4.4 Analysis

Structural Probing Tasks To check whether the representation learned by SynCLM captures syntactic knowledge effectively, following Hewitt and Manning (2019), we construct a syntax tree of a sentence with linear transformation learned for the embedding space. If the syntax tree is better constructed, the model is considered having learned more syntactic information. We use the pre-trained LM based on phrase-guided method to capture the Stanford Dependencies formalism (De Marneffe et al., 2006). Similarly, we use the *undirected attachment score* (UUAS) denoting the percentage of correctly placed undirected edges as the main metric. We also report *spearman correlation* (Spr.) between predicted and the actual distance between each token pair in a sentence. The results are shown in Table 5. It can be seen that our base model obtains SOTA results on UUAS, indicating that our method can enhance the model capability of capturing syntactic structures.

Case Study Figure 2 gives three examples to illustrate the effectiveness of incorporating syntactic information. These examples show that SynCLM can capture syntactic information and make correct predictions based on the obtained information. To give further insight into how syntactic knowledge affects prediction, we highlight the main syntax structures that affect prediction. Here, we take the third case for detailed analysis. The core tokens in the syntax trees of the two sentences are the same, so the model predicts they have the same semantics. Through more data analysis, we find that SynCLM enhances the attention weight between syntactically related words, thus increasing the importance of non-leaf tokens in model prediction. Please note that this feature also leads to wrong predictions. In the future we will attend to the problem of how to integrate syntactic and semantic information in model prediction.

Attention Visualization In order to verify the impact of syntactic information in the attention mechanisms of the pre-trained LM, we plot attention weights of baseline models and our models in Figure 3. We mainly focus on the interactions of tokens, except for [CLS] and [SEP]. Then the attention weights are averaged over all heads and layers. This visualization demonstrates the effectiveness of injecting syntactic information into self-attention. From Figure 3, we can see that higher attention weight between directly syntactically related tokens in our model. For example, our model assigns strong attentions from the token "John" to "go" and "abroad", while the baseline model assigns lower attentions for these correlated tokens.

5 Conclusion

To the best of our knowledge, this is the first work of leveraging contrasting learning to inject syntax knowledge into pre-trained LMs. Motivated by the properties of constituent and dependency structures of syntax, we design phrase-guided and tree-guided learning objectives to guide the learning of attention distributions and hidden representations in the transformer. Through extensive experiments, we show that SynCLM consistently improves a wide range of tasks, from GED, entity tasks to GLEU, which confirms the advantage of our syntax-guided contrastive learning. Detailed analysis also shows that SynCLM does incorporate rich syntax knowledge and learn explainable attention weights.

Acknowledgements

We are very grateful to our anonymous reviewers for their helpful feedback on this work. We would like to thank Ying Chen for examination and revision in paper writing; Can Gao for the help on model training. This work was supported in part by the National Key R&D Program of China under Grant 2020YFB1406701.

Improved Multi-label Classification under Temporal Concept Drift: Rethinking Group-Robust Algorithms in a Label-Wise Setting

Ilias Chalkidis and Anders Søgaard
Department of Computer Science, University of Copenhagen, Denmark
`[ilias.chalkidis,soegaard]@di.ku.dk`

Abstract

In document classification for, e.g., legal and biomedical text, we often deal with hundreds of classes, including very infrequent ones, as well as temporal concept drift caused by the influence of real world events, e.g., policy changes, conflicts, or pandemics. Class imbalance and drift can sometimes be mitigated by resampling the training data to simulate (or compensate for) a known target distribution, but what if the target distribution is determined by unknown future events? Instead of simply resampling uniformly to hedge our bets, we focus on the underlying optimization algorithms used to train such document classifiers and evaluate several group-robust optimization algorithms, initially proposed to mitigate group-level disparities. Reframing group-robust algorithms as adaptation algorithms under concept drift, we find that Invariant Risk Minimization and Spectral Decoupling outperform sampling-based approaches to class imbalance and concept drift, and lead to *much* better performance on minority classes. The effect is more pronounced the larger the label set.

1 Introduction

Large-scale multi-label document classification is the task of assigning a subset of labels from a large predefined set – of, say, hundreds or thousands of labels – to a given document. Common applications include labeling scientific publications with concepts from ontologies (Tsatsaronis et al., 2015), associating medical records with diagnostic and procedure labels (Johnson et al., 2017), pairing legislation with relevant legal concepts (Mencia and Fürnkranzand, 2007), or categorizing product descriptions (Lewis et al., 2004). The task in general presents interesting challenges due to the large label space and two-tiered skewed label distributions.

Class Imbalance In multi-label classification, datasets often exhibit class imbalance, i.e., skewed label distributions (Figure 2). Common methods include resampling and reweighting based on heuristic assumptions, but methods are known to suffer from unstable performance, poor applicability, and high computational cost in complex tasks where their assumptions do not hold (Liu et al., 2020). Datasets with long-tail frequency distributions, like the ones considered below – sometimes referred to as *power-law datasets* (Rubin et al., 2012) – can be particular challenging. Also, the heuristics fix the trade-off between exploiting as much of the training data as possible and balancing the classes, instead of trying to learn the optimal trade-off.

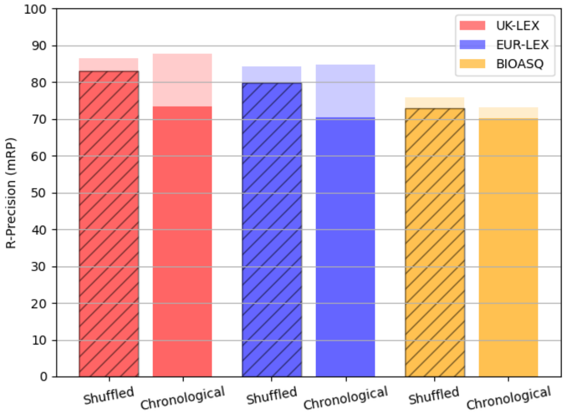

Figure 1: Model performance using *random* vs. *chronological* splits across the medium-sized datasets (Table 1). The shaded parts of the bars are the train/test discrepancy due to *over-fitting*. The performance drop from random to chronological splits demonstrates the *temporal concept drift*.

Temporal Concept Drift Moreover, class distributions may change over time. This is one dimension of the *temporal generalization* problem (Lazaridou et al., 2021). Recently, Søgaard et al. (2021) argued chronological data splits are necessary to estimate real-world performance, contrary to random splits (Gorman and Bedrick, 2019), because random splits artificially removes drift. Temporal concept drift, which we focus on here – in-

Findings of the Association for Computational Linguistics: ACL 2022, pages 2441 - 2454

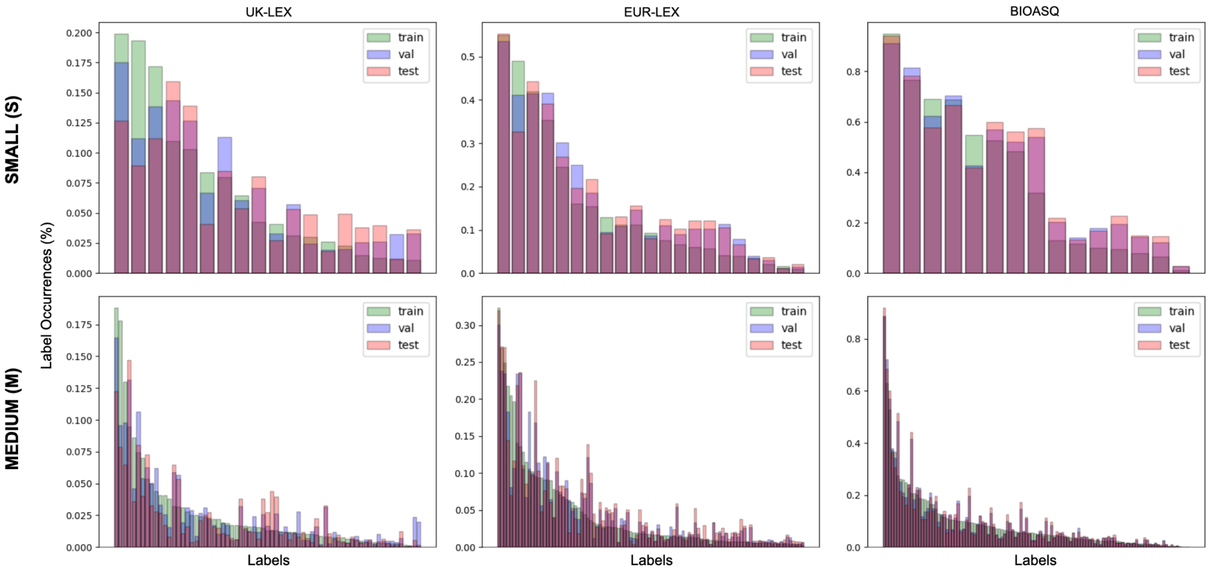

Figure 2: Label distributions of all datasets (UK-LEX, EUR-LEX, BIOASQ) and settings (small and medium sized label sets). Labels (bars) are ranked from most (left) to least (right) represented in the training set. *Class imbalance* across labels in the *x* axis and *temporal concept drift* across subsets depicted with different coloured bars in the *y* axis, i.e., a higher misalignment of color bars denotes a higher label distribution swift.

stead of covariate shift (Shimodaira, 2000), for example – is an instance of concept drift (Gama et al., 2014), often discussed in the domain adaptation literature, e.g., Chan and Ng (2006).

2 Related Work

Temporal Drift Temporal drift has been studied in several NLP tasks, including document classification (Huang and Paul, 2018, 2019), sentiment analysis (Lukes and Søgaard, 2018), Named Entity Recognition (NER) (Rijhwani and Preotiuc-Pietro, 2020), Neural Machine Translation (NMT) (Levenberg et al., 2010) and Language Modelling (Lazaridou et al., 2021). None of these papers focus on class imbalance and temporal concept drift. These papers have mainly been diagnostic, not providing technical solutions that are applicable in our case.

Multi-label Class Imbalance Class imbalance in (large-scale) multi-label classification has so far been studied through the lens of network *architectures*, searching for the best neural architecture for handling few- and zero-shot labels in the multi-label setting. To improve the performance for underrepresented (few-shot) classes, Snell et al. (2017) introduced Prototypical Networks that average all instances in each class to form *prototype* label vectors (encodings), a form of inductive bias, which improved few-shot learning. In a similar direction, Mullenbach et al. (2018) developed the Label-Wise Attention Network (LWAN) architecture, in which label-wise document representations are learned by attending to the most informative words for each label, using trainable label encodings (representations). Rios and Kavuluru (2018) extended LWAN and the idea of *prototype* label encodings. They combined label descriptors with information from a graph convolutional network (Kipf and Welling, 2017) that considered the relations of the label hierarchy to improve the results in few-shot and zero-shot settings. Alternatives to LWAN were considered by Chalkidis et al. (2020a), presenting minor improvements in the few-shot setting, but harming the overall performance.

Robustness The literature on inducing robust models from skewed data is rapidly growing. See Koh et al. (2021) for a recent survey. The group-robust learning algorithms we adapt and evaluate, e.g., Group Distributionally Robust Optimization (Sagawa et al., 2020), are discussed in detail in Section 4. Recent studies targeting fairness show that class imbalance has connections to bias (Blakeney et al., 2021; Subramanian et al., 2021), i.e., mitigating class-wise disparities has a chain effect on lowering group-wise disparities.

Main Contributions We focus on (large-scale) multi-label document classification and study a fundamental component of the learning process leading to performance disparities across labels, i.e., the underlying *optimization algorithm* used for training. We consider group-robust optimization algorithms initially proposed to mitigate group disparities given specific attributes (e.g., gender, race),

Dataset	Domain	No. of Documents	Setting	No. of Labels	Distribution Swift (WS)
UK-LEX (new)	UK Legislation	36,500	Small (S)	18 / 18	8×
			Medium (M)	69 / 69	5×
EUR-LEX (Chalkidis et al., 2021)	EU Legislation	65,000	Small (S)	20 / 21	9×
			Medium (M)	100 / 127	7×
BIOASQ (Tsatsaronis et al., 2015)	Biomedical Articles	100,000	Small (S)	16 / 16	29×
			Medium (M)	112 / 116	5×

Table 1: Main characteristics of the examined datasets. We report the application domain, the number of documents, the available settings and the corresponding number of labels (used / total), and the label distribution swift between random and chronological splits using the Wasserstein Distance (WS) between train-test label probability distributions, i.e., $WS_{chronological} = N \times WS_{random}$.

but re-frame these algorithms to optimize performance across labels rather than across groups.

3 Datasets

We experiment with three datasets (Table 1) from two domains (legal and biomedical), which support two different classification settings (label granularities), i.e., label sets including more abstract or more specialized concepts (labels).[1]

UK-LEX United Kingdom (UK) legislation is publicly available as part of the United Kingdom's National Archives.[2] Most of the laws have been categorized in thematic categories (e.g., health-care, finance, education, transportation, planing) that are presented in the document preamble and are used for archival indexing purposes.

We release a new dataset, which comprises 36.5k UK laws (documents).[3] The dataset is chronologically split in training (20k, 1975–2002), development (8.5k, 2002–2008), test (8.5k, 2008–2018) subsets. We manually extract and cluster the topics to supports two different label granularities, comprising 18, and 69 topics (labels), respectively.

EUR-LEX European Union (EU) legislation is published in EUR-Lex.[4] All EU laws are annotated by EU's Publications Office with multiple concepts from EuroVoc, a thesaurus maintained by the Publications Office.[5] EuroVoc has been used to index documents in systems of EU institutions, e.g., in web legislative databases, such as EUR-Lex and CELLAR, the EU Publications Office's common repository of metadata and content.

We use the English part of the dataset of Chalkidis et al. (2021), which comprises 65k EU laws (documents). [6] The dataset is chronologically split in training (55k, 1958–2010), development (5k, 2010–2012), test (5k, 2012–2016) subsets. It supports four different label granularities. We use the 1st and 2nd level of the EuroVoc taxonomy including 21 and 127 categories, respectively.

BIOASQ The BIOASQ (Task A: Large-Scale Online Biomedical Semantic Indexing) dataset (Tsatsaronis et al., 2015; Nentidis et al., 2021) comprises biomedical articles from PubMed,[7] annotated with concepts from the Medical Subject Headings (MeSH) taxonomy.[8] MeSH is a controlled and hierarchically-organized vocabulary produced by the National Library of Medicine. The current version of MeSH contains more than 29k concepts referring to various aspects of the biomedical research (e.g., Diseases, Chemicals and Drugs). It is used for indexing, cataloging, and searching of biomedical and health-related information, e.g., in MEDLINE/PubMed, and the NLM databases.

We use a subset of 100k documents derived from the latest version (v.2021) of the dataset.[9] We subsample documents in the period 2000-2021, and we consider chronologically split training (80k, 1964–2015), development (10k, 2015–2018), test (10k, 2018–2020) subsets. We use the 1st and 2nd levels of MeSH, including 16 and 116 categories.

4 Fine-tuning Algorithms

In our experiments, we rely on pre-trained English language models (Devlin et al., 2019) and fine-tune these using different learning objectives. Our main goal during fine-tuning is to find a hypothesis (h) for which the risk $R(h)$ is minimal:

---

[1] We originally also considered the MIMIC-III dataset of Johnson et al. (2017) including discharge summaries fro US hospitals annotated with ICD-9 medical codes, but the publication date of the documents has been "counterfeited" as part of the anonymization process. Experimental results with random splits are presented in Appendix B.1.

$$h^* = \arg\min_{h \in \mathcal{H}} R(h) \tag{1}$$

$$R(h) = \mathbf{E}[\mathcal{L}(h(x), y)] \tag{2}$$

where y are the targets (*ground truth*) and $h(x) = \hat{y}$ is the system hypothesis (model's predictions).

Similar to previous studies, $R(h)$ is an expectation of the selected loss function ($\mathcal{L}$). In this work, we study multi-label text classification (Section 3), thus we aim to minimize the binary cross-entropy loss across L classes:

$$\mathcal{L}(x) = -y \log \hat{y} - (1 - y) \log(1 - \hat{y}) \tag{3}$$

ERM (Vapnik, 1992), which stands for Empirical Risk Minimization, is the most standard and widely used optimization technique to train neural methods. The loss is calculated as follows:

$$\mathcal{L}_{ERM} = \frac{1}{N} \sum_{i=1}^{N} \mathcal{L}(x_i) \tag{4}$$

where N is the number of instances (training examples) in a batch, and $\mathcal{L}_i$ is the loss per instance.

Furthermore, we consider a representative selection of group-robust fine-tuning algorithms that try to mitigate performance disparities with respect to a given attribute (A), e.g., in a standard scenario that could be the gender of a document's author in sentiment analysis, or the background landscape in image classification. In our case, the attribute of interest is the labeling of the documents. The attribute is split into G groups, which in our case are the classes ($G = L$). All algorithms rely on a balanced group sampler, i.e., an equal number(N_{g_i}) of instances (samples) per group (g_i) are included at each batch. Most of the algorithms are built upon group-wise losses ($\mathcal{L}_{g_i}$), computed as follows:

$$\mathcal{L}(g_i) = \frac{1}{N_{g_i}} \sum_{j=1}^{N_{g_i}} \mathcal{L}(x_j) \tag{5}$$

In our case, contrary to previous applications of group-robust algorithms, the groups (classes) are not mutually exclusive (documents are tagged with multiple labels). Hence, the group sampler can only guarantee that *at least* N groups (labels) will be considered at each step, but most probably even more. In this work, we examine the following group-robust algorithms in a label-wise fashion:

Group Uniform is the more naive group robust algorithm that uses the average of the group-wise (label-wise) losses -all groups (labels) are considered equally important-, instead of the standard sample-wise average, as follows:

$$\mathcal{L}_{GM} = \frac{1}{G} \sum_{i=1}^{G} \mathcal{L}(g_i) \tag{6}$$

Group DRO (Sagawa et al., 2020), stands for Group Distributionally Robust Optimization (DRO). Group DRO is an extension of the Group Uniform algorithm, where the group-wise (label-wise) losses are weighted inversely proportional to the group (label) performance. The total loss is calculated as follows:

$$\mathcal{L}_{DRO} = \sum_{i=1}^{G} w_{g_i} * \mathcal{L}(g_i), \text{ where} \tag{7}$$

$$w_{g_i} = \frac{1}{W}(\hat{w}_{g_i} * e^{L(g_i)}) \quad \text{and} \quad W = \sum_{i=1}^{G} w_{g_i} \tag{8}$$

where G is the number of groups (labels), $\mathcal{L}_g$ are the averaged group-wise (label-wise) losses, w_g are the group (label) weights, $\hat{w}_g$ are the group (label) weights as computed in the previous update step.

V-REx (Krueger et al., 2020), which stands for Risk Extrapolation, is yet another proposed group-robust optimization algorithm. Krueger et al. (2020) hypothesize that variation across training groups is representative of the variation later encountered at test time, so they also consider the variance across the group-wise (label-wise) losses. In V-REx the total loss is calculated as follows:

$$\mathcal{L}_{REX} = \mathcal{L}_{ERM} + \lambda * \text{Var}([\mathcal{L}_{g_1}, \ldots, \mathcal{L}_{g_G}]) \tag{9}$$

where Var is the variance among the group-wise (label-wise) losses, and λ, a weighting hyper-parameter scalar.

IRM (Arjovsky et al., 2020), which stands for Invariant Risk Minimization, mainly aims to penalize variance across multiple training dummy estimators across groups, i.e., performance cannot vary in samples that correspond to the same group. The total loss is computed as follows:

$$\mathcal{L}_{IRM} = \frac{1}{G}\left(\sum_{i=1}^{G} \mathcal{L}(g_i) + \lambda * P(g_i)\right) \tag{10}$$

where $\mathcal{L}_{gi}$ is the loss of the i_{th} instance, which is part of the g_{th} group (label). Refer to Arjovsky et al. (2020) for a more detailed introduction of the group penalty terms (P_g).

Deep CORAL (Sun and Saenko, 2016), minimizes the difference in second-order statistics (covariances) between the source and target feature activations. In practice, it introduces group-pair penalties:

$$\mathcal{L}_{CORAL} = \mathcal{L}_{ERM} + \lambda * \frac{1}{G}\left(\sum_{i=1}^{G} P(g_i, g_{i+1})\right) \quad (11)$$

$$P(g_i, g_{i+1}) = [\overline{C_{g_i}} - \overline{C_{g_{i+1}}}]^2 + [\overline{X_{g_i}} - \overline{X_{g_{i+1}}}]^2 \quad (12)$$

where $\overline{C_{g_i}}$ are the averaged covariances of the ith group and $\overline{X_{g_i}}$ are the averaged features (document representations) of the ith group, respectively. Refer to Sun and Saenko (2016) for a more detailed introduction of the group penalty terms (P_g).

Spectral Decoupling (Pezeshki et al., 2020) relies on the idea of *Gradient Starvation*. Pezeshki et al. state that a network could become over-confident in its predictions by capturing only one or a few dominant features. Thus, adding an L2 penalty on the network's logits ($\hat{y}_i$) provably decouples the fixed points of the dynamics. The total loss is computed as follows:

$$\mathcal{L}_{SD} = \mathcal{L}_{ERM} + \lambda * \frac{1}{N}\sum_{i=1}^{N} \hat{y}_i^2 \quad (13)$$

In our work, we consider the aforementioned algorithms in a label-wise setting, instead of a group-wise setting given a protected attribute. In our case, $G = L$, where L is the number of labels.

5 Experimental SetUp

Baseline Models For both legal datasets (UK-LEX, EUR-LEX), we use the small LEGAL-BERT model of Chalkidis et al. (2020b), a BERT (Devlin et al., 2019) model pre-trained on English legal corpora. For BIOASQ, we use the small English BERT model of Turc et al. (2019). Following Devlin et al. (2019), we feed each document to the pre-trained model and obtain the top-level representation $h_{\texttt{[cls]}}$ of the special `[cls]` token as the document representation. The latter goes through a dense layer of L output units, one per label, followed by a sigmoid activation.

We also experiment with the Label-Wise Attention Network (LWAN) relying on a BERT encoder (Chalkidis et al., 2020a), dubbed BERT-LWAN.[10] Chalkidis et al. reported state-of-art results in EUR-LEX and AMAZON-13K using BERT-LWAN compared to several baselines. BERT-LWAN uses one attention head per label to generate L document representations d_l:

$$a_{lt} = \frac{\exp(K(h_t)Q_l)}{\sum_{t'} \exp(K(h_{t'})Q_l)} \quad (14)$$

$$d_l = \frac{1}{T}\sum_{t=1}^{T} a_{lt} V(h_t) \quad (15)$$

T is the document length in tokens, h_t the context-aware representation of the t-th token, K, V are linear transformations of h_t, and Q_l a trainable vector used to compute the attention scores of the l-th attention head; Q_l can also be viewed as a label representation. Intuitively, each head focuses on possibly different tokens of the document to decide if the corresponding label should be assigned. BERT-LWAN employs L linear layers (o_l) with sigmoid activations, each operating on a different label-wise document representation d_l, to produce the probability of the corresponding label p_l:

$$p_l = \text{sigmoid}(d_l \cdot o_l) \quad (16)$$

Across experiments, we use BERT models following a small configuration (6 transformer blocks, 512 hidden units and 8 attention heads), which allows us to increase the batch size up to 64 and consider samples with multiple labels (groups) in the group robust algorithms. In practice, this enables us to sample at least 4 samples per group (label) for all labels in the small label sets, and at least 1 sample per group (label) for 64 labels in the medium-sized label sets (69-112 labels).

Training Details We fine-tune all models using the AdamW (Loshchilov and Hutter, 2019) optimizer with a learning rate of 2e-5. We use a batch size of 64 and train models for up to 20 epochs using early stopping on the development set. We run three repetitions with different random seeds and report the test scores based on the seed with the best scores on development data. We report development scores on Appendix B.2.

Evaluation Metrics Given the large number and skewed distribution of labels, retrieval measures have been favored in large-scale multi-label text classification literature (Mullenbach et al., 2018; You et al., 2019; Chalkidis et al., 2020a). Following Chalkidis et al. (2020a), we report *mean R-Precision* (m-RP) (Manning et al., 2009), while

---

[10] The original model was proposed by Mullenbach et al. (2018), with a CNN encoder.

we also report the standard *micro-F1* (μ-F$_1$) and *macro-F1* (m-F$_1$) to better estimate the class-wise performance disparity.

Data and Code In our experiments, we extend the WILDs (Koh et al., 2021) library, which provides an experimental framework for experimenting with group-robust algorithms. We effectively rewrote all parts of code to consider label-wise groups and losses, while we also implemented the unsupported methods (Group Uniform, V-REx, and Spectral Decoupling). For reproducibility and further exploration with new group-robust methods, we release our code on Github.[11]

6 Results

Main Results To highlight the temporal concept drift, we initially fine-tune BERT in all datasets with the standard ERM optimization algorithm using both *random* and *chronological* splits. Table 3 shows that the real-world performance achieved using the chronological split is severely overestimated using the random split (approx. +10% across evaluation measures) in two out of threee datasets. While all datasets have inherently skewed distributions (class imbalance), which is naturally demonstrated by the performance discrepancy between μ-F$_1$ and m-F$_1$ scores (especially when we consider the larger label sets), the temporal dimension further exacerbate the performance discrepancy as label distributions also vary across subsets (Figure 2). Surprisingly, the performance discrepancy between chronological and random splits is much lower on BIOASQ (approx. 1-2%), which could be explained by the larger volume of training data (Table 1), and the very high representation for most of the labels in general (Figure 2).

In Table 2, we present the overall results for the different optimization algorithms considering the baseline model, BERT. We observe that using a *group sampler* (ERM+GS), which equals standard oversampling of minority classes, slightly improve the results in m-F$_1$ (+1-4%) in many cases, while the performance is comparable in μ-F$_1$ and m-RP. Considering the results of group-robust algorithms, we observe that most of them improve m-F$_1$ across datasets compared to ERM and ERM+GS, +1-4% for small-sized datasets and +5-12% in medium-sized datasets. Again the performance in μ-F$_1$ and m-RP is mostly comparable or a bit lower, as sample-wise averaged measures are dominated by frequent classes due to class imbalance.

Contrary, Group DRO is consistently outperformed even by the standard ERM. Recall that Group DRO uses a weighted average of the group-wise (label-wise) losses (Equation 7-8), where the group weights rely on the momentum of the group-wise (label-wise) losses (Equation 8). In our case, this regularization acts counter-intuitively, as weights for the infrequent classes, which are rarely present across batches, are not updated (decrease) constantly. This leads to an asymmetry, where some weights are frequently updated, while others not, and in time the latter are almost zeroed-out and not affect the training objective (loss).

The effect of group-robust algorithms in relation to the size of the label set. In Table 2, we can also observe that the performance gains of group-robust algorithms compared to ERM are greater when we use the larger label sets. This is also as the class imbalance and temporal concept drift are more severe when we consider more refined labels, especially considering m-F$_1$.

Table 4: Test results of group-robust algorithms in ***head* and *tail* classes** in the medium-sized datasets. *Head* are the 50% most represented (frequent) classes in the training set, and *tail* are the bottom 50%.

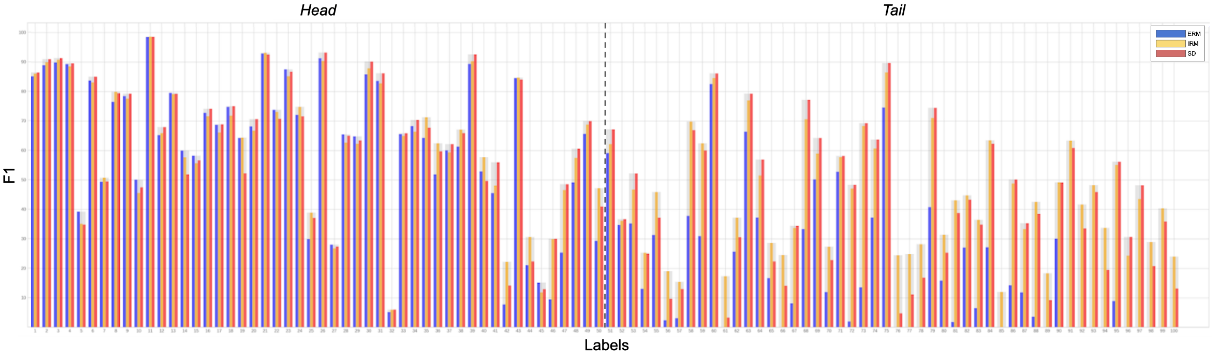

Figure 3: ***Class-wise* F1-score** results for ERM (blue), IRM (yellow) and Spectral Decoupling (red) on medium-sized EUR-LEX. The classes have been ordered (left-to-right) based on the label distribution in the training subset. Algorithms' performance on the left part (***head* classes**) is very much aligned, contrary to the right (***tail* labels**).

The effect of group-robust algorithms in relation to class frequency. In Table 4, we present results for the different optimization algorithms considering two groups of classes based on their frequency. *Head* classes are the 50% most frequent classes in the training set, while *tail* are the bottom 50%. As expected, the performance in head classes is much better compared to tail ones across datasets (approx. +20-40% in m-F_1). We observe that the performance gains of group-robust algorithms compared to ERM are greater in the tail classes (+10-40% in m-F_1). This is further highlighted in Figure 3, where we observe that IRM and Spectral Decoupling, the two best performing group-robust algorithms, have larger gains in the right part (tail labels); in fact ERM scores zero in many cases (classes) where the two group-robust algorithms don't. This is highly expected as the goal of the group-robust algorithms is to minimize the group-wise (in our case, label-wise) disparity. Group DRO is severely out-performed in both head and tail, especially in the tail classes (whose weights have been zeroed-out, as previously noticed).

