1 Semantic Spaces

Let $\mathcal{S} : \mathcal{V} \mapsto \mathbb{R}^n$ be a semantic space, i.e., a function which projects word w into Euclidean space with dimension n . The meaning of the word w is represented as a real-valued vector $\mathcal{S}(w)$.

We assume, the more similar is the attribute a to the word w in meaning, the more likely a represents some feature of w . We estimate this similarity as a cosine of the angle between the corresponding vectors

$$\varphi(w, a)^{[SS]} = \cos(\mathcal{S}(w), \mathcal{S}(a)). \quad (1)$$

2.2 Word Co-occurrences

We follow the intuition behind the Global Vectors (GloVe) model (Pennington et al., 2014), i.e., that the co-occurrence probabilities have the ability to encode the meaning of words.

We are given the corpus $c = \{c_i\}_{i=1}^k$, i.e., a sequence of words $c_i \in \mathcal{V}$, where subscript i denotes the position in the corpus. Let $N(w, a)$ denote the weighted frequency of the word w in the context of the word a

$$N(w, a) = \sum_{c_i=w, c_j=a, 1 \leq |i-j| \leq d} \lambda(|i-j|), \quad (2)$$

where λ is a weighting function. We experiment with two types of weighting: a) *uniform* weighting, where $\lambda(m) = 1$ independently of the distance between words and b) *hyperbolic* weighting, where $\lambda(m) = \frac{1}{m}$. For uniform weighting the equation expresses the number of times the word w occurs in the context of word a . Hyperbolic weighting incorporates the assumption that closer words are more important for each other (the weight decreases with increasing distance).

Let $N(w) = \sum_{a \in \mathcal{V}} N(w, a)$ be the number of times any word occurs in the context of w . We estimate the conditional probability of an attribute a given the word w and use it as an importance metric

$$\varphi(w, a)^{[WC-a|w]} = P(a|w) = \frac{N(w, a)}{N(w)}. \quad (3)$$

The core idea is that if a often occurs in the context of w_1 and not in the context of w_2 , then a is likely to be discriminative attribute between w_1 and w_2 . The similar idea can also be expressed in an opposite way, i.e., to use probability of the word w given the attribute a

$$\varphi(w, a)^{[WC-w|a]} = P(w|a) = \frac{N(w, a)}{N(a)}. \quad (4)$$

2.3 ConceptNet

ConceptNet (Speer and Havasi, 2012) is a large semantic graph, which connects words and phrases with labeled edges. It is based on knowledge collected from many sources, including Wiktionary, WordNet, DBpedia, etc. When ConceptNet is combined with state-of-the-art semantic spaces (e.g., GloVe (Pennington et al., 2014) or SkipGram (Mikolov et al., 2013)) it provides exceptional performance in intrinsic tasks (Speer and Lowry-Duda, 2017).

In this paper, we use ConceptNet API, which enables to measure the relatedness between words¹. It is built using an ensemble that combines data from ConceptNet, SkipGram, GloVe, and OpenSubtitles 2016, using a variation on retrofitting (Speer et al., 2016). We use the relatedness weight as an importance metric $\varphi(w, a)^{[CN]}$.

3 Experiments

In all our experiments we employ *Maximum Entropy* classifier (Berger et al., 1996) implemented in the Brainy machine learning library (Konkol, 2014). For every importance metric we use mapping onto $b = 5$ bins. This leads to $5 \times 5 = 25$ binary features describing the discriminativeness of an attribute for single importance metric.

We train the classifier on the *validation* dataset² proposed by the organizers of this task, containing 2722 manually annotated examples (1364 positive and 1358 negative) with total 576 distinct attributes. We do not use automatically generated data *train.txt*. For the selection of optimal feature

¹An example of the relatedness between the words *bird* and *bat*: <http://api.conceptnet.io/related/c/en/bird?filter=/c/en/bat>.

set we perform 10-fold cross-validation. The official test data consists of 2340 examples (1047 positive and 1293 negative). F1 score is the official evaluation measure of this task. Note the majority class system achieves F1 score 50.1% and 55.3% on the validation and test data sets, respectively.

3.1 Settings

We estimate word co-occurrence probabilities (Section 2.2) using the English Wikipedia corpus. We experiment with several semantic spaces:

SkipGram is a neural-network based model (Mikolov et al., 2013). Levy and Goldberg (2014) provide pre-trained SkipGram models on English Wikipedia with two sizes of the context window (2 and 5) and their own model with dependency-based context.

GloVe is a log-bilinear model for word representations, which encodes global word co-occurrences (Pennington et al., 2014). We use vectors provided by authors of the model, pre-trained on various corpus sizes (6, 42, and 840 billion words)³.

FastText (Bojanowski et al., 2017) is a character-n-gram-based SkipGram model. We use word vectors pre-trained on English Wikipedia⁴.

LexVec is based on factorization of positive point-wise mutual information matrix using proven strategies from GloVe, SkipGram, and methods based on singular value decomposition (Salle et al., 2016). We use pre-trained word vectors provided by the authors of the model⁵.

Latent Semantic Analysis (LSA) (Landauer et al., 1998) first creates a word-document co-occurrence matrix and then reduces its dimension by singular value decomposition. We trained the model on English Wikipedia.

Latent Dirichlet Allocation (LDA) (Blei et al., 2003) represents the text as a topic distribution. In our case, each value in the word vector corresponds to the probability of this word conditioned by the particular topic.

3.2 Results

In Table 1 we show F1 scores for individual importance metrics including all three approaches,

³Available at <https://nlp.stanford.edu/projects/glove>.

⁴Available at <https://fasttext.cc>.

⁵Available at <https://github.com/alexandres/lexvec>.

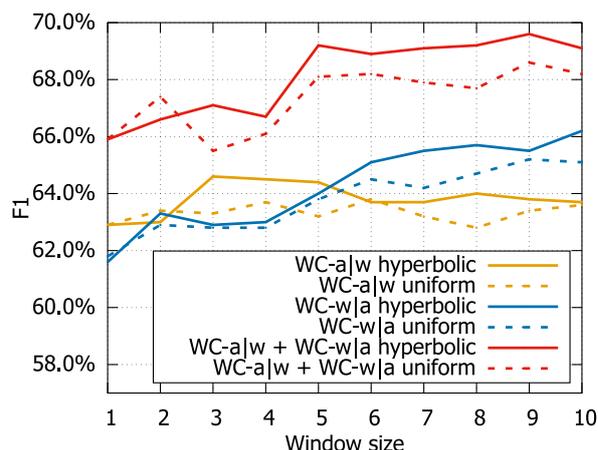

Figure 1: Results of word co-occurrence metric with different weighting and different window size d .

namely, semantic spaces (Section 2.1), word co-occurrences (Section 2.2), and ConceptNet (Section 2.3). The last two columns in the table contain F1 scores for 10-fold cross-validation on the validation dataset and F1 scores on the official test data. All three approaches provide comparable F1 scores on both datasets.

Detailed experiments with different context window sizes $1 \leq d \leq 10$ for estimating co-occurrence probabilities are shown in Figure 1. We show F1 scores achieved by 10-fold cross-validation on the validation dataset. The hyperbolic weighting performs better than uniform for both cases w|a and a|w independently on the size of the context window. Bigger context window seems to be more suitable for capturing discriminativeness. We can see that both metrics enrich each other and their combination leads to significantly better results than using standalone metrics. Based on this graph, we chose context window size $d = 9$ and use it in all further experiments.

Based on the cross-validation F1 scores, we combine different importance metrics to boost the performance (see Table 2). LexVec proved to perform best among semantic spaces. We found out that LDA enrich LexVec and improve the performance by approximately 1%. We believe this is because of the different context type (we used Wikipedia articles as documents for LDA). Significant improvements are achieved when we combine co-occurrence probabilities with semantics spaces or with ConceptNet (both cases give approximately 70% F1 score on both validation and test data). Combining all three approaches to-

Table 2: Combinations of proposed importance metrics.

gether yields additional improvements (72.0% and 71.3% on validation and test data, respectively).

Our final UWB system combines all three approaches with one extra trick. We create additional binary features represented as a product of each pair of features ($x_a \times x_b$ for $a \neq b$) and add them into the classifier. We do this to better model the dependencies between single features. In the table, we denote this trick as a *conjunction*. Despite the fact that this setting leads to increasing sparseness of the feature set, it boosts F1 score on validation data by 1.9% and on test data by 0.8%.

4 Conclusion

In this paper we described our UWB system participating in SemEval 2018 shared task for capturing discriminative attributes. We explored

three approaches based on word distribution in the corpus, including various semantic spaces, co-occurrence probabilities, and ConceptNet. Our best results have been achieved by Maximum Entropy classifier combining all three approaches with careful feature engineering. Our system is ranked #4 among 26 participating systems.

Abstract

This paper presents the two systems submitted by the meaning_space team in Task 10 of the SemEval competition 2018 entitled *Capturing discriminative attributes*. The systems consist of combinations of approaches exploiting explicitly encoded knowledge about concepts in WordNet and information encoded in distributional semantic vectors. Rather than aiming for high performance, we explore which kind of semantic knowledge is best captured by different methods. The results indicate that WordNet glosses on different levels of the hierarchy capture many attributes relevant for this task. In combination with exploiting word embedding similarities, this source of information yielded our best results. Our best performing system ranked 5th out of 13 final ranks. Our analysis yields insights into the different kinds of attributes represented by different sources of knowledge.

1 Introduction

SemEval Task 10 “Capturing Discriminative Attributes” (Krebs et al., 2018) provides participants with triples of words consisting of two concepts and an attribute. The task is to determine whether the attribute is a distinguishing property of the first concept compared to the second concept. This is the case in triple *shrimp, spinach, pink*, for instance, because shrimp can be pink whereas spinach is usually of a different color. When the first concept does not have a semantic relation with the attribute or both the concepts have the same semantic relation with it, the attribute is considered not to be discriminative.

In general, Task 10 can be understood as detecting whether there is a semantic relation between the concepts and the attribute. The dataset includes a wide range of variation. For instance, the attribute may be a part of the concept (e.g.

tortoise, snail, legs) or category membership (e.g. *polyurethane, polyester, material*), relations between entities and activities they engage in (e.g. *cheetah, lion, runs*) as well as rather specific relations, for instance the relation between a specialist and the phenomenon they are specialized in (e.g. *optician, dentist, eyes*).

Rather than finding specific solutions for each kind of relation, we investigate different approaches exploiting different sources of knowledge. Both of our systems comprise a component exploiting the glosses and hierarchical structure of WordNet (Fellbaum, 1998) in order to determine whether an attribute applies to a concept. Our underlying assumption is that definitions should provide the most important distinctive attributes of a concept. Since concepts are not necessarily always distinguished on the same level of concreteness, but might also be distinguished on a more abstract level (e.g. *herbs, root, green* v.s. *apse, nightgown, royal*) we exploit the entire WordNet hierarchy.

In both of our systems, the second component exploits information encoded in distributional vector representations of words. Word vectors have not only been shown to capture information about semantic similarity and relatedness but, beyond that, seem to encode information about individual components of word meaning that are necessary to solve analogy tasks such as in the famous example *man* is to *woman* as *king* is to *queen* (Mikolov et al., 2013b). This indicates that the dimensions of the distributional vector representations encode information about specific attributes of words. We experiment with two approaches: a basic approach comparing cosine similarities and an exploratory approach that deducts word vectors from one another to detect meaning differences. Best performance was obtained by the system using cosine similarity. The second approach per-

forms lower in isolation, but performance is comparable to the first system in combination with the WordNet component.

The main insights gained from our experiments are the following. First, despite the limited coverage of information on attributes in WordNet (as pointed out by Poesio and Almuhareb (2005)), the contribution of the WordNet component to the overall results indicates that definitions yield a valuable source of knowledge with respect to discriminative attributes. Second, we analyze how individual systems perform across different types of attributes. Our analysis shows that similarity performs best on general descriptive properties and WordNet definitions help most for finding specific properties. These observations indicate that more sophisticated methods of combining these components could lead to superior results in future work.

The remainder of this paper is structured as follows: After presenting background and related work (Section 2), our system designs are introduced in Section 3. Section 4 provides an overview of the results achieved by different systems and system components, including our analysis across attribution types. This is followed by a conclusion (Section 5).

2 Background and related work

Solving the task at hand requires both knowledge about lexical relations and the world. We assume that this knowledge cannot be found in one resource alone. Rather, different approaches of representing word meaning may comprise complementary information. In this exploratory work, we exploit explicitly encoded knowledge in a lexical resource and information encoded in the distribution of words in large corpora. While attributes of concepts have been studied before from a cognitive (e.g. McRae et al. (2005)) and computational (e.g. Poesio and Almuhareb (2005)) perspective, this task is, to our knowledge, the first task aiming at detecting discriminative features.

We use WordNet (Fellbaum, 1998) as a source of explicitly represented knowledge. Whereas the WordNet structure contains a vast amount of information about lexical relations (hyponymy, synonymy, meronymy), its definitions constitute a resource of world knowledge. WordNet definitions have been used successfully in approaches to word sense disambiguation (Lesk, 1986) and inferring verb frames (Green et al., 2004). The only

study requiring knowledge and reasoning about attributes we are aware of is an exploratory study examining what knowledge in definitions contributes to question-answering tasks (Clark et al., 2008).

Vector representations of word meaning based on the distribution of words in large corpora do not yield explicit information about specific relations, but implicitly encode all kinds of associations between concepts. In contrast to manually constructed resources, their coverage is much larger. More specifically, they have been shown to encode information relevant in solving analogy tasks (Mikolov et al., 2013a; Levy and Goldberg, 2014b; Gladkova et al., 2016; Gábor et al., 2017; Linzen, 2016) and inferring semantic hierarchies (Fu et al., 2014; Pocostales, 2016). This indicates that the dimensions of distributional representations encode information about attributes of concepts (Levy and Goldberg, 2014b, p.177). For instance, in order to find the fourth component in the analogy *man* is to *woman* as *king* is to *queen*, a model has to detect the relation holding between the pairs in the analogy. In this example, the relations are formed by the two features of royalty and gender. One way of solving this is to use the vector offsets resulting from *woman* - *man* + *king*. The result should be closest to the fourth component (*queen*). Thus, the first component for this calculation, $B - A$, should capture information about the distinguishing features between A and B, as the subtraction eliminates the identical (or very similar) dimensions in both representations, but keeps the features associated with B.

Our first system follows the basic assumption that if there is some kind of association between a concept and an attribute, this should be reflected by the vector representations. We assume that attributes occur in the linguistic contexts of the concepts they apply to and thus appear in proximity to them. In a comparative set-up such as in this task, the attribute should be closer to the concept it applies to. In our second system, we attempt to exploit the operations used for solving analogies in order to determine whether an attribute distinguishes two concepts.

3 System description

Each of our systems¹ consists of a WordNet component and a component exploiting word embed-

¹Code can be found at https://github.com/cltl/meaning_space

ding vectors. If the WordNet component is unable to classify an example, it is passed on to the word embedding component. After presenting the WordNet component, we describe the two embedding-based systems. The word vectors used in all approaches are taken from the Word2Vec Google News model (Mikolov et al., 2013a).² The systems are developed using training and validation data and evaluated using test data.³

3.1 WordNet glosses and hierarchical structure

We design rules to exploit explicitly encoded knowledge in synset glosses and the hierarchical structure. We assume that (1) the most important discriminative attributes are mentioned in definitions and (2) concepts can be distinguished on different levels of abstraction. Essentially, we check whether the attribute is in any of the definitions of the concepts. We employ two variants of the system. The first variant simply relies on string match (definition string match), whereas the second one employs cosine similarity between the attribute and the words in the glosses (definition similarity). For both variants, we retrieve the glosses of all WordNet synsets containing the concepts and the glosses of all their hypernyms. We preprocess the definitions by tokenizing them and excluding stopwords using NLTK (Bird et al., 2009). In the two best-performing full systems, we used the definition-similarity variant.

3.1.1 Definition string match

This variant employs one rule to detect positive cases and two rules to detect negative cases:

POS The attribute matches a word in the glosses of concept 1 and no word in the glosses of concept 2.

NEG The attribute matches a word in the glosses of both concepts.

NEG The attribute matches a word in the glosses of concept 2 and no word in the glosses of concept 1.

We could also count all cases in which the attribute matches no word as negative cases, but

²Downloaded from <https://drive.google.com/file/d/0B7XkCwpI5KDYN1NUTt1SS21pQmM/edit>, Nov. 1, 2017.

³<https://github.com/dpaperno/DiscriminAtt/>

since only a selection of attributes is mentioned in the glosses, this would yield a high number of false negative decisions. Instead, we fall back on one of two distributional approaches in case none of the above-mentioned cases applies. If run in isolation, we label all instances for which none of the conditions apply as negative.

3.1.2 Definition similarity

In the second variant, we replace words by their vectors and measure the cosine similarity between the attribute and the words in the glosses in order to determine positive and negative cases. As a first step, we search for the word in the glosses with the highest cosine similarity to the attribute. Next, we employ an upper and a lower threshold in order to determine whether the attribute is similar or dissimilar enough to the word in the glosses. We assume this strategy allows us to extend the scope from exact pattern match to highly similar words, such as synonyms or hypernyms. The transformed rules are shown below:

POS The similarity between concept 1 and the attribute is above the upper threshold and the similarity between concept 2 and the attribute is below the lower threshold.

NEG The similarity between concept 2 and the attribute is above the upper threshold and the similarity between concept 1 and the attribute is below the lower threshold.

NEG The similarity between concept 1 and the attribute and the similarity between concept 2 and the attribute are above the upper threshold.

NEG The similarity between concept 1 and the attribute and the similarity between concept 2 and the attribute are below the lower threshold.

Here, we do include a condition for cases in which both similarities are below the threshold, as we assume a wider coverage due to the vector representations. The best performing similarity thresholds (0.75 for upper and 0.23 for lower threshold) were determined by testing several configurations on the validation data.

In addition to glosses, several other kinds of semantic relations encoded in the WordNet hierarchy can be expected to increase the performance

on this task. We experimented with meronymy relations, synonymy as well as the hypernyms themselves. Whereas these additions increased the performance in a set-up consisting of only the WordNet component, they harmed the performance in our overall system set-ups where we also use word embeddings.

3.2 Word embeddings

As a second component, we employ two different ways of extracting semantic knowledge from word embeddings.

3.2.1 Vector similarity

This component compares the similarities between the attribute and the concept and counts all cases in which the similarity between concept 1 and the attribute is higher than the similarity between concept 2 and the attribute as positive cases. All other cases are counted as negative. Setting even low thresholds harmed performance.

3.2.2 Vector subtraction

We subtract the vector of concept 2 from the vector of concept 1 and assume that the resulting vector representation is close to the kind of attribute that distinguishes the concepts. If this vector is close to the attribute, we assume it is discriminative. The subtraction should eliminate the shared aspects leaving information about the differences. The vector resulting from for instance *man* - *woman* cannot be seen as a representation of the specific word *male*, but rather reflects something like for instance ‘maleness’.

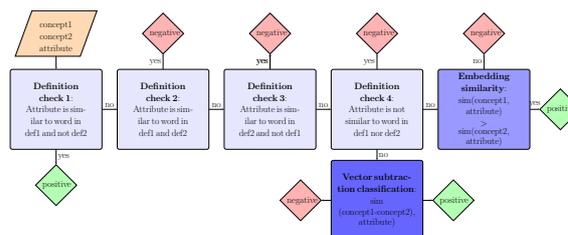

Rather than setting a definitive similarity threshold, we employ a supervised classification approach in which we use the similarity between the calculated vector and the attribute vector as a sole feature. For reasons of time constraints, we only experimented with a Multi-Layer Perceptron, implemented in the SciKit learn toolkit (Buitinck et al., 2013).⁴

4 Results

Table 1 provides an overview of our different implementations on the test set. The highest performance was reached by the combination of WordNet gloss information and embedding similarity. In the overall SemEval ranking, performance

ranges from 0.47 to 0.75. Our similarity-centered systems rank in the upper mid range (performing between 0.69 and 0.64), with the best run achieving 5th rank among 13 ranks (and 21 submitted system).

The combination of WordNet gloss information and information from subtracting word vectors performs 2 points lower than our best performing system. When comparing the two word embedding approaches in isolation, we see that the system based on subtraction performs almost 18 points lower than the system using embedding similarity. This indicates that the overlap of correct answers between the Wordnet system and the subtraction system is lower than between the WordNet system and the embedding similarity system. The following sections provide insights into the level at which properties are found in WordNet definitions and the kinds of attributes successfully recognized by the different approaches.

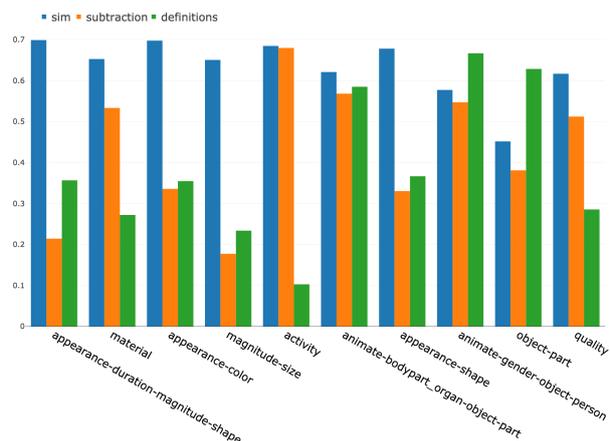

Figure 2: Comparison of f1-scores reached by the three main system components on the 10 most frequent attribute categories.

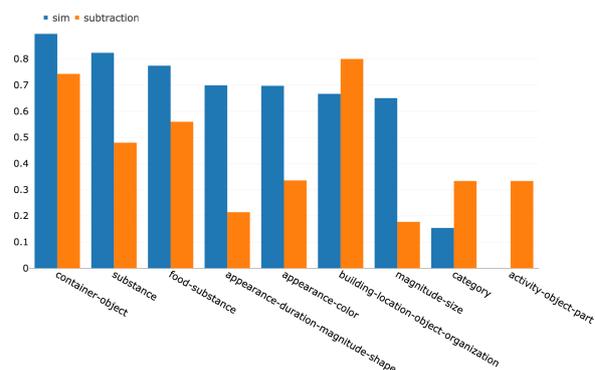

4.1 Level of distinction in the WordNet hierarchy

We hypothesized that concepts might not always be distinguished on the same level of concreteness, but could also be distinguished on a more abstract level. In order to test this, we counted how many properties are found in glosses of synsets containing the concept and how many are found in glosses of their hypernyms. Out of the total 1,098 attributes found in WordNet glosses, 699 are found on the same level as the concept (i.e. in the definitions of one of the synsets containing the concept) and 366 are found in gloss of one of the hypernyms of the synsets containing the concept.⁵ In total, the definition system is able to classify 799 (out of 2,340) concept-concept-attribute triples.

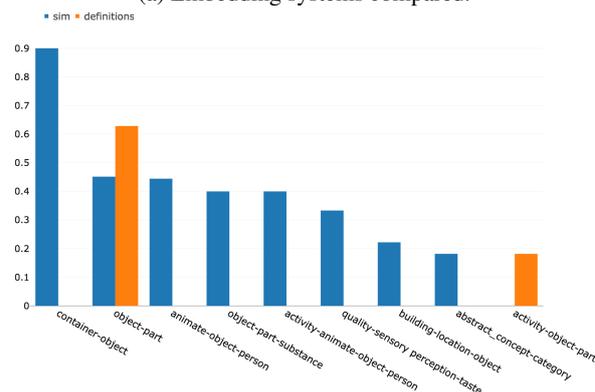

4.2 Comparison of systems across attribute categories.

In this section, we aim at giving some insights into the kinds of attributes systems can detect and identify as discriminative. The attributes in the validation set were categorized by one annotator. The categories are not based on an existing framework, but were chosen intuitively. In most cases, multiple labels are used as the attributes are ambiguous. As there is no overlap between attributes from the validation set and the test set, we present the performance of the systems across the different attribute categories on the validation set. The over-

⁵Note that attributes can be found in glosses of both concepts, meaning that these counts do not add up to the number of triples in the test set.

(a) Embedding systems compared.

(b) WordNet definition match system compared to embedding similarity system.

Figure 3: Comparison f1-scores reached by the system components showing the categories with the highest performance differences (frequency > 10).

all performance on the validation set (presented in Table 2) is similar to the test set with the exception that on the validation set, the system based on vector subtraction performed several points higher than on the test set (0.59) and ranked higher than the WordNet definition systems.

Figure 2 shows the performance of the three individual systems across the 10 most frequent categories. Overall, the vector similarity system outperforms the other system in almost all categories. Of these 10 most frequent categories, there is no category in which the subtraction system outperforms the similarity system.

One of the most striking differences between the embedding-based systems and the WordNet definition system can be seen in the ‘activity’ category, in which both embedding systems perform almost seven times higher than the WordNet system. This could be explained by the fact that activities associated with concepts can be expected to occur in large corpora, whereas they might not

be specific or relevant enough to be mentioned in a definition. In contrast, WordNet outperforms both embedding systems in the categories ‘object-part’ and ‘animate-object-gender-person’ (usually referring to a person of a specific gender), which could be expected to consist of more specific attributes.

We expected rather generic descriptions that are not specific to a concept, but mostly relevant in comparison to the other concept to be the most difficult for any system. These kinds of attributes are not relevant enough to be included in definitions nor do we expect them to frequently co-occur with concepts in texts and thus be apparent from a distributional model. It turned out, however, that these kinds of attributes (‘appearance-color’, ‘magnitude-size’) were accurately detected as discriminative by the embedding similarity system. A possible explanation might be that they can co-occur with a wide number of concepts, leading to proximity in the vector space.

When considering the categories with the biggest performance differences and a frequency of at least 10 (presented in Figure 3) the following observations can be made: Whereas the embedding similarity system outperforms the subtraction system in most categories, the subtraction system captures about twice as many attributes that indicate a category (usually meaning that the attribute is a hypernym of one of the concepts) and performs higher on ‘building-location-object-organization’ attributes (Figure 3a). It could be the case that despite their polysemy, these attributes apply to a more limited range of concepts than general descriptions on which the system performs poorly. The subtraction system also correctly detects attributes that are ambiguous between ‘activity’, ‘object’ and ‘part’ (e.g. attributes such as *sail* and *bark*) category, which is not detected by the similarity system. Finally, we observe that a number of attribute categories that are handled correctly by the embedding-based systems are not captured by WordNet definitions at all (Figure 3b).

Overall, the differences between the approaches seem to indicate that distributional models are stronger in capturing attributes expressing related concepts than attributes expressing similar concepts (e.g. hypernyms). This is in line with the general trend observed in large-scale evaluations (Levy et al., 2015; Baroni et al., 2014) of embedding models using a bag-of-words approach (such

as the Google News model). Gamallo (2017) and Levy and Goldberg (2014a) show that embedding models using dependency structures perform better on similarity than relatedness and could thus improve the results for the attributes that are similar rather than related to the concepts.

5 Conclusion

For this SemEval task, we submitted systems consisting of combinations of exploratory approaches. Our best performing systems consisted of a component exploiting knowledge in WordNet definitions and a component extracting knowledge from distributional representations. In our best performing system, the latter component consisted of comparing cosine similarities between concepts and attributes. The vector component in our second full system employs a different strategy of extracting information from vector representations than our highest ranked system. Despite its limitations, its performance is comparable to our best performing system.

As expected, WordNet definitions encode rather specific attributes that are probably most informative for distinguishing one concept from another, while they give less importance to rather general descriptions. In contrast, embedding approaches seem to perform highly on attributes that are related rather than similar to the concepts, also encompassing rather general descriptions.

The main contribution of this paper is an exploration of the different types of attributes that can be recognized by different systems. These strengths and weaknesses of the methods could be further exploited by using the information obtained by vector similarity and subtraction as input of a classifier. We plan to investigate the representation of attribute categories in the semantic space in future work.

Abstract

This paper describes our system submission to the SemEval 2018 Task 10 on Capturing Discriminative Attributes. Given two concepts and an attribute, the task is to determine whether the attribute is semantically related to one concept and not the other. In this work we assume that discriminative attributes can be detected by discovering the association (or lack of association) between a pair of words. The hypothesis we test in this contribution is whether the semantic difference between two pairs of concepts can be treated in terms of measuring the distance between words in a vector space, or can simply be obtained as a by-product of word co-occurrence counts.

1 Introduction

Equipped with their cognitive skills, encyclopedic knowledge and linguistic competence, humans generally can identify the lexical association or semantic relation between two words or concepts with relative ease. However, building a computational model for identifying fine-grained semantic relations (such as synonymy, antonymy, hyponymy, or hypernymy, meronymy, holonymy, metonymy, containment or causality) or even detecting binary relatedness has proven to be a challenging task.

Efforts to model semantic representation computationally are generally classified into statistical and knowledge-driven semantics. This classification depends on whether the assumption is that human knowledge is encapsulated in language man-

ifestation or that explicit manual encoding of this knowledge is needed. The statistical approach to the encoding of semantic relations is referred to as “distributional semantics” or “distributed word representations” (Speer et al., 2017), and its theoretical appeal stems from the fact that it gives practical application to the Firthian dictum “You shall know a word by the company it keeps” (Firth, 1957) which has become commonsense wisdom in lexical semantics. Features of the statistical model are extracted from unstructured data, such as words embeddings, n-gram counts, or directly from raw data.

The basic idea with word embeddings is to formulate semantic relations in arithmetic fashion by creating a vector space in which words with similar contextual embeddings have closer vectors distance (Hinton et al., 1986; Rumelhart et al., 1986; Elman, 1990; Bengio et al., 2003; Kann and Schtze, 2008; Mikolov et al., 2013c). The public availability of word embedding training programs such as word2vec (Mikolov et al., 2013a) and GloVe (Pennington et al., 2014) allowed researchers to create models with different parameters and dimensionality sizes for different purposes including capturing semantic relations (Gladkova et al., 2016; Attia et al., 2016).

The Google n-gram corpus (Brants and Franz, 2006) is a collection of English word n-grams and their observed counts generated from 1 trillion words of texts from web pages. This corpus has been used in many different applications including estimating word-relatedness (Islam et al., 2012),

comparison of semantic similarity (Joubarne and Inkpen, 2011), information retrieval (Tandon and De Melo, 2010; Klein and Nelson, 2009), lexical disambiguation (Bergsma et al., 2009), improving general purpose NLP classifiers (Bergsma et al., 2010), and improving parsing performance (Pitler et al., 2010).

Knowledge-driven approaches to the detection of semantic relations rely on manually constructed lexical and encyclopedic resources, such as ConceptNet (Speer et al., 2017), ImageNet (Rusakovskiy et al., 2015), WordNet (Miller and Fellbaum, 1998), Wiktionary, Open Mind Common Sense (Singh et al., 2002) and DBpedia (Mendes et al., 2012).

In this work we follow a statistical based approach and show the strengths and weakness of the distributional semantics of the word vectors and n-gram frequency counts in capturing the different types of discriminative attributes.

2 Task and Data Description

The goal of the shared task on Capturing Discriminative Attributes (Krebs et al., 2018) is to detect semantic difference between pairs of concepts, or in other words, determine whether a semantic property differentiates between two possibly related concepts. For example both ‘bear’ and ‘goat’ are animals, but only a ‘bear’ has ‘claws’. Therefore ‘claws’ is considered as a discriminative feature.

The shared task data is formatted in triples that represent a ternary relation between two concepts ($Word_1$, $Word_2$) on one hand and an attribute ($Word_3$) on the other. $Word_3$ is considered as a discriminative attribute if, and only if, it characterizes $Word_1$ but not $Word_2$. For example, in the triple (*sailboat,yacht,mast*), ‘mast’ is discriminative as it is found in $Word_1$, ‘sailboat’, but not in $Word_2$. By contrast, in the triple (*goose,duck,flies*) the event ‘flies’ is not discriminative as it characterizes both entities. Similarly in the triple (*pickle,lemon,round*), ‘round’ is not a discriminative feature, as it characterizes $Word_2$, not $Word_1$.

The size of the shared task data is described in Table 1. It is to be noted that there is no intersection between the discriminative attributes in any of the datasets. We think the purpose is to make sure that the participating systems are able to learn how to estimate the relations, regardless of the lexical items involved.

Dataset	# of triples	# of attributes
Training	17,547	1,292
Validation	2,722	576
Test	2,340	577

Table 1: Sizes of the shared task datasets.

3 System Description

In our system we use a deep neural network for the binary classification of discriminative attributes. The basic idea with deep learning is to use hidden layers of neural nets to automatically capture the underlying factors that lead from the input to the output, eliminating the need for feature engineering.

The system is trained on features extracted from two main publicly available resources that fall within the paradigm of unstructured data as no manual lexical or encyclopedic knowledge is encoded. The two resources are the Google n-gram counts and the Google News Word2Vec.

Google n-gram counts. We use the Google 5-gram counts as provided by Google Books ngrams¹ (Michel et al., 2011; Lin et al., 2012).

Google News Word2Vec. This is a publicly available pre-trained word vector², built with the word2vec architecture (Mikolov et al., 2013b) from a news corpus of 100B words (3M vocabulary entries) with 300 dimensions, negative sampling, using continuous bag of words and window size of 5.

3.1 Features Used

We describe the features used to train our DNN binary classifier to detect discriminative attributes. In this section we use the abbreviations W_1 , W_2 , and W_3 for $Word_1$, $Word_2$, and $Word_3$, respectively.

We use pre-trained word vectors in order to obtain similarity scores between words. This leads to the following features.

- $distW_1W_3$: Cosine distance between W_1 and W_3
- $distW_2W_3$: Cosine distance between W_2 and W_3
- $cosDiff$: Difference between $distW_1W_3$ and $distW_2W_3$

¹<https://books.google.com/ngrams/info>

²<https://goo.gl/tyVGqW>

- *similarityCompare*: We compute the cosine similarity between two sets of words using the Gensim ‘n_similarity’ function. So it gives a single number for comparing the similarity between W_1 and W_3 , and W_2 and W_3 .

In order to capture all morphological variations of the words, we use word lemmas and then expand to all variants that share the same lemma.

- *lemmaDist W_1W_3Ex* : The average cosine distance between W_1 and all lemma expansions of W_3
- *lemmaDist W_2W_3Ex* : The average cosine distance between W_2 and all lemma expansions of W_3

We use to Google 5-gram counts to obtain the following features.

- *cnt W_1W_3* : counts of W_1 and W_3 co-occurring
- *cnt W_2W_3* : counts of W_2 and W_3 co-occurring
- *cnt W_1W_3Ex* : counts of W_1 and the lemma expansions of W_3 co-occurring
- *cnt W_2W_3Ex* : counts of W_2 and the lemma expansions of W_3 co-occurring

3.2 Machine Learning Models

We use a deep neural network model for the binary classification of attributes as either True or False (or discriminative or non-discriminative) based on the set of features described above.

We use a simple and straight-forward architecture consisting of 5 feed-forward fully-connected (or dense) layers with single dropout layer with a rate of 0.3. The network is narrow on the top and wide on the bottom. The function of the dropout layer (Hinton et al., 2012) is to mitigate overfitting and make sure that our model learns significant representations by randomly omitting a certain percentage of the neurons in the hidden layer for each presentation of the samples during training. This encourages each neuron to depend less on other neurons and to try to learn generalizations. Table 2 shows the layer configuration of the model.

4 Experiments and Results

We test our system on various combination of the features mentioned in subsection 3.1. We assume

Layer type	Output Shape	Param #
Dense ₁	(None, 12)	132
Dropout ₁	(None, 12)	0
Dense ₂	(None, 12)	156
Dense ₃	(None, 100)	1300
Dense ₄	(None, 200)	20200
Dense ₅	(None, 1)	201

Table 2: Neural Network Layout.

the baseline is 50% as this is what a random system would generate given that the validation set has an almost equal number of True’s and False’s. Table 3 shows the system results on the dev set, with the last row showing results on the test set using our best model, “all features”. Surprisingly, using the cosine distance between pairs of words gives a low score (56.17%) which is slightly above the baseline, indicating the ineffectiveness of cosine distances in capturing this kind of relationships. Word counts alone were the most impactful of all the features.

5 Error Analysis

In order to be able to analyze the performance of the system and identify where it is faring well and where it is failing, we first manually classify the relations between concepts and attributes in the validation set into 8 types.

1. **Part-whole**. This is when the attribute denotes an entity that can be part or whole of $concept_1$, e.g. *tractor*; *wheels*; *moose*, *legs*; *cat*, *eyes*; *iguana*, *tongue*; *condos*, *rooms*.
2. **Container-contained**. This is when the entity attribute can be located/situated physically or temporally in $concept_1$, e.g. *oven*, *kitchen*; *fort*, *cannons*; *mouse*, *house*; *priest*, *parish*; *surfboard*, *water*.
3. **Made-of**. This is when the entity attribute is a material of which $concept_1$ can be made, e.g. *cart*, *wood*; *wire*, *metal*; *rum*, *sugarcane*; *scarf*, *wool*; *wine*, *grape*; *roof*, *clay*.
4. **Agent-patient**. This is when the attribute is a topic or theme on which $concept_1$ can act on, e.g. *politician*, *politics*; *physiotherapist*, *muscles*; *dermatologist*, *skin*; *mammals*, *milk*.
5. **HasAttribute**. This is when the attribute is an adjective that can be used to describe *con-*

Features	Accuracy
baseline	50.00
$distW_1W_3, distW_2W_3$	56.17
$distW_1W_3, distW_2W_3, lemmaDistW_1W_3Ex, lemmaDistW_2W_3Ex$	55.79
$cosDiff, similarityCompare$	59.12
$cntW_1W_3, cntW_2W_3$	65.27
$cntW_1W_3, cntW_2W_3, cntW_1W_3Ex, cntW_2W_3Ex$	65.45
all features	66.50
result on the test set	65.17

Table 3: System results with different feature combinations.

class	Total	% correct	%
event	346	12.71	260 75.14
containment	228	8.38	167 73.25
made-of	158	5.80	113 71.52
relates-to	164	6.02	115 70.12
agent-patient	121	4.45	84 69.42
part-whole	524	19.25	361 68.89
hasAttribute	850	31.23	515 60.59
hyper-hypo	331	12.16	196 59.21
Total	2,722		1,811 66.53

Table 4: Discriminative classes sorted by system performance.

$cept_1$, e.g. *garlic, white; girl, virgin; alligator; long; tuna, large; honey, sweet; pumpkin, round.*

- Hyper-hypo.** That is when the attribute is a hyponym or hypernym of the concept, e.g. *rum, alcohol; orthodontist, profession; steak, meat; mother, female; lorry, vehicle; lavender, plant.*
- Event.** That is when the attribute is a verb that is associated with the concept/entity, e.g. *woman, talk; educator, teaches; knee, bend; tuna, swims; frog, jumps; shirt, wear; seabirds, fly; novelist, write.*
- Relates-to.** This is when the relationship cannot be stated with any of the aforementioned types, e.g. *bus, passengers; knee, pads; lung, transplant; widow, death; brother, sister; uncle, nephew.*

Table 4 shows our manual classification of the discriminative attributes in the validation set. It is to be noted that the majority of relations (62.64%) are of three types: *hasAttribute*, *part-whole* and *hyper-hypo*.

The types of discriminative features in Table 4 are sorted by system performance, highlighting strengths and weaknesses of the system. The deep learning algorithm assumes that the attribute is discriminative for $concept_1$ if it has considerably higher n-gram counts with $concept_1$ than with $concept_2$. In the upper end n-gram counts shows strength in dealing with events and container-contained relationships, where co-occurrence statistics showed to be very helpful. The examples below shows frequency counts that indicate stronger relation between $Word_1$ and $Word_2$ than between $Word_2$ and $Word_3$. Gold answers are the numbers (0 or 1) following the triples.

(*shoulder, cheek, carry*, 1), $cntW_1W_3$: 104620, $cntW_2W_3$: 498

(*teacher, pupil, teaches*, 1), $cntW_1W_3$: 134656, $cntW_2W_3$: 0

(*albums, music, picture*, 1), $cntW_1W_3$: 3937564, $cntW_2W_3$: 374572

It is to be mentioned that in the validation set, there were 246 (9%) instances where no frequency counts were found for either concepts.

In the lower end of our system performance there were the classes of *hasAttribute*, *part-whole* and *hyper-hypo*. As these classes constitute the majority of the data, the overall system performance is compromised. We make further detailed analysis of our top losses with *hasAttribute* and *part-whole*.

Analysis of Errors with *hasAttribute*

Most of the errors in this class can be identified with one of three reasons.

- N-gram counts are not aware of the qualification scope. For example, in the tuple below, ‘large’ has equally high frequency with ‘brick’, not because a brick can be large, but

they co-occur in phrases like, “large brick house/ranch”

(*garage, brick, large, 1*), $cntW_1W_3$: 245802, $cntW_2W_3$: 193816

- Contrary to common sense knowledge, data could prove the association between a concept and attribute that might not be readily perceived. The example below shows that “green tomato” is not a rarity. This could indicate an error with manual annotation of the data.

(*zucchini, tomato, green, 1*), $cntW_1W_3$: 29280, $cntW_2W_3$: 179646

- The collocation between the attribute and $concept_2$ could be higher than with $concept_1$. (*drizzle, rain, light, 1*), $cntW_1W_3$: 231348, $cntW_2W_3$: 4108548

Analysis of Errors with *part-whole*

Similarly the errors in this class can be attributed to one of three causes.

- Disproportionate frequency count, which could be tied to the disparity in the individual frequency of the concepts themselves. This might be solved by taking the n-gram count as a function of the unigram counts of the concepts themselves.

(*car, taxi, wheels, 0*), $cntW_1W_3$: 504848, $cntW_2W_3$: 2734

- There could be an association of different kind between $concept_2$ and the attribute that yield higher frequency counts. For instance in the example below, ‘garlic’ and ‘wings’ have higher frequency, not because garlic has wings, but because they co-occur in phrases like “garlic chicken wings”.

(*pheasant, garlic, wings, 1*), $cntW_1W_3$: 500, $cntW_2W_3$: 11136

- Either of the two concepts has no n-gram co-occurrence with the given attribute leading to missing information.

(*owl, buzzard, eyes, 0*), $cntW_1W_3$: 10088, $cntW_2W_3$: 0

6 Conclusion

In this paper we have presented our system for detecting discriminative features using distributional semantics. We have shown that, without resort

to human knowledge, a great deal of encyclopedic knowledge can be captured from unstructured data. We also conducted a detailed error analysis which shows the strengths and weaknesses of the system.

In its quest to approximate the distance between words with similar contexts, the cosine distance becomes oblivious to the internal intrinsic relationship between words and their immediate neighbors, and this is why many relations that are induced from co-occurrence counts are not captured by cosine distance.

While n-gram counts from raw data can present a great wealth for mining for lexical information and inducing semantic knowledge, co-occurrence counts can suffer from considerable constraints when two or more adjacent words have different scope of predication or qualification. For example, while “wood spoon” has a high frequency due to the semantic relation of ‘made-of’, “wood pepper” has an even higher frequency count, not due to any semantic relationship, but because ‘wood’ is scoped to a subsequent word, “wood pepper mill”. If syntactic information related to the head of noun compounds and scope of modification, more meaningful assumptions can be made.

CitiusNLP at SemEval-2018 Task 10: The Use of Transparent Distributional Models and Salient Contexts to Discriminate Word Attributes

Pablo Gamallo

Centro Singular de Investigación en

pablo.gamallo@usc.es

Abstract

This article describes the unsupervised strategy submitted by the CitiusNLP team to SemEval 2018 Task 10, a task which consists of predicting whether a word is a discriminative attribute between two other words. The proposed strategy relies on the correspondence between discriminative attributes and relevant contexts of a word. More precisely, the method uses transparent distributional models to extract salient contexts of words which are identified as discriminative attributes. The system performance reaches about 70% accuracy when it is applied on the development dataset, but its accuracy goes down (63%) on the official test dataset.

1 Introduction

The goal of SemEval-2018 Task 10 (Paperno, Lenci and Krebs, To Appear) is to predict whether a word is a discriminative attribute between two other words. The key idea underlying this task is to capture semantic attributes of words in order to discriminate their senses. Distributional semantics is based on the assumption that two words have similar senses if they tend to appear with the same contextual words (Firth, 1957). As contextual words actually refer to the semantic attributes of a given word, I will focus on identifying the most salient word contexts. So, my method to identify discriminative attributes relies on the identification of salient contexts, since they represent the main semantic attributes of a word.

For this purpose, in this paper we will make use of distributional models built with transparent and lexico-syntactic contexts. To capture discriminative attributes, I will rank the most relevant contexts of a word by using lexical association measures between a given word and their contexts. My method is unsupervised and only requires pre-trained distributional models.

This paper is organized as follows. The method is described in Section 2. Experiments, results, and a discussion on them are presented in Section 3. Finally, conclusions are addressed in Section 4.

2 The method

As mentioned in the previous section, discriminative attributes might be captured by searching for the most salient contexts of words. For this purpose, the distributional vector space I have adopted is a transparent count-based model with explicit and sparse dimensions. Sparseness reduction is performed by selecting the most salient contexts per word using a filtering strategy (Bordag, 2008; Gamallo and Bordag, 2011; Gamallo, 2017). The filtering strategy to select the most salient contexts consists of selecting, for each word, the S (salient) contexts with highest lexical association scores (e.g. loglikelihood, ppmi, etc). The top S contexts are considered to be the most *relevant* and informative for each word. S is a global, arbitrarily defined constant whose usual values range from 10 to 1000 (Biemann et al., 2013; Padró et al., 2014). In short, I keep at most the S most relevant contexts for each target word. This is an explicit and transparent distributional representation giving rise to a non-zero matrix. By contrast, methods based on dimensionality reduction, such as LSA (Landauer and Dumais, 1997) or neural-based embeddings (Mikolov et al., 2013), make the vector space more compact with dimensions that are not transparent in linguistic terms (Gamallo, 2017).

SemEval-2018 Task 10 to detect discriminative attributes consists of predicting whether a word is a discriminative attribute between two other words. For instance, given a triple $\langle car, table, wheels \rangle$, the system must determine if the last word of the triple, *wheels*, represents a semantic

feature that characterizes the first word, *car*, but not the second one, *table*. The task is a binary classification task. For this particular example, the classifier must return a positive answer since cars have wheels but tables have not. By taking into account the objective of SemEval-2018 Task 10 and my concept of *salient context* introduced above, the classification method I propose is the following very simple rule:

Given the triplet $\langle w_1, w_2, att \rangle$, *att* is a discriminative attribute of w_1 and not of w_2 if *att* belongs to the most salient contexts of w_1 and not to those of w_2 .

Concerning the type of context used to represent word distributions, there is a great number of previous studies that evaluate and compare syntactic contexts (usually dependencies) with bag-of-words techniques (Grefenstette, 1993; Seretan and Wehrli, 2006; Padó and Lapata, 2007; Peirsman et al., 2007; Gamallo, 2008, 2009; Levy and Goldberg, 2014; Gamallo, 2017). The cited papers state that syntax-based methods outperform bag-of-words techniques, in particular when the objective is to compute semantic similarity between functional equivalent words, such as detection of co-hyponym/hypernym word relations (i.e. near synonymy).

In my proposal, I use lexico-syntactic contexts to model word distributions. When contexts are defined as lexico-syntactic contexts, I consider that a word is an attribute of w_1 if that word is the lexical element in at least one of the salient contexts of w_1 . For instance, consider the following three lexico-syntactic contexts:

[*NOUN*, *with*, *wheels*]
 [*NOUN*, *nsubj*, *run*]
 [*red*, *nmod*, *NOUN*]

If they are salient contexts of the word *car*, then the three lexical words of these three contexts, i.e. *wheels*, *run*, and *red*, will be considered as attributes of *car*.

The number of salient contexts considered per word will be determined experimentally.

3 Experiments

3.1 Resources

The count-based, explicit and transparent distributional model used in the experiments was generated from the English Wikipedia (August 2013

dump) containing almost 2 billion tokens. The description of this model is reported in Gamallo (2017), and a version with the 500 most salient contexts per word is freely available.¹ To process the corpus and create the transparent matrices, I used the multilingual PoS tagger of *LinguaKit*² (Garcia and Gamallo, 2015) and *DepPattern*, a rule-based and multilingual dependency parser (Gamallo, 2015) also taking part of *LinguaKit*. I also generated other models with different thresholds: from 10 to 2000 salient contexts per word.

As will be described in the next subsection, I will compare the transparent matrix with dense word embeddings, in particular with those reported in Levy and Goldberg (2014), which are publicly available.³ These embeddings were generated from the same Wikipedia dump as the transparent model. Given that embeddings are opaque and, thereby, their dimensions are not easily associated to specific words, I use Cosine similarity to find discriminative attributes. A word is a discriminative attribute of w_1 and not of w_2 , if the similarity score between the attribute and w_1 is higher than a given threshold whereas it is lower in the case of w_2 .

3.2 Preliminary Experiments

To find the best configuration of the proposed system, I carried out several experiments on the train and validation datasets (20,510 examples). As the system is unsupervised, I am not required to separate training from validation. First, I searched for the best lexical association by comparing loglikelihood (Dunning, 1993) and positive pointwise mutual information (ppmi) (Niwa and Nitta, 1994), by using models with 400 and 500 salient contexts. As loglikelihood performed slightly better than ppmi, I chose the former measure to carry out the next experiments. Second, I searched for the best number of salient contexts. For this purpose, several evaluations were made with models from 10 to 2000 salient contexts. Figure 1 shows that the peak is quickly reached with 500 contexts (more than 0.67 accuracy), while performance is getting down slowly as more contexts are added.

²<https://github.com/citiususc/LinguaKit>

³<https://levyomer.wordpress.com/2014/04/25/dependency-based-word-embeddings/>

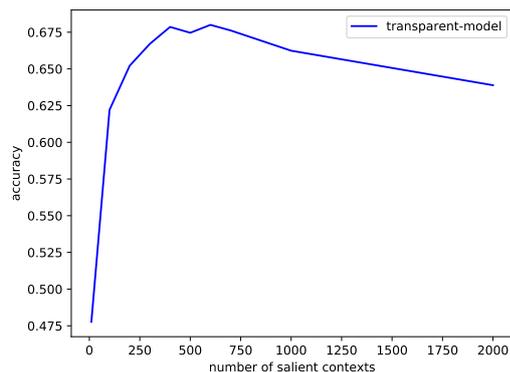

Figure 1: Accuracy of the system at different settings: from 10 to 2000 salient contexts. The experiments were carried out with the development corpus: training + validation.

models	accuracy	word-cntx pairs
wiki	0.674	36 million
wiki+bnc	0.690	38 million
wiki+bnc+reddit	0.701	45 million

Table 1: Accuracy obtained with three corpus-based models: just Wikipedia, Wikipedia and BNC, Wikipedia, BNC and Reddit. The experiments were carried out with the development dataset: training and validation. All models were built by filtering 500 contexts per word. The last column shows the size of the filtered word-context pairs.

I therefore decided to use models with 500 salient contexts per word for the next experiments.

Next, I merged the Wikipedia-based model with other models generated from two different corpora: British National Corpus (BNC),⁴ and a sample with 500 million words from Reddit corpus.⁵ Results are shown in Table 1. As expected, accuracy is improved as the model grows.

Given these preliminary experiments, I submitted the two best configurations to the test evaluation (2,340 examples):

syst.	meas.	saliency	corpora
<i>run1</i>	loglike	500 ctxs	wiki+bnc
<i>run2</i>	loglike	500 ctxs	wiki+bnc+reddit

In my preliminary experiment, I also used the word embeddings described in the previous subsection to capture discriminative attributes. As

⁴<https://corpus.byu.edu/bnc/>

⁵https://www.reddit.com/r/datasets/comments/3mg812/full_reddit_submission_corpus_now_available_2006/

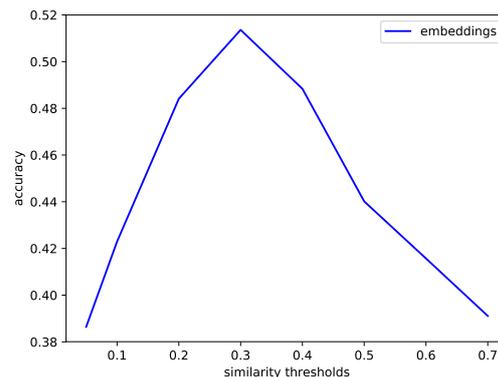

Figure 2: Accuracy of the embedding-based system at different settings: from 0.05 to 0.7 similarity values. The experiments were carried out with the development corpus: training + validation.

mentioned above, a word is considered to be an attribute of a target word if their similarity is higher than a specific threshold, otherwise it is not a discriminative attribute. Several similarity scores were set to determine whether a word is an attribute or not. Figure 2 shows that the best similarity threshold is around 0.3 (cosine value). Accuracy drops dramatically with higher threshold values. The best accuracy reached by this strategy is about 20 points below the best models based on salient contexts. Therefore, for this particular task, transparent models consistently outperform word embeddings.

3.3 Official Test

The test dataset consists of 2,340 examples. My *run1* (wiki+bnc) merely reached 0.625 accuracy while *run2* (wiki+bnc+reddit) reached 0.634. These results are very far below those obtained with the development dataset, which is nevertheless 10 times larger.

3.4 Discussion

With regard to the rest of teams at the shared task, my *run2* is just in the middle of the ranking (13 out of 26 runs). However, its performance in the development dataset (0.700 accuracy) is close to the third best system. I am not able to explain the difference between the development and the test dataset. It would require a deep error analysis to understand that significant difference. This disparity is not due to a difference in the corpus frequency of the words included in the test set. I have checked the frequency of all words (test and

development) and there is no important contrast at this regard. The reason could just be that the test dataset might contain more difficult triples.

The best system at the shared task achieves 0.75, leading by 12 points my *run2*. Even though the score of my system is lower, it is worth mentioning that my strategy is fully unsupervised and no tuning or specific configuration has been carried out to adapt the system to the test dataset.

4 Conclusions and Future Work

I presented a very basic unsupervised strategy to predict whether a word is a discriminative attribute between two other words. The current strategy relies on the correspondence between discriminative attribute and context saliency, and it works on transparent distributional models to extract salient contexts of words.

As I observed that accuracy improves as the corpus grows, in future work, I will compile specific text corpora for just the words of the test. This should lead to select more salient contexts (and so more discriminative attributes) per word. In addition, I will make new experiments with relational lexical resources, such as WordNet, to compare them with distributional models in this particular task.

Abstract

Existing semantic models are capable of identifying the semantic similarity of words. However, it's hard for these models to discriminate between a word and another similar word. Thus, the aim of SemEval-2018 Task 10 is to predict whether a word is a discriminative attribute between two concepts. In this task, we apply a multilayer perceptron (MLP)-convolutional neural network (CNN) model to identify whether an attribute is discriminative. The CNNs are used to extract low-level features from the inputs. The MLP takes both the flatten CNN maps and inputs to predict the labels. The evaluation F-score of our system on the test set is 0.629 (ranked 15th), which indicates that our system still needs to be improved. However, the behaviours of our system in our experiments provide useful information, which can help to improve the collective understanding of this novel task.

1 Introduction

Evaluating the similarity of words is an important task in semantic modeling. There have been different approaches based on corpus statistics (Jiang and Conrath, 1997; Mihalcea et al., 2006) and ontology (Seco et al., 2004; Sánchez et al., 2012). After an effective word representation proposed by Mikolov et al (2013), word similarity can be evaluated based on word embedding weights (Levy and Goldberg, 2014). Usually higher cosine similarity of word embedding vectors indicates higher semantic similarity.

However, existing semantic methods are not capable of discriminating similar words between each other without additional information. For example, it is easy for these models to tell “dog” and “puppy” is similar, but they can't tell the differences between each other. It limits the use of these models to mine such fine-grained semantic information from texts. Thus, the SemEval-2018 Task

10 is proposed to determine whether an attribute can help to discriminate between two words (Krebs et al., 2018). One can express semantic differences between concepts by referring to attributes associated with those concepts. The differences between concepts can usually be identified by the presence or absence of specific attributes. For example, the attributes “red” and “yellow” are discriminative for concepts “apple” and “banana”, while “sweet” or “fruit” are not discriminative.

Capturing such discriminative attributes can be regarded as a binary classification task: given two words and an attribute, predict whether the attribute is a difference between the two words. Existing methods to capture discriminative attributes are mainly based on dictionary (Parikh and Grauman, 2011). In recent years, CNN have been successfully applied to text classification task (Kim, 2014). In order to address this task, we develop a system based on MLP-CNN model. Firstly, the input words will be converted into dense vectors using the combination of different word embeddings. Then the CNN layers are used to extract features from these vectors. Finally, a MLP classifier is used to predict binary labels based on both embedding and CNN features. The experimental results show that our model outperforms several baseline neural model, and the additional features can improve the model performance. Our system still has room for development according to the experimental analysis. The behaviours of our system in our experiments can help to further fix and extend our model.

2 MLP-CNN model with Word Feature

2.1 Network Architecture

The architecture of our MLP-CNN model is shown in Figure 1. The input of our system is a pair of words with an attribute. First, an em-

bedding layer is used to provide different kinds of pre-trained embedding weights ($v_1 - dim$) and the word features ($v_f - dim$). We use three different pre-trained embedding weights and concatenate them together with the additional features of each word. Thus, the output of embedding layer is $(v_1 + v_f) - dim$.

Second, a 2-layer convolutional neural network take these vectors as input, and output the flatten feature maps. We use zeros to pad in both sides to keep the same output length. Since the length of inputs is 3, the 3 time steps of the convolutional feature maps can respectively extract the inherent relatedness of the first word with attribute, the second word with attribute and all three words. The feature map dimensions of the two CNN layers are v_2 and v_3 respectively. In order to reduce the difficulties of gradient propagation in neural networks, we use a over-layer connection between input and output of CNN. We concatenate the flatten feature maps with all word embedding and features together. Finally a MLP with ReLU and sigmoid activation function is used to predict the normalized binary label. With the help of the over-layer connection, the MLP classifier can learn from high-level word information and raw semantic information at the same time. Since the final labels are obtained from the triples of words through the embedding, CNN and dense layers, all parameters can be tuned in model training.

2.2 Word Embedding

Since there are several out-of-vocabulary words in the dataset when using single pre-trained word embedding, we use three different embedding models to cover them. The three embedding models include pre-trained word2vec embedding¹ provided by Mikolov et al. (Mikolov et al., 2013), the Glove embedding² provided by Pennington et al. (Pennington et al., 2014) and the fastText embedding³ released by bojanowski et al. (Bojanowski et al., 2016). These embedding weights are all 300-dim. They are concatenated together as the representation of input words.

2.3 Word Feature

In our model, we use one-hot encoded POS tags and two binary features obtained by Word-

¹<https://code.google.com/archive/p/word2vec/>

²<http://nlp.stanford.edu/data/glove.840B.300d.zip>

³<https://s3-us-west-1.amazonaws.com/fasttext-vectors/wiki.en.vec>

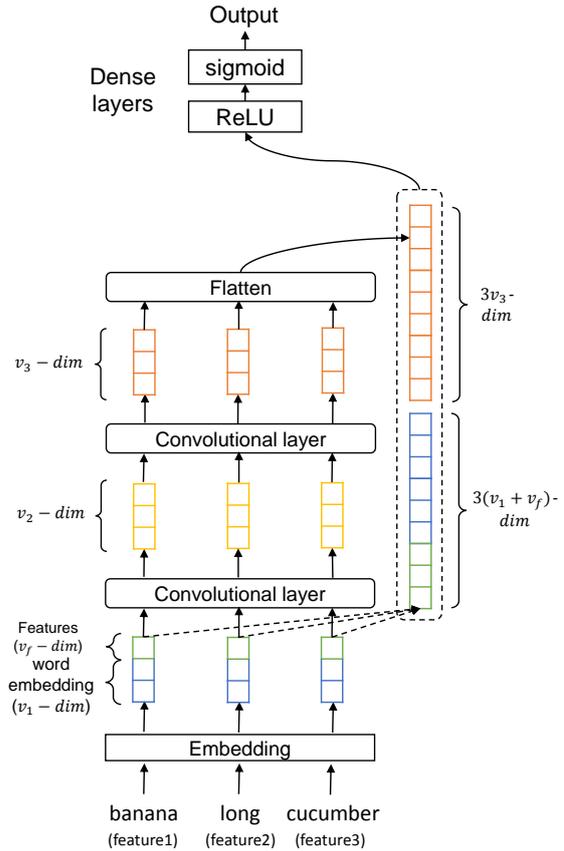

Figure 1: The architecture of our MLP-CNN model.

Net (Miller and Fellbaum, 1998). In the dataset, the words to be discriminated are nouns, but attributes are nouns, adjectives, verbs and so on. Thus, POS tags of words can help to identify the types of attributes and the relationship between them. We use the Stanford parser tool⁴ to get the POS tags of words.

The WordNet feature we use is based on synsets. Among every three input words, if one word is in the synset of another word, the corresponding feature digit will be set to 1, or it will be set to 0. In this way, a 2-dim synset feature of each word can be obtained. We use the nltk tool (Bird et al., 2009) to generate the WordNet features. The features above are concatenated with word embedding as the input of MLP-CNN model.

2.4 Model Training and Ensemble

Since the *train set* is unbalanced, we randomly select same numbers of positive (the attribute is discriminative) and negative (the attribute is not discriminative) samples from the *train set* every time. Thus, the training data we used in our experiments

⁴<https://nlp.stanford.edu/software/lex-parser.shtml>

consists of the sampled data from the *train set* and 80% data sampled from the *dev set*. The remaining 20% part in *dev set* is used for validation.

Model ensemble strategy has been proven useful to neural networks (Wu et al., 2017). Therefore, we build different training samples using the method described in the above paragraph and train our model for 10 times. The final predictions on the test set are the average of the predictions of the 10 models. In this way, the performance of neural model can be further improved.

3 Experiment

3.1 Experiment Settings

The dataset we use is constructed based on the approach proposed by Lazaridou et al. (2016) and the initial source of data is provided by McRae et al. (2005). The entire dataset contains 17,547 samples for training, 2,722 for validation and 2,340 for testing. The training set is automatically generated, while the validation and test set are manually refined. The models will be evaluated by F1-measure, as is standard in a binary classification task.

In our network, the kernel sizes of CNN are set to 3. The dimensions of feature maps v_2 and v_3 are set to 256, and the dimensions of dense layers are 300. The dropout rate of both embedding weights and CNN is set to 0.2. The training batch size is set to 50. We use Adam as the optimizer for network training, which takes 10 epochs per time. We train our model for 10 times and average their predictions on the test set.

3.2 Performance Evaluation

The experimental results on the test and validation set are shown in Table 1. For comparison, we also present several baseline models here. Our official submission is the MLP-CNN model with ensemble techniques. Our F-score is 62.9 (ranked 15th) in the evaluation phase. From the evaluation results, we can see that our model outperforms these baseline models. It shows that our network architecture can learn more semantic information from the words and attributes. However, our system needs to be improved compared with the top system (75.0 of F-score). In addition, the testing results are much lower than validation results. Some detailed information will be analysis in the next section.

Model	F-score	
	test	validation
MLP	53.5	63
CNN	57.8	66.2
MLP-CNN	61.7	71.5
MLP-CNN w/o over-layer	61.0	70.3
MLP-CNN+ensemble (ours)	62.9	73.4

Table 1: Performance evaluation of our system and several baselines.

4 Discussion

4.1 Influence of Trainable Word Embedding

The influence of different word embedding weights and fine-tuning them or not is shown in Table 2. Note that we don’t apply the model ensemble technique here. From the results, we can see that the combination of different word embedding can significantly improve the model performance. It may be because that using different word embedding can provide richer semantic information. In addition, using the combinations of different word embedding can cover more words and the out-of-vocabulary words in the single embedding file can be reduced. Thus, the predictions of such words can be more accurate.

However, we find fine-tuning the pre-trained word embedding is not a good choice. The fine-tuned model performance is significantly worse than models using untrainable embedding. Since the training, validation and test sets have no feature overlap between them, fine-tuning the embedding weights will lead to serious over-fitting and poor model generalization ability. We fine-tuned the embedding of our models used in the official submission, so the results are lower than the models with untrainable embedding.

4.2 Influence of Word Features

The influence of the two types of features is shown in Table 3. The results show that additional word features can improve the performance of our neural model. Attributes with different POS tags provide different semantic information. For example, given a pair of words “boy” and “woman”, the attributes “young” and “run” describe very different aspects. Therefore, POS tag features can help the model to extract different features from the input words. Another feature based on WordNet can also improve our model. It may be because if the attribute is in the synsets of a concept, it’s usu-

pre-trained Embedding	F-score	
	test	validation
w/o	44.9	63.7
word2vec+tune	50.6	65.8
Glove+tune	53.5	66.7
fastText+tune	51.5	64.4
all+tune	61.7	71.5

ally an attribute of this concept. Thus, the synset information can help the model to identify the relationships between words and attributes.

Features	F-score
w/o	59.2
+POS	61
+WordNet	60.1
+POS+WordNet	61.7

Table 3: Influence of word features on the test set.

4.3 Case Study

Several examples of model predictions on the test set are shown in Table 4. From the true predictions, we can see that our model can capture simple attributes of concepts such as colors. However, more complex relationships between words and attributes are difficult for our system to mine. For example, the word “mouse” can be an animal or electronic device. It’s hard to identify such semantic differences without incorporating external knowledge, since the information provided by the training data is limited.

True Positive	False Positive
corn,tomato,yellow ant,snail,black	alcohol,liquor,strong bar,shop,sell
True Negative	False Negative
father,brother,family father,mother,parent	mouse,dog,plastic engine,vehicle,component

Table 4: Representative examples of the predictions on the test set.

5 Conclusion

Discriminating similar words between each other without additional information is difficult for existing semantic models. Therefore, the SemEval-2018 task 10 is proposed to fill this gap. In this paper, we apply a MLP-CNN model with word feature to this task. In our model, the input and output of our CNN are highway connected. They are taken by a MLP classifier for binary classification. Based on this model, the local relationships between each pair of words can be mined. Our evaluation F-score is 62.9 (ranked 15th). The detailed analysis on our system shows our system can be further improved.

Abstract

Semantic difference detection attempts to capture whether a word is a discriminative attribute between two other words. For example, the discriminative feature *red* characterizes the first word from the (*apple, banana*) pair, but not the second. Modeling semantic difference is essential for language understanding systems, as it provides useful information for identifying particular aspects of word senses. This paper describes our system implementation (the ALB system of the NLP@Unibuc team) for the 10th task of the SemEval 2018 workshop, “Capturing Discriminative Attributes”. We propose a method for semantic difference detection that uses an SVM classifier with features based on co-occurrence counts and shallow semantic parsing, achieving 0.63 F1 score in the competition.

1 Introduction and Related Work

Semantic similarity detection is a well-studied research problem with numerous applications. State of the art models are extremely capable, determining the degree of semantic similarity between words with high accuracy.

However, looking the other way around, the semantic difference between words has received significantly less attention. As a result, one can argue that a semantic similarity model without the capability of spotting the semantic difference as well is not a complete system, and may not prove very useful in practice.

Semantic difference is a ternary relation (w_1, w_2, w_3) , where w_1 and w_2 are called *concepts* and w_3 is called *discriminative feature*. The discriminative feature characterizes the first concept, w_1 , but not the second one, w_2 . If the discriminative feature characterizes both w_1 and w_2 or none of them, then we do not have semantic difference.

Semantic difference detection is a binary classification task where given a triplet of words, a model needs to determine if a semantic difference is present or not. As emphasized by Krebs and Paperno (2016), this non-trivial task has numerous applications, such as automatized lexicography, conversational agents or machine translation.

Most research on discriminative features is related to computer vision (Farhadi et al., 2009; Rusakovsky and Fei-Fei, 2012), as these attributes proved to be very useful in interpreting visual data (Huang et al., 2016), being able to link visual features and semantic labels (Guo et al., 2015). A recent study on this topic belongs to Lazaridou et al. (2016), who proposed a method for identifying discriminative attributes when given word pairs and their visual representations.

In this paper, we describe a system for semantic difference detection that outputs a set of features for every triplet in the input data, based on preprocessed external resources (the English Wikipedia database). Further, these features are used to train an SVM for binary classification. The current feature selection allows even a direct approach such as evaluating the following inequation:

$$\sum_{i=1}^{|F_1|} f_i - \sum_{i=1}^{|F_2|} f_i > 0 \quad (1)$$

to obtain similar results as the SVM. Here, F_1 and F_2 are values of the same features, extracted for (w_1, w_3) and (w_2, w_3) , respectively.