Why IRM and Spectral Decoupling are a better fit compared to the rest of the algorithms? To answer this question, we need to identify the main differentiation between IRM, Spectral Decoupling and the rest of the methods. Both IRM and Spectral Decoupling follow similar incentives. IRM penalizes variance across losses in the same group (Equation 10), i.e., in our case, the network is penalized if there is a performance disparity between samples labeled with the same classes using as a reference a dummy classifier. Spectral Decoupling penalizes the variance across label predictions (Equation 13), i.e., the network is penalized for being over-confident. The rest of the algorithms mainly rely on an equal consideration of the group-wise (in our case, label-wise) losses (Equation 6), i.e., in our case, all classes are equally important for the training objective.

The latter incentive (averaging across group-wise losses) seems very intuitive, although in practice the groups (labels) co-occur (are not mutually exclusive) in a multi-label setting, thus frequent labels remain "first class citizens" in the optimization process, biasing parameter updates in their favor.

Contrary, both IRM and Spectral Decoupling use a learning component (loss term), which penalizes *label degeneration*. This is particularly important in multi-label classification, especially when we consider large label sets, as networks tend to over-fit (specialize) in few dominant (frequent) labels that shape the training loss and finally ignore

Table 5: Test results of group-robust algorithms with **different models** (BERT, and BERT-LWAN) in the medium-sized version of EUR-LEX. Deep CORAL is not applicable (n/a) in LWAN -there is not a universal featurizer-.

(zero-out) the rest of the labels. This is quite different from the concept of *Gradient Starvation*, introduced by Pezeshki et al. (2020), where a network becomes over-confident in its predictions by capturing only few dominant features, as in our case the main issue is the label degeneration rather than possible spurious correlations learned by the network. Moreover, Spectral Decoupling does not rely on group-wise losses, similar to the rest.

The effect of group-robust algorithms using BERT-LWAN. In this part, we compare the effect of the group-robust algorithms in between standard BERT and BERT-LWAN on the medium-sized EUR-LEX dataset. In Table 5, we observe that BERT-LWAN closes the gap between ERM and the best-of group-robust algorithms. The results of ERM when we use BERT-LWAN are improved across measures, especially when we consider m-F$_1$ with a 10% improvement over the standard BERT. Both IRM and Spectral Decoupling seem quite insensitive to the underlying model. Similarly, the results for the rest of the group-robust algorithms are improved. Nonetheless, there are still benefits in m-F$_1$ and less represented (*tail*) labels in general. Interestingly, Spectral Decoupling improves results in m-F$_1$, with comparable μ-F$_1$ scores. Although, we observe a performance drop (approx. 2%) in m-RP when we consider overall and head classes. We hypothesize that IRM and Spectral Decoupling negatively affect the ability of the BERT-LWAN model to correctly rank labels (Equation 16), as they force the model to consider all labels by not being over-confident (discriminatory) with one way or another, as previously explained.

In Figure 4, we compare the performance of ERM, IRM, and Spectral Decoupling across three EUR-LEX settings, small-sized, medium-sized, and one extra large-sized considering the 3rd level of EuroVoc including 500 concepts (labels). In the small label set, we observe that the use of LWAN-BERT slightly improves the performance when trained with ERM compared to standard BERT (shaded part of the bars). In the medium label set, as already discussed, we observe an approx. 10% improvement with ERM, while in case of the large label set, using LWAN-BERT leads to an approx. 20% improvement with ERM (the performance of BERT is 0%), and 6.5% with Spectral Decoupling, while IRM proves to be remarkably robust across all settings and both neural methods (BERT with or without the LWAN component).

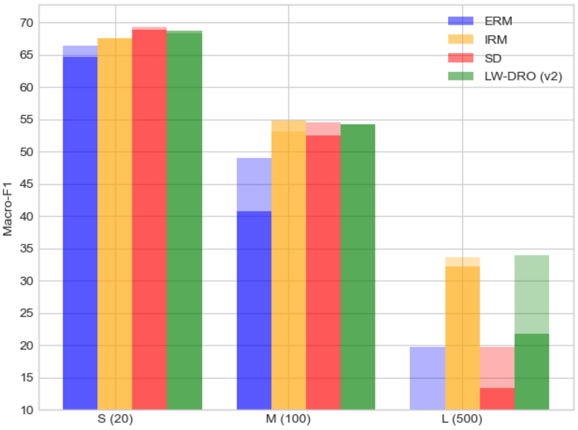

Figure 4: LWAN-BERT test performance using ERM, IRM, Spectral Decoupling (SD), and LW-DRO (v2) across **all EUR-LEX settings**. The shaded part of the bars denotes the performance improvement (of LWAN-BERT) compared to the standard BERT.

7 Alternative Combined Algorithm

Having a clear understanding of what IRM and Spectral Decoupling offer, it seems that we could combine both to leverage all features: (a) rely on group-wise (label-wise) losses as the main driver of the optimization process (Equation 6); (b) penalize the classifier if there is a performance disparity between samples labeled with the same classes (Equation 10); and (c) penalize the classifier for being over-confident (Equation 13).

We name the new algorithm *Label-Wise Distributional Robust Optimization*, LW-DRO in short, as it mainly aims to mitigate label-wise disparities, and investigate two alternatives (variants):

- In version 1 (*v1*), we combine the averaged group-wise (label-wise) losses (Equation 6) introduced with Group Uniform, with the Spectral Decoupling penalty (Equation 13). The total loss term ($\mathcal{L}_{LW-DRO}$), is computed as follows:

$$\frac{1}{G}\sum_{i=1}^{G}\mathcal{L}(g_i) + \lambda * \frac{1}{N}\sum_{i=1}^{N}\hat{y}_i^2 \tag{17}$$

- In version 2 (*v2*), we also include the group-wise penalties of IRM (Equation 10). The total loss term ($\mathcal{L}_{LW-DRO}$), is computed as follows:

$$\frac{1}{G}\left(\sum_{i=1}^{G}\mathcal{L}(g_i) + \lambda_1 * P(g_i)\right) + \lambda_2 * \frac{1}{N}\sum_{i=1}^{N}\hat{y}_i^2 \tag{18}$$

The notation used in Equations 17 and 18 follows the one presented in Section 4.

In Table 5, we observe that the second variant of LW-DRO (v2) has comparable or better performance compared to IRM and Spectral Decoupling, contrary to the first one (v1). LW-DRO (v2) is a straight forward combination of IRM and Spectral Decoupling, while LW-DRO (v1) that relies on a group-averaged loss under-performs, especially considering the m-F_1 scores. As previously explained, labels co-occur in a multi-label setting, hence averaging label-wise losses favors frequent classes and in turn limits the possible benefits in under-represented classes (perceived by m-F_1).

In Figure 4, we present the results of ERM, and the 3 overall best group-robust algorithms (IRM, Spectral Decoupling, and LW-DRO (v2)) across all EUR-LEX settings. LW-DRO (v2) has comparable performance in the first two setting (small, medium), while being slightly better than IRM in the large-sized setting. While LW-DRO (v2) seems to control the trade-offs between IRM and Spectral Decoupling, we believe that future work should better seek alternative directions with respect to algorithmic advances that possibly mitigate label degeneration and tackles label-wise disparities.

8 Conclusions & Future Work

We considered one of the main challenges in large-scale multi-label text classification, which comes from the fact that not all labels are well represented in the training set due to the class imbalance and the effect of temporal concept drift. To mitigate label disparities, we considered several group-robust optimization algorithms initially proposed to mitigate group disparities given specific attributes. Experimenting with three datasets in two different settings, we empirically find that group-robust algorithms vastly improve performance considering macro-averaged measures, while two of the group-robust algorithms (Invariant Risk Minimization and Spectral Decoupling) improve performance across all measures. Considering a more well-suited neural method (LWAN-BERT), we observe a vast performance improvement using ERM, leading to comparable overall results (μ-F_1, m-RP) with the group-robust algorithms; although is still outperformed considering m-F_1. Lastly, based on our understanding of what IRM and Spectral Decoupling, the two best group-robust algorithms, offer, we introduced and evaluated a new algorithm, Label-Wise DRO, which combines features from both, and one of its variants has comparable or better performance considering larger label sets.

In the future, we would like to further investigate the two-tier anomaly (class imbalance and temporal concept drift). In this direction, we would like to directly take into consideration the time dimension by utilizing this information in group sampling and algorithms (e.g., groups over period of time). We would also like to consider data augmentation techniques (e.g., paraphrasing via masked-language modeling (Ng et al., 2020), and teacher forcing exploiting unlabeled data (Eisenschlos et al., 2019)) to improve the data (feature) sampling variability, as the group sampler used in group-robust algorithms over-sample minority classes with the same limited instances. Further on, we would like to investigate the use of zero-shot LWAN methods (Rios and Kavuluru, 2018; Chalkidis et al., 2020a), which currently harm averaged performance in favor of improved worst case performance. Label encodings based on contextualized word representations generated by pre-trained language models (Hardalov et al., 2021) may mitigate the effect of using non-contextualized ones (e.g., Word2Vec).

A Measuring class-wise bias

Blakeney et al. (2021) recently introduced two evaluation measures to estimate class-wise bias of two models in comparison to one another in a multi-class setting, and show that these metrics can be also used to measure fairness and bias with respect to protected attributes.

Following Blakeney et al. (2021), in Figure 5 we present the normalized Combined Error Variance (CEV) in-between algorithms. CEV estimates the class-wise bias of a model A relative to another model B has increased of the change between model A and a random predictor. For a detailed analysis of the CEV metric, please refer to Blakeney et al. (2021).

In our case, as different models, we consider BERT trained with a different algorithm. In both UK-LEX and EUR-LEX, swapping Group Uniform, IRM, or Spectral Decoupling with ERM, or Group DRO leads to a higher class-wise bias, which is highly expected given the aforementioned performance analysis, i.e., improved m-F_1 scores.

B Additional Results

Algorithm	*Small*		*Medium*	
	m-F_1	μ-F_1	m-F_1	μ-F_1
ERM	71.8	60.2	47.4	10.3
ERM+GS	71.7	62.4	47.5	12.6
Group Uniform	71.9	66.1	48.2	13.3
Group DRO	65.2	47.4	14.0	3.8
Deep CORAL	72.1	67.1	47.1	12.3
V-REx	71.9	65.9	47.6	11.3
IRM	72.0	66.6	**53.3**	**18.3**
Spectral Decoupling	**72.3**	**67.2**	53.1	16.1

Table 6: **Overall** test results of the **group-robust algorithms** across on MIMIC-III dataset.

B.1 Experiments on MIMIC-III

MIMIC-III dataset (Johnson et al., 2017) contains approx. 50k discharge summaries from US hospitals. Each summary is annotated with one or more codes (labels) from the ICD-9 hierarchy, which has 8 levels.[13]. The International Classification of Diseases, Ninth Revision (ICD-9) is the official system of assigning codes to diagnoses and procedures associated with hospital utilization in the United States and is maintained by the World Health Organization (WHO).

MIMIC-III has been anonymized to protect patients privacy, including chronological information (e.g., entry/discharge dates). Hence, it is not possible to split data in chronological splits. We split the dataset randomly in training (30k), development (10k), test (10k) subsets. We use the 1st and 2nd level of ICD-9 including 19 and 184 categories, respectively.

In Table 6, we present the results, which lead to the very same observations discussed for the rest of the datasets.

B.2 Development Results

We run three repetitions with different random seeds and in the main article (Section 6, we report the test scores based on the seed with the best scores on development data. For completeness, in Tables 7, 8, 9, we report the development results of the group-robust (label-robust) algorithms across all datasets (UK-LEX, EUR-LEX, BIOASQ) and settings (small and medium sized label sets) using BERT. We report the mean and standard deviation (±) across all three examined seeds.

Abstract

Prompt-based learning, which exploits knowledge from pre-trained language models by providing textual prompts and designing appropriate answer-category mapping methods, has achieved impressive successes on few-shot text classification and natural language inference (NLI). Because of the diverse linguistic expression, there exist many answer tokens for the same category. However, both manual answer design and automatic answer search constrain answer space and therefore hardly achieve ideal performance. To address this issue, we propose an answer space clustered prompting model (ASCM) together with a synonym initialization method (SI) which automatically categorizes all answer tokens in a semantic-clustered embedding space. We also propose a stable semi-supervised method named stair learning (SL) that orderly distills knowledge from better models to weaker models. Extensive experiments demonstrate that our ASCM+SL significantly outperforms existing state-of-the-art techniques in few-shot settings.[1]

1 Introduction

Pre-trained language models (PLMs, Vaswani et al., 2017; Devlin et al., 2019; Qiu et al., 2020; Lewis et al., 2020; Clark et al., 2020) have shown a great impact on natural language processing (NLP) tasks. By adding task-specific head and fine-tuning on labeled corpora, PLMs surpass conventional fully supervised learning paradigm and come into being a "pre-train, fine-tune" paradigm (Sun et al., 2019).

However, Radford et al. (2019) demonstrate PLMs can perform downstream tasks without any additional data and modification, which reveals PLMs have the potential for knowledge exploration.

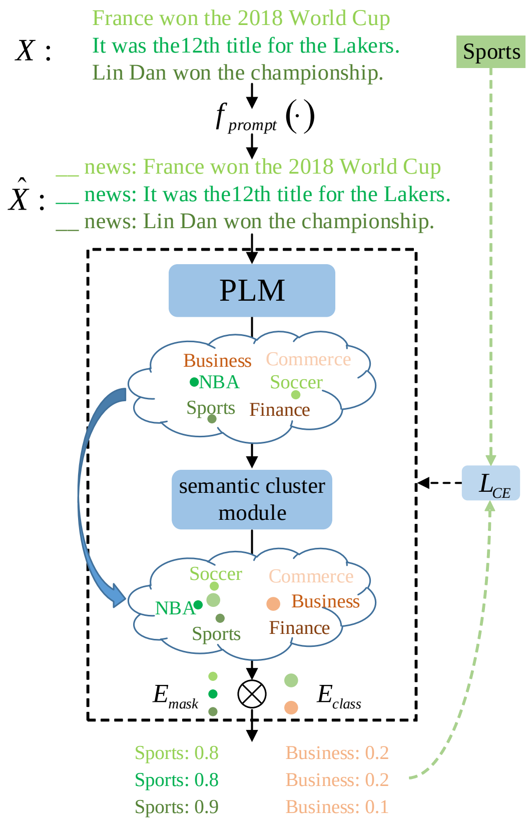

Figure 1: Illustration of ASCM. Given textual input x, ASCM adds task-specific prompt pattern to X and predicts masked token embedding by PLM encoder. Then semantic cluster module (SCM) transforms token embedding to a semantic-clustered embedding space. Finally, similarities between E_{mask} and categorized cluster centers decide the category of x.

And Petroni et al. (2019) find that BERT contains relational knowledge, factual knowledge and can be applied to QA tasks without fine-tuning.

Recently, prompting methods (Liu et al., 2021), which reformulate downstream tasks with task-specific textual prompts, is proved successful in

Findings of the Association for Computational Linguistics: ACL 2022, pages 2455 - 2469
May 22-27, 2022

many tasks such as few-shot text classification and natural language inference. For example, to classify textual news such as *"France won the 2018 World Cup"*, prompting methods may add the textual prompt *"__ news:"* before the news, then PLMs probably fill in the blank with token *"soccer"*, *"sports"*, *"football"*, *"match"*, *"FIFA"*, etc. Taking these tokens as the answer space of *sports* news category, PLMs may correctly predict the category of news even without fine-tuning. Nevertheless, former prompting methods bring in extra prompt engineering and answer engineering, which have significant influences on performance and need to be designed carefully. There exist various prompt engineering methods (Davison et al., 2019; Wallace et al., 2019; Haviv et al., 2021; Ben-David et al., 2021; Li and Liang, 2021), but answer engineering hasn't been researched enough. Former answer engineering can be categorized into manual answer design and automatic answer search. Both methods select limited answers space for each category and force PLMs to predict in that answer space. For example, former methods may force PLMs to fill the blank of *"__ news: It was the 12th title for the lakers."* with *"Sports"* if the answer space of *sports* category doesn't include *"NBA"*. Besides, manual answer design methods need additional expertise and automatic answer search methods may damage the performance (Schick et al., 2020; Schick and Schütze, 2021; Gao et al., 2021).

We find that answer tokens belonging to the same category get some kind of relationship. For sentiment analysis tasks and natural language inference tasks, same-category answer tokens usually get similar semantics (*glad*, *happy*). For topic classification tasks, same-category answer tokens may get relationships such as synonym (*soccer*, *football*), hyponym(*soccer*, *football*), hypernym, co-hyponym, etc. For convenience, we adopt *"synonym"* and *"semantic"* to represent all the relationships above. But the distribution of token embedding in PLMs isn't specially designed for text classification or NLI. It came to us that cluster centers of intra-class answer tokens can be used for classification if all token embedding distributes according to semantics. In that case, any tokens that are relevant to certain categories will get close to the corresponding cluster center and be automatically included in the corresponding answer space, which means no constraint on PLMs and no answer engineering. Following this idea, we propose the ASCM, as illustrated in Figure 1, which focuses on text classification and natural language inference. Our contributions can be summarized as follows:

- We propose ASCM that transforms token embeddings to a semantic-clustered embedding space and categorizes all answer tokens embeddings in that space. ASCM puts no constraint on answer space and doesn't need answer engineering or expertise.
- We propose a synonym initialization method for additional parameters introduced by ASCM, which makes ASCM competitive in few-shot settings.
- Besides, to exploit massive unlabeled data, we propose a semi-supervised method called stair learning (SL) which transfers knowledge orderly and further increases the performance.

We conduct extensive experiments which demonstrate the superiority of our method. Our ASCM+SL outperforms the previous prompt-based learning (manual answer design) by 10.3, 2.6, 2.3, and 2.1 on MNLI, Yahoo, Yelp, and AG's News with 50 labeled examples.

2 Related Work

2.1 Prompt-based Learning

Schick and Schütze (2021) propose to reformulate input examples into cloze-style phrases and show superiority in few-shot text classification and natural language inference. Gao et al. (2021) further propose to use T5 to automatically generate prompt patterns, which improve performance and makes minimal assumptions on domain expertise. Lester et al. (2021) propose prompt tuning to learn soft prompts with PLMs parameter frozen, which attain comparable performance with model tuning. Prompt-based learning has also been applied to knowledge probing(Ettinger, 2020; Jiang et al., 2020a,c), text generation (Brown et al., 2020; Schick and Schütze, 2020; Dou et al., 2021), machine translation (Radford et al., 2019), question answering (Khashabi et al., 2020; Jiang et al., 2020b) and information extraction (Shin et al., 2021; Cui et al., 2021; Chen et al., 2021).

2.2 Answer Engineering

Answer engineering aims to design appropriate answer space and map function to transform predictions of the masked token to task-specific results.

Answer space is often unconstrained in text generation and machine translation, while constrained in text classification and natural language inference tasks which this work focuses on.

Yin et al. (2019) manually select words for each label in topic classification, emotion classification, and situation classification task. Similar manual answer engineering also can be found in other works such as Schick and Schütze (2021). Manual answer engineering needs extra expert knowledge and is hardly convinced to be optimal due to limited answer space.

Jiang et al. (2020b) take back-translation (Sennrich et al., 2016) as the paraphrasing method to expand initial answer space and the prediction probability is the sum of category-specific probabilities over expanded answer space. Schick et al. (2020) propose a likelihood ratio verbalizer search which selects several proper tokens for each category according to their probability distributions. However, experiments show that handcrafted verbalizers still perform better than their automatic verbalizer search. Gao et al. (2021) automatically select top 30 tokens per class by simplifying and adding re-ranking to the method in Schick and Schütze (2021), which reach comparable performance with manual designed answer space. The aforementioned answer engineering methods can be categorized into the discrete answer search, where answer space is a small subset of the token space of PLMs. Hambardzumyan et al. (2021) explore to use continuous embedding called soft labels, which doesn't need answer engineering. However, some virtual answer embeddings lack of interpretability and this method still constrains answer space. Because tokens embeddings belonging to the same categories such as *"sports"*, *"soccer"* and *"football"* are dispersive in PLMs, virtual answer embedding belonging to *sports* category cannot fit all token embeddings above.

2.3 Semi-supervised Learning

Chen et al. (2020) create augmented training examples by interpolating text in hidden space and predict combined low-entropy labels. Xie et al. (2020) propose to combine advanced data augmentation methods such as RandAugment and back-translation with a consistency training framework. Schick and Schütze (2021) propose a semi-supervised learning method called iPET to iteratively distill knowledge and exploit unlabeled data with size gradually increasing. The iPET improves model performance further but the learning procedure is random which means the teacher model might be too weak for the student model.

3 Our Method

3.1 ASCM

Notice that the following discussions focus on text classification and natural language inference. Let M be a pre-trained language model, V its token vocabulary, $\_\_ \in V$ the mask token, $x \in X$ the token sequences to be predicted, and $y \in Y$ the corresponding ground-truth label. Prompting methods reformulate input text x to $\hat{x}$ with task-specific prompting functions $f_{prompt}(\cdot)$, in which mask token $\_\_$ is inserted. With proper prompting function, M is likely to fill $\hat{x}$ with a specific token at the masked position, which is helpful to downstream tasks. Former prompt-based learning usually designs a small answer space $\hat{V} \in V$ categorized by Y. Taking task AG's News as an example, $\hat{V}$ can be {["World"], ["Sports", "Soccer"], ["Business", "Commerce"], ["Tech"]} for labels {"World", "Sports", "Business", "Science/Technology"}. Let $E_{\hat{V}}$ be token embeddings corresponding to answer space $\hat{V}$ and E_{mask} be token embedding at mask position predicted from M. Then similarities between E_{mask} and $E_{\hat{V}}$ denote the probability distribution over labels. Hambardzumyan et al. (2021) propose to use soft continuous embedding E_{V_soft}, which are regarded as virtual answer space.

In this work, we propose ASCM that consists of PLMs encoder, a semantic cluster module (SCM, composed of a linear transformation layer, a BN layer, and a tanh activation function), and a semantic classifier (SC). The PLMs encoder predicts E_{mask} as former prompt-based methods does and then SCM and SC together classify on E_{mask}. SCM transforms E_{mask} to a virtual token embedding on another embedding space, where token embeddings are optimized to cluster according to semantics. With intra-class tokens such as {"sports", "soccer", "football" ...} converging to a cluster center and cluster centers of different categories diverging, SC predicts on this virtual token embedding according to the similarities with all categorized cluster centers. After SCM, because tokens that are relevant to certain categories will get close to the corresponding cluster center and automatically be included in the corresponding answer

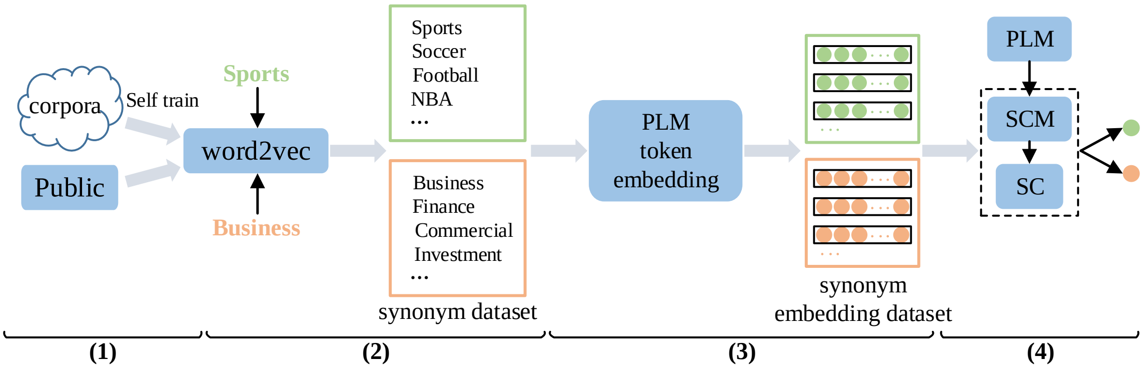

Figure 2: Illustration of synonym initialization.

space, ASCM can predict based on unconstrained answer tokens space leading to better performance.

As discussed above, PLM predicts masked token embeddings for SCM, and therefore keeping the performance for cloze question is important. We compute both cross-entropy loss L_{CE} for classification and auxiliary language modeling loss L_{MLM} (Chronopoulou et al., 2019). The final loss is as

$$L = \alpha \cdot L_{CE} + (1 - \alpha) \cdot L_{MLM} \qquad (1)$$

3.2 Synonym Initialization

Previous prompt-based learning methods require answer space engineering for $E_{\hat{V}}$, which is one kind of model initialization. ASCM needs no answer space engineering but introduces additional SCM and SC to be learned and therefore is especially hard to be fine-tuned in a few-shot task.

As discussed in Section 3.1, SCM and SC classify E_{mask} according to semantics. Therefore, establishing a synonym embedding dataset and pretraining SCM and SC on this dataset shall be a reasonable solution. In this section, a synonym initialization method for SCM and SC will be introduced to address the issue above.

The synonym initialization method can be divided into four steps(as shown in Figure 2).

1) We need a words classification method or model, such as Glove (Pennington et al., 2014) and word2vec (Mikolov et al., 2013a,b). Word2vec can explore the semantics and potential relationships of words and therefore is adopted in this work. In the first step, a word2vec model trained on a task-specific dataset by self-supervised learning or a public pre-trained word2vec model is adopted.

2) We use the similarity scores of word2vec word embeddings to select the top-100 synonyms for each category and filter those with scores lower than 0.6. If a word belongs to multiple categorized synonym sets, then it will be classified to the category with the highest similarity score.

3) All words in the synonym dataset are tokenized and the first token of multi-token words is reserved. Then the token decoder (embedding) layer of PLMs maps the synonym dataset to the synonym embedding dataset.

4) Finally, SCM and SC are pre-trained on the categorized synonym embedding dataset and the parameters will be used to initialize the ASCM.

It is notable that the synonym initialization method needs no expertise.

3.3 Stair Learning

Given different prompt patterns, PLMs usually result in different performances on corpora. Knowledge distilling (Hinton et al., 2015) is a common solution for model compression, which can transfer knowledge from a teacher model to another smaller model. It gives us a hint that we can transfer knowledge from better ASCMs to weaker ASCMs. Accordingly, we propose an orderly stair learning method (SL) to transfer knowledge between ASCMs with different prompt patterns. In each retraining round k, SL exploits the unlabeled dataset and gradually multiplies the size of unlabeled examples by a constant d_0.

Let n be number of prompt patterns, T be labeled dataset, D be unlabeled dataset, $M^0 =$

$\{M_1^0, M_2^0 \cdots M_n^0\}$ be initial ASCMs trained on T, $M^j = \left\{M_1^j, M_2^j \cdots M_n^j\right\}$ be ASCMs in the retraining round j, M_i^j be ASCM with prompt pattern i in round j and d_j be the number of unlabeled examples in round j.

$$d_j = \begin{cases} |T| * d_0, & j = 1 \\ \\ d_{j-1} * d_0, & j \neq 1 \end{cases} \tag{2}$$

All ASCMs are retrained with several rounds in SL and each ASCM will be retrained the same times per round. The procedure for each retraining rounds in SL can be divided into five steps as follows.

1) We select the worst and no-retrained model of M^{j-1} as student model $M_{i'}^j$.

2) Best Model of last rounds $M^{j-1} = \left\{M_1^{j-1}, M_2^{j-1} \cdots M_n^{j-1}\right\}$ together with models that have been fine-tuned in this round $\left\{M_{1'}^j, \cdots\right\}$ will be formed together as teacher model set M_t^j. The best model of M_t^j is selected as the teacher model $M_{t\_i'}$. If prompt pattern of $M_{t\_i'}$ is the same as $M_{i'}^j$, then the second best model of M_t^j will be selected as teacher model.

3) We evaluate $M_{t\_i'}$ on D and categorize D by the predicted labels. Then we randomly sample d_j examples from D with labels distributing uniformly. To reduce the mislabeled examples, we sample examples according to the confidence of predicted labels (Guo et al., 2017; Schick and Schütze, 2021).

4) We retrain student model $M_{i'}^j$ on L and unlabeled dataset from (3) with cross-entropy loss. After fine-tuning, $M_{i'}^j$ is added to M_t^j, which makes it possible to transfer its knowledge to other model in this round if $M_{i'}^j$ outperform $M_{t\_i'}$.

5) We repeat steps (1)-(4) until all ASCMs are fine-tuned in this round and then restart the next retraining round.

After retraining all ASCMs with the same rounds, unlabeled dataset D will be annotated by final-round ASCMs and the average probability distribution forms the soft-labeled dataset. Finally, using KL divergence loss with a temperature of 2, we fine-tune a PLM with a standard sequence classification head on this soft-labeled dataset.

4 Experiments

Following prior work, we evaluate our work on four tasks Yelp Reviews, AG's News, Yahoo Questions (Zhang et al., 2015), and MNLI (Williams et al., 2018). For comparison, we adopt RoBERTa large (Liu et al., 2019) as the pre-trained language model in all experiments except for Table 2.

To evaluate the few-shot performances, we randomly sample $|T|$ (10, 50, 100, and 1000) examples as the labeled dataset with labels distributing uniformly. And we randomly sample 10000 examples for each label to form the unlabeled dataset D for SL.

We choose the Adam optimizer with a slanted triangular schedule, an initial learning rate of 1e-5, and a maximum sequence length of 256. The batch size is set to 16 for $|T|$ equals to 50, 100, 1000 and 8 when $|T|$ equals to 10. For each training step, we randomly sample the same number of examples from D to compute auxiliary language modeling loss and the loss weight α is set to 0.5. For supervised training and individual SL, training steps are set to 300. For the final PLM classifier, training steps are set to 5000. For SL, we set $d = 5$, $k = \log_d(1000/|T|)$ and only train once for each SL round to reduce computing time. Notably, iPET trains three times for each model and the ensemble of them will improve the performance.

Training details of synonym initialization can be found in appendix A.

4.1 Prompt Pattern

In this work, we take the manual prompt engineering method to design prompt patterns for each task. Two vertical bars (‖) are used to mark boundaries between text segments.

Yelp The Yelp reviews full star task is to estimate the restaurant rating (1 to 5 stars) of customers based on their review's text. We define 4 prompt patterns for an input text x:

$f_p^1 = \mathit{It\ was}$ __. x $\quad$ $f_p^2 = \mathit{Just}$ __! ‖ x

$f_p^3 = x$. *All in all, it was* __.

$f_p^4 = x$ ‖ *In summary, the restaurant is* __.

AG's News The AG's News task is to classify textual news into one of the four categories *World*,

Examples	Method	Yelp	AG's	Yahoo	MNLI(m/mm)
$\lvert T\rvert = 10$	supervised	21.1 ±1.6	25.0 ±1.6	10.1 ±0.1	34.2 ±2.1 / 34.1 ±2.0
	PET	52.9 ±0.1	87.5 ±0.0	63.8 ±0.2	41.8 ±0.1 / 41.5 ±0.2

Table 1: Average accuracies and standard deviation of different methods on Yelp, AG's News, Yahoo, and MNLI (m: matched/mm: mismatched) for four training set sizes $|T|$.

Sports, *Business* and *Science/Technology*. Each news contains a headline a and a text body b. We define 6 prompt patterns for an input text x:

$f_p^1 = \underline{\quad} :\ a\ b$ $\qquad f_p^2 = a\ (\underline{\quad})\ b$

$f_p^3 = \underline{\quad}\ -\ a\ b$ $\qquad f_p^4 = a\ b\ (\underline{\quad})$

$f_p^5 = \underline{\quad}\ News :\ a\ b$

$f_p^6 = [Category :\ \underline{\quad}\ ]\ a\ b$

Yahoo The Yahoo Questions task is to classify text to one of the ten categories *Society*, *Science*, *Health*, *Education*, *Computer*, *Sports*, *Business*, *Entertainment*, *Relationship* and *Politics*. Each news contains a question a and an answer b. We use the same prompt patterns as for AG's News.

MNLI The MNLI task is a natural language inference task that is to estimate the relationships of text pairs $(a,\ b)$. MNLI contains three categories *contradiction*, *entailment* and *Neutral*. We define 2 prompt patterns:

$f_p^1 = ''a''?\ \|\ \underline{\quad},\ ''b''$ $\qquad f_p^2 = a?\ \|\ \underline{\quad},\ b$

4.2 Results

Table 1 shows the results of our method on different tasks. We also include the supervised method, current state-of-the-art method PET, and iPET for comparison. Mean accuracy and standard deviation for three training runs are adopted as measurements. Notably, results of the supervised, PET, and iPET method in Table 1 come from Schick and Schütze (2021).

ASCM significantly outperforms the supervised method on all configurations, especially on smaller $|T|$. The difference between ASCM+PET and PET is the base model. ASCM+PET surpasses PET on most tasks because ASCM gets better performance than conventional prompt-based learning. What's more, on several tasks, ASCM+PET even performs better than iPET, which additionally retrains models on unlabeled dataset iteratively. For example, ASCM+PET outperforms iPET by 8.1 on MNLI with $|T| = 10$, by 5.5 on MNLI with $|T| = 50$, and by 2.0 on Yelp with $|T| = 50$.

By retraining ASCM with SL, especially on smaller $|T|$, ASCM+SL gives further consistent improvements compared to ASCM+PET. ASCM+SL attains the state-of-the-art on most tasks. On MNLI, Yelp, AG's, and Yahoo, the average increments of accuracy come to 8.0, 2.4, 2.2, and 1.1. On MNLI with $|T| = 10$, ASCM+SL even surpasses iPET by 21.4. We also find that the standard deviations of ASCM+PET and ASCM+SL are much bigger than PET and iPET. It is because that Schick and Schütze (2021) train each model three times and train the final PLM classifier on $3n$ models (n prompt patterns) for three rounds. This ensemble

Ex.	Method	Yelp	AG's	Yahoo	MNLI
10	UDA	27.3	72.6	36.7	34.7
	MixText	20.4	81.1	20.6	32.9
	iPET	52.9	87.5	67.0	42.1
	Ours	**55.6**	**89.0**	**70.3**	**42.8**
50	UDA	46.6	83.0	60.2	40.8
	MixText	61.3	84.8	61.5	34.8
	iPET	56.7	87.3	66.4	56.3
	Ours	**59.1**	**89.9**	**70.1**	**61.3**

Table 2: Accuracy comparison of ASCM+SL with other semi-supervised methods using RoBERTa (base).

learning eventually will improve stability and performance. In this work, we create three different datasets for each task (dataset and $|T|$) and retrain ASCM once in each SL round. If we retrain ASCM three times in each SL round, ASCM+SL shall get better results.

We further compare our works with other semi-supervised methods such as UDA and MixText. We take RoBERTa(base) as PLM and keep other hyper-parameters. Table 2 shows that ASCM+SL outperforms other methods even with smaller PLM.

5 Analysis

5.1 ASCM

ASCM needs no answer engineering and shows better performance than conventional prompt-based learning methods based on manual answer design.

As Table 3 shows, we compare ASCM with conventional prompt-based learning baseline which needs expertise to carefully design answer space. We train ASCM and baseline with the same hyper-parameters and report the average accuracies on all prompt patterns. With $|T| = 10$, ASCM significantly outperforms baseline by 7.9, 4.6, and 3.0 on Yahoo Yelp, and MNLI. With $|T| = 1000$, ASCM still attains better results on most tasks, showing the superiority of ASCM structure (semantic cluster then classification).

Ex.	Method	Yelp	AG's	Yahoo	MNLI
10	Baseline	48.4	82.2	54.1	45.5
	w/o SI	47.1	74.6	53.6	44.8
	w/o SCM	45.3	68.0	31.0	36.6
	ASCM	**53.0**	**82.5**	**62.0**	**48.5**
50	Baseline	58.0	87.9	64.6	63.2
	w/o SI	59.7	87.6	62.0	63.7
	w/o SCM	60.2	84.9	68.0	63.8
	ASCM	**61.2**	**88.3**	**68.4**	**68.9**
100	Baseline	60.5	88.7	66.4	69.7
	w/o SI	62.4	89.2	67.1	71.9
	w/o SCM	60.2	85.9	68.5	36.9
	ASCM	**62.7**	**89.2**	**68.6**	**74.1**
1000	Baseline	64.2	90.8	71.6	**82.0**
	w/o SI	64.2	90.7	71.9	75.7
	w/o SCM	62.8	87.5	70.9	35.8
	ASCM	**64.8**	**91.1**	**73.3**	80.5

Table 3: Comparison of ASCM with baseline. Average accuracies on four tasks for four training set sizes $|T|$ are reported. Line w/o SI refers to ASCM trained without SI and Line w/o SCM refers to ASCM without SCM.

We also conduct ablation experiments by training ASCM without SI or SCM. Without SI, although we pre-train the SCM and SC with PLMs encoder frozen, accuracies of ASCM-noSI is lower than baseline by a large margin on Yahoo and AG's. Compared with ASCM-noSI, ASCM gets significant improvement on all datasets, which shows the necessity of synonym initialization in ASCM. Meanwhile, with size $|T|$ getting bigger, ASCM-noSI attains a comparable performance with ASCM which imply the ability of PLM to find appropriate answer space. A much larger decline in performance, compared with ASCM-noSI, is also found in ASCM-noSCM on most tasks, especially on smaller $|T|$ tasks and MNLI. We consider that the original distribution of PLM token embedding isn't suitable for downstream token classification and the SCM with SI eases the problem. Detailed analysis can be found in 5.2.

5.2 SCM and SI

ASCM uses SCM to transform token embeddings to a semantic-clustered embedding space and categorizes them on this space by SC. Besides, ASCM takes the synonym initialization method to initialize SCM and SC. In this section, we explore their mechanism.

We list part of the synonym dataset generated from word2vec according to similarities. As Table 4 shows, synonyms generated from word2vec mostly get similar semantics or certain relationship. However, there is also wrong word *"theworld"* and cognates such as *"sport"*, *"businesses"*, etc. These synonyms, probably because of the characteristics of word2vec, might damage the ASCM, but we still keep them to avoid additional expertise.

We also test ASCM on evaluating corpora and list the top-5 tokens predicted on masked position according to frequency. Tokens belonging to the same categories get similar semantics or certain relationship and the results are much better than that of word2vec. ASCM also finds potential relationships such as *"NFL"* and shows a different tendency of tokens such as *"Science"* even with

Model	Category	Top-1	Top-2	Top-3	Top-4	Top-5
word2vec	World	World	globe	theworld	country	continent
	Sports	Sports	sport	sporting	athletics	football
	Business	Business	businesses	business	company	entrepreneurial
	Technology	Technology	technologies	innovation	technol	innovation
ASCM	World	World	Foreign	Military	/	/
	Sports	Sports	Football	NFL	NBA	/
	Business	Business	Economic	Energy	Company	/
	Technology	Tech	Science	Space	/	/

Table 4: Top-5 synonyms of query words for each category on AG's according to word2vec embedding similarities and top-5 most frequently predicted tokens of ASCM at the masked position on AG's. Tokens with frequency less than 100 are filtered (/).

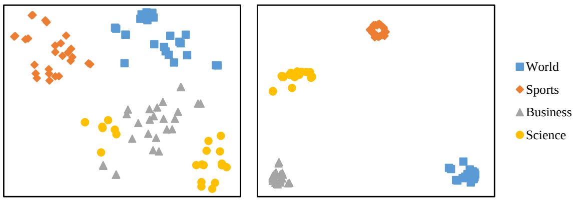

Figure 3: Distributions of original token embeddings (left) and token embeddings after SCM (Right) on AG-News.

word2vec synonym initialization. As we consider, PLM we use gets different linguistic knowledge and factual knowledge with word2vec because of different pre-training task, corpora, and network. And much knowledge existing in PLM is kept successfully thanks to the ASCM.

We further filter the misclassified tokens in synonym token embedding datasets. Then, we use PCA and tSNE (Van der Maaten and Hinton, 2008) to visualize the distributions of token embeddings before and after SCM. As Figure 3 shows, original token embeddings distribute according to categories. However, intra-class distances are too large and there exist several fault cluster, leading to poor classification performance. And just as we designed, token embeddings after SCM cluster to several embedding centers and the inter-class distances are enlarged, which makes ASCM works better especially in a few-shot setting.

Results on other tasks can be found in Table 10, Table 11, and Figure 5.

5.3 Generative Approach of Synonyms Datasets

As shown in Figure 2, both public pre-trained models and models trained on task-specific datasets can be adopted to generate synonym datasets. In this section, we evaluate several approaches on four tasks with $|T| = 10, 50$.

Ex.	Method	Yelp	AG's	Yahoo	MNLI
10	w/o SI	48.4	82.2	54.1	45.5
	Skip-gram	46.0	78.1	35.4	43.8
	CBOW	50.2	**82.7**	60.4	**51.0**
	ASCM	**53.0**	82.5	**62.0**	48.5
	Union	51.8	82.5	62.2	44.6
	Intersection	50.4	80.7	59.2	40.8
50	w/o SI	59.7	87.6	62.0	63.7
	Skip-gram	59.7	87.6	62.0	63.8
	CBOW	60.3	88.5	67.6	**69.5**
	ASCM	**61.2**	88.3	**68.4**	68.9
	Union	60.5	88.1	67.4	66.1
	Intersection	59.8	**88.7**	68.2	42.2

Table 5: Comparison of ASCM with different generative approaches. Average accuracies on four tasks for $|T| = 10, 50$ are reported. ASCM refers to adopting public pre-trained word2vec model as the generative approach.

As shown in Table 5, Skip-gram trained on task-specific datasets performs worse than ASCM-noSI, because of numerous misclassified words in synonym datasets. Public pre-trained word2vec (CBOW), which is better than CBOW trained on task-specific datasets on Yahoo and Yelp tasks but a bit worse on AG's and MNLI, is adopted as the basic approach (ASCM).

We also combine other methods such as public pre-trained FastText (Joulin et al., 2017) and Glove (Pennington et al., 2014) with word2vec. For similar reason to Skip-gram, the union set of the three synonyms datasets perform worse on most task. However, the intersection set with less misclassified words still gets worse, showing the necessity for the size of synonym dataset.

Ex.	Method	Yelp	AG's	Yahoo	MNLI
10	Baseline	63.0	88.3	71.1	63.3
	SL	**63.4**	**90.5**	**72.5**	**67.3**
50	Baseline	63.7	89.8	71.6	78.1
	SL	**64.2**	**90.8**	**72.5**	**78.4**
100	Baseline	**64.2**	90.0	71.3	79.7
	SL	63.9	**91.1**	**71.6**	**81.2**

Table 6: Accuracy comparison of SL and Baseline (iPET) method.

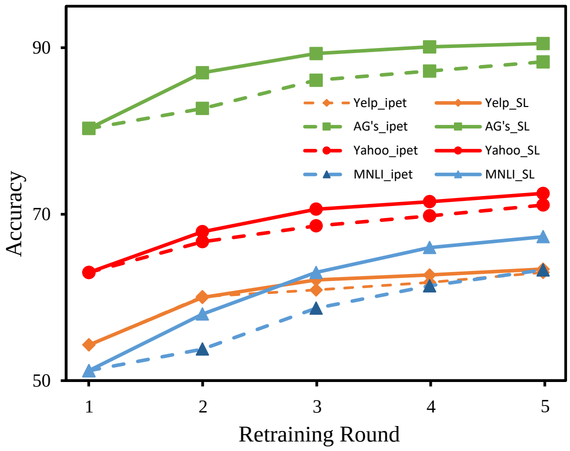

Figure 4: Average accuracy of ASCMs for each iPET and SL round with $|T| = 10$. Round 1 refers to the average accuracy of ASCMs trained on $|T|$ and round 5 refers to the training result for the final PLM classifier.

5.4 Stair Learning

We retrain ASCMs with iPET and SL on four datasets with $|T| = 10, 50, 100$. It's notable that we train ASCMs once for each iPET round. Base ASCMs and hyper-parameters are kept the same for comparison and results are reported in Table 6. ASCM+SL gets significant improvements than ASCM+iPET on most tasks especially when the size of labeled datasets is small. With $|T| = 10$, ASCM+SL outperforms ASCM+iPET by 4.0, 2.2, 1.4, and 0.4 on MNLI, AG's, Yahoo, and Yelp.

Average accuracies of all rounds with $|T| = 10$ are shown in Figure 4. The performances of iPET and SL keep improving in all rounds but the increments slow down with training rounds increasing. And SL gets larger increments because iPET distills knowledge from the randomly chosen models while SL distills knowledge from the best model of the round.

6 Conclusion

In conclusion, we propose an answer space clustered prompting model and a synonym initialization method that doesn't need answer engineering or expertise. Our method clusters token embeddings according to semantics and classifies them on unconstrained answer space. Experiments show that our method combined with a stable stair learning method outperforms the previous prompt-based learning methods based on manual answer design. Clustering multi-tokens words and phrases based on semantics is desirable for future work. In addition, research on adapting the thought of token embedding semantic-clustering to machine translation, text generation, information retrieval, and text summarization might also prove valuable.

Ex.	Yelp	AG's	Yahoo	MNLI
10	91.2	88.1	92.8	50.0
50	91.7	87.6	92.5	51.3
100	92.1	90.6	92.9	49.7
1000	92.1	88.7	93.4	51.3

Table 7: Average word classification accuracy for all ASCMs on categorized token embedding datasets.

Category	Synonyms
Contradiction	No, But, However, Instead, Yet, Actually, Whereas, Nevertheless
Entailment	Yes, Uh, yep, So, Therefore, consequently
Neutral	Maybe, probably, Further, Also, Neutral, perhaps, possibly

Table 8: Manually designed synonym dataset for MNLI.

A Synonym Initialization Details

For the synonyms generation models trained on task-specific datasets, we adopt the Genism library and the default training setting. Part of the synonym datasets generated by public pre-trained word2vec is listed in Table 10.

For fine-tuning of SCM and SC, we choose the Adam optimizer with a slanted triangular schedule with an initial learning rate of 1e-5, and a weight decay of 0.01. The batch size is set to 16 and the training epochs are set to 40. And we choose the model with the highest classification accuracy on the training synonym dataset to initialize ASCM.

B SCM and SI

We list the top-5 predicted tokens on masked position according to frequency by testing ASCM on evaluation corpora (Table 11). Compared to Table 10, there are big changes in both words (tokens) and order of words (tokens), which is similar to the analysis in section 5.2.

For the distribution visualization of token embeddings, misclassified words are removed from the synonym token embedding dataset. Besides, if a word gets multiple tokens by tokenization and the first token occurs in other words, we also filter that kind of words. For example, token “base” is the first token of “base” and “baseball”, which means ambiguity.

We further take categorized token embedding datasets as testing datasets and show the token classification accuracy of SCM and SC (Table 7). In

Method	**10**	**50**	**100**	**1000**
Auto	48.5	68.9	**74.1**	80.5
Manual	**58.7**	**71.1**	73.5	**81.4**

Table 9: ASCM accuracy on MNLI.

conformity to Figure 5, SCM and SC get high accuracy on Yelp, AG's, and Yahoo. For the MNLI task, ASCM only gets about 50% accuracy, because of the size (50) and poor quality of the MNLI synonym dataset.

Therefore, we manually designed a synonym dataset for MNLI task as shown in Table 8 and train ASCM based on it as shown in Table 9. Compared to automatically designed synonym dataset, there is a significantly increment with $|T| = 10$. It's encouraged to automatically generate a big synonym dataset at first and then do manually data cleaning.

C Training Details

All of our experiments are conducted using a single GPU with 32GB/16GB RAM (NVIDIA Tesla V100). Training a single PET with auxiliary language modeling for 300 steps on one GPU took approximately 20 minutes; retraining a single PET with auxiliary language modeling in SL for 300 steps on one GPU took approximately 20 minutes; Training a final PLM classifier for 5000 steps on one GPU took approximately 90 minutes. Labeling 10000 examples (per label) from D took approximately 13 minutes.

Why don't people use character-level machine translation?

Jindřich Libovický[1] and **Helmut Schmid**[2] and **Alexander Fraser**[2]

Abstract

We present a literature and empirical survey that critically assesses the state of the art in character-level modeling for machine translation (MT). Despite evidence in the literature that character-level systems are comparable with subword systems, they are virtually never used in competitive setups in WMT competitions. We empirically show that even with recent modeling innovations in character-level natural language processing, character-level MT systems still struggle to match their subword-based counterparts. Character-level MT systems show neither better domain robustness, nor better morphological generalization, despite being often so motivated. However, we are able to show robustness towards source side noise and that translation quality does not degrade with increasing beam size at decoding time.

1 Introduction

The progress in natural language processing (NLP) brought by deep learning is often narrated as removing assumptions about the input data and letting the models learn everything end-to-end. One of the assumptions about input data that seems to resist this trend is (at least partially) linguistically motivated segmentation of input data in machine translation (MT) and NLP in general.

For NMT, several papers have claimed parity of character-based methods with subword models, highlighting advantageous features of such systems. Very recent examples include Gao et al. (2020); Banar et al. (2020); Li et al. (2021). Despite this, character-level methods are rarely used as strong baselines in research papers and shared task submissions, suggesting that character-level models might have drawbacks that are not sufficiently addressed in the literature.

In this paper, we examine what the state of the art in character-level MT really is. We survey existing methods and conduct a meta-analysis of the input segmentation methods used in WMT shared task submissions. We then systematically compare the most recent character-processing architectures, some of them taken from general NLP research and used for the first time in MT. Further, we propose an alternative two-step decoder architecture that unlike standard decoders does not suffer from a slow-down due to the length of character sequences. Following the recent findings on MT decoding, we evaluate different decoding strategies in the character-level context.

Many previous studies on character-level MT drew their conclusions from experiments on rather small datasets and focused only on quantitatively assessed translation quality without further analysis. To compensate for this, we revisit and systematically evaluate the state-of-the-art approaches to character-level neural MT and identify their major strengths and weaknesses on large datasets.

2 Character-Level Neural MT

Character-level processing was hardly possible within the statistical MT paradigm that assumed the existence of phrases consisting of semantically rich tokens that roughly correspond to words. Neural sequence-to-sequence models (Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017) do not explicitly work with this assumption. In theory, they can learn to transform any sequence into any sequence.

The original sequence-to-sequence models used word-based vocabularies of a limited size and which led to a relatively frequent occurrence of out-of-vocabulary tokens. A typical solution to that problem is subword segmentation (Sennrich et al., 2016; Kudo and Richardson, 2018), which keeps frequent tokens intact and splits less frequent ones into smaller units.

Modeling language on the character level is attractive because it can help overcome several problems of subword models. One-hot representations

Findings of the Association for Computational Linguistics: ACL 2022, pages 2470 - 2485
May 22-27, 2022

of words or subwords do not reflect systematic character-level relations between words, potentially harming morphologically rich languages. With subwords, minor typos on the source side lead to radically different input representations resulting in low robustness towards source-side noise (Provilkov et al., 2020; Libovický and Fraser, 2020).

Models using recurrent neural networks (RNNs) showed early success with character-level segmentation on the decoder side (Chung et al., 2016). Using character-level processing on the encoder side proved harder which was attributed to the features of the attention mechanism which can presumably benefit from semantically rich units (such as subwords) in the encoder. Following this line of thinking, Lee et al. (2017) introduced 1D convolutions with max-pooling that pre-process the character sequence into a sequence of latent word-like states. Coupled with a character-level decoder, they claimed to match the state-of-the-art subword-based models. Even though this architecture works well on the character level, it does not generalize further to the byte level (Costa-jussà et al., 2017). Hybrid approaches combining tokenization into words with the computation of character-based word representations were successfully used with RNNs (Luong and Manning, 2016; Grönroos et al., 2017; Ataman et al., 2019). Later, Cherry et al. (2018) showed that RNNs perform on par with subword models without changing the model architecture if the models are sufficiently large. Kreutzer and Sokolov (2018) support this by showing that RNN models which learn segmentation jointly with the rest of the model are close to character-level.

Character-level modeling with Transformers appears to be more difficult. Gupta et al. (2019) used Transparent Attention (Bapna et al., 2018) to train deep character-level models and needed up to 32 layers to close the gap between the BPE and character models, which makes the model too large for practical use. Libovický and Fraser (2020) narrowed the gap between subword and character modeling using curriculum learning by finetuning subword models to character-level.

Gao et al. (2020) proposed adding a convolutional sub-layer in the Transformer layers. At the cost of a 30% increase in parameter count, they managed to narrow the gap between subword- and character-based models by half. Banar et al. (2020) reused the convolutional preprocessing layer with constant-size segments of Lee et al. (2017) in a Transformer model for translation into English. Without changing the decoder, they reached comparable, but usually slightly worse, translation quality compared to BPE-based models.

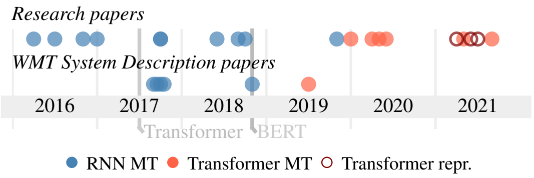

Figure 1: A timeline of research interest in character-level MT. Months of arXiv pre-print publication of the papers cited in Sections 2 and 3. Transformer repr. means pre-trained general-purpose sentence representation, not MT models.

Shaham and Levy (2021a) revisited character- and byte-level MT on rather small IWSLT datasets. Their results show that character-level and byte-level models are usually worse than BPE models, but byte-based models without embedding layers often outperform BPE-based models in the out-of-English direction. Using similarly small datasets, Li et al. (2021) claim that character-level modeling outperforms BPE when translating into fusional, agglutinative, and introflexive languages.

Nikolov et al. (2018) experimented with character-level models for romanized Chinese. These models performed comparable to models using logographic signs, but significantly worse than models using subwords. Zhang and Komachi (2018) argued that signs in logographic languages carry too much information and were able to improve the translation quality by segmenting Chinese and Japanese into sub-character units while keeping subword segmentation on the English side.

Little is known about other properties of character-level MT beyond the overall translation quality. Sennrich (2017) prepared a set of contrastive English-German sentence pairs and tested them using shallow RNN-based models. They observed that character-based models transliterated better, but captured morphosyntactic agreement worse. Libovický and Fraser (2020) evaluated Transformer-based character-level models using MorphEval and came to mixed conclusions.

Gupta et al. (2019) and Libovický and Fraser (2020) make claims about the noise robustness of the character-level models using synthetic noise. Li et al. (2021) evaluated domain robustness by training models on small domain-specific datasets and evaluating them on unrelated domains, claiming the superiority of character-level models in this setup. On the other hand, Gupta et al. (2019) evaluated the domain robustness in a more natural setup and did not observe higher robustness when evaluating general domain models on domain-specific tests compared to BPE.

Another consideration is longer training and inference times. Character-level systems are significantly slower due to the increased sequence length. Libovický and Fraser (2020) reported a 5.6-fold slowdown at training time and a 4.7-fold slowdown at inference time compared to subword models.

Recent research on character-level modeling goes beyond MT. Pre-trained multilingual representations are a particularly active area. Clark et al. (2021) propose CANINE. The model shrinks character sequences into fewer hidden states (similar to Lee et al., 2017). They use local self-attention and strided convolutions (instead of highway layers and max-pooling as in Lee's work). Their model is either trained using the masked-language-modeling objective (Devlin et al., 2019) with subword supervision, or in an encoder-decoder setup similar to Raffel et al. (2020). Both methods reach a representation quality comparable to similar subword models.

ByT5 (Xue et al., 2021a) and Charformer (Tay et al., 2021) are based on the mT5 model (Xue et al., 2021b) which uses sequence-to-sequence denoising pre-training. Whereas byT5 only uses byte sequences instead of subwords and differs in hyperparameters, Charformer uses convolution and combines character blocks to obtain latent subword representations. These models mostly reach similar results to sub-word models, occasionally outperforming a few of them, in the case of Charformer without a significant slowdown.

3 WMT submissions

The Conference on Machine Translation (WMT) organizes annual shared tasks in various use cases of MT. The shared task submissions focus on translation quality rather than the novelty of presented ideas, as most other research papers do. Therefore, we assume that, if character-level models were a fully-fledged alternative to subword models, at least some systems submitted to the shared tasks would use character-level models.

We annotated recent system description papers with the input and output segmentation method they used. We focused on information about exper-

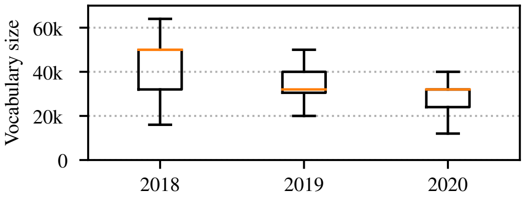

Figure 2: A boxplot of vocabulary sizes of WMT systems from 2018–2020, the median is denoted with the orange line.

iments with character-level models. Since we are primarily interested in the Transformer architecture that became the standard after 2017, we only included system description papers from 2018–2020 (Bojar et al., 2018; Barrault et al., 2019, 2020). Transformers were used in 81%, 87%, and 97% of the systems in the respective years. We included the main task on WMT, news translation, and two minor tasks where character-level methods might help: translation robustness (Li et al., 2019; Specia et al., 2020) and translation between similar languages (ibid.).

Almost all systems use a subword-based vocabulary (BPE: 81%, 71%, 66% in the respective years; SentencePiece: None in 2018, 9% and 25% in the following ones). Purely word-based (none in 2018, 2% and 3% in the later years) or morphological segmentation (4%, 2%, 3% in the respective years) are rarely used. The average vocabulary size decreases over time (see Figure 2) with a median size remaining at 32k in the last two years. The reason for the decreasing average is probably a higher proportion of systems for low-resource languages, where a smaller vocabulary leads to better translation quality (Sennrich and Zhang, 2019).

Among the 145 annotated system description papers, there were only two that used character-level segmentation. Mahata et al. (2018) used a character-level model for Finnish-to-English translation. This system, however, makes many suboptimal design choices and ended up as the last one in the manual evaluation. Scherrer et al. (2019) experimented with character-level systems for similar language translation and observed that characters outperform other segmentations for Spanish-Portuguese translation, but not for Czech-Polish. Knowles et al. (2020) experimented with different subword vocabulary sizes for English-Inuktikut translation and reached the best results using a subword vocabulary of size 1k, which makes it close to the character level. Most of the papers do not even mention character-level segmentation as a viable alternative they would like to pursue in future work (7% in 2018, 2% in 2019, none in 2020).

Character-level methods were more frequently used in WMT17 with RNN-based systems, especially for translation of Finnish (Escolano et al., 2017; Östling et al., 2017) and less successfully for Chinese (Holtz et al., 2017) and the automatic post-editing task (Variš and Bojar, 2017).

On the other hand, Figure 1 shows that the research interest in character-level methods remains approximately the same, or may have slightly increased. For practical solutions in WMT systems, we clearly show that system designers in the WMT community have avoided character-level models.

We speculate that the main reasons for not considering character-level modeling are its lower efficiency and the fact that the literature shows no clear improvement of translation quality. Most of the submissions use back-translation (85%, 82%, and 94% in the respective years), often iterated several times (11%, 20%, 16%), which requires both training and inference on large datasets. With the approximately 5-fold slowdown, WMT-scale experiments on character models are not easily tractable.