Our model uses two different classes of features. The first class is generated using simple co-occurrence counts and the second class is generated by an arc-factored approach (McDonald et al., 2005) for semantic dependency parsing.

Semantic dependency parsing aims to provide a shallow semantic analysis of the text. As distinct

from deeper semantic analysis, shallow semantic parsing captures relationships between pairs of words or concepts in a sentence (Thomson et al., 2014).

2 Dataset and Preprocessing

The input data (training, validation and testing) is translated into an intermediary configuration as described below.

Each word triplet from the input data is split into two word pairs: (w_1, w_3) and (w_2, w_3) . The initial part of our model extracts features for each pair, and in the last steps, where the performance is computed, a cross-reference is done with the original input database.

We use the English Wikipedia as an external data source for feature extraction. We convert the raw Wikipedia database to plain text and concatenate the sentences of all the articles in a large text corpus.

3 System Framework

In this section we present our approach and methodology for capturing discriminative attributes.

3.1 Problem Reduction

First, we transform the problem of semantic difference detection into a simpler one: detecting if a feature characterizes a concept. Every ternary relation in the input data is split into two subproblems of detecting if a feature (i.e. w_3) characterizes w_1 and w_2 , respectively. Solving subproblems independently gives us more flexibility in feature extraction.

Determining the validity of the ternary relation from the outputs of the newly created binary relations is achieved with the following equation:

$$o = \neg(p \implies q) \quad (2)$$

which for convenience can be rewritten as:

$$o = p \wedge \neg q \quad (3)$$

where $p = C(w_1, w_3)$, $q = C(w_2, w_3)$, o is the triplet label and $C(w_a, w_b)$ is the model or function that decides if w_b characterizes w_a .

3.2 Features

We use two categories of features in training our system: *co-occurrence* and *POS-tag* features. Features from both categories are extracted from English Wikipedia sentences.

3.2.1 Co-occurrence

This is a measure of occurrence of two words in a text alongside each other and in a specific order. For our system, we consider the two words as an unordered pair and count accordingly. For every pair of words (w_1, w_2) we extract the following features:

- *Co-occurrence₁*: counts the number of adjacent occurrences of w_1 and w_2 disregarding the order.
- *Co-occurrence₂*: counts the number of occurrences of both w_1 and w_2 in a text window of size 2.
- *Co-occurrence₃*: counts the number of occurrences of both w_1 and w_2 in a text window of size 3.

If two words occur in the same sentence, it provides the intuition that there should be a relation between the distance $d = |w_1 - w_2|$ and their semantic relation. This is what we attempt to capture with the features described above. We drop *co-occurrence₂* and *co-occurrence₃* in our final system configuration, since they do not add any contribution to the final score, as shown in Table 2.

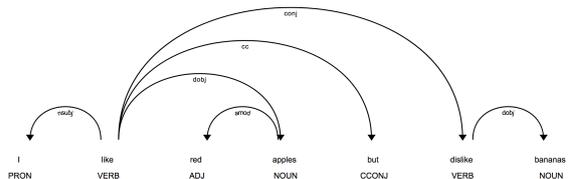

Figure 1: Syntactic dependency tree.

3.2.2 POS-tag Features

Every sentence that contains a pair of words (w_1, w_2) is parsed and tagged. Based on a statistical model, a prediction is made of which tag applies to each word. Next, a syntactic dependency tree is built as shown in Figure 1 and used to derive various rules that are used to extract POS-related features.

For every sentence containing both words of the pair, if a rule R_i hits, then we increment the total hit count H_c of that specific pair. $|R|$ represents the total number of rules to be applied and H_c is defined by the following formula:

$$H_c = \sum_{i=1}^{|R|} R_i(w_1, w_2) \quad (4)$$

As an example, if we take the pair of words ($w_1 = \text{moth}$, $w_2 = \text{flies}$), we obtain the following values: 1,088 co-occurrence_1 and a count of 763 hits of the rules on sentences containing both words. Hence the pair (moth , flies) has feature values (1,088, 763). Several more examples are presented in Table 1.

w_1, w_2	co-occurrence_1	H_c
desk, drawers	169	120
cod, honks	0	0
shirt, sleeves	450	1,109
tie, sleeves	16	13
lime, holes	0	3
cheese, holes	29	20

Table 1: Examples of word pairs and feature values.

3.3 Rules

We perform rules implementation in a purely heuristic manner, using methods from previous research (Kübler et al., 2009). While we keep rules composition simple, they turn out to be very powerful and we use only two of them in the final system implementation. Rules are prone to both false positives and false negatives, but provided enough input sentences, both errors tend to be minimized.

- *Rule₁*: if w_2 is the root of an arc in the parsing tree and w_1 is one of its children and no negation is present in the children list, then the rule will return a hit.
- *Rule₂*: if the child of a root noun is a verb, then recursively the children of the verb will be considered related to the noun and the pairs (root_noun , verb_child) will be compared with (w_1, w_2) , increasing the hit count if the pairs match.

3.4 Linear SVM

For classification we use a linear SVM (Vapnik, 1995). The output of the SVM is given by the equation:

$$u = wx - b \quad (5)$$

where w is the normal vector to the hyperplane and x represents the input data.

In the linear case, the margin is defined as the distance between the closest positive and negative example, and the hyperplane defined by the above equation (see Figure 2). Maximizing the margin can be approached as an optimization problem:

$$\text{Minimize } \frac{1}{2} \|w\|^2 \text{ subject to } y_i(wx_i - b) \geq 1, \forall i;$$

where x_i is the i th training sample and y_i is the correct classification of the sample.

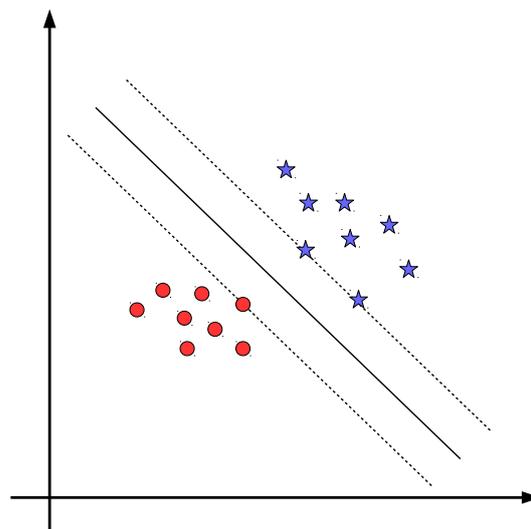

Figure 2: Linear SVM.

3.5 System Workflow

Until now we have described all the building blocks of our system. Now we chain them together.

The first step is to transform the original datasets into datasets of pairs. For all training, validation and testing data we run Algorithm 1. After this step, we end up with a dataset containing the features of all pairs, of all three datasets.

The next step is to train and validate the SVM on the datasets of triplets. The last step is to use the trained SVM to predict labels for the triplets in

```

for every dataset do
  transform data into pairs of words;
  for every pair of words do
    extract all sentences from Wikipedia
    containing  $w_1$  and  $w_2$ ;
    extract co-occurrence features;
    for every sentence do
      | run active rules;
    end
    compute  $H_c$  using active rules;
  end
end

```

Algorithm 1: Dataset preparation.

the test dataset. A slightly different approach that we try is to train the SVM on pairs extracted from triplets with label 1, and then apply Equation 2 to obtain the labels for the initial test dataset triplets.

In another system configuration, we eliminate the SVM and compute the final triplet score from the existing features using Equation 1. By doing so, we eliminate the training and validation steps, thus transforming our system from a learning one to a purely deterministic one. However, if the number of features is increased, such an approach may prove unfeasible and inefficient.

4 Results

We have implemented several system configurations by selecting different rules, features and learning methods. We have chosen three configurations: two of them produced the top results in our experiments on the development dataset, and the other had the peculiarity of not having a learning mechanism. The performance of these systems on the development dataset is reported in Table 2. The systems are evaluated using the F1 score.

The first system, *ALB*, uses only the first co-occurrence score, along with H_c . Even if only two features per pair of words are used, this system configuration produced the best F1 score of 0.69. This is the only system that we submitted for evaluation, obtaining 0.63 F1 score on the test dataset.

The second system, *ALB+*, uses all three co-occurrence scores as features and treats rules output as separate features. Both *ALB* and *ALB+* use the SVM trained on triplets.

The third system, *EQ1*, uses the same two features as *ALB* and replaces the SVM component

with Equation 1. This system obtained the lowest F1 score, but not too distant from the others.

It is interesting to mention that if we use only $co-occurrence_1$ as a discriminant, the score is > 0.6 . Analyzing the output of our best system, we observe that the errors it produces are not biased towards one of the labels (417 errors for label 0 and 430 for label 1).

System	F1 Score
ALB	0.69
ALB+	0.67
EQ1	0.62

Table 2: Results for capturing discriminative attributes on the validation dataset.

5 Conclusions

In this paper we have presented our results and system description for Task 10 of SemEval 2018, “Capturing Discriminative Attributes”.

Our approach shows promising results in using the relation between words in context for semantic differences. The obtained results are competitive, although being outperformed by other approaches in the official ranking. There is enough room for improvements and at least two possible approaches are already being analyzed.

The first one is straightforward: extending the feature set with at least one order of magnitude compared with *ALB+*, and if necessary replacing the SVM with a fully connected neural network. The heavily used sequence-to-sequence model can also be applied on sentences to automatically capture relations between word pairs.

The second possible approach is to use a neural network to automatically infer rules. Next, we can apply generated rules to compute H_c and assign a semantic difference probability to every pair in our dataset. We can use a pruned version of the training dataset from this task, extract word pairs in the same manner as we did in our system implementation and feed word pairs along with sentences and labels to a convolutional neural network.

Abstract

This paper describes the participation of ELiRF-UPV team at task 10, Capturing Discriminative Attributes, of SemEval-2018. Our best approach consists of using ConceptNet, Wikipedia and NumberBatch embeddings in order to establish relationships between concepts and attributes. Furthermore, this system achieves competitive results in the official evaluation.

1 Introduction

Capturing Discriminative Attributes, task 10 of SemEval-2018 (Krebs et al., 2018), proposes working on semantic difference detection. The goal of the task is to predict whether a word is a discriminative attribute between two other words. This problem is known as semantic difference detection, which is a binary classification task: given a triple (*apple, banana, red*), it consists in determining whether it exemplifies a semantic difference. Regarding semantic difference, it is a ternary relation between two concepts, for instance, (*apple, banana*) and a discriminative feature (*red*) that characterizes the first concept but not the other.

As task 10 is related to the semantic relations among different words, knowledge graphs seems the most appropriate resources to be used. An interesting knowledge resource that we used for this task is ConceptNet. In particular, ConceptNet (Speer et al., 2016) is a knowledge graph that connects words and phrases of natural language using labeled edges. It was designed to represent some general knowledge involved in natural language and could be used in combination with other resources. The combination of ConceptNet with distributed representations such as Word2Vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014), is known as NumberBatch

embeddings (Speer et al., 2016).

Regarding the relations specified in ConceptNet, there are a total of 36 relations such as *IsA* (A banana is a dessert), *UsedFor* (A net is used for catching fish), or *FormOf* (“Leaves” is a form of the word “leaf”), intended to represent a relationship independently of the language or the source of the terms it connects.

In this work, we propose five knowledge based systems and one additional machine learning system based on Siamese networks. We used ConceptNet in order to determine if each input concept and the input attribute are related through a relation edge or path. When there is a relationship between the first concept and the attribute and there is no relationship between the second concept and the attribute, then the answer is 1, otherwise, the answer is 0. However, there are cases in which ConceptNet does not provide enough information to take a decision. In those cases, we have implemented a system that seeks the information in Wikipedia articles by using distances between NumberBatch embeddings.

2 Resources and Preprocess

As we stated in Section 1, ConceptNet 5 is used in order to find the relationships among concepts and attributes. ConceptNet 5 is freely available under the Creative Commons Attribution-ShareAlike license (CC BY SA 4.0) from <http://conceptnet.io>. Moreover, we use two additional resources next to ConceptNet.

On the one hand, in order to use more information of each concept we used the Wikipedia articles. In this way, we get the most related article for each concept, following the recommendation of the Wikipedia disambiguation system. Wikipedia articles had been preprocessed. First, we remove non relevant sections such as “See

Also”, “References” and “External Links” which links to other resources. After that, we normalized tokens like numbers or urls e.g. “678.2” → “number” y “https://en.wikipedia.org” → “url” and we made a tokenization of the articles.

On the other hand, we used distributed representations of words, more specifically, we used NumberBatch embeddings (Speer et al., 2016).

3 System Description

We tested several approaches to address this task, mostly knowledge-based. Let (c_1, c_2, at) be a triple where, c_1 and c_2 are concepts and at is an attribute. The goal of the task is to define a function d to decide whether at is a discriminative feature of c_1 (value 1 for d) or not (value 0 for d). That is, if at characterizes c_1 but not c_2 .

Although the training and the development sets were not very large, we wanted to test the performance of Machine Learning (ML) approaches for this task. We selected a siamese neural network (Bromley et al., 1993) because these kind of systems are suitable for similar tasks such as knowledge base completion (Yang et al., 2014). This system works as follow. First, the input to this network are the NumberBatch embeddings of c_1 , c_2 and at . From this, a shared Multilayer Perceptron is applied in order to extract a complex representation of each term, $f(c_1)$, $f(c_2)$ and $f(at)$. With these representations, we compute the differences s_1 and s_2 where $s_1 = f(c_1) - f(at)$ and $s_2 = f(c_2) - f(at)$ with the aim of establishing relationships between each concept and the attribute. Finally, we concatenate s_1 and s_2 and we apply a fully-connected layer with softmax activation functions to carry out a classification i.e. $d_{Sia} = 1$ if at is discriminative for c_1 and not for c_2 or $d_{Sia} = 0$ otherwise.

The rest of the systems were knowledge-based. As first knowledge-based approach, we use the relationships between each concept and the attribute to determine if the attribute is discriminant. To do this, we use the ConceptNet relations. Note that, ConceptNet contains both positive (*IsA*, *FormOf*, *DerivedFrom*, *SimilarTo*, ...) and negative relations (*DistinctFrom*, *NotHasProperty*). In our proposals, we only consider positive edges, that is, those that denote positive relationships.

We look for positive edges between each concept and the attribute. If an edge between c_1 and at exists but there is not any edge between c_2 and

at , we assume that at is discriminant. In other words, at is discriminant if it is reachable from c_1 but not from c_2 . In this way, the function d_{CN} that determines if the attribute at is discriminant for concepts c_1 and c_2 can be defined as shown in Equation 1.

$$d_{CN} = \begin{cases} 1 & : \text{ if } at \in R(c_1) \wedge at \notin R(c_2) \\ 0 & : \text{ otherwise} \end{cases} \quad (1)$$

where, $R(c_1)$ and $R(c_2)$ are the sets of reachable nodes from c_1 and c_2 respectively using positive edges.

The main problem of this proposal is its low coverage. In many cases, there is no edge between any of the two concepts and the attribute, and therefore, it is decided that the attribute is not discriminant. In order to increase the coverage of d_{CN} , we extend the set of reachable nodes from a concept to those nodes reachable from other concepts closely related to the original concept. We have considered as related concepts those that are linked by the *FormOf* relation in ConceptNet. Considering the extended sets of reachable nodes, we can redefine the function d_{CN} of Equation 1 as shown in Equation 2.

$$d_{CN^2} = \begin{cases} 1 & : \text{ if } at \in R^2(c_1) \wedge at \notin R^2(c_2) \\ 0 & : \text{ otherwise} \end{cases} \quad (2)$$

where $R^2(c)$ is the set of nodes reachable from c or from any concept closely related to c .

Nevertheless, this approach still has coverage problems. In order to mitigate this problem, we proposed two new approaches based on Wikipedia. The main idea is simple, we search for the attribute at in the Wikipedia article of concepts c_1 and c_2 ($doc(c_1)$ and $doc(c_2)$) and, we decide if at is discriminant based on the result of this search. In this way, function d_{We} can be defined as shown in Equation 3.

$$d_{We} = \begin{cases} 1 & : \text{ if } at \in doc(c_1) \wedge at \notin doc(c_2) \\ 0 & : \text{ otherwise} \end{cases} \quad (3)$$

Further, we can relax the exact match criterion. Concretely, if we use NumberBatch distributed representations of words (h), we can compute similarities between at and all the tokens of $doc(c_1)$ and $doc(c_2)$ in order to decide which concept is the closest to at .

We define a threshold ϵ to ensure that there is enough difference between the maximum similarity $\max_{w \in doc(c_1)} \cos(h(w), h(at))$ and $\max_{w \in doc(c_2)} \cos(h(w), h(at))$. Using the development set, the value of ϵ was fixed to 0.2. This new decision function d_{Wt} is presented in the Equation 4.

$$d_{Wt} = \begin{cases} 1 & : \text{if } \max_{w \in doc(c_1)} \cos(h(w), h(at)) \\ & - \max_{w \in doc(c_2)} \cos(h(w), h(at)) \geq \epsilon \\ 0 & : \text{otherwise} \end{cases} \quad (4)$$

Finally, in order to explore the joint behavior of the knowledge-based approaches, we propose the combination of d_{CN^2} and d_{Wt} . When there is a relationship between at and any concept –it does not matter if it is c_1 , c_2 or both– we decide if at is discriminant using d_{CN^2} . But if there is no relationship in ConceptNet between them, we *smooth* the decision using d_{Wt} . Thus, we only use d_{CN^2} when we really have information in ConceptNet. The definition of this new decision function d_{CN^2+Wt} is shown in Equation 5.

$$d_{CN^2+Wt} = \begin{cases} d_{CN^2} & : \text{if } at \in R^2(c_1) \\ & \vee at \in R^2(c_2) \\ d_{Wt} & : \text{otherwise} \end{cases} \quad (5)$$

4 Experimental Results

In order to validate the correctness of the proposed approaches and also to select the one with the best performance for the competition, we carried out an evaluation of the approaches using the development set provided by the organizers. The results obtained are shown in Table 4.

d	Approach	Macro F_1
d_{Sia}	Siamese network	57.07
d_{CN}	ConceptNet	58.51
d_{CN^2}	ConceptNet ²	61.94
d_{We}	Wiki. exact match	58.46
d_{Wt}	Wiki. threshold	60.34
d_{CN^2+Wt}	ConceptNet + Wiki.	68.20

Table 1: Results on the development set.

As can be seen in Table 4, the knowledge-based systems which use knowledge resources obtain among 1.31 and 11.13 points of macro F_1 more

than the Siamese network which uses only NumberBatch embeddings. The approaches that use only ConceptNet (d_{CN} and d_{CN^2}) achieved as good results as those based on Wikipedia (d_{We} and d_{Wt}). Note that the coverage of d_{CN} and d_{CN^2} is very low, 48.71% for d_{CN} and 56.61% for d_{CN^2} . In cases where there are no links in ConceptNet –more than fifty percent of the time for d_{CN} – it is decided that the attribute is not discriminant. Moreover, the more knowledge incorporated into the system, the better results are obtained. We achieved the best results using the combination of ConceptNet graph and Wikipedia articles (d_{CN^2+Wt}), achieving 68.20 macro F_1 .

Regarding the evaluation with the test set, we used d_{CN^2+Wt} as decision function for the SemEval competition. Our system achieved competitive results (69.00 macro F_1 , 6 points of macro F_1 below the best system that obtains 75.00 macro F_1). Our proposal was ranked in 5th place out of a total of 26 participating teams. Several results from the official evaluation are shown in Table 4.

Team	Macro F_1
Sunnylnp (1/26)	75.00
Esantus (2/26)	73.00
ELiRF-UPV (5/26)	69.00
...	
Amrita_student (25/26)	49.00
Luminoso (26/26)	49.00

Table 2: Official results

5 Analysis of Results

Once the evaluation is finished, we want to carry out an analysis of the behavior of our system. Our goal is to detect in which types of attribute the system works worse. This way, we could add specific knowledge resources to deal with these attributes.

Although we have not completed this analysis, a group of attributes that caught our attention were the colors. While the overall error rate of our system was about 30%, the error in samples with attributes related to colors was about 50%. More details about the behavior of our system can be seen in Table 5.

Therefore, it would be possible to improve the system behavior by treating the color attributes in a specific way. For instance, by using image resources, such as ImageNet (Deng et al., 2009), to compute the color palette of images of each concept and compare it with the color attribute.

Attributes	Errors	Occurrences
Black	56	116
Brown	41	56
Yellow	11	46
Red	12	19
Blue	1	3
Color	121 (50.42%)	240
Other	586 (27.90%)	2100
Total	707	2340

Table 3: Error analysis in samples with attributes related to colors.

6 Conclusions and Future Work

In this work, we proposed a knowledge-based system for the discriminative attributes task. This system is based on the combination of two knowledge resources: a knowledge graph with semantic links such as ConceptNet and a general resource such as Wikipedia.

With this system, we achieved good results in the development set, compared to a supervised learning approach like siamese neural networks. That is, a combination of knowledge-based approaches produces significant improvements compared to the supervised approach. Regarding the evaluation with the test set, we obtained competitive results.

As future work, we propose an extension of our system based on the addition of more knowledge resources such DBpedia (Lehmann et al., 2015), Wordnet (Fellbaum, 1998) or Microsoft Concept Graph (Wang et al., 2015). Moreover, it could be interesting to consider the sections of Wikipedia with links to other resources in order to extract more information.

Finally, we propose the incorporation of knowledge resources into Deep Learning systems, beyond using only distributed representations of words. This offers us end-to-end systems capable of learning more complex decision algorithms. Concretely, the siamese neural networks seems to be promising for this work due to their good results in related fields such as knowledge-based completion (Yang et al., 2014).

Abstract

This paper describes the system submitted to SemEval 2018 shared task 10 ‘Capturing Discriminative Attributes’. We use a combination of knowledge-based and co-occurrence features to capture the semantic difference between two words in relation to an attribute. We define scores based on association measures, ngram counts, word similarity, and ConceptNet relations. The system is ranked 4th (joint) on the official leaderboard of the task.

1 Introduction

When it comes to investigating semantic similarities, it is worth noting that similarity between two words can be too general to quantify. Accordingly, the discriminating power of a model is also important in limiting the scope of similarity between words.

The main idea behind distributional semantics, known as Distributional Hypothesis (DH), states that linguistic items with similar distributions have similar meanings (Blevins, 2016). Therefore these methods are biased towards finding similarities between concepts. The SemEval shared task 10 ‘Capturing Discriminative Attributes’ poses the new problem of semantic difference detection, thus putting difference, rather than similarity at the forefront. It is about modeling semantic difference in the case of already related words. The idea is that while similarity can group words together in a generic way, understanding semantic differences sheds additional light on the meaning of each individual word.

A semantic model can potentially become more robust if it can benefit from sensitivity to differences alongside similarities in meaning. Considering difference can also help researchers assess semantic representations more rigorously. The effectiveness of a semantic similarity model can

be evaluated further by quantifying its strength in finding differences between words.

In the shared task, semantic difference is operationalised as the relation between two semantically related words and a discriminative feature. This relation is realised if the feature characterises only the first word. An example is the triple *airplane, helicopter, wings*. In this formulation, semantic difference is an asymmetric relation.

In this work, we compute several scores for word pairs and triples with the aim of capturing different semantic relations. Specifically, we define scores based on a knowledge-based ontology and co-occurrence counts. For knowledge-based features we rely on ConceptNet semantic network (Speer and Havasi, 2013), and our co-occurrence based features are derived from association measures, ngrams and pre-trained embeddings. We use the scores in both supervised and unsupervised scenarios to identify triples that constitute semantic difference; i.e. the attribute (third) word is discriminative between the first two words. The code and data used for this system are freely available.¹

The rest of this paper is organised as follows: Section 2 describes related work. Section 3 provides a description of the approach including the details of the features we use. Sections 4 and 5 discuss experiments and results. Section 6 involves error analysis and some closing remarks and finally the paper concludes with Section 7.

2 Related Work

Distributional similarity methods rely on classical DH, meaning in order to determine how similar two words are, they consider similarity of their contexts. This similarity is usually approximated by taking the cosine of the word vectors. In this

¹https://github.com/shivaat/discriminative_attribute

way, semantic difference can be modeled as the subtraction of vectors from semantically related words. As a classic example, subtraction of word vectors for *king* and *man* is similar to that of *queen* from *woman* (Mikolov et al., 2013).

However not all semantic differences can be adequately captured using this method. There are many cases where the difference between two words originates from the lack or presence of a feature that cannot be directly mapped to the vector difference between two related words. One such example is *dolphin* and *narwhal* that only differ in having a *horn* (Krebs and Paperno, 2016).

Therefore, combining linguistic and conceptual information would potentially strengthen a semantic model in capturing meaning of a word. To tackle this issue, some studies rely on human annotated list of different attributes related to a concept which are called feature norms (McRae et al., 2005). Despite their strength in encoding semantic knowledge, feature norms have not been widely used in practice because they are small in size and require a lot of work to assemble (Fagarasan et al., 2015). Lazaridou et al. (2016) is an earlier attempt at identification of discriminative features which focuses on visual attributes.

3 Approach

Our goal is to define a simple interpretable metric, using which we can gauge semantic difference and identify discriminative attributes. We hypothesise that for a triple in this task, a stronger relation between the first word and the attribute (in comparison with the second word and the attribute)² is indicative of the attribute word being discriminative between the two words.

For each triple we define a discriminative score $Disc_Score(w1, w2, attr)$ as follows:

$$Disc_Score(w1, w2, attr) = Score(w1, attr) - Score(w2, attr) \quad (1)$$

where $w1$, $w2$ and $attr$ are the first, second, and third word respectively. $Score$ is a variable function of relation between two words that can be any of the scores explained in Sections 3.1, 3.2, 3.3, and 3.4.

²This stronger relation corresponds to more common semantic context and/or higher co-occurrence probability.

3.1 Association-based Score

Statistical association measures have a long history in language processing. With the availability of huge corpora, these measures can be even more effective than before in finding collocations and associations between words.

Collocational behaviour between two words is a strong signal that suggests one of the words can identify the other. As an example, in the triple (*hair, body, curly*), the association score in (*hair, curly*) is much more than (*body, curly*), suggesting that *curly* is a discriminative attribute between the other two words.

For each triple in this task, collocational behaviour of the attribute word with the first two words is measured to see whether the first word can be a better collocate than the other. To this end, we use several different association measures to compute the outputs of the $Score$ function in Eq. 1.

We measure the association of two words based on their co-occurrence in the span of 5 words. We use SketchEngine (Kilgarriff et al., 2004) to extract these statistics from the huge enTenTen corpus (Jakubíček et al., 2013). Specifically, for each pair of words, we extract PMI (Church and Hanks, 1990) (known as MI in SketcEngine), MI3 (Oakes, 1998), log-likelihood (Dunning, 1993), T-score (Krenn and Evert, 2001), log-Dice (Dice, 1945), and Saliency (Kilgarriff et al., 2004) all as defined in SketchEngine.

3.2 Google Ngrams

Ngrams are frequently used in computational linguistics for a variety of purposes including language modeling and association measures based on lexical co-occurrence. Google Books Ngram Dataset³ is a collection of phrases (between 1 and 5 words long) extracted from over 8 million books printed between 1500 and 2008.

We use PhraseFinder (Trenkmann, 2016), a free web API that makes it possible to look up words or phrases from this dataset using a wildcard-supporting query language. Using this resource, we derive two different features. In the first one, we only consider bigrams, and in the other, we consider up to 5-grams. In both cases, we count the number of times that words occur near one another in a span of interest regardless of order. We follow the same formula as defined

³<https://books.google.com/ngrams>

in Eq. 1. In order to eliminate the bias of high/low frequency words we divide $Disc_Score$ by $Score(w1, attr) + Score(w2, attr)$ that we compute from ngram co-occurrence counts.

3.3 Word Embedding Based Score

In distributional semantics, word embeddings are used to induce meaning representations for words. These methods are inspired by neural network language modeling and have become a basic building block for most applications in computational linguistics. The most popular word embedding method is word2vec (with the skip-gram architecture) which learns dense vector representations for words using an unsupervised model. Word2vec’s training objective is based on DH, defined so that the model can learn word vectors that are good at predicting nearby words (Mikolov et al., 2013). Another popular embedding technique is GloVe, which like word2vec, preserves semantic analogies in the vector space. One major difference between the two models is that GloVe utilises corpus statistics by training on global co-occurrence counts rather than local context windows (Pennington et al., 2014).

In our system we use a concatenation of two sets of pre-trained embeddings. The first is trained on English Wikipedia using a variation of word2vec (Bojanowski et al., 2016). The other called ConceptNet Numberbatch (Speer and Lowry-Duda, 2017), is an ensemble of pre-trained Glove and word2vec vectors whose values are readjusted using a technique called retrofitting (Faruqui et al., 2014). In retrofitting, the values of the embeddings are updated using a training function that considers relational knowledge.

Using each word embedding, we compute cosine similarity between each word in a triple and the attribute word to account for the statistics $Score(w1, attr)$ and $Score(w2, attr)$ in Eq. 1.

3.4 ConceptNet Score

Co-occurrence based measures are not sufficient to account for all the various semantic relations that can exist between two words. Knowledge-based ontologies (e.g. ConceptNet, BabelNet etc) encode information about words and their relations in a structured way. This additional source of semantic information can be used to determine whether or not an attribute is discriminative. Because of its free web interface and ease of use, we

use ConceptNet to empower our system with relational knowledge (Speer and Havasi, 2013).

For any given $(w1, w2, attr)$ triple, using ConceptNet’s REST API we query $w1$, limiting the number of search results to 1,000. The output is a JSON file that contains all relations between the queried word and other concepts. We traverse all the relations and count the number of times $attr$ is linked to $w1$ to compute $score(w1, attr)$. We repeat the procedure for $w2$ and compute $score(w2, attr)$ and substitute them in Eq. 1.

4 Experimental Settings

We use the data as provided by the organisers of the shared task. We train our model on the train set and find the optimised parameters based on the validations set. Predictions were made on the held-out test data.

The final feature set is the collection of $Disc_Score$ measures based on the set of proposed scores. As a result we have 6 association-based scores, 2 google ngram based scores, 2 embedding based scores, and 1 ConceptNet score. In total, we have 11 scores as our features.

In ConceptNet, reliability of each relation is given by a weight score. We decided to ignore this information and opted for raw counts because it didn’t help performance. Furthermore, binarising the scores based on raw counts (with 0 as a threshold) slightly improved the results.

We use the features in both a supervised scenario (using SVM) and an unsupervised scenario (using KMeans). In both cases all of the 11 features are exploited.

The evaluation in this shared task is in terms of the average of positive and negative F1-scores. In this paper, we report the precision, recall and F1-score for both positive and negative labels separately, along with the average F1-score.

5 Results and Discussion

Table 1 shows the results on the validation set both in the supervised (SVM) and the unsupervised scenario (KMeans).

In this table, we mainly focus on the results that we achieved with our best system after the official evaluation. We also briefly report our official result for $TEST$ as recorded on the shared task leaderboard. The only difference between our system in official evaluation and post evaluation is the setting we have used to extract measures

			Precision	Recall	F1-score	Average F1-score
Validation	SVM	pos	0.7679	0.5652	0.6512	0.6913
		neg	0.6548	0.8284	0.7315	
	KMeans	pos	0.7039	0.6833	0.6935	0.6972
		neg	0.6910	0.7113	0.7010	
TEST (Official Evaluation)	SVM					0.69
TEST (Post Evaluation)	SVM	pos	0.7299	0.6065	0.6625	0.7142
		neg	0.7197	0.8183	0.7658	
	KMeans	pos	0.6464	0.7001	0.6722	0.6930
		neg	0.7396	0.6899	0.7139	

Table 1: Results on Validation and TEST sets.

from SketchEngine. For the official evaluation, by querying SketchEngine we extracted all the collocations of an attribute word. However, the lists of resulted entries in SketchEngine are limited to a 1,000 for each query. We later bypassed this limitation by searching for the attribute word with only a limited number of words (from the dataset) in its context. This improves the results on validation and test sets.

Surprisingly, it can be seen in the first part of Table 1 that the unsupervised model (KMeans) can cluster the validation data as well as or even better than the supervised classification approach (SVM).⁴ This can be explained by the fact that the features we employ for this task are all computed using a formula that is specifically defined to represent semantic difference, and finding whether a feature is discriminative between two words closely correlates with the semantic difference between them.

It can be concluded from the results that the features are well generalised as they lead to even better performance on the held-out test data.

6 Error Analysis

A sizable portion of the train and test triples bear on genealogical and kinship relations, as in (*grandson, brother, male*). Some require hierarchical reasoning, as in (*invertebrate, insect, shell*). Our model captures these kinds of relations very well, as it has access to information from a knowledge base.

In order to see the effectiveness of the scores we obtain from ConceptNet, we re-train the model excluding the ConceptNet based measure and also

⁴In order to evaluate the results from KMeans, we label the clusters in a way that best matches the truth values. These values need to be known to perform this analysis. Therefore, we used SVM for official submission since the TEST data is blind.

the vectors derived from Numberbatch embedding. As a result, the validation performance dropped to 0.6857 and the test result decreased to 0.6969 in terms of average F1-score.

A large part of the test triples require the knowledge to understand whether something is a constituent of another entity, as in (*beer, wine, foam*). It appears that these relations are well captured using co-occurrence based metrics alone since deleting knowledge-base features leaves the results for these triples for the most part unchanged.

7 Conclusions

For this shared task we develop a classification system to determine whether an attribute word can distinguish one word from another. To model semantic difference, we define a discriminative score, and make use of a variety of different association measures derived from huge corpora, and also pre-trained distributional semantic vectors. To augment our method with structured knowledge, we utilise a knowledge-based ontology. We use the feature set in supervised and unsupervised settings. The results suggest that the defined score is capable of generating features that can help our model in capturing instances where a feature is discriminative between two words. Our system shows particular strength in recognising kinship and genealogical relations that are not consistently captured using naive distributional semantic techniques.

In the future, we intend to exploit ConceptNet in a more sophisticated way rather than limiting ourselves to number of relations. It would also be interesting to extract co-occurrence measures from various corpora including domain-specific resources in order to improve the coverage of the model.

Abstract

In this paper we report an unsupervised method aimed to identify whether an attribute is discriminative for two words (which are treated as concepts, in our particular case). To this end, we use geometrically inspired vector operations underlying unsupervised decision functions. These decision functions operate on state-of-the-art neural word embeddings of the attribute and the concepts. The main idea can be described as follows: if attribute q discriminates concept a from concept b , then q is excluded from the feature set shared by these two concepts: the intersection. That is, the membership $q \in (a \cap b)$ does not hold. As a, b, q are represented with neural word embeddings, we tested vector operations allowing us to measure membership, i.e. fuzzy set operations (t-norm, for fuzzy intersection, and t-conorm, for fuzzy union) and the similarity between q and the convex cone described by a and b .

1 Introduction

There exist nowadays a number of arithmetic vector operations for computing word relationships interpreted as linguistic regularities. A very popular setting is solving word analogies (Lepage, 1998), which is mainly used to evaluate the quality of word embeddings (Mikolov et al., 2013). Recently other alternatives to solve word analogies have been proposed (Linzen, 2016), including supervised methods (Drozd et al., 2016).

Solving word analogies requires three word arguments, and a fourth one is inferred. Such an inference raises from the similarity between common or similar contexts shared by the two pairs

of words. Thus, given words “queen”, “woman”, “king”, “man”, the following arithmetic operation holds for their corresponding embeddings $x_{(\cdot)}$:
 $x_{king} - x_{man} + x_{woman} = x_{queen}$.

In this work, we explore similar approaches for Discriminative Attribute Identification (DAI). This task requires three word arguments a, b, q , and a binary label $y \in \{0, 1\}$ is inferred from them (Cree and McRae, 2003; Lazaridou et al., 2016; McRae et al., 2005). Such a label indicates whether the third word, q , is identified as a discriminative (semantic) attribute between words (concepts) a, b . We observed that the task of identifying discriminative attributes between words, represented via word embeddings, evokes that of solving word analogies.

We propose geometrically inspired vector operations on word embeddings $x_a, x_b, x_q \in \mathbb{R}^n$ of the words a, b, q , respectively. The output of each of these operations is in turn operated by a supervised decision function aimed to predict the label y . The decision functions are based on the reasoning given originally in (Lepage, 1998) for solving word analogies. Under this reasoning, the important thing is to look for those items shared by the objects compared, and verify whether the item of interest is included among them.

In other words, in the case of DAI, if we are asked whether x_q , the attribute embedding, discriminates x_a from x_b , then an idea is to verify whether the attribute is contained in the set shared by the two concepts in question, i.e. does the set operation $q \in (a \cap b)$ hold? Our hypothesis, is that x_q discriminates x_a from x_b if the result of such an operation is false in terms of the subspace delimited by x_a and x_b , i.e. a convex cone. Thus, a number of vector operations and decision functions were tested as different vector versions of this set operation on state-of-the-art neural word embeddings.

The proposed method does not rely on language or knowledge resources (i.e. knowledge bases and graphs, PoS or any kind of taggers, etc.). Furthermore, with the help of the geometrical insight that our method provides, we also discuss the possibilities of it for being used to study measures of how concepts can be generated from attributes in the sense of vector space modeling of natural language. Thus, this study can be considered, e.g., for designing semantically driven word embedding methods or to explore alternatives for building knowledge resource applications.

Our results showed that the proposed approach hold coherence with respect to the semantic notions proposed in the DAI task. This approach reached 0.622 of F-measure in predicting discriminative attributes.

2 Literature Review

Up to our knowledge, there is not work proposing unsupervised methods for discriminative attribute identification or extraction with a direct link to word embeddings. Most related work deals with semantic relation extraction or with labeling semantic relations in lexical semantics, e.g. given a hypernym, to perform hyponym extraction (Fu et al., 2014).

There is also work on using semantic attributes to classify images of objects in a supervised fashion (Chen et al., 2012; Lazaridou et al., 2016). In this case, dictionaries of discriminative attributes of objects are used (e.g. fruits by their *color or form*), but experiments are not performed on text data, e.g., a snippet describing the object. In more applicative cases, the use of dictionaries of object attributes has shown to be a good approach in clothing recommender systems. These systems group images of items sharing attributes the customers are usually interested in, e.g. images of jackets *with a hat* (Chen et al., 2012; Kalra et al., 2016; Zhou et al., 2016).

Other contributions provide methods for object classification by using multiple data sources, including text. In (Farhadi et al., 2009, 2010; Lampert et al., 2009) it is proposed supervised learning of semantic attributes and textual descriptions of objects. Their methods are aimed to generalize recognition and (template) textual description of unseen objects with similar and shared attributes. In the particular case of (Berg et al., 2010), a supervised algorithm learns to label object attributes

by fitting multinomial associations between text segments and recognized image segments as co-occurring objects within a Web corpus (Su and Jurie, 2012). After that, the learned attributes of the objects are detected and used as features for feeding an unsupervised method for categorizing images and text. In (Deeptimahanti and Sanyal, 2011; Overmyer et al., 2001) natural language descriptions of case uses of user requirements are parsed to obtain Unified Modeling Language (UML) diagrams including object attributes. This approach is aimed to facilitate design in software engineering by semi-automatically building code objects (Yue et al., 2011).

3 A Convex Combination

Lepage (1998) proposed solving word analogies based on characters shared by words and sentences. We extrapolated such an idea for feature similarities, similarly to what (Mikolov et al., 2013) did on vectors for solving word analogies. Thus, our method attempts taking into account these two ideas in the following way. Thinking about neural word embeddings as vectors generated by axis of attributes, our approach is to observe the linear subspace A delimited by embeddings of words a and b , and to see how the embedding of q is contained in it. This linear subspace has the properties of a convex cone. Thus, in geometrical terms, to assess whether an attribute can generate a pair of concepts or not, we propose to measure the degree, λ , to which the embedding x_q is a convex combination of the embeddings x_a and x_b . This measure can be derived from the convex combination

$$\lambda x_a + (1 - \lambda)x_b = x_q, \quad (1)$$

where $\lambda \in [0, 1]$. The embeddings $x_a, x_b, x_q \in \mathbb{R}^d$ represent nouns a and b and the query attribute q , respectively (see Figure 1). The requirement of x_a, x_b to describe a convex cone A is due to the fact that, geometrically, features shared by these embeddings would be enclosed within such cone. This can be observed by testing extreme values in Eq. (1). Assume all embeddings are normalized in magnitude. Let us making q to be, simultaneously, as far as possible from a and b while keeping the volume of A greater than zero. Also make that $\langle x_a, x_b \rangle$ to be small. In this scenario, embeddings x_a, x_b delimit a cone of less than 90 degrees. As the embedding x_q is as far as possible from the

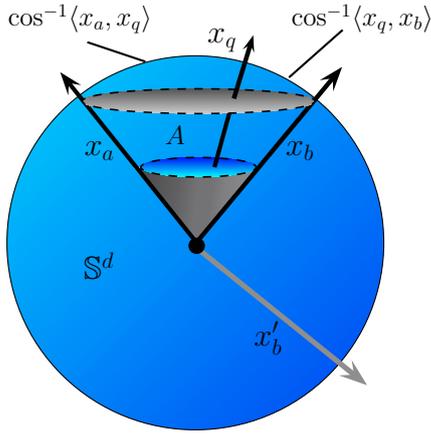

Figure 1: The d -dimensional vector space defined in the unitary-sphere \mathbb{S}^d .

x_a and x_b and it is contained in A , then it passes close to the center of the circular basis of the cone. Thus, we have

$$\|x_q - x_a\| \approx \|x_q - x_b\|.$$

This geometrical scenario indicates that q is shared equably by a and b , so it is not discriminative for them. In the case of $\langle x_a, x_b \rangle \approx -1$ it means that the set A is not convex. This is because x_a and x_b describe a unique line and have opposite directions (they are anti-parallel). This geometrical scenario prevents the pair of word embeddings from being generated by linear combinations of attributes in common to them (see x_a and x'_b in Figure 1). In the case when a, b are semantically very similar, we have that¹ $\langle x_a, x_b \rangle \rightarrow 1$. It means that both vectors are (almost) parallel, so they refer concepts sharing most of their attributes. In this case, if x_q is far away from both x_a and x_b , then determining discriminativeness has not sense (probably x_q is not an attribute of either of them).

The geometrical scenario of identifying a discriminative attribute q can occur when $\langle x_a, x_b \rangle$ is small and either $\langle x_q, x_a \rangle \rightarrow 1$ or $\langle x_q, x_b \rangle \rightarrow 1$. For example, if $\langle x_q, x_b \rangle \rightarrow 1$, it means that x_q tends to be parallel to x_b and we can see x_b as a linear combination of x_q . As $\langle x_a, x_b \rangle$ is small (x_a and x_b are almost orthogonal), then $\langle x_a, x_q \rangle$ is also small. Therefore, this analysis leads us to think that q discriminates a from b , and that q is an attribute of b rather than of a .

¹The symbol ‘ \rightarrow ’ denotes tendency (“tends to”).

4 The Convex Cone Method

The scenarios depicted in Section 3 overall show how projections among word embeddings form convex combinations and how these projections can be exploited in DAI. Without loss of generality, these projections can be seen as distances. In this sense, the convex parameter λ in Eq. (1) indeed weighs distances involving x_a, x_b, x_q . Now, notice that Eq. (1) expresses x_q in terms of x_a and x_b . However, in DAI they are known and we would like to measure the relationship among them given they are d -dimensional vectors. This measure can be given by λ , which now becomes into the unknown. In this case, λ acts as a bounded measure of how much a given pair of concepts a, b shares a given attribute q . Thus, by performing some comprehensive algebra starting from Eq. (1), we arrive at

$$\lambda(x_a - x_b) + x_b = x_q,$$

which leads to the d -dimensional Euclidean (cone) version of the convex parameter

$$\lambda = \frac{\|x_q - x_b\|}{\|x_a - x_b\|}. \quad (2)$$

Furthermore, in addition to (2), we consider an alternative distance criterion. That is, it is possible measuring distance in terms of arcs instead of doing it in terms of straight line segments. Therefore, we have the arc (arcone) version of the convex parameter:

$$\lambda = \frac{\cos^{-1}\langle x_q, x_b \rangle}{\cos^{-1}\langle x_a, x_b \rangle}, \quad (3)$$

where $\langle x, x' \rangle \in [-1, 1]$ given that $\|x\| = 1$ for all $x \in \mathbb{S}^d$ (the unitary sphere). Both arcs $\cos^{-1}\langle x, x' \rangle$ in the numerator and in the denominator of (3) are in the interval $[0, 2\pi]$.

The convex parameter λ measures the degree to which x_q is a convex combination of x_a and x_b . From the point of view of the combination degree, rather than from the point of view of the absolute value of λ , some function $f(\lambda)$ must be maximum at $\lambda = 0.5$ (see Figure 2). When it occurs, x_q passes close to the axis of the cone A (so it also passes close to the center of the shaded circular area of radius $0.5\|x_a - x_b\|$ in Figure 1). Therefore, $\lambda \rightarrow 0.5$ indicates that the attribute q is highly shared by both concepts a and b .

The extreme values of λ must be interpreted contrarily by f , i.e. $\lambda \rightarrow 0$ means that, on the

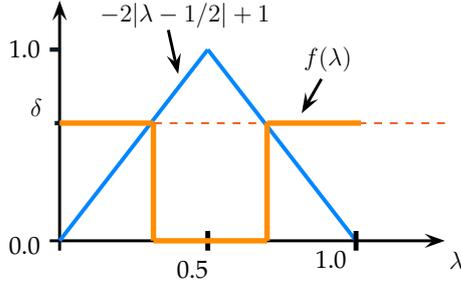

Figure 2: The decision function $f(\lambda)$.

one hand, the attribute q uniquely characterizes (or generates) the concept a , so x_a is approximately parallel to x_q . On the other hand, $\lambda \rightarrow 1$ means that the attribute q uniquely characterizes the concept b . Thus, we need that some decision function f to take advantage of extreme values of λ for making decision on whether an attribute q is discriminative of a pair of concepts a and b .

Therefore, we define our decision criterion subject to some threshold $\delta \in [0, 1]$ (say $\delta = 0.7$):

$$f(\lambda) = \begin{cases} 1 & \text{if } -2|\lambda - 1/2| + 1 < \delta \\ 0 & \text{if } -2|\lambda - 1/2| + 1 \geq \delta \end{cases} \quad (4)$$

where if upper inequality (4) holds, it means either that $\lambda \rightarrow 0$ or that $\lambda \rightarrow 1.0$, so $f(\lambda) = 1$ and therefore attribute q discriminates concepts a and b . Conversely, if lower inequality (4) holds, it means that $\lambda \rightarrow 0.5$. Therefore, $f(\lambda) = 0$ and the decision function determines that q does not discriminate a and b . See Figure 2.

5 Other Geometrical Methods

In addition to the convex cone method, we also tested mean-based, sum-based and fuzzy methods for quantifying the containment $q \in (a \cap b)$.

5.1 Similarity with Respect to the Sum and to the Mean

The sum-based method computes the resultant vector of x_a and x_b . The similarity between such a vector and the candidate attribute x_q should be smaller than some threshold δ so as to consider that q discriminates a from b , that is:

$$f(x_q; x_a, x_b) = \begin{cases} 1 & \text{if } \langle x_q, x_a + x_b \rangle < \delta \\ 0 & \text{if } \langle x_q, x_a + x_b \rangle \geq \delta \end{cases} \quad (5)$$

Unlike to the convex cone method, Eq. (5) indicates that the sum-based method measures directly the similarity between the resultant vector $x_a + x_b$

and x_q . The motivation of this operation is similar to that of the convex cone method. That is, $x_a + x_b$ is an embedding that embeddings x_a and x_b have in common. Therefore, probably such embedding is similar to x_q if this latter also is common to x_a and x_b .

The mean-based method follows exactly the same principle, but only requires multiplying $x_a + x_b$ in (5) by 0.5.

5.2 Similarity with Respect to a Fuzzy Connective

The fuzzy method computes the connective:

$$x_{\{a,b\}} = \alpha \min\{x_a, x_b\} + (1 - \alpha) \max\{x_a, x_b\}$$

between the fuzzy intersection ($\min\{\cdot\}$) and the fuzzy union ($\max\{\cdot\}$) of the embeddings x_a, x_b (Zadeh, 1965). These set operations are known as the Gödel's t-norm and t-conorm (Klement et al., 2013), respectively and they are defined element-wise for vectors. α is known as the compensation parameter and controls the mixture between union and intersection. Thus, the connective acts as a convex combination of the fuzzy union and the fuzzy intersection operators, so if $\alpha \rightarrow 0$ it causes that the intersection ($\min\{\cdot\}$) vanishes whereas the union ($\max\{\cdot\}$) survives. The contrary effect can be induced if $\alpha \rightarrow 1$.

Fuzzy set operations are conceptually more akin to the idea of observing whether the intersection set of concept attributes contains some query attribute. To contextualize word embeddings with fuzzy sets, we assume the embedding $x_a \in \mathbb{R}^d$ is given by a membership function $x_a = \mu(\mathcal{A})$. Herein, \mathcal{A} is the set of items in some subset (of cardinality d) of the contexts of the word a . We also assume that the subset of contexts was statistically estimated by the word embedding method, which is in this case though as the membership function defined on the set $\mathcal{C} \supset \mathcal{A}$ of all contexts in the corpus $\mu : \mathcal{C} \rightarrow \mathbb{S}^d$.

As a first attempt to explore a relationship between fuzzy sets and word embeddings, in this paper we induced bias α to a decision function f based on the inner product between the connective $x_{\{a,b\}}$ (a biased version of $x_a + x_b$) and the query attribute x_q . In this way, the decision of DAI is made according to the threshold δ , i.e.:

$$f(x_q; \alpha; x_a, x_b) = \begin{cases} 1 & \text{if } \langle x_q, x_{\{a,b\}} \rangle < \delta \\ 0 & \text{if } \langle x_q, x_{\{a,b\}} \rangle \geq \delta \end{cases} \quad (6)$$

where α is the tolerance parameter of the fuzzy connective and it must be manually set.

6 Experiments and Results

For our experiments, we computed our decision functions $f(\cdot)$ on tuples of the form $\{x_a, x_b, x_q, y\}$. To this end, we used state-of-the-art word embeddings, i.e. Glove (Pennington et al., 2014), FastText (Bojanowski et al., 2016), Word2Vec (Mikolov et al., 2013) and Dependency-Based Word2Vec (DBW2V) (Levy and Goldberg, 2014). We also explored embeddings taking into account external knowledge. This is the case of ConceptNet embeddings (Speer and Lowry-Duda, 2017). DBW2V embeddings are W2V embeddings enriched by using syntactic dependencies and Conceptnet are embeddings enriched with both syntactic dependencies and knowledge graphs (Faruqui et al., 2015). We trained W2V and FastText by using the Wikipedia dataset². In the case of Glove³, ConceptNet⁴ and DBW2V⁵ we downloaded pretrained embeddings from authors’ websites. For Word2Vec and FastText we trained models of 200, 300, 400, 500 and 1000 dimensions. In our results we only report the dimensionality that performed best.

As our approach is unsupervised, we report experiments on the validation dataset available on the competition’s repository⁶. We can see in Table 1 that the arcone operation defined in (3) provided the best results for all word embedding methods. Our general best result was obtained by using Glove embeddings of 300 dimensions. We expected a good result from these embeddings as they specifically learn from mutual information statistics of word pairs. This enables Glove to encode feature contrasts, which also allows it for being the state-of-the-art method in word analogy tasks. During the competition we submitted our best configuration as unique run (Glove 300d and arcone operation with $\delta = 0.4$), which gave us $F1 = 0.60$ (place 19/26).

²The 2012 English Wikipedia available at <http://inex.mmci.uni-saarland.de/data/documentcollection.html>

³<https://nlp.stanford.edu/projects/glove>

⁴<https://github.com/commonsense/conceptnet-numberbatch>

⁵<https://levyomer.wordpress.com/2014/04/25/dependency-based-word-embeddings>

⁶<https://github.com/dpaperno/DiscrimAtt/tree/master/training>

Regarding to the threshold δ of the decision functions $f(\cdot)$, we tested a set of values $\delta \in \{0.0, 0.1, 0.4, 0.7, 1.0\}$. Our best result was obtained when $\delta = 0.4$ for almost all embedding methods, excepting DBW2V. This means that the convex parameter λ can vary 60% around the maximum (0.5) in order to consider that an attribute q is shared by (or to generate) both concepts a, b . Thus, by evaluating δ in (4) we see either that x_q is too biased towards x_a if it holds that $\lambda < 0.4(0.5) = 0.2$, or that x_q is too biased towards x_b if it holds that $\lambda > 0.3 + 0.5 = 0.8$. In these cases we can say that q is discriminative for the concepts a, b as it is an attribute only (or mainly) of one of them.

Embedding	Dim.	$f(\cdot)$	δ	F1-score
Glove	300	arcone	0.4	0.622
		cone	0.4	0.615
		sum	-0.4	0.457
		fuzzy	-0.4	0.438
		mean	-0.4	0.426
ConceptNet	300	arcone	0.4	0.585
		cone	0.4	0.581
		mean	0.1	0.469
		fuzzy	-0.1	0.465
		sum	-0.4	0.451
Word2Vec	300	arcone	0.4	0.584
		cone	0.4	0.577
		fuzzy	-0.1	0.448
		mean	-0.1	0.444
		sum	-0.4	0.439

		cone	0.4	0.568
		fuzzy	0.4	0.451
		mean	0.4	0.450
		sum	0.7	0.437
DBW2V	300	arcone	0.7	0.541
		cone	0.7	0.536
		sum	-0.7	0.498
		fuzzy	-0.4	0.485
		mean	-0.4	0.475

Table 1: Best results for all the word embedding and vector operation methods on the validation dataset.

Given that it was needed $\delta = 0.7$ for DBW2V, we inferred that these embeddings allowed much less bias from the center of the cone and λ must be within 30% of its maximum in order to decide that an attribute is shared by two concepts. In other

words, with DBW2V, it is more difficult to distinguish whether the attribute q is discriminative of a, b because it is allowed to be distant from both them even when it can be discriminative. This condition allows for much more feature overlapping and therefore the ranking on bottom of these embeddings can be explained.

Notice that the Euclidean version of the cone vector operation was the second best method for all word embedding methods. In fact, no difference was registered greater than 0.7% between cone and arcone operations.

The fuzzy approach did not show noticeable results. The variation of both, the threshold and the compensation parameter.

7 Discussion

We consider a bit surprising the difference in performance of Glove with respect to knowledge-based (ConceptNet) and Dependency-based (DBW2V) embeddings: 5.9% with respect to ConceptNet and 13.0% with respect to DBW2V. Such embeddings were expected to provide much more information about discriminative features because they are trained by taking into account semantic features explicitly by using knowledge and language resources for training. By using our arcone vector operation, W2V was ranked barely next to ConceptNet with a small difference of 0.17%. We think there are three possible motivations for this behavior. The first one is that the nature of our decision functions did not allowed to capture semantic features embedded into ConceptNet and into DBW2V. The second possibility is that semantic features are better embedded by Glove and, the third possibility, is that embedding semantic features explicitly can lead to overfitting of the resulting word representations. This latter possibility could be an additional explanation that DBW2V ended at bottom of our ranking.

In the case of FastText, these embeddings have been tested in word analogy tasks with success. However, as in the case of DBW2V, they are better than W2V or Glove mainly for syntactic analogies, which probably makes better FastText (and probably DBW2V) for NLP tasks other than DAI, e.g. sentence representation (Arroyo-Fernández et al., 2017).

Some assumptions were made for practical reasons in the case of fuzzy set operations. We are

aware that this could affected drastically the results. The first assumption was that word embeddings were produced by membership functions, which take values in $[0, 1] \subset \mathbb{R}$ exclusively. This is not the case of word embeddings and they cannot directly mapped to identifiable textual items. Therefore, applying the t-norm and the t-conorm to these vectors is not completely intuitive. Nevertheless, with real-valued vectors we still had: as both embeddings tend to be in the same quadrant, the larger the magnitude of the connective embedding $x_{\{a,b\}}$. This latter embedding is somewhat oriented to the direction of the resultant $x_a + x_b$, which can be regulated by α , inducing a bias with respect to that direction. Although, this interpretation was worth exploring it did not gave us interesting results. Thus a better version of this fuzzy approach is pending.

At this moment, we have not clear what was the reason several of our results were contradictory with respect to the F-measure. Particularly for distributed representations. That is, we have balanced binary labels in the gold standard, but some scores resulted less than 50%. It is difficult to figure out how it happened analyzing directly distributed representations. Therefore, it remains an open issue proposing an alternative geometrical approach to tackle this inconsistency with respect to the main hypothesis of this paper.

8 Conclusions

The results of our experiments showed that the arcone vector operation is a simple method for quantifying discriminativeness. This operation showed to be correlated with respect to human judgments annotated in the validation dataset when Glove word embeddings were used. From the vector operations presented in this paper, the arcone operation, Eq. (3), best represents the abstract operation between sets $a \cap b = A$. Notice that the concept of cone is limited to euclidean metrics neither on \mathbb{R}^d nor on \mathbb{S}^d . Therefore, other kind of transformations and related theories can be explored.

The effectiveness of our approach can be further explored as part of a learning algorithm aimed to obtain specialized (or enriched) word embeddings such that their geometrical structure is fitted in sets of convex volumes. An immediate experiment is using vector operations proposed in this paper as restrictions or as objectives for learning such embeddings for building knowledge resources.

Abstract

Luminoso participated in the SemEval 2018 task on “Capturing Discriminative Attributes” with a system based on ConceptNet, an open knowledge graph focused on general knowledge. In this paper, we describe how we trained a linear classifier on a small number of semantically-informed features to achieve an F_1 score of 0.7368 on the task, close to the task’s high score of 0.75.

1 Introduction

Word embeddings are most effective when they learn from both unstructured text and a graph of general knowledge (Speer and Lowry-Duda, 2017). ConceptNet 5 (Speer et al., 2017) is an open-data knowledge graph that is well suited for this purpose. It is accompanied by a pre-built word embedding model known as ConceptNet Numberbatch¹, which combines skip-gram embeddings learned from unstructured text with the relational knowledge in ConceptNet.

A straightforward application of the ConceptNet Numberbatch embeddings took first place in SemEval 2017 task 2, on semantic word similarity. For SemEval 2018, we built a system with these embeddings as a major component for a slightly more complex task.

The Capturing Discriminative Attributes task (Paperno et al., 2018) emphasizes the ability of a semantic model to recognize relevant differences between terms, not just their similarities. As the task description states, “If you can tell that americano is similar to capuccino and espresso but you can’t tell the difference between them, you don’t know what americano is.”

The ConceptNet Numberbatch embeddings only measure the similarity of terms, and we hy-

pothesized that we would need to represent more specific relationships. For example, the input triple “frog, snail, legs” asks us to determine whether “legs” is an attribute that distinguishes “frog” from “snail”. The answer is yes, because a frog *has* legs while a snail does not. The *has* relationship is one example of a specific relationship that is represented in ConceptNet.

To capture this kind of specific relationship, we built a model that infers relations between ConceptNet nodes, trained on the existing edges in ConceptNet and random negative examples. There are many models designed for this purpose; the one we decided on is based on Semantic Matching Energy (SME) (Bordes et al., 2014).

Our features consisted of direct similarity over ConceptNet Numberbatch embeddings, the relationships inferred over ConceptNet by SME, features that compose ConceptNet with other resources (WordNet and Wikipedia), and a purely corpus-based feature that looks up two-word phrases in the Google Books dataset.

We combined these features based on ConceptNet with features extracted from a few other resources in a LinearSVC classifier, using liblinear (Fan et al., 2008) via scikit-learn (Pedregosa et al., 2011). The classifier used only 15 features, of which 12 ended up with non-zero weights, from the five sources described. We aimed to avoid complexity in the classifier in order to prevent overfitting to the validation set; the power of the classifier should be in its features.

The classifier produced by this design (submitted late to the contest leaderboard) successfully avoided overfitting. It performed better on the test set than on the validation set, with a test F_1 score of 0.7368, whose margin of error overlaps with the evaluation’s reported high score of 0.75.

At evaluation time, we accidentally submitted our results on the validation data, instead of the

¹<https://github.com/commonsense/conceptnet-numberbatch>

test data, to the SemEval leaderboard. Our code had truncated the results to the length of the test data, causing us to not notice the mismatch. This erroneous submission got a very low score, of course. This paper presents the corrected test results, which we submitted to the post-evaluation CodaLab leaderboard immediately after the results appeared. We did not change the classifier or data; the change was a one-line change to our code for outputting the classifier’s predictions on the test set instead on the validation set.

2 Features

In detail, these are the five sources of features we used:

ConceptNet vector similarity. Given the triple $(term_1, term_2, att)$, we look up the ConceptNet Numberbatch embeddings for the root words of the three terms (with root words determined using ConceptNet’s built-in lemmatizer). We determine the cosine similarity of $(term_1, att)$ and the cosine similarity of $(term_2, att)$. We then subtract the square roots of the similarity scores (floored at 0). If this difference is large enough, it indicates a positive example, a discriminative attribute that applies to $term_1$ and not to $term_2$.

ConceptNet relational inference. We train a Semantic Matching Energy model to represent ConceptNet nodes and relations as vectors, along with a 3-tensor of interactions between them. This model can then assign a confidence score to any triple (a relation connecting two terms). We used this model to infer values for each of 11 different ConceptNet relations. As in the case of vector similarity, each feature value is the difference between the value inferred for $rel(term_1, att)$ and $rel(term_2, att)$. This model is described in more detail in the next section.

Wikipedia lead sections. This feature expands on ConceptNet vector similarity: instead of computing the similarity between the attribute and the term, it computes the maximum of the similarity between the attribute and any word that appears in the lead section of the Wikipedia article for the term (Wikipedia, 2017). This helps to identify attributes that would be used to define the term, such as “amphibian” as an attribute for “frog”.

WordNet entries. This feature is similar to the “Wikipedia lead sections” feature. It expands

each term by looking up its synonyms in WordNet (Miller et al., 1998), the synonyms in synsets it is connected to, and the words in its gloss (definition), and taking the maximum similarity of the attribute to any of these terms.

Google Books 2-grams. This feature determines if $term_1$ forms a significant two-word phrase with att , more than $term_2$ does, based on the Google Books English Fiction data (Lin et al., 2012). The “significance” (s) of a two-word phrase is determined by comparing the smoothed log-likelihood of the individual unigrams to the smoothed log-likelihood of the phrase:

$$s(term, att) = 10 + \log_{10}(\#(term, att) + 1) - \log_{10}((\#(term) + 10^5)(\#(att) + 10^5))$$

where $\#$ represents the number of occurrences of a unigram or bigram in the corpus.

The “ConceptNet relational inference” feature provides 11 entries to the feature vectors, while the other sources each provide one. In total, there are 15 features that represent each input triple.

Across multiple data sources, we use the square root of cosine similarity to measure the strength of the match between a term and an attribute. Because attributes should be at least somewhat related to the terms they describe, and because weak semantic similarity can be interpreted as relatedness, the square root helps us emphasize the important part of the scale. The difference between “somewhat related” and “not related” is more important to the task than the difference between “very similar” and “somewhat related”, as a discriminative attribute should ideally be unrelated to the second term.

2.1 The Relational Inference Model

To infer truth values for ConceptNet relations, we use a variant of the Semantic Matching Energy model (Bordes et al., 2014), adapted to work well on ConceptNet’s vocabulary of relations. Instead of embedding relations in the same space as the terms, this model assigns new 10-dimensional embeddings to ConceptNet relations, yielding a compact model for ConceptNet’s relatively small set of relations.

The model is trained to distinguish positive examples of ConceptNet edges from negative ones. The positive examples are edges directly contained in ConceptNet, or those that are entailed by changing the relation to a more general one or

switching the directionality of a symmetric relation. The negative examples come from replacing one of the terms with a random other term, the relation with a random unentailed relation, or switching the directionality of an asymmetric relation.

We trained this model for approximately 3 million iterations (about 4 days of computation on an nVidia Titan Xp) using PyTorch (Paszke et al., 2017). The code of the model is available at <https://github.com/LuminosoInsight/conceptnet-sme>.

To extract features for the discriminative attribute task, we focus on a subset of ConceptNet relations that would plausibly be used as attributes: *RelatedTo*, *IsA*, *HasA*, *PartOf*, *CapableOf*, *UsedFor*, *HasContext*, *HasProperty*, and *AtLocation*.

For most of these relations, the first argument is the term, and the second argument is the attribute. We use two additional features for *PartOf* and *AtLocation* with their arguments swapped, so that the attribute is the first argument. The generic relation *RelatedTo*, unlike the others, is intended to be symmetric, so we add its value to the value of its swapped version and use it as a single feature.

3 The Overfitting-Resistant Classifier

The classifier that we use to make a decision based on these features is scikit-learn’s LinearSVC, using the default parameters in scikit-learn 0.19.1. (In Section 4, we discuss other models and parameters that we tried.) This classifier makes effective use of the features while being simple enough to avoid some amount of overfitting.

One aspect of the classifier that made a noticeable difference was the scaling of the features. We tried L_1 and L_2 -normalizing the columns of the input matrix, representing the values of each feature, and decided on L_2 normalization.

We took advantage of the design of our features and the asymmetry of the task as a way to further mitigate overfitting. All of the features were designed to identify a property that $term_1$ has and $term_2$ does not, as is the case for the discriminative examples, so they should all make a non-negative contribution to a feature being discriminative. We can inspect the coefficients of the features in the SVC’s decision boundary. If any feature gets a negative weight, it is likely a spurious result from overfitting to the training data. So, af-

Feature	Coefficient

Google Ngrams	28.82

Table 1: Coefficients of each feature in our linear classifier. x represents a term and a represents the attribute.

ter training the classifier, we clip the coefficients of the decision boundary, setting all negative coefficients to zero.

If we were to remove these features and re-train, or require non-negative coefficients as a constraint on the classifier, then other features would inherently become responsible for overfitting. By neutralizing the features *after* training, we keep the features that are working well as they are, and remove a part of the model that appears to purely represent overfitting. Indeed, clipping the negative coefficients in this way increased our performance on the validation set.

Table 1 shows the coefficients assigned to each feature based on the training data.

4 Other experiments

There are other features that we tried and later discarded. We experimented with a feature similar to the Google Books 2-grams feature, based on the AOL query logs dataset (Pass et al., 2006). It did not add to the performance, most likely because any information it could provide was also provided by Google Books 2-grams. Similarly, we tried extending the Google Books 2-grams data to include the first and third words of a selection of 3-grams, but this, too, appeared redundant with the 2-grams.

We also experimented with a feature based on bounding box annotations available in the Open-Images dataset (Krasin et al., 2017). We hoped it would help us capture attributes such as colors, materials, and shapes. While this feature did not improve the classifier’s performance on the validation set, it did slightly improve the performance on the test set.

Before deciding on scikit-learn’s LinearSVC,

Dataset	F1	Error (SEM)
train	.7617	$\pm .0032$
validation	.7281	$\pm .0085$
test	.7368	$\pm .0091$

Table 2: F_1 scores by dataset. The reported F_1 score is the arithmetic mean of the F_1 scores for both classes.

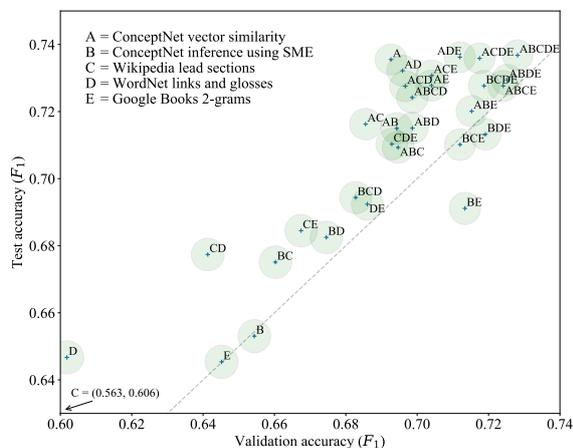

Figure 1: This ablation analysis shows the contributions of subsets of the five sources of features. Ellipses indicate standard error of the mean, assuming that the data is sampled from a larger, unseen set.

we experimented with a number of other classifiers. This included random forests, differentiable models made of multiple ReLU and sigmoid layers, and SVM with an RBF kernel or a polynomial kernel.