4 Evaluated Models

We evaluate several Transformer-based architectures for character-level MT. A major issue with character-level sequence processing is the sequence length and low information density compared to subword sequences. Architectures for character-level sequence processing typically address this issue by locally processing and shrinking the sequences into latent word-like units. In our experiments, we explore several ways to do this.

First, we directly use character embeddings as input to the Transformer. Second, following Banar et al. (2020), we use the convolutional character processing layers proposed by Lee et al. (2017). Third, we replace the convolutions with local self-attention as proposed in the CANINE model (Clark et al., 2021). Finally, we use the recently proposed Charformer architecture (Tay et al., 2021).

Lee-style encoding. Lee et al. (2017) process the sequence of character embeddings with convolutions of different kernel sizes and number of output channels. In the original paper, this was followed by 4 highway layers (Srivastava et al., 2015). In our preliminary experiments, we observed that a too deep stack of highway layers leads to diminishing gradients, and we replaced the second two Highway layers with feedforward sublayers as used in the Transformer architecture (Vaswani et al., 2017).

CANINE. Clark et al. (2021) experiment with character-level pre-trained sentence representations. The character-processing architecture is in principle similar to Lee et al. (2017) but uses more modern building blocks. Character embeddings are processed by a Transformer layer with local self-attention which only allows the states to attend to states in their neighborhood. This is followed by downsampling using strided convolution.

Originally, CANINE used a local self-attention span as long as 128 characters. In the case of MT, this would usually span the entire sentence, so we use significantly shorter spans.

Charformer. Unlike previous approaches, Charformer (Tay et al., 2021) does not apply a non-linearity on the embeddings and gets latent subword representations by repeated averaging of character embeddings. First, it processes the sequence using a 1D convolution, so the states are aware of their mutual local positions in local neighborhoods. Second, non-overlapping character n-grams of length up to N are represented by averages of the respective character embeddings. This means that for each character, there is a vector that represents the character as a member of n-grams of length 1 to N. In the third step, the character blocks are scored with a scoring function (a linear transformation), which can be interpreted as attention over the N different n-gram lengths. The attention scores are used to compute a weighted average over the n-gram representations. Finally, the sequence is downsampled using mean-pooling with window size and stride size N (i.e., the maximum n-gram size).

Whereas Lee-style encoding allows using low-dimensional character embeddings and keeps most parameters in the convolutional layers, CANINE and Charformer need the character representation to have the same dimension as the following Transformer layer stack.

Two-step decoding. The architectures mentioned above allow the Transformer layers to operate more efficiently with a shorter and more information-dense sequence of states. However, while decoding, we need to generate the target character sequence in the original length, by outputting a block of characters in each decoding step. Our preliminary experiments showed that generating

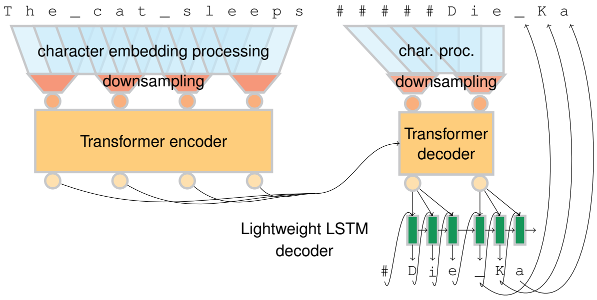

Figure 3: Encoder-decoder architecture with character-processing layers and a two-step decoder with lightweight LSTM for output coherence.

blocks of characters non-autoregressively leads to incoherent output. Therefore, we propose a two-step decoding architecture where the stack of Transformer layers operating over the downsampled sequence is followed by a lightweight LSTM autoregressive decoder (see Figure 3).

The input to the LSTM decoder is a concatenation of the embedding of the previously generated character and a projection of the Transformer decoder output state. At inference time, the LSTM decoder generates a block of characters and inputs them to the character-level processing layer. The Transformer decoder computes an output state that the LSTM decoder uses to generate another character block. More details are in Appendix A.

Modifying Charformer for the two-step decoding would require a long padding at the beginning of the sequence causing the decoder to diverge. Because of that, we use Lee-style encoding on the decoder side when using Charformer in the encoder.

First, we conduct all our experiments on the small IWSLT datasets. Then we evaluate the most promising architectures on larger datasets.

5 Experiments on Small Data

We implement the models using Huggingface Transformers (Wolf et al., 2020). We take the CANINE layer from Huggingface Transformers and use an independent implementation of Charformer[1]. Our source code is available on Github.[2] Hyperparameters and other experimental details can be found in Appendix B.

5.1 Experimental Setup

We evaluate the models on translation between English paired with German, French, and Arabic (with English as both input and output) using the IWSLT 2017 datasets (Cettolo et al., 2017) with a training data size of around 200k sentences for each language pair (see Appendix B for details).

For the subword models, we tokenize the input using the Moses tokenizer (Koehn et al., 2007) and then further split the words into subword units using BPE (Sennrich et al., 2016) with 16k merge operations. For the character models, we limit the vocabulary to 300 UTF-8 characters.

We use the Transformer Base architecture (Vaswani et al., 2017) in all experiments. We make no changes to it in the subword and baseline character experiments. In the later experiments, we replace the embedding lookup with the character processing architectures. For the Lee-style encoder, we chose similar hyperparameters as related work (Banar et al., 2020). For experiments with Charformer and CANINE models, we set the hyperparameters such that they cover the same character span before downsampling as the Lee-style encoder, which causes the models to have fewer parameters than a Lee-style encoder. Note however that for both the Charformer and the CANINE models, the number of parameters is almost independent of the character window width. For all three character processing architectures, we experiment with downsampling factors of 3 and 5 (a 16k BPE vocabulary corresponds to a downsampling factor of about 4 in English).

5.2 Translation Quality

We evaluate the translation quality using the BLEU score (Papineni et al., 2002), the chrF score (Popović, 2015) (as implemented in SacreBLEU; Post, 2018),[3] and the COMET score (Rei et al., 2020). We run each experiment 4 times and report the mean value and standard deviation.

The results are presented in Table 1. Except for translation into Arabic, where character methods outperform BPEs (which is consistent with the findings of Shaham and Levy, 2021a and Li et al., 2021), subword methods are always better than characters.

The Lee-style encoder outperforms the two more recent methods and the method of using the character embeddings directly. Charformer performs similarly to using character embeddings directly,

Table 1: Translation quality of the models on the IWSLT data. The fourth column shows the size of the character-processing layers expressed as the vocabulary size of Transformer Base having the same number of parameters in the embeddings.

CANINE is significantly worse. The results are mostly consistent across the language pairs.

Increasing the downsampling rate from 3 to 5 degrades the translation quality for all architectures. Employing the two-step decoder matches the decoding speed of subword models. However, the overall translation quality is much worse.

The three metrics that we use give consistent results in most cases. Often, relatively small differences in BLEU and chrF scores correspond to much bigger differences in the COMET score.

5.3 Inference

Inference algorithms for neural MT have been discussed extensively (Meister et al., 2020; Massarelli et al., 2020; Shi et al., 2020; Shaham and Levy, 2021b) for the subword models. Subword translation quality quickly degrades beyond a certain beam width unless heuristically defined length normalization is applied.

As an alternative, Eikema and Aziz (2020) recently proposed Minimum Bayes Risk (MBR; Goel and Byrne 2000) estimation as an alternative. Assuming that similar sentences should be similarly probable, they propose repeatedly sampling from the model and selecting a sentence that is most similar to other samples. With subword models, MBR performs comparably to beam search.

Intuitive arguments about the inference algorithms are often based on the properties of the subword output distribution. On average, character models will produce distributions with lower perplexity and thus likely suffer more from the exposure bias which might harm sampling from the model. Therefore, there is a risk that these empirical findings do not apply to character-level models.

We explore what decoding strategies are best suited for the character-level models. We compare the translation quality of beam search decoding with different degrees of length normalization.[4] Further, we compare length-normalized beam search decoding with MBR (with 100 samples), greedy decoding, and random sampling. We use the chrF as a comparison metric which allows pre-computing the character n-grams and thus faster sentence pair comparison than the originally proposed METEOR (Denkowski and Lavie, 2011).

Figure 4 shows the translation quality of the selected models for different beam sizes. The dotted lines denoting the translation quality without length normalization show that the quality of the subword models quickly deteriorates without length normalization, whereas vanilla and Lee-style character-level models do not seem to suffer from this problem.

Table 2 presents the translation quality for different decoding methods. In all cases, beam search

---

[4] As we increase beam size, the number of search errors is decreasing, but here we are evaluating modeling errors, not search errors.

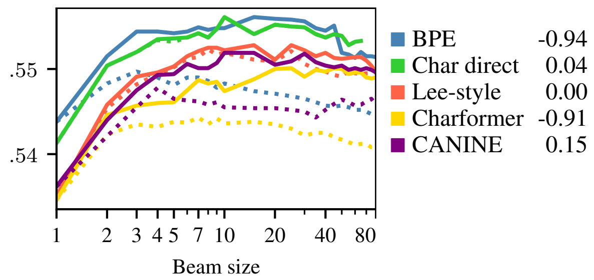

Figure 4: chrF scores for IWSLT en-de translation for different models and beam sizes. The dotted lines are without length normalization, the solid lines are with length normalization. All character processing architectures use a downsampling window of size 3. The legend tabulates the Pearson correlation of the beam size (starting from 5) and the chrF score.

Model	Enc. downsample	Dec. downsample	Sample	Greedy	Beam	MBR

			-1.500	0.051	0.121	-0.838
	3	3	0.253	0.516	0.534	0.413
			-1.680	-0.097	-0.034	-1.130

Table 2: chrF (yellow-green scale) and COMET (yellow-red scale) scores for decoding methods for models trained on en-de systems.

is the best strategy. Sampling from character-level models leads to very poor translation quality that in turn also influences the MBR decoding leading to much worse results than beam search.

Our experiments show that beam search with length normalization is the best inference algorithm for character-level models. They also seem to be more resilient towards the beam search curse compared to subword models.

6 Experiments on WMT Data

Based on the results of the experiments with the IWSLT data, we further experiment only with the Lee-style encoder using a downsampling factor of 3 on the source side. Additionally, we experiment with hybrid systems with a subword encoder and character decoder. We train translation systems of competitive quality on two high-resource language pairs, English-Czech and English-German, and perform an extensive evaluation.

6.1 Experimental Setup

For English-to-Czech translation, we use the CzEng 2.0 corpus (Kocmi et al., 2020b) that aggregates and curates all sources for this language pair. We use all 66M authentic parallel sentence pairs and 50M back-translated Czech sentences.

For the English-to-German translation, we use a subset of the training data used by Chen et al. (2021). The data consists of 66M authentic sentence pairs filtered from the available data for WMT and 52M back-translated German sentences from News Crawl 2020.

We tag the back-translation data (Caswell et al., 2019). We use the Transformer Big architecture for all experiments with hyperparameters following Popel and Bojar (2018). For the Lee-style encoder, we double the hidden layer sizes compared to the IWSLT experiments (following the hidden size increase between the Transformer Base and Big architectures). In contrast to the previous set of experiments, we use Fairseq (Ott et al., 2019). Our code is available on Github[5]. System outputs are attached to the paper in the ACL anthology.

We evaluate the systems not only on WMT20 test sets but also on data that often motivated the research of character-level methods. We evaluate the out-of-domain performance of the models on the NHS test set from the WMT17 Biomedical Task (Jimeno Yepes et al., 2017) and on the WMT16 IT Domain test set (Bojar et al., 2016). We use the same evaluation metrics as for the IWSLT experiments. We estimate the confidence intervals using bootstrap resampling (Koehn, 2004).

We also assess the gender bias of the systems (Stanovsky et al., 2019; Kocmi et al., 2020a), using a dataset of sentence pairs with stereotypical and non-stereotypical English sentences. We measure the accuracy of gendered nouns and pronouns using word alignment and morphological analysis.

Morphological generalization is often mentioned among the motivations for character-level modeling. Therefore, we evaluate our models using MorphEval (Burlot and Yvon, 2017; Burlot et al., 2018).

---

Table 3: Results of the WMT-scale experiments.

Similar to the gender evaluation, MorphEval also uses contrastive sentence pairs that differ in exactly one morphological feature. Accuracy on the sentences is measured. Besides, we assess how well the models handle lemmas and forms that were unseen at training time. We tokenize and lemmatize all data with UDPipe (Straka and Straková, 2017). On the WMT20 test set, we compute the recall of test lemmas that were not in the training set and the recall of word forms that were not in the training data, but forms of the same lemma were. Note that not generating a particular lemma or form is not necessarily an error. Therefore, we report the recall in contrast with the recall of lemmas and forms that were represented in the training data.

Character-level models are also supposed to be more robust towards source-side noise. We evaluate the noise robustness of the systems using synthetic noise. We use TextFlint (Wang et al., 2021) to generate synthetic noise in the source text with simulated typos and spelling errors. We generate 20 noisy versions of the WMT20 test set and report the average chrF score.

6.2 Results

The main results are presented in Table 3. The main trends in the translation quality are the same as in the case of IWSLT data: subword models outperform character models. Using Lee-style encoding narrows the quality gap and performs similarly to models with subword tokens on the source side. Although domain robustness often motivates character-level experiments, our experiments show that the trends are domain-independent, except for English-German IT Domain translation.

The similar performance of the subword encoder and the Lee-style encoder suggests that the hidden states of the Lee-style encoder can efficiently emulate the subword segmentation. We speculate that the main weaknesses remain on the decoder side.

In the English-to-Czech direction, the character-level models perform worse in gender bias evaluation, although they better capture grammatical gender agreement according to the MorphEval benchmark. On the other hand, character-level models make more frequent errors in the tense of coordinated verbs. There are no major differences in recall of novel forms and lemmas.

For the English-to-German translation, character-level methods reach better results on the gender benchmark. We speculate that getting gender correct in German might be easier because unlike Czech it does not require subject-verb agreement. The average performance on the MorphEval benchmark is also slightly better for character models. Detailed results on MorphEval are in Tables 7 and 8 in the Appendix. The higher recall of novel forms also suggests slightly better morphological generalization.

The only consistent advantage of the character-level models is their robustness towards source side noise. Here, the character-level models outperform both the fully subword model and the subword encoder.

7 Conclusions

In our extensive literature survey, we found evidence that character-level methods should reach comparative translation quality as subword methods, typically at the expense of much higher computation costs. We speculate that the computational cost is the reason why virtually none of the recent WMT systems used character-level methods or mentioned them as a reasonable alternative.

Recently, most innovations in character-level modeling were introduced in the context of pretrained representations. In our comparison of character processing architectures (two of them used for the first time in the context of MT), we showed that 1D convolutions followed by highway layers still deliver the best results for MT.

Character-level systems are still mostly worse than subword systems. Moreover, the recent character-level architectures do not show advantages over vanilla character models, other than improved speed.

To overcome efficiency issues, we proposed a two-step decoding architecture that matches the speed of subword models, however at the expense of a further drop in translation quality.

Furthermore, we found that conclusions of recent literature on decoding in MT do not generalize for character models. Character models do not suffer from the beam search curse and decoding methods based on sampling perform poorly, here.

Evaluation on competitively large datasets showed that there is still a small quality gap between character and subword models. Character models do not show better domain robustness, and only slightly better morphological generalization in German, although this is often mentioned as important motivation for character-level modeling. The only clear advantage of character models is high robustness towards source-side noise.

In contrast to earlier work on character-level MT, which claimed that decoding is straightforward and which focused on the encoder part of the model, our conclusions are that Lee-style encoding is comparable to subword encoders. Even now, most modeling innovations focus on encoding. Character-level decoding which is both accurate and efficient remains an open research question.

Acknowledgement

Many thanks to Martin Popel for comments on the pre-print of this paper and to Lukas Edman for discovering a bug in the source code and for a fruitful discussion on the topic of the paper.

A Two-step decoder

Here, we describe details of the architecture of the two step decoder shown in Figure 3. The input of the decoder are hidden states of the character processing architecture, i.e., for a downsampling factor s, a sequence that is s times shorter than the input sequence. The output of the Transformer stack is a sequence of the same length.

For each Transformer decoder state h_i, the decoder needs to produce s characters. This is done by a light-weight autoregressive LSTM decoder. In each step, it has two inputs: the embedding of the previously decoded character and a projection of the decoder state h_i. There are s different linear projections for each of the output character generated from a single Transformer state.

At inference time, the LSTM decoder gets one Transformer state and generates s output characters. The characters are fed to the character processing architecture, which is in turn used to generate the next Transformer decoder state.

B IWSLT Experiments

B.1 Dataset details

We used the `tst2010` part of the dataset for validation and `tst2015` for testing and did not use any other test sets. The data sizes are presented in Table 4.

B.2 Model Hyperparameters

All models are trained with initial learning rate: $5 \cdot 10^{-4}$ with 4k warmup steps. The batch size is 20k tokens for both BPE and character experiments with update after 3 batches. Label smoothing is set to 0.1.

Lee-style. The character embedding dimension is 64. The original paper used kernel sizes from 1 to 8. For ease of implementation, we only use even-sized kernels up to size 9. The encoder uses 1D convolutions of kernel size 1, 3, 5, 7, 9 with 128, 256, 512, 512, 256 filters. Their output is concatenated and projected to the model dimension, followed by 2 highway layers and 2 Transformer feed-forward layers.

CANINE. The local self-attention span in the encoder is 4× the downsampling factor, in the encoder, equal to the downsampling factor.

Two-step decoder. The decoder uses character embeddings with dimension of 64, which is also the size of the projection of the Transformer decoder state. The hidden state size of the LSTM is 128.

B.3 Validation Performance

The validation BLEU and chrF scores and training and inference times are in Table 5. The training times were measured on machines with GeForce GTX 1080 Ti GPUs and with Intel Xeon E5–2630v4 CPUs (2.20GHz), a single GPU was used.

Note that the experiments on IWSLT were not optimized for speed and are thus not comparable with the times reported on the larger datasets.

C WMT Experiments

C.1 Training Details

We use the Transformer Big architecture as defined FairSeq's standard `transformer_wmt_en_de_big_t2t`. The Lee-style encoder uses filters sizes 1, 3, 5, 7, 9 of dimensions 256, 512, 1024, 1024, 512. The other parameters remains the same as in the IWSLT experiments.

We set the beta parameters of the Adam optimizer to 0.9 and 0.998 and gradient clipping to 5. The learning rate is $5 \cdot 10^{-4}$ with 16k warmup steps. Early stopping is with respect to negative log likelihood with patience 10. We save 5 best checkpoints and do checkpoint averaging before evaluation. The maximum batch size is 1800 tokens for the BPE experiments and 500 for character-level experiments. We train the models on 4 GPUs, so the effective batch size is 4 times bigger.

C.2 Validation Performance

During training, we evaluated the models by measuring the cross-entropy on the validation set. After model training, we use grid search to estimate the best value of length normalization on the validation set. The translation quality on the validation data is tabulated in Table 6.

C.3 Detailed Results

The detailed results on the MorphEval benchmark are in Tables 7 (Czech) and 8 (German). The details of the noise evaluation are in Table 9.

Abstract

Math Word Problem (MWP) solving needs to discover the quantitative relationships over natural language narratives. Recent work shows that existing models memorize procedures from context and rely on shallow heuristics to solve MWPs. In this paper, we look at this issue and argue that the cause is a lack of overall understanding of MWP patterns. We first investigate how a neural network understands patterns only from semantics, and observe that, if the prototype equations like $n_1 + n_2$ are the same, most problems get closer representations and those representations apart from them or close to other prototypes tend to produce wrong solutions. Inspired by it, we propose a contrastive learning approach, where the neural network perceives the divergence of patterns. We collect contrastive examples by converting the prototype equation into a tree and seeking similar tree structures. The solving model is trained with an auxiliary objective on the collected examples, resulting in the representations of problems with similar prototypes being pulled closer. We conduct experiments[1] on the Chinese dataset Math23k and the English dataset MathQA. Our method greatly improves the performance in monolingual and multilingual settings.

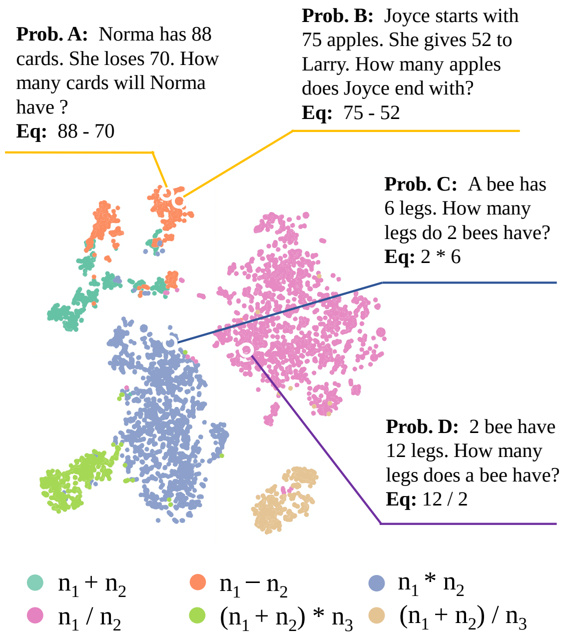

Figure 1: The visualization of the problem representations by T-SNE. "Prob." and "Eq" are short for the math word problem and its solution equation. The problem A and B are in the same prototype equation "$n_1 - n_2$". The problem C and D are semantically similar.

1 Introduction

A Math Word Problem (MWP) is described as a natural language narrative with a math question. The MWP solver is required to generate a solution equation, which can be calculated to get the numerical answer, by understanding the contextual problem description.

In teaching, students are encouraged to recognize that mathematics is really about patterns and not merely about numbers (Council, 1989). Mathematically excellent students explore patterns, not just memorize procedures (Schoenfeld, 1992). Recently, Patel et al. (2021) mention that existing MWP models (Xie and Sun, 2019; Zhang et al., 2020) rely on shallow heuristics to generate equations. These models can predict solutions well even if leaving only narratives without questions, which suggests that neural networks learn to solve MWPs by memorizing the lexical input like rote learning. Thus, existing models get stuck in memorize procedures. We look at this issue and hypothesize it is because they focus on text understanding or equation generation for one problem. The same quantitative relationship corresponds to many problems of different themes and scenarios, but previ-

ous methods overlook the outlining and distinction of MWP patterns.

In this work, we first investigate how a neural network understands MWP patterns only from semantics. We adopt the widely used encoder-decoder model structure (Cho et al., 2014). BERT (Devlin et al., 2019) is employed as the semantic encoder, and a tree decoder (Xie and Sun, 2019) is adopted to generate equations. We probe the problem representations in BERT. The visualization by T-SNE (van der Maaten and Hinton, 2008) in Figure 1 shows that, through the semantic encoder, most representations of problems with the same prototype equation are pulled closer, even if their narratives are semantically different. We also analyze the representations in different BERT layers, and the results show the lexical semantics mainly affects the problem-solving in lower layers. Besides, for each prototype equation, those problem representations far away from its center representation tend to produce incorrect solutions.

Inspired by it, we propose a contrastive learning approach that seeks similar prototypes to support model to better understand patterns and perceive the divergence of patterns. When collecting contrastive examples, we follow Xie and Sun (2019) to convert the prototype equation to a tree. Given an equation tree, the positive examples are retrieved if their trees or subtrees have the same structure, and the negative examples are collected from the rest in terms of the operator types and the size of the tree. The solving model is first jointly optimized by an equation generation loss and a contrastive learning loss on the collected examples, and then, is further trained on the original dataset. While the generation loss empowers the model to memorize procedures from the semantics, the contrastive learning loss brings similar patterns closer and disperses the different patterns apart.

We conduct experiments on the Chinese dataset Math23k (Wang et al., 2017) and the English dataset MathQA (Amini et al., 2019) in monolingual and multilingual settings. To support constructing multilingual contrastive examples, we follow Tan et al. (2021) to adapt MathQA as the counterpart of Math23k. Experimental results show that our method achieves consistent gains in monolingual and multilingual settings. In particular, our method allows the model to improve the performance in one language using data in another language, which suggests that MWP patterns are language-independent. Furthermore, we verify that, through our contrastive learning, the representations that previously generate wrong solutions get closer to their centers, and several problems are solved well.

To summarize, the contributions of this paper include: i) An analysis of the MWP model showing that the semantic encoder understands lexical semantics in lower layers and gathers the prototype equations in higher layers. ii) A contrastive learning approach helping the model to better understand MWP patterns and perceive the divergence of patterns. iii) Applications in the multilingual setting suggesting that we can further improve the model performance using data in different languages.

2 Related Work

2.1 Math Word Problem Solving

Given a natural language narrative with a mathematical question, the task is to generate a solution equation to answer the question. The methods can be divided into four categories: rule-based methods (Fletcher, 1985; Bakman, 2007), statistical machine learning methods (Kushman et al., 2014; Hosseini et al., 2014), semantic parsing methods (Shi et al., 2015; Koncel-Kedziorski et al., 2015) and deep learning methods (Wang et al., 2017; Huang et al., 2018a,b; Xie and Sun, 2019; Zhang et al., 2020).

Deep learning methods have achieved significant improvement on MWP solving. Wang et al. (2017) first attempt to use recurrent neural networks to build a seq2seq solving model. Xie and Sun (2019) propose a tree-structured decoder to generate an equation tree. Syntactically correct equations can be generated through traversing the equation tree. Zhang et al. (2020) apply graph convolutional networks to extract relationships of quantities in math problems. Recently, unsupervised pretraining of language models (Devlin et al., 2019; Yang et al., 2019a) has provided informative contextual representations for text understanding, and fine-tuning techniques (Cui et al., 2019; Li et al., 2021) have brought further performance gains. Several works (Kim et al., 2020; Tan et al., 2021; Cobbe et al., 2021) based on pretrained language models enhance the ability of problem understanding.

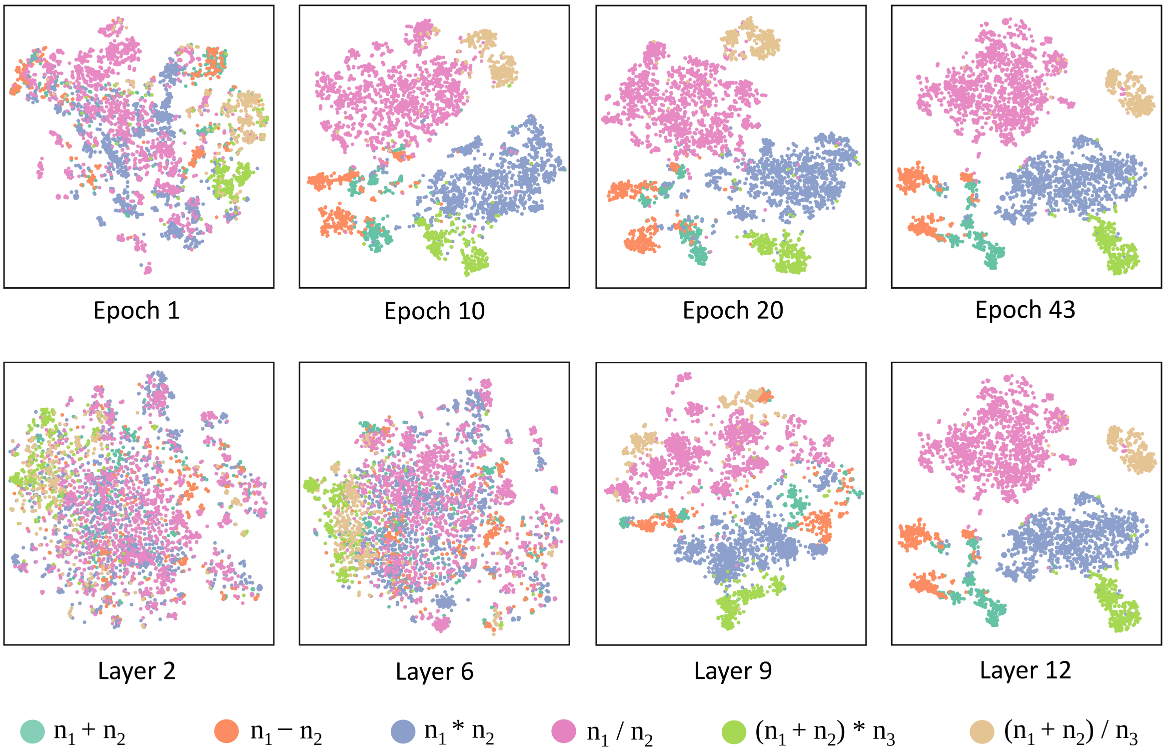

Figure 2: The T-SNE visualization of problem representations in different epochs and different layers. Different colors represent different prototype equations. The model achieves the highest accuracy at the training epoch 43.

2.2 Contrastive Learning

Contrastive learning is a method of representation learning, which is first designed by Hadsell et al. (2006). By pulling semantically similar embeddings together and pushing semantic different ones apart, contrastive learning can provide more effective representations. In NLP, similar approaches have been explored in many fields. Bose et al. (2018) develop a sampler to find harder negative examples, which forces the model to learn better word and graph embeddings. Yang et al. (2019b) use contrastive learning to reduce word omission errors in neural machine translation. Clark et al. (2020) train a discriminative model on contrastive examples to obtain more informative language representations. Gao et al. (2021) advance the performance of sentence embeddings by using contrastive learning in supervised and unsupervised settings. Yu et al. (2021) develop a contrastive self-training to help language model fine-tuning and label denoising in weak supervision.

To the best of our knowledge, this is the first work to adopt contrastive learning to MWP solving. With the supervision of contrastive learning, we seek similar MWP patterns to pull them closer, and collect confusing patterns to push them apart.

3 Semantic Encoder Gathers Prototypes

In this section, we explore how a neural network understands patterns from semantics. We adopt the encoder-decoder model structure to solve problems, and perform analyses on the problem representations. The observation is that the semantic encoder understands lexical semantics at lower layers and gathers the prototype equations at higher layers.