We also experimented with different parameters to LinearSVC, such as changing the default value of the penalty parameter C of the error term, changing the penalty from L_2 to L_1 , solving the primal optimization problem instead of the dual problem, and changing the loss from squared hinge to hinge. These changes either led to lower performance or had no significant effect, so in the end we used LinearSVC with the default parameters for scikit-learn version 0.19.1.

5 Results

When trained on the training set, the classifier we describe achieved an F_1 score of 0.7617 on the training set, 0.7281 on the validation set, and 0.7368 on the test set. Table 2 shows these scores along with their standard error of the mean, supposing that these data sets were randomly sampled from larger sets.

5.1 Ablation Analysis

We performed an ablation analysis to see what the contribution of each of our five sources of features was. We evaluated classifiers that used all non-empty subsets of these sources. Figure 1 plots the results of these 31 classifiers when evaluated on the validation set and the test set.

It is likely that the classifier with all five sources ($ABCDE$) performed the best overall. It is in a statistical tie ($p > .05$) with $ABDE$, the classifier that omits Wikipedia as a source.

Most of the classifiers performed better on the test set than on the validation set, as shown by the dotted line. Some simple classifiers with very few features performed particularly well on the test set. One surprisingly high-performing classifier was A (ConceptNet vector similarity), which gets a test F_1 score of 0.7355 ± 0.0091 . This is simple enough to be called a heuristic instead of a classifier, and we can express it in closed form. It is equivalent to this expression over ConceptNet Numberbatch embeddings:

$$\text{sim}(\text{term}_1, \text{att}) - \text{sim}(\text{term}_2, \text{att}) > 0.0961$$

where $\text{sim}(a, b) = \sqrt{\max\left(\frac{a \cdot b}{\|a\| \cdot \|b\|}, 0\right)}$.

It is interesting to note that source A (ConceptNet vector similarity) appears to dominate source B (ConceptNet SME) on the test data. SME led to improvements on the validation set, but on the test set, any classifier containing AB performs equal to or worse than the same classifier with B removed. This may indicate that the SME features were the most prone to overfitting, or that the validation set generally required making more difficult distinctions than the test set.

6 Reproducing These Results

The code for our classifier is available on GitHub at <https://github.com/LuminosoInsight/semEval-discriminatt>, and its input data is downloadable from <https://zenodo.org/record/1183358>.

³ Aix-Marseille University

Abstract

This paper describes BomJi, a supervised system for capturing discriminative attributes in word pairs (e.g. *yellow* as discriminative for *banana* over *watermelon*). The system relies on an XGB classifier trained on carefully engineered graph-, pattern- and word embedding-based features. It participated in the SemEval-2018 Task 10 on Capturing Discriminative Attributes, achieving an F1 score of 0.73 and ranking 2nd out of 26 participant systems.

1 Introduction

The recent introduction of popular software packages for training *neural word embeddings* (Mikolov et al., 2013a,b; Levy and Goldberg, 2014) has led to an increase of the number of studies dedicated to lexical similarity and to remarkable performance improvements on related tasks (Baroni et al., 2014).

However, the validity of similarity estimation as the only benchmark for semantic representations has been questioned, for several reasons. One for all, most evaluation datasets provide human-elicited similarity scores, with the consequences that the ratings are subjective and the performance of some automated systems is already above the upper bound of the inter-annotator agreement (Batchkarov et al., 2016; Faruqui et al., 2016; Santus et al., 2016a).

Originally proposed as an alternative benchmark for Distributional Semantic Models (DSMs), the Discriminative Attributes task focuses instead on the extraction of *semantic differences* between lexical meanings (Krebs and Paperno, 2016): given two words and an *attribute* (i.e., a discrete semantic feature), a system has to predict whether the attribute describes a difference between the corresponding concepts or not (e.g. *wing* is an attribute of *plane*, but not of *helicopter*).

Since even related words may differ for some non-shared attributes (e.g. hypernyms and hyponyms), the ability of automatically recognize discriminative features would be an extremely useful addition for the creation of ontologies and other types of lexical resources and would make machine decisions interpretable, enabling human validation (Biemann et al., 2018). Moreover, one can think to applications to many other NLP domains, such as machine translation and dialogue systems (Krebs and Paperno, 2016).

In the present contribution, we describe the BomJi classification system, which we used for the identification of discriminative features between concept pairs. According to the official evaluation results provided by the organizers¹, our system ranked second out of 26 participants. Our score, $F1 = 0.73$ lags slightly behind the best score of 0.75. After the evaluation period, we run further experiments including all investigated features and found that the system can achieve up to 0.75 F1 score.

2 Capturing Discriminative Attributes

2.1 Task and Dataset Description

The task of capturing discriminative attributes between words can be described as a binary classification task, in which the system has to assign a positive label if the feature is discriminative for the first concept over the second one, and a negative label otherwise.

In the test data, the first two words correspond to the concepts being compared (they are called, respectively, the *pivot* and the *comparison* term) and the third word is the feature, which could describe a discriminative attribute or not (some examples are shown in Table 1). In the paper, we will refer

¹<https://competitions.codalab.org/competitions/17326#results>

to the elements of the triples as w_1 , w_2 and $feat$.

A training and validation set have been provided for system development (figures in Table 2).

2.2 Embeddings and Graphs

For the Discriminative Attributes task, we combined word embeddings, patterns and information extracted from a graph-based distributional model.

Concerning the word embeddings, we used the vectors produced by two popular frameworks for word embeddings: Word2Vec (Mikolov et al., 2013a,b) and GloVe (Pennington et al., 2014).² The Word2Vec Skip-Gram architecture is a single-layer neural network, based on the dot-product between word vectors, in which the vector representation is optimized to predict the context of a target word given the word itself. The context generally consists of a word window of a fixed width around the target. The other framework, GloVe, is similar to traditional count models based on matrix factorization (Turney and Pantel, 2010; Baroni et al., 2014), in the sense that vectors are trained on global word-word co-occurrence counts. In the case of GloVe, the training objective is to learn word vectors such that their dot product equals the logarithm of the probability of the word to co-occur (Pennington et al., 2014).

As for graph-based information, we used the JoBimText architecture introduced by Biemann and Riedl (2013). In JoBimText, lexical items are represented as the set of their p most salient contexts, where the contexts are words connected to the target by a given syntactic link or by a lexical pattern, and saliency is defined as an association measure

²The pre-trained vectors are available, respectively, at <https://code.google.com/archive/p/word2vec/> (Google News, 300 dimensions) and at <https://nlp.stanford.edu/projects/glove/> (Common Crawl, 840B tokens, 300 dimensions).

between target and context, such as Positive Local Mutual Information (Evert, 2004). Differently from vector models, similarity between words in JoBimText is simply based on the overlap count of their common contexts.

Regarding patterns, first we extracted sentences where words and their features co-occur from a web-scale sentence-based index of English web (Panchenko et al., 2018) and then we extracted the patterns connecting our target words.

2.3 Methodology

The predictions submitted for the evaluation of Task 10 were obtained with a system that consists of a classifier, the Extreme Gradient Boosting (or XGBoost, Chen and Guestrin (2016)), trained on vectors aggregating carefully engineered graph-, pattern- and word embedding features.

In this section, we provide an overview of each feature type, leaving the discussion of their contribution to Section 3. The total of 55,026 features we used can be divided into five major groups.

CO-OCCURRENCE. Thirteen features related to word and word-feature frequency were calculated on the basis of the information extracted from a corpus of 3.2B words, corresponding to about 20% of the Common Crawl. For each word-feature combination (i.e. $w_1 - feat$ and $w_2 - feat$), we calculated: i) the co-occurrence count; ii) word count; iii) feature count; iv) Positive Pointwise Mutual Information (PPMI (Church and Hanks, 1990)) between each word and the feature; v) Positive Local Mutual Information (PLMI (Evert, 2004)) between each word and the feature. Further, we added three features representing the subtractions between the values of i), iv) and v) for the two word-feature combinations.

JOBIMTEXT. Another set of twenty-four features comes directly from JoBimText. They were calculated after extracting information through the public accessible JoBimText API³, which returns a JSON file containing - for every target - a sorted list of N features and their association scores (up to $N = 1,000$). As JoBimText distinguishes features according to their POS and dependency roles (i.e. features are in form WORD#POS#DEPENDENCY), a given $feat$ may appear multiple times in different POS-dependency combinations. However, we found that $feat$ rarely appears in the top N features

³See www.jobimtext.org

of w_1 and w_2 , so we calculated our features not only for the given targets (i.e. w_x), but also for the first among their top 10 neighbors for which $feat$ was found (i.e. $top(neighbor(w_x) \ni feat, max = 10)$) and the first among the top 10 $feat$ neighbors for which the target was found (i.e. $top(neighbor(feat) \ni w_x, max = 10)$). This allowed us to check also whether the neighbors of the given words were associated with the candidate discriminative attributes or *vice versa*. The features are defined as follows (here they are described only with reference to the query on w_x , but this should be generalized to the other cases):

- *prediction by rank*: it is 1 if $feat$ is ranked higher for w_1 than for w_2 , 0 otherwise;
- *prediction by score*: it is 1 if the total score between $w_1 - feat$ is higher than for $w_2 - feat$, 0 otherwise;
- *total score*: sum of the scores of $w_1 - feat$ if prediction by score is 1, of $w_2 - feat$ otherwise;
- *top rank*: top rank of $feat$ for w_1 if prediction by score is 1, for w_2 otherwise;
- *bottom rank*: last rank of $feat$ for w_1 if prediction by score is 1, for w_2 otherwise;
- *number of occurrences*: count of how many times a feature appears among the features of w_1 if prediction by score is 1, otherwise the occurrences among the features w_2 are counted;
- *which neighbor?*: integer showing whether the query was performed on w_1/w_2 (in this case it would be initialized to 0), or on its neighbors (in this case it would be initialized with the rank of the first neighbor where $feat$ was found);
- *which feat neighbor?*: integer showing whether the query was performed on w_1/w_2 (in this case it would be initialized to 0) or on the $feat$ neighbors (in this case it would be initialized with the rank of the first $feat$ neighbor where w_1 or w_2 was found).

WORD EMBEDDING FEATURES. Mikolov et al. (2013a) showed how vector offsets encode semantic information. We decided to include five features computed from either the Word2Vec or the Glove vectors, in order to take advantage of the offset information.

They are computed, respectively, as: $cos((w_1 - w_2), feat)$, $cos((w_1 - feat), (w_2 - feat))$, $cos((w_1 - feat), w_2)$, $cos((w_2 - feat), w_1)$. Finally, also the cosine between the word vectors (i.e. $cos((w_1, w_2))$) has been included.

WORD EMBEDDING VECTORS. These features are the simple concatenation of the three vectors of w_1 , w_2 and $feat$. Again, we have two

versions of these features, one for Word2Vec and one for Glove.

PATTERNS. In order to characterize the relation between words and features, we used an index to extract patterns occurring between them, independently of the order in which they appeared, and limited the maximum number of results to 10,000 sentences.

The patterns consist of sequences of either lemmatized tokens, POS or dependency tags, which are used to abstract from the surface form, thereby increasing the recall. Since the number of extracted patterns was far too high, we decided to use only patterns with a frequency higher than 100, obtaining a set of 53,136 items, using the observed pattern frequency per word pair as a predictor.

3 Experiments

3.1 Choosing the Training Set

During the practice phase, we noticed that the training set and the validation set show very different distributions. Running 5-fold cross validation experiments on either dataset, we obtained very high scores (sometimes close to 0.95). However, such scores did not generalize to the other dataset, where they dropped to about 0.60.

This was only partially due to lexical memorization (some lexemes were present in multiple triples of the same dataset, cf. Levy et al. (2015); Santus et al. (2016b)). In fact, investigating the frequency of the words in the triples, we found that, on average, in our index, the first and the second words, w_1 and w_2 , were about four times more frequent in the validation than in the training set (respectively 4.7M and 5.4M versus 0.9M and 1M); similarly, the third word (i.e. $feat$) was almost twice more frequent in the validation than in the training set (i.e. 3.9M versus 2.9M). When the test set was made available, we could verify that its frequency distribution resembled the one in the validation set, with the first and second words respectively at 3.3M and 2M, and the third at about 4.5M occurrences.

Given these differences, we have chosen to train our system only on the validation set, tuning the hyper-parameters by means of 5-fold cross validation. Because of its small size, we decided to train our second submission on a derived training set (henceforth New Validation), consisting of the 2,722 triples from the validation set plus 2,278 triples randomly extracted from the training, for a

	Feature Type	# Feat	Training/Test		Validation/Test		NewValidation/Test	
			<i>17547 vs. 2340</i>		<i>2722 vs 2340</i>		<i>5000 vs 2340</i>	
			F1	F1++	F1	F1++	F1	F1++
1	Co-occurrence	13	0.68	0.68	0.72	0.72	0.72	0.72
2	W2V Features	5	0.55	NA	0.66	NA	0.63	NA
3	W2V + Vectors	905	0.57	0.68 (1 & 3)	0.67	0.75 (1 & 3)	0.66	0.73 (1 & 3)
4	Glove Features	5	0.61	NA	0.66	NA	0.67	NA
5	Glove + Vectors	905	0.62	0.66 (1 & 5)	0.68	0.74 (1 & 5)	0.68	0.73 (1 & 5)
6	JoBim Features	24	0.53	0.68 (1 & 6) 0.67 (1, 3 & 6) 0.66 (1, 5 & 6)	0.62	0.74 (1 & 6) 0.75 (1, 3 & 6) <i>*0.74 (1, 5 & 6)</i>	0.62	0.74 (1 & 6) 0.75 (1, 3 & 6) <i>*0.73 (1, 5 & 6)</i>
7	Patterns	53176	0.56	0.67 (1, 3, 6 & 7) 0.67 (1, 5, 6 & 7) 0.68 (1, 3, 5, 6 & 7)	0.52	0.75 (1, 3, 6 & 7) 0.74 (1, 5, 6 & 7) 0.74 (1, 3, 5, 6 & 7)	0.51	0.71 (1, 3, 6 & 7) 0.69 (1, 5, 6 & 7) 0.69 (1, 3, 5, 6 & 7)

Table 3: Results both in absolute (F1) and in incremental terms (F1++: in brackets the features used to obtain the score) on the test set, organized by training set. In bold, we report the best results. In bold-italics, we report the submitted systems.

total of 5,000 samples. The use of different training data was the only difference between the two submissions.

3.2 Model Selection

During the practice phase, we performed experiments with several classifiers, including K-Neighbors (with $K = 3$), Decision Tree (with $max_depth = 5$), Random Forest (with $max_depth = 5$, $n_estimators = 10$ and $max_features = 1$), Multilayer Perceptron (with $alpha = 1$), AdaBoost and XGB (the latter two with default settings).

Before running the classifiers, we also used Linear Support Vector Classification (SVC) with $penalty = 'l1'$ and we tested several values of C (i.e. 0.05, 0.1, 0.25, 0.5, 1) for feature selection.

In almost all settings we found that the best performing classifiers were the Random Forest, the Multilayer Perceptron and, above all others, XGB. With respect to the value of C for the feature selection, instead, we noticed that it varied in relation to the feature types, with minor influence on the performance of XGB (+/-2%). In the final submission, therefore, we opted for removing this step from the pipeline and for keeping the full vector.

Concerning feature selection, we found that the pattern features had a neutral effect on the performance during cross validation. Similarly we noticed that Glove and Word2Vec performed comparably. Thus, we opted for submitting the output of the systems without using the pattern features and only Glove features (Word2Vec had lower coverage on the dataset). As it can be noticed in Table 3, however, this decision has slightly lowered the

performance of our system in the competition.

3.3 Feature Contribution

In order to measure the contribution of the features, we re-ran the experiments over the test set, after training our model on the three available sets: training, validation and new validation sets.

Results are reported in Table 3, in which it is easy to notice a few things: the performance is strongly related to the choice of the training set, with Validation being better than New Validation, which is in turn better than the original Training set; the thirteen co-occurrence features are those that provide the major contribution to the performance, reaching a F1 score of 0.72. Further useful features are the word embedding vectors (900 features), the word embedding features (5 features) and, to some extent, the information from JoBim-Text. Pattern-based features perform the worst, almost on par with random guessing.

The submitted systems do not correspond to the systems obtaining the best performance in post-evaluation experiments (see the bold and bold-italics scores in Table 3); this was due to the use of Glove instead of Word2Vec in our submitted systems, because none of the embedding models had an edge over the other in the validation process.

4 Conclusions

In this paper we have presented BomJi, a supervised system for capturing discriminative attributes in word pairs (e.g. *yellow* as discriminative for *banana* over *watermelon*). BomJi relies on an XGB classifier trained on carefully engineered

graph-, pattern- and word embedding-based features. In the paper we have reported the contribution for each features, discussing the model selection and showing that a major factor affecting the performance was the choice of the training data.

In the official Task 10 evaluation, our submitted systems achieved an F1 score of 0.73, ranking 2nd out of 26 participant systems.

Igevorse at SemEval-2018 Task 10: Exploring an Impact of Word Embeddings Concatenation for Capturing Discriminative Attributes

Maxim Grishin

Innopolis University

Innopolis, Russia

m.grishin@innopolis.ru

igevorse@gmail.com

Abstract

Semantic differences extraction is a challenging problem in Natural Language Processing and its solution is necessary for a realistic semantic representation as similarity information is not sufficient to capture individual aspects of meaning. This paper presents a comparison of several approaches for capturing discriminative attributes and considers an impact of concatenation of several word embeddings of different nature on the classification performance. A similarity-based method is proposed and compared with machine learning approaches. It is shown that this method outperforms others on all the considered word vector models and there is a performance increase when concatenated datasets are used.

1 Introduction

Detecting semantic similarity is done well by state-of-the-art models. However, if the model is only good at similarity detection, it would have a limited practical usage (Krebs et al., 2018), since the task of *understanding* the semantics of words cannot be done without capturing semantic differences.

Semantic difference is a ternary relation between two concepts (*apple, banana*) and a discriminative feature (*red*) that characterizes the first concept but not the other. Semantic difference detection is a binary classification task: given a triple (*apple, banana, red*), the task is to determine whether it exemplifies a semantic difference or not (Krebs et al., 2018). In this paper two concepts and a discriminative attribute *attr* are represented as ($word_1, word_2, attr$).

This research was done during the participation in "Capturing Discriminative Attributes" task of SemEval 2018 competition.

The paper is organized as follows. Section 2 describes the methods used. Section 3 shows the

results and analyzes them. Section 4 mentions future directions. Section 5 concludes the paper.

2 Methods

There were several approaches considered: classical machine learning algorithms and a similarity-based model.

2.1 Data Preparation

Dataset is provided by SemEval 2018 challenge organizers.

- The train set consists of 17501 automatically generated samples of the form ($word_1, word_2, attr, y$), where y is a binary target variable indicating whether *attr* is a discriminative attribute for $word_1$ and $word_2$. Classes are imbalanced: there are 63.83% samples for class 0 (not a discriminative attribute) and 36.16% for class 1 (is a discriminative attribute).
- The validation set contains 2722 manually curated samples of the same form. Classes are almost balanced: 50.1% of samples have class 0, 49.9% - class 1.
- There are 2340 samples in the test set, 55.3% for class 0, 44.7% for class 1.

Each triple ($word_1, word_2, attr$) was converted to a numeric vector using pre-trained word embeddings. These vectors form a vector space, such that words that share common contexts in the corpus are located in close proximity to one another in space.

Three word embedding models were used:

1. Google News (Mihltz, 2017) corpus word vector model (3 million 300-dimension English word vectors). The disadvantage of this

model is that despite having a lot of words, it includes misspellings and multiple cases of the same word (McCormick, 2017). Its vocabulary does not contain all words from the dataset, so 45 samples (1.27%) are missing.

2. Wikipedia 2014 + Gigaword 5 (Pennington et al., 2014) dataset has 400 thousand 300-dimension word vectors. It contains almost all words from the dataset: only 4 samples (0.11 %) are missing.
3. Concatenated word embeddings of different nature, i.e. collected on different corporas using different methods. It consists of concatenated word vectors from both Google News and Wikipedia models. Thus, each word is represented as a 600-dimensional vector.

The problem of missing words was solved by replacing them with another spelling or a synonym. For each triple $(word_1, word_2, attr)$ corresponding word vectors were concatenated, so each triple is converted to a 900-dimensional vector when using Google News or Wikipedia word vectors, and 1800-dimensional for concatenated word embeddings.

2.2 Machine Learning Approaches

There were several machine learning classification approaches chosen for comparison: logistic regression, stochastic gradient descent (SGD) classifier, k-nearest neighbors classifier and artificial neural network.

The best parameters that maximize F_1 score on the validation set:

- **Logistic regression** with L_2 regularization with regularization strength set to 10.
- **Stochastic gradient descent classifier** with perceptron loss and regularization term set to $1e-05$.
- **K-nearest neighbors** with $k = 1$ using Manhattan distance metric and weighting points by the inverse of their distance.
- The multilayer perceptron **neural network** model was built using Keras with TensorFlow as a backend. Structure of this network is described in Table 1.

Layer	# of inputs	Activation function
Input	900	-
Dense	128	tanh
Dense	64	relu
Dense	1	sigmoid

Table 1: Structure of the neural network.

2.3 Similarity-based Approach

Another approach is to derive an interpretable algorithm based on knowledge about word semantics. The intention is to use word similarities for distinguishing discriminative attributes while keeping the model as simple as possible. Cosine similarity between words a and b is represented as the cosine between corresponding word vectors A and B .

$$sim(a, b) = cos(A, B) = \frac{A \cdot B}{\|A\| \|B\|}.$$

For each given triple $(word_1, word_2, attr)$ similarities of $attr$ with $word_1$ and $attr$ with $word_2$ are computed. Then obtained similarities are compared using a threshold t . If the gap between them is big enough, i.e.

$$sim(word_1, attr) > sim(word_2, attr) + t,$$

$attr$ is treated as a discriminative attribute of $word_1$. It means that the $attr$ word vector is much closer to $word_1$ than to $word_2$ in vector space. Thus, this model has only one tunable hyperparameter: t . Dependency of F_1 score on the threshold is shown in Figure 1.

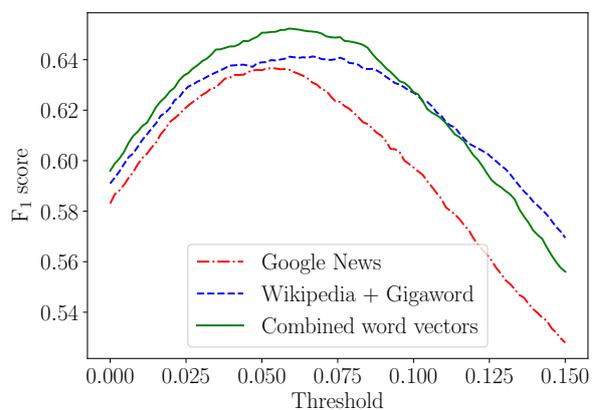

Figure 1: Dependency of F_1 score on the threshold in similarity-based model.

Model \ Embeddings	Google News	Wikipedia	Concatenated
K-nearest neighbors	0.4778	0.4832	0.4809
SGD classifier	0.5211	0.5036	0.5169
Logistic regression	0.4843	0.5036	0.5120
Neural network	0.5169	0.5625	0.5440
Similarity-based	0.6066	0.6126	0.6131

Table 2: Experimental results on the validation set (F_1 score).

3 Results and Discussions

3.1 Experimental Results

Models are evaluated on F_1 measure.

Figure 1 shows that the behavior of the similarity-based model is highly dependent on the selected word vectors model. Thresholds, learned from the train set for Google News, Wikipedia and concatenated word vectors are 0.053030, 0.066667 and 0.060606 correspondingly.

Experimental results on the validation set are presented in Table 2. K-nearest neighbors showed the worst F_1 score, while neural network is the best among machine learning methods. The proposed similarity-based method outperforms all other models on all considered word embeddings.

Word embeddings with the highest F_1 score on the validation set were chosen for the final comparison: Google News for SGD classifier, Wikipedia for k-nearest neighbors and neural network, concatenated embeddings for logistic regression and similarity-based model. The results on the test set are presented in Table 3. K-nearest neighbors has the smallest F_1 score. In contrast with the performance on the validation set, the result of neural network is noticeably worse, which means that overfitting took place. Logistic regression performed better than SGD classifier, while similarity-based method showed the highest score.

Model	Best F_1 score
K-nearest neighbors	0.502
SGD classifier	0.515
Logistic regression	0.527
Neural network	0.503
Similarity-based	0.646

Table 3: Experimental results on the test set.

3.2 Error Analysis

In this section error analysis of similarity-based model is provided. During the evaluation on the test set 65.5% of samples were classified correctly, while 34.5% were not. Predicted classes are imbalanced: 1436 (61.4%) samples were classified as 0 and 904 (38.6%) samples as 1.

Considering misclassified samples, 332 of them were assigned class 1 while it should have been 0, whereas 475 of them got label 0, when it should have got 1. As we can see, the model is more likely to consider attributes as non-discriminative.

108 distinct attributes (130 samples) were misclassified completely. 270 distinct attributes (480 samples) were classified 100% correctly. 70 attributes (180 samples) were classified 50% correctly.

Attributes could be divided in several categories. For example, there are attributes representing colors: 'black', 'brown', 'red', 'blue' and 'yellow'. It worth mentioning that 43.36% of samples with color attributes were misclassified, which is more than 34.5% of misclassified samples for the whole test set.

As can be seen from Table 4, other categories of attributes have 33.4% of misclassified samples.

Attribute	Misclassified	Total occurrences
Color	111 (43.36%)	256
Other	696 (33.4%)	2084
Total	807 (34.5%)	2340

Table 4: Error analysis of attribute categories.

4 Future Work

It was shown that there is a performance increase of the similarity-based model when concatenated word vectors are used. Training a Word2Vec model specifically for the task instead of using pre-trained models can solve the mentioned prob-

lem of missing words and multiple cases of the same word in word embeddings.

According to SemEval Task 10 organizers, training set contains noisy data, which was not verified by humans. Another potential improvement is training models only on validation dataset, since it was created manually and should not have noise.

It was discovered that samples with color attributes have higher misclassification rate than other samples. There are proposed solutions for learning discriminative properties of images (Lazaridou et al., 2016), which could be combined with a text-based approach to derive a multimodal classifier.

It also worth analyzing other categories of attributes and their misclassification rate.

5 Conclusion

This paper presents several approaches for capturing discriminative attributes. The main contribution is the proposed similarity-based method, which is interpretable and takes into account the semantic similarity of words. This method is compared with machine learning methods, such as Logistic regression, SGD classifier, KNN and Multi-layer perceptron neural network. Experiments on

three pre-trained word vector models show that similarity-based method outperforms others. It was discovered that concatenation of word embeddings of different nature leads to a quality improvement for several methods.

Abstract

This paper describes the system we submitted to Task 10 (Capturing Discriminative Attributes) in SemEval 2018. Given a triple ($word_1$, $word_2$, $attribute$), this task is to predict whether it exemplifies a semantic difference or not. We design and investigate several word embedding features, PMI features and WordNet features together with supervised machine learning methods to address this task. Officially released results show that our system ranks above average.

1 Introduction

The Capturing Discriminative Attributes task (Paperno et al., 2018) in SemEval 2018 is to provide a standard testbed for semantic difference detection, which will benefit many other applications in Natural Language Processing (NLP), such as automatized lexicography and machine translation (Krebs and Paperno, 2016). The goal of this task is to predict whether a word is a discriminative attribute between two concepts. Specifically, given two concepts and an attribute, the task is to predict whether the first concept has this attribute but the second concept does not. For example, given the concepts *apple* and *pineapple*, participants are required to predict whether the attribute *seeds* characterizes the first concept but not the other. In other words, semantic difference detection is a binary classification task: given a triple (*apple*, *pineapple*, *seeds*), the task is to determine whether it exemplifies a semantic difference or not, i.e., *positive* or *negative*. Table 1 shows more data examples.

If $word_1$ has a specific attribute but $word_2$ does not, then the correlation of attribute and $word_1$ should be higher than that of attribute and $word_2$. The semantic similarity is in the same way. In view of the above considerations, to address this task, we explore supervised machine learn-

$word_1$	$word_2$	attribute	label
apple	pineapple	seeds	positive
candle	chandelier	melts	positive
apple	coconut	brine	negative
apple	cucumber	seeds	negative

Table 1: Examples from the training data.

ing methods which use PMI features and WordNet features. In recent years, more and more studies have focused on word embeddings as an alternative to traditional hand-crafted features (Pennington et al., 2014; Tang et al., 2014). Therefore we use word embeddings to obtain the semantic similarity as word embedding features. Besides, we perform a series of experiments to explore the effectiveness of feature types and supervised machine learning algorithms.

2 System Description

To perform semantic difference detection of given triples, we adopt supervised learning algorithms with several features that represent semantic similarity and correlation. In the next paragraphs, we will introduce feature engineering and learning algorithms.

2.1 Feature Engineering

In this task, we design three types of features: WordNet features, PMI features and word embedding features.

2.1.1 WordNet Features

WordNet (Miller et al., 1990) is an on-line lexical reference system, which is organized by semantic properties of words. Therefore, the WordNet features are designed to utilize WordNet to obtain the semantic information.

Each word may have a number of different semantics, corresponding to different senses in the

WordNet. And the WordNet provides the definitions of the senses for each word. If a word is an attribute of the target word, the attribute word may appear in the sense definition of the target word. For example, a semantic definition of “snow” is “white crystals of frozen water” and “white” is the attribute of “snow” which appears in the above definition. Therefore, we design the following features to record the semantic information. Given the triple ($word_1$, $word_2$, $attribute$), we first load all senses definitions of $word_1$, $word_2$ and $attribute$. Then we implement four types of binary features: (1) whether $attribute$ appears in the senses definitions of $word_1$, (2) whether $attribute$ appears in the senses definitions of $word_2$, (3) whether $word_1$ appears in the senses definitions of $attribute$ and (4) whether $word_2$ appears in the senses definitions of $attribute$. As a result, we get four features.

2.1.2 PMI Features

Pointwise mutual information (PMI) (Church and Hanks, 1990) is a measure of association between two things used in information theory and statistics. And in NLP, this metric can be used to measure the correlation between two words. The higher the PMI, the stronger the correlation between the two words. So we obtain the PMI features of the given triple ($word_1$, $word_2$, $attribute$). We record the PMI value of $word_1$ and $attribute$ as well as the PMI value of $word_2$ and $attribute$ as PMI features. The PMI values we used are calculated using Wikimedia dumps¹ and directly obtained from SEMILAR (Rus et al., 2013). As a result, we get four PMI features.

2.1.3 Word Embedding Features

Word embedding is a continuous-valued vector representation for each word, which usually carries syntactic and semantic information. In this work, we employ two types of word embeddings which are pre-trained word vectors downloaded from Internet with dimensionality of 300: *GoogleW2V* (Mikolov et al., 2013) and *GloVe* (Pennington et al., 2014). The former is pre-trained on News domain, available in Google². And the latter is pre-trained on tweets, available in GloVe³.

- **WE_similarity:** Given the triple ($word_1$,

$word_2$, $attribute$), if $attribute$ characterizes $word_1$ rather than $word_2$, the semantic similarity score of $attribute$ and $word_1$ should be higher than that of $attribute$ and $word_2$. After acquiring the vectors of three words in the triple, we calculate the similarity scores of $attribute$ and $word_1$ as well as $attribute$ and $word_2$ using *cosine similarity* and *pearson coefficient*. Finally, we got four word embedding similarity features.

- **WE_operation:** In addition to the above similarity functions, we also explore two different ways of interaction between word vectors in order to capture the semantic information as much as possible. The operations between three vectors include *concatenation* and *subtraction*. Specifically, given the vectors V_1 , V_2 and V_a of the triple ($word_1$, $word_2$, $attribute$), the concatenation operation is to concatenate three vectors as $[V_1 \oplus V_2 \oplus V_a]$, and the subtraction operation is the element-wise subtraction of $attribute$ from $word_1$ and $word_2$ respectively, i.e., $[V_1 - V_a]$ and $[V_2 - V_a]$. Since we employ two types of word embeddings, finally, we get 3,000 dimensional vectors as word embedding operation features.

2.2 Learning Algorithm

We grant this task as a binary classification task and explore six supervised machine learning algorithms: Logistic Regression (LR) and Support Vector Machine (SVM) both implemented in Liblinear toolkit (Fan et al., 2008), Stochastic Gradient Descent (SGD), RandomForest and AdaBoost all implemented in scikit-learn tools (Pedregosa et al., 2011), and XGBoost⁴ provided in (Chen and Guestrin, 2016). All these algorithms are used with default parameters.

3 Experiments

3.1 Datasets

Table 2 shows the statistics and distributions of training, development, test data sets of this task provided by task organizers.

3.2 Evaluation Metric

To evaluate the system performance, the official evaluation criterion is *macro-averaged F1-score*,

²<https://code.google.com/archive/p/word2vec>

³<http://nlp.stanford.edu/projects/glove>

⁴<https://github.com/dmlc/xgboost>

Dataset	Positive	Negative	Total
train	6,330 (36%)	11,171 (64%)	17,501
dev	1,364 (50%)	1,358 (50%)	2,722
test	1,293 (55%)	1,047 (45%)	2,340

Table 2: The statistics of data sets in training, development and test data. The numbers in brackets are the percentages of different classes in each data set.

which is calculated among two classes (positive and negative) as follows:

$$F_{macro} = \frac{F_{Pos} + F_{Neg}}{2}$$

3.3 Experiments on Training Data

Firstly, in order to explore the effectiveness of each feature type, we perform a series of experiments. Table 3 lists the comparison of different contributions made by different features on development data with *Logistic Regression* algorithm. We observe the following findings.

(1) The simple PMI features and word embedding similarity features are effective for semantic difference detection and it shows the effectiveness of semantic similarity and correlation for semantic difference detection.

(2) The combination of the first three features not only achieves the best performance for the overall classification but also for each class. These three types of features make contributions to semantic difference detection task. Therefore we use these features in following experiments.

(3) The result of merging the *WE_operation* features is not as good as we expected and the possible reason is that the dimensionality of *WE_operation* features is quite huger than the other three features(3,000 Vs. 16), which dominates the performance of classification rather than other low dimension features. And the operations of word vectors are too simple to detect the semantic difference.

(4) The WordNet features are not as effective as expected, and the reason maybe that in many cases the attribute words do not appear in the sense definitions of concepts, so we can not get nonzero features.

Secondly, we also explore the performance of different supervised machine learning algorithms. Table 4 lists the comparison of different learning algorithms with *WordNet*, *PMI* and *WE_similarity* features. We find:

Features	F _{Pos}	F _{Neg}	F _{macro}
WordNet	0.683	0.237	0.459
.+PMI	0.653	0.598	0.625 (+0.166)
.+WE_similarity	0.684	0.64	0.662 (+0.037)
.+WE_operation	0.561	0.616	0.588 (-0.074)

Table 3: Performance of different features on development data in terms of F1-score. “.+” means to add current features to the previous feature set. The numbers in the brackets are the performance increments compared with the previous results.

(1) LR and SVM achieve better results than the other supervised machine learning algorithms and Logistic Regression algorithm achieves the best performance when considering single classification algorithm.

(2) The ensemble of the top 3 machine learning algorithms (LR + SVM + XGBoost) achieves high performance than any single learning algorithm, i.e., 0.663.

Algorithms	F _{Pos}	F _{Neg}	F _{macro}
LR	0.684	0.64	0.662
SVM	0.681	0.64	0.661
XGBoost	0.598	0.613	0.606
SGD	0.623	0.559	0.591
AdaBoost	0.631	0.551	0.591
RandomForest	0.565	0.607	0.586
Ensemble	0.683	0.643	0.663

Table 4: Performance of different learning algorithms on development data in terms of F1-score.

Based on the above results, the system configuration of our final submission is ensemble of LR, SVM and XGBoost algorithms with WordNet, PMI and WE_similarity features. The models are trained on both training and development data sets.

3.4 Results on Test Data

Table 5 shows the results of our system and the top-ranked systems provided by organizers for this semantic difference detection task. Compared with the top ranked systems, there is much room for improvement in our work. There are several possible reasons for this performance lag. First, the features we used are simple. We only record some semantic similarity information and correlations between words. More complex interactions of word vectors could be tried. Second, we only extract features from three words that need to

be classified and have not used some extended resources like the sentences returned from search engines when retrieving these words.

Team ID	F_{macro}
ECNU	0.67 (8)
SUNNYNLP	0.75 (1)
BomJi	0.73 (2)
NTU NLP Lab	0.73 (2)

Table 5: Performance of our system and the top-ranked systems. The numbers in the brackets are the official rankings.

4 Conclusion

In this paper, we extract WordNet features, PMI features and word embedding features from triples and adopt supervised machine learning algorithms to perform semantic difference detection. The system performance ranks above average. In future work, we consider to try more complex interactions of word vectors and use more web resources to capture semantic information.

Abstract

The "Capturing Discriminative Attributes" sharedtask is the tenth task, conjoint with SemEval2018. The task is to predict if a word can capture distinguishing attributes of one word from another. We use GloVe word embedding, pre-trained on openly sourced corpus for this task. A base representation is initially established over varied dimensions. These representations are evaluated based on validation scores over two models, first on an SVM based classifier and second on a one dimension CNN model. The scores are used to further develop the representation with vector combinations, by considering various distance measures. These measures correspond to offset vectors which are concatenated as features, mainly to improve upon the F1score, with the best accuracy. The features are then further tuned on the validation scores, to achieve highest F1score. Our evaluation narrowed down to two representations, classified on CNN models, having a total dimension length of 1204 & 1203 for the final submissions. Of the two, the latter feature representation delivered our best F1score of 0.658024 (as per [result](#)¹.)

1 Introduction

As famously quoted by firth "You shall know a word by the company it keeps" that is, the semantic information embedded in a representation can only be described by the words surrounding it. This can only get you somewhere when, company itself is unambiguous and a representation goes through capturing "hypothetically" every sense of the word over a corpus. The capturing discriminative attributes sharedtask, conducted with SemEval(2018) is a task proposed by alicia kerbs and denis paperno (2016). It describes, how lexical similarity may not be enough to access qualitatively, the semantic information for a multitude of tasks. Wherein they propose that, with this task, a

system can be modelled for effectively extracting certain semantic differences in the words for understanding the sense embedded within them. This is provided as a proof of concept dataset for this sharedtask, where a certain word is used to check if it can distinguish between a pair of words. The dataset in itself seems simple where, in the training set a label information for the two classes, positive or negative are provided making this a binary classification task.

The three words that are provided in each instance are given in the order as, a pivot word followed by a compare word and ending with a attribute or feature word, that may or may not be associated with the pivot word. Based on the last word it is decided, if that attribute word actually is a distinguishing feature that is able to discriminate the pivot word from that of the compare word. *e.g (apple,banana,red)* here apple is the pivot word, banana the compare word and red, the word which decides if this is a feature that can be associate with apple to distinguish it from banana. This is a rather oversimplified example to a human, as from a very young age we are taught to distinguish objects based on visual aid, which simplifies the task for us as we have embedded subconsciously to differentiate the fruits mainly based on their color or size. This information is seldom used to describe the fruits when illustrated in written form, thus lacking that visual form of information for a machine to make this judgment call, making it that much more difficult to take an informed decision. Their work is based on a method, that was presented by Lazaridou et al. (2016) for prediction of distinguishing feature with use of image as reference for visual discrimination attribute identification task, more prominently it was related to capturing of lexical information using offset vectors.

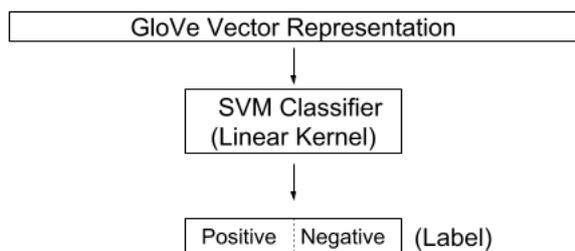

Figure 1: SVM architecture for feature representation.

2 Dataset

The dataset in the sharedtask2018 (Krebs and Paperno, 2018) is divided into three sets namely train test and validation. The training set contains automatically generated examples which are not manually curated. Whereas, the test and validation set are manually verified examples which include just over 5000 instances. The test set instances are made keeping in consideration that feature word overlap between the words in train and test are minimal. The validation set is similar to that of the test set and is used for parameter tuning of the models.

There are in total 17782 instances in the training set, 2722 in the validation set and 2340 in the test set. With the automated nature of the data, the training set is noisier in comparison to that of the validation and test set.

In the dataset, positive examples are annotated with the label '1', signifying that the attribute/feature word is a positive association only to the pivot word in the order presented and not vice versa. *e.g. (airplane, helicopter, wings)* here 'wings' is an attribute only associated to 'airplane', whereas *(helicopter, airplane, wings)* is an invalid entry. The combination of *(helicopter, airplane)* in this order will only be added if the concept 'helicopter' has a feature that airplane does not have in this set.

On the other hand, the negative examples are annotated with label '0' at the end. These are considered when the attribute/feature words are either similar to both pivot and the compare word or are dissimilar to them, *e.g. (Tractor, scooter, wheels), (Spider, elephant, legs) e.t.c.*

In the training dataset, there is a total of 508 unique concepts (pivot) words, of which 375 words have positive attributes and 505 of these have negative attributes, seeing the big contrast between the two labeled attributes we can infer that

not every concept word has an equal proportion of labeled instances.

W_p	Pivot word
W_c	Compare word

3 Methodology

Here discussed are methods which are considered in our implementation. On a cursory look at the dataset, we decided to go with a pre-trained representation of the words, rather than preparing a word embedded representation of the dataset. This is devised with a notion that, word pair associated models on this dataset would not help educate the

Table 3: Validation accuracy for varied dimension GloVe representation using CNN.

embedding. Further, using the pre-trained embeddings, the representation are evaluated based on validation accuracy with machine learning techniques like SVM, where we use ten fold ten cross with linear kernel for validation. This algorithm was earlier explored for sense disambiguation of a native language (Tamil), having rich feature representation presented in his work by Anand Kumar et al. (2014a), and is also implemented in his work (2014b). A simple one dimension convolution neural networks model is also illustrated upon, based on the works by Vinayakumar et al. (2017). The CNN model is fixed on an empirical method where the representation is convoluted with *twenty* filters, of size *three*, on a batch size of *sixty-four*, with activation ReLU over a wayward *ten* epochs, which are flattened and reduced to *thirty-two* and later to one at the final layer for evaluation. The architectures for the models, are as shown in Figure 1 & 2 respectively.

Moving ahead, a GloVe pre-trained word embed-

ding (Pennington et al., 2014) of various dimensions are considered, which is learned over public data, available under the PDDL.² (100, 300 dimension word representation, embedded over 6B, 840B sizes common crawl corpus are considered). The focus is on using one of these representations for our base method. Upon these embedding, various distance, dissimilarity and similarity measures are considered, to provide a measure between vectors or in our case between the words.

In Table 1, provided are abbreviations that we used through out the upcoming discussion regarding the methods and the representations. With the implementation of pre-trained vectors, we refer few vector measurement technique that could be used to measure a sense of semantic similarity among them. These vector carry within them a spacial correlation between words which has been discussed in their work by (Pennington et al.,

Table 5: Validation accuracy of 300 dimension, GloVe representations on 840B common crawl tokens using CNN.

2014).

Initially, a simple concatenation of the three words is considered as an instance, which are the pivot(W_p), compare(W_c) and attribute(W_a) words, for the entire dataset. The same representation is taken of two different dimensions lengths as mentioned earlier. Based on the model fit across training data, the validation accuracy and F1score are measured, these are as shown in Table 2. Similarly, these representations are also passed on to a convolution neural network, where their respective accuracy and F1scores are measured and shown in Table 3.

With an empirical approach, the representations are further extended by appending (W_a) to (W_p) and (W_c) sequentially and passing it to the two models(As shown by representation two in the Table 2). The SVM model did not show any significant improvement in the score, over the representations. In comparison, the CNN model observed a slight improvement in scores on the same representation. Word embedding being a vector representation in higher dimensional space, has proved (Pennington et al., 2014) to captures spatial information, that can be employed to use as features for the representation. This is exerted by using certain measures between the (W_p), (W_a) and (W_c), (W_a). These measures are cal-

culated using Scipy libraries (Jones et al., 2001) and Sklearn library (Pedregosa et al., 2011) to find the distance, similarity and dissimilarity measure between the two 1-D array words. The similarity of the two words indicates how similarly associated these words are, this measure is calculated using the cosine distance which is a scalar representation that signifies, larger the number between the two words the more similar they are. Whereas, the dissimilarity is the vice-versa of this measure. Of the various distance measures explored, we considered euclidean, chebyshev, squeueclidean, minkowski and for dissimilarity measures jaccard, kulsinski, Hamming and these are implemented using the Scipy (Jones et al., 2001) library. Amongst the measures considered, kulsinski dissimilarity gave the nearest disambiguation between the comparison of W_p, W_a and W_c, W_a , thus we chose it as the threshold measured for differentiating the representations between a positive and a negative instances i.e if the dissimilarity of W_c, W_a is greater than that of the W_p, W_a then the W_a were added to the W_p and concatenated to form a representation. Otherwise the second representation is considered where the W_a is subtracted from both the words. This is as shown in the first conditional representation (CR) of the Table 4.

The CR based representation accuracy decreased for SVM models. Whereas, the F1score and accuracy increased for the CNN model over the initial representations shown in Table 3. Thus, the further representation were improved on the CNN model to achieve better F1score with good accuracy. Comparing the two GloVe pre-trained vectors of 300 dimension for varied corpus size shown in Table 3, the 840B_300d trained model has achieved better F1score and accuracy compared to the other, thus moving along further with word embedding.

In Table 5 we see that subsequent representations, built upon the simple representation of CR1 are concatenated with kulsinski(Dis³) distance and Cosine similarity (Cos³) have improved the F1score. As show in the third representation, where the F1score increased to 53.1% with a considerable accuracy over the previous iteration. Further improvisation on CR1 representation with different features like correlation coefficient have increased the F1score to 56.8% but brought down the accuracy. Representation six is the next feature representation for which the accuracy, as well as the F1score, increases to 54.6% and 58.9% respectively. After many iterations of adding features, the representation eleven is the one that gave the highest F1score with the best accuracy, and this representation based model is submitted along with the representation ten, which also had good F1score, but a lower accuracy on the validation dataset.

4 Results & Conclusion

The tenth and eleventh representation of Table 5 are the two feature set based on CNN models, which are predicted on the test set and submitted for the competition. The results published for our models showed that the first set was scored at 0.52, where as the second set was scored at 0.66 for F1score. Comparing the predicted labels of the two systems with that of the gold standard, we see that our system fit over the tenth representation predicted correctly only 399 of 1293 as negative example and 855 of 1047 as the positive example. On the eleventh representation it gave 857 of 1293 and 687 of 1047 for negative and positive example respectively. Comparing the outcomes of the sys-

tems we see that majority of negative sample are mis-classified for system ten, on the other hand, the eleventh system improved upon this classification of the negative samples which increased the F1score for the system.

Abstract

We participated to the SemEval-2018 shared task on capturing discriminative attributes (Task 10) with a simple system that ranked 8th amongst the 26 teams that took part in the evaluation. Our final score was 0.67, which is competitive with the winning score of 0.75, particularly given that our system is a minimally supervised system that requires no training and minimal parameter optimisation. In addition to describing the submitted system, and discussing the implications of the relative success of such a system on this task, we also report on other, more complex models we experimented with.

1 Introduction and Background

Traditional evaluation tasks for semantic models have aimed to evaluate semantic relatedness (Bruni et al., 2014; Agirre et al., 2009) or similarity (Hill et al., 2014). More recently, analogy tasks (Mikolov et al., 2013; Gladkova et al., 2016; Abdou et al., 2018) have emerged in order to assess a model’s ability to correctly answer questions in the form of “a is to b as c is to ?” using vector arithmetic. However, these approaches are not sufficient in evaluating the semantic competence of any given model: there are numerous flaws with similarity and analogy-based evaluation, the most pressing being the lack of correlation with downstream performance in real-world tasks (Schnabel et al., 2015). Furthermore, though analogy questions can assess how well certain semantic relations are modeled (*country* : *capital*, *country*: *language*), this is arguably more of a measure of context co-occurrence than it is a testament to any semantic understanding.

Capturing Discriminative Attributes is a novel semantic evaluation task which aims to assess the extent to which semantic models can capture semantic *differences* between words. Particularly,

the task is concerned with identifying how well a given model represents attributes that discriminate between two related semantic concepts. For instance, given the terms *steak* and *salad*, **meat** would serve as a discriminative attribute, drawing a distinction between the former and latter as a quality that the two do not have in common.

2 Data

The data provided for this task was split between training and validation sections, with 17,500 and 2,721 samples comprising the former and latter, respectively. Every sample was composed of three terms (*pivot*, *comparison*, and *feature*) and their corresponding label $\in \{0, 1\}$. A sample was deemed as discriminative (label 1) if the *feature* served as an attribute that distinguished the *pivot* from the *comparison*. Otherwise, the sample was labeled as non-discriminative (0). Examples from the data are shown in Table 2. Please note that directionality is meaningful, i.e., swapping the *pivot* and *comparison* columns for the first two examples can change the label. For instance, *pink* is considered as discriminative for *pig* with regard to *sheep* (label is 1), but not the other way round (label would be 0). For a detailed description of the dataset, see (Krebs et al., 2018).

pivot	comparison	feature	label
sandwiches	breakfast	lunch	1
pig	sheep	pink	1
banana	raisin	round	0
uncle	father	male	0

Table 1: Samples of provided data. In the first two samples, the feature is discriminative (sandwiches are eaten at lunch; pigs are pink). In the last two, the feature is not discriminative (neither bananas nor raisins are round; an uncle and a father are both male).

It is important to note that only 5,000 instances were manually verified for consistency out of the combined training and validation datasets. Thus, whilst the entire validation set comprised of a subset of these verified samples (2,721), only 2,279 were represented in the training set (13%). Furthermore, the training set was heavily imbalanced towards negative (“non-discriminative”) samples, accounting for a total 11,171 out of 17,500 (63.8%). As such, we largely focused our experiments on the validation set, since it was comprised entirely of manually curated data.

3 Models

In all models we describe, words not present in the vocabulary of a vector-space model were assigned the same ‘unknown’ vector drawn randomly from a normal distribution.

3.1 Baseline

The baseline we constructed was a simple support-vector machine classifier. We converted each word into a vector from a vector-space model. For every 4-tuple example, we passed the concatenation of vectors of the three words as a feature with the fourth as a label. This model failed to learn sufficiently, performing at near-chance levels on the validation set for all vector-space models.

3.2 Neural Models

Another model (NN) that we investigated was a feed-forward network with the concatenation of the word vector representations as an input layer, and a single binary output neuron as the output. Ultimately, we employed three hidden layers of sizes 450, 200 and 100, with ReLU as the activation function for each, and 20% dropout between each layer. Our output function was a sigmoid function. We used binary cross-entropy loss with a learning rate of 10^{-5} and Adam (Kingma and Ba, 2014) as our stochastic optimization function. This model outperformed the baseline for all vector-space models on the validation set.

Our next model (NN-WN) was built on the intuition that representations of more descriptive elements than just words could prove to be more helpful. We therefore converted each word into its first matching definition in WordNet (Miller, 1995), and condensed this definition into a dimension 4096 representation using Conneau et al. (2017)’s BiLSTM-max pooling encoder which is

pre-trained on the *Stanford Natural Language Inference* dataset (Bowman et al., 2015). Similar to the previous model, this representation was passed to a feed-forward network, albeit with two hidden layers of sizes 1024 and 128 and sigmoid nonlinearities. We did not evaluate this model with every set of embeddings due to time constraints and disappointing initial results; evaluated on standard GloVe (840B) embeddings, the performance of this model on the validation set was slightly lower than the feed-forward network (NN) (when utilizing the same vector-space model).

3.3 Discriminator

Our final submitted system (**Discriminator**), unlike any of our other models, consisted of a surprisingly simple set of rules which were designed to leverage the information encoded in distributional semantic vector-space models (VSM) for the purpose of classifying an attribute as discriminative or non-discriminative. We relied on the widely-used metric of cosine similarity; we measured the cosine similarities between the vector assigned to the *pivot* (word 1), *comparison* (word 2), and *feature* (word 3) in a given VSM. Words not found in the VSM were assigned the vector for the UNK token. Our algorithm is summarized in Algorithm 1.

Algorithm 1 Classification algorithm

```

1: procedure CLASSIFY( $w$ )
2:    $s_{12} \leftarrow \text{SIM}(w_1, w_2)$ 
3:    $s_{13} \leftarrow \text{SIM}(w_1, w_3)$ 
4:    $s_{23} \leftarrow \text{SIM}(w_2, w_3)$ 
5:   if  $s_{13} - s_{23} > 0.015 \ \& \ s_{12} > 0.30 \ \& \ s_{13} >$ 
       $0.1 \ \& \ s_{23} < 0.54$  then
6:     return 1
7:   else
8:     return 0

```

These thresholds were obtained via grid-search over both the training data and validation data, per VSM. The range of evaluated thresholds was between 0 and 0.50, with strides of 0.02. Besides choice of VSM, these thresholds were the only variable parameters in our model. The VSM used in our final submission consisted of an average of three sets of embeddings: GloVe word embeddings trained on Common Crawl (840B tokens) (Pennington et al., 2014), the same GloVe embeddings post counter-fitting (Mrkšić et al., 2016) using data from the training and valida-

tion sets, and Paragram_{sl999} embeddings provided by Wieting et al. (2015), also post counter-fitting. Counter-fitting is detailed in Section 4.2. The VSM obtained by averaging these three models (AvgVSM) outperformed each individual VSM, and was therefore submitted as our official system.

4 Model Variations

4.1 Distributional Vector-Space models

In the course of our investigation we tested a large number of vector-space models which were generated using different methods. All VSMs were evaluated with each of our models and with our final system in order to determine the model which best encodes the discriminative information required for this task. Below is a description of all VSMs we tried:

- (a) Skipgram embeddings trained on the Google News Corpus (Mikolov et al., 2013).
- (b) Glove embeddings trained on Common Crawl (6B and 840B tokens).
- (c) LexVec embeddings trained on Common Crawl (58B tokens) (Salle et al., 2016).
- (d) Paragram embeddings trained on English Wikipedia¹ and tuned on SimLex-999.
- (e) Items (b) (840B), (c), and (d) counter-fitted using the training and validation sets.
- (f) AvgVSM: Average of three models cf. Section 3.3.

4.2 Counter-fitting

Counter-fitting is a method of post-processing VSMs to adapt them to certain linguistic constraints such as information from semantic lexicons or ontologies. Mrkšić et al. (2016) for instance, successfully used counter-fitting with semantic lexicons to achieve a new state of the art on the SimLex-999 similarity judgment dataset.

We employed counter-fitting to move pivot and comparison vectors (from the training set)² closer together in the vector-space for all training and validation examples with label 1, under the rationale that pivot and comparison words should be related for a feature to be considered discriminative.

¹December 2, 2013 snapshot

²The lexicon used for counter fitting can be found at <https://github.com/rutrastone/discrimemb>

4.3 kNN Averaging

In evaluating VSMs, we experimented with words outside of the *pivot*, *comparison*, *feature* triples that occurred in the data. For all three words, we extracted the respective k -nearest neighbors ($k \in \{5, 10, 20\}$) and averaged their corresponding vectors. This was motivated by the intuition that it is not just the *pivot*, *comparison* pairs that determine a discriminative feature distance threshold, but also their general semantic neighborhoods. As in the main approach, we computed cosine difference thresholds via grid search for a variety of *term-neighborhood*, *neighborhood-neighborhood* combinations. Unfortunately, this approach brought marginal improvements (when tested on the validation set) at best under any configuration of thresholds, models, etc. and was thus discarded in favor of the much more lightweight **Discriminator** model.

4.4 Hierarchical Vector-Space models

Poincaré embeddings (Nickel and Kiela, 2017) are a new approach to learning representations for datasets with a latent hierarchal structure. By learning embeddings in hyperbolic spaces instead of euclidean vector spaces using an algorithm based on Riemannian optimization, this method has been shown to outperform Euclidean embeddings on datasets with latent hierarchies, such as HYPERLEX (Véronis, 2004), a dataset used to evaluate if semantic models can capture hyponymy-hypernymy or lexical entailment relationships. This can be seen as closely related to capturing concept attribute relationships, as is required in this task. We used two different sets:

- Size 50 embeddings, trained on the all WordNet common-noun hypernyms, provided by Nickel and Kiela (2017)³;
- Size 50 embeddings trained on all feature norm derived concept-attribute pairs (i.e. all pivot-feature pairs when label is 1).

Since there was no overlap between the features in the training and testing sets, this method was not of immediate use for the task, as it could not account for the features in the test set. Therefore, our objective was solely to measure the embedding method’s effectiveness in modeling the dataset’s

³<https://github.com/TatsuyaShirakawa/poincare-embedding>

VSM	NN (T)	Dsc. (T)	Dsc. (V)
Skipgram	55.00	65.42	64.62
GloVe (6B)	55.38	66.06	64.30

Poincare (FN)	57.22	62.29	56.91
AvgVSM	58.63	67.01	68.21

Table 2: Performance of different Vector-space models on the official test set (T) and the validation set (V).

concept-attribute relations. To achieve this, we trained it on attribute concept pairs extracted from the feature norms which were used to build the task’s dataset (McRae et al., 2005; Krebs et al., 2018). Since the use of feature norms was not permitted in this shared task, the results from this method were not submitted.

5 Results and Discussion

We report the performance of all vector-space models for each classification system in Table 2. The NN model is trained on the validation set⁴ and all results for both models are reported on the official test set. Validation set results are only reported for the Discriminator models as the NN model fails to learn when training on the training set and testing on the validation set.

5.1 Discriminator

Considering its simple architecture, our system’s performance was remarkable. Using nothing but cosine similarity, it performed on a level that is well above our far more complex models, and competitive with the task’s best performing systems. This is demonstrative of two things: a) the information required to classify an attribute as discriminative or not with respect to two concepts is (to different extents) present in the distributional vector-space models, and b) the concatenation of the vectors associated with each word is not a sufficient feature for our trained models to learn the simple thresholds which our final model uses. We hypothesize that this is because concatenation fails

⁴While larger, the training set is very noisy.

to account for the interactions between the *pivot*, *comparison*, and *feature*. Further investigation is needed to assert this.

5.2 Vector-space models

Examining the degree to which different VSM could capture whether an attribute is discriminative was one of our main goals. Our initial intuition was that the relationship between concept and attribute is too specific to be adequately captured by distributional vector-space models which are, after all, based only on co-occurrence. Our results, however, contradict this expectation, showing that they are, to a certain extent, successful. For Discriminator, the best performing vector-space model was AvgVSM.

Furthermore, we found that counter-fitting using the training and validation sets did not prove effective, leading to a degradation in performance, with the exception of LexVec-cf when it did lead to improvements and AvgVSM when it was averaged with non-counter-fit models. Further investigation is required to determine exactly under what conditions counter-fitting works well.

Finally, we note that the WordNet-trained Poincaré hierarchical vector-space model had low coverage and performed poorly. However, the model trained on feature norms showed promise, particularly as it required far less space, training time, and data in order to model the dataset when compared to the distributional models.

6 Conclusion and Future work

In this paper we present Discriminator, our contribution to *SemEval 2018 Task 10: Capturing Discriminative Attributes*. Though this model is simple and does not require any training, our minimally supervised thresholding system achieved a score of 0.67, which was 0.08% below the top submitted system. We found the average of GloVe (840B), GloVe counter-fitted, and Paragram_{sl999} counter-fitted vector-space models to achieve best performance in our system, out of a set of 8 different models. Future work will explore leveraging image-processing inspired models, given the intuition that such methods have the ability to capture attributes-concept relations. Preliminary work with a 2D convolutional architecture, where different sets of word embeddings serve as channels in the feature space, has shown promise.

Abstract

In this paper we present three unsupervised models for capturing discriminative attributes based on information from word embeddings, WordNet, and sentence-level word co-occurrence frequency. We show that, of these approaches, the simple approach based on word co-occurrence performs best. We further consider supervised and unsupervised approaches to combining information from these models, but these approaches do not improve on the word co-occurrence model.

1 Introduction

In the task of capturing discriminative attributes, a system is presented with three words, and must determine whether the third word — the attribute — characterizes the first word, but not the second. For example, for the triple (*chicken, bread, legs*), *legs* is a discriminative attribute because chickens typically have legs, but bread typically does not. On the other hand, for the triple (*mother, woman, female*), *female* is not a discriminative attribute because both mothers and women are typically female. In the case of the triple (*brush, chocolate, chicken*), *chicken* is not a discriminative attribute because there is no clear relationship between chicken and brushes, or between chicken and chocolate.

In this paper we focus primarily on unsupervised approaches to the task of capturing discriminative attributes. We consider three unsupervised models drawing on information from word embeddings, WordNet (Fellbaum, 1998), and sentence-level word co-occurrence frequency. We then consider three approaches to combining information from these models: one unsupervised majority vote approach, and two supervised approaches. Somewhat surprisingly, we achieve our best F1 score of 0.61 with the remarkably simple approach

based on word co-occurrence. None of the approaches to model combination improve over this.

2 Base models

In this section, we discuss three unsupervised models for identifying discriminative attributes that incorporate information from word embeddings, WordNet, and word co-occurrences. We refer to these models as “base models”. In Section 3 we describe unsupervised and supervised approaches to combining these base models. Throughout the description of our models we refer to the words in the triples in the dataset as *word1*, *word2*, and *attribute*, respectively.

2.1 Word2vec

If an attribute is a discriminative attribute for *word1*, then we hypothesize that *word1* and the attribute will be more semantically similar than *word2* and the attribute. We use similarity of word embeddings as a proxy for semantic similarity.

We train word2vec’s skip-gram model (Mikolov et al., 2013) on a snapshot of English Wikipedia from 1 September 2015 containing roughly 2.6 billion tokens, tokenized using the tokenizer available in the Stanford CoreNLP tools (Manning et al., 2014).¹ We use a window size of ± 8 and 300 dimensions. We remove all words that occur less than 15 times in the corpus. We did not set a maximum vocabulary size. We train our model using negative sampling, and set the number of training epochs to 5.

We then calculate the cosine similarity between the word embeddings for *word1* and the attribute ($\cos(\text{word1}, \text{attribute})$), and *word2* and the attribute ($\cos(\text{word2}, \text{attribute})$). We label the instance as a discriminative at-

¹<http://nlp.stanford.edu/software/corenlp.shtml>

tribute if $\cos(\text{word1}, \text{attribute})$ is greater than $\cos(\text{word2}, \text{attribute})$.

2.2 WordNet

In this approach we again hypothesize that if an attribute is a discriminative attribute for word1, then word1 and the attribute will be more similar than word2 and the attribute. Here, however, we take an approach loosely inspired by (Lesk, 1986) and (Banerjee and Pedersen, 2002), and measure similarity based on word overlap in definitions, and information available through various lexical relations, in WordNet (Fellbaum, 1998).

For each of word1, word2, and the attribute, we represent that word by a set of words that includes, for each synset for the word, all lemmas in each synset, and all words in the definition and example sentences in each synset.² We then optionally also include the same information — i.e., the lemmas, and the words in the definition and example sentences — for hypernyms up to level three, and meronyms. Casefolding was applied to all words in the sets of words representing word1, word2, and the attribute.

An instance is labeled as a discriminative attribute if the size of the intersection of the set of words representing word1 and the set of words representing the attribute is greater than the intersection of the set of words representing word2 and the set of words representing the attribute.

We considered various configurations of this model, differing with respect to the level of hypernyms considered, and whether meronyms were included, for word1, word2, or the attribute. The specific configurations considered, and their average F1 score on the validation data, are shown in Table 1. In subsequent experiments we only use the configuration found to perform best in Table 1.

2.3 Word co-occurrence

We hypothesize that if an attribute is a discriminative attribute for word1, then word1 and the attribute will co-occur more frequently than word2 and the attribute. Various definitions of co-occurrence could be used to operationalize this, for example, co-occurrence within a window of $\pm n$ words, a sentence, or a document. In this preliminary work we consider co-occurrence within a sentence.

²We tokenize the definitions and example sentences using a simple regular expression-based tokenizer, and exclude stopwords.

We calculate sentence-level co-occurrences for each pair of (word1,attribute) and (word2,attribute) in the provided shared task datasets using the ukWaC (Ferraresi et al., 2008), a corpus of roughly 1.9 billion tokens automatically constructed from a web crawl of the .uk domain. This model then predicts that an attribute is a discriminative attribute if the number of sentences in which word1 and the attribute co-occur is greater than the number of sentences in which word2 and the attribute co-occur. Based on its performance on the validation data (see Section 4), this model was submitted as one of our two official runs.

3 Combined models

In this section, we consider one unsupervised, and two supervised, approaches to combining the individual models discussed in Section 2.

3.1 Majority vote

In this unsupervised approach we use a majority vote of the output of the word2vec, WordNet, and word co-occurrence models. We label an attribute as a discriminative attribute if at least two of the three models predict that it is. This approach was submitted as our second official run, again based on its performance over the validation data (see Section 4), and because we are particularly interested in unsupervised approaches to this task.

3.2 Supervised: output

In this supervised approach, we represent each instance as a vector of three binary features, corresponding to the output of the word2vec, WordNet, and word co-occurrence models. We then train a logistic regression classifier on these representations of the instances. Specifically, we use the logistic regression implementation available in scikit-learn (Pedregosa et al., 2011), with l2 normalization using the liblinear solver for a maximum of 100 iterations and a stopping criteria of 0.0001.

3.3 Supervised: features

In this supervised approach we use a total of 8 features that are based on the information used by the word2vec, WordNet, and word co-occurrence models. The following features are used:

1. the cosine similarity between the word embeddings for word1 and the attribute, based

Synsets	Hypernymy level 1	Hypernymy level 2	Hypernymy level 3	Meronymy	Validation average F1
w1,w2,att	w1,w2,att	w1,w2,att	w1,w2,att	w1,w2,att	0.544
w1,w2,att	w1,w2	w1,w2	w1,w2	w1,w2	0.566
w1,w2,att	w1,w2	w1,w2	w1,w2	w1	0.567
w1,w2,att	w1,w2			w1,w2	0.565
w1,w2,att	w1				0.553
w1,w2,att					0.553

Table 1: F1 score on the validation data for the WordNet method. Each row corresponds to a different configuration for this model, with information for word1 (w1), word2 (w2), and the attribute (att) taken from the indicated relations in WordNet. The best F1 is indicated in boldface.

- on the word2vec approach (Section 2.1);
- the cosine similarity between the word embeddings for word2 and the attribute;
 - the size of the intersection between the set of words representing word1 and the set of words representing the attribute, as formed for the WordNet approach (Section 2.2);
 - the size of the intersection between the set of words representing word2 and the set of words representing the attribute;
 - 3–4, i.e., the difference between the previous two features;
 - the number of times word1 and the attribute co-occur, using the sentence-level approach to co-occurrence (Section 2.3);
 - the number of times word2 and the attribute co-occur;
 - 6–7, i.e., the difference between the previous two features.

Similarly to the supervised: output approach (Section 3.2), we train a logistic regression classifier (using the same settings as for that model) on these representations of the instances.

4 Results

Table 2, shows the average F1 score for each of our models on the validation and test sets. For the test set, the supervised models (supervised: output and supervised: features) were trained on the validation data, and tested on the test set; for the validation data, results for the supervised models are for 10-fold cross-validation.³

³We did not use the training data, which was not constructed in the same way as the test data, for training our

Model	Average F1	
	Validation	Test
Word2vec	0.57	0.58
WordNet	0.57	0.56
✓ Word co-occurrence	0.61	0.61
✓ Majority vote	0.60	0.61
Supervised: output	0.59	0.61
Supervised: features	0.60	0.59

Table 2: Average F1 score for each of our models on the validation and test sets. Officially submitted runs are indicated with checkmarks. The highest F1 for each dataset is shown in boldface.

On the validation data, the word co-occurrence model achieved the highest F1 of the base models of 0.61, and indeed the highest F1 overall; none of the approaches to combining information from the base models (i.e., majority vote, supervised: output, or supervised: features) improved over the word co-occurrence model. The word co-occurrence model was therefore submitted as an official run. The majority vote and supervised: features models achieved the next best F1 of 0.60. Keeping with our primary interest of exploring unsupervised approaches to this task, the majority vote model was selected as our second official run.