3.1 Experimental Setup

3.1.1 Datasets

We perform analyses on two widely used datasets Math23k (Wang et al., 2017) and MathQA (Amini et al., 2019). The Math23k dataset is composed of 23k MWPs in elementary education, and the MathQA has 37k MWPs with multiple choices and equations.

3.1.2 Model Architecture

Semantic Encoder The pre-trained language model BERT (Devlin et al., 2019) is employed as the semantic encoder. The unsupervised pre-training on large corpora renders the model to learn linguistic knowledge, which provides rich textual representations.

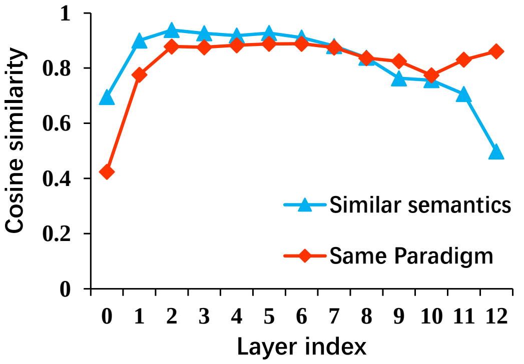

Figure 3: Similarities of problem representations in different BERT layers. The blue polyline corresponds to the semantically similar problems. The red polyline corresponds to problems with same prototype equation.

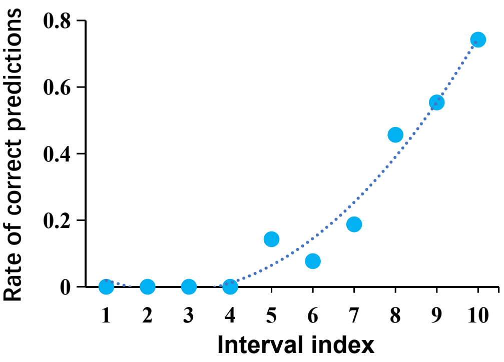

Figure 4: Model performance in each distance interval. The interval index x indicates the cosine distances are in the interval $[0.1 \times (x-1), 0.1 \times x)$. The dotted line is computed by polynomial least squares fitting.

Equation Decoder A tree decoder (Xie and Sun, 2019) is adopted to generate solution equations. We use the BERT-encoded representation of `[CLS]` token to initialize the root node when decoding. Recursively, the decoder generates the embedding of each node, and predicts the probabilities of number and operator candidates.

For brevity, we denote our model as **BERT-TD**. The model takes the textual problem description as the input and is optimized by minimizing the negative log-likelihoods of node probabilities for predicting the ground-truth equation tree.

3.2 Shifts of Problem Representation

To explore how the neural model learns MWP patterns during training, we first extract BERT-encoded representations of `[CLS]` token in different epochs and different layers. Then we perform the T-SNE visualization (van der Maaten and Hinton, 2008) shown in Figure 2. The representations of different epochs are picked from the top layer of BERT, and the representations of different layers are picked from the best trained model. It can be seen that, as the training goes on, the representations with the same prototype equation are gathering. Besides, with the increase of the depth of encoder layers, the gathering tendency becomes more and more obvious.

Intuitively, the prototype equation exhibits the essential relationship between the quantities in MWP. These results also verify that the patterns learned by the neural model are directly associated with the prototype equations.

3.3 Semantics and Prototype Equation

From the visualizations, we can not see how semantics affects problem-solving. To this end, we collect 20 problem pairs with similar lexical semantics but exactly different prototypes, and 20 problem pairs with the same prototype but in different themes or scenarios. Not like taking the `[CLS]` representation in Section 3.2, we average the representations over all words in one problem. The cosine similarities of the averaged representations are calculated for these problem pairs in different BERT layers.

The averaged similarities are shown in Figure 3. The semantically similar problems obtain higher values in lower layers but the similarity gradually decreases as the model deepens. Meanwhile, with the increase of the model depth, although in different semantics, the problems with the same prototype equation achieve higher similarity. This demonstrates that lexical semantics affects problem-solving at lower layers, and the model further extracts prototypes from the semantics at higher layers.

3.4 Clustering and Solving Ability

With the above observation, we attempt to discover the relationship between prototype clustering and model performance. For each prototype equation, we first average the representations of the corresponding problems to obtain its center point, and then calculate the cosine distances between representations and its centers. A higher cosine distance means the representation is closer to its center. We split the cosine distance into several intervals and compute the proportion of correct predictions for each interval. The results are shown in Figure 4,

Problem	Prototype Equation
Larry starts with n_1 cards. n_2 are eaten by a hippopotamus. How many cards does Larry end with?	$n_1 - n_2$
Frank made n_1 dollars mowing lawns over the summer. If he spent n_2 dollars buying new mower blades, how many n_3 dollar games could he buy with the money he had left?	$(n_1 - n_2)/n_3$

Table 1: Math word problems with the same quantitative relationship, i.e. the subtraction of numerics n_1 and n_2. The same prototype equations are in red color.

which suggests that the representations apart from centers tend to produce wrong solutions.

4 Contrastive Learning

In this section, we propose a contrastive learning approach to help the model to perceive the divergence of MWP patterns. One drawback of existing deep learning methods is that they overlook the outlining and distinction of MWP patterns. In contrast, we seek similar prototype equations from various problems to support model to understand patterns, and collect easily confused patterns for model to distinguish.

4.1 Data Collection

We construct contrastive MWP triples (p, p^+, p^-) containing a basic problem p and its positive and negative examples $\{p^+, p^-\}$.

Positive Example One direct way is to collect problems whose prototype equation is completely the same as the given problem p. However, the same quantitative relationship in p also exists in other problems. As shown in Table 1, for the second problem, before answering "How many games could he buy?", another hidden question is "How much money does he have?" whose solving equation is in the same prototype as the first problem. Thus, we parse the prototype equation to tree structure by following Xie and Sun (2019) and consider its sub-equations and subtrees. The problem p^+ is taken as a positive example if its tree or subtree has the same structure as p, such as "$tree$" and the subtree of "$tree^+$" in Figure 5.

Negative Example Bose et al. (2018) and Kalantidis et al. (2020) stress the importance of hard negative examples in contrastive learning. If we choose p^- whose prototype is totally different from p, the original MWP model can easily distinguish them apart. Thus, in this work, the problem p^- is chosen as a hard negative example if its tree has the same number of nodes but different operator node types, such as "$tree$" and "$tree^-$" in Figure 5. With the training on hard negative examples, our model can distinguish more subtle differences from various prototypes, and further grasp the inner pattern of MWP.

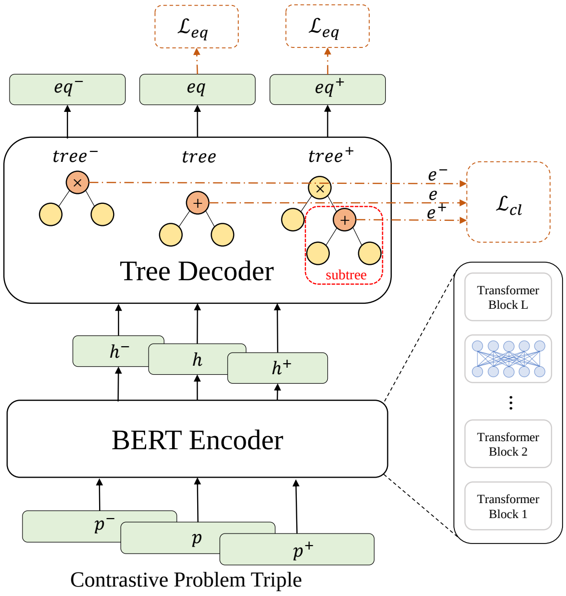

Figure 5: An overview of our model.

4.2 Training Procedure

We train the model on our contrastive problem triples. As shown in Figure 5, the problems are first encoded by BERT, and then the tree decoder predicts the nodes of the equation tree.

During contrastive learning, the triple $z = (p, p^+, p^-)$ are input to the model together to predict equation trees. Owing to the decoding manner of Xie and Sun (2019), each node embedding represents the whole subtree information rooted in it. The root node embeddings of the problem p and its negative problem p^- are picked for model to distinguish. For its positive problem p^+, we find the root node of the tree or subtree containing the same structure as p, and pull its embedding closer to that of p. For brevity, we denote these node embeddings as (e, e^+, e^-) and the contrastive learning loss becomes:

$$\mathcal{L}_{cl} = \sum_{z} \max(0, \eta + sim(e, e^-) \\ - sim(e, e^+)), \tag{1}$$

Dataset	#Train	#Dev	#Test
Math23k	21,162	1,000	1,000
MathQA	29,837	4,475	2,985
MathQA†	23,703	3,540	2,410

Table 2: Statistics of the used datasets. The "MathQA†" is the adapted MathQA dataset by following Tan et al. (2021).

where $sim(\cdot)$ is the cosine similarity, and the η is a margin hyper-parameter.

The basics of a MWP solving model is to generate a solution equation to answer the math question. We transform the target equation y into Polish notation as $[y_1, y_2, ..., y_m]$, where m is the equation length. The tree decoder generates k-node token y_k recursively, and the loss of generating equation is computed as:

$$\mathcal{P}(y|p) = \prod_{k=1}^{m} \mathcal{P}(y_k|p) \tag{2}$$

$$\mathcal{L}_{eq} = \sum_{p} - \log \mathcal{P}(y|p) \tag{3}$$

The final training objective is to minimize the equation loss and contrastive loss as follows:

$$\mathcal{L} = \mathcal{L}_{eq} + \alpha \cdot \mathcal{L}_{cl} \tag{4}$$

where α is a hyper-parameter that represents the importance of the contrastive learning.

However, not all problems have positive examples, such as those problems whose solution is one value without any operator. With this in mind, we develop the two-stage training strategy. The MWP solver is first trained on our contrastive triples at stage I, and then further trained on the original dataset at stage II.

5 Experiments

We evaluate our method on two widely used datasets (Wang et al., 2017; Amini et al., 2019), and demonstrate its effectiveness in monolingual and multilingual settings.

5.1 Configuration

Data and Metrics We collect problems from the Chinese dataset Math23k (Wang et al., 2017) and the English dataset MathQA (Amini et al., 2019). As the formula formats of the two datasets are different, we follow Tan et al. (2021) to adapt MathQA as a counterpart of Math23k. Table 2 shows data statistics. We report the accuracy of equation generation, namely as "Acc (eq)", that the problem is solved well if the generated equation is equal to the annotated formula. Considering several equations satisfy the problem solution, we report the accuracy of answer value, namely as "Acc (ans)", to see whether the value calculated by the generated equation is equal to the target value.

Implementation We conduct our contrastive learning in the monolingual and multilingual perspectives. In the monolingual setting, we construct contrastive triples inside each dataset. In the multilingual setting, for each problem, the positive and negative examples are from different sources. Specifically, given a Chinese MWP in Math23k, we collect positive examples from MathQA and negative examples from Math23k. We adopt BERT-base (Devlin et al., 2019) as the problem encoder, and follow Xie and Sun (2019) to build the tree-decoder for solution generation. The hidden size of the decoder is set to 768. Multilingual BERT is used in the multilingual setting. The max input length is set to 120 and the max output length is set to 45. The loss margin η is set to 0.2. The weight α of contrastive learning loss is set to 5. We use AdamW (Loshchilov and Hutter, 2017) as our optimizer, and perform grid search over the sets of the learning rate as {5e-5, 1e-4} and the number of epochs as {30, 50} for each training stage. The batch size is fixed to 16 to reduce the search space, and we evaluate models for every epoch. We use the dropout of 0.5 to prevent over-fitting and perform a 3-beam search for better generations.

5.2 Baselines

To verify the effectiveness of the proposed method, we directly train our model on original datasets without contrastive learning. In particular, the multilingual baseline model is trained by mixing Math23k and the adapted MathQA. In addition to comparing with BERT, we also investigate the following approaches:

GroupAttention[2] (Li et al., 2019) develop an attention mechanism to capture the quantity-related and question-related information.

GTS[3] (Xie and Sun, 2019) generate equation

"Same" indicates the positive examples have exactly the same prototype equations. "Rand" indicates the negative examples are randomly selected from the rest.

trees through a tree structure decoder in a goal-driven mannner.

Graph2Tree[4] (Zhang et al., 2020) design a graph-based encoder for representing the relationships and order information among the quantities.

5.3 Main Results

Experimental results are shown in Table 3. Training the MWP solver with our proposed contrastive learning outperforms the baseline models on all datasets.

Monolingual Results Compared to previous methods, the pretrained linguistic knowledge in BERT can help the MWP solver improve performance greatly. With our proposed contrastive learning method, our model achieves consistent gains on Math23k and the adapted MathQA. This suggests that seeking patterns with supervision benefits the model to solve MWPs.

Margin η	0.05	0.1	0.15	0.2	0.3
Math23k	82.6	83.7	83.4	**83.9**	81.8
MathQA†	76.1	76.2	76.1	**76.3**	76.0

Table 5: Results (answer accuracy) of using different loss margin η in the multilingual setting.

		Acc (eq)	Acc (ans)
Baseline		71.2	82.4
CL ($\alpha = 1$)	Stage I	70.1	81.5
	Stage II	70.5	83.0
CL ($\alpha = 5$)	Stage I	70.6	82.5
	Stage II	**71.8**	**83.2**

Table 6: Results of using different loss weight α on Math23k in the monolingual setting. Two-stage results are reported.

Multilingual Results We adapt our model to the multilingual setting by using multilingual BERT and mixing two train sets. The contrastive learning improves Math23k answer accuracy to 83.9 (3.4 absolute improvements) and MathQA answer accuracy to 76.3 (2.8 absolute improvements), which are competitive with the monolingual results. This demonstrates that the model can learn similar patterns in different languages.

5.4 Analysis

We conduct ablations to better understand the contributions of different components in our contrastive learning method.

5.4.1 Effects of Data Collection

The contrastive examples consist of positive examples with similar patterns and negative examples with exactly different patterns. In this work, we investigate different strategies of collecting positive and negative examples. As well as our strategy, we attempt to collect MWPs containing the same prototype equation to be the positive examples, and randomly select negative examples from the rest.

Table 4 shows that our strategy achieves better performance on all datasets. In addition to the problems with the same prototype equations, our collected examples include more problems having the same equation subtree structures. It can be seen that the model can benefit from these examples. For the negative examples, we take the problems with the same number of operators but different operator types. If performing random selection, the model performance drops, which suggests that our collected examples can support the model to disperse the different patterns. No matter which strategy we use, compared to the baseline without contrastive learning, our method advances MWP solving and gives one way to improve the performance by using data in different languages.

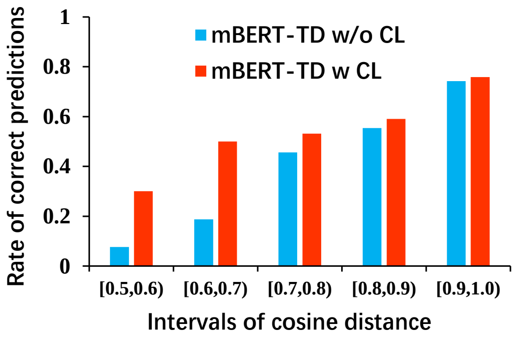

Figure 8: Equation accuracy in each distance interval with and without our contrastive learning.

Input: A boatman selling a boat along river flow. If he sell boat in steal water at 3 m/sec and flow of river is 2 m/sec, how much time he will take to sell 100 m. **Output (w/o CL):** 100 / (3 / 2) **Output (w CL):** 100 / (3 + 2)
Input: A pipe can fill the tank in 30 minutes and pipe b can empty the tank in 90 minutes. How long it will take to fill the tank if both pipes are operating together? **Output (w/o CL):** 1 / ((1 / 30) + (1 / 90)) **Output (w CL):** 1 / ((1 / 30) - (1 / 90))
Input: If 20 liters of chemical x are added to 80 liters of a mixture that is 25% chemical x and 75% chemical y, then what percentage of the resulting mixture is chemical x? **Output (w/o CL):** 1 + ((25 / 100) * 5) **Output (w CL):** 20 + ((25 / 100) * 80)

Table 7: Examples of the problem input and equation output of MWP solvers.

5.4.2 Effects of Hyperparameters

We train the "mBERT-TD" model with several loss margins (0.05, 0.1, 0.15, 0.2 and 0.3) to disperse the different patterns. As shown in Table 5, the margin 0.2 can help the model achieve the best performance but lower margins 0.1 and 0.15 also perform well.

As introduced in Section 4.2, we train our model in two stages and the loss weight α represents the importance of the contrastive learning. Table 6 shows the results of using different weights in each stage. It can be seen that the higher weight achieves better performance, and at stage II, training on all examples further improves the performance.

5.4.3 Visualization and Statistics

We perform the T-SNE visualization shown in Figure 6. The problem representations with the same prototype equation are more gathered through our contrastive learning. To measure this variation, we calculate the Calinski-Harabasz index (Caliński and Harabasz, 1974). Figure 7 shows that our method supports the model to gain higher clustering scores.

The above results illustrate that, for each prototype equation, the representations are pulled closer to its centers. We re-compute the proportion of correct predictions as described in Section 3.4. The results are shown in Figure 8. We observe the accuracy increases in most intervals, which also verifies the effectiveness of contrastive learning. In particular, our model also performs well in lower intervals such as [0.6,0.7) and [0.7,0.8), which indicates those problems a little far away from their centers are not easily confused with other problems of different patterns, and our model disperses different patterns apart indeed.

Besides, we show few examples in Table 7. It can be seen that the contrastive learning method helps the model capture the quantitative relationships exactly.

6 Conclusion

In this paper, we find the neural network generates incorrect solutions due to the non-distinction of MWP patterns. To this end, we propose a contrastive learning approach to support the model to perceive divergence of patterns. We seek similar patterns in terms of the equation tree structure and collect easily confused patterns for our model to distinguish. Our method outperforms previous baselines on Math23k and MathQA in monolingual and multilingual settings.

Abstract

Recent advances in multimodal *vision and language* modeling have predominantly focused on the English language, mostly due to the lack of multilingual multimodal datasets to steer modeling efforts. In this work, we address this gap and provide xGQA, a new multilingual evaluation benchmark for the visual question answering task. We extend the established English GQA dataset (Hudson and Manning, 2019) to 7 typologically diverse languages, enabling us to detect and explore crucial challenges in cross-lingual visual question answering. We further propose new adapter-based approaches to adapt multimodal transformer-based models to become multilingual, and—vice versa—multilingual models to become multimodal. Our proposed methods outperform current state-of-the-art multilingual multimodal models (e.g., M^{3}P) in zero-shot cross-lingual settings, but the accuracy remains low across the board; a performance drop of around 38 accuracy points in target languages showcases the difficulty of zero-shot cross-lingual transfer for this task. Our results suggest that simple cross-lingual transfer of multimodal models yields latent multilingual multimodal misalignment, calling for more sophisticated methods for vision and multilingual language modeling.[1]

1 Introduction

Transformer-based architectures (Vaswani et al., 2017) have become ubiquitous in NLP (Devlin et al., 2019; Liu et al., 2019; Conneau et al., 2020, *inter alia*) and in computer vision (CV) (Carion et al., 2020; Dosovitskiy et al., 2021), offering unmatched task performance. Having a shared architecture for multiple modalities opened up possibilities for effective fusion of information, yielding impressive performance gains across various multimodal tasks such as image captioning, phrase grounding, visual question answering, referring expression comprehension and image-text retrieval (Lu et al., 2019; Tan and Bansal, 2019; Li et al., 2020b; Zhang et al., 2021; Ni et al., 2021; Kamath et al., 2021; Miech et al., 2021; Frank et al., 2021; Bugliarello et al., 2021; Radford et al., 2021; Jia et al., 2021; Eichenberg et al., 2021; Singh et al., 2021; Fu et al., 2021; Yang et al., 2021; Yuan et al., 2021; Wang et al., 2021a; Li et al., 2021; Geigle et al., 2022, *inter alia*). Yet, progress in this area has been limited mostly to the English language, as the main multimodal datasets consist only of English text. Due to the scarcity of multilingual evaluation benchmarks, there has been limited development of models that tackle this joint problem.

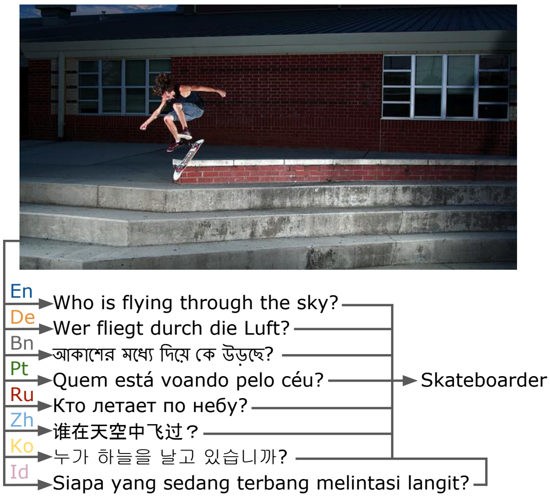

Figure 1: Example taken from the xGQA dataset with the same question uttered in 8 languages.

Aiming to address this gap, in this paper we propose **xGQA**, a multilingual evaluation benchmark for the visual question answering task, extending the monolingual English-only GQA dataset (Hudson and Manning, 2019). For xGQA we manually translate and adapt the balanced GQA test-dev set into 7 new languages from 7 language families, covering 5 distinct scripts; see Figure 1 and Ta-

ble 1 later. In addition, we provide new fixed data splits to guide cross-lingual few-shot learning experiments, where only a small number of examples in the target language are utilized.

As pretraining is (i) notoriously computationally expensive for high-resource languages and (ii) only limited amounts of multilingual multimodal resources are available, we also propose computationally efficient adapter-based (Houlsby et al., 2019) approaches as additional baselines for constructing multilingual multimodal models. In a nutshell, we extend multimodal models pretrained only on English text (Zhang et al., 2021) to become multilingual and—vice versa—multilingual models (Devlin et al., 2019) to become multimodal. To this end, we follow the approaches of Artetxe et al. (2020) and Pfeiffer et al. (2020b, 2021) and extend monolingual and multilingual models to new languages and scripts via learning new tokenizers and corresponding word-embedding matrices, as well as adapters for the target languages. To transfer the respective multilingual multimodal adapter-based models to the target task, we propose a novel *modality-specific split architecture*, which uses modality dependent adapter weights (see Figure 2 for an illustration of the architecture).

Our results clearly indicate that the proposed adapter-based architecture outperforms the recent state-of-the-art pretrained multilingual multimodal M^{3}P model (Ni et al., 2021) in zero-shot cross-lingual settings. However, the overall performance of zero-shot transfer remains low across the board, with an average drop of around 38 accuracy points across target languages. Using a small number of target language examples in a few-shot setup considerably improves performance for all approaches, but cross-lingual transfer performance still lags substantially behind source language performance. This demonstrates the inherent difficulty of the task, even though the corresponding questions are arguably simple as they are template based and only contain 8.5 words on average (see Figure 1).

Contributions. **1)** We propose the first evaluation benchmark for cross-lingual visual question answering, covering 7 diverse target languages; **2)** we propose novel adapter-based approaches for the creation of multilingual multimodal models; **3)** we systematically benchmark state-of-the-art and new multilingual multimodal models in zero-shot and few-shot learning setups, demonstrating the difficulty of the proposed task and serving as strong reference points for future work; **4)** we provide a thorough analysis of the different approaches, highlighting the aspects and question types that lead to the most common model failures, again motivating future work in this domain.

2 Background and Related Work

Multilingual Language Models. Pretrained multilingual transformer-based LMs such as mBERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020) adopt the same pretraining regime as their respective monolingual counterparts: BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019). They are pretrained via self-supervised masked language modelling objective (MLM) on concatenated text corpora of more than 100 languages, where text is tokenized using WordPiece, SentencePiece or BytePair encodings. These multilingual models have been shown to work surprisingly well for cross-lingual tasks, despite the fact that they do not rely on direct cross-lingual supervision (e.g., parallel data, translation dictionaries; Pires et al., 2019; Wu and Dredze, 2019; Artetxe et al., 2020; Hu et al., 2020; K et al., 2020; Rust et al., 2021).

Vision and Language Models. Most transformer-based multimodal models (Lu et al., 2019; Tan and Bansal, 2019; Chen et al., 2020; Li et al., 2020a; Gan et al., 2020; Li et al., 2020b; Bugliarello et al., 2021; Ni et al., 2021, *inter alia*) jointly encode text tokens and image region features by preprocessing images using object detection models—such as Faster R-CNN (Ren et al., 2015)—to extract features for regions of interest (RoI) (Anderson et al., 2018). The image region features are passed through an affine layer, which learns to project the region features to the joint embedding space of the multimodal transformer. The bounding box coordinates of the RoI act as positional embeddings for the visual features. As such, they undergo an affine transformation to the embedding space and are combined with their respective image region representation. The position-aware image region embeddings get passed into the transformer. The multi-head attention then attends over all text and image inputs at every layer, learning a joint representation of both modalities. On the other hand, Kamath et al. (2021) avoid using object detectors as a black-box for pre-extracting these region features and instead make it a central part of the multimodal transformer architecture. Training the object detector end-to-end with the multimodal transformer adds flexibility and better representation capacity.

Similar to MLM, multimodal transformer-based models are trained with self-supervised objectives such as masked feature regression, masked object detection, masked attribute detection, and contrastive losses such as cross-modality matching (Tan and Bansal, 2019). Typically, image captioning datasets are used for pretraining such as COCO (Lin et al., 2014), Flickr30k (Plummer et al., 2015), Conceptual Captions (CC) (Sharma et al., 2018), and SBU (Ordonez et al., 2011). Similar to unimodal language models, the [CLS] token is used as a contextual representation for classification tasks.

Multilingual multimodal models have also been proposed recently: M^{3}P (Ni et al., 2021) is trained on the Wikipedias of 50 different languages and the English multimodal CC dataset. In order to align tokens of languages other than English with image representations, M^{3}P utilizes a code-switching mechanism, where words of the English CC examples are randomly replaced with words from corresponding bilingual dictionaries. In UC^2, Zhou et al. (2021) augment English multimodal datasets with other languages via machine translation and propose masked region-to-token modeling and visual translation language modeling.[2]

Adapters (Rebuffi et al., 2017; Houlsby et al., 2019) have been introduced as a more efficient fine-tuning strategy for transfer learning in NLP and CV. Instead of fine-tuning all the weights of a pretrained model on the target task, small feed-forward layers are introduced at each layer of the pretrained model. During task fine-tuning, only the adapter weights are updated, while the pretrained parameters remain fixed/frozen. Adapters have been shown to be very training efficient (Rücklé et al., 2021), and among an increasing amount of applications they can be utilized to transfer between domains (Rücklé et al., 2020) and tasks (Poth et al., 2021), and in machine translation (Bapna and Firat, 2019; Philip et al., 2020; Le et al., 2021) and cross-lingual transfer (Pfeiffer et al., 2020b, 2021; Üstün et al., 2020; Ansell et al., 2021, *inter alia*) scenarios.

Datasets. Pretraining and fine-tuning data for multilingual multimodal models is typically based on (multimodal information from) Wikipedia (**WikiCaps**, **WIT**, Schamoni et al., 2018; Srinivasan et al., 2021), or on available downstream task data. **Multi30k** (Elliott et al., 2016) is a multilingual image captioning dataset for retrieval-type questions, covering English, German, French, and Czech; **GEM** (Su et al., 2021) covers image and video retrieval tasks across 20 and 30 different languages, respectively; **HowTo100M** (Huang et al., 2021) is a multilingual and multimodal pretraining dataset for image and video retrieval; **MultiSubs** (Wang et al., 2021b) focuses on fill-in-the-blank tasks and lexical translation, covering English, Spanish, German, Portuguese, and French. Gao et al. (2015); Shimizu et al. (2018) propose bilingual visual question answering datasets for English, and Chinese and Japanese respectively. In contemporary work Liu et al. (2021) propose **MaRVL**, a binary multilingual question answering dataset similar to NLVR2 (Suhr et al., 2019), spanning 5 typologically diverse languages (Chinese, Tamil, Swahili, Indonesian, and Turkish).

Previous datasets predominantly focus on (arguably simpler) retrieval-type tasks, only cover a small set of similar languages (e.g., Multi30k, MultiSubs), or only cover binary questions. In contrast, we propose the first multilingual visual question answering dataset, which covers a typologically more diverse set of languages.

Most recently, **IGLUE** (Bugliarello et al., 2022)—a multilingual multimodal benchmark that integrates xGQA—was proposed: IGLUE brings together visual question answering, cross-modal retrieval, grounded reasoning, and grounded entailment tasks across 20 diverse languages.

3 xGQA

The original English GQA dataset (Hudson and Manning, 2019) was constructed by leveraging Visual Genome scene graphs (Krishna et al., 2017). An English question engine that utilizes *content* (i.e. information about objects, attributes, and relations provided) and *structure* (a linguistic grammar that couples hundreds of structural patterns and detailed lexical semantic resources) was used to generate over 22 million diverse questions, which are visually grounded in the image scene graphs. As the questions are automatically generated using templates, they do not necessarily reflect the wide spectrum of natural language, making any assumptions on the performance in the wild difficult.

Each question is associated with additional metadata such as **structural types**: (1) *verify* for yes/no questions (e.g. "Do you see any cats?"), (2) *query* for all open questions (e.g. "Who is wearing

---

jeans?"), (3) *choose* for questions that present two alternatives to choose from (e.g. "Is it red or blue?"), (4) *logical* which involve logical inference (e.g. "Is the field soft and snowy"), and (5) *compare* for comparison questions between two or more objects (e.g. "Are all the animals zebras?"). For further details regarding the metadata, we refer the reader to Hudson and Manning (2019).