Turning to results on the test set, the word co-occurrence, majority vote, and supervised: output models all achieved the highest F1 of 0.61. That the word-cooccurrence model outperforms the other two base models — word2vec and WordNet — shows that sentence-level word co-occurrence is more informative about discriminative attributes than the information carried by

supervised models. In preliminary experiments we considered models trained on the training data, and tested on the validation data, but found the performance to be relatively poor.

word embeddings and the information available in WordNet, at least as it has been incorporated in these models. That none of the combined models is able to improve on the best base model suggests that, although these models are based on very different sources of information, they are not complementary.

5 Conclusions

In this paper we evaluated three unsupervised models for capturing discriminative attributes based on information from word embeddings, WordNet, and sentence-level word co-occurrence frequency. Surprisingly we found that the simple approach based on word co-occurrence performed best. We further considered supervised and unsupervised approaches to combining information from these models, but were unable to improve on the word co-occurrence model.

In future work, because of its relatively good performance, we intend to further explore the word co-occurrence model. In this work we only considered sentence-level co-occurrence. In future work we intend to consider other definitions of co-occurrence, such as co-occurrence within a window of $\pm n$ words, and document-level co-occurrence. We also only considered raw frequency in the word co-occurrence model. As an alternative to this, we also intend to consider using various lexical association measures, such as pointwise mutual information (Church and Hanks, 1990) and log-likelihood ratio (Dunning, 1993). In a similar vein, we also intend to explore the impact of the window size and number of dimensions on the word2vec model. Finally, we intend to consider other WordNet-based measures of similarity (e.g., Resnik, 1995; Jiang and Conrath, 1997).

Abstract

This paper describes the system that we submitted for SemEval-2018 task 10: capturing discriminative attributes. Our system is built upon a simple idea of measuring the attribute word's similarity with each of the two semantically similar words, based on an extended word embedding method and WordNet. Instead of computing the similarities between the attribute and semantically similar words by using standard word embeddings, we propose a novel method that combines word and context embeddings which can better measure similarities. Our model is simple and effective, which achieves an average F1 score of 0.62 on the test set.

1 Introduction

Capturing discriminative attributes is a novel task, which is very different from classical semantic tasks that model similarities in semantics. The task aims to recognise semantic differences between words. Traditional semantic similarity evaluation tasks were designed for evaluating the quality of word representations based on the fact that words with similar semantics will be close to each other in vector space. Recent state-of-the-art distributed semantic models (Ling et al., 2015; Bojanowski et al., 2017) inspired by the success of word2vec (Mikolov et al., 2013) gave good performance in these similarity measure tasks. Nevertheless, how to capture discriminative attributes between semantically similar words is still a challenge for traditional word embedding methods, because these methods are designed to capture similar semantics.

We have two observations for the nature of the task and the provided data: (1) only limited data is available for model training; (2) the inputs of the model are merely isolated words themselves, which lack context information for apply-

ing complex models. Therefore, we propose a novel framework that differentiates two semantically similar words with the attribute word by using their word and context embeddings. We experimented with both Continuous Bag of Words (CBOW) and Skip-gram, demonstrating that using the combination of word and context embeddings outperforms using word embeddings alone.

The contribution of this work can be summarised as follows. We examine word and context embeddings in CBOW and Skip-gram, showing that using both word and context embeddings can better measure the co-occurrence of two words in sentences than simply using word embeddings. Hence our similarity measure can recognise the discriminative attributes of two semantically similar words more accurately.

2 System Description

Our system is trained based on word and context embedding features as well as WordNet features (Fellbaum, 1998). Before introducing our framework in detail, we first introduce the two key technical parts of our framework, i.e., context embedding and WordNet.

2.1 Context embeddings

In contrast to simply using traditional word embeddings which model semantic similarities based on contextual similarities, we consider using both word and context embeddings. Word and context embeddings are the vectors of target words and context words in CBOW and Skip-gram. Using them together can model the co-occurrence of attribute words and distinguished words in a sentence, which is useful in predicting whether the attribute word can distinguish two semantically similar words.

Take the Skip-gram model as an example. Skip-gram uses a neural network with a single hidden

layer of neurons. Given a target word, the objective function is to maximize the probability of predicting each context word (several words before and after the target word in a training sentence) (Rong, 2014):

$$\arg \max p(w_c|w_t) \quad (1)$$

where w_t is a target word in a training sentence, w_c is a context word of w_t , appearing within the same sentence.

During every training epoch on each context word, the weight matrices before and after the hidden layer will be updated. A row vector in the matrix before the hidden layer is a traditional word embedding v_t , as the vector is updated when the corresponding word w_t is in the target word position. A column vector in the matrix after the hidden layer is defined as context embedding v_c , as the column vector is updated when the corresponding word w_c is in the context word position. Each word has two vectors, v_t and v_c , as each word can be a target word or a context word of other target words. Some popular toolkits, e.g., gensim word2vec (Řehůřek and Sojka, 2010), abandon Skip-gram’s context embeddings v_c after training, as experimental research (Nalisnick et al., 2016) proves that simply using v_t or v_c (IN-IN or OUT-OUT in the original paper) for two function or type similar words to measure their similarity yields higher scores.

Actually, the conditional probability in the objective function in Eq. 1 can be expanded as:

$$p(w_c|w_t) = \frac{\exp(v_t \cdot v_c)}{\sum_{i \in |V|} \exp(v_t \cdot v_i)} \quad (2)$$

where V is the vocabulary of the training set, the dot product $v_t \cdot v_c$ in numerator computes the similarity between the target word vector and the context word vector. The denominator is to normalise the similarity into a probability. Thus, given a target word, training the whole model involves updating the matrices before and after the hidden layer to maximize the probability of predicting the context word. This is similar to maximizing the similarity between the target word embeddings v_t and context word embeddings v_c . It means that if we can reuse this trained similarity measure, to compute e.g., cosine similarity, then we will get a much better result. In other words, using both the word and context embeddings of two words that frequently appeared within each other’s contexts

will result in a better similarity measure, which may be incorporating the co-occurrence information of the two words.

CBOW can be considered as the reverse of Skip-gram. Given a context, the target is to maximize the probability of predicting the target word appearing in the context. Later, we will examine both CBOW and Skip-gram’s word and context embeddings in our model.

2.2 Word definition in WordNet

We also introduce features based on word sense definitions in WordNet (Fellbaum, 1998), considering the differences between the definitions of two semantically similar words. The two words may be similar in semantics, but different in definitions. An eligible discriminative attribute word may have high possibility to appear within one of the two word definitions, rather than both of them. For example, *ears* can distinguish *corn* and *broccoli*, as in WordNet, *ears* occurs in the definition of *corn* as “*tall annual cereal grass bearing kernels on large ears: widely cultivated in America in many varieties; the principal cereal in Mexico and Central and South America since pre-Columbian times*”, rather than *broccoli*’s definition that “*plant with dense clusters of tight green flower buds*”. We will also capture such characters to distinguish two words.

2.3 Hypothesis and framework

Our first hypothesis is that an attribute word w_A can distinguish two semantically similar words w_1 and w_2 , if the attribute word co-occurs much more frequently with one word than the other in the corpora. In vector space, the attribute word can be closer to a distinguished word than the other one. Our second hypothesis is that if w_A can distinguish w_1 and w_2 , w_A may appear within one of the definitions of w_1 and w_2 in WordNet.

The framework of our model can be summarized as: (1) we firstly train word embeddings v_t and context embeddings v_c on a Wikipedia dump. (2) Given a triple (w_1, w_2, w_A) , we then compute w_A ’s cosine similarities with w_1 and w_2 , and the difference in their similarities, which are used as three input features in the following classifications. For example, given the context embeddings of w_1 and w_2 and the word embedding of w_A , we compute Feature 1: $\text{cosine}(v_c^{w_1}, v_t^{w_A})$; Feature 2: $\text{cosine}(v_c^{w_2}, v_t^{w_A})$; and Feature 3: $|\text{cosine}(v_c^{w_1}, v_t^{w_A}) - \text{cosine}(v_c^{w_2}, v_t^{w_A})|$, respec-

1	$\text{cosine}(w_1, w_A)$
2	$\text{cosine}(w_2, w_A)$
3	$ \text{cosine}(w_1, w_A) - \text{cosine}(w_2, w_A) $
4	binary variable, indicating if w_A appears in the WordNet definitions of w_1
5	binary variable, indicating if w_A appears in the WordNet definitions of w_2

Table 1: Feature descriptions.

tively. (3) Next, we introduce two binary features to indicate whether w_A appears in any sense definitions of w_1 and w_2 in WordNet (Feature 4 and 5), respectively. (4) We train a random forest classifier with the above five features (see Table 1) to classify if the attribute word w_A can distinguish two semantically similar words w_1 and w_2 .

3 Experimental Settings

Data. The data was provided by the organizers of SemEval 2018 Task 10: Capturing Discriminative Attributes¹. There are 17,501, 2,722 and 2,340 triples (w_1, w_2, w_A) in training, validation and testing sets, respectively. All the words in the triples are nouns. Note that the discriminative attribute words w_A in the given dataset are selected, because they represent the visual attribute of one of two semantically similar words. For example, *red* can differentiate *apple* and *banana*, because visually, apple is red, while banana is yellow. The task does not consider other discriminative features, such as sound and taste. So, using image features may take advantages in this dataset, however, semantic features can also capture invisible discriminative attributes.

Word and context embedding. We first iteratively train 300 dimensional word and context embeddings based on CBOW and Skip-gram with a Wikipedia dump² for 3 epochs respectively, setting a context window of 5 words before and after the target word. Words with frequency less than 5 in the Wikipedia are ignored. The down sampling rate is 10^{-4} .

Based on CBOW and Skip-gram, we test all possible combinations of word and context embeddings to compute cosine similarities. The first combination is context embeddings of the two semantically similar words w_1 and w_2 , and word embeddings of the attribute word w_A . In Table 2

¹<https://competitions.codalab.org/competitions/17326>

²<https://dumps.wikimedia.org/enwiki/20170920/>

and 4, this approach is represented as $v_c^{w_1} v_c^{w_2} v_t^{w_A}$. The second $v_t^{w_1} v_t^{w_2} v_c^{w_A}$ uses word embeddings of w_1 and w_2 , and context embeddings of w_A . The third $v_c^{w_1} v_c^{w_2} v_c^{w_A}$ is simply context embeddings of w_1, w_2 and w_A . The fourth $v_t^{w_1} v_t^{w_2} v_t^{w_A}$ is simply word embeddings of w_1, w_2 and w_A .

4 Results

We cast the challenge task as a supervised classification problem. We first examine which combination of word and context embeddings and which training method (CBOW or Skip-gram) is optimal in this task. In this step, we only use Feature 1-3 (see Table 1) to classify the triple (w_1, w_2, w_A) .

As can be seen in Table 2, both the CBOW based methods that use word and context embeddings yield the highest average F1 of 0.55 in the validation set. Skip-gram based models generally perform worse than CBOW based models, but using Skip-gram word embeddings of w_1 and w_2 and context embeddings of w_A also outperforms the word embedding based model in the validation set. The experiments running on the test set show similar trends that word and context embedding based models outperform word embedding based models. Such results demonstrate that using word and context embeddings together can better distinguish two semantically similar words with an attribute word, than simply using standard word embeddings. The results also support our first hypothesis that if the attribute word frequently appears in one word’s context than the other one, it can distinguish the two words.

We also examine WordNet definition features individually. As shown in Table 3, simply using Feature 4-5 cannot classify the triple accurately. The F1 score of setting positive label as 1 is very low on the validation set (F1=36%). This is for the reason that an eligible discriminative attribute word cannot always associate with the definitions of one of two semantically similar words. So, simply using such features cannot identify discriminative words precisely.

Finally, we combine both similarity and WordNet features together to address this challenge. There is no significant difference between CBOW based $v_c^{w_1} v_c^{w_2} v_t^{w_A}$ and $v_t^{w_1} v_t^{w_2} v_c^{w_A}$ in the validation set in terms of average F1. We select $v_c^{w_1} v_c^{w_2} v_t^{w_A}$ as the winner combination of word and context embeddings, because this approach has closer F1 scores, when setting different la-

setup		positive=1			positive=0			average F1	
		P	R	F1	P	R	F1		
CBOW+WordNet	validation	$v_c^{w_1} v_c^{w_2} v_t^{w_A} + \text{WN}$	0.57	0.53	0.55	0.56	0.59	0.57	0.56
	test	$v_c^{w_1} v_c^{w_2} v_t^{w_A} + \text{WN}$	0.58	0.60	0.59	0.66	0.65	0.65	0.62

Table 4: Final results by using CBOW word and context embeddings, and WordNet features (Feature 1-5).

bels (1 or 0) as the positive label. Thus, in the final submission, we use CBOW trained context embeddings of w_1 and w_2 , and word embeddings of w_A to compute similarity features. We identify whether an attribute word w_A can distinguish w_1 and w_2 by using the above similarity features and WordNet definition features together. Although word and context embedding based similarity features are much more effective than WordNet features, by introducing WordNet features, the model further improves its performance, achieving 62% F1 on the test set (Table 4). WordNet definitions are also supportive features in this task.

Error analysis. We found that a significant portion of failures appear in those examples that the textual associations of the attribute words and the semantically similar words are not always discriminative. E.g., given a triple, (sons, father, young), our model failed in identifying *young* as a discriminative attribute, because *young* has been widely used to describe *sons* and *father* in the text (e.g., *young sons* and *a young father*). In this case, our word co-occurrence based method is suboptimal.

5 Conclusion

In this paper, we extended traditional word embedding methods (CBOW and Skip-gram) to distinguish two semantically similar words using an attribute word. In contrast with simply using traditional word representations, using both context and word embeddings can better model the co-occurrence between the two similar words and their discriminative attribute word. If the attribute word frequently co-occurs with one of the similar words more than another one within the same sentences, then the two semantically similar words can be distinguished by the attribute word. By using CBOW word and context embedding based similarity features and simple WordNet based word sense definition features, our model performs an average F1 of 62% on the test set.

UMD at SemEval-2018 Task 10: Can Word Embeddings Capture Discriminative Attributes?

Alexander Zhang and Marine Carpuat

Department of Computer Science

University of Maryland

College Park, MD 20742, USA

alexz@umd.edu, marine@cs.umd.edu

Abstract

We describe the University of Maryland’s submission to SemEval-018 Task 10, “Capturing Discriminative Attributes”: given word triples (w_1, w_2, d) , the goal is to determine whether d is a discriminating attribute belonging to w_1 but not w_2 . Our study aims to determine whether word embeddings can address this challenging task. Our submission casts this problem as supervised binary classification using only word embedding features. Using a gaussian SVM model trained only on validation data results in an F-score of 60%. We also show that cosine similarity features are more effective, both in unsupervised systems (F-score of 65%) and supervised systems (F-score of 67%).

1 Introduction

SemEval-2018 Task 10 (Krebs et al., 2018) offers an opportunity to evaluate word embeddings on a challenging lexical semantics problem. Much prior work on word embeddings has focused on the well-established task of detecting semantic similarity (Mikolov et al., 2013a; Pennington et al., 2014; Baroni et al., 2014; Upadhyay et al., 2016). However, semantic similarity tasks alone cannot fully characterize the differences in meaning between words. For example, we would expect the word *car* to have high semantic similarity with *truck* and with *vehicle* in distributional vector spaces, while the relation between *car* and *truck* differs from the relation between *car* and *vehicle*. In addition, popular datasets for similarity tasks are small, and similarity annotations are subjective with low inter-annotator agreement (Krebs and Paperno, 2016).

Task 10 focuses instead on determining semantic difference: given a word triple (w_1, w_2, d) , the task consists in predicting whether d is a discriminating attribute applicable to w_1 , but not to w_2 . For instance, $(w_1 = \text{apple}, w_2 = \text{banana}, d = \text{red})$ is a positive example as *red* is a typical attribute of *apple*, but not of *banana*.

This work asks to what extent word embeddings can address the challenging task of detecting discriminating attributes. On the one hand, word embeddings have proven useful for a wide range of NLP tasks, including semantic similarity (Mikolov et al., 2013a; Pennington et al., 2014; Baroni et al., 2014; Upadhyay et al., 2016) and detection of lexical semantic relations, either explicitly by detecting hypernymy, lexical entailment (Baroni et al., 2012; Roller et al., 2014; Turney and Mohammad, 2013), or implicitly using analogies (Mikolov et al., 2013b). On the other hand, detecting discriminating attributes requires making fine-grained meaning distinctions, and it is unclear to what extent they can be captured with opaque dense representations.

We start our study with unsupervised models. We propose a straightforward approach where predictions are based on a learned threshold for the cosine similarity difference between (w_1, d) and (w_2, d) , representing words using Glove embeddings (Pennington et al., 2014). We use this unsupervised approach to evaluate the impact of word embedding dimensions on performance.

We then compare the best unsupervised configuration to supervised models, exploring the impact of different classifiers and training configurations. Using word embeddings as features, supervised models yield high F-scores on development data, on the final test set they perform worse than the unsupervised models. Our supervised submission yields an F-score of 60%. In later experiments, we show that using cosine similarity as features

is more effective than directly using word embeddings, reaching an F-score of 67%.

2 Task Data Overview

Dataset	Pos	Neg	Total	d Vocab
<i>train</i>	6,591	11,191	17,782	1,292
<i>validation</i>	1,364	1,358	2,722	576
<i>test</i>	1,047	1,293	2,340	577

Table 1: Dataset statistics for the training and validation set: number of positive examples (Pos), number of negative examples (Neg), total number of examples (total), size of vocabulary for discriminant words d (d Vocab)

For development purposes, we are provided with two datasets: a training set and a validation set, whose statistics are summarized in Table 1.

Word triples (w_1, w_2, d) were selected using the feature norms set from [McRae et al. \(2005\)](#). Only visual discriminant features were considered for d , such as *is_green*. Positive triples (w_1, w_2, d) were formed by selecting w_2 among the 100 nearest neighbors of w_1 such that a visual feature d is attributable to w_1 but not w_2 . Negative triples were formed by either selecting an attribute attributable to both words, or by randomly selecting a feature not attributable to either word.

The distribution of the training and validation sets differ: the validation and test sets are balanced, while only 37% of examples are positive in the training set. In addition, the validation and test sets were manually filtered to improve quality, so the training examples are more noisy. The data split was chosen to have minimal overlap between discriminant features.

3 Unsupervised Systems

All our models rely on GloVe ([Pennington et al., 2014](#)), generic word embeddings models, pre-trained on large corpora: the Wikipedia and English Gigaword newswire corpora. In addition to capturing semantic similarity with distances between words, GloVe aims for vector differences to capture the meaning specified by the juxtaposition of two words, which is a good fit for our task.

Because the discriminant features are distinct between train, validation and test, our systems should be able to generalize to previously unseen

discriminants. This makes approaches based on word embeddings attractive, as information about word identity is not directly encoded in our model.

3.1 Baseline

We first consider the baseline approach introduced by [Krebs and Paperno \(2016\)](#) to detect the positive examples, where cs denotes the cosine similarity function:

$$cs(word_1, disc) > cs(word_2, disc) \quad (1)$$

3.2 2-Step Unsupervised System

We refine this baseline with a 2-step approach. Our intuition is that d is a discriminant between w_1 and w_2 if the following two conditions hold simultaneously:

1. w_1 is more similar to d than w_2 by more than a threshold t_{thresh} :

$$cs(w_1, d) - cs(w_2, d) > t_{thresh} \quad (2)$$

2. d is highly similar to w_1 :

$$cs(w_1, d) > t_{diverge} \quad (3)$$

The condition in Equation 2 aims at detecting negative examples that share the discriminant attribute, and the condition defined by Equation 3 targets negative examples that share a random discriminant. Thresholds t_{thresh} and $t_{diverge}$ are hyper-parameters tuned on the *train.txt*.

3.3 Results

We evaluate unsupervised systems using word embeddings of varying dimensions on the validation set, and report averaged F-scores. As can be seen in Table 2, increasing the dimension of word embeddings improves performance for both systems, and the 2-step model consistently outperforms the baseline. The best performance is obtained by the 2-step model with 300-dimensional word embeddings. We therefore select these embeddings for further experiments.

Vector Dim	50	100	200	300
baseline	.5765	.5965	.6171	.6183
2-step model	.4034	.6130	.6266	.6312

Table 2: Averaged F-Score across GloVe Dimensions between our 2-step unsupervised system and the baseline from [Krebs and Paperno \(2016\)](#), for word vectors of size 50, 100, 200 and 300.

4 Supervised Systems

4.1 Submitted System

During system development, we consider a range of binary classifiers that operate on feature representations derived from word embeddings \vec{w}_1, \vec{w}_2 and \vec{d} . We describe the system used for submission which was selected based on 10-fold cross-validation using the concatenation of the training and validation data.

Feature Representations We seek to capture the difference in meaning between w_1 and w_2 and its relation to the meaning of the discriminant word d . Given word embeddings for each of these words \vec{w}_1, \vec{w}_2 and \vec{d} , respectively, we therefore construct input features based on various embedding vector differences. We experimented with the concatenation of $\vec{w}_1, \vec{w}_2, \vec{d}, \vec{w}_1 - \vec{d}$ and $\vec{w}_1 - \vec{d}$. Based on cross-validation performance on training and validation data, we eventually settled on the concatenation of $\vec{w}_1 - \vec{d}$ and $\vec{w}_1 - \vec{d}$, which yields a compact representation of $2D$ features, if D is the embedding dimension.

Binary Classifier We consider a number of binary classification models found in scikit-learn: logarithmic regression (LR), decision tree (DT), naïve Bayes (NB), K nearest neighbors (KNN), and SVM with linear (SVM-L), and Gaussian (SVM-G) kernels. We compare linear combinations of word embeddings to the more complex combinations enabled by non-linear models.

Submission Our submission used the refined SVM-G trained on *validation.txt*. There were three input triplets for which one word was out of the vocabulary of the Glove embedding model: random predictions were used for these. This system achieved an F-Score of .6018. This is a substantial drop from the averaged cross-validation F-scores obtained during development which reached F-scores of 0.9318 using cross-validation on the validation and training sets together, and 0.9674 using cross-validation on the training set only. Using the released test dataset, *truth.txt*, we consider various experiments to understand the poor performance of the model.

4.2 Analysis: Embedding Selection

We first evaluate our hypothesis that word embeddings that perform well in the unsupervised setting

would also, in general, perform well for classification. We vary embedding dimensions keeping the rest of the experimental set-up constant (train on *validation.txt*, evaluate on *truth.txt*).

Table 3 shows the performance of all supervised model configurations and of the 2-step unsupervised system. Increasing the word embedding dimensions improves the performance of the 2-step unsupervised system, as observed during the development phase (Section 3). However, the supervised classifier behaves differently: for several linear classifiers (e.g., LR, DT, SVM-L) the best performance is achieved with smaller word embeddings. For the non-linear SVM used for submission (SVM-G), varying the embedding dimensions has little impact on overall performance. The SVM-G classifier’s performance is now on par with the linear classifiers, while it performed better on development data.

The best performance overall is achieved by the unsupervised model, and taken together, the supervised results suggest that the submitted system overfit the validation set, and was not able to generalize to make good predictions on test examples.

4.3 Analysis: Feature Variants

Motivated by the good performance of the unsupervised model based on cosine similarity, we consider four feature representations variants for the supervised classifiers,¹:

$$\begin{aligned} V1 &= [cs(w_1, w_2), cs(w_1, w_d), cs(w_2, d)] \\ V2 &= [V1, w_1 - w_2, w_d] \\ V3 &= [V1, w_1 - w_d, w_2] \\ V4 &= [V1, cs(w_1 - w_2, w_d), cs(w_1 - w_d, w_2)] \end{aligned}$$

Variant V1 based only on cosine similarity between all pairs yields competitive F-scores from both the SVM-G and LR models (Table 4), and it competitive with the best-performing unsupervised model. We thus use it as a starting point for subsequent variants. Variants V2 and V3 encode the intuition that we expect $w_1 - w_2 \approx w_d$ and $w_1 - w_d \approx w_2$ for positive examples, and therefore, it is possible that these input representations may perform better than the differences-only model. In doing so, we also risk memorizing actual input words as w_d and w_2 are encoded directly as features. These two variants performed worse than the cosine-only models, suggesting that cosine similarity captures semantic

¹The KNN, SVM-L, and SVM-G used tuned hyperparameters.

V4-SVMG	.6102	.6239	.6451	.6708

Table 4: F-score for well-performing models of alternative input variant representations

difference better than the high-dimensional word vectors themselves. Also interestingly, the KNN model performed significantly worse in these two variants. The best result is achieved using V4, which augments V1 with cosine features that better capture word relations through embedding differences, with an averaged F-score of .6708 using the SVM-G classifier.

4.4 Analysis: Cross-Validation Set-up

We further explore why cross-validation scores differed greatly from the final test scores. We constructed initial cross-validation sets using sequential 10% cuts of the training set. This is inconsistent with the actual experimental setup, which had distinct sets of d , the discriminating attribute, between the training and test sets. We experiment segmenting the validation dataset so that each of the cross-validation sets had distinct discriminat-

ing attributes. This yields only minor gains (Table 5), suggesting that overfitting to the identity of the discriminating attributes was not an issue.

Vector Dim.	50	100	200	300
V4-KNN	.6050	.6172	.6394	.6574
V4-SVML	.6109	.6042	.6301	.6478
V4-SVMG	.6104	.624	.6404	.6716

Table 5: F-score from well-formed cross-validation sets

5 Conclusion

This study showed the limits of directly using word embeddings as features for the challenging task of capturing discriminative attributes between words. Supervised models based on raw embedding features are highly sensitive to the nature and distribution of training examples. Our Gaussian Kernel SVM overfit the training set and performed worse than unsupervised models that threshold cosine similarity scores on the official evaluation data. Based on this finding, we explore the use of cosine similarity scores as features for supervised classifiers, to capture similarity between word pairs, and between words and word relations as represented by embedding differences. These features turn out to be more useful than directly using the word embedding themselves, yielding our best performing system (F-score of 67%).

While these results are encouraging, it remains to be seen how to best design models and features that capture nuanced meaning differences, for instance by leveraging metrics complementary to cosine and resources complementary to distributional embeddings.

Abstract

This paper presents the NTU NLP Lab system for the SemEval-2018 Capturing Discriminative Attributes task. Word embeddings, point-wise mutual information (PMI), ConceptNet edges and shortest path lengths are utilized as input features to build binary classifiers to tell whether an attribute is discriminative for a pair of concepts. Our neural network model reaches about 73% F1 score on the test set and ranks the 3rd in the task. Though the attributes to deal with in this task are all visual, our models are not provided with any image data. The results indicate that visual information can be derived from textual data.

1 Introduction

Modern semantic models are good at capturing semantic similarity and relatedness. The widely-used distributional word representations, or word embeddings, have achieved promising performance on various semantic tasks. The word pair similarities calculated with these models are to some extent consistent with human judgments, and many downstream applications such as sentiment analysis and machine translation have benefited from word embeddings' ability to aggregate the information of lexical items with similar meaning but different surface forms.

However, the ability to *distinguish* one concept from another similar concept is also core to linguistic competence. Our knowledge about what is a “subway”, for example, may contain “it is a kind of train that runs underground”. Also, discriminating things is an important mechanism for teaching and learning. For example, if we would like to explain how a “plate” is different from a “bowl”, we may use expressions like “a plate is flatter” or “a bowl is deeper”. All these examples show that one form of semantic difference is a *discriminative at-*

tribute which applies to one of the two concepts being compared but does not apply to the other.

In the SemEval-2018 Capturing Discriminative Attributes task (Krebs et al., 2018), participants need to put forward semantic models that are aware of semantic differences. A data instance consists of a triple and a label. In this paper, we denote a triple with $\langle w_1, w_2, a \rangle$, in which w_1 and w_2 are the two words (concepts) to be compared, and a is an attribute. The label is either positive (1) or negative (0). In a positive example, a is an attribute of w_1 but not an attribute of w_2 . For negative examples, there are two cases: 1) both w_1 and w_2 have attribute a ; 2) neither w_1 nor w_2 has attribute a . In this task, a is limited to visual ones such as color and shape. The evaluation metric is the macro-averaged F1 score of the positive and the negative classes.

Visual attribute learning has been investigated by past researchers. Silberer et al. (2013) build a dataset of concept-level attribute annotations based on images in ImageNet (Deng et al., 2009). For each attribute, they train a classifier to predict its presence or absence in the input image. Lazaridou et al. (2016) propose a model that does not learn visual attributes explicitly, but learns discriminativeness. Their model predicts whether an attribute can be used to discriminate a referent from a context. Both the referent and the context are represented by visual instances sampled from ImageNet. This setting is similar to that of this SemEval task. However, one critical difference is that in this task, the set of attributes is open. The dataset is partitioned so that all the attributes in the test set are unseen in the training set, which makes this task more challenging.

The use of word embeddings for detecting semantic properties is studied by Rubinstein et al. (2015). They focus on a fixed set of properties and train a binary classifier for each property. Their

results indicate that word embeddings capture taxonomic properties (e.g. “an animal”) better than attributive properties (e.g. “is fast”), possibly because attributive signal is weak in text.

In this task, most visual attributes are attributive properties. The signal of “visual” attributes can be even weaker in text since they are not mainly communicated through language in human cognition. The word “red” in “I bought a red apple” sounds more like a linguistic redundancy than that in “I bought a red jacket” does, since “red” is a typical attribute of apples. However, these visual attributes may impose constraints on valid expressions. For instance, we can say “the bananas turned yellow”, but it would be extremely difficult to find some context where “the bananas turned red” makes sense. Therefore, visual attributes can be signaled in some implicit and indirect ways. By utilizing several computational approaches, we reveal to what extent visual attributes can be acquired from text.

This paper aims at capturing semantic difference by incorporating information from both corpus statistics and expert-constructed knowledge bases. We build a rule-based system and a learning-based system for the binary classification problem, i.e., to tell whether an attribute is discriminative for two concepts. The learning-based system achieved F1 score of 0.7294, which is the third best in the official evaluation period of SemEval-2018 Task 10. Our approach is purely based on textual data, without access to image instances, which indicates that it is possible to figure out substantial visual information from text.

2 Distributional Information

We utilize two kinds of computational approaches to derive information from co-occurrence statistics in large corpora. The first one is word embedding, which has been shown to encode semantic information in low-dimensional vectors. The second one is pointwise mutual information (PMI), which is a commonly-used measurement of the strength of association between two words. We analyze the performance of rule-based or learning-based models with different sets of features to reflect their effectiveness.

2.1 Concatenation of Word Embeddings

A very straight-forward approach is concatenating the embedding of w_1 , w_2 and a into a fea-

Embeddings			Train		Validation	
w_1	w_2	a	Acc.	Macro F1	Acc.	Macro F1
V	V	V	0.7468	0.6484	0.5184	0.3409
		V	0.6379	0.5216	0.5180	0.2908
V	V		0.7017	0.5040	0.4996	0.2748
V		V	0.6790	0.5938	0.4945	0.3558
	V	V	0.6733	0.5421	0.5029	0.3170

Table 1: Training and validation scores of MLP model with embeddings of different subsets of the triple.

ture vector to train a binary classifier. We use the pre-trained 300-dimensional Word2vec embeddings (Mikolov et al., 2013) trained on Google News¹ as input features. We construct a multi-layer perceptron (MLP) model with two hidden layers of size 1,024 to conduct preliminary experiments. The activation function is ReLU and the dropout rate is 0.5. The model is implemented with Keras (Chollet, 2015). We train for 20 epochs and report the best validation scores.

However, we find out that there is a serious issue of overfitting. As shown in Table 1, the gap between training and validation scores is large. We also experimented simpler models such as Logistic Regression and Random Forest, and got similar results. A possible cause of overfitting is that the model does not learn to extract and compare attributes, but learns the “pattern” of some combination of words in the triples.

To verify the above speculation, we train similar MLP models which only take “partial” triples as input. Theoretically, the label cannot be determined correctly with an incomplete triple. However, according to the results shown in Table 1, the models considering solely a part of every triple can still “learn” some information from the training set (majority-class baseline accuracy on the training set: 0.6383). Some models with partial information even achieve better validation scores than that with complete information. This indicates that the models overfit to the vocabulary of the training set. At the test time, all the attributes are unknown, so the model cannot make effective predictions. In fact, these results are similar to the lexical memorization phenomenon reported by Levy et al. (2015) on the hypernym detection task.

2.2 Embeddings Similarity Difference

Because “raw” word embedding features do not work, we turn to more abstract features. Let sim_1 and sim_2 be the cosine similarity of the vector of a

¹<https://code.google.com/archive/p/word2vec/>

to the vector of w_1 and w_2 respectively. We compare the values sim_1 and sim_2 . The rationale is that if a word w has an attribute a , then it tends to, though not necessarily, be more similar to a than other words without a .

The following six embedding models are experimented with. The embedding size is fixed to 300.

1. **W2V(GNews)**: The standard Word2vec model as described in Section 2.1.
2. **fastText**: fastText (Bojanowski et al., 2017) is a modification of Word2vec that takes subword information into account. We adopt the pre-trained vectors trained on 6B tokens².
3. **Numberbatch**: Numberbatch embeddings are built upon several corpus-based word embeddings and improved by retrofitting on ConceptNet, a large semantic network containing an abundance of general knowledge (Speer et al., 2017). We use the pre-trained embeddings of English concepts³.
4. **GloVe(Common Crawl)**: The GloVe model (Pennington et al., 2014) obtains word representation according to global co-occurrence statistics. We use the pre-trained vectors trained on 840B tokens of Common Crawl⁴.
5. **Sense(enwiki)-c**: Sense vectors may encode more fine-grained semantic information than word vectors do, so we also experimented with sense vectors. We perform word sense disambiguation (WSD) on the English Wikipedia corpus to get a sense-annotated corpus, using the Adapted Lesk algorithm implemented in pywsd⁵. The sense inventory is based on synsets in WordNet. We train a Word2vec Skip-gram (SG) model with this corpus to obtain sense vectors. To apply sense vectors to words and attributes in this SemEval task, we propose the following *closest* sense-selection method (denoted by *-c*) to choose a sense for each of w_1 , w_2 and a . $S(w)$ denotes the set of synsets that a word w belongs to and $emb(s)$ denotes the vector of synset (sense) s .

$$s_{1*}, s_{a*} = \underset{\substack{s_1 \in S(w_1) \\ s_a \in S(a)}}{\operatorname{argmax}} \cos(\operatorname{emb}(s_1), \operatorname{emb}(s_a))$$

$$s_{2*} = \underset{s_2 \in S(w_2)}{\operatorname{argmax}} \cos(\operatorname{emb}(s_{1*}), \operatorname{emb}(s_2))$$

²<https://fasttext.cc/docs/en/english-vectors.html>

³<https://github.com/commonsense/conceptnet-numberbatch>

⁴<https://nlp.stanford.edu/projects/glove/>

⁵<https://github.com/alvations/pywsd>

Since a might be an attribute of w_1 , we choose the closest pair of senses for them. Then, we choose the sense of w_2 that is closest to s_{1*} , the selected sense for w_1 . The reason is that a semantic difference is more likely to be meaningful for two similar concepts. Finally, we use the vector of the selected senses to compute similarities.

6. **Sense(enwiki)-f**: We use the same sense embeddings as described previously but directly select the *first* sense (predominant sense) in WordNet for w_1 , w_2 and a respectively, without performing WSD. This method is denoted by *-f*.

We first use these similarities in a simple rule-based model: if $sim_1 > sim_2$ then output 1; otherwise output 0. The results are summarized in Table 2. In general, this similarity comparison rule performs better on the positive class than on the negative class. GloVe results in the highest negative F1, while Numberbatch results in the best macro-averaged F1. We show the confusion matrix for this rule with Numberbatch in Table 3. As can be seen, similarity differences are helpful for discriminating the positive examples, but they are not good indicators of negative examples.

We use $sim_1 - sim_2$ of different kinds of embeddings as features and train MLP models as described in the previous section. The results of different combinations of embeddings are shown in Table 4. However, there is only slight macro-

Embeddings	Acc.	Pos. F1	Neg. F1	Macro F1

F1 improvement over the rule-based models. On the other hand, though including the last three embedding models does not yield better result in this setting, we find them useful when combined with other kinds of features. Therefore, they are included in one of our submitted systems.

2.3 PMI Difference

Similar to word embedding, PMI reflects the co-occurrence tendencies of words. It has been shown that the Skip-gram with Negative Sampling (SGNS) algorithm in Word2vec corresponds to implicit factorization of the PMI matrix (Levy and Goldberg, 2014). Nevertheless, PMI should be interpreted differently from word vector similarity. Since PMI is calculated in an exact matching manner, there is no propagation of similarity as in the case of word vectors. That is, suppose that both $PMI(\text{“red”}, \text{“yellow”})$ and $PMI(\text{“apple”}, \text{“banana”})$ are high, this does not imply that $PMI(\text{“red”}, \text{“banana”})$ will be high. Thus, PMI might be less prone to confusion of similar concepts.

We calculate PMI on the English Wikipedia corpus. We first experimented with a $PMI_1 > PMI_2$ rule that is similar to the one for vector similarities. In Table 5, we report

Context window	Acc.	Pos. F1	Neg. F1	Macro F1

Table 8: Performance of MLP models with combinations of word vector similarity differences and sign of PMI differences.

the results of PMI calculated with different sizes of context window within which a pair of words is considered to be a co-occurrence. 20-word context window yields the best performance so we show its corresponding confusion matrix in Table 6. As can be seen, PMI performs slightly better in discriminating the negative class, compared to word similarities (Table 3).

Based on the above observation, we propose a heuristic rule of combining vector similarity and PMI: if $sim_1 > sim_2$ and $PMI_1 > PMI_2$ then output 1. We use the Numberbatch embeddings and PMI of 20-word context. This majority-voting model is more reliable and achieves macro-F1 above 0.69. It is one of our submitted systems so the result is shown in Table 14. According to the confusion matrix in Table 7, both the positive and the negative classes can be discriminated well with the combination of distributional vectors and PMI.

We also build learning-based models with combinations of PMI of different context window sizes. Since the range of PMI can be large, we only consider the sign of the difference. The sign of zero is defined to be negative. In addition, we also combine vector similarities to train the MLP model. The results are all shown in Table 8. However, none of the results show improvement over the corresponding rule-based models.

3 Expert Knowledge from ConceptNet

3.1 Edge Connection

ConceptNet can be regarded as a directed graph of concepts (vertices) connected by different relations (edges). There are 47 relation types in ConceptNet. Some of them, such as `HasProperty` and `CapableOf`, are directly related to attributes. Other relations such as `RelatedTo` can also reflect some kinds of attributes.

We experiment with a simple rule-based model that outputs 1 if there exists a relation from w_1 to a and there is no relation from w_2 to a . Additionally, we augment the ConceptNet graph with reverse edges and apply the rule again. The results of both versions are shown in Table 9. The

Graph	Acc.	Pos. F1	Neg. F1	Macro F1
ConceptNet edges	0.5996	0.4593	0.6820	0.5707
+ reverse edges	0.6297	0.5140	0.7009	0.6074

Table 9: Performance of the $w_1 \rightarrow a \ \& \ w_2 \not\rightarrow a$ rule with the ConceptNet graph and its extension on the validation set.

Features	Acc.	Pos. F1	Neg. F1	Macro F1
$w_1/w_2 \xleftrightarrow{r} a$ for each r	0.5724	0.4785	0.6376	0.5581
$w_1/w_2 \xleftrightarrow{r} a$ for any r	0.5974	0.4931	0.6661	0.5796

Table 10: Performance of MLP models with ConceptNet edge features on the validation set.

version with reverse edges performs competitively with the vector similarity rule (macro F1 about 0.6), but the behavior is quite different. As can be seen, the ConceptNet features help achieve better negative F1. The relatively low performance on the positive class might be due to the sparseness of the knowledge graph. Some w_1 might have attribute a but it is not directly connected to a on the graph.

To encode edge connection information for training learning-based models, we compute the following four binary features:

- Is there an edge from w_1 to a ?
- Is there an edge from a to w_1 ?
- Is there an edge from w_2 to a ?
- Is there an edge from a to w_2 ?

We also experimented with two versions. In the first version, each type of relations are considered separately, so the total dimensionality is $4 * 47 = 188$. In the second version, we set a binary feature to 1 if there is at least one edge that satisfies its condition, so the feature dimensionality is only 4. The results are shown in Table 10. Although different types of relations have different semantics and should be treated differently, the version considering relation type does not perform better. A possible reason is that it can suffer from the data sparseness problem, since some dimensions are zero for almost all the instances.

3.2 Shortest Path Length

To include connections between words and attributes that take more than one step, we calculate the shortest path lengths. Let $dis(w_i, a)$ be the shortest path length between w_i and a on the ConceptNet graph. We first experiment with a simple rule-based model that outputs 1 when $dis(w_1, a) < dis(w_2, a)$, that is, when w_1 is closer to a . The results are reported in Table 11. Including reverse edges slightly improves the accuracy but does not improve the macro F1 score. A confusion matrix is presented in Table 12, showing that this rule is a strong indicator for the negative class. Compared to the ones with edge connection features, however, these rule-based classifiers

Graph	Acc.	Pos. F1	Neg. F1	Macro F1
ConceptNet edges	0.6308	0.5740	0.6742	0.6241
+ reverse edges	0.6315	0.5622	0.6819	0.6220

Table 11: Performance of the $dis(w_1, a) < dis(w_2, a)$ rule with the ConceptNet graph and its extension on the validation set.

True label	$dis(w_1, a) < dis(w_2, a)$	otherwise
1	644	720
0	283	1075

Table 12: Confusion matrix of the $dis(w_1, a) < dis(w_2, a)$ rule (reverse edges considered) on the validation set.

Graph	Acc.	Pos. F1	Neg. F1	Macro F1
ConceptNet edges	0.6532	0.6629	0.6430	0.6529
+ reverse edges	0.6646	0.6984	0.6223	0.6603

Table 13: Performance of MLP models with one-hot representation of ConceptNet shortest path lengths on the validation set.

achieve slightly lower negative F1 but higher positive F1.

Since the maximum shortest path distance between a word and an attribute in the training set is 5 (when reverse edges are included), we encode $dis(w_i, a)$ into 6-dimensional discrete binary features as follows.

- No path from w_i to a
- $dis(w_i, a) = 1$
- $dis(w_i, a) = 2$
- $dis(w_i, a) = 3$
- $dis(w_i, a) = 4$
- $dis(w_i, a) \geq 5$

We build similar MLP models that take these features as input. The features for w_1 and w_2 are computed separately and then concatenated. There are clear improvements of learning-based models (Table 13) over rule-based ones (Table 11). The improvements are mostly contributed by the higher positive F1 scores. On the other hand, in general it is helpful to include a separate set of features calculated on the graph with reverse edges.

4 Submitted Systems

We submitted the predictions of a rule-based system and a learning-based system. The evaluation results are summarized in Table 14. Run 1 system is a rule-based combination of similarity differences of the Numberbatch embedding and the sign of PMI differences (window size 20). Run 2 is an MLP model with three size-2048 hidden layers that takes input features of the similarity dif-

Model	Validation				Test			
	Acc.	Pos. F1	Neg. F1	Macro F1	Acc.	Pos. F1	Neg. F1	Macro F1
[1] Rule: $sim_1 > sim_2 \ \& \ PMI_1 > PMI_2$	0.6954	0.6993	0.6915	0.6954	0.7047	0.6944	0.7143	0.7044
[2] MLP: sim x6 + PMI(10,20,30) + ConceptNet	0.7175	0.7213	0.7136	0.7174	0.7303	0.7138	0.7451	0.7294

Table 14: Evaluation results of the two submitted systems.

ference of the six kinds of embeddings, the sign of PMI differences of three different context window sizes and the ConceptNet edge and shortest path length features.

Our run 2 system performed the third best among all 26 participants with macro-F1 0.7294, showing that the features we proposed are highly effective. On the other hand, our run 1 system got an only slightly lower macro-F1 of 0.7044 and would get a rank between 5 (0.69) and 4 (0.72) if it was considered. This again proves the complementary effect of word vector similarity and PMI.

5 Error Analysis

Since even the top system in this task did not achieve macro-F1 above 75%, we think that there might be some cases that are very difficult to handle. Based on the test ground-truth released officially, we analyze the errors of our best system. We find out that the difficulties mainly arise from the following cases.

Ambiguous concept: Word ambiguity is not considered in this task. However, this may be problematic in some cases such as the positive example <mouse, squirrel, plastic>. According to the answer, we know that the word “mouse” is interpreted as a “computer device” instead of an “animal”. Therefore, sometimes the answer is dependent on which sense is selected.

Vague or ambiguous attribute: Since the attribute is expressed only with a single word in this task, sometimes it is hard to tell what the attribute means, even from a human’s perspective. For example, the triple <philanthropist, lawyer, active> is labeled 0 in the gold answer. Nevertheless, a positive interpretation also makes sense: philanthropists usually engage in philanthropy actively, while lawyers usually handle matters under the authorization of someone.

Relative attribute: In some positive examples, w_1 does not necessarily have a , but only more likely to have it. In the positive example <father, brother, old>, “father” might be “old” when being compared to “brother”, but not necessarily so when considered isolatedly. It is even more diffi-

cult to determine when to evaluate the absence of an attribute relatively, given that we also encounter cases such as <banker, lawyer, rich>, whose gold label is 0.

6 Conclusions

We propose several approaches to tackle the SemEval 2018 Capturing Discriminative Attributes task in this paper. We utilize information derived from both corpus distribution statistics and expert knowledge in ConceptNet to build our systems. According to the experimental results, word embedding and PMI, though both based on co-occurrence, can complement each other in a simple heuristic rule-based system. Moreover, the ConceptNet features with high sensitivity to the negative class can complement the corpus-based features, which are more sensitive to the positive class. Our best learning-based system achieved F1 score of 0.7294 and got the 3rd place in the official run. We did not adopt image features, which suggests that it is possible to learn substantially about visual attributes solely from text.

Given the limited advancement of the learning-based model over the rule-based one, it is worth studying how to design some mechanism in machine learning models that can guide them to “compare” the features of the two concepts and determine the discriminativeness.

Abstract

This paper describes the participation of ELiRF-UPV team at task 11, Machine Comprehension using Commonsense Knowledge, of SemEval-2018. Our approach is based on the use of word embeddings, NumberBatch Embeddings, and a Deep Learning architecture to find the best answer for the multiple-choice questions based on the narrative text. The results obtained are in line with those obtained by the other participants and they encourage us to continue working on this problem.

1 Introduction

In the Machine Comprehension using Commonsense Knowledge task, systems must answer multiple-choice questions given narrative texts about everyday activities. In addition to what is mentioned in the text, a substantial number of questions require inference using script knowledge about different scenarios.

In order to capture some script knowledge we decided to use a word representation based not only on distributional semantics word models but also on a knowledge graph, ConceptNet (Speer et al., 2016). ConceptNet is a knowledge graph that connects words and phrases of natural language with labeled edges. It is designed to represent the general knowledge involved in understanding language. ConceptNet could be used in combination with sources of distributional semantics, particularly the word2vec Google News skip-gram embeddings (Mikolov et al., 2013) and GloVe 1.2 (Pennington et al., 2014), to produce new embeddings, NumberBatch embeddings, with state-of-the-art performance across many word-relatedness evaluations (Speer and Lowry-Duda, 2017).

More specifically, NumberBatch is a list of semantic word vectors which contains a complex

meaning of those terms, beyond containing only contextual information like other kinds of embeddings based on distributional semantics e.g. Word2Vec or Glove. These embeddings are obtained through a combination of Word2Vec and Glove embeddings with knowledge extracted from ConceptNet by means of a technique known as retrofitting (Faruqui et al., 2014).

In this work, we used word representations based on NumberBatch embeddings because these representations encode semantically rich information related to the commonsense. Moreover, in order to tackle this machine comprehension task, we used a Deep Learning architecture with new attention mechanisms. The inclusion of these new attention mechanisms allow us to better capture the similarities among the elements of the input. The attention mechanisms we introduce in this work are suggested in the work (Seo et al., 2016), that obtained very competitive results in Question Answering tasks.

2 Resources and Preprocess

As we pointed in Section 1, NumberBatch embeddings were used for the representation of words. These embedding are provided by ConceptNet 5, which was compiled by the Commonsense Computing Initiative. ConceptNet 5 is freely available under the Creative Commons Attribution-ShareAlike license (CC BY SA 4.0) from <http://conceptnet.io>.

We explored several preprocessing techniques in the development phase. The best results were obtained with the following preprocess: the conversion of all text to lowercase and the elimination of the question marks “?”. After this, we carried out a tokenization process.

3 System Description

We tested Deep Learning architectures based on similarities between d -dimensional NumberBatch embeddings of story (x), question (q) and answer (r). Specifically, our approaches learn representations of x , q and r to first compute similarities, and then make a classification decision.

These kind of systems work well in Question Answering tasks, for instance, BiDAF (Seo et al., 2016) or QA-LSTM-Story (Pal and Sharma, 2016). For this reason, with the aim of improving the accuracy of these systems for this task, we incorporated some attention mechanisms of BiDAF in the QA-LSTM-Story system. A scheme of our system is shown in Figure 1.

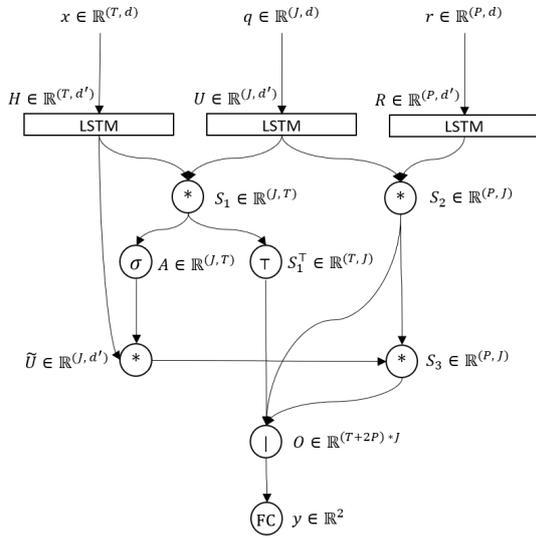

Figure 1: System architecture.

All Deep Learning systems tested in this work take first a story ($x \in \mathbb{R}^{\{T,d\}}$), a question ($q \in \mathbb{R}^{\{J,d\}}$) and an answer ($r \in \mathbb{R}^{\{P,d\}}$) as input. Specifically, each of these elements is a matrix with their word embeddings as rows. Note that the length of the representations (T , J and P) is fixed by adding zero padding at the beginning to reach the length of the longest element.

Second, x , q and r are processed by means of three non-shared Bidirectional Long Short Term Memory (BLSTM) (Hochreiter and Schmidhuber, 1997) (Schuster and Paliwal, 1997). These networks capture useful features (X , Q and R) to make decisions based on similarities among the inputs. Moreover, we used BatchNormalization (Ioffe and Szegedy, 2015) and Dropout (Srivastava et al., 2014) with $p = 0.3$, after the input layer and

after the BLSTM output to improve the generalization of the model.

After that, we compute similarities between each term of Q and each term of X ($S_1 = QX \in \mathbb{R}^{\{J,T\}}$) and similarities between each term of R and each term of Q (in a similar way, $S_2 = RQ \in \mathbb{R}^{\{P,J\}}$).

Now, if we concatenate S_1 and S_2 , and we apply a fully-connected layer with softmax activation functions to classify, we reproduce exactly the QA-LSTM-Story system. However, in this work, we incorporated several attention mechanisms to this architecture in order to learn more complex relationships among the inputs.

One of these attention mechanisms is an adaptation of BiDAF. This adaptation used, in addition to Query2Context (Q2X) and Context2Query (X2Q), two additional attention mechanisms, Answer2Query (R2Q) and Query2Answer (Q2R). R2Q and Q2R are identical to X2Q and Q2X but applied to the question q and the answer r .

We have also tested many other attentions, but the best system obtained in the development phase only contains X2Q. In order to obtain this attention, we first transform the similarities S_1 by applying a softmax activation function to each row i.e. $A[i, j] = \frac{e^{S_1[i, j]}}{\sum_{t=0}^T e^{S_1[i, t]}}$. After this, we compute $\tilde{Q} = AX$, to represent each row of Q as a weighted sum of the rows in X . That is, each row of Q is adapted in order to consider the most relevant rows of X .

From \tilde{Q} , we can consider more explicit relationships between x and r if we compute the similarities between \tilde{Q} and R , in the same way as S_1 and S_2 , to obtain S_3 .

With all, we transpose the matrix S_1 to later concatenate all the similarity matrices. The result, $(S_1^T, S_2, S_3) \in \mathbb{R}^{\{(T+2P), J\}}$, is flattened by concatenating all rows as columns to obtain a vector $O \in \mathbb{R}^{(T+2P)*J}$. Finally, we apply a softmax fully-connected layer to O to carry out the classification.

To train the system, we generated a training set consisting of all the triples of the corpus (x , q , r). Thus, for each x and q , we generate two triples, (x , q , r_1) and (x , q , r_2). Then, if r_1 is correct, $y(x, q, r_1) = 1$, else $y(x, q, r_1) = 0$. At inference time, given x , q and their two possible answers r_1 and r_2 , we first build two triples (x , q , r_1) and (x , q , r_2) and, second, we obtain the network outputs y_1 and y_2 , respectively. Finally, in order to decide which answer is correct, we select the one

Sys.	System Description	Acc. (%)

that maximizes the output for the correct class i.e. $y_i[1]$ (2nd component of the network output for a triple i).

4 Experimental Results

The results obtained during the development phase for the different systems above mentioned are shown in the Table 1. It can be observed that Deep Learning systems with simpler attention mechanisms worked better than those with more complex attention mechanisms (system 2 versus systems 1 and 3). If X2Q was added to compute more explicit relations between x and r , the accuracy slightly improved from 79.21% to 80.08% (system 1 versus system 3). Moreover, we tested system 3 with word2vec (Google News skip-gram) instead of NumberBatch embeddings obtaining an accuracy of 78.84%.

With these results, we chose the best system in the development phase (system 3 in Table 1).

The results obtained with this system on the test set are shown in Table 2.

5 Analysis of Results

Now, we make an analysis of the results obtained with our best system. In particular, we analyze the network confidence at intervals when deciding what is the correct answer (r_1 or r_2) given a story x and a question q . This confidence c is defined as the absolute difference between the outputs for the correct class of each answer ($y_1[1]$ and $y_2[1]$) i.e. $c = |y_1[1] - y_2[1]|$.

During this analysis, we get a maximum confidence $c = 0.999$ and a minimum confidence $c = 0.000$. Thus, there are extreme cases where the system is totally sure about what is the correct answer, or has total uncertainty. In the instance ($ix = 235$, $iq = 1$), we observe that the system is totally sure about the correct answer due to the answer has been explicitly found in the story. In a second instance ($ix = 131$, $iq = 4$), the system has total uncertainty because “\$20.00” and “\$15.00” do not appear in the NumberBatch embeddings. (Where ix and iq refers to the index of the story and the question in the test set).

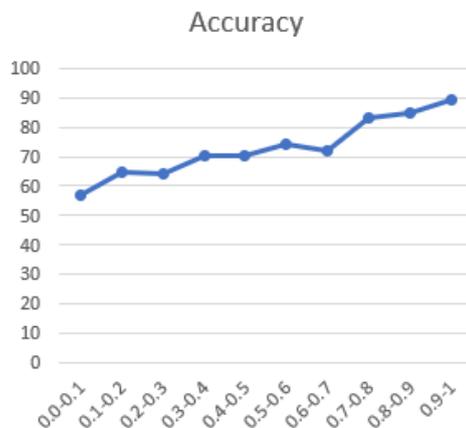

Figure 2: Accuracy in each confidence interval.

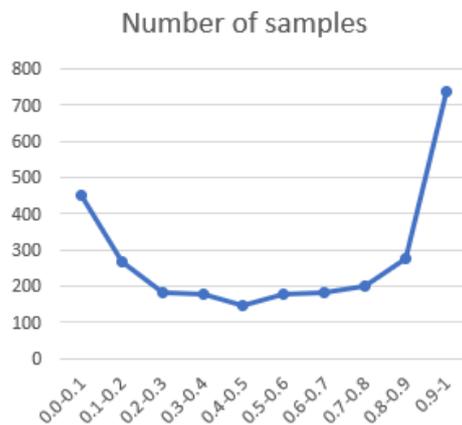

Figure 3: Number of samples in each confidence interval.

Moreover, we have also performed a study on the system accuracy and the number of samples for each confidence level between $[0, 1]$. The results obtained are shown in the Figures 2 and 3.

In general, as it can be observed in Figure 2,

the greater the confidence, the better results were obtained. However, in Figure 3, we observed that there are many samples with very low confidence values, e.g. 0.0-0.1. We think that in order to reduce the number of samples in this confidence interval, it would be necessary to incorporate new knowledge resources.

6 Conclusions

In this work, we presented a Deep Learning architecture with new attention mechanisms in order to learn more complex representations and similarities among input elements (story x , question q and answer r). In order to capture some script knowledge, NumberBatch embeddings were used for the representation of words. With this approach we obtained competitive results.

As future work, we propose the study and development of new attention mechanisms to learn complex features and relationships. Moreover, we also find interesting the enrichment of the Deep Learning architectures with some commonsense information beyond the use of NumberBatch embeddings, such as the script knowledge resources suggested by the competition organizers.

Abstract

In this paper, we describe a machine reading comprehension system that participated in SemEval-2018 Task 11: Machine Comprehension using commonsense knowledge. In this work, we train a series of neural network models such as multi-LSTM, BiLSTM, multi-BiLSTM-CNN and attention-based BiLSTM, etc. On top of some sub models, there are two kinds of word embedding: (a) general word embedding generated from unsupervised neural language model; and (b) position embedding generated from general word embedding. Finally, we make a hard vote on the predictions of these models and achieve relatively good result. The proposed approach achieves 8th place in Task 11 with the accuracy of 0.7213.

1 Introduction

Machine Comprehension using Commonsense Knowledge is a well-researched problem in NLP. In order to simplify the task of the process, we turn this task into text classification work and use a deep learning neural network to fulfill it. The method of deep learning models used in text analysis has achieved numerous notable advances in recently years (e.g., (Breck et al., 2007), (Yessenalina and Cardie, 2011) and (Socher et al., 2011)). However, in most previous works, the tasks are to apply a single model to a particular data set task.

The single model is a vertical stack of multiple hidden layers, which is not good for text analysis and processing. The first drawback is the need to consume more hardware resources, followed by over-fitting and loss of feature information. So the task here is to apply different structure sub models to the same train-set. We train many classic sub models with one layer on top of word embedding, like LSTM, CNN, Attention, Attention+BiLSTM, multi-BiLSTM+CNN and some other models

which are slightly different from the above models with different activation functions and different layers inside the model. In each single model, we use a flag to determine which embedding tool is used or not.

Most of the deep learning involve word vectors represented by neural language models ((Morin and Bengio, 2005), (Yih et al., 2011) and (Mikolov et al., 2013)). Using the learned word vectors for classification task will naturally increase the effect. Word vectors are expressed as a hidden-layer word vector of the specified dimension (1-of- V , here V is the vocabulary size), the training methods can be found here¹. In our system, we introduce different word vectors: 100 billion words of Google News, Glove vectors of 100 dimensions and word vectors self-trained on the basis of official task data. Finally, a hard vote(the majority voting from result document) is made on the results of those different models. Many tasks often suffer from insufficient training data. In this work, we parse external data from CodaLab introduction data, including DeScript(?) data, RKP(Regneri et al., 2010) data and OMCS (Singh et al., 2002) data to trained embedding.

2 System Description

We treat this task as a classification process. First we repeat the question and answer text, making it match instance texts. The final number of samples are same as the number of answers in the data-set. After statistical analysis of the data-set, we treat Instance texts, Question texts and Answers texts as to a rational text length of words $\{w_1, w_2, \dots, w_n\}$ in which n is the max length of a text. Here, the length of Instance is controlled as 350, and the length of Question is controlled as 14 as well as Answer. Before that, we count the frequency of

¹<https://radimrehurek.com/gensim/models/word2vec.html>

occurrence of each word in the data-set, and use this word frequency to create a dictionary, then express each word in terms of frequency order of corresponding word (Kim, 2014). Next, we train word embedding according to (Chiu et al., 2016), and at the same time download the trained embedding sets that have been trained².

The ensemble model architecture, shown in figure 1, is an ensemble of many single models(We call them sub models). Because each sub model is independent of each other, their weights are not shared and just use the same word embedding when training each sub model. The process of the whole ensemble model is carried out model by model. First, each model is run independently, and then the result file is saved. After running all the independent models, the result files are taken out and the final result is determined by the majority vote. In model training, we use the early stop mechanism (Sarle, 1995) to terminate the training of subsequent epoch when the overfitting is appeared. At the same time, the data is shuffled on every epoch. The core of our paper is based on classic models, adding other network layers, so that the independent models have their own structure. Next, are introduced the input structures of the sub models.

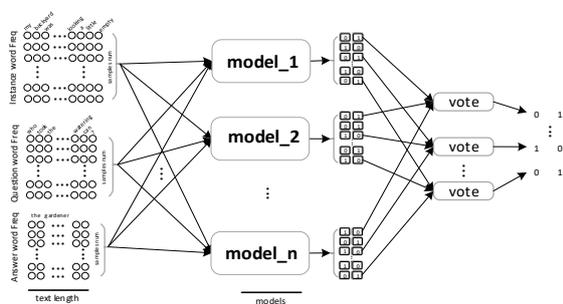

Figure 1: The architecture of the models ensemble.

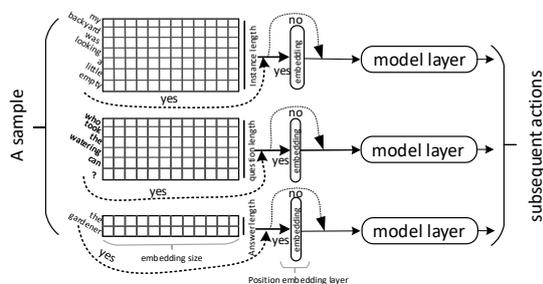

Figure 2: The input structure of the submodel

²<https://github.com/xgli/word2vec-api>

2.1 Similar input structures

Figure 2 shows the architecture of the sub models input. The input part of all sub models uses this structure. Within the structure, two flag variables are used to control the use of word embedding. One is whether to use the position embedding, and the other is to control whether or not the trained word embedding is used. From this structure, data flow to the subsequent network layer such as the classic model layer CNN, LSTM, BiLSTM and Attention.

2.2 The merge layer

In order to combine three text feature information, we have a merge layer in all of our sub models. The merge layer of these sub models is almost the same. Only the attention layer merge is different from other sub models. The merge of most sub models first combines the instance matrix data with the question in sum operation, while combining the matrix data with the answer, and finally combining the two sets of matrix data in the *dot* operation. However, in the sub model with Attention, merge layer combines the matrix data of the three texts with *dot* operation. Next, we will focus on two sub models using classical models, while the rest of the other part of each sub models are similar to the two models.

2.3 Based on multi-BiLSTM+CNN model

Long short-term memory (LSTM or BiLSTM) is applied to text classification ((Liu et al., 2016) and (Lai et al., 2015)). The Convolutional Neural Networks (CNN) is for local feature extraction (LeCun et al., 1998). CNN can achieve good results in the semantic analysis (Yih et al., 2014), and other traditional NLP tasks (Collobert et al., 2011), especially in sentiment analysis and question classification (Kim et al., 2016). It is our novelty to combine CNN with multiple layers of BiLSTM with BiLSTM in front.

Here set the *multi* = 2, of course, it can be 3 or more. Each multi-BiLSTM internal implies a dropout layer to prevent over-fitting (Srivastava et al., 2014). Multi-BiLSTM is one of the core layers in this model which takes an input sequence of word embedding. Just like (Liu et al., 2016) and (Lai et al., 2015), this layer runs on the data of word embedding. After these three branches running (Just as the three model layers in Figure 2), we make batch normalization and then merge

them into CNN1D layer. Finally, we use the Softmax classifier to predict the results. Other sub models that do not use Attention are similar to the sub model structure, instead of replacing CNN1D with other structures.

2.4 Based on Attention + BiLSTM model

Attention is mostly used for document categorization (Yang et al., 2016). The model architecture is different from the multi-BiLSTM+CNN architecture of word embedding layer. The structure of this model is roughly: a word embedding input structure, followed by attention layer which include the merge layer. Next to the batch normalization layer, BiLSTM layer, Softmax layer. We do a position embedding operation before inputting the word embedding into attention layer. According to (Vaswani et al., 2017), the formula for constructing Position Embedding is as follows:

$$\begin{cases} PE_{2i(p)} = \sin(p/10000^{2i/dpos}) \\ PE_{2i+1(p)} = \cos(p/10000^{2i/dpos}) \end{cases} \quad (1)$$

Here is to map the position p to the position vector of $dpos$ dimension. The value of the i th element of this vector is $PE_i(p)$. Word embedding first goes through the position embedding layer which is included in the architecture of the sub model input. Then the feature data enters into attention layer. In attention layer, weights and bias are randomly added to position embedding and excess numbers are masked as zero. We do batch normalization for the data coming out of attention layer, then input them into BiLSTM. Similarly, the results are obtained after Softmax layer.

3 Data Preparation

Although official data is regular, we have done a further normalization. All data set used by each model undergoes the following preprocessing steps:

- 1) The texts were lowercased
- 2) Using NLTK to tokenize each text
- 3) Abbreviations:

We're very careful about the abbreviation, as "s" in "it's time for me to take her out." is not the same as "s" in "Tom's dad ordered pizza yesterday for the family." We treat the first "s"

examples	normalization
I'm	I am
n't	not
does't	does not
it's	it is
...	...
that's	that is
neighbor's	neighbor
wouldn't	would not
won't	will not

Table 1: normalization patterns.

as "is," and the second, of course, is an adjective. We restore those abbreviations in Table 1 to normal forms.

- 4) Removing other characters:

Removing other characters, such as "!", "%", "?", "#", ",", "@", etc. Of course, not all other symbols that seem useless are removed. Like "\$" are not removed.

4 Experiments and Results

In order to optimize our network, we use (Kingma and Ba, 2014) optimizer on training model. All our experiments have been developed using an open source software library of Tensorflow with CUDA enabled, and run on a computer with Intel Core(TM) i3 CPU 760 @2.8GHz, 8GB of RAM and GeForce GTX960 GPU. Due to the lack of hardware capacity, we do not run the entire system in one time. Instead, we run single model each time with different word embeddings. When we use the word embedding of Google News 300d on some sub models, the system gives memory exhausted, and we switch to a smaller glove_27B_100d to run successfully. Table 2 shows our results for various models. As it can be seen from the table, ensemble results from the more different models get better results when other conditions are similar. Here we ensemble these models: RNN, GRU, BiLSTM, multi-BiLSTM+CNN and Attention+BiLSTM, based on their high accuracy. The dropout probability is 0.6 in each model, and the initial learning rate is 0.01.

5 Conclusion

In this project, we ensemble a variety of structurally different models to tackle this task. The

model	self trained	glove_twitter_27B_100d	GoogleNews_300d.bin
RNN	—	0.6638	—
LSTM	0.7001	0.7042	0.6932
GRU	—	0.6732	—
CNN1D	0.5634	0.6324	—
CNN2D	—	0.5683	—
CNN2D+LSTM	—	0.5573	—
BiLSTM	0.6734	0.7135	—

Combine to all models	0.6550	0.7213	0.6923

Table 2: Result for various models on task data set.

performance of a single model is poorer than the ensemble model. And the bigger the difference between the models, the higher performance the ensemble model makes. Still our results are less satisfying than top teams on the leaderboard. We will adjust the model, improve the hardware configuration of the computer, collect more external data, and do more experiments to get a better result in the future.

YNU_Deep at SemEval-2018 Task 11: An Ensemble of Attention-based BiLSTM Models for Machine Comprehension

Peng Ding, Xiaobing Zhou*

School of Information Science and Engineering
Yunnan University, Yunnan, P.R. China

*Corresponding author, zhouxb.cn@gmail.com

Abstract

This paper reports our submission to task 11 (Machine Comprehension using Commonsense Knowledge) in SemEval 2018. We firstly use GloVe to learn the distributed representations automatically from the instance, question and answer triples. Then an attention-based Bidirectional LSTM (BiLSTM) model is used to encode the triples. We also perform a simple ensemble method to improve the effectiveness of our model. The system we developed obtains an encouraging result on this task. It achieves the accuracy 0.7472 on the test set. We rank 5th according to the official ranking.

1 Introduction

Machine comprehension of text is one of the ultimate goals of natural language processing. The machine comprehension problem can be formulated as follows: Given an instance i , a question q and an answer candidate pool $\{a_1, a_2, \dots, a_s\}$, the aim is to search for the best answer candidate a_k , where $1 \leq k \leq s$. The major challenge of this task is that the words in the answer do not necessarily appear in the instance.

In recent years, deep learning models are widely used in the field of NLP, such as semantic analysis (Tang et al., 2015), machine translation (Bahdanau et al., 2014) and text summarization (Rush et al., 2015). (Bahdanau et al., 2014) also introduced the attention mechanism into NLP task for the first time. This attention-based model yielded state-of-the-art performance on the machine translation task. (Hermann et al., 2015) built a supervised reading comprehension data set, the CNN/Daily Mail data sets¹. They also presented Attentive Reader for machine comprehension, which allows a model to focus on the aspects of an instance that

can help to answer a question, and also allows us to visualize its inference process (Hermann et al., 2015). The key point of the attention-based models is the design of attention function. Compared to Attentive Reader, Attention Sum Reader (Kadlec et al., 2016) used the dot products instead of a \tanh layer to compute the attention between question and contextual embeddings. Stanford Attention Reader (Chen et al., 2016) took a bilinear term as the attention function and obtained state-of-the-art results on the CNN/Daily Mail data sets.

The reasoning process was implemented in some models for machine comprehension. Memory Networks (Sukhbaatar et al., 2015) was the first model to propose reasoning process, which had important influence on other follow-up models. Compared to the traditional attention model, Memory Networks additionally uses a function t that constantly updates the representation of the instance and the question so as to realize the reasoning process. (Tseng et al., 2016) proposed an attention-based multi-hop recurrent neural network which achieved good performance on the machine listening comprehension test of TOEFL. Other reasoning models (Dhingra et al., 2017; Sordoni et al., 2016) shared the same idea as previous models, i.e., the representations of the instance and the question embedding were updated through continuous conversion of attention. Some more complex models (Hu et al., 2017; Liu et al., 2017) were proposed based on SQuAD data set (Rajpurkar et al., 2016). Their performances have been very close to or even exceeded the human performance on this dataset.

In this paper, we introduce a simple ensemble method on multiple identical attention-based BiLSTM models, only changing the dropout parameters in each model. We use each model to generate a soft prediction, and sum each result, then take the sum as the final prediction result. Experiments

¹<http://www.github.com/deepmind/rc-data/>

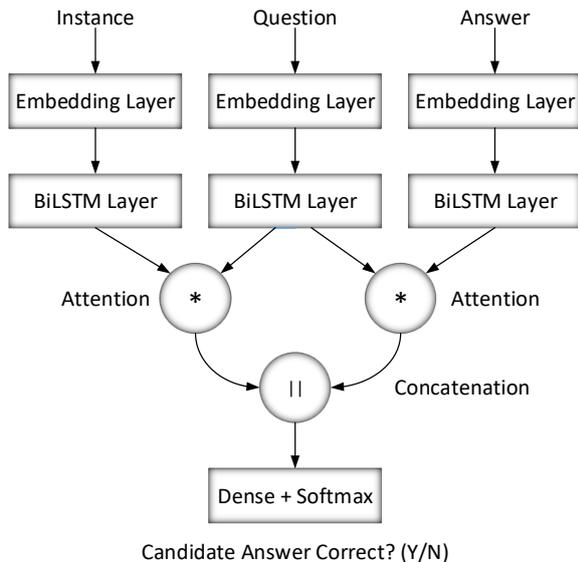

Figure 1: Our attention-based BiLSTM model for machine comprehension.

show that the ensemble model is about 2% higher than the single model in terms of accuracy on both development and test sets. Besides, we also made our code available online².

2 System Description

Our model is called an ensemble of attention-based BiLSTM models. Firstly, we use an embedding layer to obtain the distributed representations of the instance, question and answer triples. They are encoded by three different BiLSTM layers. The attention mechanism is implemented by *dot* products via a merge layer. Finally, we assign the same weight to each model when ensembling. The final result is the sum of the soft probabilities yielded by each single model. We keep the structure of each model the same, just fine tune the dropout parameters. The model architecture is shown in Figure 1. The attention mechanism is developed by calculating the *dot* product of the outputs from two BiLSTM layers. Then we use ‘||’ operation to concatenate two matrices from the previous layer in the specified dimension. Finally, a *Dense* fully connected layer with activation *softmax* is used to get the predicted probabilities.

²<https://github.com/Deep1994/An-Ensemble-of-Attention-based-BiLSTM-Model-for-Machine-Comprehension>

2.1 BiLSTM

Single direction LSTM (Hochreiter and Schmidhuber, 1997) suffers a weakness of not using the contextual information from the future tokens. Bidirectional LSTM (BiLSTM) exploits both the previous and future context by processing the sequence on two directions and generates two independent sequences of LSTM output vectors. One processes the input sequence in the forward direction, while the other processes the input in the backward direction. The words in the instances, questions and answers are represented by the concatenation of the hidden layer outputs in both directions at each time step.

2.2 Word Embedding

Word embedding is arguably the most widely known technology in the recent history of NLP. It is well-known that using pre-trained embedding helps (Kim, 2014). We try two word embedding tools, GloVe (Pennington et al., 2014) and Word2Vec (Mikolov et al., 2013) on this task.

Tool	Size	Vocab	Dimension
GloVe	5.5G	2.2million	300
Word2Vec	3.5G	3million	300

Table 1: Summary statistics for the embedding tools: Size is the file size after decompression. Both tools have a dimension of 300. The Vocab is the number of word vectors contained in the tool.

2.3 Attention Mechanism

The LSTM model can alleviate the problem of gradient vanishing, but this problem persists in long range reading comprehension contexts. The attention mechanism breaks the constraint on fix-length vector as the context vector, enables the model to focus on those more helpful to outputs. (Luong et al., 2015) presented several attention computation ways, such as *dot*, *general*, *concat*. In our model, we adopt the *dot* mode to compute the attention. After BiLSTM layer, we implement a *dot* product operation on the output vectors produced by previous layer. It is proven effective to improve the performance of our model.

The attention mechanism in our model uses a matching function f to associate the target module with the source module, the function f is implemented as follows:

$$f(m_t, m_s) = m_t^T m_s \quad (1)$$

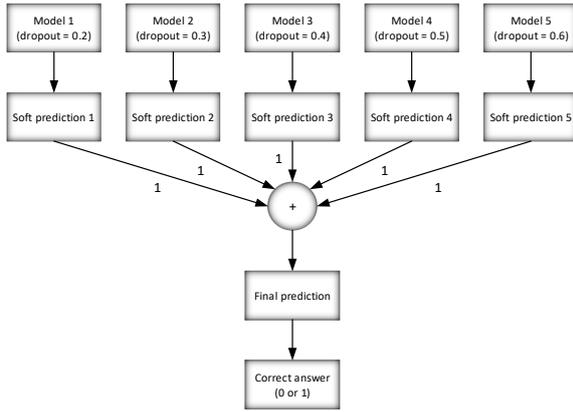

Figure 2: The ensemble method used in our model. The dropout parameters for the five models varied from 0.2 to 0.6 after the BiLSTM layer.

where m_t and m_s correspond to instance and question vectors, or answer and question vectors produced by previous BiLSTM layers, respectively.

2.4 Model Ensemble

Combining multiple models into an ensemble by averaging their predictions is a proven strategy to improve model performance. While predicting with an ensemble is expensive at test time, recent advances in distillation allow us to compress an expensive ensemble into a much smaller model (Hinton et al., 2015; Kuncoro et al., 2016; Kim and Rush, 2016).

In our model, each single model will yield a soft probability to determine if the candidate answer is correct or not. As is shown in figure 2, we train several models and sum the results produced by them. Then we use the sum of the probabilities as the final prediction. We found that the performance of the ensemble model is always better than that of a single model.

3 Experiments

We run each model 10 times, taking the average results as the final experimental results to enhance reliability. In all single models, the dropout parameter is taken as 0.3, and the ensemble model is trained through 5 BiLSTM models. Their dropout parameters are changed from 0.2 to 0.6, respectively, and then the results of the 5 models are summed as the final prediction. We set $epoch = 6$, $batch\ size = 512$ and $LSTM\ Units = 64$. Optimization is carried out using Adaptive Moment Estimation (Adam).

3.1 Data Processing

The organizers provided training, development, and test sets, containing 9837, 1417, 2797 questions, respectively. Each question corresponds two answers, only one is correct.

We firstly substitute the abbreviation characters and remove the meaningless characters. Then we combine the instance, question and answer as the supervised training set. Labels are represented by 0 (False) or 1 (True). The *TweetTokenizer*³ in NLTK is adopted for word segmentation. Furthermore, we find the maximum length of instances is much longer than that of questions and answers, so we remove the stop words in the instances. Our experiments show that doing so not only does not harm the accuracy, but also drastically reduces the training time.

3.2 Experiments and Result Analysis

We compare two word embedding tools, Word2Vec and GloVe, and the experimental results show that GloVe almost always outperforms Word2Vec on this task. Although the vocabularies in GloVe are less than those in Word2Vec, GloVe contains more abbreviations, which are especially useful after tokenizing the instance, question and answer triples, and greatly reduce the number of unknown words in word embedding, making the context semantics better learned by the model. We make random assignments on unknown words, ranging from -0.25 to 0.25.

Tool	Ukw	Time	Dev Acc	Test Acc
GloVe	33	597s	0.7448	0.7276
Word2Vec	276	40s	0.7415	0.7087

Table 2: Comparison between Word2Vec and GloVe tools on BiLSTM models. Ukw is the number of unknown words. Time is the loading time of two tools. We can see GloVe performs better, but its loading time is much longer than that of Word2Vec.

As seen in Table 3, we compare two network architectures, LSTM and BiLSTM. The results show that the BiLSTM model performs better than the LSTM model on this task.

Based on Glove word embedding and BiLSTM architecture, we train 5 single models for ensemble. The only difference between them is the difference in dropout parameters, which increases from 0.2 to 0.6. In our experiments, we train the

³<http://www.nltk.org/api/nltk.tokenize.html>

Network	Tool	Dev Acc	Test Acc
LSTM	GloVe	0.7448	0.7276
BiLSTM	GloVe	0.7508	0.7301

Table 3: Comparison between LSTM and BiLSTM. BiLSTM performs better than LSTM on both datasets.

single model with the dropout in order of 0.3, 0.5, 0.4, 0.2, 0.6, then the first ensemble is the result of adding the first two models with the dropout of 0.3, 0.5 as the predictive result, the result of the second ensemble is based on the first ensemble plus the single model with dropout of 0.4, and so on. We perform a total of 4 ensemble experiments, the results show that the accuracy of each ensemble model improved on both datasets. The final ensemble model has an accuracy rate of 0.7699 on the development set and 0.7472 on the test set. However, we find that our model was slightly more accurate on the test set without the ensemble of the model with a dropout of 0.6, but the overall effect is not obvious. Ensemble makes our model perform well on this task, ranking 5th out of 11 submissions.

Dropout	Dev Acc	Test Acc
0.3	0.7476	0.7311
0.5	0.7516	0.7183
Ensemble 1	0.7608	0.7386
0.4	0.7615	0.7294
Ensemble 2	0.7692	0.7408
0.2	0.7354	0.7143
Ensemble 3	0.7664	0.7479
0.6	0.7410	0.7308
Ensemble 4	0.7699	0.7472

Table 4: Results on single and ensemble models. All models adopt GloVe + Attention-based BiLSTM architecture. The dropout layer is behind the BiLSTM layer.

4 Conclusion and Future Work

In this paper, we present an ensemble of attention-based BiLSTM models for machine comprehension task. We find GloVe is superior to Word2Vec on this task, a simple ensemble method can significantly enhance the overall performance.

In the future, we plan to explore more ways to compute the attention, such as a bilinear term. Future work also involves using more external knowledge and deeper network to improve model performance. We will explore the ensemble method in greater depth, trying ensemble on the models with more structural difference.

Abstract

This paper describes the system we submitted to the Task 11 in SemEval 2018, i.e., Machine Comprehension using Commonsense Knowledge. Given a passage and some questions that each have two candidate answers, this task requires the participate system to select out one answer meet the meaning of original text or commonsense knowledge from the candidate answers. For this task, we use a deep learning method to obtain final predict answer by calculating relevance of choices representations and question-aware document representation.

1 Introduction

In recent years, the presentation of challenge and large-scale reading comprehension corpora has driven the development of technology for machine reading comprehension, and most of these machine comprehension datasets do not need commonsense knowledge to answer questions. The purpose of Machine Comprehension using Commonsense Knowledge task in Semeval 2018 is to provide a platform for finding a way for the machine to better understand the text and enable the machine answer questions based on the text, and encourage participants to make use any external resources (e.g., DeScript, narrative chains, Wikipedia, etc) to improve the system performance (Ostermann et al., 2018b). The task 11 is a multiple-choice machine comprehension, which requires a system read a narrative text about everyday activities (Ostermann et al., 2018a) and then answer multiple-choice questions based on this text. Some questions need to be answered according to the original text, and others can be answered by commonsense knowledge. Each question is associated with a set of two answers. Table 1 gives an example of the dataset.

To address this machine comprehension task, we utilized rule-based methods and a deep learn-

document: Early this morning I woke up to the sound of my newspaper landing on my driveway. I sat up and wrapped my pink robe around me. I slipped my feet into my slippers and looked at the clock. It was only 7:00 but it was time for me to get my newspaper and drink some coffee. I looked out the window and noticed it was raining quite a bit. I saw the newspaper at the end of my driveway, as far away as it could be. I grabbed my umbrella out of my coat closet and opened my front door enough to stick the umbrella through and open it outside. I stepped out the door and quickly covered my head with the umbrella. Then I ran to the end of my driveway, scooped up the newspaper in its plastic wrapping, and ran back to my front door. I closed my umbrella, took off my slippers, and dried off. Then, I unwrapped my newspaper and sat down to read it.

question: Do they read the paper daily?

candidate answers:

0. No they usually watch TV in the mornings.

1. Yes

answer: 1

ing method. Our final submission use Gated-Attention Reader (Dhingra et al., 2016) to fuse question information into document and acquire a question-aware document representation, the degree of interaction between choices and document are regard as the probabilities of choices being returned as an answer. The above two methods do not use additional commonsense knowledge, which may lead to the poor performance of our system. In future work, we may explore more methods to integrate common knowledge into models.

The rest of this paper is organized as follows. Section 2 describes our systems. Section 3 describes datasets, experimental setting and analyse results on datasets. Finally, Section 4 concludes this work.

2 System Description

2.1 Task Description

Formally, this multiple-choice machine comprehension task can be expressed as a quadruple: $\langle \mathbf{D}, \mathbf{Q}, \mathbf{A}, \mathbf{a} \rangle$. Where \mathbf{D} represents a narrative text about everyday activities, \mathbf{Q} represents a question for the content of the narrative text, \mathbf{A} is the candidate answer choice set to the question (this task contains two candidate answers choice a_0 and a_1) and \mathbf{a} represents the correct answer. The system is expected to select an answer from \mathbf{A} that best answers \mathbf{Q} according to the evidences in document \mathbf{D} or commonsense knowledge.

2.2 Two Rule-based Baselines

First of all, we implemented a rule-based system proposed in (Richardson et al., 2013), which used the sliding-window (SW) and word distance-based (WD) algorithms to calculate the answer scores according to the rules and return the highest-score answer. We also tried the improved SW and WD algorithms proposed in (Smith et al., 2015), and the system performance has improvement. Sliding-window and Word Distance-based algorithms are described as follows:

Sliding-Window: Given a data sample $\langle \mathbf{D}, \mathbf{Q}, a_0(\text{or } a_1), \mathbf{a} \rangle$, firstly, we calculate the inverse word counts of each word in the document \mathbf{D} . Then we set a window that slides word by word from the beginning of the document to the end. When the window slides to a position, the sum of inverse word counts of all the words that appears in the question \mathbf{Q} or the candidate choice a_0 (or a_1) is the score of the window at this moment. Until the window slides to the end of the passage, we choose the highest window score as the final score of the candidate choice a_0 (or a_1). Window size is size of union of the question \mathbf{Q} and the choice a_0 (or a_1), and the window slides over full passage only once. In the improved SW algorithm, the window size is 2-30, and window passes full passage window several times, and increasing the size of the window by one after each sliding over the full passage. The summing up values of all passes is served as improved sliding window score.

Word Distance-based: Given a data sample $\langle \mathbf{D}, \mathbf{Q}, a_0(\text{or } a_1), \mathbf{a} \rangle$, firstly, we define two collections, set_{dq} and set_{dc} , set_{dq} represents the intersection of the question words and the document words, and set_{dc} represents the intersection of the words in the choice and the words of the docu-

ment. If neither set_{dq} nor set_{dc} is empty set, we calculate the shortest distance between words of set_{dq} and words of set_{dc} in the document, denote the shortest distance as d_{min} , and the word distance score of the choice is $\frac{d_{min}+1}{|D|-1}$, otherwise, the word distance score of the choice is zero.

The sliding-window score minus the word distance-based score is the final score of the choice. We separately calculated the scores of the two choices for the question and then selected the choice with higher score as the answer to the question.

2.3 Deep Learning model

Both of the above unsupervised methods score the overlap that between each answer and the document by making a sliding-window passes over the document. Therefore, we roughly count the proportion of words in correct answers appear in the document¹, and we find that the proportion of correct answers whose words appear entirely in the article is not high in all correct answers. The proportion show that there is a limit to using the above method to improve system performance. Hence we used a deep learning approach to passage representations modeling. Inspired by (Lai et al., 2017), we use the state-of-art Gated-Attention Reader which performs well on several datasets. When a sample data $\langle \mathbf{D}, \mathbf{Q}, \mathbf{A}, \mathbf{a} \rangle$ is given, the steps of the model processing this data sample are described below, Figure 1 shows the system.

2.3.1 Passage, Question and Choice Encoder

First, each word in \mathbf{D} , \mathbf{Q} , and choices (two choices in candidate answer set \mathbf{A}) is mapped to d-dimensional vector. The 300-dim GloVe embedding (Pennington et al., 2014) is used. For the input word vectors of \mathbf{D} , we also include a 5-dim binary feature to indicates the overlap between the document and the question(or choices) which inspired by (Chen et al., 2017). Each dimension of the 5-dim binary match feature represent whether the word present in the query, in the choice a_0 , in the choice a_1 , in both question and

¹We use the following equations to estimate how many answers appear entirely in the document: if $|\text{answer word} \cap \text{document word}| / |\text{answer word}| = 1$, it means the answer appears entirely in the document, where $|A|$ means size of set A. Then we calculate $|\text{ans}_{ce}| / |\text{ans}_c|$, where ans_{ce} means correct answers which entirely appeared in document, and ans_c means correct answers. The percentage of the correct answers entirely appeared in document is about 24%.

choice a_0 , in both question and choice a_1 , respectively. Take passage as an example, we have document \mathbf{D} : $x_1^{\mathbf{D}}, x_2^{\mathbf{D}}, \dots, x_m^{\mathbf{D}} \in R^{|D|*dim}$, and next we use bi-directional GRU to encode each document word embedding $x_i^{\mathbf{D}}$,

$$\overrightarrow{h_i^{\mathbf{D}}} = biGRU(\overrightarrow{h_{i-1}^{\mathbf{D}}}, x_1^{\mathbf{D}}), i = 1, 2, \dots, m$$

$$\overleftarrow{h_i^{\mathbf{D}}} = biGRU(\overleftarrow{h_{i+1}^{\mathbf{D}}}, x_1^{\mathbf{D}}), i = m, m-1, \dots, 1$$

we define $\mathbf{h}_i^{\mathbf{D}} \in R^{2d}$ is concatenation of the $\overrightarrow{h_i^{\mathbf{D}}}$ and $\overleftarrow{h_i^{\mathbf{D}}}$, where d is hidden size. At this time, we get the encoded document representation $\mathbf{D}^e = \{ \mathbf{h}_1^{\mathbf{D}}, \mathbf{h}_2^{\mathbf{D}}, \dots, \mathbf{h}_m^{\mathbf{D}} \}$. Meanwhile, we use separate bi-directional GRU to form representation for question, we denote these representations as $\mathbf{Q}^e = \{ \mathbf{h}_1^{\mathbf{Q}}, \mathbf{h}_2^{\mathbf{Q}}, \dots, \mathbf{h}_n^{\mathbf{Q}} \}$. As for choices, we concat $\overrightarrow{h_n^{\mathbf{C}}}$ and $\overleftarrow{h_1^{\mathbf{C}}}$ to make up a vector represent a choice, so we get $\mathbf{C}_0 \in R^{2d}$ and $\mathbf{C}_1 \in R^{2d}$.

2.3.2 Summarize Question-aware Passage Representation

The interaction layer of Gated-Attention Reader is a l -layers multi-hop architecture with gated-attention units. Each multi-hop layer contain a bi-GRU and a gated-attention unit. As shown in Figure 1, we sent $\mathbf{Q}^e \in R^{|Q|*2d}$ and $\mathbf{D}^e \in R^{|D|*2d}$ into a gated-attention unit. Gated-attention unit fuses information from question to each document tokens and generates a set of vectors $\mathbf{D}_l^{GA} = \{ \mathbf{d}_1^{(l)}, \mathbf{d}_2^{(l)}, \dots, \mathbf{d}_m^{(l)} \}$, where superscript (l) denote l -th multi-hop layer. To generates \mathbf{D}_l^{GA} , firstly, the question soft attention to each document word to obtain attention weight α_i , and then we use α_i to calculate a weighted question representation \overline{q}_i for i -th word in \mathbf{D} , finally, the weighted question \overline{q}_i representation is element-wise multiplied by \mathbf{h}_i makes \mathbf{d}_i . The specific calculation steps of a gated-attention unit are as follows.

$$\alpha_i = softmax(\mathbf{Q}^e \mathbf{h}_i) \quad (1)$$

$$\overline{q}_i = \mathbf{Q}^{eT} \alpha_i \quad (2)$$

$$\mathbf{d}_i = \mathbf{h}_i \cdot \overline{q}_i \quad (3)$$

After obtaining the current layer question-aware document representation, we put this representation into next hop layer, until after l layers multi-hops, we generate the a set of question-aware vectors \mathbf{D}_l^{GA} for document. Finally, we sent \mathbf{D}_l^{GA} into a layer biGRU and concat the last outputs of each direction ($\overrightarrow{h_{l+1}^{GA}}$ and $\overleftarrow{h_{l+1}^{GA}}$) to get a ultimate question-aware document representation vector $\tilde{\mathbf{D}} \in R^{2d}$

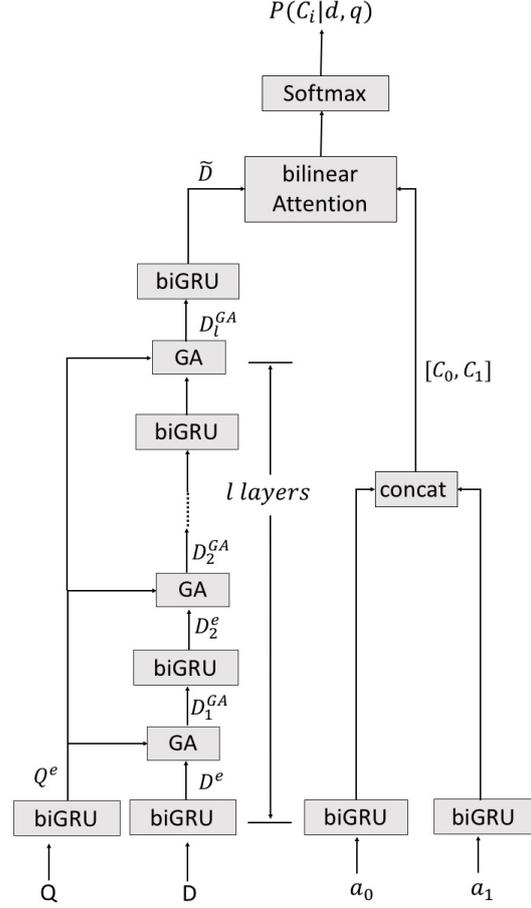

Figure 1: Architecture of our system.

2.3.3 Answer Selection

Now, we have a question-aware representation $\tilde{\mathbf{D}}$, two choice representations \mathbf{C}_0 and \mathbf{C}_1 . We estimate the probability that the choice selected as the correct answer by equation (4), and the choice with a higher-probability is returned as the predict answer.

$$[p_0, p_1] = softmax([\mathbf{C}_0, \mathbf{C}_1] W \tilde{\mathbf{D}}) \quad (4)$$

3 Experiments

3.1 Datasets and Evaluation Metric

Table 2 shows the statistics of articles and questions in training, development, test data sets of this task. Here “#text” and “#commonsense” represent the question types, which are unknown during test and officially provided by organizers after test. Therefore, we do not use the class information of questions for system construction. Clearly, around 70% questions are from text and 30% are from commonsense. Without the aid of additional commonsense knowledge base, these questions from commonsense makes this task a huge challenge.

Dataset	Articles	Questions		
		#text	#commonsense	#total
train	1,470	7,032	2,699	9,731
dev	219	1,006	405	1,411
test	429	2,074	723	2,797

Table 2: The statistics of data sets in training, development and test data.

To evaluate the system performance, the official evaluation criterion is *accuracy*.

3.2 Preprocessing and Experimental Setting

For rule-based baselines, we first converted words into their lowercase and then performed tokenization and stemming using Stanford CoreNLP². For deep learning system, we use 300-D pretrained word vectors provided by GloVe³ as initial word embedding, which are fine-tuned during training. The encoding layer use one layer biGRU with 128-dims hidden size to encoder texts. Learning rate is 0.3, droprate is 0.5, epoch is 100, and num of multi-hops is 2. We use cross entropy and vanilla stochastic gradient descent (SGD) to train our models.

3.3 Experiments on Training Data

Table 3 shows the results of Task 11 with different methods on dev dataset, where “GA(biGRU)” denotes the final system we submit, “GA(biLSTM)” represents the experiment that we replace all biGRU units in the system with biLSTM units, “GA - f_{match} ” represents the system without 5-dim match feature, “#text” and “#commonsens” represent the accuracy under different question types, respectively.

Methods	Accuracy		
	#text	#commonsense	#total
SW + WD	62.62%	45.92%	57.83%
improved SW+WD	65.01%	47.65%	60.02%
GA(biGRU)	77.33%	78.51%	77.63%
GA(biLSTM)	76.41%	77.53%	76.76%
GA - f_{match}	76.34%	78.02%	76.82%

Table 3: The results on dev.

Based on above experimental results, we find that the performance of GA system is much better than rule-based approaches, this is because

²<https://stanfordnlp.github.io/CoreNLP/>

³<http://nlp.stanford.edu/data/wordvecs/glove.6B.zip>

the multi-hop structure merges the information of the question and the document repeatedly which is helpful to select final answer, unlike the rule-based approach that considers only word matching within a window-size distance. Furthermore, we find that the improved SW + WD algorithm is better than SW + WD algorithm, because the improved SW + WD algorithm considers the degree of word matching at different distances. From the GA system results, we find the performance of using biGRU units is better than that of biLSTM units and matching features also improves the system performance. Compare the accuracy of different types of questions under different methods, we find that the rule-based approaches considers only the word-matched features lead to lower accuracy on the commonsense type questions. GA systems perform better than rule-based systems on both types of questions, because the GA system takes into account the semantic similarity of the question-aware document and choices. Further, there are some commonsense types questions which the document content does not clearly indicate the correct answer but clearly does not meet the meaning of wrong answer. This may be the reason why we did not use external resources but the accuracy of the commonsense type question predicted by GA system is improved.

3.4 Results on Test Data

Table 4 shows the our result and official results of top-ranked teams on SemEval 2018 Task 11 test set.

Teamname	Rank	Accuracy(total)
ECNU	10	0.7311
iFLYTEK & HIT (HFL)	1	0.8413
Yuanfudao	2	0.8395
MITRE	3	0.8227

Table 4: Our result and the top three results on test sets.

The final result we submitted is generated by GA system used biGRU units, the specific configuration of which is mentioned in Section 3.2. Compared with the top ranked systems, there is much room for improvement in our work. In addition, the use of external knowledge resources by the system also have an impact on system performance because there are about 26% commonsense type questions in the dataset. This is where our

system lacks.

4 Conclusion

In this paper, we implement rule-based and deep learning approaches to address Machine Comprehension Using Commonsense Knowledge task in SemEval 2018. We explored two rule-based algorithm i.e., sliding window and word distance-based algorithm. We also utilized a deep learning method which use a multi-hop architecture (Gated-attention Reader). The above two methods do not use additional commonsense knowledge, this is a point that we need to improve.

Abstract

In this document we present an end-to-end machine reading comprehension system that solves multiple choice questions with a textual entailment perspective. Since some of the knowledge required is not explicitly mentioned in the text, we try to exploit common sense knowledge by using pretrained word embeddings during contextual embeddings and by dynamically generating a weighted representation of related script knowledge. In the model two kinds of prediction structure are ensemble, and the final accuracy of our system is 10 percent higher than the naïve baseline.

1 Introduction

K. M. Arivuchelvan et al.(2017) stated that machine reading comprehension can be defined as a task that deals with the automatic understanding of texts. In their paper, it was also mentioned that machine comprehension can be evaluated by two methods, namely (1) translating the text into formal language representations and evaluating it using structured queries. (2) evaluating it through natural language questions. Recently a lot of datasets are available for evaluating machine reading comprehension systems, for example, there are SQuAD(Rajpurkar et al., 2016) and the MCTest(Richardson et al., 2013). On many of these datasets human-like performance has been achieved. However, one of the biggest challenges in machine comprehension is how to provide common sense knowledge regarding daily events to machines(Mostafazadeh et al., 2016). The SemEval2018-Task11(Ostermann et al., 2018) provides a dataset containing questions that can only be answered with the help of common sense knowledge.To address this problem, we first propose a model to solve normal reading comprehension problems and then try to modify the model to embody common sense knowledge. In section two, we give a brief in-

roduction to ideas and models that might be useful to a comprehensive understanding of our work. Section three carefully describes our model implementation, and why we chose this kind of model structure. And section four briefly examines the datasets used. Section five provides a simple evaluation of our result. Finally, our conclusion can be found in section six.

2 Background Knowledge

In this section, we present some basic knowledge required for a comprehensive understanding of our model. We first give a basic introduction to RNN models and the implementation of GRU Cell, then cast a little glance upon the textual entailment problems.

2.1 Recurrent Neural Network

Lipton et al.(2015) stated that Recurrent neural networks (RNNs) are “connectionist models with the ability to selectively pass information across sequence steps, while processing sequential data one element at a time.” An RNN model captures features of a sequence by updating a hidden set of variables at every input element, as illustrated in figure 1. In many language modelling tasks, the output of every RNN iteration step will simply be a prediction of the one-hot representation of the next element in the sequence. However, as we intended to train our model end-to-end, we will not care much about the output of the RNN model, but pay attention instead to the hidden state because it is likely to be a contextual representation influenced by every input element.

2.2 GRU Cell

One of the commonly used RNN hidden units is LSTM (Hochreiter and Schmidhuber, 1997). This kind of hidden unit can retain short-term memory for a long time during sequence processing, thus

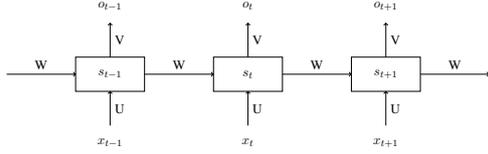

Figure 1: An illustration of unfolded RNN cells.

is able to recognize long-term dependency information. GRU Cell (Cho et al., 2014) is inspired by LSTM, and is simpler to compute. For each timestep t , two gating vector is computed, i.e., the reset gate r and the update gate z by

$$r_j = \sigma([W_r x]_j + [U_r h^{<t-1>}]_j)$$

$$z_j = \sigma([W_z x]_j + [U_z h^{<t-1>}]_j)$$

Where x is the input vector and h is the hidden-state vector, and $[\cdot]_j$ means the j th element of a given vector. $W_{(\cdot)}$ $U_{(\cdot)}$ are matrix parameters to be trained. With these variables defined, the hidden state can be updated as

$$h_j^{<t>} = z_j h_j^{<t-1>} + (1 - z_j) \tilde{h}_j^{<t>}$$

where \tilde{h} is calculated as

$$\tilde{h}_j^{<t>} = \phi([W x]_j + [U(r \odot h^{<t-1>})]_j)$$

Therefore with the interaction of these two gate the cell is able to learn a pattern whether to reset the hidden state using current input, or to retain the previous hidden state largely.

2.3 Textual Entailment Model

We try to first adapt an existing textual entailment model to this machine comprehension problem. The model is first proposed by Rocktaschel et al. (2015)., in which the premise is first contextually encoded, then a hypothesis-to-premise word by word attention is calculated. The model implicitly modify a hidden variable r_t to regulate the attention distribution at timestep t as

$$M_t = \tanh(W^y Y + (W^h h_t + W^r r_{t-1}) \otimes e_L)$$

$$\alpha_t = \text{softmax}(w^T M_t)$$

$$r_t = Y \alpha_t^T + \tanh(W^t r_{t-1})$$

Here we have maintained the original symbol usage of Rocktaschel et al., where $W_{(\cdot)}$ and $U_{(\cdot)}$ are variable matrices to be trained, and Y is the matrix containing all hidden states of the premise

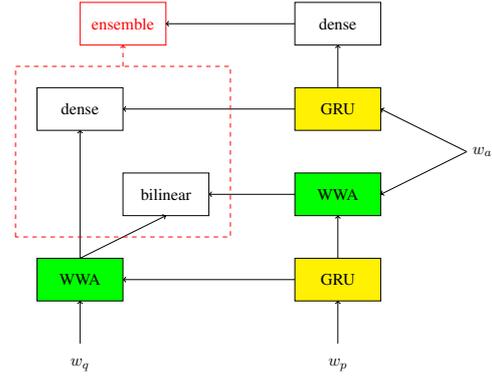

Figure 2: Our basic model, where “dense” represents fully connected layers, and WWA represents word-wise-attention structure described in section 2.3.

encoder. We generally follow the framework of this model, with modifications made to embody common sense knowledge and answer multiple choice questions.

3 Method

3.1 Bilinear Form

One of our classifiers uses the bilinear form. According to Milnor et al. (1973), a bilinear form is a function:

$$\beta: X \times X \rightarrow R$$

such that $\beta(x, y)$ is R -linear as a function of x for fixed y , and is R -linear as a function of y for fixed x . Then such a bilinear form can be called as an inner product on X . Thus this kind of inner product can intuitively be used to measure similarity between two representations of the same space, we design our bilinear classifier as follow:

Let α_1^N and α_2^N denote answer representations generated by our word-wise-attention mechanism from answers to text described in last section, and let q^N denote the question representation generated through the same process. Then we construct a trainable matrix $B^{N \times N}$. Then we can get a similarity score vector s where:

$$s_i = \alpha_i^T B q$$

Then to normalize probability representation we perform a softmax function upon s to give our classification result.

3.2 Dense Classifier

We have another fully-connected classifier that works as described below. Let α_1^N and α_2^N denote the answer representations generated with

pure RNN layer with GRU cell (compare with the WWA generated representation in the bilinear classifier), and let q^N denote the attended question representation generated by word-wise-attention mechanism described in subsection 2.3. Then we concatenate these three representation as c :

$$c = [q: \alpha_1 : \alpha_2]$$

Then we use c as the input of a two layer fully-connected neural network, where the hidden layer in the middle has nodes only half the number of the input, and the output layer is a softmaxed probability distribution representing our model's final choice.

3.3 General Model

Our model answers the multiple choice question by first encoding the question and the passage combined using the aforementioned textual entailment encoding, and then using two different question answering classifier to choose one of the two choices. A weighted sum is then calculated from the two answers each represented by a binary distribution. The weight is dynamically decided by a feed-forward network taking two contextually encoded answer strings as input. First the contextual embedded answer string representations of two answer choices are calculated by RNN-encoder, then we concatenate them and put them into a feed-forward network to calculate weights for the ensemble of the two aforementioned classifier. A general illustration can be seen in figure 2. Here GRU stands for an rnn unit using GRU cell, while WWA stands for word-wise attention used in textual entailment. We can see that our model can be trained end-to-end, and most of the weights can be dynamically learnt during training.

During training, the text is tokenized and lemmatized using python NLTK (Bird and Loper, 2002), and word stemming is not performed. We have made this choice because which words should be classified as stop word is hard to decide for an RNN model that are likely to capture some of the syntactic features of a given language.

The motivation for our using two different classifier is that we want to softly provide different solutions to different kinds of problems. The bilinear classifier measures similarity between question-attended and answer-attended contextual representations, which we believe should have better result on non-TF questions (By non-TF questions

we mean those open questions which can not be answered by "Yes—True" or "No—False"), while the dense classifier should do better on TF questions according to our expectation. A detailed analysis of the model weights can be seen in next section.

3.4 Common Sense Knowledge

However some of the question in the test set cannot be answered merely with information provided in the passage. We try to embody some kinds of common sense knowledge representation into the general model, however their influence to system performance varies.

3.4.1 Word Embedding

In the general model, the embedding layer that converts the one-hot representation of an input word to its corresponding embedding vector is trainable, and is optimized during training using back-propagation (Rumelhart et al., 1986) algorithm. However, due to the relatively small database size, we have finally marked the embedding layer untrainable, and use GloVe (Pennington et al., 2014) word embeddings instead.

3.4.2 Script Knowledge

The script knowledge we have chosen is the OMCS (Singh et al., 2002) database. In the database are presented many different step by step descriptions of some daily events. To use this script knowledge, we first encode every single description as a passage using the RNN that was once used to encode our mission text. Then for every event e_i we calculate the event representation as an average of each description representation in that event category:

$$e_i = \frac{1}{M} \sum_{j=1}^M x_{i,j}^N$$

Where $x_{i,j}$ is the j^{th} description representation of event i . Then let E denote the event representation matrix with its i^{th} row representing event i , then every time context representation r_t is calculated, we calculate a similarity vector s as:

$$s = \text{softmax}(EW r_t)$$

Then if $\max_{i < M}(s_i) > t$ where t is a threshold hyper-parameter, we substitute r_t and its time series matrix with corresponding e_i and its time series matrix. But as this treatment provided little enhancement to our accuracy, we excluded

System	Accuracy
1 st place	0.843
SCReader	0.631
baseline	About 0.53

Figure 3: Table comparing performance of different systems.

this structure from our final submission. Still we believe that other common sense representation might be helpful, like ConceptNet (Liu and Singh, 2004).

4 Experiment Setting and Evaluation

4.1 Overview

We Trained our model using SGD with weight decay. No minibatch grouping is used, and we trained our model on training set for 20000 time steps. When near convergence, our model can reach around 80% to 90% accuracy upon training set (The accuracy is sampled), and in last two model we trained that finally lead to our only submission, we get an accuracy result of about 68% on developing set. This accuracy is a little higher than our final accuracy on test set. Our final result compared with baseline and the first rank system is given in the form.

4.2 Preprocessing

Before inputting the raw text into our model, we first transform words into their one-hot representation without stemming and lemmatization, and tokenization is done using NLTK toolkit. Then we push the data through an embedding layer in which the GloVe 50 was used due to time concerns.

4.3 Further Discussion

Providing our scarce usage of common sense knowledge, our model performed surprisingly well on time deduction problems. Even in questions where an addition of fifteen minutes to thirty minutes to get forty-five minutes as answer is required, our model successfully chose the right answer. However, the ensemble didn't work as we intended. The bilinear classifier was unalterably providing $[0, 1]$ after softmaxing, probably due to machine floating point precision limit. And the result weight determiner always assign the GRU related classifier a far greater weight. This is

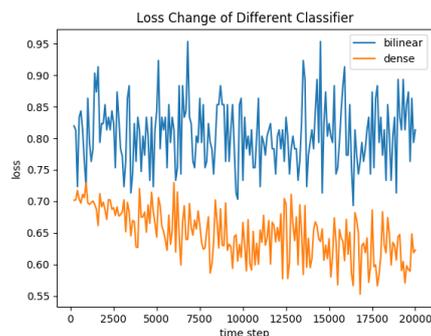

Figure 4: The loss change of our two classifier.

very counterintuitive, and we are still trying hard to find its real cause. Pre-trained word embedding boosted our accuracy for about 5% - 10% on developing set, and the training became faster and converged far more quickly. To further analyse the prediction ability of our two classification, we trained our two classifier separately by 20,000 steps, and calculated a sampled loss function according to 100 samples every 100 steps. The result is given in figure 4. We found that the bilinear classifier converges very slowly, while the dense classifier, if used separately, has a converging tendency even in 20,000 timesteps. This result corresponds with our observation that when used together, the weights assigned to these two classifiers always converge to $[0, 1]$, where little importance is given to the bilinear classifier, which is counter-intuitive.

5 Conclusions and Future Work

Our model is a machine comprehension model based on textual entailment logics, and on the basis of previous works we made several renovations to embody common sense knowledge representation. We finally reached accuracy for about 63% on test dataset, however due to time limit, we have never tried any fine-tuning techniques. Observing this model we are able to say that it is useful to have common sense knowledge data integrated to machine comprehension problems, though a proper knowledge representation should be worked out. We are currently switching to other kinds of common sense knowledge representations, and trying to devise new answer selection logics. From the competition result it is very clear that there's still much space for our accuracy improvements.

Abstract

This shared task is a typical question answering (QA) task. Specially, this task must give the answer to the question based on the text provided. The essence of the problem is actually reading comprehension. For each question, there are two candidate answers, and only one of them is correct. Existing method for this task is to use convolutional neural network (CNN) and recurrent neural network (RNN) or their improved models, such as long short-term memory (LSTM). In this paper, an attention-based CNN-LSTM model is proposed for this task. By adding an attention mechanism and combining the two models, the experimental results have been significantly improved. The accuracy of our final submission is 0.7143.

1 Introduction

Question answering has long been an important research topic in the field of natural language processing. Prior to this, there have been many similar tasks, and many scholars have made very significant contributions to the research in this field. Such as the Allen AI Science Challenge on the Kaggle (Schoenick et al., 2016) and the IJCNLP-2017 shared task 5: Multi-choice Question Answering in Exams (Yuan et al., 2017).

Machine comprehension using commonsense knowledge is required to answer multiple-choice questions based on narrative texts about daily activities of human beings. The answer to many questions does not appear directly in the text, but requires simple reasoning to achieve. In terms of the nature of the problem, this task can be considered as a binary classification. That is, for each question, the candidate answers are divided into two categories: the correct answers and the wrong answers.

In recent years, many achievements have been made in machine comprehension-based question answering. Among the existing methods, the main differences are in the data processing and the application of the model. A dataset for multi-choice question answering was released by Richardson et al. (2013). Clark (2015) described how to obtain more information from the background knowledge base by introducing the use of background knowledge to build the best scene. A large cloze-style dataset using CNN and Daily Mail news articles was created by Hermann et al. (2015). Unlike previous datasets, Rajpurkar et al. (2016) released a machine comprehension-based dataset (SQuAD dataset). It contains over 1M text-question-answer triples crawled from 536 Wikipedia articles, and the questions and answers are structured primarily through crowdsourcing. It also requires people to submit up to five article-based questions and provide the correct answer that has appeared in the original text. For the open-domain QA dataset, it is even more challenging to get answers because it requires simple word matching and some simple reasoning. In SearchQA (Dunn et al., 2017), the question-answer pairs are crawled from the Jeopardy archives and are augmented with text snippets retrieved from Google search. Kundu and Ng (2018) proposed an end-to-end, problem-based, multi-factor attention network that addresses the task of answering document-based questions. This model can collect scattered evidence from multiple sentences for the generation of answers.

In this paper, we mainly propose to use an attention-based CNN-LSTM model for this task. The word-embedding model we choose is Word2Vec. Then, the word vectors are fed into the convolutional neural network (CNN) layer. After that, the results of the CNN layer are fed into the long short-term memory (LSTM) layer. Finally, an attention mechanism is added into the neu-

ral networks, and the prediction results are output via the softmax activation. All the data is processed into (text-question-answer) form. For each candidate answer, the system will give a correct probability (probability of a correct answer) and a wrong probability (probability of a wrong answer), and the sum of these probabilities is 1. The answer with the larger correct probability of those two candidate answers will be selected by the system as the correct answer. Furthermore, in order to exclude the experimental error caused by chance, nine such models are assembled together for training. The answers are obtained by hard voting. At the same time, we also selected a number of other models (such as the Bi-LSTM, the attention-based Bi-LSTM and the attention-based LSTM) for comparative experiments. The experimental results show that attention-based CNN-LSTM can achieve better results when using Word2Vec as the word embedding technique.

The rest of our paper is structured as follows. Section 2 introduces the CNN, LSTM and attention-based CNN-LSTM. Experiments and evaluation will be described in Section 3. The conclusions are drawn in Section 4.

2 Model

For this task, we select 10 models for comparison. Among these models, the attention-based CNN-LSTM models can get the best results. This model combines the CNN with the LSTM and incorporates the attention mechanism. The most important elements of this model are the CNN, the LSTM and the attention mechanism.

The CNN has been proven to be very effective for local feature extraction. Since the operation of the CNN layer will lose the long-distance dependency, a LSTM layer is added to handle the sequential information of the input vectors. The attention mechanism is a good solution to the information vanish problem in long sequence input situations. When dealing with machine comprehension problems, their combined use is more effective than their use individually.

2.1 Convolutional Neural Network

The convolutional neural network was originally used to process image data. In recent years, the application of the convolution neural network has gradually infiltrated into many fields, such as speech recognition and natural language process-

ing. The convolutional neural network consists of three parts. The first part is the input layer. The second part consists of a combination of n convolution layers and a pooling layer. The third part consists of a fully connected multi-layer perceptron classifier. The difference between the convolutional neural networks and ordinary neural networks is that the convolutional neural networks consist of a feature extractor made up of the convolutional layers and the sub-sampling layers. In the convolutional layers, one neuron is connected to only a few adjacent neurons.

In our experiment, the convolution layer was mainly used to extract features. The convolution matrix has m columns, and m is the maximum length of the sentence. The convolution matrix has n rows, and n refers to the number of sentences. The direct benefit of sharing weights (convolution kernels) is to reduce the number of connections between layers of the network while reducing the risk of overfitting.

2.2 Long Short-Term Memory

Traditional recursive neural networks are ineffective when dealing with very long sentences. The LSTM model is developed to solve the gradient vanishing or exploding problems in the RNN. Currently, the LSTM is mainly used in natural language processing such as speech recognition and machine translation. Compared with the traditional RNN, a LSTM unit is added to the traditional model for judging the usefulness of information. Each unit mainly contains three gates (the forget gate, the input gate, and the output gate) and a memory cell. The system will judge the usefulness of the information after the input information is fed into an LSTM. Only the information that matches the rules of the algorithm will be saved, and the other information will be discarded by the forget gate.

In our experiment, the LSTM layer is designed to ensure that important information in the front part of a long sequence can also have an impact on the processing of the latter part of the long sequence.

2.3 Attention-based CNN-LSTM

Both the CNN and LSTM models have their own advantages and disadvantages. The former performs well in local feature extraction, but easily loses the long-distance dependency of words. The latter can only solve the problem of information

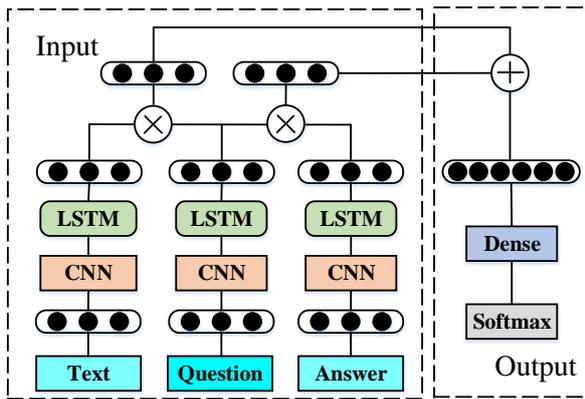

Figure 1: Architecture of a AT-CNN-LSTM.

vanish in long sequence input situations to a certain extent. Therefore, we combined the two models with additional attention mechanisms to form an attention-based CNN-LSTM model for this task, as shown in Fig 1.

In this model, all the texts, questions, and answers will be converted into word vectors through the word-embedding layer. These word vectors will be first fed into the CNN layer, and then the output feature vectors will be fed into the LSTM layer. Subsequently, the word vectors are expressed as hidden vectors. Next, the attention mechanism assigns a weight to each hidden vector. The attention mechanism produces an attention weight vector and a weighted hidden representation. The attention weight vector is mainly obtained by calculating the similarity. The main operation here is dot. An attention weight vector is generated by computing the question vector matrix and answer vector matrix. Another attention weight vector is generated by computing the question vector matrix and text vector matrix. Next, two attention weight vectors are connected via contact method. Then the attention weight vector is fed into the softmax layer.

The attention mechanism allows the model to retain some important hidden information when the sentences are quite long. In our task, the text, questions and answers are relatively long sentences. The use of a standard CNN or LSTM will result in the loss of hidden information. To address this possible problem, the attention-based CNN-LSTM model is used to design the machine comprehension system.

Word2Vec	Acc

Table 1: Comparative experiment results

3 Experiments and Evaluation

3.1 Experiments

Data Pre-processing. The dataset provided by the organizer mainly include three parts: texts, questions, and answers. In the data pre-processing phase, texts and questions-answers pairs are divided into two separate files. The content of each piece of text data mainly includes the text id and the text content. Each question-answer pair data mainly includes the text id, the question id, and the question-answer pair content. In the final experiment, we added validation data to the training set to expand the training data. We also tried sorting the training data randomly to expand the data set, but the result was not satisfactory. All input data is converted into word vectors through the word-embedding layer, and the word-embedding model is Word2Vec. Here, all the punctuation is ignored, and all non-English characters are treated as unknown words. In the word vectors, unknown word vectors are randomly generated from a uniform distribution $U(-0.25, 0.25)$.

Two different methods of word-embedding are used in this experiment: Word2Vec and GloVe (Pennington et al., 2014). They are used to initialize the weights of the embedding layer in building 300-dimension word vectors for all the texts and question-answer pairs. Word2Vec achieved better performance than GloVe in every model we used. Through the list of unknown words, we know that the use of Word2Vec results in fewer unknown words than GloVe.

Implementation Details. All the code involved in this experiment was written in Python 3.5.2. Keras 2.0.4 is used as the framework for the program. The backend used in this experiment is Ten-

Parameters	Optimal
Filter size	250
Kernel size	3
Dropout rate	0.3
Epoch	10
Batch size	64
Word embedding dim	300
Accuracy	0.7143

Table 2: Optimal parameters

Flow 1.1.0. We use the attention-based CNN-LSTM to obtain the results for the test dataset.

The first model we use is a standard CNN model. As shown in Table 1, it can achieve an accuracy of 0.638 and 0.629 when respectively using Word2Vec and GloVe as the word-embedding layer. Due to the impact of jagged sentences, the poor result obtained by the CNN model is predictable. After that, a standard LSTM model is used to complete this task. It can achieve an accuracy of 0.651 and 0.642 when respectively using Word2Vec and GloVe as the word-embedding layer. However, the results obtained by the LSTM model have been somewhat improved over the CNN model. Next, we also apply the BiLSTM model and the best result is 0.654, but there are still many points that can be improved. Combining the two models effectively seems to be the perfect choice. In this way, we achieve an accuracy of 0.687. Finally, after adding the attention mechanism, the result is raised to 0.699. Under the same experimental conditions, the attention-based CNN-LSTM model obtained a better result than other models we used in most cases (Wang et al., 2016). To exclude the experimental error caused by chance, nine such models are assembled together for training. The final accuracy can be raised to 0.714. Table 1 presents the results of a comparative experiment for all models we used.

The choice of model parameters has a significant effect on the final accuracy. The main parameters of this model are the word-embedding dimension, the batch size, the epoch, the filter size, the kernel size, the dropout and so on. To get the optimal parameters, the Sklearn grid search function (Liu et al., 2015) is used to determine the best combination of the parameters. Table 2 lists the parameters of the model when the best result is obtained.

3.2 Evaluation

Evaluation Metrics. For this experiment, it measures how well a system is capable of correctly an-

swering questions that may involve commonsense knowledge. This problem is a typical binary classification problem. Therefore, the system is evaluated by calculating the accuracy.

Results. According to the final results provided by the organizers, a total of 199 teams enrolled in the competition. Only 24 teams eventually submitted their results. Our team ranked 13th overall among all teams. As shown in Table 1, the attention-based CNN-LSTM model can achieve the highest accuracy when using Word2Vec as the word-embedding layer. This model combines the advantages of the CNN model, the LSTM model and the attention mechanism. Furthermore, the use of Word2Vec for word-embedding is better than the GloVe word-embedding. The main difference between the two embeddings is in the training sets. The training sets of Word2Vec are practically from the news, while the training sets of GloVe are from Twitter. Therefore, the Word2Vec data source is better suited to this task.

4 Conclusion

This paper mainly focuses on our attention-based CNN-LSTM system for the task of machine comprehension using commonsense knowledge. It gives a brief introduction of the model and gives a detailed description for the experimental process and results. Compared with the attention-based LSTM model, the attention-based CNN-LSTM is better at feature extraction. The experimental results also show that the use of multiple models for ensemble training can also, to some extent, avoid the accidental results and improve the accuracy of the experiment. In the future, we will focus on methods combination and models ensemble. In addition, our team will also continue to propose a new model that can improve the existing results.

Jiangnan at SemEval-2018 Task 11: Deep Neural Network with Attention Method for Machine Comprehension Task

Jiangnan Xia

Alibaba Group

Hangzhou, China

jiangnan_xjn@alibaba-inc.com

Abstract

This paper describes our submission for the International Workshop on Semantic Evaluation (SemEval-2018) shared task 11– Machine Comprehension using Commonsense Knowledge (Ostermann et al., 2018b). We use a deep neural network model to choose the correct answer from the candidate answers pair when the document and question are given. The interactions between document, question and answers are modeled by attention mechanism and a variety of manual features are used to improve model performance. We also use CoVe (McCann et al., 2017) as an external source of knowledge which is not mentioned in the document. As a result, our system achieves 80.91% accuracy on the test data, which is on the third place of the leaderboard.

1 Introduction

In recent years, machine reading comprehension (MRC) which attempts to enable machines to answer questions when given a set of documents, has attracted great attentions. Several MRC datasets have been released such as the Stanford Question Answering Dataset (SQuAD) (Rajpurkar et al., 2016) and the Microsoft MACHine Reading COMprehension Dataset (MS-MARCO) (Nguyen et al., 2016). These datasets provide large scale of manually created data, greatly inspired the research in this field. And a series of neural network model, such as BiDAF (Seo et al., 2016), R-Net (Wang et al., 2017), have achieved promising results on these evaluation tasks. However, machine reading comprehension is still a difficult task because without knowledge, machines cannot really understand the question and make a correct answer.

As an effort to discover how machine reading comprehension systems would be benefited from commonsense knowledge, (Ostermann et al., 2018b) developed the Machine Comprehension

using Commonsense Knowledge task. In this task, commonsense knowledge is given as the form of script knowledge. Script knowledge is defined as the knowledge about everyday activities which is mentioned in narrative documents. For each document, a series questions are asked and each question is associated with a pair of candidate answers. Machines have to choose which is the correct answer. To let machines make correct decisions, explicit information which can be found in the document and external commonsense knowledge are both required. Table 1 shows an example of the dataset in this task.

In this paper, we make a description about our submission system for the task. The system is based on a deep neural network model. The input of the model is a (*document, question, answer*) triple and the output is the probability that the answer is the correct one for the given document and question. We also combine the neural network model with a variety of manual features, including word exact match features and token features such as part-of-speech (POS), named entity recognition (NER) and term frequency (TF). These manual features are helpful in solving the problem that the correct answer can be easily found in the given document.

Furthermore, for more complicated problem that the answer is not explicitly mentioned in the document, we try to model the interactions between document, question and answer by computing the attention score of question to document and question to answer respectively, which is described in (Lee et al., 2016). These features add soft alignments between similar but non-identical words (Chen et al., 2017). We evaluate our system on the shared task and obtain 80.91% accuracy on the test set, which is on the third place of the leaderboard.

The rest of this paper is organized as follows.

Document:

I went into my bedroom and flipped the light switch. Oh, I see that the ceiling lamp is not turning on. It must be that the light bulb needs replacement. I go through my closet and find a new light bulb that will fit this lamp and place it in my pocket. I also get my stepladder and place it under the lamp. I make sure the light switch is in the off position. I climb up the ladder and unscrew the old light bulb. I place the old bulb in my pocket and take out the new one. I then screw in the new bulb. I climb down the stepladder and place it back into the closet. I then throw out the old bulb into the recycling bin. I go back to my bedroom and turn on the light switch. I am happy to see that there is again light in my room.

Question1: Which room did the light go out in?

0. Kitchen. (Wrong)

1. Bedroom. (Correct)

Question2: Was the light bulb still hot?

0. yes. (Wrong)

1. No. (Correct)

Table 1: An example from the machine comprehension using commonsense knowledge task (Ostermann et al., 2018b). The first line shows the document and the following lines show question and answer pair respectively. The answer of *question1* can be easily found in the text while answering *question2* requires external knowledge which is not mentioned in the text.

Section 2 describes the submission system. Section 3 presents and discusses the experiment results. Section 4 makes a conclusion about our work.

2 Model

In this task, a document (D), a question (Q), and a pair of answers (A_0, A_1) are given and a machine comprehension system should choose the correct answer from the answers pair. We attempt to solve this problem by leveraging a deep neural network model which can generate the probability $p_\theta(A_i|D, Q), i = 0 \text{ or } 1$ that the input answer is correct for the given document and question. The system predicts the probability for each answer in (A_0, A_1) respectively and decides which is the correct answer by comparing their probability scores. We represent the set of all trainable parameters of

the neural network model as θ . The model basically consists 3 parts: an encode layer, an interaction layer and a final inference layer, which is depicted in figure 1. Below we will discuss the model in more detail.

2.1 Encode layer

We first represent all tokens of document $\{d_1, \dots, d_m\}$, question $\{q_1, \dots, q_n\}$ and answer $\{a_1, \dots, a_l\}$ as sequences of word embeddings $\{E_1^d, \dots, E_m^d\}$, $\{E_1^q, \dots, E_n^q\}$ and $\{E_1^a, \dots, E_l^a\}$, where m , n and l are sequence lengths of document, question and answer respectively. In this task, we use the 300-dimensional 840B Glove word embeddings (Pennington et al., 2014). We then pass each sequence through a multi-layer bidirectional long short term memory network (BiLSTM) to get the word level semantic representations of each sequence:

$$h_j^d = BiLSTM_j(\{E_i^d\}_{i=1}^m) \quad (1)$$

$$h_j^q = BiLSTM_j(\{E_i^q\}_{i=1}^n) \quad (2)$$

$$h_j^a = BiLSTM_j(\{E_i^a\}_{i=1}^l) \quad (3)$$

The index j represents the j th BiLSTM layer. We concat all the output units of each BiLSTM layer and get the final word level representations: h^d , h^q and h^a . The BiLSTM layers used to encode document, question and answer sequence share same parameters in order to reduce the number of trainable parameters and make the model uneasily overfitting.

2.2 Interaction layer

This layer models the interactions between document, question and answer. We first align each word representation vectors in the question sequence to document and answer by leveraging attention mechanism and get question-aware representation Att^d , Att^a for document and answer respectively:

$$Att_i^d = \sum_j s_{i,j}^d h_j^q \quad (4)$$

$$Att_i^a = \sum_j s_{i,j}^a h_j^q \quad (5)$$

The attention score $s_{i,j}^d$ captures the similarity between the word representation vector d_i and q_j in document sequence and question sequence respectively. And $s_{i,j}^a$ captures the similarity between answer vector a_i and question vector q_j .

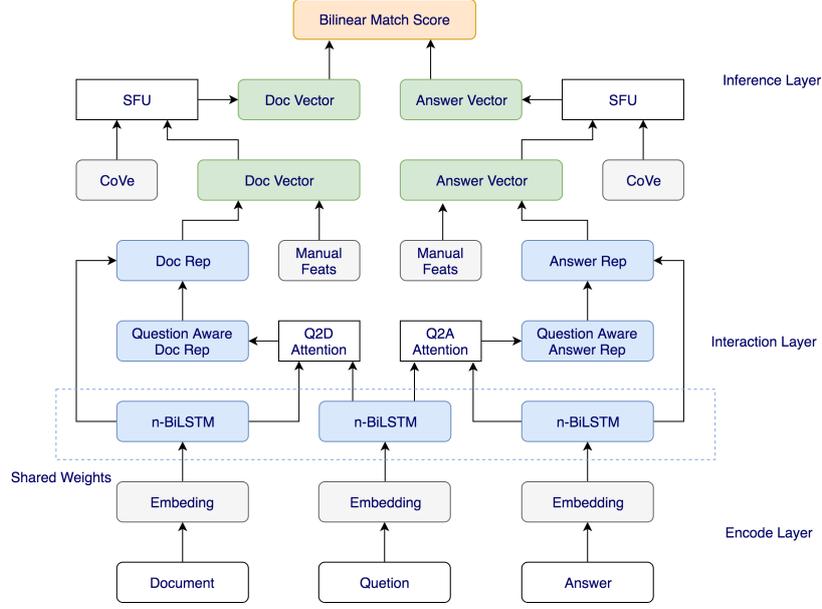

Figure 1: Neural network model architecture for the machine comprehension task

We get $s_{i,j}^d$ and $s_{i,j}^a$ by computing the dot products between the nonlinear mappings of two word representation vectors:

$$s_{i,j}^d = \frac{\exp(\alpha(d_i) \cdot \alpha(q_j))}{\sum_{j'} \exp(\alpha(d_i) \cdot \alpha(q_{j'}))} \quad (6)$$

$$s_{i,j}^a = \frac{\exp(\alpha(a_i) \cdot \alpha(q_j))}{\sum_{j'} \exp(\alpha(a_i) \cdot \alpha(q_{j'}))} \quad (7)$$

$\alpha(\cdot)$ is a single dense layer with ReLU nonlinearity. We concat Att_i^d and Att_i^a behind each h_i^d and h_i^a and get new word representation vectors r^d and r^a for document and answer.

Following (Chen et al., 2017), we combine the model with a variety of manual features, including word exact match features and token features. For exact match features, we use three binary features indicating whether a token in d and a can be exactly matched by one token in q , either in its original, lowercase or lemma form. For token features, we use part-of-speech (POS), named entity recognition (NER) and term frequency (TF). For document and answer, we combine the manual features as vectors f_i^d, f_i^a and concat to r_i^d, r_i^a and get new word level representation vectors $r_i^{\prime d}$ and $r_i^{\prime a}$:

$$r^{\prime d} = \{r_i^{\prime d}\}_{i=1}^m = \{[r_i^d; f_i^d]\}_{i=1}^m \quad (8)$$

$$r^{\prime a} = \{r_i^{\prime a}\}_{i=1}^l = \{[r_i^a; f_i^a]\}_{i=1}^l \quad (9)$$

2.3 Inference layer

In inference layer, we first convert the document and answer sequence $r^{\prime d}, r^{\prime a}$ into fixed length

vectors with weighted pooling method and get sequence level representation vectors R_d and R_a :

$$R_d = \sum_{i=1}^m u_i^d r_i^{\prime d} \quad (10)$$

$$R_a = \sum_{i=1}^l u_i^a r_i^{\prime a} \quad (11)$$

$$u_i^d = \frac{\exp(w^d \cdot r_i^{\prime d})}{\sum_{j'=1}^m \exp(w^d \cdot r_{j'}^{\prime d})} \quad (12)$$

$$u_i^a = \frac{\exp(w^a \cdot r_i^{\prime a})}{\sum_{j'=1}^l \exp(w^a \cdot r_{j'}^{\prime a})} \quad (13)$$

The weight vector w^d and w^a are learnable parameters of the model.

As we haven't use any external source of knowledge, we attempt to use other pre-trained language model as external knowledge, in order to get more implicit information which is not mentioned in the document. Here we use CoVe (McCann et al., 2017) in document and answer sequences. The Glove embedding of each token will pass through a pre-trained BiLSTM layer. The BiLSTM layer outputs a sequence of CoVe vectors of document and answer $c^d = \{c_i^d\}_{i=1}^m, c^a = \{c_i^a\}_{i=1}^l$. We then convert the sequences into fixed length vectors C_d and C_a by using the weighted pooling method which is mentioned above.

We fuse the pooled CoVe vectors with the sequence level representation vectors with semantic fusion unit (SFU) (Hu et al., 2017) and get the final sequence level representation vectors R_d' and R_a' :

$$R_d' = SFU_d(R_d, C_d) \quad (14)$$

$$R'_a = SFU_a(R_a, C_a) \quad (15)$$

Finally, we represent the probability that the answer is correct by computing the bilinear match score of document and answer vectors:

$$P = \sigma(R'_d W R'_a) \quad (16)$$

W is a trainable matrix and $\sigma(\cdot)$ is the sigmoid function. In this task, we use this model to predict the probability for each answer in (A_0, A_1) and decide which is the correct one by selecting the answer with higher probability score.

3 Experiments

3.1 Datasets

The statistics of official training, development and test data are shown in Table 2.

	Training	Dev	Test
Num of examples	9,731	1,411	2,797

Table 2: Statistics of the official datasets

We remove the words occurring less than 2 times and finally get about 12000 words in the vocabulary. We keep most pre-trained word embeddings fixed during training and only fine-tune the 100 most frequent words. For manual features, we get POS and NER features by using Stanford CoreNLP¹ toolkits.

3.2 Experimental Settings

We implement our model by using PyTorch². The model is trained in the given training set and we choose the model which performs best on the development set among training epochs. We train the model with mini batch size 32. We use two layers BiLSTM with 128 hidden units. A dropout rate of 0.4 is applied to word embeddings and all hidden units in BiLSTM layers. We use logistic loss as the loss function optimized by using Adamax optimizer (Kingma and Ba, 2014) with learning rate $\eta = 0.002$.

3.3 Results

The performances of our model are depicted in Table 3. The single model achieves accuracy of 85.05% on the development data and 79.03% on

the test data. The ensemble model which we finally submitted to the shared task achieves accuracy of 87.30% on the development data and 80.91% on the test data. From the result we can see that there is a gap between development data and test data for both single model and ensemble model. The model overfits the development data but does not perform well on the test data. Shows that the robustness of our model needs to be improved.

We conduct ablation analysis of different features used in the model on the development data. Table 4 shows the ablation analysis results from which we can see that all the features we used can contribute to model performance. Without manual features, the model accuracy is 83.70%, which is 1.3% less than the full model. and without CoVe, the accuracy drops 1.8%. The accuracy drops 6.6% when neither manual features nor CoVe are used. The results show that the model requires both explicit information which can be found in the document and external source of knowledge to make correct decisions.

Model	Acc.(Dev)	Acc.(Test)
Single Model	0.8505	0.7903
Ensemble Model	0.8730	0.8091

Table 3: Results of the single and ensemble model on development data and test data.

Features	Acc.(Dev)
Full	0.8505
w/o Manual features	0.8370
w/o CoVe	0.8320
w/o Manual features and CoVe	0.7845

Table 4: Ablation analysis of features.

4 Conclusion

In this paper, we make a description of our submitted system to the SemEval-2018 shared task 11. The system is based on a deep neural network model which will choose the correct answer from the answers pair when the document and question are given. We combine the model with a variety of manual features which are helpful in solving the problem that the correct answer can be easily found in the given document. For the problem that the answer is not explicitly mentioned in the document, we model the interactions between

¹<https://stanfordnlp.github.io/CoreNLP/>

²<http://pytorch.org/>

document, question and answers by using attention mechanism. We also attempt to use CoVe as an external source of knowledge. We conduct experiment and prove that the features we used are helpful in contributing to the model performance. Our system achieves 80.91% accuracy on the test data, which is on the third place of the leaderboard.

Abstract

This paper describes the IUCM entry at SemEval-2018 Task 11, on machine comprehension using commonsense knowledge. First, clustering and topic modeling are used to divide given texts into topics. Then, during the answering phase, other texts of the same topic are retrieved and used as commonsense knowledge. Finally, the answer is selected. While clustering itself shows good results, finding an answer proves to be more challenging. This paper reports the results of system evaluation and suggests potential improvements.