Dataset Design. The principal objective when devising xGQA was to create a genuinely typologically diverse multimodal and multilingual evaluation benchmark for visual question answering. We utilize the balanced[3] test-dev set of GQA, which consists of 12,578 questions about 398 images.[4] Due to the defined structural patterns, the formulation of the questions is simple, with an average length of 8.5 words.[5] The resulting xGQA dataset covers translations in 7 languages, each representing a distinct language family, and contains examples written in 5 different scripts (see Table 1).

Few-Shot Data Splits. In order to conduct cross-lingual few-shot learning experiments, we provide new data splits of different sizes. We split on images and add all questions associated with the image to the respective set. The development and test sets consist of 50 and 300 images, respectively. The training splits consist of 1, 5, 10, 20, 25, and 48 images, see Table 2. We ensure that the distribution of structural types within each set is maintained.

xGQA is the first truly typologically diverse multilingual multimodal benchmark, unlocking new experimentation and analysis opportunities in cross-lingual zero-shot and few-shot scenarios. While the questions in xGQA are intuitive and easy for humans to solve, we later show that current state-of-the-art models still have difficulty with transfer.

4 Baselines

To analyze the performance and current gaps on xGQA, we first evaluate the recently proposed M^{3}P model, which has been pretrained on multilingual and multimodal data. However, pretraining is computationally expensive and only limited amounts of multilingual multimodal resources are available. Therefore, we further propose new and more efficient approaches that (1) extend state-of-the-art multilingual language models to the multimodal domain and (2) provide multilingual capabilities to state-of-the-art multimodal models.

Unless noted otherwise, we follow the predominant fine-tuning strategy for GQA; a prediction head is placed on top of the output of a pretrained transformer. All possible 1853 answers of the GQA task are mapped to a class label. The question associated with an image together with the position-aware region features are passed as input to the transformer, supervised using a cross-entropy loss.[6]

4.1 Multimodal $\rightarrow$ Multilingual

OSCAR+^{Emb}. To extend a monolingual transformer LM to a multilingual domain, Artetxe et al. (2020) fine-tune a new word-embedding layer in the target language. Inspired by this idea, we now describe how we extend the current state-of-the-art monolingual multimodal transformer model OSCAR+ (Zhang et al., 2021) to learn new embeddings for the target languages.

In the *language-extension* phase, we replace the embedding matrix of OSCAR+ with a randomly

---

[3] To reduce biases in the conditional answer distribution Hudson and Manning (2019) utilize the structural metadata to downsample and create balanced datasets that are more robust against shortcuts and guesses.

[4] We chose to translate the test-dev set of GQA, as the labels for test-std are not released.

[5] For this reason, we chose to hire university students that are currently conducting their (Computer Science or Computational Linguistics) studies in English and are all fluent English speakers to translate the question into their native language. They were paid above the minimum hourly wage of the country of their respective university. After all questions have been translated, another, independent native speaker then verified the translations based on random spot checks.

[6] For instance, we use this strategy to fine-tune all parameters of M^{3}P on the GQA training data.

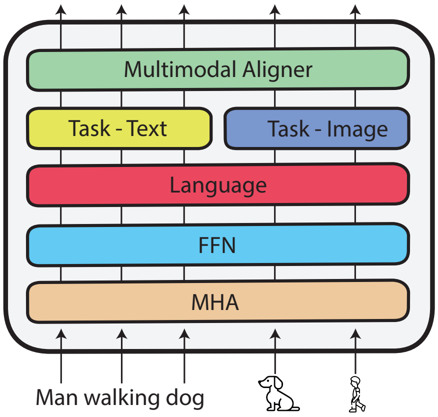

Figure 2: Architecture of an adapter-based multilingual multimodal model. Text and image inputs share the weights of the multi-head attention (MHA) and feed-forward (FFN) layers, as well as the *language* and *multimodal align* adapters. Each modality is passed through a modality specific *task* adapter, the outputs of which are concatenated.

initialized embedding matrix.[7] The transformer weights are frozen while only the newly introduced embeddings are fine-tuned on unlabeled text data of the target language with the MLM objective.

In the *target-task* phase, the original OSCAR+ model is fine-tuned on the English training data of GQA, where the transformer layers are fine-tuned, but the embedding layer is frozen. During inference, the embedding layer is replaced with the target language's embedding layer.

OSCAR+^{Ada}. We extend this by adding adapters.

In the *language-extension* phase we follow Pfeiffer et al. (2021) in order to extend the model to the target languages. Similar to OSCAR+^{Emb}, we train a new embedding layer. We further add *language* adapters at every transformer layer. Given that OSCAR+ is trained on English text, we follow Pfeiffer et al. (2020b) when training English *language* adapter modules, without replacing the embedding matrix. The transformer weights are frozen while only the *newly* introduced embeddings and *language* adapter weights are fine-tuned on unlabeled text data of the language.

For the *target-task* phase, we propose a novel modality-split architecture (see Figure 2) inspired by the cross-lingual transfer method of Pfeiffer et al. (2020b). At each transformer layer, text and image representations are passed through the pretrained multi-head attention (MHA) and feed-forward (FFN) layers. Both image and text representations are also passed through the pre-trained *language* adapters. Each modality is then passed through modality-specific *text* and *image task* adapters and next through a shared *multimodal alignment* adapter.[8] We follow Pfeiffer et al. (2020b), freezing transformer, embedding and *language* adapter weights during training, thus fine-tuning only the *task* and *multimodal aligner* adapter weights, together with the prediction head. At inference time, the embedding layer and the *language* adapters are replaced with the target language weights.

4.2 Multilingual → Multimodal

mBERT^{Ada}. For experiments where we extend a multilingual model to become multimodal, we utilize mBERT (Devlin et al., 2019).

Given that mBERT is able to represent many different languages, it is not necessary to learn new embedding layers for the target languages in the *language-extension* phase. Instead, we utilize the mBERT-compatible *language* adapters available on AdapterHub.ml (Pfeiffer et al., 2020a).[9]

For the *target-task* phase, we follow OSCAR+ for the image representation layer, where image features are combined with their respective positional information and passed through an affine transformation layer. We experiment with the same adapter architecture from Figure 2, as described for OSCAR+^{Ada}. We again freeze transformer, embedding and *language* adapter weights during training. However, in contrast to OSCAR+*, we randomly initialize and fine-tune the affine image transformation layer. We also fine-tune the *task*, *multimodal aligner* adapter weights, and prediction head, all on the GQA task. At inference time, the embedding layer and the *language* adapters are replaced with the corresponding target language weights.

5 Experimental Setup

5.1 Language-Extension Phase

For OSCAR+^{Emb} and OSCAR+^{Ada}, we follow the general setups proposed by Pfeiffer et al. (2020b,

---

[7] Following Pfeiffer et al. (2021), we copy the embeddings of lexically overlapping tokens (if such tokens exist) from the original embedding space to the new embedding space, as it typically works better than fully random initialization.

[8] We have compared multiple different architectures as illustrated in Figure 6 in the Appendix, finding this setup to perform best. We present results of the alternative architectures also in the Appendix.

[9] While all xGQA languages already have readily available language adapters on AdapterHub, any hypothetical extension of experiments to languages without such adapters would involve training their dedicated language adapters, e.g., following the procedure of Pfeiffer et al. (2020b).

2021). We train a new word-piece tokenizer for each target language with a vocabulary size of 30k. We fine-tune the randomly initialized embedding layer, and (for OSCAR+^{Ada}) adapter layers for 100k update steps with a batch size of 64 and a learning rate of $1e{-}4$. For mBERT^{Ada}, we utilize the language adapters from AdapterHub.ml.

5.2 Fine-tuning on GQA

We follow the standard setup proposed by Li et al. (2020b), passing the representation of the [CLS] token through a prediction head. We fine-tune the respective models using a cross-entropy loss with labels being all possible answers in the GQA dataset. Following prior work (Li et al., 2020b), we use a batch size of 192 and train for 5 epochs on the unbalanced GQA training portion.

M^{3}P. We fine-tune all weights of the pretrained model with a learning rate of $3e{-}5$.

OSCAR+^{Emb}, OSCAR+^{Ada}, and mBERT^{Ada}. We use the pretrained weights and image region features provided by Zhang et al. (2021). However, we do not pass the object attribute labels as inputs to the model. The object attribute labels are in English and utilizing them in cross-lingual scenarios is non-trivial.[10] We leave this for future work.

For the OSCAR+^{Emb} setting, we fine-tune the transformer weights and the prediction head and freeze the embedding layer, using a learning rate of $3e{-}5$. For the OSCAR+^{Ada} and mBERT^{Ada} settings, we add adapter layers as described in §4.1 and illustrated in Figure 2. We freeze all pretrained weights–including embeddings, transformer layers, and language adapters–and only fine-tune the newly introduced adapters and the prediction head. For mBERT^{Ada}, we also add and train the affine image transformation layer. We fine-tune the adapter-based models with a learning rate of $1e{-}4$.

5.3 Zero-Shot Cross-Lingual Transfer

For zero-shot cross-lingual evaluation, we utilize the model fine-tuned on the GQA training data and evaluate on the multilingual xGQA test data. The model checkpoint that performed best on the English GQA validation data is selected for transfer.

M^{3}P. As the model is pre-trained to cover, among others, xGQA languages, no additional steps are required for cross-lingual transfer.

OSCAR+^{Emb}. We replace the English embedding layer with the target-language embedding layer.

OSCAR+^{Ada}. We replace the English embedding and language adapter layers with the embedding and adapters layers of the target language.

mBERT^{Ada}. We replace the language adapter layers with the adapters layers of the target language.

5.4 Few-Shot Cross-Lingual Transfer

For few-shot cross-lingual scenarios we follow Lauscher et al. (2020) and start from the same fine-tuned model as for zero-shot transfer (see §5.3). We then fine-tune the same parts of the model as when training on the English training data as in §5.2, but on the small portions of multimodal data available in the target language. We train on the different data splits, consisting of 1, 5, 10, 15, 20, 25, and 48 images (see Table 2). We experiment with training for a different number of epochs (5, 10) using different learning rates ($1e{-}5$ and $5e{-}5$ for M^{3}P and OSCAR+^{Emb}, and $5e{-}5$ and $1e{-}4$ for OSCAR+^{Ada} and mBERT^{Ada}). We find that training for longer and with a larger learning rate performed best for all settings.

6 Results and Discussion

The main results are presented in Table 3 (zero-shot experiments) and in Table 4 (few-shot).

6.1 Zero-Shot Cross-Lingual Transfer

One of our core findings is that multimodal zero-shot cross-lingual transfer is extremely difficult; we witness an average drop in accuracy of more than 38 points on the target languages of the xGQA dataset compared to English GQA scores (e.g., compare the results with M^{3}P).

While, as expected, OSCAR+ achieves the best accuracy on the English test set, the massively multilingual models—M^{3}P and mBERT—perform considerably better in cross-lingual transfer.[11] This

---

[10] The replaced tokenizer and embedding representations of the target language potentially do not adequately represent English terms, resulting in a misalignment between the question (in the target language) and the object attributes (in English).

[11] The superior accuracy of OSCAR+ on the English test set is expected as the model was pretrained on large English multimodal data. We find that fine-tuning all transformer weights (OSCAR+^{Emb}) achieves slightly better results than only training adapter weights (OSCAR+^{Ada}). Our slightly lower scores compared to results by Zhang et al. (2021) can be explained by us (1) not fine-tuning the embedding layer, and (2) not utilizing the attribute labels. Further, previous works that focus only on English add the official *validation* set to the *training* set, use the official *test-dev* set as their dev set, and report their test scores of the official GQA test benchmark *test-std* for which labels are not available. Our scores follow the training splits, where we use the official *test-dev* set as the final test set, as described before in §3.

indicates, that joint multilingual pretraining is important and a simple multilingual adapter-based or embedding-based extension of monolingual models achieves inferior cross-lingual performance.

While the pretraining method M^{3}P achieves better accuracy on the English test set, the adapter-based multimodal extension of mBERT outperforms M^{3}P in cross-lingual transfer. We hypothesize that, when fine-tuning all transformer weights on monolingual multimodal data, the cross-lingual alignment breaks within M^{3}P. However, this does not happen in adapter-based settings, as the multilingual weights are frozen and thus remain intact.

Analysis of Structural Question Types. Figure 3 depicts our analysis of the structural question types in zero-shot experiments. We observe large drops in accuracy especially for *query* and *choose* type questions. *Query* type questions are free-form and thus semantically the most difficult to answer, even in the source language (English). This explains the overall low accuracy across all approaches in zero-shot settings for this question type.

This is in stark contrast with the *choose*-type questions, which the models perform very well on in the source language. However, we report a substantial accuracy drop in zero-shot cross-lingual transfer. This decrease is most likely due to the nature of the question formulation and the modelling implementation. *Choose*-type questions are formulated such that the answer to the question is a word or phrase which appears in the question, i.e. "Is it red or blue?". The label classes, and consequently the prediction head, are constructed as a set of all answers appearing in the dataset. This means that the model learns a distributed repre-

Table 4: Average accuracy of few-shot results, utilizing different amounts of training data. The *0* column presents the best zero-shot results. These models are used as initialization for the subsequent few-shot experiments. **Bold** numbers indicate the best scores.

sentation of each answer in its final layer. Consequently, in cross-lingual transfer, the model is required to automatically align the question's options "red" or "blue" (translated in their respective language), with their English latent representation of the model's prediction head. The very low results in this category indicate that this cross-lingual word alignment breaks in zero-shot scenarios.

Overall, zero-shot transfer with our proposed multimodal adapter-based extension of mBERT (mBERT^{Ada}) achieves the best accuracy, with almost 3 points increase over M^{3}P and almost 5 points increase over OSCAR+. However, the overall accuracy of all approaches remains low in comparison to the results in English. This indicates that zero-shot multimodal cross-lingual transfer is extremely difficult, most likely due to the misalignment issue between visual and cross-lingual internal representations. To investigate this conjecture further, we run similar tests in few-shot setups, which should potentially mitigate the misalignment issue observed in zero-shot setups.

6.2 Few-Shot Cross-Lingual Transfer

The main results of few-shot experiments are provided in Table 4, while the plot illustrating the impact of different amounts of training data is shown in Figure 5. One crucial finding is that, as expected, utilizing an increasing amount of data instances in the target language consistently improves accuracy for all methods. This culminates in an improvement of up to 20 accuracy points when specializing the model with only 48 images in the target language. This indicates that a small number of target-language examples supports the models in partially repairing its internal cross-lingual multimodal alignment. Interestingly, we find that with as little as 5 images, and their corresponding questions, M^{3}P begins to outperform mBERT$^{\text{Ada}}$—the best performing zero-shot model.

We again analyze the impact of few-shot learning on accuracy across different structural question types, with the results depicted in Figure 4. The overall accuracy increases across all types compared to zero-shot scenarios (cf., Figure 3). However, the most pronounced gains are reported for *query* and *chose*-type questions, on which the model performed the worst in zero-shot setups. This implies the improved alignment between latent multimodal and multilingual representations, achieved via fine-tuning the model on a small amount of examples in the target language.

6.3 Language Transfer

We witness cross-lingual transfer capability patterns similar to those shown by previous work, where our models perform best on typologically close languages (Pires et al., 2019; Lauscher et al., 2020). Our models transfer best to German (de) and Portuguese (pt), both being part of the Indo-European (IE) language family and also sharing the same script (Latin) with the source language English (en). We see a small drop in accuracy for Russian (ru), Indonesian (id), and Chinese (zh) and a larger drop in accuracy for Bengali (bn) and Korean (ko). All of these languages are typologically different to the source language and in most cases do not share the same script. These differences highlight the importance of language diversity in cross-lingual transfer. Our benchmark thus enables experimentation and evaluation of multilingual multimodal models on a representative set of truly typologically diverse languages.

7 Contemporary Work

With the recent rise in interest in multilingual vision and language learning, contemporary work has

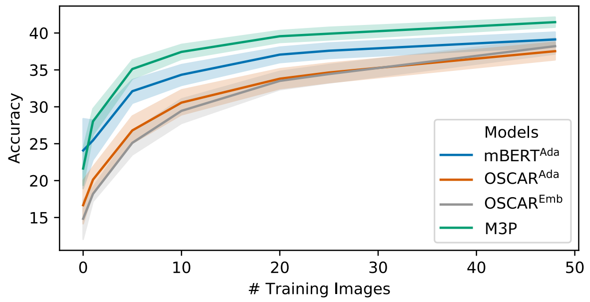

Figure 5: Few-shot accuracy with different training dataset sizes of the different approaches. Scores are averaged over all languages.

already further analyzed and extended the proposed xGQA dataset. We provide a brief description and pointers to this work in what follows.

Further Analysis. Liu et al. (2022) provide an extensive analysis of multilingual and multimodal models trained on cross-lingual visual question answering, and propose several approaches to mitigate the multilingual misalignment problem discussed in §6.1. Their results suggest that standard approaches taken from text-only cross-lingual transfer scenarios (Pires et al., 2019; Hu et al., 2020) do not leverage the full multilingual capability of the pretrained models. Interestingly, they find that a deeper prediction head does not have any measurable impact on the model's performance in the source language, while at the same time it considerably improves zero-shot transfer results across all target languages.

Translated Test Data. Bugliarello et al. (2022) propose the first benchmark for transfer learning across modalities, tasks, and languages, covering visual question answering, cross-modal retrieval, grounded reasoning, and grounded entailment tasks across 20 diverse languages. They extend the xGQA dataset by providing machine translated test-set questions and evaluate state-of-the-art monolingual multimodal models in a translate-test setup. In this setting, they achieve slightly better results. However, the performance remains to fall behind source language performance. The translate-test data can be found at iglue-benchmark.github.io.

8 Conclusion

We have proposed xGQA, a first cross-lingual evaluation benchmark for the visual question answering task. xGQA extends the English GQA dataset with development and test data in 7 more typologically diverse languages, covering 5 different scripts. As additional baselines, we have further proposed new adapter-based methods to extend unimodal multilingual models to become multimodal and—vice-versa—monolingual multimodal models to become multilingual. Our results have indicated that 1) efficient adapter-based methods slightly outperform the pretrained multilingual multimodal model M^{3}P in zero-shot scenarios, but 2) the overall zero-shot cross-lingual transfer yields harsh accuracy drops compared to the English performance for all models in comparison. Further, accuracy can be partially recovered via few-shot learning, where small amounts of training data are available in the target language. However, the large gaps remain, suggesting the inherent complexity of the cross-lingual task despite it being extremely intuitive and easy to solve by (bilingual) humans.

We hope that our dataset and error analysis will motivate future work on this task and, more broadly, in the exciting emerging domain of multilingual multimodal representation learning.

A Appendix

We experiment with different multimodal adapter architectures as illustrated in Figure 6. In initial experiments we find that splitting the modalities (settings 2-5) outperforms a joint adapter (setting 1). However, a joint "alignment" architectures (settings 4-5) outperform settings where we only use modality-specific adapters (settings 2-3). We more thoroughly investigate settings 4-5 and report scores in Table 5. Interestingly, we find that when only using the language adapter for the textual inputs, cross-lingual accuracy drops for both OSCAR+ and mBERT; The difference is more pronounced for OSCAR+. We speculate that this is due to a latent misalignment of the representation spaces, partly due to the residual connection. Due to the better performance of setting 5 on average, we have reported scores of this architecture in the main paper (as illustrated in Figure 2).

model	Setting	en	de	pt	ru	id	bn	ko	zh	mean
OSCAR+$^{\text{Ada}}$	4	60.21	18.60	25.48	8.22	17.79	10.47	9.97	12.54	14.72
OSCAR+$^{\text{Ada}}$	5	**60.30**	**18.91**	**27.02**	**17.50**	**18.77**	**15.42**	**15.28**	**14.96**	**18.27**
mBERT$^{\text{Ada}}$	4	**57.83**	27.86	28.88	22.87	**20.86**	14.74	18.30	24.39	22.56
mBERT$^{\text{Ada}}$	5	56.25	**29.76**	**30.37**	**24.42**	19.15	**15.12**	**19.09**	**24.86**	**23.25**

Abstract

We investigate the exploitation of self-supervised models for two Creole languages with few resources: Gwadloupéyen and Morisien. Automatic language processing tools are almost non-existent for these two languages. We propose to use about one hour of annotated data to design an automatic speech recognition system for each language. We evaluate how much data is needed to obtain a query-by-example system that is usable by linguists. Moreover, our experiments show that multilingual self-supervised models are not necessarily the most efficient for Creole languages.

1 Introduction

There is a long tradition of description of creole languages since, at least, the pioneering work of Hugo Schuchardt (1842-1927). Creole languages have sometimes been assigned a special role in linguistics: as a type of 'mixed languages', they are often considered as illustrating a break in language transmission and do not fit the generally assumed historical/genetic tree model[1]. Meanwhile they remain, for many of them, under-resourced languages. Gwadloupéyen, spoken mainly on Guadeloupe Island (France) by around 700.000 speakers, is a vigorous but largely under-equipped and under-resourced language. Morisien, (Mauritius Island) is spoken by approximately a million speakers. These two languages still suffer from a low social status and remain mainly spoken languages (rather than written).

The CREAM project aims at providing linguists with new methods for computational language documentation: Automatic Speech Recognition and keyword-spotting (Query-by-Example, Ram et al., 2020). The CREAM project teams up field linguists with computer scientists in order to address this low resource challenge.

Our contribution is twofold: 1) we introduce new methods for creole language documentation based on a combination of automatic speech recognition and keyword-spotting (in particular Query-by-example QbE) ; 2) our experiments shed new light on some key assumptions about creole languages, i.e. its distance from the lexifier language[2]. Gwadloupéyen (**gcf**) and Morisien (**mfe**) are two French-based creole languages. This category groups languages that share French as the most important part of their lexicon, but have a significantly different grammar.

We illustrate this phenomenon in (1-a.) and (1-b.) for gcf and mfe respectively, where most of the words (if not all) are clearly identifiable by a French speaker despite the difference in orthography:

(1) a. fo ou desann Gwadloup
need 2SG go.down Guadeloupe
'you've got to come to Guadeloupe"

b. Zan kontign reste.
John continue stay
'John continues to stay.' (from Henri and Kihm, 2015)

While these languages are well studied and vigorous, they are mostly spoken languages used in context of a dominant language: French for Gwadloupéyen (see Hazaël-Massieux, 1978; Managan, 2004, a.o.), French and English for Morisien (see Boswell, 2006; Rajah-Carrim, 2005, a.o.). Since they are spoken in two distinct linguistic and geographic areas (Lesser Antillean Island of Guadeloupe for Gwadloupéyen and Mauritius, in the Indian Ocean, for Morisien), there is no contact between these two languages, which makes them an interesting case study for a comparison (no con-

---

[1] But see DeGraff (2004) or Corcoran (2001) for a severe criticism of the "creation myth".

Findings of the Association for Computational Linguistics: ACL 2022, pages 2512 - 2520
May 22-27, 2022

tact[3], lexicon based on French, different grammars).

2 Transcribing Creole Languages

Since Gwadloupéyen and Morisien are mostly spoken languages, their written form is not stable. There are resources such as dictionaries and grammars for both languages (Tourneux and Barbotin, 2009; Ludwig et al., 1990; Damoiseau, 2012; Police-Michel et al., 2012; Baker, 1972; Baker and Hookoomsing, 1987), but writing in creole and transcribing spoken speech are two separate tasks.

In the context of diglossia, code-switching is very frequent (see Auckle, 2015; Jeannot and Jno-Baptiste, 2008; Hazaël-Massieux, 1978) and obviously causes problems for an automatic transcription task.

We focused here mainly on Gwadloupéyen and we identified three main problems with the transcriptions available in (Glaude, 2013).

First, several words are transcribed in two different forms: *anko* vs *ankò* ‘again’, *apré* vs *après* ‘after’, *bitin* vs *biten* ‘thing’.

Second, the transcriber hesitates between a transcription in French or in Creole:

(2) modes de cuisson qui adaptés osi
fr fr fr fr fr cr
methods of cooking that adapt too
‘cooking methods which are adapted too’

As shown in (2), the transcriber chose in this segment to write a large segment in French (fr), except for the word *osi* ‘too, also’, which is pronounced the same way in French and Gwadloupéyen (i.e. [osi]) but written *aussi* in French. However, one can wonder why *adapté* is not written in creole (no number agreement then), why *qui* is not written *ki* and, perhaps *modes de cuisson* transcribed *mode dé kwison* (since *é* in creole can be pronounced [ø]).

And last, the transcriber chose to transcribe in the proper creole form (identified as basilectal) while the speaker pronounced a word quite similar to its form in French: transcribed *dantis* but pronounced as in French *dentiste*.

Creole languages are known to have a large range of variation, often described as the ‘Creole continuum’, (see Bickerton, 1973; Mufwene, 1997; Winford, 1997, among many). This fact has even been theorized as a historical evolution towards the lexifier language, but see Mufwene (1997); Aceto (1999); Prudent (1999); Aboh (2015) for a more nuanced approach or a radical critic of this approach (DeGraff, 2004). In any case, Creole variations is a source of difficulty for ASR systems.

In order to efficiently correct these errors and to allow the linguist to search for a word (i.e. a segment of speech) in the corpus independently of its transcription, we designed an experiment of keyword spotting (**QbE**). This task is in line with Bird (2021), and is brought into action when there is a need for the linguist to verify or correct the transcription.

Speech processing for creole languages has not received much attention so far. For Gwadloupéyen, Delumeau (2006) is, to our knowledge, the only relevant work in NLP, but it does not address speech recognition. For Haitian Creole, Breiter (2013) explores speech recognition but Haitian and Gwadloupéyen are clearly distinct languages. For Morisien (Noormamode et al., 2019) is a recent initiative for creating a Creole speech engine. However, it does not seem to address the same tasks as this work.

3 ASR with Self-supervised Learning

Self-supervised learning (SSL) is the task of learning powerful representations from huge unlabeled data (called pretraining) to recognize and understand patterns from a less common problem (called fine-tuning). Recent work focused on speech data have reported impressive results for representation learning, and more specifically improved performance on downstream tasks for ASR in low-resource contexts (Baevski et al., 2019; Kawakami et al., 2020). These work are based on the Wav2Vec2.0 (Baevski et al., 2020) model.

In our approach, we consider 2 models : 1) *XLSR-53* (Conneau et al., 2021), a multilingual pretraining of Wav2Vec2.0 model on 53 languages with more than 56k hours of unlabeled speech data (*XLSR-53*) which has been shown to construct better speech representations for cross-lingual transfer (Conneau et al., 2021); 2) *LeBenchmark* (Evain et al., 2021a,b), a French-based Wav2Vec2.0 model with the assumption that these creoles are closely related to French.

4 Query by Example

Query by Example (QbE) consists in detecting specific words in speech recordings thanks to the use of speech recognition approaches. Keywords are

---

[3] And no mutual understanding (Chaudenson, 2004).

defined according to the user's request. Within the scope of this work, our keyword spotting approach firstly uses self-supervised learning models to predict the word in a speech segment. In the second phase, it searches for the prediction in a set of transcriptions.

5 Methodology

Dataset We consider two creole languages: Gwadloupéyen (gcf, 80 min and 5 speakers) and Morisien (mfe, 60 min and 2 speakers). Corpora are provided by Glaude (2013) for gcf and by courtesy of Dr. Tonjes Veenstra[4] for Morisien. Both corpora contain paired data of spontaneous speech with corresponding transcriptions.

Pre-processing for Fine-tuning Each audio recording is segmented into small segments, each corresponding to a sentence. Audio segments are mono, with a sampling frequency of 16 kHz. The pre-processing of textual data involves the deletion of punctuation marks, and a harmonization of specific characters (lowercase, the substitution of accentuated vowels such as 'à' into 'a', 'ê' into 'e', ...). For each experiment, we split the data into train, validation and test sets with a ratio of 80/8/12. Details about the datasets are given in Appendice A.1.1.

Implementation Details The fine-tuning is performed using the Wav2Vec2.0 model (Wolf et al., 2020). We used two pretrained models available in HuggingFace (Wolf et al., 2020): *XLSR-53-large* multilingual model (Conneau et al., 2021), and *LeBenchmark/wav2vec2-FR-7K-large* (Evain et al., 2021b). Hyperparameters are the same as Conneau et al. (2021), except for the batch size, set to 8 due to memory limitations (see Appendice A.1.2). For LM rescoring, we build 3-gram language models (LM) using KenLM (Heafield, 2011) on the training transcriptions (see Table 1 for details). Results are generated with a CTC beam search decoder (Graves et al., 2006).

Query by example We create a set of speech segments for Gwadloupéyen language, with each corresponding to a word. The utterances are carefully chosen: we extracted pieces of signals (outside the train and test sets) that could be found in the test data to simulate the work of a linguist. We used the fine-tuned models to generate the corresponding transcription of an audio segment. In this part, we do not decode with a LM to get closer to the signal. We base our approach on the Smith-Waterman algorithm (Smith and Waterman, 1981). This method provides an optimal local alignment between two given sequences by looking at matching areas (Lecouteux et al., 2012). QbE approach was performed with non-optimized weights by default (substitution, insertion, and deletion set to 1).

Language	# 1gram	# 2grams	# 3grams	Perplexity (%)
gcf	1584	6530	9431	112.82
mfe	1293	5274	7308	141.14

Table 1: Statistics and perplexity of 3-gram LM of Gwadloupéyen (gcf) and Morisien (mfe) languages.

6 Results

Automatic Transcription Performance We evaluate the fine-tuned models performance using the Word Error Rate (WER) and the Character Error Rate (CER) with and without a 3-gram LM. Results are displayed in Table 2.