1 Introduction

The goal of SemEval-2018 Task 11 is to find a way to incorporate commonsense knowledge into a question-answering task (Ostermann et al., 2018b). In this case, questions are either directly or indirectly related to given English texts; some questions may be answered using the text while others require background (commonsense) knowledge. The challenge is to use this knowledge in such a way as to enhance the quality of chosen answers.

There are many approaches to question answering including using structured knowledge (Yao and Durme, 2014), knowledge databases (Yih et al., 2015), deep learning methods (Minaee and Liu, 2017) and hybrid methods (Xu et al., 2016; Das et al., 2017). The present task accepts any method or any source of background knowledge.

The training data consists of 1469 texts covering more than 100 topics. The number of questions per text varies from 1 to 14 and there are two answer options. The development data has 219 texts and the test data has 430. (Ostermann et al., 2018a)

The main idea behind the method proposed in this paper is to use the given texts as potential sources of knowledge. Texts from training and

development data can be divided into topics using existing clustering algorithms (e.g. k-Means, Hierarchical, Grid-based or Density-based). The hypothesis is that texts which come from the same topic as the current question’s text may contain the correct answer. A matching function with a scoring scheme is used to identify the correct combination of words for the answer.

Another potential source of knowledge is scripts (Wanzare et al., 2016) that have been used to search for an answer. The DeScript dataset includes descriptions of everyday activities such as baking, getting a haircut, going grocery shopping, and others, corresponding to topics present in the given data.

Section 2 describes the methods as well as specifics of implementation. Section 3 provide interpretation and analysis of the results. Section 4 concludes the present paper.

2 Methodology

All texts, questions and answers were tokenized, punctuation and extra symbols were removed. WordNet (Fellbaum, 1998) was used for lemmatization using its *morph()* function. Transforming all words into their initial form resulted in an approximately 1% increase of accuracy.

The overall process of answering a question could be broadly divided into two phases: clustering texts (or searching for the most similar DeScript’s topic), and finding the correct answer. The former is discussed in the following subsections, and the latter is described below.

There are minor modifications to the base *choose-answer* method across all solutions but overall the structure is as follows. First, we search for a full-length match. If one is found, then we consider it to be a correct one. If not, we remove all common words (such as articles, prepositions

and auxiliary verbs) from the answer, and count how many words can be found in text. Finally, we compare all answers and choose the one with the highest match count.

A modification was introduced to account for yes-no questions. If words from the question were present in the text, the “yes” answer was selected; otherwise, the “no” answer was selected. This, however, actually decreased the accuracy as it did not consider negations that occurred in the text and were tokenized separately. Therefore, the prior version of the method was used in all submissions.

The baseline solution used the method described above to find the answer in the given text only. This resulted in accuracy of around 60% for all data sets (see Section 3).

2.1 Comparison of BigARTM and KMeans

The next step was to cluster texts from training and development data into topics, in order to use them later as sources of background knowledge. BigARTM, a tool to infer topics based on additive regularization of topic models proposed in [Vorontsov and Potapenko \(2014\)](#), was used to model the texts as topics.

Since the language of the given texts consisted of many everyday words, it was necessary to first make sure that the data used for clustering was clear of common, uninformative words. BigARTM provides tools to make the resulting matrix of document-topic mapping sparser, however, it did not provide as good a result as simple removal of the English stopwords contained in the NLTK library ([Bird and Loper, 2004](#)).

The texts then were transformed into batches in vectorized form, the number of topics varied between 100 and 110, and the model initialized with scores for sparsity (PhiScore and ThetaScore) and perplexity. The model was then trained with 15 passes through the collection of texts (bigger numbers didn't result in better accuracy).

Topic	Probability
topic 33	0.024480
topic 90	0.021954
topic 26	0.020483
topic 37	0.017545
topic 82	0.016841

Table 1: Probability of the topic being the top choice for the text

Table 1 shows five most frequent topics and the probability of the topic being the top one for the text. Below are the top 15 tokens for three most frequent topics:

- 'pan', 'eggs', 'milk', 'heat', 'stove', 'egg', 'turn', 'make', 'pour', 'cook', 'add', 'hot', 'get', 'omelette', 'bowl'
- 'wall', 'paint', 'room', 'new', 'floor', 'look', 'decide', 'house', 'want', 'put', 'buy', 'color', 'get', 'painting', 'work'
- 'water', 'shower', 'get', 'soap', 'rinse', 'towel', 'turn', 'body', 'hot', 'take', 'bucket', 'dry', 'clean', 'start', 'warm'

Another approach to clustering was to use k-Means. First, texts were embedded in the vector space using the gensim ([Řehůřek and Sojka, 2010](#)) implementation of Doc2Vec ([Le and Mikolov, 2014](#)), and then NLTK's k-Means was applied over the result.

The Doc2Vec model was trained on the texts from all data sets and for several runs DeScript's gold standard was also added. At each step the learning rate was decreased by 0.002. Number of epochs varied from 20 to 30 and window size was also experimented with.

The top 15 tokens for three most frequent topics are as follows:

- 'wall', 'paint', 'painting', 'room', 'look', 'get', 'would', 'want', 'go', 'hang', 'decide', 'put', 'nail', 'wallpaper', 'color'
- 'bed', 'sheet', 'pillow', 'put', 'make', 'take', 'top', 'get', 'corner', 'tuck', 'fit', 'sure', 'clean', 'mattress'
- 'dish', 'put', 'dishwasher', 'dry', 'sink', 'plate', 'water', 'clean', 'rack', 'wash', 'silverware', 'one', 'start', 'top', 'take'

The top clusters for the two methods are slightly different in terms of their topics but there are obvious differences in words: k-Means clusters include more general language (e.g. verbs like 'go', 'take', 'make') and less specific language related to the topic. At the same time k-Means' distribution of classes has a larger number of texts per cluster on average. This can be seen in Figures 1 and 2. The horizontal axis is number of texts and the vertical one is the cluster ID number.

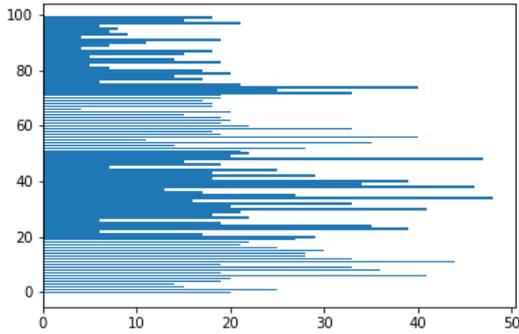

Figure 1: Distribution of texts for KMeans (*y-axis*: topic numbers, *x-axis*: number of texts belonging to the topic)

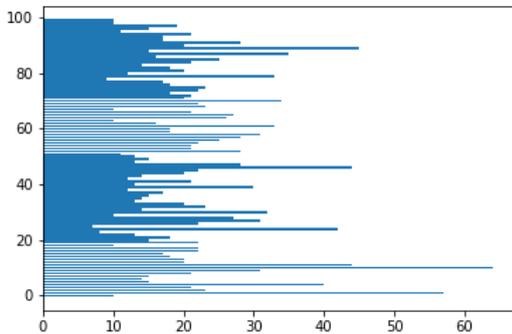

Figure 2: Distribution of texts for BigARTM (*y-axis*: topic numbers, *x-axis*: number of texts belonging to the topic)

For both clustering methods, choosing the correct answer was done in two steps. The first step was the same as in the baseline, finding full answers or scoring individual words. If the answer was not found, the second step was carried out, which involved looking up other texts from the same cluster as the given text and searching for an answer in them.

2.2 Using DeScript

DeScript (Wanzare et al., 2016) sequences are divided into events which, in turn, include many different paraphrases of the same event (*check timetable, locate a train schedule, check train schedules* and other similar ones).

To simplify comparison between training data texts and DeScript sequences, all events corresponding to the same topic were combined. Then the vector for each topic was built using the 15 most frequent words from the topic as keys and

their TF-IDFs as values. The same was done for each text.

The method for choosing the answer was as described above. The difference was that instead of using texts from the same cluster as a source of commonsense knowledge, DeScript paraphrases were used. Cosine similarity between the given text and each DeScript topic was calculated based on most frequent word vectors, in order to find the most suitable events. This approach resulted in better performance than with clustering methods (Section 3).

3 Evaluation

The results for the test data are summarized in Table 2. These are the configurations that resulted in the best performance.

Model	Accuracy
Baseline	60.70
Yes/No Modification	59.52
BigARTM topics	61.38
DeScript paraphrases	61.67
Doc2Vec/KMeans	61.95

Table 2: Results

BigARTM’s advantage over the baseline solution is not much, but there is an interesting trend that explains why the score is higher. Questions with no word-for-word answer in the texts were answered correctly when individual words were found within the same-topic clusters. This showed that given texts could be a useful knowledge source.

There are also cases when both answers get zero scores and in that case the first one is chosen.

Another observation is that correct answers were more often selected if they contained full sentences rather than a couple of words.

The DeScript and BigARTM methods answered 6% of questions differently. These were, for the most part, for answers that were not explicitly phrased in the text but obvious to a human (such as *evening* when the text talked about dinner, or *bedroom* when a bed was mentioned). This requires an additional logical step, so this kind of questions can be in a category of their own – neither text nor commonsense.

For k-Means the number of clusters was 100. Table 3 describes the results for Doc2Vec/k-Means method with various configurations (number of

epochs, window size, whether DeScript texts were included into the training or not).

Epochs	Window	DeScript	Accuracy
20	10	No	61.70
20	12	No	61.60
20	10	Yes	61.56
30	10	No	61.74
30	12	No	61.88
30	10	Yes	61.24
30	12	Yes	61.95

Table 3: Doc2Vec/KMeans configurations and accuracy

The model with a larger window size performs better as it takes into account more words at the same time, sometimes spanning multiple sentences at once. Adding DeScript dat does not have significant impact on the results. However, as the scripts are succinct and topic-related they give a slight boost to the overall accuracy.

The k-Means-based system generally does better in questions related to timing (e.g. how much some activity takes) and in questions about text’s meta-information (answers that include *author* or *narrator*). This observation could be explained by the fact that there are some activities that happen at a specific time of the day (e.g. breakfast, going out and others) and Doc2Vec could do a better embedding for numbers.

Overall, while the clustering step provided commonsense knowledge for the system and successfully mapped texts to topics, the bottleneck was the method of choosing an answer. It is based on the assumption that finding the exact answer or individual words from it leads to the correct solution. Different scoring and prioritizing methods for searching did not improve accuracy in any significant way. Therefore, a function that incorporates different approaches (e.g. comparing vector representations of questions and answers, POS-tagging for the question, deep similarity) along with simple matching might lead to better results.

4 Conclusion

This paper described the methodology behind the IUCM at SemEval-2018 Task 11 on machine comprehension using commonsense knowledge. The proposed solution is based on different techniques of unsupervised learning. The method shows above-the-baseline

performance and results in clear topic division and mapping. The code for the system is available here: <https://github.com/sonyareznikova/semEval2018Task11>.

Abstract

Machine Comprehension of text is a typical Natural Language Processing task which remains an elusive challenge. This paper is to solve the task 11 of SemEval-2018, Machine Comprehension using Commonsense Knowledge task. We use deep learning model to solve the problem. We build distributed word embedding of text, question and answering respectively instead of manually extracting features by linguistic tools. Meanwhile, we use a series of frameworks such as CNN model, LSTM model, LSTM with attention model and biLSTM with attention model for processing word vector. Experiments demonstrate the superior performance of biLSTM with attention framework compared to other models. We also delete high frequency words and combine word vector and data augmentation methods, achieved a certain effect. The approach we proposed rank 6th in official results, with accuracy rate of 0.7437 in test dataset.

1 Introduction

Machine Comprehension of text is one of the important goals of natural language processing. The traditional approaches to machine reading and comprehension have been based on either hand engineered grammars (Riloff and Thelen, 2000), or information extraction methods of detecting predicate argument triples that can later be queried as a relational database (Poon et al., 2010). These methods show effectiveness, but they rely on feature extraction and language tools. Recently, with the advances of neural networks, there have been great interests in building neural architectures for various NLP task, including several pieces of work on machine comprehension (Hermann et al., 2015; Hill et al., 2015; Yin et al., 2016; Kadlec et al., 2016; Cui et al., 2016), which have gained significant performance in machine comprehension do-

main. We also adopt deep learning models to solve this task.

The goal of Machine Comprehension using Commonsense Knowledge task is to choose a correct answer in two candidates to the question based on the contents of text. This task relates to how the inclusion of commonsense knowledge in the form of script knowledge would benefit machine comprehension systems, answering the questions requires knowledge beyond the facts mentioned in the text. We do not employ extra commonsense knowledge resources in the proposed approach, we assume that word vectors have contained some commonsense knowledge information, so we only use the deep learning model to solve this problem.

In the train dataset provided by this task, there are 1432 instances, each instance contains a text and several questions, and each question is associated with a set of two answers which are short and limited to a few words. The texts used in this task cover more than 100 everyday scenarios, hence include a wide variety of human activities. Therefore, each example can be summed up as $\{text, question, answer_0, answer_1, correct\ option\}$. There are 9731, 1411, 2797 examples in train, validation, test datasets, respectively.

Being a binary classification task, we split an example into two triples, which are $\{text, question, answer_0\}$ and $\{text, question, answer_1\}$, the label is true or false. In validation and test datasets, we employ the same processing mode to determine the matching degree of fit between triples, the highest will be chosen. We adopt the method of word distributed representation from (Mikolov et al., 2013) and a series of deep learning (DL) models, such as Convolutional Neural Network (CNN) from (Kim, 2014), Long Short-Term Memory (LSTM) model proposed from (Hochreiter and Schmidhuber, 1997) and improved by (Graves et al., 2013), attention mechanism from

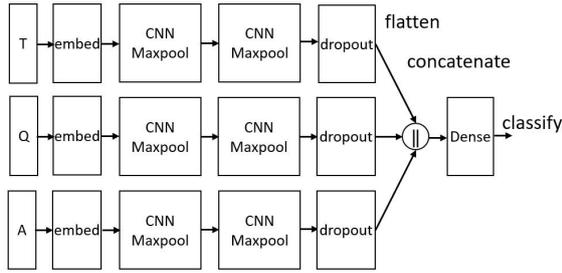

Figure 1: The architecture of CNN framework, T for text, Q for question, A for answer.

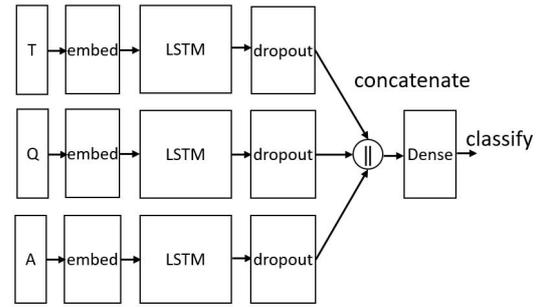

Figure 2: The architecture of LSTM framework.

(Graves and Schmidhuber, 2005). The four main frameworks we applied are as follows:

- CNN framework
- LSTM framework
- LSTM with attention framework
- biLSTM with attention framework

Above the framework, a joint feature vector is constructed, which is used to classify (Tan et al., 2015). In order to increase the accuracy of the model, we also delete high frequency word and combine word vector and data augmentation methods, thus achieve a better effect. Experiments demonstrate the superior performance of biLSTM with attention framework compared to other models, and data preprocessing is also important to improve the model accuracy.

2 Model description

In this section, we describe the four main proposed deep learning frameworks, which are shown in figures 1 to 4. The main idea of these systems is the same: learn a distributed vector representation of given text, question and answer candidates, then use a dense layer which processes the joint feature to measure the matching degree.

2.1 CNN framework

The first framework is based on CNN model. Step one is to obtain word embedding from pre-trained word distributed representation models. In preliminary experiment, there are two distributed representation models used. One is the pre-trained word2vec model which is trained by 100 billion words of Google News and has a dimensionality

of 300, the other is pre-trained Glove model which is trained by Wikipedia data and has a dimensionality of 300 too. The two models are all initialized from an unsupervised neural language model. The word embedding provides the distributed representation for each token in sequence.

Text, question and answer will be transformed to a word vector matrix and be entered into CNN layer respectively. In order to get more comprehensive representation of semantic features, we adopt double layer CNN model. The numbers of filters are 64 and 32, respectively, and the filter size is set as 3. After each CNN layer, we resort to a MaxPooling layer of size 2.

Above the CNN layer, the output of text, question and answer is merged to one and performs flatten operations, through a dense layer, the final output is passed through a two-dimensional softmax layer.

2.2 LSTM framework

Its the same way of producing word vector representation in embedding layer. Because LSTM model can process variable length sequence, masking method is introduced. The main principle of masking is to skip time steps which tokens are equal to zero, thus ignoring the meaningless padding in the text.

Above the embedding layer, we introduce the LSTM layer with a unit number of 64. LSTM is a special type of RNN that has three gates (input i , forget f and output o), and a cell memory vector C , and can learn to rely on long-distance history and the immediate previous hidden vector. Its a remarkable variations of RNN to alleviate the gradient vanish problem. Through the LSTM layer, text, question and answer will be transformed to a vector respectively.

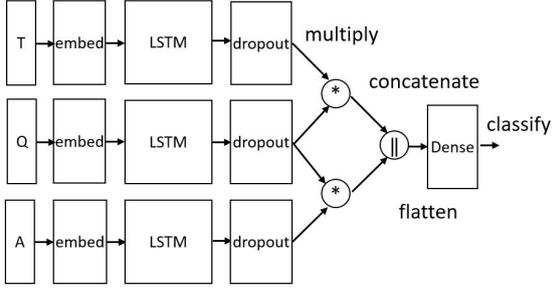

Figure 3: The architecture of LSTM with attention framework.

2.3 LSTM with attention framework

Like the LSTM framework, the masking method is used in the embedding layer. Text, question and answer are respectively processed through the embedded layer and the LSTM layer, generating three sequences of LSTM output vectors. Unlike the LSTM framework, here returns full output sequences, instead of the final output of model.

Now, we investigate a state-of-the-art attention model for the question vector generated by text, and the answer vector generated by question, instead of generating representation respectively. If the input sentence is long, semantics are expressed by an intermediate semantic vector, and the information of the word itself has disappeared, which results in the loss of a great deal of detail information. An attention mechanism is used to alleviate the weakness by dynamically aligning the more informative parts. Specifically, attention model gives more weights on certain words, just like tf-idf for each word, while the weight is calculated by another vector. Therefore, the formula of the attention matrix f of text and question vectors is as follows:

$$f(m_t, m_q) = m_t^T m_q \quad (1)$$

where m_t and m_q correspond to text and question vectors produced by previous LSTM layers, respectively. The attention matrix of answer and question is constructed in the same way.

2.4 biLSTM with attention framework

The framework is similar to the above, just changing the LSTM model into a biLSTM model. Single direction LSTMs suffer a weakness of not utilizing the contextual information from the future tokens. biLSTM utilizes both the previous and future context by processing the sequence on

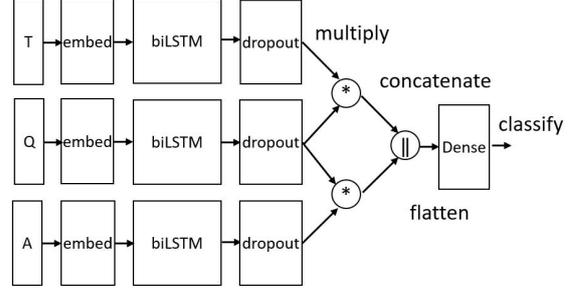

Figure 4: The architecture of biLSTM with attention framework.

two directions, and generates two independent sequences of LSTM output vectors.

3 Data Preprocessing

In order to improve the accuracy of the model, we have tried a series of data preprocessing methods, such as deleting high frequency words, combining word vectors and data augmentation methods, which achieve a certain effect.

3.1 Deleting high frequency words

In a large corpus, many common words appear, such as "the", "a" and so on. Although these words have higher word frequency, few useful information can be provided. We try to delete stopwords through the NLTK tools, but the effect was not ideal. So we calculate the word frequency statistics on the words in all dataset, and delete the top 20 words in frequency, that is, the most frequently occurring 20 words. We also tried other numbers in preliminary experiment, but 20 worked best.

3.2 Combining word vectors

Pre-trained word2vec model is trained by Google News, Glove model is trained by Wikipedia data. The effect of the former is slightly better. In order to obtain more comprehensive semantic features, we try to combine two vectors of each token, so that the word vector of each token is transformed into 600 dimensions, which is better than using only one word vector model.

3.3 Data augmentation

Our idea is inspired by data augmentation in the image domain, where one can increase the amount of train data by the geometric transformation of the image. In order to enrich the train dataset of

	Framework	val	test
1	CNN	71.32	70.13
2	CNN(data augmentation)	72.86	70.65
3	LSTM	72.10	69.57
4	LSTM(data augmentation)	72.57	70.36
5	LSTM with attention	73.11	69.97
6	LSTM with attention(data augmentation)	73.99	70.15
7	biLSTM with attention	75.90	71.11
8	biLSTM with attention(data augmentation)	76.61	72.47
9	biLSTM with attention(data augmentation and combine word vector)	77.75	74.37

Table 1: Results of four main framework

images, extract image features better and generalize models (prevent models from over fitting), data augmentation is done on images data. We know that in text understanding, we can still read articles even if we disorder the order of the words. In this task, we've implemented the data augmentation by randomly disordering the word order in the sentence. The preliminary implementation proves that this method is effective.

4 Experimental setup

Our approach in this task use the accuracy on validation dataset to locate the best parameters. The final rate of accuracy is expressed in the correct proportion chosen in test dataset. **All the model parameters were adjusted by preliminary experiment, at the same time, the results are taken three times, and the average value is taken.**

In the experiment, we use the loss function of categorical cross entropy and the optimizer of adaptive moment estimation. The length of text, question and answer tokens sequence all take the maximum length, if the length is not enough, then zero is added. To prevent over fitting, we employ dropout layers which the parameter is 0.3.

For comparison, we report the performance and analysis of four framework in Table 1, which summarizes the results of our system for this task. All the experiments have deleted the high frequency words. The word embedding we employed is word2vec in Rows (1) to (8). Because in preliminary experiment, the accuracy of model using word2vec is generally better than Glove.

In Row (1) to (2), we list the results on validation dataset and test dataset respectively of CNN framework which employ filter size of 3, and filter number of 64. The difference is that Row (2) model uses the data augmentation. Row (3) to

(4) correspond to LSTM framework which uses 64 as output dimensionality parameter of LSTM unit. The framework results in similar result with the CNN framework. In Row (5) to (6), we can observe that the framework for using the attention mechanism has been significantly improved in the accuracy rate. In Row (7) to (8), the improvement from biLSTM with attention compared to LSTM with attention is remarkable, increase more than 2%, illustrating that Bi-directional LSTM can achieve more comprehensive features than unidirectional LSTM. Row (9) is the approach proposed in this paper, which combines word2vec vector and Glove vector of each tokens. The model gets a significantly result, achieving a precision of 77.75% in validation dataset and 74.37% in test dataset. Compared to single word2vec, the improvement on the test set is more significant.

5 Conclusion

In this paper, we solve the Machine Comprehension Task by employing four main frameworks and a series of Data Preprocessing methods. Although the commonsense knowledge library is not used, the results are acceptable. The experiment results demonstrate the effectiveness of the biLSTM with attention framework in dealing with this task, the Bi-directional LSTM model is more advanced than the unidirectional LSTM model, and attention mechanism allows a model to focus on the aspects of a text that it will help answering a question. For a deep learning model, the Data Preprocessing is more critical, data augmentation and combining word vectors are beneficial to improve the model ability in some task backgrounds.

Abstract

This paper describes MITRE’s participation in SemEval-2018 Task 11: Machine Comprehension using Commonsense Knowledge. The techniques explored range from simple bag-of-ngrams classifiers to neural architectures with varied attention and alignment mechanisms. Logistic regression ties the systems together into an ensemble submitted for evaluation. The resulting system answers reading comprehension questions with 82.27% accuracy.

1 Introduction

Reading comprehension tasks measure the ability to answer questions that require inference from a free text story. This SemEval task, like many standardized tests (e.g., the SAT), provides multiple-choice answers. Reading comprehension may rely on information explicitly contained in the text, such as which actors are present, as well as elements of world knowledge, like understanding common scripts.

Early attempts at statistical reading comprehension include fill-in-the-blank questions and combine rich question categorization, information retrieval techniques, and entity recognition with type-specific, hand-crafted tactics (Hirschman et al., 1999; Anand et al., 2000).

More recent neural work uses continuous, distributed semantic space rather than n-gram overlap to find answers similar to the story. Trischler et al. (2016) compute a version of word overlap by finding cosine similarity of word representations between sections. Yin et al. (2016) restate the question and answer and incorporate a question-type classifier.

In this effort we explored neural distributed representations and lexicon-based machine learning approaches, especially attention and word overlap.

2 Task, Data and Evaluation

Machine Comprehension using Commonsense Knowledge was a shared task organized within SemEval-2018 (Ostermann et al., 2018b).

The task organizers released a dataset of 1,689 stories and 10,872 questions (up to 14 questions per story), split into training and development sets. The stories were first-person, English language narratives written by Mechanical Turk workers in response to prompts asking them to describe a scenario, like going on a date. Stories were up to 860 words long, with 90% under 273 words and a median length of 183 words. Questions are up to 22 words long, with a median length of seven. Each question has two possible answers. Answers vary in length from a single word, including *yes* or *no*, to 30 words, with a median length of three. Many questions are repeated between multiple stories. A sample story and questions are shown in Figure 1. Dataset construction is detailed in Ostermann et al. (2018a). The evaluation metric for the task is simple accuracy: the portion of correct answers.

Question types Table 1 quantifies the question types in the development set. We created this taxonomy to better understand the dataset. It also allowed us to direct our development toward model weaknesses.

Common Sense Knowledge and Inference Types

Reading comprehension relies on inference. We explored an inference taxonomy outlined in Chikalanga (1992) to better characterize the types of questions and answers involved in this shared task. For a subset of the training dataset, we manually classified whether questions required a reader to make lexical, propositional, or pragmatic inferences about the story. We found that many questions could be answered with more than one type of inference and some questions required multiple inferences. We considered which infer-

I went to the airport to go see my friend in North Carolina. So I drove up and had to go to the gate to go park. I paid my money to go park and went to park. From there I walked up into the airport to figure out where I need to check in. After much confusion, I found the place to check in and walked up. I gave them my boarding pass and they took my bags. From there they weighed them to make sure that they were not over the weight limit for carry on items. After that I went to security. I arrived super early so that I would have plenty of time in the line. I got in line for security and just waited. After getting to the front of the line, I took off my shoes and belt and put those on an x-ray scanner and got scanned myself. I put them back on and went to my flight.

Did they check in any baggage?
 yes
 no

Where were they flying to?
 North Carolina
 South Carolina

Why did they arrive to the airport early?
 They were not early, they were late.
 To have enough time to wait in line

Why do they have to check in?
 To board their flight
 They had to check in because they were going overseas.

Figure 1: Sample story with questions.

ences could require knowledge and data sources external to the story, like temporal-spatial relationships or physical properties such as temperature. Our analysis determined that this was unnecessary for task completion.

3 System Overview

We created an ensemble of three systems, each of which independently predicted the correct answer. Two of the systems use a neural attention architecture, and the third is a logistic regression.

3.1 Neural Attention

A recurrent neural system uses attention to create a representation for each answer that considers the question and story. Our ensemble includes two versions of this model with word embeddings trained on different corpora.

The words of each section (story, question, and answer) are embedded using a frozen projection layer, a fully-connected layer, and a recurrent layer. Another Long Short-Term Memory (LSTM) layer operates over the words in each story sentence to represent the story as a sequence of sentence embeddings. Each embedded answer sequence attends the words of the question using a parameterized attention mechanism (described below). This output attends the story sentences using

%	description
22.8	yes/no questions – One answer began with the string <i>yes</i> and the other answer began with the string <i>no</i>
9.4	yes/no only questions – answers were entirely the word <i>yes</i> or <i>no</i>
13.0	<i>who</i> questions
12.8	<i>what</i> questions
8.9	<i>where</i> questions
5.4	<i>when</i> questions
17.6	<i>how</i> questions
12.1	<i>why</i> questions
0.4	<i>which</i> questions
23.7	all correct answer words are in the story
30.7	none of the correct answer words are in the story
13.7	all incorrect answer words are in the story
37.6	none of the incorrect answer words are in the story
15.6	none of the correct or incorrect answer words are in the story

Table 1: Question types in the development set.

a similar attention mechanism, and an LSTM reduces the sequence. A fully-connected layer produces a prediction for each answer output, and a softmax converts these to probabilities over the two answers. All hidden layers are of size 128, 50% dropout follows on the embedding and RNN layers, and the adam optimizer is used for training.

Components of this neural system include: pre-trained distributed word representations, word overlap/hard attention features, and an attention mechanism.

For one model, **NN-T**, we used `word2vec` (Mikolov et al., 2013) to learn distributed representations of words from the text of English tweets collected from 2011 to 2016. We applied `word2phrase` twice to identify phrases of up to four words, and trained a skip-gram model of size 256, using a context window of 10 words and 15 negative samples per example. Twitter embeddings were chosen because at least some of the corpus matches the informal, first-person register of the task dataset. Our other set of word vectors, used in **NN-GN**, was released by Google alongside the tool and is made up of 300-vectors trained on a billion words of Google News (GoogleCode, 2013 (accessed March 3, 2018)). For both vector sets, we used only the 100,000 most frequent vocabulary items, since the shared data vocabulary was quite limited.

Word-overlap features were concatenated to the pretrained word embeddings. These consist of four channels that compare the present section (question or answer) with the story and question. The first two channels are binary overlap: whether

	$\sigma w $	w	description
1	1.99	1.2814	$ S \cap A $
2	1.18	-0.5591	answer length (words)
3	0.49	0.0394	answer length (chars)
4	0.15	-0.1728	$ Q \cap A $
5	0.11	-0.0005	story length (chars)
6	0.09	0.0026	story length (words)
7	0.04	0.0041	question length (chars)
8	0.03	-0.0219	$ S \cap Q $
9	0.02	0.0114	question length (words)

Table 2: Length and count features in the logistic regression model, ranked by influence ($\sigma|w|$).

the word in this position appears in the compared section. The cosine similarity channels contain the similarity of the present word with the closest word in the other section, computed using the same set of pretrained word vectors used by the neural model.

Our model adapts the attention mechanism described in Vaswani et al. (2017). The scaled dot product attention mechanism takes a memory and a query representation, e.g., the embedded words of the question and answer, respectively. Linear transformations are used to create a key and value from the former, and a query from the latter. Compatibility is computed as the scaled dot product of the key and query. This determines the weights over each timestep in the value, for each timestep of the query. Our model did not improve using parallel multi-head memory mechanisms nor by including fully-connected layers on top of them.

3.2 Logistic Regression

A logistic regression (LR) system was developed as a baseline against which the neural approach would be compared. This system was competitive enough to be included in the final ensemble.

The vocabulary of the LR system was limited to the training set. The Porter stemmer (Porter, 1980) was used to strip the non-information bearing suffixes from all of the words. Standard stopword lists removed words like *yes* and *no* that were important to the questions and answers, so the stopword list was reduced to just $\{a, an, the\}$. Various lengths were included as features. Taking S , Q , and A as the sets of words in the story, question, and answer respectively, the following three counts were added to the feature set: $|S \cap A|$, $|Q \cap A|$ and $|S \cap Q|$. Table 2 shows the full list of length and word count features.

The rest of the features were lexicalized patterns. Table 3 shows examples. Features include

	$\sigma w $	w	story	question	answer

Table 3: Stemmed word factors in the logistic regression model ranked by influence ($\sigma|w|$).

the set of words in the answer (A), the words common to the story and the answer ($S \cap A$) and the Cartesian product of the question and answer ($Q \times A$).

A bias term was added and Liblinear (Fan et al., 2008) was used to compute the model. L2 regularization was used to encourage generalization. The best value for the regularization parameter was the default, 1. The target variable for the LR model to predict was the distinction between a correct answer and an incorrect answer. At decode time, the answer with the higher probability of being correct was chosen. This simple logistic regression model performed surprisingly well, less than 1% off from our best neural model.

Tables 2 and 3 show each feature’s influence on fitting the training set. The rank ordering is standard deviation times the magnitude of the feature weight, $\sigma|w|$. This figure of merit balances features with high weights that were rare and features with low weights that were common.

3.3 Ensemble

An L2-regularized logistic regression weights the predictions of the above systems. MITRE’s offi-

cial submission is an ensemble of the subsystems’ binary class predictions. We submitted this system because it is simpler than an ensemble of continuous predictions and found it had the same accuracy on the development data, though more than 50 test set predictions were different.

4 Additional Experiments

We applied several approaches to the problem that did not generalize as well to the development data and were not included in the final ensemble.

Baselines We trained two baseline classifiers with incomplete information to gauge the difficulty of the task and to measure the relative importance of the story, question, and answers separately. Each baseline was a recurrent neural network with a layer of pretrained word embeddings and a stack of two 128-dimensional GRU layers. The *QA-only* baseline received as input only a concatenation of a question and its candidate answers, separated by special tokens. The *A-only* baseline received only a concatenation of the two candidate answers. *A-only* scored at 71.9% accuracy on the dev set, while *QA-only* was slightly higher at 73.2% accuracy. Other attempts to augment these models with attention over a lengthy story sequence frequently failed to eclipse the *QA-only* baseline, leading us to investigate hierarchical attention models and explicit overlap features.

Negative sampling We explored negative sampling to augment the training data, to improve our models’ ability to exclude wrong answers. We selected the 10 nearest neighbors for each question and supplemented the original positive and negative answer with the other questions’ answers. These were deduplicated after minimal preprocessing (normalizing case and punctuation), increasing the number of answers per question to between four and 20. Our nearest neighbors calculation is based on the average of word vectors for the in-vocabulary words in the questions.

Negative sampling did not improve accuracy. We tested conditions where 1) the original negative answer was sampled with equal probability or 2) always kept, and considered different values of N , where N is the total number of answers the model considered. We found no accuracy gain from using negative sampling beyond normal variance when the original negative was always included. When N was small, not necessarily in-

Component	Factored		Ablated	
	dev	test	dev	test
NN-T	81.93	80.23	81.72	79.76
NN-GN	81.01	80.12	83.06	79.51
LR	81.36	79.66	81.64	79.87
All In			85.12	82.27

Table 4: Factored and ablated system components evaluated on our dev set and the official test set.

cluding the original negative seems to hurt accuracy, suggesting that the randomly drawn negatives were not as plausible as the original negatives. For larger values of N , both conditions hurt performance.

We experimented with condition 1 and the LR model. The best value of N was 5 for this model, but accuracy was still below the model trained with the original dataset.

5 Experiment Details

The systems included in our model were trained only on the data released for this task, aside from word vector pretraining. The dev set was used to select hyperparameters for individual components and final ensemble.

6 Results

The columns of Table 4 show the accuracy of each system in isolation on the dev and test data (“Factored”) and the performance of the ensemble when the individual system was removed (“Ablated”). The final line shows the overall accuracy of the submission.

7 Conclusion

An ensemble of models was used to answer multiple-choice reading comprehension questions about informal, first person narratives. The resulting official system ranked second in the shared task. Our system relies heavily on lexical and overlap features, without an explicit reasoning component or external sources of world knowledge. Word embeddings trained on larger corpora contribute a semantic space that supports some inference beyond simple word overlap.

Abstract

We present a novel neural architecture for the Argument Reasoning Comprehension task of SemEval 2018. It is a simple neural network consisting of three parts, collectively judging whether the logic built on a set of given sentences (a claim, reason, and warrant) is plausible or not. The model utilizes contextualized word vectors pre-trained on large machine translation (MT) datasets as a form of transfer learning, which can help to mitigate the lack of training data. Quantitative analysis shows that simply leveraging LSTMs trained on MT datasets outperforms several baselines and non-transferred models, achieving accuracies of about 70% on the development set and about 60% on the test set.

1 Introduction

The Argument Reasoning Comprehension Task (Habernal et al., 2018) is a newly released task that tackles the core of reasoning in natural language argumentation, highlighting the importance of implicit warrants.

Even though the task could be regarded as simple binary classification, it is quite challenging in several perspectives. First, the task requires human-level reasoning to judge whether a claim supported by a reason and a warrant is logically correct. Second, common knowledge, which is not present in the input sentences themselves, is often required to solve the problem. Third, even though each instance of the data is helpful, the number of training data is relatively small to train prevailing complex neural models such as convolutional neural networks (Kim, 2014; Kalchbrenner et al., 2014) and recurrent neural networks (Hochreiter and Schmidhuber, 1997; Chung et al., 2014) with (or without) attention mechanisms (Liu et al., 2016; Lin et al., 2017).

In this paper, we propose a new architecture named **SECOVARC**¹ (Sentence Encoder with COntextualized Vectors for Argument Reasoning Comprehension) to deal with the complicated task. The main idea behind our model is that *transfer learning* can be a remedy to resolve the difficulties we face. With experimental results and analysis, we show that the simple neural model enhanced by transferred knowledge can be competitive, compared to complex models trained on the given data only.

2 Related Work

2.1 Argument Reasoning Comprehension

The argument reasoning comprehension task is a new dataset whose goal is to choose the correct implicit reasoning from two warrants, given a natural language argument with a reason and a claim. It consists of about 2K crowdsourced instances, each of which has a title and a short description of the debate from which the claim, reason, and two candidates arose. For more details, refer to Habernal et al. (2018).

2.2 Transfer Learning in NLP

Transfer learning is a classic technique in machine learning, which seeks to transfer beneficial knowledge from external resources to target models. It is well-known to be effective especially when one suffers from the lack of training data.

An important example showing the successfulness of transfer learning in natural language processing (NLP) is pre-trained word representations such as Word2Vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014), on which most of the modern models for NLP have been built.

¹The implementation of our model is available at <https://github.com/galsang/SemEval2018-task12>

Furthermore, there are some recent works (Collobert et al., 2011; Mou et al., 2016; Min et al., 2017) that concentrate on pre-training more sophisticated neural modules over word embeddings, proving that transfer learning can be a key to boost the performance of NLP systems.

2.3 Unsupervised Sentence Representation

Following the success of unsupervised word representations, there arises another line of research to facilitate transfer learning in sentence-level. The idea is that a generic sentence encoder, which is pre-trained in an unsupervised way, can generate sentence representations suitable for downstream tasks.

For instance, Kiros et al. (2015) propose an approach called Skip-Thoughts vectors that abstracts the skip-gram of Word2Vec (Mikolov et al., 2013) to the sentence-level. Moreover, many other unsupervised methods (Le and Mikolov, 2014; Dai and Le, 2015; Hill et al., 2016; Gan et al., 2017; Chen, 2017) are also introduced as a way of building sentence representations.

2.4 Supervised Sentence Representation

Despite several attempts at learning sentence representations in an unsupervised manner, there has been no consensus established thus far, on which is the best method and can be adopted as a standard.

Meanwhile, sentence encoders trained on labeled datasets are proposed as an alternative, showing that they outperform the previous models even with the limited number of data. Conneau et al. (2017) suggest a method named InferSent, which uses a simple bidirectional LSTM (Long Short Term Memory, Hochreiter and Schmidhuber (1997)) with max-pooling trained on the Stanford Natural Language Inference (SNLI, Bowman et al. (2015)). And McCann et al. (2017) propose CoVe and demonstrate that the encoder part of the trained sequence-to-sequence (Sutskever et al., 2014) model for machine translation can be reused as a generic sentence encoder.

In the paper, we focus on supervised pre-training with external data as an instantiation of transfer learning.

3 Model

In this section, We describe SECOVARC (Figure 1) which takes a set of 3 sentences, i.e. a claim,

reason, and warrant, as input and outputs a score between 0 and 1, indicating *how reasonable the claim is when it is based on the reason and the warrant*.

3.1 Model Design

Before jumping into the details, we explain about our motivation upon which the decisions on model design were made.

First, we let the model accept only one warrant instead of two candidates. This decision comes from the intuition that it may learn how to reason better when it *judges* whether the logic constructed on a set of a claim, reason, and warrant is plausible, instead of just *choosing* the more probable one between the two candidates.

Second, as mentioned earlier, one of the main concerns behind the model design is the lack of training data. To alleviate this problem, we decide to utilize transfer learning while maintaining the model as simple as possible (e.g. without introducing complex architectures such as attention mechanism).

3.2 Model Specification

In this part, we describe the details of the proposed model, which is composed of three layers.

3.2.1 Encoding Layer

The encoding layer is the first part of our model, which is in charge of encoding three input sentences to corresponding sentence representations. In detail, it accepts the sequence of n words (w_1, w_2, \dots, w_n) in a sentence at a time and outputs a fixed-length sentence representation s . Note that the same generic encoder is used to encode each input sentence.

Formally, each one-hot encoded word $w_i \in \mathbb{R}^V$ of the input sentence is converted into the corresponding word vector $\mathbf{x}_i \in \mathbb{R}^{d_w}$ by a word embedding matrix $\mathbf{E} \in \mathbb{R}^{d_w \times V}$. Then, a sequence of the word vectors $\mathbf{x} = [\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n]$ is combined into $\mathbf{s} \in \mathbb{R}^{d_s}$ by an encoder. While a wide range of selection for the encoder is possible, in our case we utilize CoVe² (McCann et al., 2017) (with pooling operation), which is a two-layered Bi-LSTM pre-trained on large MT datasets, to obtain meaningful and contextualized sentence representations that would not be achieved if we train the encoder from scratch.

²Available at <https://github.com/salesforce/cove>

As a result, each representation for the claim (\mathbf{s}_c), reason (\mathbf{s}_r), and warrant (\mathbf{s}_w) is derived from \mathbf{x}_c , \mathbf{x}_r and \mathbf{x}_w as follows.

$$\begin{aligned} \mathbf{s}_c &= \text{Pooling}(\text{CoVe}(\mathbf{x}_c)) \\ \mathbf{s}_r &= \text{Pooling}(\text{CoVe}(\mathbf{x}_r)) \\ \mathbf{s}_w &= \text{Pooling}(\text{CoVe}(\mathbf{x}_w)) \end{aligned}$$

From various options for the pooling operation, we use max-pooling, which selects the maximum value over each dimension of the output, and last-pooling that just selects the last state of the output. We call the CoVe encoder with max-pooling as SECOVARC-max and the encoder with last-pooling as SECOVARC-last.

3.2.2 Localization Layer

Although all of the input sentences (i.e. the claim, reason, and warrant) are encoded by the universal encoder, there is a need to make a difference among them so that each of the sentence representations keeps its own role. For this reason, the localization layer is introduced to project (or ‘localize’) each \mathbf{s} onto its own semantic space.

We implement this layer simply in the form of three separate fully-connected layers, pursuing the intuition that our model should be simple. Therefore, a set of the sentence representations $\{\mathbf{s}_c, \mathbf{s}_r, \mathbf{s}_w\}$ is converted into $\{\mathbf{v}_c, \mathbf{v}_r, \mathbf{v}_w\} \in \mathbb{R}^{d_f}$ as follows.

$$\begin{aligned} \mathbf{v}_c &= \tanh(\mathbf{W}_c \mathbf{s}_c + \mathbf{b}_c) \\ \mathbf{v}_r &= \tanh(\mathbf{W}_r \mathbf{s}_r + \mathbf{b}_r) \\ \mathbf{v}_w &= \tanh(\mathbf{W}_w \mathbf{s}_w + \mathbf{b}_w) \end{aligned}$$

3.2.3 Output Layer

The output layer collects all features extracted from the previous layer and computes a final score between 0 and 1. To help the model make correct decisions, we introduce heuristic methods such as $|\mathbf{v}_w - \mathbf{v}_r - \mathbf{v}_c|$ and $\mathbf{v}_w \odot \mathbf{v}_r \odot \mathbf{v}_c$ ³, inspired from the work of Mou et al. (2015) for the SNLI task.

In the end, a final feature \mathbf{v}_f for computing a score $y \in \mathbb{R}$ ($0 \leq y \leq 1$) becomes a concatenation of the five vectors,

$$\mathbf{v}_f = \begin{bmatrix} \mathbf{v}_c \\ \mathbf{v}_r \\ \mathbf{v}_w \\ |\mathbf{v}_w - \mathbf{v}_r - \mathbf{v}_c| \\ \mathbf{v}_w \odot \mathbf{v}_r \odot \mathbf{v}_c \end{bmatrix}$$

³ \odot : element-wise multiplication

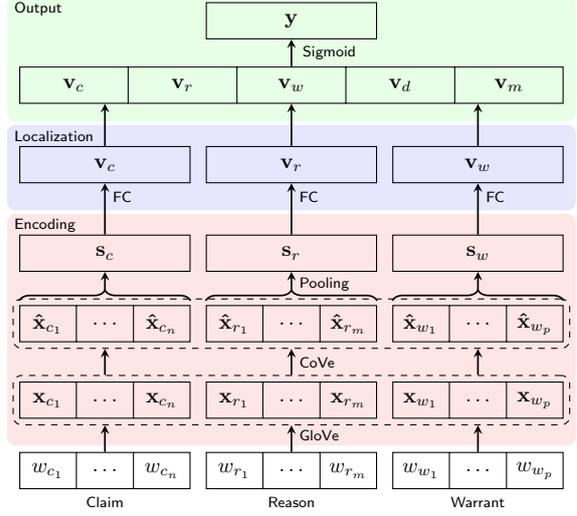

Figure 1: The architecture of SECOVARC. Dotted boxes represent the elements computed by parameter-shared modules (GloVe and CoVe) for all inputs. Note that $\mathbf{v}_d : |\mathbf{v}_w - \mathbf{v}_r - \mathbf{v}_c|$ and $\mathbf{v}_m : \mathbf{v}_w \odot \mathbf{v}_c \odot \mathbf{v}_r$. FC means a fully connected layer.

where $\mathbf{v}_f \in \mathbb{R}^{5d_f}$. Then, logistic regression (for simplicity) is performed on \mathbf{v}_f to compute the final score.

$$y = \sigma(\mathbf{W}_f \mathbf{v}_f + \mathbf{b}_f)$$

During training, the score can be directly utilized to optimize the model. At test time, on the other hand, we derive y_1 and y_2 from the trained model with the input sentences such that

$$\begin{aligned} y_1 &= \text{SECOVARC}(\mathbf{c}, \mathbf{r}, \mathbf{w}_1) \\ y_2 &= \text{SECOVARC}(\mathbf{c}, \mathbf{r}, \mathbf{w}_2) \end{aligned}$$

where \mathbf{c} , \mathbf{r} , \mathbf{w}_1 and \mathbf{w}_2 is the claim, the reason, the first warrant, and the second warrant respectively. Then, we select the warrant whose score is greater than that of the other as a final decision.

4 Experiment and Discussion

4.1 Data Manipulation

As our model requires only one warrant at a time, data preprocessing is inevitable before training. We manipulate the original data so that the correct warrant has a score of 1 and the opposite warrant has 0. Note that this pre-processing procedure has a side effect of doubling the original training data.

4.2 Training Details

The dimension of a word vector (d_e) is fixed to 300. And hyper-parameters for other vectors are

Approach	Dev (\pm)	Test (\pm)
Human average	-	.798 .162
Human w/ training in reasoning	-	.909 .114
Random baseline	.473 .039	.491 .031
Language model	.617	-.500
Attention	.488 .006	.513 .012
Attention w/ context	.502 .031	.512 .014
Intra-warrant attention	<u>.638</u> .024	.556 .016
Intra-warrant attent. w/ context	.637 .040	<u>.560</u> .055
SECOVARC (official record)	.731	-.565
SECOVARC-last (w/o heuristics)	.701 .011	.559 .019
SECOVARC-last (w/ heuristics)	.706 .014	.554 .015
SECOVARC-max (w/o heuristics)	.680 .007	.591 .016
SECOVARC-max (w/ heuristics)	.684 .008	.592 .016

Table 1: Comparison of baselines and variants of our model on the development set and the test set.

set to $d_s = 600$, $d_f = 300$. We use 840B GloVe to initialize a word embedding matrix. Other model weights are randomly sampled from uniform distribution(-0.005, 0.005), except for the CoVe encoder, and biases are initialized with 0.

Our model is trained using Adam (Kingma and Ba, 2014) optimizer with a learning rate 0.001 and a batch size 64. The maximum number of training epoch is limited to 10 and we choose the best model based on development accuracy. All parameters in the model, including the word vectors, are fine-tuned during training.

For regularization, L2-norm of the parameters is added to the Cross Entropy objective with the weight of $1e-5$, and Dropout (Srivastava et al., 2014) technique is also applied with $p = 0.1$.

4.3 Experimental Results

Table 1 shows the accuracies of variants of our model and baselines (Habernal et al., 2018) on the development set and the test set. Due to the instability of results caused by random initialization, we report the mean and standard deviation of 20 experimental runs (with the same hyperparameters) for each model.

The reported results show that SECOVARC-last (w/ heuristics) outperforms all the baselines on the development set, with a mean accuracy of 70.6%. However, it is SECOVARC-max (w/ heuristics) that performs best on the test set, with a mean accuracy of 59.2%. We submitted an instance obtained from SECOVARC-last (w/ heuristics) and achieved the official result of 56.5% on the leaderboard. Table 1 also demonstrates that our model benefits from the heuristics applied in the output

Approach	Dev (\pm)	Test (\pm)
BoW	.677 .006	.502 .014
Bi-LSTM-last	.678 .010	.554 .024
Bi-LSTM-max	.670 .011	.543 .027
SECOVARC-last	.706 .014	.554 .015
SECOVARC-max	.684 .008	.592 .016

Table 2: Experiment on the possibility of transfer learning in case of the argument reasoning comprehension task. Note that the heuristic methods are employed for all models.

layer, except for the test accuracy of SECOVARC-last.

4.3.1 Does transfer learning really work?

Even with the promising outcome presented by SECOVARC, an issue remains regarding how to show the effectiveness of transfer learning for the task. For this objective, we conduct additional experiments with three baselines called BoW, Bi-LSTM-last, and Bi-LSTM-max. Bi-LSTM-last and Bi-LSTM-max have the same architecture with SECOVARC, but the Bi-LSTMs in the encoding layer are randomly initialized rather than pre-trained. BoW is different from our proposed model in that it leverages the average of word vectors as a sentence representation instead of using CoVe with pooling.

Table 2 reports the comparison of the baselines and the variants of our model. The results show that our model consistently outperforms the baselines which are trained from scratch. Moreover, the smaller deviations of SECOVARCs demonstrate that transfer learning can lead to more stable and successful training of models.

5 Conclusion

In this paper, we present a novel neural architecture called SECOVARC, that utilizes a two-layered Bi-LSTM trained first on a large amount of machine translation data. And we demonstrate that the neural model for the argument reasoning comprehension task can benefit from transfer learning when it is properly designed.

As a future work, there is a way to apply contemporary works for generic sentence encoders such as Subramanian et al. (2018) and Peters et al. (2018) instead of CoVe. On the other hand, we can consider expanding the data itself directly with sophisticated rules or heuristics.

Abstract

Reasoning is a very important topic and has many important applications in the field of natural language processing. Semantic Evaluation (SemEval) 2018 Task 12 “The Argument Reasoning Comprehension” committed to research natural language reasoning. In this task, we proposed a novel argument reasoning comprehension system, ITNLP-ARC, which use Neural Networks technology to solve this problem. In our system, the LSTM model is involved to encode both the premise sentences and the warrant sentences. The attention model is used to merge the two premise sentence vectors. Through comparing the similarity between the attention vector and each of the two warrant vectors, we choose the one with higher similarity as our system’s final answer.

1 Introduction

Reasoning is a very challenging, but basic part of Natural Language Inference (NLI) (Chen et al., 2017), and many relevant tasks have been proposed such as Recognizing Textual Entailment (RTE) and so on. Stanford University provided Stanford Natural Language Inference (SNLI) corpus to support Natural Language Inference task. It contained two kinds of sentences-the premise sentence and the warrant sentence. The mission is to judge whether the two sentences are inference or not. Semantic Evaluation (SemEval) 2018 Task 12-The Argument Reasoning Comprehension-give an argument consisting of the claim, the reason and two warrants. The goal is to select the correct warrant that explains reasoning with this particular argument. There are two options given and only one is correct. Compare with Stanford Natural Language Inference (SNLI) task (Bowman et al., 2015; Shen et al., 2018), it has more challenges. Because it has abundant premise in-

formation such as the reason, the claim, text information, as well as the option warrants have high semantic textual similarity (Habernal et al., 2017). In this task, we need to find an effective method to extract important information from these premise sentences.

Natural Language Reasoning can be applied to various fields such as question and answering, information retrieval and so on. With the development of Neural Networks applied in Natural Language Processing, sentence representation and reasoning have been researched and taken significant step forwards. In order to deal with the sequence problem, recurrent neural networks (RNN) (Mikolov et al., 2010, 2011) proposes the concept of hidden state, which can extract features from sequence-shaped data and then convert it to output. It can be used to encode the sentence to fixed-length vector representations. In most recent years, long short-term memory (LSTM) network (Bengio et al., 1994; Hochreiter and Schmidhuber, 1997), BiLSTM (Pennington et al., 2014a) and gated recurrent unit (GRU) (Cho et al., 2014) are widely used to get sentence representative vector, and achieved better result compared with traditional methods. Attention model also known as alignment model pays more attention to two sentences interaction (Zheng et al., 2018; Gao et al., 2018), which is usually applied in information extraction, relation extraction, text summarization and machine translation. In machine translation, the attention model can be focused on one or a few words of input to make the translation more accurate when generating each new word. (Rocktäschel et al., 2015) extend a neural word-by-word attention mechanism to encourage reasoning over entailment of pairs of words and phrases.

In our system, we use long short-term memory network to encode sentence. To make full use of

the information of the reason and the claim, we use attention model to get the attention sentence vector. Then, we compare the warrant sentence vector and the attention sentence vector similarity. The warrant with higher similarity is taken as an answer. In order to make the system more accurate, we use ensemble result as our final answer.

2 Method

The dataset composes with four items which are the reason, the claim, the warrant and the alternative warrant (R, C, W, AW), and two additional information: debateTitle and debateInfo. Let R be a reason for a claim C, both of which are propositions extracted from debateTitle and debateInfo. There are two warrants (AW, W) that justify the use of the reason R as support for the claim C. In this task, we choose the correct warrant by these premise information. In our system, we encode sentence with LSTM, and merge two sentences with attention. Then choose the one (AW or W) with higher similarity between the warrant vector and the attention vector as our answer. The system's neural networks model shown as Fig 1. We build the system with five parts, the following is a detailed description.

2.1 LSTM

Long short-term memory (LSTM) network is a variant of RNN, and it has been successfully applied to various kinds of NLP tasks. It can solve RNN's problem of gradient vanishing and gradient explosion and be good at dealing with sequence-shaped data. LSTM model controls the memory unit through the input gate, output gate and forget gate. The input is a sequence of sentence $X = \{x_1, x_2, \dots, x_n\}$, where x_i is the word vector of i 'th word in the sentence. The output is $H = \{h_1, h_2, \dots, h_n\}$, where h_i is the i 'th step of the LSTM's output. Here, we use the pre-trained vector of global vectors (GloVe) (Pennington et al., 2014b) as the embedding layer initialization, and the word embedding dimension is 300. The formulas for LSTM include:

$$i_t = \sigma(W_i \cdot [h_{t-1}, x_t] + b_i) \quad (1)$$

$$f_t = \sigma(W_f \cdot [h_{t-1}, x_t] + b_f) \quad (2)$$

$$\widetilde{C}_t = \tanh(W_c \cdot [h_{t-1}, x_t] + b_c) \quad (3)$$

$$C_t = f_t * C_{t-1} + i_t * \widetilde{C}_t \quad (4)$$

$$o_t = \sigma(W_o \cdot [h_{t-1}, x_t] + b_o) \quad (5)$$

$$h_t = o_t * \tanh(C_t) \quad (6)$$

In our experiment, we encode the reason sentence and the claim sentence with one LSTM encoder, and encode the warrant sentence with another. We try to use the LSTM's last output, mean pooling and max pooling as the sentence vector representation.

2.2 Attention

In argument reasoning comprehension task, the claim sentence is extracted from title and information, and it supports the result. Therefore, the claim has a great impact on the reason sentence. So, we use attention model to force the reason's and the claim's similarity word, and get the better premise sentence representation. In this task, we use two kinds of attention model to merge reasons and claims vector representation. Let's $R \in \mathbb{R}^{k \times l_r}$ be a matrix consisting of the reason's LSTM output vector $R = \{r_1, r_2, \dots, r_{l_r}\}$, and $C \in \mathbb{R}^{k \times l_c}$ be a matrix consisting of the claim's LSTM layer output vector $C = \{c_1, c_2, \dots, c_{l_c}\}$, where l_r is the length of the reason, l_c is the length of the claim, and k is the LSTM's outputs dimension.

One of the attention model is seq-attention model. In our system, we try to represent the claim sentence vector as $c \in \mathbb{R}^k$, where c is the LSTM's last output, mean pooling or max pooling. Then, calculating the claim sentence vector c and the reason sentence vector's $\{r_1, r_2, \dots, r_{l_r}\}$ similarity as the attention weight. We use the result of two vectors multiplication as the similarity weight. Finally, we can obtain the reason sentence vector with weight. The calculation process is as following:

$$e_i = c \bullet r_i \quad (7)$$

$$\alpha_i = \frac{\exp(e_i)}{\sum_{i=1}^l \exp(e_i)} \quad (8)$$

$$Rtt^* = \sum_{i=1}^l \alpha_i \bullet r_i \quad (9)$$

where α is the attention weight. The attention vector represent as $Rtt^* \in \mathbb{R}^k$.

Another kind of attention uses matrix to calculate the weight of the claim sentence vector and the reason sentence vector. Give each sentence vector a weight matrix, and obtain the attention vector by learning the weight matrix. The formula is:

$$M = \tanh(W_y R + W_h C_{l_c} \otimes e_{l_r}) \quad (10)$$

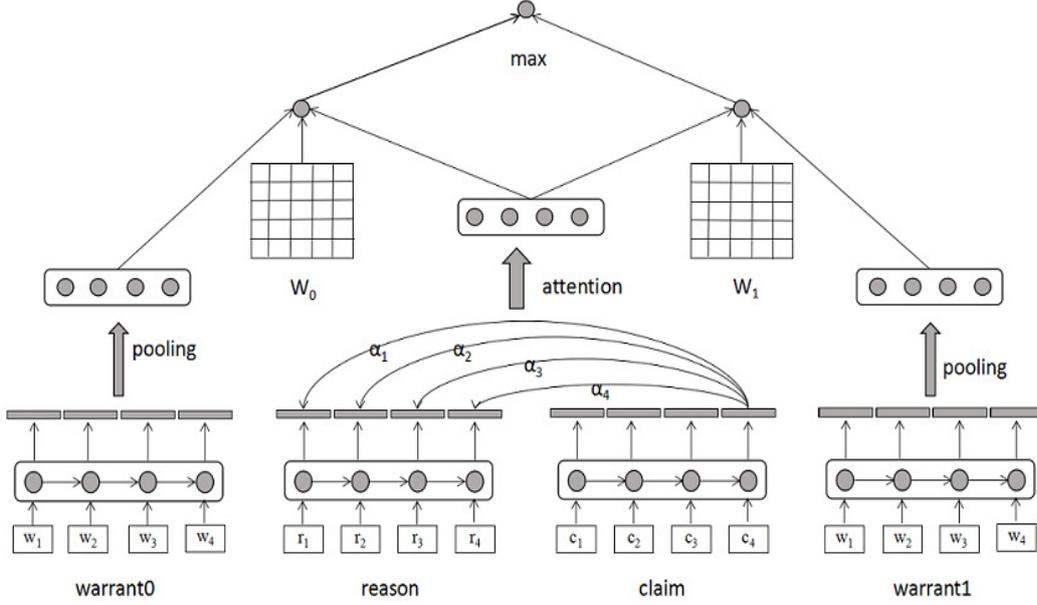

Figure 1: Our system model with attention-encoding with LSTM, merge the reason and the claim with attention, and calculating text similarity with bilinear.

$$\alpha = \text{softmax}(w^T M) \quad (11)$$

$$r = R\alpha^T \quad (12)$$

$$Rtt^* = \tanh(W_p r + W_x C_{l_c}) \quad (13)$$

where $W_y \in \mathbb{R}^{k \times k}$, $W_h \in \mathbb{R}^{k \times k}$, $w \in \mathbb{R}^k$, $W_p \in \mathbb{R}^{k \times k}$ and $W_x \in \mathbb{R}^{k \times k}$ is a matrix with random initialization. C_n is the LSTM's last output, max pooling or mean pooling, and α is the attention weight. $Rtt^* \in \mathbb{R}^k$ is the attention vector.

2.3 Text Similarity

There are many ways to calculate the similarity of text vectors, such as cosine distance, dot product and so on. In our system, we use a Bilinear way to calculate the similarity of attention vector and warrant vector. The formula is:

$$h = Rtt^* \times W_m \times W \quad (14)$$

where Rtt^* is the attention vector, $W_m \in \mathbb{R}^{k \times k}$ is the randomly initialized weight matrix, and W is the warrant sentence vector that using LSTM's last output, max pooling or mean pooling.

2.4 Ensemble

Since neural networks have a large number of random parameters, we try to use different random initialization or change the network layer dimensions to adjust the network structure. In order to make the prediction more accurate, we run the program many times and use the voting method to obtain the final result.

2.5 Loss Function and Evaluation

We treat this task as a classification problem, and use log-loss as our loss function. The format is:

$$\log - \text{loss} = \sum_{i=1}^n y_i \log(h_i) + (1 - y_i) \log(1 - h_i) \quad (15)$$

where y_i is the label of i 'th instance, and h_i is the probability calculated by the system.

We also treat it as a sort problem, and choosing the top 1 of sorting results as the answer. The loss function format is:

$$\text{loss} = \sum_{i=1}^n \max(0, 1 - \text{sim}(r, wa) + \text{sim}(r, w)) \quad (16)$$

where $\text{sim}(r, wa)$ is the true similarity of the premise and the warrant, and $\text{sim}(r, w)$ is the false similarity of the premise and the warrant.

Systems will be scored using accuracy. The format is:

$$\text{accuracy} = \frac{\text{correct predictions}}{\text{all instances}} \quad (17)$$

3 Experiments and Results

Table 1 shows the parameter setting in our system. Because we use Tensorflow to build our system, the sentence needs to be set to a fixed length. The sentences with length greater than 30 words are

lstm_input_unit	lstm_output_unit	lstm_input_dropout	lstm_output_dropout	epoch
300	200	0.6	0.6	40

Table 1: parameter setting in ITNLP_ARC system.

Ensemble	0.8319	0.7246	0.5521

Table 4: The accuracy of ensembling all neural network model.

truncated from the back, with length less than 30 words are added 0 in the behind.

In our system, we build the argument reasoning comprehension task with neural networks. We try to use the LSTM’s last output, max pooling or mean pooling to represent the sentence vector, and use two kinds of attention to merge the reason and the claim. Because of neural networks contains a lot number of randomly initialized parameters, we run our system ten times and average the accuracy. Table 2 shows the accuracy with log-loss function. Table 3 shows the accuracy with sort loss function. From Table 2 and Table 3, we can get conclusion that mean pooling performed better than last output and max pooling. Table 4 shows the accuracy ensemble all neural network model, and this is our system’s final result.

4 Conclusion and Future Works

We propose a neural network model to solve reasoning in NLP. We use attention model and bilinear to calculate the similarity between the premise and the warrant. Our system’s final result achieved 0.5521. From the experiment, we can see the train accuracy and the development accuracy is much higher than test accuracy. This may be due to over fitting. Maybe decreasing learning rate, and using batch normalization can reduce over fitting. We will try it in the future work.

Abstract

This paper presents our submissions to SemEval 2018 Task 12: the Argument Reasoning Comprehension Task. We investigate an end-to-end attention-based neural network to represent the two lexically close candidate warrants. On the one hand, we extract their different parts as attention vectors to obtain distinguishable representations. On the other hand, we use their surrounds (i.e., claim, reason, debate context) as another attention vectors to get contextual representations, which work as final clues to select the correct warrant. Our model achieves 60.4% accuracy and ranks 3rd among 22 participating systems.

1 Introduction

Reasoning is a crucial part of natural language argumentation. In order to comprehend an argument, one must analyze its *warrant*, which explains why its *claim* follows from its premises (aka *reasons*) (Habernal et al., 2018a).

SemEval-2018 Task 12 provides the argument reasoning comprehension task (Habernal et al., 2018b). Given a reason and a *claim* along with the *title* and a short *description* of the debate they occur in, the goal is to identify the correct *warrant* from two candidates. Figure 1 gives an example. The abstract structure of an argument is: *reason* → (since) *warrant* → (therefore) *claim*.

The challenging factor is that both candidate warrants are plausible and lexically very close while leading to contradicting claims (Habernal et al., 2018a). Here we give three examples of the two candidate warrants:

Ex1: A huge pandemic would (not) be a great news story.

Ex2: The role of a citizen and a supreme court justice are inseparable /separable.

Ex3: The rest of the comments can be skipped easily /make the section unreadable.

Title: Have Comment Section Failed?

Description: In recent years, many media companies have disabled them because of widespread abuse and obscenity.

Reason: Many comments are thoughtful and insightful. And since {Warrant0 | Warrant1},

Claim: Comment sections have not failed.

✓ **Warrant0:** The rest of the comments can be skipped easily.

✗ **Warrant1:** The rest of the comments make the section unreadable.

Figure 1: An example of a debate in the argument reasoning comprehension task.

The differences are either negative words, or antonyms, or opposite phrases. Therefore, it is important to emphasize the different parts to obtain distinguishable representations of the two warrants, which express the opposite meanings.

To address this factor, we proposed an end-to-end attention-based neural network. On the one hand, we extract the different parts of the two warrants and use them as attention vectors to obtain warrants' distinguishable representations. On the other hand, we represent their surrounds (i.e., reason, claim, debate context) as another attention vector to get the contextual representations.

2 System Architecture

Formally, given an instance containing two candidate warrants (W_0, W_1) and the context around the warrants (i.e., R, C, T, I), the goal is to choose the correct warrant $y \in \{0, 1\}$, where $y = 0$ means W_0 is the correct answer, and $y = 1$ otherwise.

2.1 Overview

The network is inspired by Siamese network (Mueller and Thyagarajan, 2016). The two candidate warrants are modeled in the same structure. Figure 2 illustrates our system architecture.

First, we first extract the different parts of war-

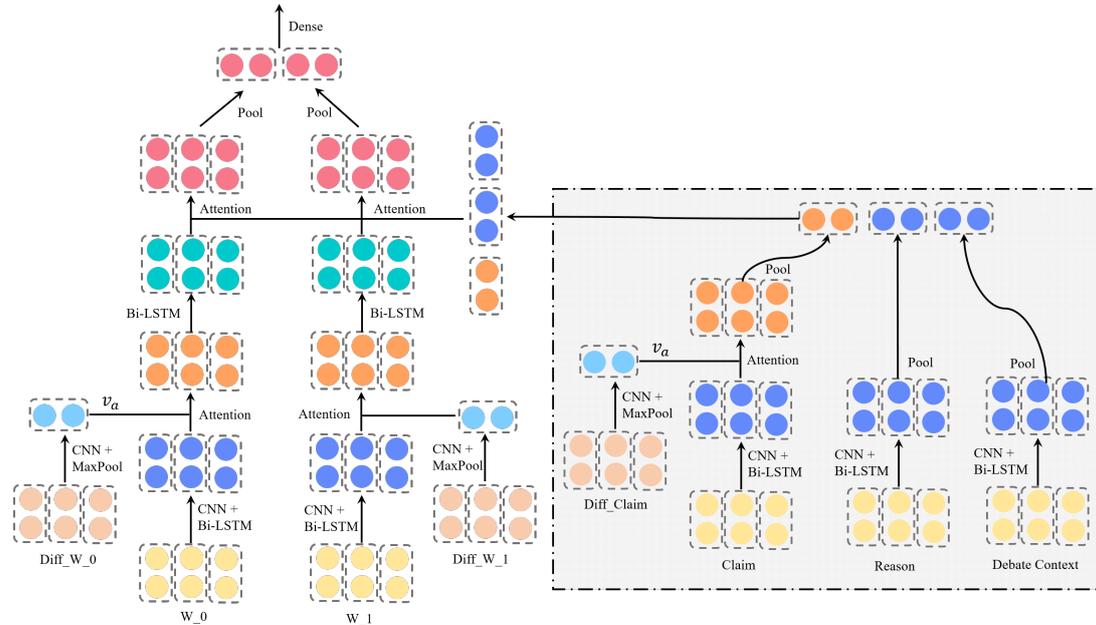

Figure 2: The system architecture

warrant0, warrant1 and claim to get $\text{Diff_}W_0$, $\text{Diff_}W_1$ and $\text{Diff_}Claim$ (see in Sec. 2.2).

Then, we stack a CNN and a RNN to represent each component to obtain representation of each component, because the combination of CNN and RNN can make use of the spatial and temporal context information (in Sec. 2.3).

Next, the intra-temporal attention is adopted to obtain distinguishable representations of warrants. Similarly, we apply the same strategy to the claim. The intra-temporal attention is introduced in Sec. 2.4).

After that, we concatenate the representation of surrounds (i.e., reason, claim, debate context and warrant) as another attention vector to obtain the contextual representations of the warrants.

Last, we adopt a dense layer to obtain the probability of the two candidate warrants (in Sec. 2.5). The contextual representations work as hidden clues to select the correct warrant.

2.2 Extract the Different Part

The two candidate warrants are lexically close (since they often mean the opposite), thus we extract the different part between them to serve as attention vector to guide the neural network to generate distinguishable representation for the warrants.

To do this, we remove the longest common prefix and suffix, and let the remain part as the different part, denoted as $\text{Diff_}W_0$, $\text{Diff_}W_1$. Take cases

mentioned in Sec. 1 as examples, it would extract “not be ” as $\text{Diff_}W_0$ and “be” as $\text{Diff_}W_1$ in Ex1; “inseparable” as $\text{Diff_}W_0$ and “separable” as $\text{Diff_}W_1$ in Ex2; “can be skipped easily” as $\text{Diff_}W_0$ and “make the section unreadable” as $\text{Diff_}W_1$ in Ex3. Note that if the remain part is empty, we use the word after the prefix as the different part.

Similarly, we also get the different part between the claim and its opposite, denoted as $\text{Diff_}Claim$. There always exists the opposite claims in debates, since the reason chains $R \rightarrow W \rightarrow C$ and $R \rightarrow \neg W \rightarrow \neg C$ both exists. We collected the claims and warrants under the same debate. If the warrants express the opposite meaning, then the two claims are opposite. Besides, the organizers also provide similar dataset in “data/train-w-swap-doubled.tsv”.

2.3 Context Representation

To incorporate contextual information of each components in a debate, we combine Convolutional Neural Network (CNN) and Recurrent neural network (RNN) to encode the input word vectors. CNN is good at dealing with spatially related data, such as “sometimes warranted” and “rarely warranted”, while RNN is good at temporal signals. Instead of using a typical vanilla RNN, we use Long Short-Term Memory Network (Hochreiter and Schmidhuber, 1997) for eliminating the issue of long term dependencies.

Given a sentence $S = \{w_i\}_1^n$, we first map each word w_i into its vector representation $x_i \in \mathbb{R}^d$ via a look-up table of word embeddings (d is the dimension of the word embeddings).

Then, we adopt CNN on the input sequence $\{x_i\}_1^n$ to obtain the spatial representation $\{x'_i\}_1^n$:

$$e_i^j = \text{ReLU}(w^j[x_i, \dots, x_{i+k-1}]) \quad (1)$$

$$x'_i = [e_i^1, \dots, e_i^m] (1 \leq j \leq m) \quad (2)$$

where k is the window size, w^j is the parameter of a filter, m is the number of the filters. We also adopt padding before the convolution operation. As a result, we obtain the spatial representations $x'_i \in \mathbb{R}^m$, which has the same length as the input sequence.

After that, we utilize a bi-directional LSTM (Bi-LSTM) to obtain the temporal information. For each time step t , the LSTM unit computation corresponds to :

$$i_t = \sigma(W_i x'_t + U_i h_{t-1} + b_i) \quad (3)$$

$$f_t = \sigma(W_f x'_t + U_f h_{t-1} + b_f) \quad (4)$$

$$o_t = \sigma(W_o x'_t + U_o h_{t-1} + b_o) \quad (5)$$

$$\tilde{c}_t = \tanh(W_c x'_t + U_c h_{t-1} + b_c) \quad (6)$$

$$c_t = i_t \odot \tilde{c}_t + f_t \odot c_{t-1} \quad (7)$$

$$h_t = o_t \odot \tanh(c_t) \quad (8)$$

where σ is the element-wise sigmoid function, \odot is the element-wise product and i_t, f_t, o_t, c_t denote the input gate, forget gate, output gate and memory cell respectively.

2.4 Intra-Temporal Attention

Inspired from Habernal et al. (2018a), we use an intra-temporal attention function to attend over specific parts of the input sequence. This kind of attention encourages the model to generate different representation according to the attention vector. Habernal et al. (2018a) have shown that such intra-temporal attention outperforms standard attention.

We define v_a as the attention vector, and h_t as the hidden states at time step t :

$$m_t = \tanh(U_m h_t \odot v_a + b_m) \quad (9)$$

$$a_t = \sigma(W_a m_t + b_a) \quad (10)$$

$$h_t = h_t \odot a_t \quad (11)$$

where a_t is the attention weights over the hidden states h_t , \odot is element-wise multiplication.

We first apply the intra-temporal attention over W_0 and W_1 , in order to obtain different warrant representations from $\text{Diff}.W_0$ and $\text{Diff}.W_1$. As a result, the model can easily distinguish the two candidate warrants. Similarly, we apply the attention over claim to make the claim representation distinguishable.

Moreover, we adopt another intra-temporal attention over W_0 and W_1 , with the concatenation of {claim, reason, debate context} representations as attention vector. The candidate warrants receive the information from the claim, reason and debate context, and the model would select the correct warrant which satisfies the reasoning chain $R \rightarrow W \rightarrow C$.

Finally, we obtain two attended warrant vectors att_{W_0}, att_{W_1} .

2.5 Output

To evaluate the probability distribution of the two candidate warrants, we employ a feed-forward neural network with one dense layer, and apply the *Softmax* function to predict the probability.

$$h_o = \text{ReLU}(W_o[att_{W_0}, att_{W_1}]) \quad (12)$$

$$\hat{p} = \text{Softmax}(W_p h_o) \quad (13)$$

As for the optimization, cross-entropy loss is used as the loss function since we are handling a binary classification problem:

$$\mathcal{L} = -\left(y_i \log \hat{p}_i + (1 - y_i) \log(1 - \hat{p}_i)\right) \quad (14)$$

where y_i is the gold label.

3 Experiments

3.1 Datasets

SemEval 2018 provided 1,970 instances for the argument reasoning comprehension task (Habernal et al., 2018b). The instances are divided into three sets based on the year when the debates are taken from. Table 1 lists the statistics of the datasets. We also include the number of debate topics of each set.

Dataset	# Pairs	# Topics	Source Year
Train	1,210	111	2011-2015
Dev	316	31	2016
Test	444	30	2017

Table 1: The statistics of the datasets

Being a binary task, accuracy (Acc) is adopted as the evaluation metric.

Approach	Dev
Intra-warrant attention	0.638 (± 0.024)
Intra-warrant attention w/ context	0.637 (± 0.040)
Our basic model	0.666 (± 0.019)
· + Diff_{ $\{W_0, W_1\}$ }	0.678 (± 0.001)
· + Diff_{ $\{W_0, W_1\}$ } + CNN	0.675 (± 0.010)
· + Diff_{ $\{W_0, W_1, Claim\}$ } + CNN	0.676 (± 0.010)
Ensemble (Vote)	0.708

Table 2: Accuracy of each approach on the developing dataset.

3.2 Parameters Setting

The word embeddings are initialized with the 300d pre-trained word2vec (Mikolov et al., 2013), and do not fine-tune during training. The window sizes of CNN is (1,2,3) and the kernel size is 50. The dimensions of the hidden size in Bi-LSTM and Att-LSTM are set to 50. The dense layer in Output is 25. We train the model using Adam (Kingma and Ba, 2014) with gradient clipping (the max norm is set to 30, batch size is 32), The networks are regularized by dropout (the dropout ratio equals 0.8). We ran each model three times with random initializations. Our code is available at <https://github.com/rgtjff/SemEval2018-Task12>.

3.3 Results on Training Data

Table 2 shows the results of each components of our attention-based neural network. We have the following findings:

(1) Comparing with the Intra-warrant attention (w/ context) provided by the organizer, our basic model obtains 2.8% improvement through sharing parameters in Bi-LSTM. It indicates that the neural network need sufficient training data and parameters sharing could alleviate the demand.

(2) All of the three improvements achieves improved accuracy. It suggests that utilizing the different part as attention vector can obtain discriminative representation, which is beneficial for choosing the correct answer.

(3) The introduction of CNN does not seem to improve the performance of the model. The possible reason may be that RNN actually learn any computational function and capture the spatial information.

(4) The ensemble of the three networks can further improve the performance. Therefore, we configure the ensemble model as our final submission.

Approach	Test
Human average	0.798 (± 0.162)
Human w/ training in reasoning	0.909 (± 0.114)
Random baseline	0.508 (± 0.015)
Intra-warrant attention w/ context	0.584 (± 0.015)
Rank 1: GIST	0.712
Rank 2: blcu_nlp	0.606
Rank 3: ECNU	0.604

Table 3: Accuracy of each approach (humans and systems) on the test set.

3.4 Results on Test Data

Table 3 lists the results of three top systems and several baselines provided by the organizer. We find that: (1) Comparing with Intra-warrant attention w/ context model, our model outperforms it by 2% in terms of accuracy, which demonstrates the efficiency of the proposed attention-based model. (2) Comparing with GIST and blcu_nlp, our result is comparable to blcu_nlp but worse than GIST. Both of them use the pre-trained ESIM model (Chen et al., 2017) trained on SNLI (Bowman et al., 2015) and MultiNLI (Nangia et al., 2017) dataset. Our model only uses the training dataset and does not require any extra resources. However, this is also the limitation of our model because this small-size dataset is insufficient to learn parameters in our model.

4 Conclusion

In this work, we propose an end-to-end neural network for the reading comprehension task. We stack a CNN and a RNN to represent each component in a debate and extract the warrants' and claim's different part as attention vector to obtain their distinguish representation. Moreover, we use another attention network to incorporate the information of reason, claim, debate context into the contextual representation of the warrants for final decisions. Our model achieves 60.4% accuracy and ranks 3rd among 22 participating systems.

Abstract

The Argument Reasoning Comprehension Task requires significant language understanding and complex reasoning over world knowledge. We focus on transfer of a sentence encoder to bootstrap more complicated models given the small size of the dataset. Our best model uses a pre-trained BiLSTM to encode input sentences, learns task-specific features for the argument and warrants, then performs independent argument-warrant matching. This model achieves mean test set accuracy of 64.43%. Encoder transfer yields a significant gain to our best model over random initialization. Independent warrant matching effectively doubles the size of the dataset and provides additional regularization. We demonstrate that regularization comes from ignoring statistical correlations between warrant features and position. We also report an experiment with our best model that only matches warrants to reasons, ignoring claims. Relatively low performance degradation suggests that our model is not necessarily learning the intended task.

1 Introduction

The Argument Reasoning Comprehension Task (ARCT) (Habernal et al., 2018) addresses a significant open problem in argumentation mining: connecting reasons and claims via inferential licenses, called warrants (Toulmin, 1958). Warrants are a form of shared world knowledge and are mostly implicit in argumentation. This makes it difficult for machine learning algorithms to discover arguments, as they must acquire and use this knowledge to identify argument components and their relations. ARCT isolates the reasoning step by not requiring warrants to be discovered. A correct warrant **W** and an incorrect alternative **A** are given, and the correct one must be predicted given the corresponding claim **C** and reason **R**.

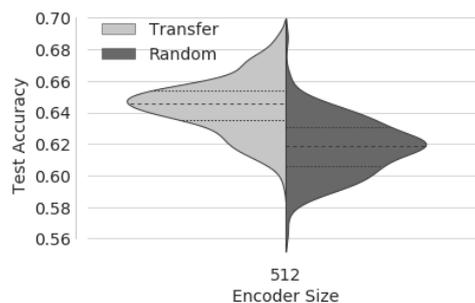

Figure 1: Benefit of transfer to our best model, COMP. Distributions come from 200 runs with different random seeds. Mean accuracy for transfer (64.43%) is higher than random (61.81%) and is significant with $p = 9.68 \times 10^{-41}$.

However, this does not eliminate the need for other forms of world knowledge. Consider the following example from the test set:

- C** Google is not a harmful monopoly
- R** People can choose not to use Google
- W** Other search engines do not re-direct to Google
- A** All other search engines re-direct to Google

It is required to know how consumer choice and web re-directs relate to the concept of monopoly in this context, and that Google is a search engine.

We do not attempt to address these other forms of world knowledge. Given the small size of the dataset we focus on transfer of semantic knowledge in the form of a sentence encoder to bootstrap inference over learned features. Following Conneau et al. (2017), we pre-train a BiLSTM encoder with max pooling on natural language inference (NLI) data (Williams et al., 2017; Bowman et al., 2015). Their results indicate transfer from the NLI domain to be useful. They hypothesized that due to the challenging nature of the

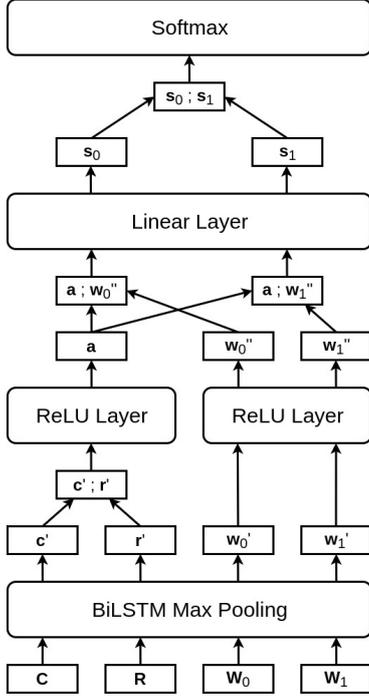

Figure 2: COMP model architecture.

task, successful encoders must necessarily learn good semantic representations. However, Nie et al. (2017) argue that due to the relatively easy nature of their out of domain generalization tasks (sentiment classification and textual similarity), they did not sufficiently demonstrate that deep semantic understanding had been learned.

In this respect our work extends the results of Conneau et al. (2017). They performed transfer by passing encoded sentence vectors to a logistic regression classifier. Our implementation of this model demonstrated very poor performance on ARCT. However, we experiment with a more complicated model (Figure 2) which significantly benefits from transfer (Figure 1). We therefore extend previous results to demonstrate the utility of this technique not only for a more semantically challenging task, but also a more complicated neural network architecture.

A key feature of our model is independent warrant classification which effectively doubles the size of the dataset. We demonstrate that it also provides regularization due to ignoring statistical correlations between warrant features and position.

Finally, we experiment with a version of our model that only matches reasons to warrants, ignoring claims. The relatively low drop in performance suggests that our model may not necessarily be learning the intended task.

2 System Description

2.1 COMP Model

A diagram of our best model which we call COMP is given in Figure 2. The key idea is to learn independent features for argument components and then perform independent warrant matching.

The inputs are word vectors for the claim C , reason R , and warrants W_0 and W_1 . We use GloVe embeddings with 300 dimensions pre-trained on 640B tokens (Pennington et al., 2014). First, a bi-directional LSTM (Hochreiter and Schmidhuber, 1997) with max pooling learns semantic representations of the input sentences.

$$c' = \text{BiLSTM}_{\max}(C)$$

$$r' = \text{BiLSTM}_{\max}(R)$$

$$w'_0 = \text{BiLSTM}_{\max}(W_0)$$

$$w'_1 = \text{BiLSTM}_{\max}(W_1)$$

Dropout (Srivastava et al., 2014) is then applied to these vectors. If d is the encoder size then each vector is of dimension $2d$ due to the concatenation of forward and backward LSTMs.

Parameter matrix $U \in \mathbb{R}^{4d \times h}$ with ReLU activation (Nair and Hinton, 2010) learns argument specific feature vectors of length h from the concatenation of the claim and reason. Parameter matrix $V \in \mathbb{R}^{2d \times h}$ with ReLU activation learns specific features for each warrant independently. Biases are omitted for clarity.

$$a = \text{ReLU}(U[c'; r'])$$

$$w''_0 = \text{ReLU}(Vw'_0)$$

$$w''_1 = \text{ReLU}(Vw'_1)$$

Dropout is then applied to these vectors prior to classification. Parameter vector $z \in \mathbb{R}^{2h}$ is used to independently determine a matching score for each argument-warrant pair. The scores are concatenated and passed through softmax to determine a probability distribution \hat{y} over the two warrants. Cross entropy is then used to calculate loss with respect to the gold label y .

$$s_0 = z^\top [a; w''_0]$$

$$s_1 = z^\top [a; w''_1]$$

$$\hat{y} = \text{softmax}([s_0; s_1])$$

$$J(\theta) = \text{CE}(\hat{y}, y)$$

Encoder Size	Random	Transfer	Difference	Significance (p)
2048	0.5975	0.5942	-0.55 %	1.72×10^{-1}
1024	0.6058	0.6025	-0.54 %	1.05×10^{-1}
512	0.6181	0.6443	+4.24 %	9.68×10^{-41}
300	0.6285	0.6260	-0.40 %	1.41×10^{-1}
100	0.6310	0.6329	+0.30 %	2.89×10^{-1}

Table 1: Transfer results for our COMP model with different encoder sizes. Learning rates and dropout are tuned to specific encoder sizes. All other hyperparameters are the same. Results are the mean test set accuracy of 200 runs from different random seeds. “Difference” shows the percentage change of transfer relative to random.

2.2 Training Details

Pre-training BiLSTMs was done according to the specifications of Conneau et al. (2017). For all ARCT models we followed their annealing and early stopping strategy: after each epoch, if development set accuracy does not improve the learning rate is reduced by a factor of five. Training stops when the learning rate drops below 1×10^{-5} . This algorithm was found to outperform a steadily decaying learning rate. Adam (Kingma and Ba, 2014) was used for optimization.

We used grid search to find our best parameters. Best results were achieved with a batch size of 16. Dropout with $p = 0.1$ was found to be superior to $L2$ -regularization. For the COMP model, a hidden representation size of 512 worked best. Tuning word embeddings was found to overfit compared to freezing them. However, tuning the transferred encoder was far superior to freezing for the COMP model.

We did not find reducing the learning rate on the encoder helped transfer. Bowman et al. (2015) also transferred AdaDelta accumulators along with an encoder on the principle that lowering the starting learning rate should help avoid blowing away transferred knowledge. Our results rather agree with Mou et al. (2016) who also found that learning rate reduction did not help transfer.

Our code is publicly available, including scripts to reproduce our results.¹

2.3 Submission

Our submission “NLITrans” was our COMP model with a transferred encoder of dimension 2048. The principal learning rate was 0.002 and we tuned embeddings at their own rate of 0.0002. The encoder was tuned at the principal rate. Hidden representation size was 512.

Our submission test set accuracy of 59.0%

¹<https://github.com/IKMLab/arct>

achieved fourth place. Following Riemers and Gurevych (2017), we consider a single run an insufficient indication of the performance of a model due to the variation resulting from random initialization. Evaluation over 20 runs with different random seeds revealed our entry was close to the mean for this configuration of 59.24%.

2.4 Best Configuration

Extended post-competition tuning on the development set revealed better hyperparameter settings that boost the generalization ability of our COMP model. Specifically, we freeze word embeddings and use an encoder of size 512. On the test set this configuration achieves a mean accuracy of 64.43% over 200 random initializations.

3 Analysis

3.1 Transfer Performance

We measure the performance of transfer by comparison with random initialization. The results in Table 1 show the performance of different encoder sizes for our best COMP model. Learning rate and dropout are re-tuned via grid search for each encoder size. More investigation is required, however these results suggest that the success of transfer depends on finding an optimal encoder size for a given model. We note that the best random performance came from the smallest encoder size, confirming that transfer is helping us bootstrap the use of more complicated models.

3.2 Independent Warrant Classification

Ablation studies showed that independent warrant classification is a significant advantage. For comparison, we built a model that considers both warrants and the argument together by replacing parameter vector \mathbf{z} with a matrix $\mathbf{Z} \in \mathbb{R}^{3h \times 2}$. We call this model CORR, as it considers correlations between warrant features and position. The scores

Model	Dataset	Train	Test	Overfit
COMP	Full	0.8807	0.6443	36.69 %
	Half	0.8925	0.6332	40.95 %
	Unbal.	0.9109	0.6353	43.38 %
CORR	Full	0.8155	0.5912	37.94 %
	Half	0.8287	0.5649	46.70 %
	Unbal.	0.9368	0.5750	62.92 %

Table 2: Comparison of independent (COMP) and correlated (CORR) models on full, half, and unbalanced (Unbal.) datasets. COMP has 6,541,057 parameters and CORR has 6,543,106.

for the warrants are then calculated as

$$\mathbf{s} = \mathbf{Z}[\mathbf{a}; \mathbf{w}_0''; \mathbf{w}_1'']$$

The results in Table 2 demonstrate poorer generalization and increased overfitting relative to the independent model on the full dataset.

Independent warrant classification effectively doubles the size of the dataset. It can be seen that two separate multiplications of argument-warrant vectors with \mathbf{z} lead to two backpropagated supervision signals with each data sample. To quantify this effect we evaluated the independent model trained on a randomly sampled half of the the training set. It still generalized better than CORR on twice the data (Table 2).

We hypothesized that additional regularization follows from ignoring statistical correlations between warrant features and position. To investigate this hypothesis, we picked an obvious linguistic phenomenon and looked at the statistics of its occurrence at each warrant position. We used SpaCy’s dependency parser to identify tokens with the negation relation to its head. Results showed negation is ubiquitous in this dataset, covering approximately 70% of training samples - perhaps reflecting a natural way to generate pairs of conflicting warrants. Whilst the warrant with negation is correct half of the time in the training set, negation in position one is slightly more likely to be correct than position zero (26% to 25%).

To quantify model susceptibility to such correlations we created an unbalanced training set in which all correct warrants with negation occur in position one. This resulted in relabeling 300 warrants. We randomly relabeled the same amount of warrants without negation to position zero to re-balance the dataset. The results (Table 2) con-

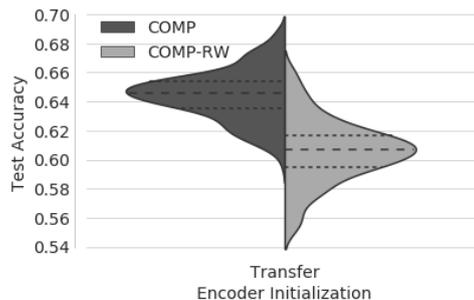

Figure 3: Results of our COMP-RW model that doesn’t consider the claim, compared to our best model COMP. Distributions are calculated from 200 runs with different random seeds. The mean for COMP is 64.43%, compared to 60.60% for COMP-RW.

firm that the CORR model is more susceptible to this change, resulting in a large overfit, whilst the generalization ability of the independent model is essentially unaffected.

3.3 Matching Warrants to Reasons

In the following example a position toward the claim seems to be embedded in the reason.

- C** Comment sections have not failed
- R** They add a lot to the piece and I look forward to reading comments
- W** Comments sections are a welcome distraction from my work
- A** Comments sections always distract me from my work

Cases such as this may provide an alternative learning signal and lead our model to stray from the intended task. For example it might be possible to correctly classify this example by comparing the sentiment of the warrants to that of the reason.

To quantify this effect we experimented with a model that considers only the reasons and warrants, called COMP-RW. Since we do not input the claim we resize \mathbf{U} from $\mathbb{R}^{4d \times h}$ to $\mathbb{R}^{2d \times h}$. We use an encoder of size 640 to balance this reduction which evens the parameter count for a fair comparison. Figure 3 shows the relative performance of COMP-RW versus our best COMP model. Test set accuracy deteriorates from 64.43% to 60.60%. This suggests there is enough signal coming from the reasons alone to achieve approximately two thirds of what our model is capable of above random guessing. We therefore suspect our model is not necessarily learning the intended task.

4 Conclusion

Our entry NLITrans achieved test set accuracy of 59.0% for fourth place, close to the mean for its configuration of 59.24% over 20 random initializations. Extended post-competition tuning on the development set led us to a superior configuration of our COMP model that achieved a mean of 64.43%. Transfer of an encoder pre-trained on NLI data resulted in a 4.24% boost to test set accuracy for this model. This extends previous results with this transfer technique, demonstrating its effectiveness in a more complicated neural network architecture, and for a much more semantically challenging task. An outstanding question is whether there is an optimal encoder size for transfer given a specific architecture, and how to efficiently and reliably find it. Independent argument-warrant matching proved to be beneficial, doubling the effective size of the dataset and providing additional regularization. We demonstrated that regularization comes from ignoring the correlations between warrant features and position. Adapting our model to ignore the claims resulted in a relatively low drop in performance, suggesting our model is not necessarily learning the intended task. We leave a more thorough analysis of this phenomenon for future work.

yudong@blcu.edu.cn

Abstract

The argument comprehension reasoning task aims to reconstruct and analyze the argument reasoning. To comprehend an argument and fill the gap between claims and reasons, it is vital to find the implicit supporting warrants behind. In this paper, we propose a hierarchical attention model to identify the right warrant which explains why the reason stands for the claim. Our model focuses not only on the similar part between warrants and other information but also on the contradictory part between two opposing warrants. In addition, we use the ensemble method for different models. Our model achieves an accuracy of 61%, ranking second in this task. Experimental results demonstrate that our model is effective to make correct choices.

1 Introduction

The argument reasoning comprehension is a crucial part for natural language understanding and inference, since argument comprehension requires reconstruction and analysis for its reasoning. Lack of common sense makes it difficult to infer claims from corresponding reasons directly. To fill the gap between claims and reasons, several explorations have been performed on argumentative structure of a debate (Hastings, 1963; Walton et al., 2008; Walton, 1990). Argument reasoning comprehension, a new task in SemEval 2018, sheds some light on the core of reasoning in natural language argumentation: implicit warrants, which are seen as a bridge between claims and reasons. Given a reason R , a claim C and two alternative warrants W_0 and W_1 , the goal of this task is to identify the right warrant which can justify the use of R as support for C . The difficulty of the task is the warrants are plausible and lexically close

but lead to contradicting claims (Habernal et al., 2018).

To be more specific, the reason R and the claim C are propositions extracted from a natural language argument. And warrant W is the relation between R and C which is characterized by a rule of inference (Newman and Marshall, 1992). Walton proposed that an argument refers to a claim based on reasons given in the premises (Walton, 1990). The most central part of this task is how to find the warrant for the given R and C . In the argument reasoning comprehension task, the organizer extracts the instances from Room for Debate section of the New York Times. After a complex crowd-sourcing process, 1970 valid instances are provided for the task. Two alternative warrants are provided as candidates, where one can justify the use of R as support for C and the other one can justify R as support for the opposite side of C . We need to reconstruct the reasoning and select the right warrant which stands for claim in this task. The average score for human is 79.8%, while for those with extensive formal training is 90.9% (Habernal et al., 2018).

In this paper, we not only pay attention to the similar part between each warrant and other information but also pay close attention to the contradictory part between two warrants. We propose a model for this task which consists of four components: sentence representation layer, attended warrant layer, enhanced attention layer and prediction layer. All the sentences are represented with word embeddings in the sentence representation layer. And to better understand the meaning of warrant, we incorporate the additional information to re-represent the two warrants. Then we apply an enhanced attention layer to emphasize the similar and contradictory part between the two alternative warrants W_0 and W_1 . At last, we make prediction through a feedforward neural network layer (Fine,

*The corresponding author

2001). In addition to the primary model, we propose an ensemble method to achieve a stable and credible accuracy. This method is well established for obtaining highly accurate classifiers by combining less accurate ones (Dietterich, 2000). Our model improves the accuracy by 4% compared to the baseline model.

2 Model Description

Our hierarchical attention model is composed of the following major components: sentence representation, attended warrant layer, enhanced attention layer and prediction layer. Figure 1 shows a high-level view of sentence representation and attended warrant layer. And Figure 2 shows a high-level view of the enhanced attention layer and prediction layer. Our code is implemented with TensorFlow and is available on github¹.

In the attended warrant layer, we pay attention to the relevant part between each warrant and other information, and get two attended representation for the two warrants. While in the enhanced attention layer, we focus on the similarities and differences between two attended warrants. The output of our model is the predicted label for each instance, where label 0 means warrant0 stands for the claim and label 1 means warrant1 does.

2.1 Sentence Representation

We implement five BiLSTM networks with shared weights to learn each of the sentence representation. It is reasonable to use shared weights among BiLSTM networks because all the sentences are in the same vector space. The input of BiLSTM network is the sentence represented with word embeddings. For later use, we use $w0$ for the hidden states of $W0$ generated by the BiLSTM at time i over the input sequence. And $w1$, c , r , d for the hidden states of $W1$, C , R and D information at each time step.

$$w0_i = BiLSTM(W0, i), \forall i \in [1, \dots, l_{W0}] \quad (1)$$

$$w1_j = BiLSTM(W1, j), \forall j \in [1, \dots, l_{W1}] \quad (2)$$

$$c_k = BiLSTM(C, k), \forall k \in [1, \dots, l_C] \quad (3)$$

$$r_m = BiLSTM(R, m), \forall m \in [1, \dots, l_R] \quad (4)$$

$$d_n = BiLSTM(D, n), \forall n \in [1, \dots, l_D] \quad (5)$$

Where l_{W0} , l_{W1} , l_C , l_R and l_D are the length of $W0$, $W1$, C , R and D respectively.

¹https://github.com/blcunlp/SemEval2018-argument_reasoning_comprehension

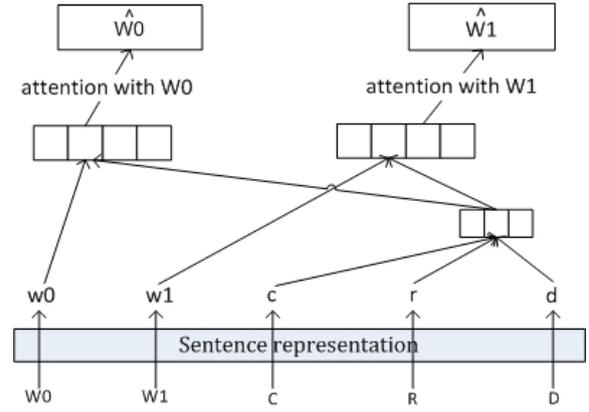

Figure 1: Sentence representation and attended warrant layer

2.2 Attended Warrant Layer

Considering the importance of the hint of reason sentence and claim sentence, we try to pay attention to the most relevant part between each warrant and these additional information. So we implement standard attention mechanism over each warrant with additional information including C , R and D , which is represented with A .

$$A = [c; r; d] \quad (6)$$

For better comprehension, we apply intra-attention over each warrant. For convenience, we combine the two processes above by concatenating the two vectors for attention. For further use, we denote attention vectors for $W0$ and $W1$ as $\overline{W0}$ and $\overline{W1}$.

$$\overline{W0} = [w0; A] \quad (7)$$

$$\overline{W1} = [w1; A] \quad (8)$$

Specifically, we apply attention over $W0$ and the concatenate vector for $W0$ as the following formulas (Tan et al., 2015). We can get $\hat{W0}_i$ to represent the vector for $W0$ after attention.

$$M0_i = \tanh(Uw0_i + V\overline{W0}) \quad (9)$$

$$S0_i \propto \exp(wM0_i(t)) \quad (10)$$

$$\hat{W0}_i = w0_i S0_i \quad (11)$$

Where U , V and w are attention weight parameters. In the same way, we can compute $\hat{W1}_j$ to represent the vector for $W1$ after attention.

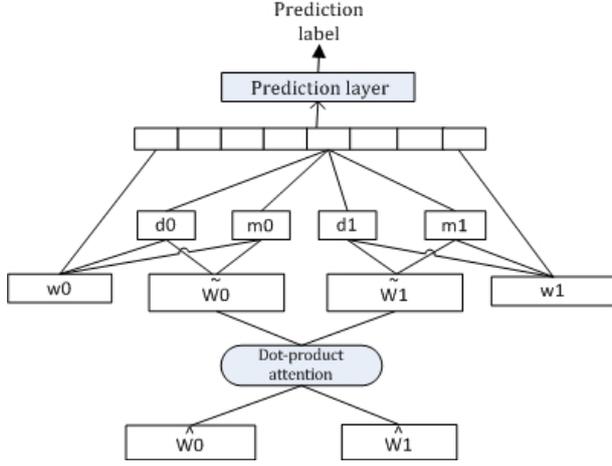

Figure 2: Enhanced attention layer and prediction layer

2.3 Enhanced Attention Layer

The similar and contradictory parts of the two warrants are the most important information for argument reasoning comprehension. In the enhanced attention layer, our model align the two warrants to focus on their similarities and differences.

$$e_{i,j} = \hat{W}0_i^T \hat{W}1_j \quad (12)$$

$$\widetilde{W}0 = \sum_{j=1}^{l_{W1}} \frac{\exp(e_{i,j})}{\sum_{k=1}^{l_{W1}} \exp(e_{i,k})} \hat{W}1_j \quad (13)$$

$$\widetilde{W}1 = \sum_{i=1}^{l_{W0}} \frac{\exp(e_{i,j})}{\sum_{k=1}^{l_{W0}} \exp(e_{k,j})} \hat{W}0_i \quad (14)$$

Where $\widetilde{W}0$ is a weighted summation of each element in $W1$, the relevant element in $W1$ is selected and represented into $\widetilde{W}0$. We can get $\widetilde{W}1$ in the same way.

To extract the different part in $W0$, we let $\hat{W}0_i$ subtract $\widetilde{W}0$. To get the similar part in warrant0, we let $\hat{W}0_i$ multiply $\widetilde{W}0$ (Chen et al., 2017). In the formulas, \odot is element-wise multiply of two vectors. The same is performed for $W1$.

$$d0 = \hat{W}0 - \widetilde{W}0 \quad (15)$$

$$d1 = \hat{W}1 - \widetilde{W}1 \quad (16)$$

$$m0 = \hat{W}0 \odot \widetilde{W}0 \quad (17)$$

$$m1 = \hat{W}1 \odot \widetilde{W}1 \quad (18)$$

2.4 Prediction Layer

To make best use of all provided information, we concatenate all the representations.

$$W0_inf = [\hat{W}0; d0; m0] \quad (19)$$

$$W1_inf = [\hat{W}1; d1; m1] \quad (20)$$

$$all_info = [W0_inf; W1_inf] \quad (21)$$

We implement a simple feedforward neural network to make the final prediction.

2.5 Model Ensemble

Ensemble learning helps improve machine learning performance by combining several models (Zhou, 2012). This approach allows the production of a better predictive performance compared to a single model. To improve and stabilize the performance of our model, we ensemble different models by majority voting strategy. We choose five models which have best performance on development data. The final result is better than every single model.

3 Experiments

3.1 Dataset

The argument reasoning comprehension task chooses the Room for Debate section of the New York Times as source data. The given reason sentences come from stance-taking comments, and the false warrant is generated by annotators. It is validated manually that the created false warrant can prove the reason which will lead to the opposite claim. And the right warrant is written by minimal modifications to the false one, which can ensure that this warrant can be inferred from the reason and stands for the claim. And also, to evaluate the performance of the models, each instance in the dataset is represented as a tuple (R;C;W0;W1) along with a label (0 or 1). If the label is 0, $W0$ is the correct warrant, otherwise $W1$. More details about dataset can be found in the work of Habernal (2018)

All the data of the argument reasoning comprehension task is provided in the GitHub by task organizers². For the availability and validity, after complex manual processing, only 1955 instances are selected from 11k comments.

3.2 Experimental Setup

We use the development set to select models for testing. Training details are as follows. We use ADAM optimizer (Kingma and Ba, 2014) for training, setting the first hyperparameter to be

²the data can be found in github <https://github.com/habernal/semEval2018-task12/tree/master/data>

0.9 and the second 0.999. The initial learning rate is 0.001 and the batch size is 32. We use word2vec((Mikolov et al., 2013)) to pre-train the word embedding of 300 dimension and keep them from updating while training. The numbers of hidden units and layers of biLSTM networks are 64 and 1 respectively. And the dropout rate is set to be 0.1, and is applied to all biLSTM networks. For the prediction layer, we choose standard FNN with 1 layer and set the hidden cells number to 64.

3.3 Evaluation Method

We use accuracy to evaluate the performance of the models, that is, computing the ratio of the right predicted labels of all instances. A scorer and detail information are described in the task introduction website³. The scorer can give us the expected accuracy of the model.

3.4 Results

models	dev acc	test acc
baseline model	0.632	0.548
attention model	0.653	0.585
hierarchical model	0.672	0.599
ensemble model-3	0.670	0.602
ensemble model-5	0.686	0.606
ensemble model-7	0.681	0.610

Table 1: results of different models

Table 1 shows the accuracy of different models on development dataset and test dataset. The first row is a baseline model which uses intra-warrant attention between two warrants (Habernal et al., 2018). In this model, all the representations of input sentences except warrant0 are concatenated as an attention vector for warrant0, and all sentences except warrant1 are concatenated as an attention vector for warrant1. And the attentive representations is used for prediction.

To evaluate the performance of each part of our model, we implement experiments on different parts of our model. The attention model in Table1 includes three parts: sentence representation, attended warrant layer and prediction layer. In the prediction layer, the two attended warrant vectors are used to predict the right label. And the third model is a single hierarchical attention model, which adds the enhanced attention layer

³scorer can be found in <https://github.com/habernal/semEval2018-task12>

based on the second model. The accuracy improved by 1.4% on the test data.

We use an ensemble method for different models with majority voting strategy. As we can see in Table 1, the ensemble model for 5 single models achieves the highest accuracy on development dataset.

3.5 Results Analysis

For the attended warrant layer, we use shared weights of biLSTM networks to get the representations of sentences. Also we implement intra-attention over each warrant and implement attention over each warrant and other sentences. These changes help to better understand and represent the warrant meaning itself. We introduce intra-attention to emphasize the important meaning in the warrant sentence. The alignment over warrants and the additional information provide the relativity of words in warrant and other sentences. With these attention information, we can see there is an improvement of 2%.

In the enhanced attention layer based on attended warrant layer, we emphasize the similar part and the contrary part between two warrants. The difference of attended warrant0 and warrant1 focuses on the contrary information and the multiplication of attended warrant0 and warrant1 emphasizes the similar part. So the model assigns different weights to different words of warrants according to their relativity. We can see there is about 2% points improvement for this part.

All the results mentioned above are based on the single model. And to get more stable performance, we use an ensemble method for different single models. In our experiment, the top 5 models voting result shows the best performance on development dataset, and the top 7 models voting result shows the best performance on test dataset.

4 Conclusion

In this paper, we propose a hierarchical attention model to select the supporting warrant for the argument. The model performs well in SemEval-2018 Task12: The Argument Reasoning Comprehension Task. We find that the information from both the similar part and contrary part between two alternative warrants is crucial to reconstruct the argument reasoning. Moreover, the ensemble method is of great help for the good performance and stability of our model.

Abstract

An argument is divided into two parts, the claim and the reason. To obtain a clearer conclusion, some additional explanation is required. In this task, the explanations are called warrants. This paper introduces a bi-directional long short term memory (Bi-LSTM) with an attention model to select a correct warrant from two to explain an argument. We address this question as a question-answering system. For each warrant, the model produces a probability that it is correct. Finally, the system chooses the highest correct probability as the answer. Ensemble learning is used to enhance the performance of the model. Among all of the participants, we ranked 15th on the test results.

1 Introduction

Reasoning is an important part of human logical thinking. It gives us the ability to draw fresh conclusions from some of the known points (Judea, 1988). Argument is the basis for reasoning. Except for the argument's claim and reason, usually, it needs some additional information. Therefore, what we know is the additional information and arguments reason. The claim also needs warrants for an explanation. An example is shown in Table 1.

Obviously, A is a reasonable explanation. The task is to get the reader to find a reasonable explanation for the known messages and claims in the two warrants. Due to the small number of alternative warrants, this problem can be considered to be a binary classification problem. This idea can be used as the baseline model. However, for system scalability and effectiveness, we treat this problem as the regression problem of probability prediction. The idea calculates the probability for each warrant that it is correct. Because of the diversity of natural language expression, there are

many ways in which the same meaning can be expressed. Thus, this approach can be better to address this situation (Collobert et al., 2011).

Another benefit of addressing the problem in this way is to make the problem similar in form to the multi-choice question-answering system. The question-answering system is a classic problem of natural language processing. Many methods and models can be used for reference.

The traditional question-answering system is based on semantic and statistical methods (Alfonseca et al., 2002). This method requires an enormous background knowledge base. In addition, it is not very effective for nonstandard language expression. The state-of-the-art methods are usually based on neural networks. The trained word

embedding can fully express the semantics and knowledge. Therefore, the new method is usually better than the traditional statistical-based method.

In this paper, we proposed a bi-directional LSTM with an attention model. The model uses a bi-LSTM network to encode the original word embedding. Then, the semantic outputs are fed into the dense decoder with an attention mechanism. Due to the uncertainty of a single model, ensemble learning is used to enhance the performance of the model.

The remainder of the paper consists of 3 parts. The second part introduces the proposed model in detail, and the implementation is presented in the third part, while the last part presents our conclusions.

2 Model

The model contains several elements, word embeddings, the bi-directional recurrent neural network (Bi-RNN), a semantic encoder (Chen et al., 2016), the attention mechanism and dense layer decoder. Word embedding is a layer before Bi-RNN. This layer contains a map from a word index to the word embedding. This map is a pre-trained word vector look-up table. This task is dependent on semantics, and the question-answering system relies more on knowledge. Therefore, the choice of the word embedding training corpus must pay more attention to the correct grammar. Since a sentence is a whole, a single word in a semantic expression is context dependent. On the other hand, due to the variable length of the input, the Bi-RNN is the choice to complete this encoding task.

Attention mechanisms are used to remind the model of the claim's information. The final result is the probability of a fixed length. In a simple consideration, we use the full connection layer to decode under a softmax function.

2.1 Bi-directional LSTM

The RNN has a powerful ability to extract full-text features (Schuster and Paliwal, 1997), and thus, it is a good tool to obtain the word semantic information. Based on past experience, an LSTM cell is selected to avoid vanishing and exploding gradients. The LSTM is an improved RNN cell. It has two distinct improvements over traditional RNN cells. The first is the gradient problem mentioned above, and the second is the ability to carry long-

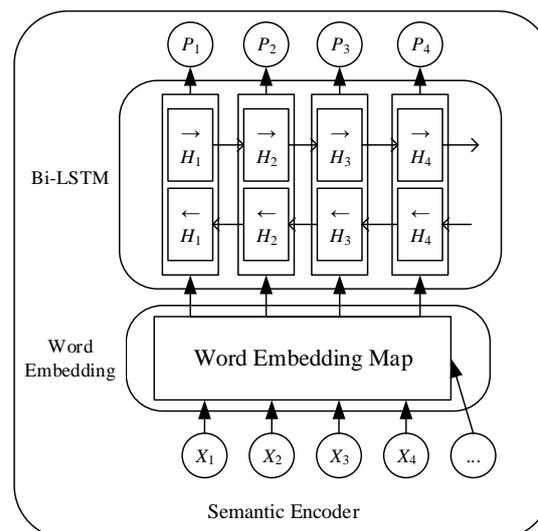

Figure 1: Semantic Encoder

term information. This arrangement is chosen because LSTM uses a gate structure to make the useful information available for long-term transmission, and the useless information can be filtered out over time. The Bi-directional network allows the forward and backward information to both be expressed.

The Bi-LSTM network is chosen to obtain semantic information over all locations in a sentence.

2.2 Semantic Encoder

Putting word embedding and Bi-LSTM together is a semantic encoder. The original text is encoded by it and has global information for each location. The structure of the semantic encoder is shown in Figure 1. The original text index sequence is fed into the encoder. Then, the word embedding layer turns it into a word embedding sequence by a pre-trained word embedding map. Bi-LSTM has forward and backward, 2 directions, to capture the global features. It outputs the combination of two directions results. The final outputs of encoder are the semantic information sequences for original text.

2.3 Attention Mechanism

Attentional mechanisms in natural language processing are usually used to provide the decoder with the source text information (Bahdanau et al., 2014). Semantic information in the original text can be fully obtained when decoding, instead of relying only on the semantic vector.

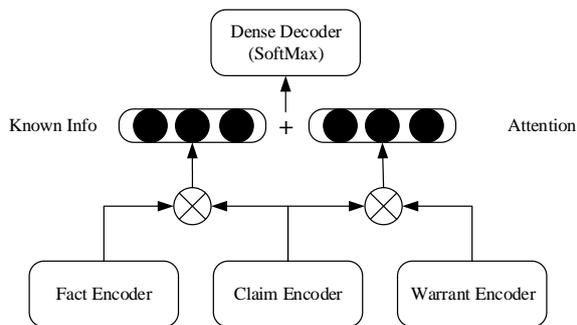

Figure 2: Model Summary

In this task, the attention mechanism is used to provide the model with the semantic information of the claim as the model is decoded.

Overall, the structure of the model is shown in Figure 2. As shown in Figure 2, the model contains 3 semantic encoders. The Fact, Claim, and Warrant are the 3 parts of the training data. Their clear definitions are presented in Part 3.1. The dot product of the two outputs of the fact encoder and claim encoder are combined with the dot product of the claim and warrants outputs. The fact and claim is referenced as known information. The result of the combination is the dense layer that is used to decode. In the decoding phase of the model, a softmax function arrives at the final prediction probability that we need. The output of the claim encoder is used twice during decoding. Its output is the attention mechanism to remind the model to focus on the valuable part of the claim.

3 Experiment

The experiment contains three parts. The first part is the selection and preprocess of experimental data. The second part is the implementation details. The third part is to show and analyze the results.

3.1 Dataset

The training corpus of the word vector, the training set of the model and the test set must be selected and processed.

As mentioned above, reading comprehension focuses more on semantic understanding (Tang et al., 2014), so GoogleNews is a good choice. Because news reports use more cautious words and more rigorous grammar. The mainstream word vector training tools are Word2Vec or GloVe. According to previous experimental results of related tasks, Word2Vec trained vector of words significantly better than GloVe (Yang et al., 2016). Thus,

in this experiment, Word2vec was chosen to train the word vector.

The form of the task data is complicated. It is more difficult to obtain the data by artificial generation or online acquisition. Thus, the training data and test data are given by the official data set. Each row of the test data set is divided into several sections, including the id, topic, additional information, reason, claim, warrant0, warrant1 and label. For each row of data, it is processed into two test data of the model. Each training data contains four parts. They are fact, warrant, claim and label. Here, fact is the original topic, with additional information of reason. Warrant, claim and label are not changed. Because there are two warrants in one line, it generates two training data. This approach is similar to a question-answer system, where claim is the question, and warrant is the answer. Additionally, model is used to predict whether this answer is correct for the question.

Because English words have some special forms, such as past tense, past participle, abbreviation and so on, the lemmatisation is needed (Karr, 2006).

3.2 Implementation Detail

The model is implemented using the Keras framework with TensorFlow backend. The program based on python 3.6. The LSTM network and Bi-LSTM network are used as the baseline model.

The proposed model contains 3 semantic encoders, *i.e.*, 3 Bi-LSTM layers and 3 word embedding layers. Using the dense layer as the final decoder outputs the result. Thus, the model contains 3 hyper-parameters, including the number of units of Bi-LSTM layers (Bi-LSTM Unit Number), the dimension of the word embedding (Word Embedding Dimension) and the epochs of the training (Training Epoch).

Due to the lack of training data, when there are more parameters of the model, it is easy to cause over-fitting. There are two improvements to avoid over-fitting. The first is dropout. Dropout is a classic way to avoid over-fitting. A dropout layer is added behind each Bi-LSTM. Thus, the model has one more hyper-parameter, which is the probability of dropout (Dropout Probability).

The second method is ensemble learning. Because of the implicit relationship between claim and reason, this task is very difficult (Habernal et al., 2018). To express all of the features of the

Parameter	Pre-set Values
Bi-LSTM Unit Number	64, 96, 128
Word Embedding Dimension	200, 300
Training Epoch	5, 8
Dropout Probability	0.3, 0.4, 0.5
Ensemble Model Number	5, 7, 9, 11

Table 2: Pre-set Parameter.

Model	Acc
LSTM	0.5126
Bi-LSTM w/o ATT	0.5253
Bi-LSTM w/ ATT	0.5696

Table 3: Results of Proposed Model and Baseline Model.

input, a sufficiently complex model is required. However, too little training data is not sufficient for the model to learn all of the features. This concern is a large limitation of a single model. Ensemble learning can effectively alleviate overfitting and greatly enhance the performance of the model.

The hard voting is chosen to implement the ensemble model (Dietterich, 2000). The hard voting means training multiple models at the same time. After training, it takes all the results of the model vote. The voting results are the result of the system.

Finally, the model has a total of 5 hyperparameters, including the ensemble model number. The grid search algorithm is used as the parameter tuning method. However, because the space of the parameters are too large, a few pre-set values are used to narrow the search. The pre-set values are shown in Table 2.

3.3 Result Analysis

Because of the lack of data, the following results are the result of dev data test under official train data training unless otherwise specified. Two baseline models are used to test the performance of the proposed model. In the case of no tuning parameters, finding the average number of test results in 3 times is shown in Table 3. As seen from the results in Table 3, the attention mechanism can effectively improve the accuracy of the prediction in this task. The result is also consistent with most experimental results.

In Table 4, **Epoch** is used for the Training Epoch, **Bi-LSTM** for Bi-LSTM Unit Number, **Em-**

Ensemble Model Number	Acc
6	0.6646
7	0.6741
9	0.6803
11	0.6772

Table 5: Results of Ensemble Learning.

b Dim for Word Embedding Dimension, **Dropout** for Dropout Probability, and **Acc** for Accuracy, the best 3 results are shown for the parameter tuning for the single model before the ensemble learning. The time spent to tune the parameters on multiple models is very large. Hence, during the implementation of hard voting, only the number of models will be tuned. The remaining parameters are the parameters that give the best result when there is only one model. (the first line in Table 4). The results are shown in Table 5.

It can be seen that the effect on the result tends to be stable when the model is over seven. However, the improvement from ensemble learning in the results is enormous. The accuracy increased by approximately 6 percentage points.

In the official test data of the competition, we chose the hard voting with nine models. The accuracy is 0.550. We rank 15th in all 22 teams.

4 Conclusions

Due to the complexity and abstraction of the logical system of human reasoning, it is not easy for a machine to learn its laws. Thus, this task is very challenging and difficult. The attention mechanism and ensemble learning are the key points to improve the performance of the model. In the experiment, both have a very large impact on the accuracy. The final result and rankings are not very good. After analysis, there could be two reasons. The first reason is that the data cleaning was not done well. The training data is mixed with a large amount of useless information. The second point is that the model parameter tuning was very limited.

This competition has benefited us greatly. We will continue to improve our model.

andreas.funke@hhu.de

Abstract

This paper describes our participation in the SemEval-2018 Task 12 *Argument Reasoning Comprehension Task* which calls to develop systems that, given a reason and a claim, predict the correct warrant from two opposing options. We decided to use a deep learning architecture and combined 623 models with different hyperparameters into an ensemble. Our extensive analysis of our architecture and ensemble reveals that the decision to use an ensemble was suboptimal. Additionally, we benchmark a support vector machine as a baseline. Furthermore, we experimented with an alternative data split and achieved more stable results.

1 Introduction

Argument mining is a trending research domain that focuses on the extraction of arguments and their relations from text. It has been applied to multiple languages and multiple application domains, including the legal domain (Palau and Moens, 2009), persuasive essays (Stab and Gurevych, 2014), online participation (Liebeck et al., 2016), and web discourse (Habernal and Gurevych, 2017). The three most common subtasks are: argument identification, argument classification, and argument linking. These focus on the identification of argumentative text content, the extraction of argument components according to a specific argument model, and the extraction of relations between arguments components, respectively.

Currently, different argument models comprising different argument components are being used throughout the community, such as the *claim-premise family* or Toulmin’s model (Toulmin, 1958). In the scope of this paper, claims, premises, and warrants are the most important argument components. Claims are often defined as controversial statements that are either true or false.

Premises are reasons that support or attack claims. In Toulmin’s model, they are connected with warrants that state why the premise supports the claim.

Habernal et al. (2018b) introduced a new argument mining task called *argument reasoning comprehension* with the following definition: Given a reason and a claim, identify the correct warrant from two opposing options.

This paper describes our participation in the SemEval-2018 Task 12 *The Argument Reasoning Comprehension Task* (Habernal et al., 2018a) that uses the dataset from Habernal et al. (2018b) as a shared task. Besides a description of our machine learning systems, we evaluate additional machine learning models (we were only allowed to submit a single set of predictions for the official ranking) and we further analyze the test set.

The dataset for the challenge consists of annotated news comments from the New York Times user debate section. With Amazon Mechanical Turk as a crowdsourcing platform, 5000 randomly selected user comments were annotated in a multi-step annotation process that included three free text annotation steps (gist summarization, the creation of warrants, and of alternative warrants). After the final filtering, the dataset for the Argument Reasoning Comprehension Task comprises 1970 instances, where each instance is a tuple of (R, C, W, AW, G, T, I) comprising a reason (R), a claim (C), a warrant (W), an alternative warrant (AW), a gold label (G) indicating which of both warrants is correct, a debate title (T), and additional debate information (I) about the debate. The task organizers split the dataset into three distinct groups: training set (1,210 instances), development set (316 instances), and a test set (444 instances).

Figure 1 shows a training example of the dataset. The machine learning task of predicting the correct warrant is difficult since both warrants

Title: Do We Still Need Libraries?
Debate information: Do We Still Need Libraries? What are libraries for, and how should they evolve?
Claim: We need libraries
Reason: Libraries have lots to offer in addition to books they provide music, dvd's, magazines and more.
✓ **Warrant 1:** all these things are readily available to everyone online
✗ **Warrant 2:** none of these things are readily available to everyone online

Figure 1: Example of a training instance with warrant 1 as the correct gold label.

are lexically similar, and can differ in just one or two words.

In the trial phase of the challenge, the participants were given access to the training set and the dev test with gold labels. In the test phase of the challenge, the task participants were given access to the test set (with omitted gold labels) and had to submit predictions for all test instances.

2 Our Approach

For our participation in the challenge, we experimented with deep learning architectures in Keras (Chollet, 2015) with TensorFlow (Abadi et al., 2015) as the backend. We tested multiple deep learning architectures comprising different layers and input channels. For each of these models, we performed an extensive grid search for hyperparameters, such as layer sizes, embedding sizes, activation functions, optimizers, loss functions, batch sizes, dropout, number of training iterations, and different seeds for the initialization.

In our final experiments, we evaluated four different embeddings: pre-trained fastText embeddings (Bojanowski et al., 2017) on the entire Wikipedia corpus, two word embeddings with different dimensionality trained on the task’s dataset with the word2vec (Mikolov et al., 2013) skip-gram model implemented in gensim (Řehůřek and Sojka, 2010), and a fourth embedding based on the task’s vocabulary and corresponding Wikipedia articles.

We benchmarked each trained model on the development set. This yielded thousands of trained models. Ultimately, we selected a deep learning architecture with high accuracy scores and a low

variance, as outlined below. Our motivation was to select a model that we believed to be stable and able to generalize well on the test set.

2.1 Architecture

We now outline our deep learning architecture, as visualized in Figure 2. We use warrants, reasons, claims, and alternative warrants as input channels of our neural network. The preprocessing for each channel consists of tokenization, padding, and word embeddings as representations for individual words, as it is common for recurrent neural networks in NLP. First, each input sequence is fed into a bidirectional LSTM (Schuster and Paliwal, 1997; Graves and Schmidhuber, 2005). In the next layer, we use two parallel LSTMs (Hochreiter and Schmidhuber, 1997). The first LSTM uses a concatenation of the warrant, the reason, and the claim as the input, whereas the concatenation of the alternative warrant, reason, and claim is used as the input of the other LSTM. The output of both LSTMs is then concatenated, dropout is applied, and finally mapped as output through two dense layers.

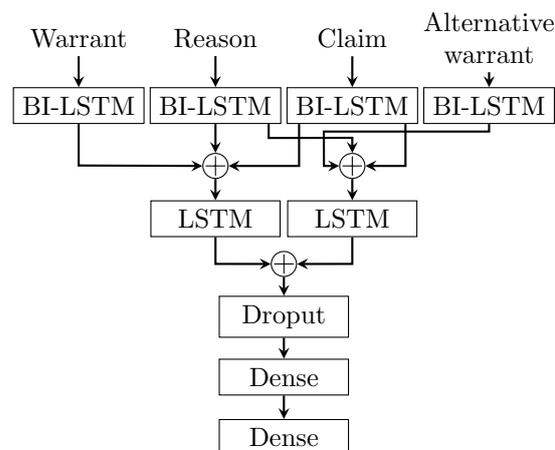

Figure 2: Illustration of our deep learning architecture.

In our experiments, we benchmarked our model with 10 different seeds and achieved an average accuracy of 67.7% ($\pm 2.2\%$) on the development set.

2.2 Ensemble

We experimented with additional ways of increasing our performance on the development set under the assumption that the test set would be very similar. By using an ensemble of multiple trained models with a majority vote as the prediction, we were

able to improve our results considerably. First, we trained 2560 models of the above-described architecture with four different embeddings and various hyperparameters. Then, we combined all 623 of these models with a development set accuracy of above 67% into our final ensemble. Our ensemble yielded a promising result of 73.3% accuracy on the development set, which is a higher accuracy than all submitted and benchmarked systems in the trial phase of the challenge. Therefore, we decided to use the ensemble for our predictions instead of a single model.

3 Results

We now report the official results of our ensemble on the test set, as well as benchmarks of the single models. Additionally, we compare our deep learning approaches with a support vector machine as a classical machine learning baseline.

3.1 Deep Learning

Our ensemble achieved 17th place in the competition and yielded an accuracy score of 53.4%, which was lower than we anticipated based on our good performance on the development set.

Since we were curious to see whether the decision to use an ensemble was beneficial and in order to better understand the low results on the test set, we further analyzed all trained models on the test set after the release of the gold labels. The performance difference in terms of accuracy scores on the development set and the test set of all 2560 models that we considered for the ensemble is visualized in Figure 3. It can immediately be seen that all our models achieved better scores on the development set than on the test set and that some hyperparameters lead to models yielding bad performances. The most interesting insight from this plot is that the majority of our single models performed better than the ensemble score of 53.4%. Upon further analysis of the 623 models with a development set accuracy of above 67% that we used for our ensemble, we can observe an average accuracy score of 54.4% ($\pm 2.0\%$) on the test set. This also shows that the decision to opt for an ensemble was disadvantageous, since the ensemble was not able to generalize better than individual models.

The influence of the number of selected models from the 2560 available models is further visualized in Figure 4a, where the models were be-

ing added in descending order based on the development set performance. In our submission, we decided to use the 623 best-ranked models with a majority voting. Figure 4a shows that an ensemble with a considerably smaller number of models would have performed better on both sets, as the test scores with the majority voting began to deteriorate quickly.

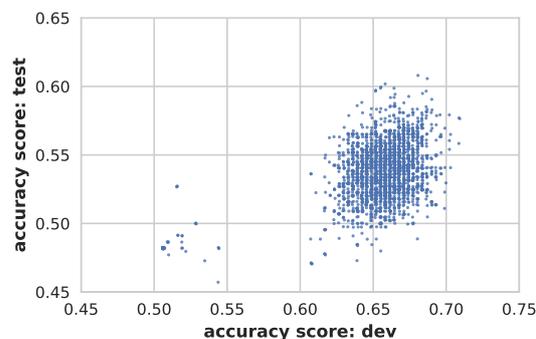

Figure 3: Performances of 2560 trained models with different hyperparameters on the development set and the test set

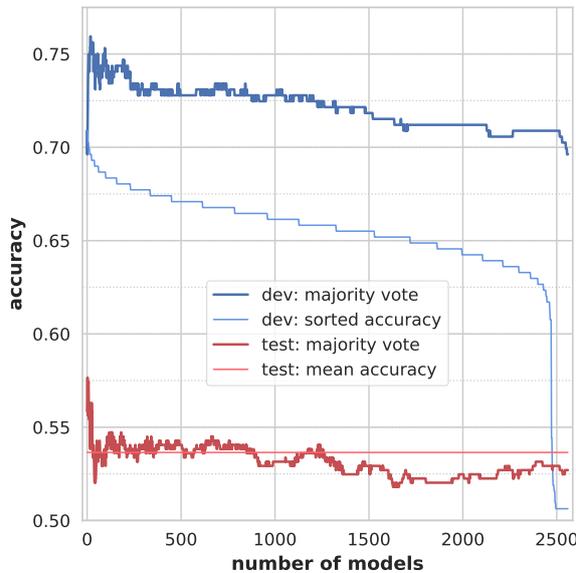

3.2 Support Vector Machine Baseline

Furthermore, we compared our deep learning approaches with a support vector machine (SVM). We used the same input data for the SVM as for our neural networks by using claims, reasons, warrants, and alternative warrants. All four input strings were tokenized, padded to a fixed length, represented by embedding vectors, and concatenated to achieve a fixed input length for the SVM.

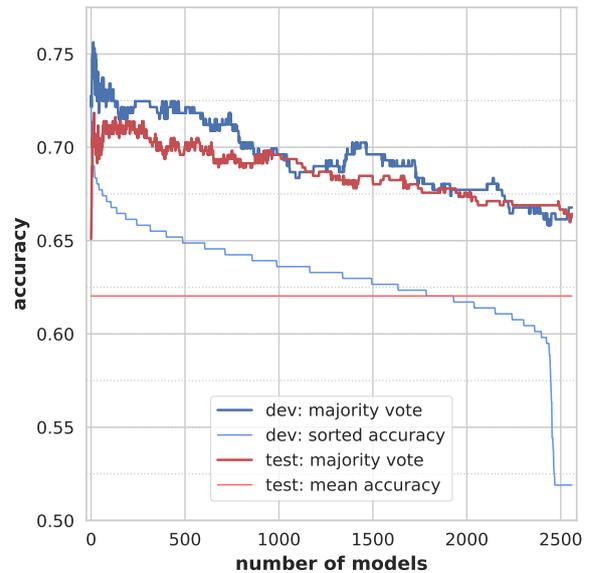

In total, we trained 72 SVMs with different hyperparameters. Their performances on both sets are visualized in Figure 5. Compared with our deep learning approach, the results of the SVMs on the development set are lower, with an average score of 58.8% ($\pm 2.8\%$), but comparable for the test set, with 53.6% ($\pm 2.3\%$). Again, we observed lower accuracies for the test set than for the development set.

4 Observations of an Alternative Data Split

The performance difference on both sets motivated us repeat our experiments on an alternative data split, in which we shuffled all data points together and created three new sets (training, development, and test) with the same sizes as the original split.

(a) Original dataset

(b) Ensemble experiment with our alternative data split

Figure 4: Influence of the number of models in our ensemble.

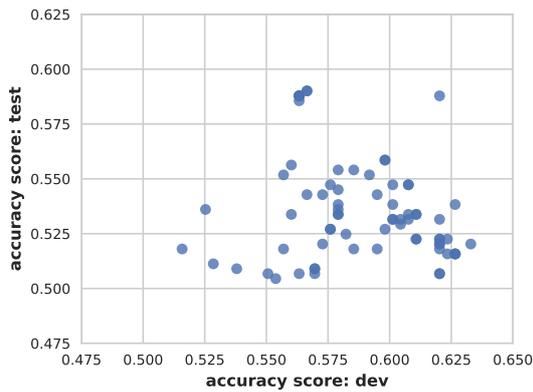

Figure 5: Performances of support vector machines on the development set and the test set.

4.1 Single Model

On the alternative split, we benchmarked our single model with 20 different seeds and achieved higher results of 63.7% ($\pm 1.6\%$) on the dev set and 62.1% ($\pm 2.5\%$) on the test set.

4.2 Ensemble

For the ensemble, we trained 2560 models with the same hyperparameters as for the original dataset. The models behaved more similarly on both the alternative development set (63% ($\pm 3.0\%$)) and the test set (62% ($\pm 4.1\%$)), as visualized in Figure 6. If we take a look at the performance of the ensemble's majority vote in Figure 4b and compare it with the original dataset in Figure 4a, we can see

that the idea of using an ensemble can be beneficial. However, this is dependent on a more evenly represented data split. In hindsight - with posterior knowledge of the test set - it would have been a better choice to decide for the ensemble's peak performance (original split dev: 76%, test: 55.6%; alternative split dev: 75.6%, test: 71.3%).

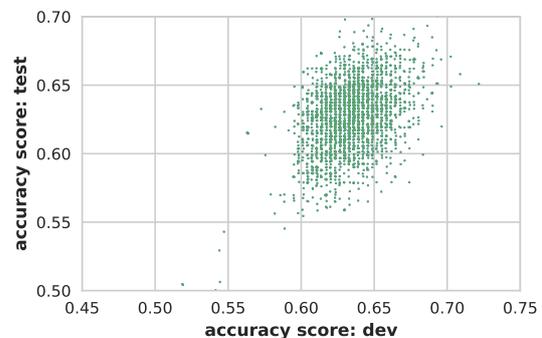

Figure 6: Performances of 2560 trained models with different hyperparameters on the alternative data split.

4.3 Support Vector Machine

We again trained 72 SVMs with different hyperparameters. With the alternative split, we achieved an average score of 55.5% ($\pm 2.3\%$) on the new dev set and 57.7% ($\pm 2.1\%$) on the new test set. Compared with our neural network, the SVM approach now performs worse.

5 Conclusion

For our participation in *The Argument Reasoning Comprehension Task*, we benchmarked several deep learning approaches with different layers, embeddings, and hyperparameters. For our final submission, we decided to use an ensemble comprising 623 models with a majority voting that performed much better on the development set than a single model.

Unfortunately, our ensemble underperformed on the test set. Therefore, we extensively analyzed our ensemble approach after the release of the gold labels. We ascertained that the use of an ensemble was a suboptimal choice, and the predictions of most single models would have performed better and that the choices of hyperparameters and seeds influenced the stability of the predictions, as illustrated in Figure 3.

We compared our deep learning approach with a support vector machine as a baseline. Although our models and our ensemble performed much better on the development set, the SVM produced slightly better results on the test set.

Finally, we repeated our experiments on an alternative data split and achieved more stable results. Therefore, we conclude that the test set comprises data points with characteristics that are not present in the original training data.

Because we - and other task participants with deep learning approaches - had trouble providing a satisfying solution to the task, we also believe that additional preprocessing steps are required for a machine learning approach, since the warrants and alternative warrants are so lexically similar.

Abstract

This paper describes the system submitted to SemEval-2018 Task 12 (The Argument Reasoning Comprehension Task). Enabling a computer to understand a text so that it can answer comprehension questions is still a challenging goal of NLP. We propose a Bidirectional LSTM (BiLSTM) model that reads two sentences separated by a delimiter to determine which warrant is correct. We extend this model with a neural attention mechanism that encourages the model to make reasoning over the given claims and reasons. Officially released results show that our system ranks 6th among 22 submissions to this task.

1 Introduction

Machine comprehension of text is an important problem in natural language processing. Traditional approaches to machine comprehension are based on either hand engineered grammars (Riloff and Thelen, 2000), or information extraction methods (Poon et al., 2010).

Recently, recurrent neural networks (RNNs) with long short-term memory (LSTM) cells (Hochreiter and Schmidhuber, 1997) have been successfully applied to a wide range of NLP tasks, such as machine translation (Sutskever et al., 2014), constituency parsing (Vinyals et al., 2015), language modeling (Zaremba et al., 2014) and machine comprehension (Hermann et al., 2015). A potential issue with the LSTM models is that a neural network needs to be able to compress all the necessary information of a source sentence into a fixed-length vector (Bahdanau et al., 2014). This may make it difficult for the neural network to cope with long sentences. In order to address this issue, attention mechanisms have been successfully extended to the LSTMs. Attentive Reader (Hermann et al., 2015) used a *tanh* layer to compute the attention between document and question

embeddings. This allows a model to focus on the aspects of a document that it believes helpful to answer a question. The attention-based LSTM models have achieved state-of-the-art results in machine comprehension tasks (Kadlec et al., 2016; Chen et al., 2016; Tseng et al., 2016).