For both creole languages, models using the *LeBenchmark* model perform better in comparison to the multilingual model with a gain of over 5 to 8 percentage points (35.96%/40.68% WER for gcf, 36.19%/44.66% WER for mfe). To support our results, we performed cross-validation on the Gwadloupéyen corpus (see Appendice A.2.1). We conducted complementary experiments to assess the model's performance on data from an unseen speaker (see Appendice A.2.2).

Query by example and ASR In an attempt to know how much data is needed to get satisfactory performance (usability in the context of linguistic fieldwork), and whether the approach can be generalized to other related creole languages, we conducted several fine-tuning runs with different training dataset sizes (from 10 min to 70 min), only on Gwadloupéyen data[5]. The WER on the test data is given for each fine-tuned model in Figure 1. We observe impressive results with less

---

[4] The data on Kreol Morisien were collected by Tonjes Veenstra within the context of the A02-project, entitled "Speaker's choices in a creole context: Bislama and Morisien", of the CRC 1412 on Register, funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) – SFB 1412, 416591334. The data will be made publicly available at the end of the project.

[5] Audio segments were selected by an expert of Gwadloupéyen.

Model	Training size (in min)	Pretrained model	LM	dev		test	
				WER (%)	CER (%)	WER (%)	CER (%)
gcf_xlsr	68	facebook/wav2vec2-large-xlsr-53	-	47.58	22.60	40.68	17.81
			3-gram	-	-	37.91	18.59
gcf	68	LeBenchmark/wav2vec2-FR-7K-large	-	39.50	17.89	35.96	15.86
			3-gram	-	-	**34.74**	**16.96**
mfe_xlsr	52	facebook/wav2vec2-large-xlsr-53	-	48.08	21.56	44.66	20.06
			3-gram	-	-	41.60	20.12
mfe	52	LeBenchmark/wav2vec2-FR-7K-large	-	41.44	18.23	**36.19**	**16.70**
			3-gram	-	-	38.83	18.03

Table 2: Word Error Rate (WER) and Character Error Rate (CER) on different creole languages when fine-tuning the Wav2Vec2.0 model with multilingual (*XLSR-53*) and monolingual (*LeBenchmark/wav2vec2-FR-7K-large*) models. The WER and the CER are given with and without a 3-gram LM on the test sets.

than 1 hour of paired audio and transcriptions. Our query by example approach, over a set of 13 Gwadloupéyen audio segments, gives precision and recall scores of over 70% (84.52%/84.94% with the Gwadloupéyen model trained on 60 minutes). In addition, using the model trained with only 10 minutes of data gives very good performance (83.33% Precision/74.36% Recall), which shows its effectiveness in low resource contexts.

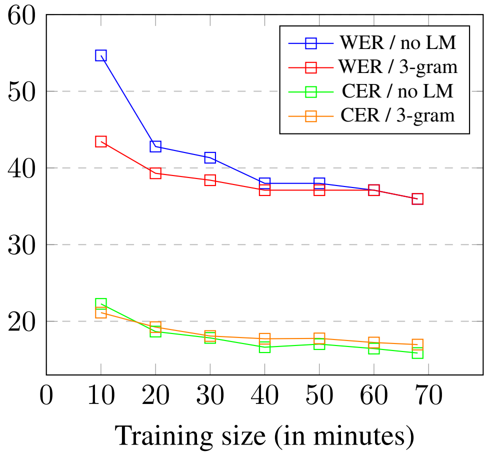

Figure 1: WER and CER (%) with respect to different training sizes (in minutes) when fine-tuning LeBenchmark pretrained model on the Gwadloupéyen corpus. The WER and the CER are given on the test sets with (in red and orange) or without a 3-gram LM (in blue and green).

7 Discussion

Field linguists from the CREAM project evaluate very positively the results given in Table 2. As shown in Appendice A.3, the automatic transcription can already save a huge amount of time and is accurate enough to allow for a fast manual correction.

Fine-tuned model	Precision (%)	Recall (%)	F-measure (%)
gcf_10	83.33	74.36	78.59
gcf_20	83.33	76.28	79.65
gcf_30	72.50	79.49	75.83
gcf_40	75.00	74.36	74.68
gcf_50	66.67	66.67	66.67
gcf_60	**84.52**	**84.94**	**84.73**

Table 3: Precision, Recall and F-measure computed on the Qbe results of 13 Gwadloupéyen audio segments when using the fine-tuned *gcf* models trained with 10 (gcf_10) to 60 minutes (gcf_60) of training data to predict the utterance. Audio segments contain single words (e.g. 'dépi', 'fè') and multiple words (e.g. 'an pa sav', 'nou ka rivé').

Moreover Table 2 sheds new light on the question of the link between a Creole language and the so-called 'lexifier' language (French for Gwadloupéyen and Morisien). It has been hypothesized that creole languages form a special typological class of languages (see Bakker et al., 2017, for a detailed discussion) or even a class of simple languages (see McWhorter, 2001). At the phonological level, creole languages are supposed to have phonological inventories that are distinct from those of their lexifiers. However, our results show that a model pretrained on French performs better than a model trained on a typologically wide sample (53 languages are taken into account in *XLSR-53*, including Haitian, which is a French-based creole language). If creole languages were so different from their lexifier languages (French in our case), we should expect a better performance on a 53 languages pretrained model. Interestingly, for Gwadloupéyen and Morisien, French is obviously the common connection. But in the case of

Morisien, most speakers are also fluent in English (Atchia-Emmerich, 2005), which could also have had an impact on the results. As underlined in Atchia-Emmerich (2005), French still remains an important language for Mauritians, and English, despite its high social prestige, does not have a significant impact on Morisien.

8 Conclusion and perspectives

Of course, an ASR system cannot solve the problems that the human transcribers have not solved, i.e. the choice of transcribing a word in French or in Creole (code-switching or not)[6].

Our results show that QbE can complement ASR and provide an easy way to scan the corpus for relevant examples. We found that a model pretrained on French performed better for Gwadloupéyen and Morisien than a model pretrained on a large typological set of languages[7].

For future work, we intend to apply the same method on English-based creole languages (such as Jamaican Creole) and Portuguese-base creoles (Kriol of Guinea-Bissau), to allow for a comparison and a generalization.

Acknowledgments

The CREAM project (Documentation des Langues CREoles Assistée par la Machine) is funded by the ANR (Agence Nationale de la Recherche, CS-38, 2020-2024). We would like to thank Dr. T. Veenstra (ZAS, Berlin) and Dr. F. Henri (University at Buffalo) for sharing with us their data on Morisien.

A Appendices

A.1 Appendice A: Implementation details

A.1.1 Datasets

Corpus	Train	Dev	Test	OOV (%)
gcf	68	4	8	24.68
mfe	52	3	5	24.82

Table 4: Train, dev and test sizes in minutes of the Creole corpora used to fine-tune Wav2Vec2.0 pretrained models, as well as the percentage of out-of-vocabulary words.

A.1.2 Hyperparameters

Hyperparameters are given in Table 5.

A.2 Appendice B: Complementary results

A.2.1 Cross-validation results

Results of the cross-validation experiments are printed in Table 6.

A.2.2 Experiments on an unseen speaker in the training set

In the experiments on Gwadloupéyen, the train/test split has been randomly performed, speakers can be both in the train and the test sets. This is frequent in speech recognition evaluations. It corresponds to our use case (in a low-resource context and working with few recordings). We conduct a complementary experiment that excludes a speaker from the training set and evaluates the performance of the fine-tuned model on two test sets: with or without speaker audio segments. Results are displayed in Table 7.

The results show that the model has a close word and character error rates on the audio segments of a speaker not seen in the training data (40.66% WER against 36.46% WER). When decoding with a 3-gram language model, the WER on the test data of the unseen speaker is degraded by one percentage point compared to the other test set (37.62%/36.29% WER).

A.3 Appendice C: Sample of Error Analyses for Gwadloupéyen

False negatives In some cases the manual transcription (Ref) was incorrect and the model (Hyp) provides an accurate hypothesis. Among others, these are several problems:

Missing word 'la' in the manual transcription:

```
Ref: sé timoun pa ni pon rèspè
Hyp: sé timoun la pa ni pon
     respè
```

Dysfluences 'é' (hesitation) are missing in Ref:

```
Ref: donk chak ritm la
ka espliké on biten
Hyp: donk é chak ritm la
ka espliké on biten
```

The Ref version makes an **inappropriate elipsis** (grammatical but not in the recording):

```
Ref: <pou pé> négosyé
sé péyi [...]
Hyp: <pou ou pé> négosi
sé péyi la [...]
```

The Hyp version detects the correct spelling of the pronoun (atone vs tonic):

```
Ref: <mwen> pa ka di lafrans
     [...]
Hyp: <an> pa ka di la frans [...]
```

Non decidable Some words are not present in (Poullet et al., 1984; Telchid et al., 2009; Tourneux and Barbotin, 2009) and the Hyp is rather correct:

```
Ref: tandis ké gwada
Hyp: tandiské gwada
```

Since 'tandis' cannot occur without 'ké', the Hyp makes a correct guess.

In the cases where it is impossible to decide if the segment is in French (with a creole accent) or in Creole, the Hyp is not faulty:

parameter	value
`pretrained model`	`wav2vec2-large-xlsr-53` `LeBenchmark/wav2vec2-FR-7K-large`
`attention_dropout`	0.1
`hidden_dropout`	0.1
`feat_proj_dropout`	0.1
`mask_time_prob`	0.075
`layerdrop`	0.1
`ctc_loss_reduction`	mean
`train_batch_size`	8
`num_train_epochs`	60
`fp16`	True
`learning_rate`	3e-4

Table 5: Value of the hyperparameters used to fine-tune the Wav2Vec2.0 model on Gwadloupéyen and Morisien datasets.

Model	**WER (%)**		**CER (%)**	
	None	3-gram	None	3-gram
split 1	34.64	32.59	16.62	15.57
split 2	34.65	33.60	14.83	15.24
split 3	34.85	33.92	13.83	15.07
split 4	35.18	35.61	14.36	16.15
split 5	35.48	34.74	15.33	16.38
split 6	36.36	37.48	16.17	18.35
split 7	35.50	36.10	15.21	16.23
split 8	37.55	37.55	16.76	18.00
split 9	35.37	36.25	16.07	17.06

Table 6: Cross validation on Gwadloupéyen dataset when fine-tuning Wav2Vec2 model with the *LeBenchmark/wav2vec2-FR-7K-large* pretrained model. 9 different datasets were created from the Gwadloupéyen dataset, with 68 minutes of training data, 4 minutes of validation data and 8 minutes of test data. The WER and the CER are given with and without a 3-gram language model on the test sets.

```
Ref: é le grand bourg exactement
Hyp: é le gran bou egzaktéman
```

Grand Bourg is the French name for a town of Marie-Galante Island, and the adverb ‘exactement/egzaktéman’ can be pronounced in the same way in fr and gcf.

```
Ref: é on avansé o nivo <mantal>
     paské
Hyp: on avansé o nivo <mental>
     paské
```

Here, ‘mental’ (fr) and ‘mantal’ (gcf) have the same spelling.

```
Ref: a sé jèn la èvè <lentènèt> é
     tou sa
Hyp: sé jann la èvè <lintenèt> é
     tou sa
```

```
Ref: an plas an fòs mèm an plas
<sitou> an frans
Hyp: an plas an fòs mèm an plas
<soutou> an frans
```

Both forms can be found.

A.4 Appendice D: Query-by-Example outputs

Correct QbE The *gcf_60* fine-tuned model predicts the word ‘depi’ for a given speech segment. The QbE approach extracts several results where this keyword is seen in a transcription, one of which is the following:

```
Query: 13 depi 18
          ||||
Ref  :  1 depi 6

Score: 12
Matches: 6 (100.0%)
Mismatches: 0

File name: 1016_273.wav
Complete sentence:
sa vle di ke depi le le an rantre
tale a kaz prepare sak an mwen
```

Incorrect QbE The *gcf_60* fine-tuned model predicts the word ‘pasew’ for a given speech segment. In this case, the prediction is incorrect (‘pase’ is the keyword we are looking for).

```
Query: 31 paske-  37
         |||| | |
Ref  : 1  pas-ew  7
```

Model	Training size (in min)	LM	dev		test no speaker		test speaker	
			WER (%)	CER (%)	WER (%)	CER (%)	WER (%)	CER (%)
gcf_speaker	64	-	42.48	19.02	36.46	16.37	40.66	17.12
		3-gram	-	-	36.29	17.55	37.62	19.05

Table 7: Word Error Rate (WER) and Character Error Rate (CER) on gwadeloupean language when fine-tuning the Wav2Vec2.0 model with *LeBenchmark/wav2vec2-FR-7K-large* model by excluding one speaker from the train set. The WER and the CER are given with and without a 3-gram LM on two test sets: one with speaker audio segments (test speaker, 7.5 minutes) and one without (test no speaker, 5 minutes).

```
Score: 10
Matches: 6 (75.0%)
Mismatches: 2
Path of the file: 1041_0194.wav

Complete sentence: tou se moun la
ki ka tout moun paske tout moun
ka rankontre obstak
```

MReD: A Meta-Review Dataset for Structure-Controllable Text Generation

Abstract

When directly using existing text generation datasets for controllable generation, we are facing the problem of not having the domain knowledge and thus the aspects that could be controlled are limited. A typical example is when using CNN/Daily Mail dataset for controllable text summarization, there is no guided information on the emphasis of summary sentences. A more useful text generator should leverage both the input text and the control signal to guide the generation, which can only be built with a deep understanding of the domain knowledge. Motivated by this vision, our paper introduces a new text generation dataset, named MReD. Our new dataset consists of 7,089 meta-reviews and all its 45k meta-review sentences are manually annotated with one of the 9 carefully defined categories, including abstract, strength, decision, etc. We present experimental results on start-of-the-art summarization models, and propose methods for structure-controlled generation with both extractive and abstractive models using our annotated data. By exploring various settings and analyzing the model behavior with respect to the control signal, we demonstrate the challenges of our proposed task and the values of our dataset MReD. Meanwhile, MReD also allows us to have a better understanding of the meta-review domain. [1]

meta-review:
[This paper studies n-step returns in off-policy RL and introduces a novel algorithm which adapts the return's horizon n in function of a notion of policy's age.]←ABSTRACT [Overall, the reviewers found that the paper presents interesting observations and promising experimental results.]←STRENGTH [However, they also raised concerns in their initial reviews, regarding the clarity of the paper, its theoretical foundations and its positioning (notably regarding the bias/variance tradeoff of uncorrected n-step returns) and parts of the experimental results.]←WEAKNESS [In the absence of rebuttal or revised manuscript from the authors, not much discussion was triggered.]←REBUTTAL PROCESS [Based on the initial reviews, the AC cannot recommend accepting this paper, but the authors are encouraged to pursue this interesting research direction.]←DECISION

Table 1: An example of annotated meta-review. CATEGORY indicates the category of each sentence.

1 Introduction

Text generation entered a new era because of the development of neural network based generation techniques. Along the dimension of the mapping relation between the input information and the output text, we can roughly group the recent tasks into three clusters: more-to-less, less-to-more, and neck-to-neck. The more-to-less text generation tasks output a concise piece of text from some more abundant input, such as text summarization (Tan et al., 2017; Kryściński et al., 2018). The less-to-more generation tasks generate a more abundant output from some obviously simpler input, such as prompt-based story generation (Fan et al., 2018b). The neck-to-neck generation aims at generating an output text which conveys the same quantity of knowledge as the input but in natural language, such as typical RDF triples to text tasks (Gardent et al., 2017).

To some extent, the existing task settings are not so adequate because they do not have a deep understanding of the domains they are working on, i.e., domain knowledge. Taking text summarization as an example, the most well-experimented dataset CNN/Daily Mail (Nallapati et al., 2016) is composed of the training pairs of news content and human-written summary bullets. However, it does not tell why a particular piece of news content should have that corresponding summary, for example for the same earnings report, why one

May 22-27, 2022

media emphasizes its new business success in the summary, but another emphasizes its net income. Obviously, there is not a standard answer regarding right or wrong. For such cases, if we can specify a control signal, e.g., "emphasizing new business", the generated text would make more sense to users using the text generator.

To allow controlling not only the intent of a single generated sentence but also the whole structure of a generated passage, we prepare a new dataset MReD (short for Meta-Review Dataset) with in-depth understanding of the structure of meta-reviews in a peer-reviewing system, namely the open review system of ICLR. MReD for the first time allows a generator to be trained by simultaneously taking the text (i.e. reviews) and the structure control signal as input to generate a meta-review which is not only derivable from the reviews but also complies with the control intent. Thus from the same input text, the trained generator can generate varied outputs according to the given control signals. For example, if the area chair is inclined to accept a borderline paper, he or she may invoke our generator with a structure of "abstract | strength | decision" to generate a meta-review, or may use a structure of "abstract | weakness | suggestion" otherwise. Note that for ease of preparation and explanation, we ground our dataset in the peer review domain. However, the data preparation methodology and proposed models are transferable to other domains, which is indeed what we hope to motivate with this effort.

Specifically, we collect 7,089 meta-reviews of ICLR in recent years (2018 - 2021) and fully annotate the dataset. Each sentence in a meta-review is classified into one of the 9 pre-defined intent categories: abstract, strength, weakness, rating summary, area chair (AC) disagreement, rebuttal process, suggestion, decision, and miscellaneous (misc). Table 1 shows an annotated example, where each sentence is classified into a single category that best describes the intent of this sentence. Our MReD is obviously different from the previous text generation/summarization datasets because, given the rich annotations of individual meta-review sentences, a model is allowed to learn more sophisticated generation behaviors to control the structure of the generated passage. Our proposed task is also noticeably different from the existing controllable text generation tasks (e.g., text style transfer on sentiment polarity (Shen et al., 2017; Liao et al., 2018) and formality (Shang et al., 2019)) because we focus on controlling the macro structure of the whole passage, rather than the wordings.

To summarize, our contributions are as follows. (1) We introduce a fully-annotated meta-review dataset to make better use of the domain knowledge for text generation. With thorough data analysis, we derive useful insights into the domain characteristics. (2) We propose a new task of controllable generation focusing on controlling the passage macro structures. It offers stronger generation flexibility and applicability for practical use cases. (3) We design simple yet effective control methods that are independent of the model architecture. We show the effectiveness of enforcing different generation structures with a detailed model analysis.

2 MReD: Meta-Review Dataset

In this paper, we explore a new task, named the structure-controllable text generation, in a new domain, namely the meta-reviews in the peer-reviewing system. Unlike the previous datasets that mainly focus on domains like news, the domain for meta-reviews is worth-studying because it contains essential and high-density opinions. Specifically, during the peer review process of scientific papers, a senior reviewer or area chair will recommend a decision and manually write a meta-review to summarize the opinions from different reviews written by the reviewers. We first introduce the data collection process and then describe the annotation details, followed by dataset analysis.

2.1 Data Collection

We collect the meta-review related data of ICLR from an online peer-reviewing platform, i.e., OpenReview[2] from 2018 to 2021. Note that the submissions from earlier years are not collected because their meta-reviews are not released. To prepare our dataset for controllable text generation, for each submission, we collect all of its corresponding official reviews with reviewer ratings and confidence scores, the final meta-review decision, and the meta-review passage. Table 2 shows the statistics of data collected from each year. Initially, 7,894 submissions are collected. After filtering, 7,089 meta-reviews are retained with their corresponding 23,675 reviews. Note that even without any further annotation, the dataset can already naturally serve the purpose of multi-document sum-

---

Year	#Submissions	#withReviews	#Meta-Reviews
2018	994	942	892
2019	1,689	1,639	1,412
2020	2,595	2,517	2,169
2021	2,616	2,616	2,616
Total	7,894	7,714	7,089

Table 2: Dataset statistics of MReD.

Categories	Definitions
abstract	A piece of summary about the contents of the submission
strength	Opinions about the submission's strengths
weakness	Opinions about the submission's weaknesses
rating summary	A summary about reviewers' rating scores or decisions
ac disagreement	Area chair (AC) shares different opinions to reviewers
rebuttal process	Contents related to authors' rebuttal with respect to reviews or discussions between reviewers in the rebuttal period
suggestion	Concrete suggestions for improving the submission
decision	Final decision (i.e., accept or reject) on the submission
miscellaneous	None of the above, such as courtesy expressions.

Table 3: Category definition of meta-review sentences.

marization (MDS). Compared with those conventional datasets for MDS, such as TAC (Owczarzak and Dang, 2011) and DUC (Over and Yen, 2004), which contain in total a few hundred input articles (equivalent to reviews in MReD), our dataset is more than 10 times larger.

2.2 Data Annotation

As aforementioned, the structure-controllable text generation aims at controlling the structure of the generated passage. Therefore, we need to comprehensively understand the structures of meta-reviews so as to enable a model to learn how to generate outputs complying with certain structures.

Specifically, based on the nature of meta-reviews, we pre-define 9 intent categories: abstract, strength, weakness, suggestion, rebuttal process, rating summary, area chair (AC) disagreement, decision, and miscellaneous (misc). Table 3 shows the definition for each category (see example sentences in Appendix A.1). The identification of category for some sentences is fairly straightforward, while some sentences are relatively ambiguous. Therefore, besides following the definition of each category, the annotators are also required to follow the additional rules as elaborated in Appendix A.2

For conducting the annotation work, 14 professional data annotators from a data company are initially trained, and 12 of them are selected for the task according to their annotation quality during a trial round. These 12 annotators are fully paid for their work. Each meta-review sentence is independently labeled by 2 different annotators, and a third expert annotator resolves any disagreement between the first two annotators. We label 45,929 sentences from 7,089 meta-reviews in total, and the Cohen's kappa is 0.778 between the first two annotators, showing that the annotation is of quite high quality.

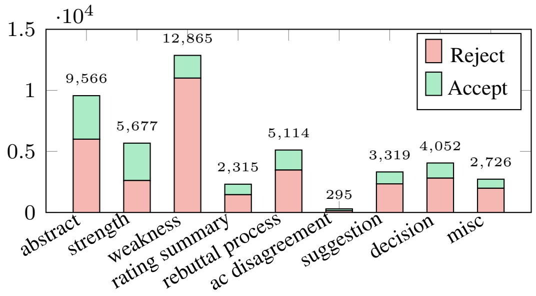

Figure 1: Sentence numbers in different categories.

2.3 Data Analysis

To better understand the MReD dataset, we conduct the following analysis along different dimensions.

Sentence distribution across categories. The number of sentences in different categories are shown in Figure 1, breakdown by the decision (i.e., accept or reject). Among 7,089 submissions, there are 2,368 accepted and 4,721 rejected. Among all submissions and the rejected submissions, "weakness" accounts for the largest proportion, while across the accepted ones, "abstract" and "strength" take up a great proportion. To some extent, these three categories which dominate in meta-reviews could be easily summarized from the reviewers' comments. However, some minor or subjective categories (e.g., "ac disagreement") are hard to generate.

Breakdown analysis by meta-review lengths and average rating scores. We present the percentage of meta-reviews of different lengths in each score range, as shown in Figure 2. For example, among the meta-reviews that receive the reviewers' average score below 2 (i.e., the first column in the figure), 28% are less than or equal to 50 words, and 38% fall in the length range of 51 to 100 words. We can observe that the meta-reviews tend to be longer for those submissions receiving scores in the middle range, while shorter for those with lower scores or higher scores. This coincides with our com-

	[1,2)	[2,3)	[3,4)	[4,5)	[5,6)	[6,7)	[7,8)	>=8
<=50	28% (48)	29% (83)	26% (169)	18% (270)	8% (170)	14% (254)	24% (132)	36% (29)
[51,100]	38% (65)	33% (94)	37% (247)	30% (470)	29% (583)	30% (526)	34% (192)	29% (23)
[101,150]	17% (30)	22% (64)	19% (124)	23% (354)	25% (495)	24% (431)	24% (135)	23% (18)
>150	17% (29)	16% (45)	18% (118)	29% (455)	38% (771)	32% (555)	18% (100)	12% (10)

Figure 4: Transition matrix of different categories.

monsense that for high-score and low-score submissions, the decision tends to be a clear accept or reject so that meta-reviews can be relatively shorter, while for those borderline submissions, area chairs have to carefully weigh the pros and cons to make the final decision (see Appendix B.1 for borderline submission analysis). As shown in Figure 3, the meta-reviews with more than 150 words generally have a larger proportion of sentences describing "weakness" and "suggestion" for authors to improve the submissions. Additional analysis on the category breakdown for accepted and rejected papers across the score ranges is shown in Appendix B.2.

Meta-review patterns. To study the common structures of meta-reviews, we present the transition matrix of different category segments in Figure 4, where the sum of each row is 1. Note that each segment represents the longest consecutive sentences with the same category. We add "<start>" and "<end>" tokens before and after each meta-review accordingly to investigate which categories tend to be at the start/end of the meta-reviews. It is clear to see that "abstract" usually positions at the beginning of the meta-review, while "suggestion" and "decision" usually appear at the end. There are also some clear patterns appearing in the meta-reviews, such as "abstract | strength | weakness", "rating summary | weakness | rebuttal process", and "abstract | weakness | decision".

3 Structure-Controllable Text Generation

3.1 Task Definition

As aforementioned, in uncontrolled generation, users cannot instruct the model to emphasize on desired aspects. However, in a domain such as meta-reviews, given the same review inputs, one AC may emphasize more on the "strength" of the paper following a structure of "abstract | strength | decision", whereas another AC may prefer a different structure with more focus on reviewers' opinions and suggestions (i.e., "rating summary" and "suggestion"). To achieve such flexibility, the task of structure-controllable text generation is defined as: given the text input (i.e., reviews) and a control sequence of the output structure, a model should generate a meta-review that is derivable from the reviews and presents the required structure.

3.2 Explored Methods

As the recent generation works (Vaswani et al., 2017; Liu and Lapata, 2019; Xing et al., 2020) basically adopt an encoder-decoder based architecture and achieve state-of-the-art performance on many tasks and datasets, we primarily investigate the performance of such a framework on our task. Thus in this subsection, we mainly present how to re-organize the input reviews and the control structure as an input sequence of the encoder. We also explore other baselines in the experiments later.

In order to summarize multiple reviews into a meta-review showing a required structure, we explicitly specify the control label sequence that a model should comply with during generation.

Combination	Obtained Text Input
rate-concat	R1 rating score: S_1, R2 rating score: S_2, R3 rating score: S_3. Review1 <REVBREAK> Review2 <REVBREAK> Review3
Control	**Examples of Encoder Input**
sent-ctrl	abstract | abstract | decision ==> [TEXT INPUT]
seg-ctrl	abstract | decision ==> [TEXT INPUT]
unctrl	[TEXT INPUT]

Table 4: Upper: example for the review combination method. S_i represents the score given by reviewer Ri. <REVBREAK> is the special separator used to concatenate different review texts. Lower: examples of control methods. [TEXT INPUT] refers to the obtained text from the upper section.

Specifically, we intuitively add the control sequence in front of the input text. By directly combining both the control and textual information as a single input, our control method is independent of any specially designed encoder and decoder structures. Moreover, by placing the short control sequence in front, an encoder can immediately observe the control signal at the very beginning, thus avoids the possible interference by the subsequent sequence. Moreover, the control sequence in front will never be truncated when the encoder truncates the input to a certain length limit.

Given the multiple review inputs, we need to linearize them into a single input. One simple method, ***concat***, is to concatenate all inputs one after another (Fabbri et al., 2019). Besides the text inputs, the review rating, which cannot be found in the review passages but exists in the field of rating score, is also crucial information for writing meta-reviews. Therefore, we create a rating sentence that consists of the extracted ratings given by the corresponding reviewers and prepend it to our concatenated review texts to obtain the final input. We name this method ***rate-concat*** (see Table 4, upper). We also explore an alternative method, ***merge***, as follows: From all review inputs, we use the longest one as a backbone. We segment all reviews' content on a paragraph level, and encode them using SentenceTransformers (Reimers and Gurevych, 2019). Then, for each paragraph embedding in the non-backbone reviews, we calculate a cosine similarity score with each backbone paragraph embedding. We then insert each non-backbone paragraph after the backbone paragraph with which it has the highest similarity score. We repeat the process for all paragraphs in non-backbone reviews to obtain a single passage. We further add rating sentences in front of the results of *merge* to obtain ***rate-merge***. Additionally, we provide a ***longest-review*** baseline, which does not combine reviews but only uses the longest review as the input.

As aforementioned, we place the control sequence in front of the re-organized review information. Specifically, we explore two different control methods, namely, ***sent-ctrl*** and ***seg-ctrl***. *Sent-ctrl* uses one control label per target sentence and controls generation on the sentence-level. Note that this method can allow implicit control on the length (i.e., number of sentences) of the generation. *Seg-ctrl* treats consecutive sentences of the same label as one segment and only uses one label for a single segment. Example inputs of different control settings are shown in Table 4 (lower). For instance, sent-ctrl repeats "abstract" in its control sequence whereas seg-ctrl does not. This is because seg-ctrl treats the 1st and 2nd target sentences of "abstract" as the same segment and only uses a single label to indicate it in the sequence. Additionally, we provide a vanilla setting for uncontrolled generation, ***unctrl***, where no control sequence is used.

Using the above input sequence as the source and the corresponding meta-review as the target, we can train an encoder-decoder model for controllable generation. Many transformer-based models have achieved state-of-the-art performance. Common abstractive summarization models include BART (Lewis et al., 2020), T5 (Raffel et al., 2020) and PEGASUS (Zhang et al., 2020). In this paper we focus on the *bart-large-cnn* model, one variant of the BART model (results on other pretrained models can be found in Appendix C.1, which show similar trend). More specifically, we use the PyTorch implementation in the open-source library Hugging Face Transformers (Wolf et al., 2020) and its hosted pretrained models[3].