The argument reasoning comprehension task has been presented by (Habernal et al., 2018). The problem can be described as follows: Given an argument consisting of a claim and a reason, the goal is to select the correct warrant that explains reasoning of this particular argument. Compared to traditional machine comprehension task, argument reasoning comprehension requires models to possess extra reasoning abilities. Some models increase the depth of the network, continuously updating the representations of the documents and questions to realize the reasoning process (Sukhbaatar et al., 2015; Tseng et al., 2016; Dhingra et al., 2017; Sordoni et al., 2016).

In this paper, we use a BiLSTM model to encode the reason and claim pairs (reason-claim) and warrants. Then a word-to-sentence neural attention mechanism is implemented to improve the model performance.

The rest of the paper is organized as follows: Section 2 provides the details of the proposed model; Experimental settings and results are discussed in section 3. Finally, we draw conclusions in section 4.

2 System Description

Firstly, we concatenate the reason-claim and warrants with a delimiter, then we encode the reason-claim via a BiLSTM. A second BiLSTM with different parameters is used to encode the delimiter and the warrants, but its memory state is initialized with the last cell state of the previous BiLSTM. The attention mechanism is implemented by the

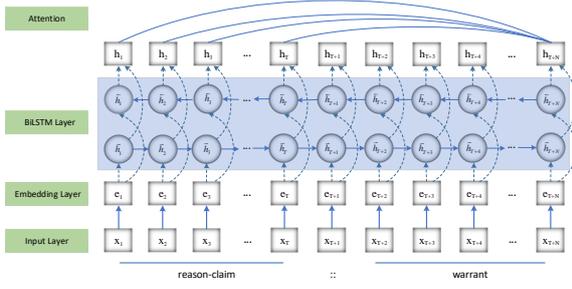

Figure 1: Our BiLSTM model with neural attention for argument reasoning comprehension, basically follows the attention model described in (Rocktäschel et al., 2015).

last output vector of the second BiLSTM and the output vector at each time step produced by the first BiLSTM. Then we use a \tanh activation to obtain the final representation. Finally, we predict the correct label via a fully connected layer and a softmax activation.

2.1 LSTM & BiLSTM

Recurrent Neural Networks (RNNs) have been widely exploited to deal with variable-length sequence input. RNNs are networks with loops in them, allowing information to persist. A potential issue of RNNs is that they become unable to learn to connect the previous information when the length of the document grows. LSTM (Hochreiter and Schmidhuber, 1997) is one of the popular variations of RNN to mitigate the gradient vanish problem. LSTMs have three gates: input gate, forget gate and output gate. Gates are a way to optionally let information through. With these gates, LSTMs can remember information for long periods of time and avoid the long-term dependency problem. Given an input vector x_t at time step t , the previous output h_{t-1} and cell state c_{t-1} , an LSTM with hidden state size k computes the next output h_t and new cell state c_t as:

$$H = \begin{bmatrix} x_t \\ h_{t-1} \end{bmatrix} \quad (1)$$

$$i_t = \sigma(W_i H + b_i) \quad (2)$$

$$f_t = \sigma(W_f H + b_f) \quad (3)$$

$$o_t = \sigma(W_o H + b_o) \quad (4)$$

$$c_t = f_t \odot c_{t-1} + i_t \odot \tanh(W_c H + b_c) \quad (5)$$

$$h_t = o_t \odot \tanh(c_t) \quad (6)$$

where W_i, W_f, W_o, W_c are trained matrices, b_i, b_f, b_o, b_c are trained biases, σ and \odot denote the

sigmoid function and the element-wise multiplication of two vectors, respectively.

Single direction LSTM has one drawback of not using the contextual information from the future tokens. BiLSTM exploits both the previous and future context by processing the sequence on two directions and generates two independent sequences of LSTM output vectors. One processes the input sequence in the forward direction, while the other processes the input in the backward direction. The output at each time step is the concatenation of the two output vectors from both directions, i.e. $h_t = \vec{h}_t \parallel \overleftarrow{h}_t$.

2.2 Attention

The LSTM model can alleviate the problem of gradient vanishing, but this problem persists in long range contexts. The attention mechanism is introduced to address this issue. Attention is the idea of freeing the encoder-decoder architecture from the fixed-length internal representation. This is achieved by keeping the intermediate outputs from the encoder LSTM and training the model to learn to pay selective attention to these inputs and relate them to items in the output sequence. These attention-based models have achieved state-of-the-art performance on many natural language processing tasks.

Let $C \in \mathbb{R}^{k \times T}$ be a matrix consisting of output vectors $[h_1, h_2, \dots, h_T]$ produced by the first BiLSTM when reading the T words of the reason-claim, where k is a hyperparameter denoting the hidden units of LSTM. Moreover, let h_{T+N} be the last output vector after the reason-claim and warrant are processed by the two BiLSTMs, respectively. The attention mechanism will produce a vector of attention weights and a weighted representation r of the reason-claim via:

$$M = \tanh(W_c + W_h h_{T+N} \otimes e_T) \quad (7)$$

$$\alpha = \text{softmax}(W_m M) \quad (8)$$

$$r = C\alpha \quad (9)$$

where e_T is a vector of ones, $W_c, W_h \in \mathbb{R}^{k \times k}$ are trained projection matrices. $W_m \in \mathbb{R}^k$ is a trained parameter vector. The final sentence-pair representation is obtained from a non-linear combination of the attention-weighted representation r of the reason-claim and the last output vector

h_{T+N} using

$$h^* = \tanh(W_i r + W_j h_{T+N}) \quad (10)$$

where $W_i, W_j \in \mathbb{R}^{k \times k}$ are trained projection matrices.

3 Experiments

The organizers provided training, development, and test sets, containing 1210, 316, 444 instances, respectively. We combine the reason and claim to one sentence which can determine if the warrant is correct or not. The word tokenizer we adopted is *TweetTokenizer* in Natural Language Toolkit (NLTK¹).

We compare two word embedding tools, Word2Vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014). Out-of-vocabulary words in the data sets are randomly initialized by sampling values uniformly from (-0.25, 0.25) and optimized during training. We set *epoch* = 10, *batchsize* = 256 and *LSTMUnits* = 64. Optimization is carried out using Adaptive Moment Estimation (Adam). All models are attention-based LSTM or BiLSTM architecture.

Model	Tool	Dev Acc	Test Acc
LSTM	Word2Vec	0.626	0.577
LSTM	GloVe	0.646	0.567

Table 1: Comparison between Word2Vec and GloVe. GloVe performs better on dev data set, but Word2Vec outperforms GloVe on test data set.

We additionally try bidirectional LSTMs through experiments. Given the small scale of the data sets, we run each model 10 times, taking their average as the final result. We also use data augmentation such as shuffle the sentence order to expand the data set. Specifically, we randomize the word order of the reason-claims and the warrants to double the data set. A *random.seed* is set to ensure our results are reproducible.

Model	Dev Acc	Test Acc
BiLSTM	0.690	0.583
BiLSTM+Shuffle	0.642	0.570

Table 2: Performance on models with or without shuffle. Both models are based on attention-based BiLSTM + GloVe architecture.

The results show that data augmentation like shuffling the sentence order does not have much

¹<http://www.nltk.org/>

effect on the performance of our models. So, we use the attention-based BiLSTM model as our final system to the task. Our final result on the test set is 0.583, which ranks 6th according to the official ranking.

4 Conclusion and Future Work

In this paper, we present a BiLSTM model for argument reasoning comprehension. We adopt a word-to-sentence attention mechanism to make model perform better. In the future, we will utilize external knowledge to enhance the reasoning ability of our models. We will also pay more attention to the generalization of models on small data sets.

Abstract

This paper describes a warrant classification system for SemEval 2018 Task 12, that attempts to learn semantic representations of reasons, claims and warrants. The system consists of 3 stacked LSTMs: one for the reason, one for the claim, and one shared Siamese Network for the 2 candidate warrants. Our main contribution is to force the embeddings into a shared feature space using vector operations, semantic similarity classification, Siamese networks, and multi-task learning. In doing so, we learn a form of generative implication, in encoding implication interrelationships between reasons, claims, and the associated correct and incorrect warrants. We augment the limited data in the task further by utilizing WordNet synonym “fuzzing”. When applied to SemEval 2018 Task 12, our system performs well on the development data, and officially ranked 8th among 21 teams.

1 Introduction

This paper describes our system for the *Argument Reasoning Comprehension Task of SemEval 2018* (Habernal et al., 2018). The main goal of our system is to learn semantic representations of reasons, claims and warrants upon which vector operations can be applied which encode their interrelationships, whilst sharing encodings.

We train our system over the 1274 candidate reason, claim, first and second warrant examples from the edited *Room for Debate* New York Times dataset provided by the task organizers (Habernal et al., 2018), which we augment to generate a dataset that is used with a multi-task based objective function to learn semantically meaningful representations.

Our system combines these vectors to make a determination, via vector operations and semantic

similarity classification, to determine which of the two warrants best fits the reason and claim representations, and best encodes the relationships between them. We replicate this for each sentence type, and mirror it for each warrant. In doing so we were able to achieve strong results on the development set, and ranked 8th overall in the competition.

2 Approach

2.1 Model Overview

As detailed in Figure 1, our system is made up of 3 stacked LSTMs, with one being essentially a Siamese network shared between the two warrants, and the other two encoding the reason and the claim. We take an average pool over the top-layer hidden representations and use them as the semantic feature vectors for each respective sentence. We take these semantic vectors and apply vector operations to them to generate embeddings for each reason, claim and warrant, which we found in practice to perform well. We then do semantic comparisons between the generated and actual encodings, marking as the same those between generated and actual encodings that include the correct warrant (i.e. correct interrelationships) and not the same for those that do not (through a logistic unit). We also do a joint loss on both warrant’s logistic output with a softmax to the ground truth (same/not same), and use that as our tracking metric during training.

We tokenize each sentence using Keras (Chollet, 2018) and utilize an embedding layer based on the GloVe 300-dimensional, 840 billion token, uncased word embeddings (Pennington et al., 2014). We then push these through three stacked LSTM networks (Hochreiter and Schmidhuber, 1997) — one each for the reasons, claims and warrants —

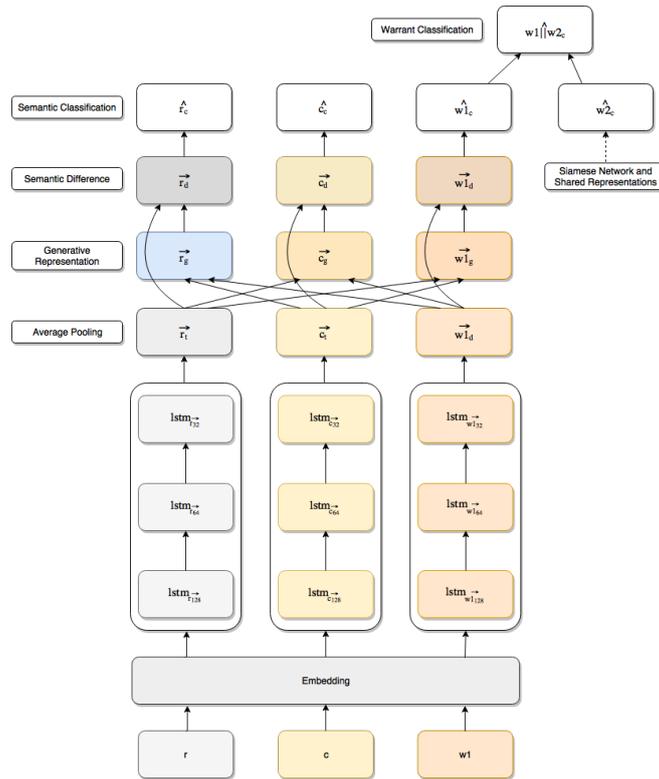

Figure 1: An overview of our model.

to generate the pooled semantic feature vectors of each phrase. Each stacked LSTM network is comprised of three layers, of 128, 64 and 32 nodes, respectively. We do this to force compression and to avoid overfitting on the dataset.

We take the final 32-dimensional embedding of each reason, claim and warrant, and apply average pooling over time to create robust compressed representations of each.

We take these representations and then perform various vector operations (addition/subtraction) between them. We use these operations as a form of implication to generate a warrant using the reason and claim representations. The generation operation does not necessarily require vector additivity (e.g. operations need not be constrained across tasks). For example the operation to learn the generative representation from a reason and a claim to a warrant can be a simple addition/subtraction, or an affine transformation, or in future scenarios it can be even more complicated dense networks.

For example given a reason and a claim, we wish to combine them together with an operation that creates a generative representation of a warrant (simple vector operations for example), and

accordingly generate a representation using the operation $\vec{r}_t - \vec{c}_t = \vec{w}_g$ (where the t subscript entails the true representation, and the g the generated one). We then set up our loss function such that we compare the absolute semantic difference between the true generative encoding (generated with the correct two representations) with that of a query encoding and compare them to determine whether or not they are the same (i.e. the correct or incorrect warrant vs. the true generative representation).

We additionally embed both the correct and incorrect warrant for each example, and use these representations to drive multi-task learning using a Siamese network (as each reason, claim and warrant are compared to their true generative representations with only correct triplet combinations being classified as being the same). We use Siamese networks as they have been shown to work well in settings where semantic text document comparisons are involved (Mueller and Thyagarajan, 2016).

Our objective function is intended to minimize the difference between generative and actual warrant representations, and maximize the difference between generative and incorrect warrant repre-

sentations. We do this via analogy to both DeepFace’s semantic similarity classification (Taigman et al., 2014) and FaceNet’s anchor representations (Schroff et al., 2015): for the similarity classification we use a logistic regression atop the absolute difference between the generative and the actual representations for the multiple tasks (same/not same), and we combine a joint softmax discriminative function that selects between the candidate warrants on that output, $\overline{w1\|w2_c}$, as our tracking objective (for early stopping and checkpointing). In doing so we aim to push the generative and true representations closer together, and push the generative and incorrect representations further apart. In this process we should then be able to perform Generative Implication, where the semantic representations across implication tasks can be shared, but where differing operations between the representations can be used to generate each other.

Due to the small data size (~1k), we explored a variety of approaches to augment the training data. One approach is to use multiple implication tasks to generate representations. Our tasks use the two warrants and reason + conclusion to generate representations of each other. We tried multiple operations including affine transforms and dense networks, as well as vector additivity constraints across tasks (i.e. the projection operations from the shared embeddings must reconcile, cf. Mikolov et al. (2013)). However we found that they led to overfitting, and hence sought to split the implication projection from the shared representations into unconstrained operations (two of which are vector additive, \vec{r}_g and \vec{c}_g , with \vec{w}_g being split off, with the split likely acting as a regularizer):

$$\begin{aligned}\vec{r}_g &= \vec{c}_t - \vec{w}_t \\ \vec{w}_g &= \vec{r}_t - \vec{c}_t \\ \vec{c}_g &= \vec{r}_t + \vec{w}_t\end{aligned}$$

From this, we have a multi-task output with the generative representation of correct/incorrect warrants being compared to their semantic representations, correct with the true warrant, and incorrect with the wrong warrant.

We also augmented the data by taking random combinations of single synonym fuzzed WordNet (Miller, 1995) sentences using their sampled closest synonyms (using the NLTK toolkit (Bird et al., 2009) and pywds (Tan, 2014)). Through this

method we generated a much larger dataset (~20×, depending on how many synonyms we could sample per sentence). We also swapped the warrants to double the size of the dataset. In doing so we ended up with ~234K examples. We did this to ensure a large enough dataset that included numerous subtleties.

2.2 Training

2.2.1 Optimization and Regularisation

We used heavy dropout (Srivastava et al., 2014), as we found overfitting to be an endemic problem, requiring heavy regularization. Along with the layers being smaller as we go up the stack, we applied progressively reduced dropout rates, from 0.8 at the 128 layer, to 0.6 (64) and 0.4 (32). We found this led to better generalization on the development set. We use Adam as our optimizer (Kingma and Ba, 2014), and checkpointing (with an accuracy max of the joint softmax with $\overline{w1\|w2_c}$) and early stopping (Caruana et al., 2001). We trained our models using 3–10 epochs, depending on when they began to overfit.

3 Results

We ranked 8th in the competition (among 21 teams) with a test accuracy of 0.577. Amongst the teams there was a clear outlier in the GIST system (which we note used transfer learning), with the remaining systems incrementally falling from ~0.6 downwards, with the random baseline at 0.527, and the example test system at 0.56 (Haber et al., 2018).

In terms of the different systems we trained, our top three would have ranked 4th in the competition, two of which used more aggressive dropout, and one of which used a combination of features identified above (including attention between the other two sentences). The development to test set gap was wide, indicating generalization was extremely hard (similarly with others in the competition). In terms of performance, we found early on that constrained (i.e. vector additive operations) led to lower development performance, which continued on to the test set. With the remaining systems we used the operations as defined previously (unconstrained). In general we found that regularization dominates performance measures, above and beyond operations.

System	Development	Test
Higher Starting Dropout (0.9)	0.658	0.597
Lower Dropout Reduction Between LSTM Layers (0.1)	0.658	0.592
Combination	0.668	0.592
Equal Dropout on each LSTM Layer (0.5)	0.646	0.583
Extra Layer (4 Layer, 256 Base Latent LSTM)	0.652	0.579
Test System	0.671	0.577
Attention (with Double Batch Size for speed)	0.639	0.574
Test System (Constrained)	0.665	0.568
Large Batch Size (1024 minibatch)	0.617	0.538
Noise Semantic Output Layers (Gaussian)	0.627	0.527

Table 1: Accuracy over the development and test sets for various system configuration and our official submission (“Test System”), sorted by test set accuracy. “Combination” = attention, equal dropout, 4-Layer, noise semantic layer (with double batch size for speed)

4 Discussion

A few things helped performance (specifically generalization): (1) average pooling, most likely by making the overall meaning of the sentence more stable; (2) WordNet fuzzing and the resultant data augmentation; (3) progressively reduced dropout; (4) adding layers somewhat improved performance; (5) using progressively smaller LSTM layers; (6) using uncased, larger token size GloVe vectors, likely due to the larger coverage and more specific embeddings; and (7) multi-task learning.

We did not find that using dense networks for generative semantic operations worked well, as overfitting was endemic. We tried to enforce constrained vector additivity between tasks, but found that this harmed performance, and instead we took the path of multiple unconstrained tasks projected from the shared embeddings. In future, these operations should be fully-fledged generative functions, to account for the inherent complexity of the task itself. Adding noise to the embeddings (e.g. Gaussian) as a form of data augmentation also did not aid performance. Larger batches in general did speed up training, but in general harmed overall performance. We experimented with L1/L2 regularization, but found dropout to be far more robust. We attempted shared LSTM layers (between reason, claim, warrants), but again, found it be to detrimental. We tried BiLSTMs (which did not improve performance), and GRUs (which took longer to train with comparable performance). We also tried attention (e.g. a warrant on its respective reason and claim), but this too did not improve performance.

4.1 Future Directions

There are numerous future directions from this work, mostly in the integration of transfer learning, more complicated generation functions, and low resource learning. As we found overfitting to be an endemic problem across approaches, we believe that aggressive use of transfer learning of higher-level concepts from parallel domains will likely be of use. The operations for the different tasks were originally trained to be vector additive, but we found in practice that they harmed performance. Instead, complex embedding generation will almost certainly require more complex operations than the simple ones we found to work well in this work. This opens up new directions in terms of classification and text generation within argument mining, such as the generation of implicit warrants between reasons and claims, or the detection of reasoning triplets for dataset generation. We also believe aggressive use of low resource (e.g. few-shot) learning mechanisms will be beneficial in the future.

5 Conclusion

In this paper we demonstrated a system that attempts to learn a form of generative implication from sets of reasons, claims and warrants. There was a large generalization gap between the development and test test results for both of the tested systems, as well as the competition as a whole, which highlights how large an issue overfitting is for problems based on small datasets. We demonstrated our tested models’ performance on both the development and test sets, with our final submission coming in 8th (among 21).

Abstract

This paper describes a classification system that participated in the SemEval-2018 Task 12: The Argument Reasoning Comprehension Task. Briefly the task can be described as that a natural language “argument” is what we have, with reason, claim, and correct and incorrect warrants, and we need to choose the correct warrant. In order to make fully understand of the semantic information of the sentences, we proposed a neural network architecture with attention mechanism to achieve this goal. Besides we try to introduce keywords into the model to improve accuracy. Finally the proposed system achieved 5th place among 22 participating systems.

1 Introduction

In recent years, as an extremely important part of argument mining, argument reasoning has received considerable research. The argumentation reasoning can be used in many situations such as automatic score, policy decision, stance detection, and many others (Habernal et al., 2018). The task can be described as follows in detail: Given an argument consisting of a claim and a reason, the goal is to select the correct warrant that explains reasoning of this particular argument. There are only two warrants given and only one answer is correct. The correct warrant inferred from the argument has a supported relation with the argument. However the other warrant either opposes the argument or has no correlation with the argument. Actually, this task could be treated as a binary classification (A vs. B).

The task could be regarded as an argumentative relation work. The argumentative relation mining aims at identifying relations of attack and support between natural language arguments in text, by classifying pairs of pieces of text as attack, support or neither attack nor support relations (Cocarascu and Toni, 2017). The corrected warrant means supporting the argument, while the other means attacking the argument. So we refer to some literature methods on

the relationship between arguments. Cocarascu and Toni (2017) use Long Short Term Memory (LSTM) to classify the relations between arguments. Rocktäschel et al. (2016) propose neural network with attention mechanism, making neural networks interpretable. We infer to their methods and construct our model in new manner. In this paper, we use the LSTM networks with attention mechanism to construct the classification system.

The following sections are arranged as follows. In section 2, we will give an overview on the task and have an analysis of the datasets. In section 3 we describe the system used in this paper and introduce some interesting attempt in detail. Section 4 introduces the experiment and results. Finally, we get conclusions and have an outlook of the future work.

2 Task Definition

We use the corpus provided by the SemEval-2018 Task 12, which has a training corpus of 2420 samples with gold labels. The organization website also provides a corpus of 316 samples with gold labels as verification set. And finally about 444 samples without gold labels are provided by the organization website as the final test corpus. This data has a variety of contemporary issues across topics in user-generated web comments (Habernal et al., 2018).

For example:

Topic: There She Is, Miss America

Additional info: In 1968, feminists gathered in Atlantic City to protest the Miss America pageant, calling it racist and sexist. Is this beauty contest bad for women?

Argument: Miss America gives honors and education scholarships. And since ..., Miss America is good for women.

Warrant options:

- a) scholarships would give women a chance to study
- b) scholarships would take women from the home

Only (a) fills the gap in this argument; (b) would in fact lead to the opposite claim (such that Miss America is not good for women).

Observing the data, we find this task has some challenges. We notice that many warrants have high

* Corresponding author.

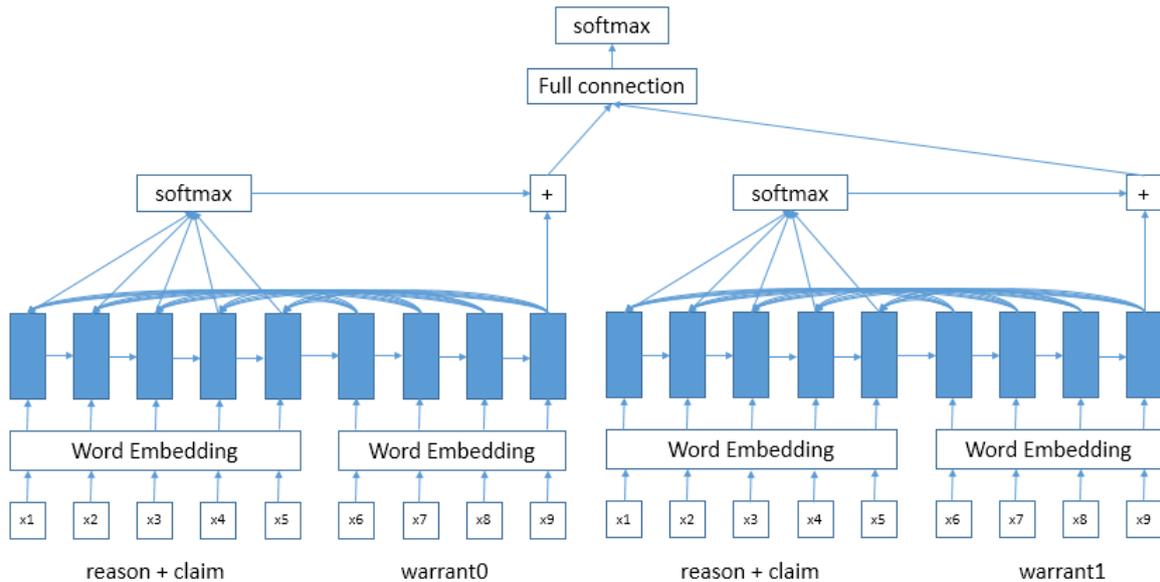

Figure 1: The system architecture - LSTM model with word-by-word attention mechanism.

semantic similarity, which makes it difficult to have a correct choice. In order to distinguish the similar sentences, the model must have the ability to model sentence semantics well. Besides, we find that many pairs of warrants' difference is the negative words. For example, consider the following warrant options from the training corpus. One warrant is “we can't have citizens being loyal to their home country”, the other is “we can have citizens being loyal to their home country”. The difference of them is the first one has the negative word “n't”, which makes the sentences have different semantics. Every sentence has keywords which make a contribution to understand the sentence. We hope that putting the keywords extracted from the sentence into the model could enhance the comprehension of the sentences. We have a try with all these ideas.

3 System description

Our system is based on the LSTM model with word-by-word attention which could be seen as an encoder to decoder model. The encoder encodes the reason and claim and gives the initialization to the decoder. The decoder decodes the warrant and uses its output to compute the weight of tokens from the reason and claim. The higher the weight is, the more important the token is to choose the correct warrant. Besides, we introduce the keywords into the model to improve the accuracy.

3.1 Sequence model

In order to have a full understanding of the sentences, we try to use the neural network to model the sentences. The LSTM model could capture long-term dependencies (Hochreiter and Schmidhuber, 1997) so we use

that to construct the sequence model.

LSTM models, a type of RNNs, address the problem of the vanishing gradients problem while trying to capture long-term dependencies by introducing memory cells and gates into networks (Cocarascu and Toni, 2017). Although the LSTM models could solve the problem of the long-term dependencies, it usually captures the words behind the sentence, which causes a problem that the words before the sentence make a little contribution. In order to achieve full comprehension of the sentences, an attention mechanism is introduced into the model. The attention mechanism has been demonstrated success in a wide range of tasks from handwriting synthesis (Graves, 2013), machine translation (Bahdanau et al., 2015) and sentence summarization (Rush et al., 2015). In view of the effectiveness of the attention mechanism, we combine it with the LSTM model expecting a great performance.

Based on the statistics on sentence lengths in training corpus, we set the length of the reason, claim, warrant to 50, 15, 30 respectively. In this paper, we propose three deep learning methods to represent the sentences. The first is that we use BiLSTMs to parse the semantics of the sentences and then merge their output of the BiLSTMs. The concatenated vector is fed into a fully-connected neural network whose output is concatenated with the softmax function to have a prediction. The detailed computation is described in (1-5). The R_i , C_i , $W0_i$ and $W1_i$ are the embedding presentations of the reason, claim, warrant0 and warrant1 respectively and the R_o , C_o , $W0_o$ and $W1_o$ are the outputs of the BiLSTMs. V is the vector connecting

them. This model is the baseline of our paper.

$$R_o = BiLSTM_s(R_i) \quad (1)$$

$$C_o = BiLSTM_s(C_i) \quad (2)$$

$$W0_o = BiLSTM_s(W0_i) \quad (3)$$

$$W1_o = BiLSTM_s(W1_i) \quad (4)$$

$$V = [R_o; C_o; W0_o; W1_o] \quad (5)$$

The second and the third method refer to the methods (Rocktäschel et al., 2016) where the author proposed LSTM with attention and word-by-word attention mechanism to solve the problem of reasoning about entailment and achieved the state-of-the-art results. We refer to their model to construct our model. The second and the third method are called LSTM model with attention and LSTM model with word-by-word attention. From the figure 1, there is the LSTM with attention and word-by-word attention mechanism. The two methods see reason and claim as the part of encoder, which gives the initial weight to the warrant and treats the warrant as decoder. The difference between them is that attention is only based on the last output vector of warrant, while the word-by-word attention is based on all output vectors of warrant.

$$Y = BiLSTM_s(R_i; C_i) \quad (6)$$

$$H = BiLSTM_s(W_i) \quad (7)$$

$$M_t = \tanh(W^y Y + (w^h h_t + W^r r_{t-1}) \otimes e_L) \quad (8)$$

$$\alpha_t = \text{softmax}(w^T M_t) \quad (9)$$

$$r_t = Y \alpha_t^T + \tanh(W^t r_{t-1}) \quad (10)$$

$$h^* = \tanh(W^p r_N + W^x h_N) \quad (11)$$

Equation (6-11) provide the details about the computation on word-by-word attention. Y is the output vector of the encoder whose input is embedding representation of reason and claim. H is the output of the decoder with the embedding representation of warrant. h_t is the state of H at time t . We use h_t to compute the weight of the token from reason and claim at every time. Then we can get the weight matrix which means how important the token is for the decoder at every time. The weight matrix of attention is one dimension while the word-by-word attention has n dimensions. So the computation of the attention is simple and the same as the word-by-word attention. The two warrants with the reason and claim are used to construct the word-by-word attention respectively. Then the outputs of them are merged by concatenation and are put into a fully-connected neural network to make a prediction.

3.2 Keywords

We expect that introducing the keywords into the model could improve the accuracy. The sequence model can only express the basic meaning of the sentence and can't grab the main part. So the keywords can semantically enhance the sentence meaning. Based on that, we carry out the keywords extraction using

text rank algorithm based on the graph. The specific method is described in the paper (Mihalcea and Tarau, 2004). For getting the keywords, we let $G=(V,E)$ be a undirected graph with the set of vertices V and set of edges E where V is the token corpus and E is the weight between two tokens. The formula could be calculated according to the following equation (12) where the $S(V_i)$ is the score of the vertex V_i , the w is the edges and d is a damping factor that is usually set to 0.85. $Out(V_j)$ and $In(V_i)$ are the adjacent vertices of V_i in undirected graph. Based on the scores we could get the keywords from the sentence. The higher the score is, the more important the word is.

$$S(V_i) = (1-d) + d * \sum_{v_j \in In(V_i)} \frac{w_{ij}}{\sum_{v_k \in Out(V_j)} w_{jk}} S(V_j) \quad (12)$$

According to observing the keywords from the two warrants, we find that some pairs of warrants have the same keywords but different negative word. So we do statistics on negative words. If the number of the negative words is odd, we will add a negative word such as "not" into the keyword corpus. However, if the number of the negative words is even, we won't add any negative word into the keyword corpus. We expect to make a difference between the two warrants with the same keywords. We use the bag-of-word model to model the corpus of the keywords. Every keywords are put into the pre-trained embedding layer to get the word representation. In order to ignore the difference in the number of keywords, we adopt the average operation. The computation is introduced in equation (13-16) where r_i , c_i , $w0_i$ and $w1_i$ are the word representations of reason, claim, warrant0 and warrant1 generated from the Glove vectors (Pennington et al., 2014). The output I_i is then put into a fully-connected neural network to make a classification decision.

$$R_{ave} = \frac{1}{len(R)} \sum_{i=1}^{len(R)} r_i \quad (13)$$

$$C_{ave} = \frac{1}{len(C)} \sum_{i=1}^{len(C)} c_i \quad (14)$$

$$W0_{ave} = \frac{1}{len(W0)} \sum_{i=1}^{len(W0)} w0_i \quad (15)$$

$$W1_{ave} = \frac{1}{len(W1)} \sum_{i=1}^{len(W1)} w1_i \quad (16)$$

$$I_i = [R_{ave}; C_{ave}; W0_{ave}; W1_{ave}] \quad (17)$$

We introduce the keywords into the sequence model and combine the bag-of-word model with the word-by-word attention model. We train the bag-of-word model and incorporate it into LSTM model with word-by-word attention by averaging the predicted probabilities to get the final label to make a correct choice. We call the combination hybrid model. The details of the experiment will be introduced in next section.

Model	dev corpus	test corpus
LSTMs model	0.500	0.504
Attention	0.657	0.571
WBW attention	0.684	0.586
BOW model	0.606	0.524
hybrid model	0.654	0.585

Table 1: The results of the experiments. Attention, WBW attention, BOW model stand for LSTM model with attention, LSTM model with word-by-word attention, bag-of-word model respectively. Training on the training corpus while testing accuracy is computed on the dev corpus and test corpus.

4 Experiment and result

While training the model, the input sentences are separately embedded as 100-dimensional GloVe vectors (Pennington et al., 2014) and the embedding layer is based on the 100-dimensional GloVe vectors. We use ADAM (Kingma and Ba, 2015) for optimization and set the initial learning rate 0.001. We trained for 13 epochs or until the performance on development set stopped improving so as to avoid overfitting. Some Hyper-parameters for model: the dropout is 0.9, the embedding size is 100, the size of LSTM is 64 and the batch size is 256.

We conduct experiment on the training, dev and test corpus downloaded from the SemEval-2018 Task 12. There are five models used to make experiments are LSTM model, LSTM model with attention, LSTM model with word-by-word attention, bag-of-word model and hybrid model. The results of the experiments could be seen in Table 1. We choose the LSTM model without attention as baseline.

According to the experiment, the simple sequence model couldn't complete the semantic understanding task well. The bag-of-word model performs better than the LSTM model, which proves that the keywords could express the semantics of the sentences. As for the keywords can't express all the information of the sentences while the LSTM model with attention can not only express the whole information but also grab the important part, the bag-of-word performs worse than the attention model. LSTM model with word-by-word attention makes a great contribution to the best result. The hybrid model doesn't have an improvement in dev corpus but have a similar results with the word-by-word attention model. We guess that what causes such a result is the small data corpus and simply mechanically combining the models with each other. So we don't get a satisfactory result from the hybrid model. The LSTM model with word-by-word attention gets the accuracy of 0.586 in the final submission, achieving the fifth place in the shared task.

In the future, we will consider more reasonable combinations of the sentence model with keywords to enhance the comprehension of the sentences. Besides,

we will introduce the CNN into our model to extract the word character to improve the accuracy.

5 Acknowledgments

We very appreciate the comments from reviewers which will help further improve our work. This work is supported by National Key Research and Development Program of China (Grant No. 2017YFB1402400) and National Science Foundation of China (No. 61602490).

Abstract

This paper describes our system for the SemEval-2018 Task 12: Argument Reasoning Comprehension Task. We utilize skip-thought vectors, sentence-level distributional vectors inspired by the popular word embeddings and the skip-gram model. We encode preprocessed sentences from the dataset into vectors, then perform a binary supervised classification of the warrant that justifies the use of the reason as support for the claim. We explore a few variations of the model, reaching 54.1% accuracy on the test set, which placed us 16th out of 22 teams participating in the task.

1 Introduction

Reasoning is the process of thinking in a logical way to form a conclusion. Inferring conclusions using commonsense reasoning has become a popular topic in NLP. *Textual entailment* (TE) aims to determine whether a *hypothesis* can be inferred from a *premise* (Dagan et al., 2006). Approaches to solving TE have ranged from robust approaches based on shallow lexical and semantic features (Marelli et al., 2014) to formal computational semantics approaches based on translating sentences into logical form (Beltagy et al., 2015). The current state-of-the-art approaches to TE use deep learning for *natural logic inference* to capture human deductive reasoning (Bowman et al., 2015; Rocktäschel et al., 2015).

In online discussions, when arguing for or against a stance, people provide arguments leaving their readers to rely on common sense and non-deductive reasoning to evaluate the validity of their arguments. Human annotators can infer the reasons from claims fairly well (Boltužić and Šnajder, 2014; Hasan and Ng, 2014), even when additional (implicit) premises are required to make reasoning deductive (Boltužić and Šnajder, 2016). Habernal et al. (2018) emphasize the importance of implicit

premises in argumentation by introducing the *argument reasoning comprehension* task, where one chooses between two mutually exclusive warrants to make a reason warrant the claim. They demonstrate that human experts can perform this task extremely well (up to 90% accuracy).

In this paper, we describe a system for solving the argument reasoning comprehension task, with which we participated in the SemEval-2018 Task 12. Given the reason R and claim C , debate title, debate description, and two warrants, W_1 and W_2 , the task is to choose warrant W that justifies the use of R as support for C . For all warrant pairs (W_1, W_2) , it holds that if warrant W_1 is W , then W_2 is $\neg W$, which justifies the use of R as support for $\neg C$ and vice versa.

Our system frames the problem as supervised classification and utilizes skip-thought vectors to represent sentences. Our system (TakeLab) ranked 16th out of 22 systems submitted to the SemEval-2018 Task 12, achieving 54.1% accuracy on the test set and 69.0% on the development set.

2 Related Work

Structuring argumentative discussions using Toulmin’s argumentation model (Toulmin, 2003) is an established research area in *argumentation mining*, involving detecting claims (Levy et al., 2014; Lippi and Torroni, 2015; Rinott et al., 2015), detecting claim relations (Cabrio and Villata, 2012; Boltužić and Šnajder, 2014; Stab and Gurevych, 2014), and even reconstructing entire argumentation graphs from text (Stab and Gurevych, 2017). While systems have been proposed that tackle some of these problems, they do not as yet provide mechanisms for commonsense reasoning. The *argument comprehension problem*, warranting reasons for claim, explores the problems when the gap between the claim and reason is too wide for textual entailment.

3 System Description

Our system works in three steps. First, we preprocess the dataset ending up with the claim, reason, both warrant sentences, and the correct warrant sentence label per instance. Second, we utilize *skip-thought vectors* (Kiros et al., 2015) to encode sentences as vectors. Third, we use encoded sentences as features in a supervised classification setup where we predict the warrant label given the encoded sentences.

3.1 Preprocessing

We extract only the warrants, reasons, claims, and labels from the dataset, disregarding optional additional information about the debates. We clean up this data by merging multi-sentence elements in a natural way, i.e., connecting the sentences with the conjunction “and” and modifying the punctuation accordingly. For example, the two-sentence reason:

Biking is good for one’s health and the environment. It is more expensive to maintain roads than bike lanes.

becomes a single sentence:

Biking is good for one’s health and the environment and it is more expensive to maintain roads than bike lanes.

The motivation behind this is to obtain sentences that convey a single *idea* behind the reason or warrant (claims were always single-sentence). This way, we attempt to extract a *vector per thought*. This results in a consistent set of four sentences per instance.

As the warrant and alternative warrant were extremely similarly worded (68% had two or less different words), we represent warrants W_1 and W_2 as word-level relative complements:

$$\begin{aligned} W'_1 &= W_1 \setminus W_2 = \{w_i \in W_1 \mid w_i \notin W_2\} \\ W'_2 &= W_2 \setminus W_1 = \{w_j \in W_2 \mid w_j \notin W_1\} \end{aligned}$$

where w_i and w_j denote words. This allowed us to boil down the warrants to their meaningful differences, e.g., just the words “does” and “doesn’t” in instances where the warrants were negated, but otherwise identically worded. We experimented with other combinations, but as they did not lead to performance improvement, we omit them here.

3.2 Skip-Thought Vectors

The skip-thoughts model (Kiros et al., 2015) is a sentence-level abstraction of the skip-gram model (Mikolov et al., 2013). Instead of predicting the surrounding text from a word, it predicts sentences around the target sentence in the text. Kiros et al. (2015) chose to implement an encoder-decoder model, using an RNN encoder with GRU (Chung et al., 2014) activations and an RNN decoder with a conditional GRU. This model is nearly identical to the RNN encoder used by Cho et al. (2014) for machine translation. The encoder-decoder is trained on a large dataset of English books – *Book-Corpus* (Zhu et al., 2015), chosen for its abundance of long, context-building sentences. A trained skip-thoughts model can be used as an out-of-the-box encoder-decoder able to convert sentences to skip-thought vectors. The encoder maps words to a sentence vector and the decoder is internally used by the model to generate the surrounding sentences.

The skip-thoughts model was tested on the tasks of semantic relatedness, image-sentence ranking, and paraphrase detection. The last, when combined with basic pairwise statistics, becomes competitive with the state of the art which incorporates much more complicated features and hand-engineering. On the task of semantic relatedness, the model of Kiros et al. (2015) outperformed all previous systems from the SemEval 2014 competition despite its simplicity and the lack of feature engineering. The authors also report good results on a number of classification benchmarks for evaluating sentence representation learning methods.

The model’s consistently good results on a variety of tasks motivated us to apply these vectors on our own task, which relies on the interpretation of sentences. We encode the sentences obtained from the preprocessing step into skip-thoughts using Kiros et al. (2015)’s encoder, which gives four feature vectors with 4,800 dimensions with values ranging from -0.2 to 0.2 .

3.3 Classification

The final step in our system is classifying instances using an SVM classifier, whose hyperparameters were optimized with a 5-fold cross-validated grid search.¹ We also explored Gaussian Processes, Random Forests, and AdaBoost models, which were all outperformed by the SVM. Input features

¹We obtained best results on the dev set with: gamma=0.3, C=3.8, degree=2, kernel='poly'.

Classifier	Features	Dev accuracy score	Test accuracy score
AdaBoost	W'_0, W'_1, R, C	0.614	0.520
Random forest	W'_0, W'_1, R, C	0.623	0.498
Gaussian process	W'_0, W'_1, R, C	0.642	0.547
SVM	W_0, W_1, R, C	0.630	0.538
	W'_0, W'_1, R, C	0.642	0.536
	$W_0 - W_1, R$	0.661	0.570
	$W'_0 - W'_1, R, C$	0.665	0.561
	$W'_0 - W'_1, R$	0.687	0.552*

Table 1: Accuracy scores of model variants. All models have skip-thought vectors as features, where R stands for reason, C for claim, W_1 and W_2 for warrants, and, W'_1 and W'_2 for warrant word differences vectors. (* The official results are lower (0.541) due to an error while preparing the output)

are created by concatenating skip-thought vectors obtained in the previous step. We experimented with different variants of features by applying arithmetic operations on the vectors before concatenating them, i.e., calculating the difference between warrants. It should be noted that this difference is calculated as an element-wise subtraction of the vectors, as opposed to the word set difference in the preprocessing step. Furthermore, we experimented with two variations of skip-thought vectors – one with the original warrants intact (W_0, W_1) and one with the warrant subset differences (W'_0, W'_1).

4 Evaluation

4.1 Dataset Analysis

The dataset consists of 1210 training instances, 317 validation instances, and 445 test instances. Each instance is a tuple $(W_1, W_2, R, C, debateTitle, debateInfo, y)$, with y as the label of the correct warrant (0 for W_1 or 1 for W_2). Among the 1210 training instances, there are 111 different debate titles and 169 different claims, indicating the diversity of the training set. Furthermore, we found that 47.75% of the debate titles had unanimous claims (all for or all against) and 56.69% of the claims were affirmative, but only 21.62% had a balanced number of claims for both sides of the debate (a difference of 10% or less). The debate title *Do We Still Need Libraries?* was the most common debate title, and it had unanimously affirmative claims. Around 35% of the instances contained warrants worded differently, as opposed to being directly negated (by adding *not*). All of this presented a challenge in training the system, since the dataset is small, highly variable, and involves multiple domains.

4.2 Results

The official evaluation measure for this task was the accuracy of the classified instances. In the development phase, the system showed promising results – 0.690 accuracy on the validation set, after training with only the training set. Table 1 shows performances of the model variants we explored. Interestingly, the best results were obtained using the least amount of data – the difference between the modified warrants and only the reason, completely disregarding the claim. On the test set, however, the results were much lower, the official result being 0.541. The final result surprised us, since the system showed good results using various “plain” classifiers without fine-tuning the hyper-parameters (around 0.60). We hypothesize that this was due to overfitting, which was difficult to avoid completely of the small size of the dataset.

5 Conclusion

The argument reasoning comprehension task, recognizing the warrant between a claim and a supporting reason, is a challenging but important task for understanding human reasoning in argumentation. We aim to solve the task by converting sentences into skip-thought vectors and classifying justifying warrants given claims and reasons using an SVM model. This approach showed some promising results in the development stage (69% accuracy), but did not succeed to adequately generalize in order to provide competitive results in the test stage (54% accuracy). Besides using a larger sample for training, this system could be improved by applying transfer learning from other similar tasks, such as paraphrase detection or textual entailment.

Abstract

Reasoning is a crucial part of natural language argumentation. In order to comprehend an argument, we have to reconstruct and analyze its reasoning. In this task, given a natural language argument with a reason and a claim, the goal is to choose the correct implicit reasoning from two options, in order to form a reasonable structure of (Reason, Warrant, Claim). Our approach is to build distributed word embedding of reason, warrant and claim respectively, meanwhile, we use a series of frameworks such as CNN model, LSTM model, GRU with attention model and biLSTM with attention model for processing word vector. Finally, ensemble mechanism is used to integrate the results of each framework to improve the final accuracy. Experiments demonstrate superior performance of ensemble mechanism compared to each separate framework. We are the 11th in official results, the final model can reach a 0.568 accuracy rate on the test dataset.

1 Introduction

Argument reasoning comprehension is a crucial part of natural language argumentation, and the realization of argument reasoning requires the understanding of the deep meaning of the text by the computer. At the same time, argument reasoning is also an important evaluation criterion for the understanding of natural language by computer. This paper is based on the argument reasoning comprehension task proposed by (Haber et al., 2018), which proposed a complex, yet scalable crowdsourcing process, and created a new freely licensed dataset based on authentic arguments from news comments. The dataset consists of three parts: train dataset, validation dataset and test dataset, with the quantity being 1210, 316 and 444 respectively.

The task is formally defined as follow: given an argument consisting of a reason R and a claim

C along with the title and a short description of the debate they occur in, identify the correct warrant W from two candidates, the goal is to select the correct warrant W that explains reasoning of this particular argument. There are only two options given and only one answer is correct. The key point of the task is that it is difficult to find the answer through the shallow semantics, and the answer is usually implicit.

Being a binary classification task, through preliminary experiment, our approach is combining debate title and description into reason, and splitting a sample $\{\mathbf{R}$ (with debate title and description) ; \mathbf{C} ; \mathbf{W}_0 ; \mathbf{W}_1 ; correct_label $\}$ into two quadruples, which are $\{\mathbf{R}$; \mathbf{C} ; \mathbf{W}_0 ; label $\}$ and $\{\mathbf{R}$; \mathbf{C} ; \mathbf{W}_1 ; label $\}$. On the validation, we employ the same processing mode, determining the matching degree of fit between a quadruples, the highest will be chosen. The four main deep learning(DL) frameworks we employed are based on Convolutional Neural Network(CNN) model, Long Short-Term Memory(LSTM) model, GRU with attention model and Bidirectional Long Short-Term Memory (biLSTM) with attention model, which are based on utilizing word distributed representation on R and C and W respectively, on top of models, a dense layer is used to determine the matching degree.

In our paper, an ensemble mechanism is introduced into neural network (NN) models, we integrate the results of each model to improve the final accuracy. Experiments demonstrate superior performance of ensemble mechanism compared to each separate model. For confirming the effect of ensemble method, we use each separate model as a reference.

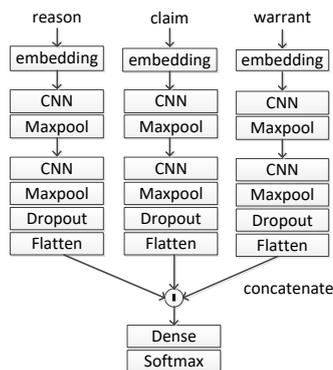

Figure 1: The architecture of CNN framework

2 Related work

An argument consists of a claim and multiple premises was pointed out in (Damer, 2009). Toulmin elaborated on a model of argument in which the reason supports the claim on behalf of a warrant. The abstract structure of an argument then is reason \rightarrow (since) warrant \rightarrow (therefore) claim. But, making comprehending and analyzing arguments is hard, for claims and warrants are usually implicit (Freeman, 2011). The phenomenon is referred to as common knowledge (Macagno and Walton, 2014).

Previous, feature extraction and semantic analysis are usually used in natural language argumentation. With the development of neural networks, we adopt the method of word distributed representation from (Hinton, 1986), CNN model refers to (Kim, 2014), the LSTM model from (Hochreiter and Schmidhuber, 1997) and be improved by (Graves et al., 2013), the attention mechanism from (Hermann et al., 2015), eventually converted the task into a classification problem (Wang and Nyberg, 2015). Meanwhile, inspired by the ensemble method in statistical learning domain, we develop a very simple but efficient integrated method.

3 Model description

In this section, we describe the four main proposed deep learning frameworks, the framework architectures are shown in figure 1 to 4. The main idea of these different systems is the same: learn a distributed vector representation of given reason and claim and warrant candidates, and use a dense layer to measure the matching degree.

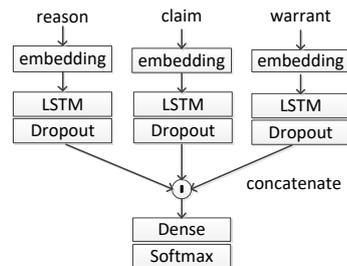

Figure 2: The architecture of LSTM framework

3.1 CNN framework

The first framework is based on CNN model. Step one is to obtain word embedding by pre-trained word2vec (Mikolov et al., 2013), the word embedding provides the distributed representation for each token in reason, claim and warrant candidates respectively. The vectors have dimensionality of 300 and were trained by 100 billion words of Google News, and was initialized from an unsupervised neural language model.

Reason, claim and warrant will be transformed to a word vector matrix and be entered into CNN layer respectively. In order to get more composite representation of semantic features, we adopted double layer CNN model. The numbers of filters are 64 and 32, and the filter size is set as 3, after each CNN layer, we resort to a MaxPooling layer of size 2.

Above the CNN layer, the output of reason, claim and warrant are merged to one and performed flatten operations, through a dense layer, the final output is passed through a two-dimensional softmax layer.

3.2 LSTM framework

LSTM is a special type of RNN that can learn to rely on long-distance history and the immediate previous hidden vector, its a remarkable variation of RNN to alleviate the gradient vanish problem.

In the same way of producing word distribution vector representation in embedding layer, the difference is that, as the LSTM model can process variable length sequences, so we employ masking method to skip (filter out) time steps whose tokens are equal to zero. Above the embedding layer, we introduced the LSTM layer with unit number of 64. Through the LSTM layer, reason, claim and warrant will be transformed to a vector respectively.

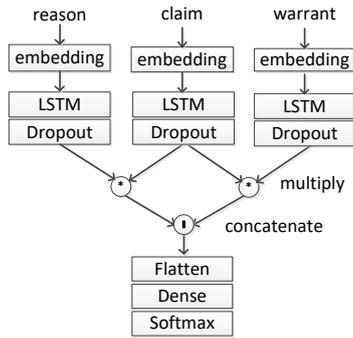

Figure 3: The architecture of GRU framework

3.3 GRU with attention

Like the LSTM framework, the masking method is used in the embedding layer. Reason, claim and warrant will be transformed to a word vector matrix and be entered into GRU layer respectively. Gated recurrent unit (GRU), was proposed by (Cho et al., 2014) to make each recurrent unit to adaptively capture dependencies of different time scales. Similarly to the LSTM unit, the GRU has gating units that modulates the flow of information inside the unit, without having a separate memory cells. Unlike the LSTM framework, GRU with attention return full output sequences, instead of the final output of the model.

Through the GRU layer, reason, claim and warrant are converted into three vector matrices. Now, we investigate a state-of-the-art attention model for the warrant vector generation based on claim which is called fact matrix, and the claim vector generation based on warrant which is called attention matrix. An attention mechanism are used to alleviate weakness by dynamically aligning the more informative parts. Specifically, attention model gives more weights on certain words, just like tf-idf for each word, however, the weight is calculated by another vector. Final, we merge the two sequences to one and perform flatten operations.

3.4 biLSTM with attention

The framework is similar to the above one, just changing the GRU model into a biLSTM model, Single direction LSTMs suffers a weakness of not utilizing the contextual information from the future tokens. biLSTM utilizes both the previous and future context by processing the sequence on two directions, and generates two independent sequences of LSTM output vectors.

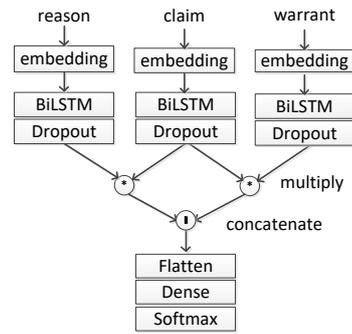

Figure 4: The architecture of biLSTM framework

4 Ensemble Methods

Ensemble methods is an important method in statistical learning, which combines a number of weak models into a strong model through a certain combination. The most famous of them are the Bagging algorithm and the Boosting algorithm.

Our method is inspired by the bagging method, the differences between our method and the traditional bagging method are as follows: we use several strong classifiers for combination, and use all the data to train a single model.

Specifically, we use three ensemble methods. The first method is the soft voting based on Bagging method, that is, each framework outputs a class probability and takes the average to judge the category. The second method is hard voting, each framework predicts categories separately, and finally votes. Because four frameworks are used in the paper, the weight of the best framework is set to 2. The third method is finding the best weight which is the best accuracy on the validation dataset by the exhaustive method.

5 Experimental setup

Our approach in this task is realized by keras, we use the accuracy on validation dataset to locate the best parameters. All the results are taken three times, and the average value is taken.

In the experiment, we use the loss function of categorical cross entropy and the optimizer of adaptive moment estimation. The length of reason, claim and warrant tokens sequence all take the maximum length, if the length is not enough, then zero is added.

For comparison, we report the performance and analysis of four frameworks in Table 1. Rows (1) to (2), list accuracy of task originators models on the validation set and the test set respectively

	Framework	val	test
1	Intra-warrant attention	63.8	55.6
2	Intra-warrant attention w/context	63.7	56.0
3	CNN	63.92	52.93
4	LSTM	66.46	54.95
5	GRU with attention	67.72	56.19
6	biLSTM with attention	67.09	57.21

Table 1: Results of originator and the four main frameworks which our paper employed

	Weight	val	test
soft voting	1 1 1 1	68.35	56.85
hard voting	1 1 1 2	68.03	56.63
exhaustion weight	1 4 2 3	69.93	55.50
	0 2 1 5	69.62	56.41
	1 0 1 5	69.30	55.28

Table 2: Results of ensemble method

(Habernal et al., 2018), we take the results as the baseline to measure other frameworks. Rows (3) to (6) corresponds to our main four frameworks. Row (3) achieve acceptable results on validation set compared to the baseline. Row (4) has been greatly improved compared with CNN on the validation set and test set, especially on the validation set, reaching a 66.46% accuracy rate, proving that the LSTM model is more advantageous in processing sequence text. Row (5) has a better effect on the validation set and test set, the results have exceeded to the baseline. In these four major frameworks, the result of Row (6) is the most satisfying, improves over the baseline already, especially on the validation set, 4% higher than the baseline, on the test set, the accuracy rate of 57.21% is also reached. From the Table 1, we can perceive that the attention mechanism is beneficial to improve the capability of the model.

We report the performance of ensemble method in Table 2. As can be seen from the result, we can observe that Row (1) uses the soft voting method, which achieves a 68.35% accuracy rate on the validation set, which surpasses all the single frameworks. The performance on the test set is also good, reaching 56.85%, more than the baseline model 1%, though it is not as good as the best result of single framework, but it is also a good result. Row (2) is the hard voting method, which is slightly worse than the soft voting. The weight of Rows (3) to (5) which were found on validation set achieve the highest accuracy on the validation set, more than 69%, this is a huge improvement, but the performance on the test dataset is not the best, the reason may be the overfitting caused by this

method. **It needs to be emphasized that soft voting method is adopted in the actual tasks, that is, the Row (1). The other methods listed here are only theoretical discussions on the ensemble method from the perspective of research.**

Through these experiments, we can conclude that remarkable results can be achieved through the ensemble method. At the same time, the soft voting method is better than other methods, although the results of the validation dataset are not the best in three method, but the effect on test dataset is the best.

6 Conclusion

In this paper, we solve the Argument Reasoning Comprehension Task by employing four main frameworks and ensemble mechanism. Through a series of attempts, our experimental results demonstrate that: comparing to a single framework, ensembling a series of models can effectively improve the accuracy of the model; the results of the single framework are unstable, and the stability of the model can be improved effectively through the ensemble method, the accuracy of the integrated system on the test set is guaranteed to be above 55%; in the experiment, soft voting is a good way to integrate and achieve better results.

Abstract

This paper describes our system in SemEval-2018 task 12: Argument Reasoning Comprehension. The task is to select the correct warrant that explains reasoning of a particular argument consisting of a claim and a reason. The main idea of our methods is based on the assumption that the semantic composition of the reason and the warrant should be close to the semantic representation of the corresponding claim. We propose two neural network models. The first one considers two warrant candidates simultaneously, while the second one processes each candidate separately and then chooses the best one. We also incorporate sentiment polarity by assuming that there are kinds of sentiment associations between the reason, the warrant and the claim. The experiments show that the first framework is more effective and sentiment polarity is useful.

1 Introduction

Argument reasoning is a key step in the process of argumentation mining and is a very challenging task in natural language processing and artificial intelligence. Maccartney and Manning (2008) suggested that the key factor in the study of natural language understanding is the mastery of natural language reasoning. When we argue for an argument, it is necessary to reconstruct the implicit reasoning (Newman and Marshall, 1992; Habernal et al., 2017) under the relevant assumption and premise to get a simple and concise explanation of the whole reasoning process.

The Argument Reasoning Comprehension task is defined as following:

Given an argument consisting of a claim C and a reason R , the goal is to select the correct warrant that explains reasoning of this particular ar-

gument. There are only two options W_0 and W_1 given and only one answer is correct.

Our solution is based on the assumption that the semantic composition of the reason and the true warrant should be close to the semantic representation of the claim. We propose two frameworks. First one is dependent on the task settings that two warrant candidates are considered simultaneously to make a decision. The second one is more general that the task is simplified as determine whether a warrant candidate can explain argument reasoning. We found that the first one performed better.

In addition, we attempt to incorporate sentiment polarity to capture the sentiment association between the reason, the warrant and the claim. The experimental results demonstrate that adding sentiment polarity can improve the performance.

The final result is produced by an ensemble approach that combines the outputs of multiple single models. Our system achieves an accuracy of 0.67 on development dataset and 0.57 on test dataset.

2 System Description

2.1 Model1: Competitive Model

The first proposed model is designed depending on the specific task setting. The architecture of Model1 is shown in Figure 1. We first get the representations of the claim C , the reason R and the two warrant candidates W_0 and W_1 . Then we use a transformer to get the representation of a pseudo claim, by compositing the reason R and a warrant candidate W . Finally, the model predicts which warrant candidate is the correct one by considering the claim C and two pseudo claims.

2.1.1 Sentence Representation

Figure 2 illustrates the architecture for getting the sentence representation.

*corresponding author

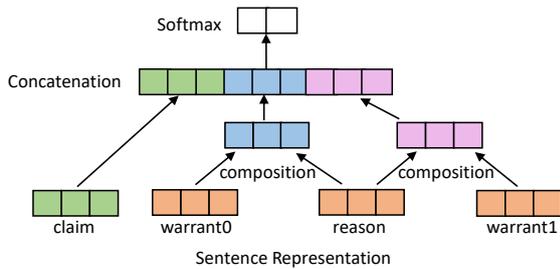

Figure 1: The architecture of Model1: Competitive Model.

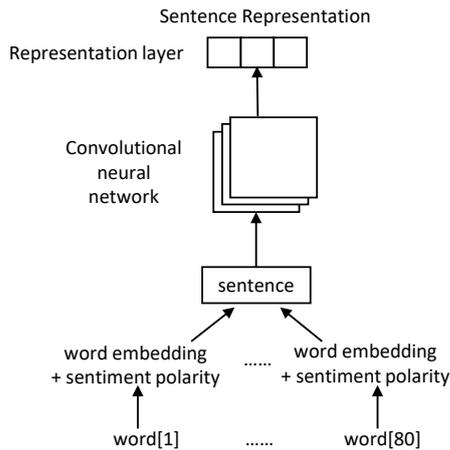

Figure 2: The representation of the sentence obtained by the convolutional neural network.

Word Embeddings. We first map each word to a word embedding, which is a dense distributed vector. Since the dataset of this task is relatively small, we hope the word embeddings can improve generalization. The word embeddings we used were pre-trained and released by Huang et al. (2012).

Sentiment Polarity of Words. We expect that there are relations between the claim, the reason and the warrant. For example, they may have the same sentiment polarity, while there may be polarity conflicts when involving a false warrant.

Therefore, we use the sentiment polarity of words as a kind of common sense knowledge. The negative words and positive words come from the dictionary provided by Hu and Liu (2004). The polarity representation of each word is a two dimensional vector. A positive word is represented as $[1, 0]$ and a negative word is represented as $[0, 1]$. The representation of out-of dictionary words is $[0, 0]$.

We concatenate the word embedding and sentiment polarity representation together as the final representation of a word.

Convolutional Neural Networks. The word em-

beddings are feed into a convolutional neural network (CNN) to get the representation of a sentence. We mainly follow the architecture of Kim (2014), which reports excellent performance for several sentence classification tasks. The dimension of word embeddings is k and the sentence length is fixed. A sentence s consisting of n words can be represented as the concatenation of the embeddings of the n words:

$$s = \vec{e}_1 \oplus \vec{e}_2 \oplus \dots \oplus \vec{e}_n, \quad (1)$$

where \vec{e}_i is the k -dimensional word vector of the i_{th} word. A convolution operation involves a filter $\mathbf{w} \in R^{h,k}$, which is applied to a window of h words to produce a new feature a_i :

$$a_i = f(\mathbf{w} \cdot s_{i:i+h-1} + b), \quad (2)$$

where f is a non-linear activation function, which is set to Relu (Nair and Hinton, 2010) and b is a bias term. The feature map \mathbf{a} can be represented as

$$\mathbf{a} = [a_1, a_2, \dots, a_{n-h+1}]. \quad (3)$$

Then a max-pooling operation is applied to the resulted feature map to get the sentence representation.

In experiments, $k = 52$, $h = 3$, and we used 64 filters. A dropout layer is added after the word embedding layer with a probability 0.25. The representations of the claim, reason and warrant candidates are all learned in this way.

2.1.2 Pseudo Claim Representation

We assume that the claim is a semantic composition of a reason and a warrant. Therefore, we use a composition operator to combine the representations of the reason and a warrant candidate to get the representation of a *pseudo* claim, noted as C_0 and C_1 respectively.

We have tried four composition operators: ADD, INNERPRODUCT, CONCATENATION and FULLYCONNECTEDNETWORK. In experiments, ADD performs best.

2.1.3 Prediction

Finally, we connect the representations of C , C_0 and C_1 to fully connect layers and concatenate them into one representation. And we connect the representation to the output layer through a non-linear transformation layer (Relu). The output is expected to be 1 if W_1 is right and expected to be 0 if W_0 is right. In experiments, we permuted the order of W_0 and W_1 to enlarge the training dataset.

2.2 Model2: Isolation Model

We consider a more general setting: Given the claim and reason of argument, determine whether a warrant candidate can support the argumentation. As shown in Figure 3, Model2 is just a simplification of Model1. It processes one warrant candidate individually. The output indicates whether the given warrant candidate is right.

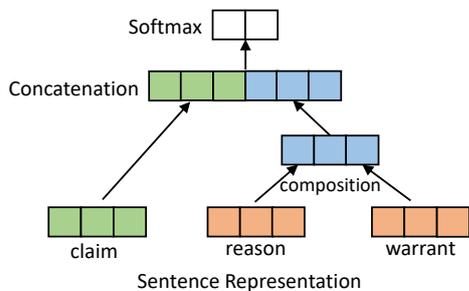

Figure 3: The architecture of Model2: Isolation Model.

For W_0 and W_1 , we can get their corresponding probability $p(1|W_0)$ and $p(1|W_1)$. We choose the one with a higher probability as the predicted right warrant for the task.

2.3 Ensemble Model

We have already described the two proposed models. For each model, we trained several times with different initialization parameters. Finally, we chose 3 models from Model1 and 3 models from Model2, which performed well on the development dataset. We used the prediction probabilities of the 6 models as features and trained a random forest classifier for ensemble (Pal, 2005).

3 Evaluation

We conducted experiments on the official datasets of SemEval-2018 Task 12. The model parameters are trained using the training dataset and tuned based on the performance of development dataset. We will report the results on both development dataset and test dataset. Accuracy is the official evaluation metric. We also report precision, recall and F_1 score.

We are interested in two research questions:

- RQ1: Which proposed model is more effective?
- RQ2: Whether incorporating sentiment polarity can benefit this task?

3.1 Results on Development Dataset

Table 1 shows the results on the development dataset. The accuracy of the random baseline is 0.503. The proposed models significantly outperform the baseline.

By adding sentiment polarity representations, Model1 and Model2 both improve a lot. The accuracy of Model1 increases 3.16%, while the accuracy of Model2 increases 2.43%. The precision, recall and F_1 score all have the same trend. With the sentiment polarity added, the Model1 performs better than Model2. Without the sentiment polarity, their performance is very close.

3.2 Results on Test Dataset

Table 2 shows the results on test dataset. The random baseline submitted by task organizer is 0.527. The accuracy of the ensemble model is 0.57, which outperforms the random baseline by 4.3%. After the task organizer released the gold test dataset, we predicted it again using the ensemble model and the accuracy is 0.5811.

Similar to the results on development dataset, with the sentiment polarity added, both Model1 and Model2 achieve a better performance. We can see that on test dataset, Model1 outperforms Model2 no matter using or removing sentiment polarity representations. When using sentiment polarity, the performance difference is larger.

3.3 Discussion

From the experimental results on the development dataset and the test dataset, we can see that sentiment polarity is always useful for distinguishing the correct warrant from the false one. Model1 performs slightly better than Model2. It is reasonable since Model1 considers richer information than Model2. But Model2 actually is a more general model. With sentiment polarity added, the advantage of Model1 is amplified. This also indicates the usefulness of sentiment polarity of words.

The model performance is better on the development dataset than on the test dataset. The proposed models may still suffer the overfitting problem, since the training dataset is not very large.

4 Conclusion

In this paper we presented our system that participated in the SemEval-2018 Task 12: Argument Reasoning Comprehension. Our assumption is

Model	Precision	Recall	F_1 score	Accuracy
Random Baseline	-	-	-	0.503
Model1	0.6380 ± 0.018	0.6276 ± 0.010	0.6216 ± 0.010	0.6276 ± 0.010
w/o polarity	0.5982 ± 0.007	0.5960 ± 0.006	0.5932 ± 0.005	0.5960 ± 0.006
Model2	0.6244 ± 0.013	0.6203 ± 0.016	0.6157 ± 0.019	0.6203 ± 0.016
w/o polarity	0.5968 ± 0.018	0.5960 ± 0.017	0.5946 ± 0.017	0.5960 ± 0.017

Table 1: Results on the development dataset and w/o polarity means sentiment polarity representations of words are removed.

Model	Precision	Recall	F_1 score	Accuracy
Random Baseline	-	-	-	0.527
Model1	0.5457 ± 0.013	0.5420 ± 0.013	0.5347 ± 0.007	0.5420 ± 0.013
w/o polarity	0.5381 ± 0.009	0.5338 ± 0.011	0.5277 ± 0.010	0.5338 ± 0.011
Model2	0.5392 ± 0.019	0.5338 ± 0.021	0.5263 ± 0.028	0.5338 ± 0.021
w/o polarity	0.5340 ± 0.016	0.5285 ± 0.018	0.5227 ± 0.022	0.5285 ± 0.018
Ensemble	0.5806	0.5811	0.5805	0.5811

Table 2: Results on the test dataset and w/o polarity means sentiment polarity representations of words are removed.

that the semantic composition of the reason and the warrant should be close to the semantic representation of the corresponding claim. We proposed two neural networks based models: a competitive model that knows two warrant candidates and an isolation model that only considers one candidate for classification. In particular, we incorporated sentiment polarity of words into the models. The experimental results demonstrate that incorporating sentiment polarity of words always improves the performance. The competitive model is slightly better than the isolation model. All proposed models outperform the random baseline by a large margin.