4 Experiments

4.1 Baselines

Extractive Baselines. We employ three common extractive summarization baselines each of which basically provides a mechanism to rank the input sentences. ***LexRank*** (Erkan and Radev, 2004) represents sentences in a graph and uses eigenvector centrality to calculate sentence importance scores. ***TextRank*** (Mihalcea and Tarau, 2004) is another graph-based sentence ranking method that obtains vertex scores by running a "random-surfer model"

---

[3] `https://huggingface.co/models`

until convergence. ***MMR*** (Carbonell and Goldstein, 1998) calculates sentence scores by balancing the redundancy score with the information relevance score. After ranking with each of the above models, we select sentences as output with different strategies according to the controlled and uncontrolled settings. For the uncontrolled setting, we simply select the top k sentences as the generated output, where k is a hyperparameter deciding the size of the generated output. For the controlled setting, we select only the top sentences with the right category labels according to the control sequence. To do so, we employ an LSTM-CRF (Lample et al., 2016) tagger trained on the labeled meta-reviews to predict the labels of each input review sentence. Refer to Appendix C.2 for more details of the tagger.

Generic Sentence Baselines. Considering the nature of meta-reviews, we could imagine some categories may have common phrases inflating the Rouge scores, such as "This paper proposes ..." for abstract, and "I recommend acceptance." for decision, etc. To examine such impact, we select sentences that are generic in each category and combine these sentences to generate outputs according to the control sequences. For instance, if the control sequence is "abstract | strength | decision", we take the most generic sentences from the categories of "abstract", "strength" and "decision" respectively to form the output. Specifically, we create two generic sentence baselines by obtaining generic sentences from the training data from either the meta-review references (i.e., target) or the input reviews (i.e., source), namely "Target Generic" and "Source Generic". Moreover, we also study such impact on the high-score and low-score submissions respectively, since an AC may write more succinct meta-reviews for clear-cut papers, as suggested by Figure 2. See Appendix C.3 for more details and results on generic sentence baselines.

4.2 Experimental Setting

To conduct text generation experiments, we preprocess our MReD dataset by filtering to ensure the selected meta-reviews have 20 to 400 words, as certain meta-review passages are extremely short or long. After preprocessing, we obtain 6,693 source-target pairs, for which we randomly split into train, validation, and test sets by a ratio of 8:1:1. We evaluate our generated outputs against the reference meta-reviews using the F_1 scores of ROUGE$_1$, ROUGE$_2$, and ROUGE$_L$ (Lin, 2004) [4].

	R_1	R_2	R_L
Source Generic	27.58	3.97	14.14
Target Generic	**27.98**	**5.52**	**15.01**
MMR, *unctrl*	31.43	5.45	16.31
LexRank, *unctrl*	31.74	6.67	16.71
TextRank, *unctrl*	32.72	**7.37**	17.25
MMR, *sent-ctrl*	32.37	6.28	17.58
LexRank, *sent-ctrl*	32.60	6.66	17.48
TextRank, *sent-ctrl*	**33.52**	7.20	**17.75**
bart-large-cnn, *unctrl*	33.31	8.63	19.67
bart-large-cnn, *sent-ctrl*	**38.73**	**10.82**	**23.05**
bart-large-cnn, *seg-ctrl*	36.38	10.04	21.90

Table 5: Meta-review generation results on MReD.

For the extractive and generic baselines, a key hyperparameter is the sentence number k. Recall that under the *sent-ctrl* setting, the control sequence length is the same as the sentence number of the target meta-review. Therefore, to conduct a fair comparison, we set the hyperparameter k equal to the number of labels in the control sequence for both controlled and uncontrolled extractive baselines, and *sent-ctrl* is used for all controlled extractive baselines. We also adopt the same k for the generic baselines.

For bart-large-cnn, we first load the pretrained model and then fine-tune it on MReD. All experiments are conducted on single V100 GPUs, using a batch size of 1 in order to fit the large pretrained model on a single GPU. During fine-tuning, we set the hyperparameters of "minimum_target_length" to 20, and "maximum_target_length" to 400, according to our filter range on the meta-review lengths. Due to long inputs (see Table 17), we experiment with different source truncation lengths of 1024, 2048, and 3072 tokens. We cannot explore truncation length of more than 3072 tokens due to the limitation of GPU space. Our learning rate is 5e-5, and we use Adam optimizer with momentum $\beta_1 = 0.9$, $\beta_2 = 0.999$ without any warm-up steps or weight decay. We set the seed to be 0, and train the model for 3 epochs with gradient accumulation step of 1. For decoding, we use a beam size of 4 and length penalty of 2.

4.3 Main Results

We show results in Table 5. Only the best settings of *rate-concat* (Section 4.4) and input truncation

---

[4] We use the Hugging Face Transformers' Rouge evaluation script, which has the field "use_stemmer" enabled. We include the evaluation script in our code.

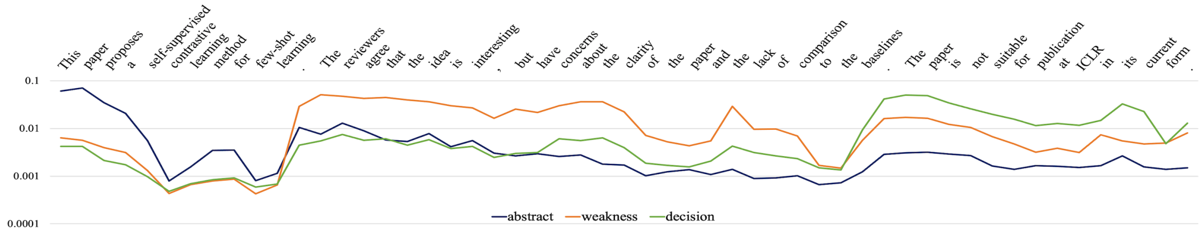

Figure 5: Cross attention weights of each generated token towards the control tokens in logarithmic scale.

of 2048 tokens (Appendix C.4) for bart-large-cnn are included. Amongst the extractive baselines, TextRank performs the best in both *unctrl* and *sent-ctrl* settings. Nevertheless, all controlled methods outperform their *unctrl* settings (same for the Transformers). This validates our intuition that structure-controlled generation is more suitable for user-subjective writings such as meta-reviews, because the model can better satisfy different structure requirements when supplied with the corresponding control sequences. On the other hand, for bart-large-cnn, *sent-ctrl* is the best, followed by *seg-ctrl*. This is most likely due to the former's more fine-grained sentence-level control that provides a clearer structure outline, as compared to the coarser segment-level control.

Moreover, bart-large-cnn far outperforms the extractive baselines, showing that the extraction-based methods are insufficient for MReD. This also suggests that meta-review writings are different from the input reviews, therefore copying full review sentences to form meta-reviews doesn't work well. This is also validated by the "Target Generic" baseline's consistent improvement over the "Source Generic" baseline, which shows that generic sentences from meta-reviews can suit generation better than those in reviews. Nevertheless, all Transformers results are still much better than the "Target Generic" sentence baseline, showing that despite generic phrases in some categories contributing to Rouge, the Transformers model is capable of capturing content-specific information for each input.

4.4 Review Combination Results

We also show uncontrolled generation results for different review combination methods in Table 6, with source truncation of 2048. The *longest-review* setting has the worst performance, thus validating that the review combination methods are necessary in order not to omit important information. *Rate-concat* has the best overall performance, which is the setting we used for the main results. Nevertheless, it is not significantly better than *merge*. It is also interesting to see that for *merge*, providing additional rating information (*rate-merge*) slightly worsens the performance. We will leave the investigation of better review combination methods for future work.

	R_1	R_2	R_L
longest-review	32.07	7.86	19.00
concat	32.88	8.58	19.63
merge	33.19	**8.77**	19.31
rate-concat	**33.31**	8.63	**19.67**
rate-merge	33.05	8.54	19.01

Table 6: Meta-review uncontrolled generation results for different review combination methods.

4.5 Case Study

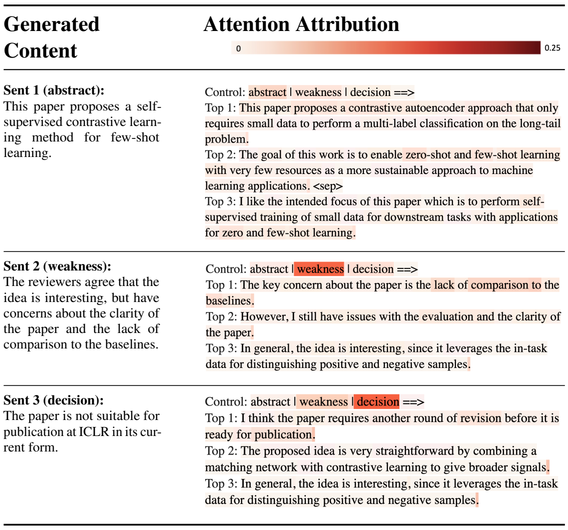
We study some cases for a better understanding of the structure-controllable generation.

Identify the control label for each sentence. We first evaluate whether the model is able to attend to the correct control label during generation. For each generation step, we obtain the cross attention weights from the decoder's output token towards the control labels, and plot them in Figure 5. The given control sequence is "abstract | weakness | decision". When generating each sentence, we can see that the attention weights of the corresponding control token are the highest, which demonstrates that our model can effectively pay attention to the correct control label and thus generate the content complying with the intent.

Extract information from the input sentences. To understand what information the model attends to when generating each sentence, we aggregate the cross attention weights to obtain the attention scores from each generated sentence towards all input sentences (Appendix C.5). Then, we select the top 3 input sentences with the highest attention scores for each generated sentence, and visualize the normalized attention weights on all tokens in

	Gold Labels	**Gold Meta-review**
0	abstract ∣ weakness ∣ decision	[The paper presents a self-supervised model based on a contrastive autoencoder that can make use of a small training set for upstream multi-label/class tasks.]←ABSTRACT [Reviewers have several concerns, including the lack of comparisons and justification for the setting, as well as the potentially narrow setting.]←WEAKNESS [Overall, I found the paper to be borderline, the cons slightly greater than the pros, so I recommend to reject it.]←DECISION
	Control Sequence	**Generated Passage**
1	abstract ∣ weakness ∣ decision	[This paper proposes a self-supervised contrastive learning method for few-shot learning.]←ABSTRACT [The reviewers agree that the idea is interesting, but have concerns about the clarity of the paper and the lack of comparison to the baselines.]←WEAKNESS [The paper is not suitable for publication at ICLR in its current form.]←DECISION
2	abstract ∣ abstract ∣ weakness ∣ decision	[This paper proposes a self-supervised contrastive learning method for few-shot learning.]←ABSTRACT [The idea is to learn the label embeddings using in-task data, and then use those for training a contrastive autoencoder for multi-label classification on the long-tail problem.]←ABSTRACT [The reviewers and AC note the following potential weaknesses: (1) limited novelty, (2) limited evaluation, and (3) lack of comparison to relevant baselines.]←WEAKNESS [AC agrees with the reviewers that the paper is not ready for publication in its current form.]←DECISION
3	strength ∣ weakness ∣ weakness ∣ rebuttal process ∣ suggestion ∣ decision	[Pros: The paper is well-motivated and the idea is simple and straightforward.]←STRENGTH [However, the reviewers have raised several concerns about the evaluation and the clarity of the paper.]←WEAKNESS [In particular, the lack of comparison to the baselines is a major concern.]←WEAKNESS [The authors have addressed some of these concerns in the rebuttal, but the reviewers are still not convinced about the significance of the results.]←REBUTTAL PROCESS [The paper would be much stronger if the authors could compare their method to more baselines for zero-shot learning, such as matching networks and Siamese networks.]←SUGGESTION [Overall, the paper is not ready for publication at ICLR.]←DECISION

Table 7: Varied generation outputs by giving different control sequences.



Generated Content	**Attention Attribution**
Sent 1 (abstract): This paper proposes a self-supervised contrastive learning method for few-shot learning.	Control: abstract ∣ weakness ∣ decision ==> Top 1: This paper proposes a contrastive autoencoder approach that only requires small data to perform a multi-label classification on the long-tail problem. Top 2: The goal of this work is to enable zero-shot and few-shot learning with very few resources as a more sustainable approach to machine learning applications. <sep> Top 3: I like the intended focus of this paper which is to perform self-supervised training of small data for downstream tasks with applications for zero and few-shot learning.
Sent 2 (weakness): The reviewers agree that the idea is interesting, but have concerns about the clarity of the paper and the lack of comparison to the baselines.	Control: abstract ∣ weakness ∣ decision ==> Top 1: The key concern about the paper is the lack of comparison to the baselines. Top 2: However, I still have issues with the evaluation and the clarity of the paper. Top 3: In general, the idea is interesting, since it leverages the in-task data for distinguishing positive and negative samples.
Sent 3 (decision): The paper is not suitable for publication at ICLR in its current form.	Control: abstract ∣ weakness ∣ decision ==> Top 1: I think the paper requires another round of revision before it is ready for publication. Top 2: The proposed idea is very straightforward by combining a matching network with contrastive learning to give broader signals. Top 3: In general, the idea is interesting, since it leverages the in-task data for distinguishing positive and negative samples.

Table 8: Attention analysis for each output sentence.

the selected sentences and the control sequence in Table 8. As shown, the model can correctly extract relevant information from the source sentences. For example, it identifies important phrases such as "interesting", "clarity" and "lack of comparison to baselines" when generating "Sent 2".

Generate varied outputs given different control sequences. To further investigate the effectiveness of the control sequence, we change the control sequence of the above example and re-generate the meta-reviews given the same input reviews. In Table 7, we first show the gold meta-review and the model output using the original control sequence in Row 0 and Row 1, and then show the model outputs with alternative control sequences in Row 2 and Row 3. From the outputs, we can see that indeed each generated sentence corresponds to its control label well. In Row 2, we add an additional control label in the sequence and by repeating the "abstract" label, the generator can further elaborate more details of the studied method. This is one key advantage of our *sent-ctrl* compared to the *seg-ctrl*, which allows the control of length and the level of the generation details. In Row 3, a very comprehensive control sequence is specified. We can see that the output meta-review is quite fluent and polite to reject the borderline paper. See Appendix C.6 for more examples.

4.6 Human Evaluation

In addition to the Rouge evaluation, we ask 3 human judges to manually assess the generation quality of the bart-large-cnn model trained under different control methods from Table 5 on 100 random test instances. For each test instance, we provide the judges with the input reviews and randomly ordered generations from different models, and ask them to individually evaluate the generations based on the following criteria: (1) *Fluency*: is the generation fluent, grammatical, and without unnecessary repetitions? (2) *Content Relevance*: does the generation reflect the review content well, or does it produce general but trivial sentences? (3) *Structure Similarity*: how close does the generation structure resemble the gold structure (i.e., the control sequence)? (4) *Decision Correctness*: does the gen-

	Unctrl	Sent-ctrl	Seg-ctrl
Fluency	4.145	**4.630***	4.090
Content Relevance	**4.585**	4.335	4.410
Structure Similarity (sent)	0.298	**0.706***	-
Structure Similarity (seg)	0.363	-	**0.623***
Decision Correctness	0.685	**0.830***	0.695

Table 9: Human evaluation. * indicates the ratings of corresponding models significantly (by Welch's t-test) outperform the *unctrl*: $p < 0.01$ for decision correctness, $p < 0.0001$ for fluency and structure similarity.

eration correctly predicts the gold human decision? We grade fluency and content relevance on a scale of 1 to 5, whereas structure similarity and decision correctness are calculated from 0 to 1 (Appendix C.7). For structure similarity, because *sent-ctrl* and *seg-ctrl* have different control sequences, we evaluate the two models on sentence-level (sent) and segment-level (seg) structures respectively, and provide both evaluations for *unctrl*.

As shown in Table 9, both *sent-ctrl* and *seg-ctrl* models show significant improvements on the generation structure over the uncontrolled baseline, which affirms the effectiveness of our proposed methods for structure-controllable generation. *Sent-ctrl* also has better fluency and decision correctness, suggesting that having a better output structure can benefit readability and decision generation. For the content relevance, the scores of all methods are reasonably good, and significance tests cannot prove any best model ($p > 0.08$). Nevertheless, it is possible that the looser control a method applies, the better relevance score it achieves. It is because a tighter control narrows the content that a model can use from the reviews.

5 Related Work

To facilitate the study of text summarization, earlier datasets are mostly in the news domain with relatively short input passages, such as NYT (Sandhaus, 2008), Gigaword (Napoles et al., 2012), CNN/Daily Mail (Hermann et al., 2015), NEWSROOM (Grusky et al., 2018) and XSUM (Narayan et al., 2018). Datasets for long documents include Sharma et al. (2019), Cohan et al. (2018), and Fisas et al. (2016). In this paper, we explore text summarization in a new domain (i.e., the peer review domain) and provide a new dataset, i.e., MReD. Moreover, MReD's reference summaries (i.e., meta-reviews) are fully annotated and thus allow us to propose a new task, namely, structure-controllable text generation.

Researchers recently explore the peer review domain data for a few tasks, such as PeerRead (Kang et al., 2018) for paper decision predictions, AMPERE (Hua et al., 2019) for proposition classification in reviews, and RR (Cheng et al., 2020) for paired-argument extraction from review-rebuttal pairs. Additionally, a meta-review dataset is introduced by Bhatia et al. (2020) without any annotation. Our work is the first fully-annotated dataset in this domain for the structure-controllable generation task. There are also some datasets and annotation schemes on research articles (Teufel et al., 1999; Liakata et al., 2010; Lauscher et al., 2018), which differ in nature from the peer review domain and cannot be easily transferred to our task.

A wide range of control perspectives has been explored in controllable generation, including style control (e.g., sentiments (Duan et al., 2020), politeness (Madaan et al., 2020), formality (Wang et al., 2019), domains (Takeno et al., 2017) and persona (Zhang et al., 2018)) and content control (e.g., length (Duan et al., 2020), entities (Fan et al., 2018a), and keywords (Tang et al., 2019)). Our structure-controlled generation differs from these works as we control the high-level output structure, rather than the specific styles or the surface details of which keywords to include in the generated output. Our task also differs from content planning (Reiter and Dale, 1997; Shao et al., 2019; Hua and Wang, 2019), which involves explicitly selecting and arranging the input content. Instead, we provide the model with the high-level control labels, and let the model decide on its own the relevant styles and contents.

6 Conclusions

This paper introduces a fully-annotated text generation dataset MReD in a new domain, i.e., the meta-reviews in the peer review system, and provides thorough data analysis to better understand the data characteristics. With such rich annotations, we propose simple yet effective methods for structure-controllable text generation. Extensive experimental results are presented as baselines for future study and thorough result analysis is conducted to shed light on the control mechanisms.

7 Ethical Concerns

We have obtained approval from ICLR organizers to use the data collected from ICLR 2018-2021 on OpenReview.

Categories	Examples
abstract	“The paper presents/explores/describes/addresses/proposes ...”
strength	“The reviewers found the paper interesting.” “The method and justification are clear.” “The quantitative results are promising.”
weakness	“The paper is somewhat incremental ...” “... claims are confusing” “The main concern is ...” “... unfair experimental comparisons ...”
rating summary	“R1 recommends Accept.” “All four reviewers ultimately recommended acceptance.” “Reviews were somewhat mixed, but also with mixed confidence scores.”
ac disagreement	“The area chair considers the remaining concerns by Reviewer 3 as invalid.” “I do not agree with the criticism about ...” “I disagree with the second point ...”
rebuttal process	“The authors have made various improvements to the paper” “... remained after the author rebuttal ...” “Authors provided convincing feedbacks on this key point.”
suggestion	“... more analysis ...” “The authors are advised to take into account the issues about ...”
decision	“The paper is recommended as a poster presentation.” “AC recommends Reject.” “I recommend rejection.”
miscellaneous	“Thank you for submitting you paper to ICLR.” “I’ve summarized the pros and cons of the reviews below.”

Table 10: Category examples of meta-review sentences.

A Data Annotation

A.1 Category definitions

We show category examples in Table 10.

A.2 Additional annotation rules

The additional rules for annotation are as follows: First, instead of only labeling the individual sentences per se, the annotators are given a complete paragraph of meta-review to label the sentences with context information. For example, if the area chair writes a sentence providing some extra background knowledge in the discussion of the weakness of the submission, even though that sentence itself can be considered as “misc”, it should still be labeled as “weakness” to be consistent in context.

Second, not every sentence can be strictly classified into a single category. When a sentence contains information from multiple categories, the annotators should consider its main point and primary purpose. One example is: “Although the paper discusses an interesting topic and contains potentially interesting idea, its novelty is limited.” Although the first half of the sentence discusses the strength of the submission, the primary purpose of this sentence is to point out its weakness, and therefore it should be labeled as weakness.

Furthermore, there are still some cases where the main point of the sentence is hard to differentiate from multiple categories. We then define a priority order of these 9 categories according to the importance of each category for annotators to follow: decision $>$ rating summary $>$ strength $\overset{?}{=}$ weakness $>$ ac disagreement $>$ rebuttal process $>$ abstract $>$ suggestion $>$ miscellaneous. We use the sign “$\overset{?}{=}$” because there are some rare cases where a sentence contains both “strength” and “weakness” while there is no obvious emphasis on either, and it is hard to tell whether “strength” should have a priority over “weakness” or the other way round. We then label this sentence based on the final decision: if this submission is accepted, we label the sentence as “strength”, and vice versa.

	Accept	Reject
abstract	23.8%	18.1%
strength	18.1%	9.3%
weakness	13.5%	34.3%
rating summary	6.3%	4.1%
ac disagreement	2.2%	0.5%
rebuttal process	13.2%	11.0%
suggestion	7.7%	8.2%
decision	9.2%	8.1%
miscellaneous	6.2%	6.4%

Table 11: Category distribution of borderline submissions (average score in the range of [4.5,6) breakdown by final decision.

B Data Analysis

B.1 Borderline papers

We further analyze the category distribution in borderline papers. As shown in Table 11, for submissions within the score range of [4.5,6), there are 713 accepted submissions and 2,588 rejected submissions. One clear difference is the percentage of “strength” and “weakness”. Another difference is the percentage of “ac disagreement”, where the accepted papers have four times the value than rejected ones. This suggests that for the accepted borderline papers, the area chair tends to share different opinions with reviewers, and thus deciding to accept the borderline submissions.

B.2 Percentage of each category for accepted and rejected papers across score ranges

We further analyze the occurrence of each category for accepted papers and rejected papers separately across different score ranges, as shown in Table 12. For accepted papers, as the score increases, the percentage of meta-reviews having “weakness” and “suggestion” drops because the high-score submissions are more likely to be accepted. Even the percentage of “decision” drops following the same trend. In addition, the proportion of meta-reviews

	Accept			Reject		
	Low	Med	High	Low	Med	High
abstract	**79**	75	74	69	69	74
strength	64	**71**	70	26	43	50
weakness	49	44	32	79	84	**88**
rating summary	25	**33**	32	29	25	24
ac disagreement	1	**6**	2	1	2	3
rebuttal process	**52**	47	37	35	39	39
suggestion	29	26	23	23	32	**38**
decision	**56**	53	46	53	53	**56**
miscellaneous	19	19	14	24	35	**45**

Table 12: Occurrence of different categories for accepted and rejected papers, breakdown by average scores. Low for scores ≤ 5.5, high for scores ≥ 6.5, and med for borderline scores in between.

having “rebuttal process” is larger for submissions with lower scores. This suggests that the rebuttal process plays an important role in the peer review process, especially in helping the borderline papers to be accepted.

On the other hand, for rejected papers, the percentage of meta-reviews having “strength” increases as the average score increases. This coincides with our common sense that the submissions receiving higher scores tend to have more strengths. One interesting finding here is that the percentage of “weakness” and “suggestion” also increases as the average rating score increases. This may be due to two main reasons. First, to reject a submission with higher scores, the area chair has to explain the weakness with more details and provide more suggestions for authors to further improve their submissions. Second, compared to the percentage of “strength”, “weakness” definitely has a larger percentage within any range of rating scores. The difference in the percentage of “strength” and “weakness” is intuitively different between the accepted papers and the rejected papers.

C Experiments

C.1 Additional transformers models

We provide baselines of uncontrolled generation and controlled generation on MReD using other common Transformer pretrained models in Table 13. Note that due to limited GPU space, we cannot fit 2048 input tokens for T5. Thus, for fair comparison, all results shown are from source truncation of 1024.

C.2 Tagger for source sentences

To obtain labels on source input, we train a tagger based on the human-annotated meta-reviews, then use it to predict labels on the input sentences.

Pretrained Model	R_1	R_2	R_L
Uncontrolled Generation			
facebook/bart-large-cnn*	**33.20**	**8.55**	19.62
facebook/bart-large	28.86	6.20	19.02
t5-large	30.75	8.44	**20.23**
google/pegasus-cnn_dailymail	28.76	6.37	16.79
Controlled Generation, *sent-ctrl*			
facebook/bart-large-cnn*	**38.39**	10.60	22.86
facebook/bart-large	38.05	**10.66**	23.39
t5-large	35.90	10.18	**23.92**
google/pegasus-cnn_dailymail	33.48	8.68	21.03

Table 13: Results of other common Transformers summarization models using source truncation of 1024. * represents our selected model in the main paper.

Specifically, we define the task as a sequence labeling problem and apply the long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) networks with a conditional random field (CRF) (Lafferty et al., 2001) (i.e., LSTM-CRF (Lample et al., 2016)) model on the annotated MReD dataset. The same data split as the meta-review generation task is used. We adopt the standard IOBES tagging scheme (Ramshaw, 1995; Ratinov and Roth, 2009), and fine-tune BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) models in Hugging Face. All models are trained for 30 epochs with an early stop of 20, and each epoch takes about 30 minutes. We select the best model parameters based on the best micro F_1 score on the development set and apply it to the test set for evaluation. All models are run with single V100 GPUs. We use Adam (Kingma and Ba, 2014) with an initial learning rate of 2e-5.

We report the F_1 scores for each category as well as the overall micro F_1 and macro F_1 scores in Table 14. Micro F1 is the overall accuracy regardless of the categories, whereas macro F1 is an average of per category accuracy evaluation. Since some of the category labels (eg. “ac disagreement”) are very rare, their classification accuracy is low. Overall, micro F1 is a more important metric since it suggests general performance. The results stand proof that the majority of the categories have their own characteristics that can be identified from other categories. RoBERTabase is the best performing model, therefore we use this model to predict review sentence labels.

C.3 Generic sentence baselines

Besides the baselines of “Source Generic” and “Target Generic”, we explore subsets of papers with

	Micro F_1	Macro F_1	abstract	strength	weakness	rating	ACdisagree	rebuttal	suggestion	decision	misc
BERT-base-cased + CRF	85.27	76.71	**94.58**	86.12	86.21	85.21	30.77	73.80	73.89	91.30	68.49
BERT-large-cased + CRF	84.68	77.84	93.93	**86.71**	84.36	84.07	40.00	72.60	74.35	91.60	**72.96**
RoBERTa-base + CRF	**85.83**	**79.99**	94.47	86.43	86.73	84.56	**54.84**	**74.44**	72.79	**93.08**	72.54
RoBERTa-large + CRF	85.72	79.34	94.42	85.61	**87.09**	**85.40**	50.00	73.97	**75.63**	90.93	71.00

Table 14: MReD sentence classification results.

	R_1	R_2	R_L
Source Generic	**27.58**	3.97	14.14
Source High Score	26.95	**4.38**	**15.18**
Source Low Score	25.82	4.14	14.40
Target Generic	27.98	5.52	15.01
Target High Score	31.10	5.76	16.82
Target Low Score	**32.04**	**7.21**	**19.09**

Table 15: MReD generic sentence baseline results on various score subsets.

high scores (average reviewers' rating $\geqslant 7$) or low scores (average reviewers' rating $\leqslant 3$) to obtain 4 additional generic baselines: "Source High Score", "Source Low Score", "Target High Score", "Target Low Score".

We use "Target High Score" as an example to explain how we obtain the generic sentences: From the training subset of high score papers, We first separate all meta-review sentences into the corresponding label categories, obtaining a total of 9 groups of sentences. Then, we re-arrange the sentences in each group using TextRank (our best extractive model). Since TextRank ranks the input sentences based on each sentence's content connection with others, sentences with higher rankings are also more general in the sense that they have more shared content with others.

After obtaining the generic sentence sets, we can create baseline generations using the *sent-ctrl* sequence on the corresponding high score paper test data. We avoid using the same sentence twice inside the same generation, so if the same label appears multiple times in a control sequence, we will use the same number of generic sentences for that category down the ranking order.

All generic sentence baselines can be obtained in a similarly procedure as outlined above, and we show results in Table 15. Both "Target High Score" and "Target Low Score" perform much better than the "Target Genric" baseline, suggesting that papers with very high or low scores tend to have more typical patterns in their meta-reviews. Nevertheless, the pattern is less evident in the source (reviews) baselines.

C.4 Ablation on truncation length

By default, the Transformers truncate the source to 1024 tokens. We further investigate the performance of different source truncation lengths under the setting of *rate-concat*. As shown in Table 18, truncating the source to 2048 tokens consistently achieves the best performance.

C.5 Attention aggregation method

During generation, we can obtain the attention weights of each output token towards all input tokens. Specifically, we average all decoder layers' cross attention weights for the same output token generated at each decoding step. We then calculate an attention value for that output token on each input sentence, by aggregating the token's attention weights on the list of input tokens that belong to the same sentence by max pooling. Finally, we can calculate an output-sentence-to-input-sentence attention score, by adding up these attention values for the output tokens that belong to the same sentence.

Common attention aggregation methods include summation, average-pooling, and max-pooling. We use max-pooling to aggregate attention for same-sentence input tokens, because summation unfairly gives high attention scores to excessively long sentences due to attention weight accumulation, whereas average-pooling disfavors long sentences containing a few relevant phrases by averaging the weights out. With max-pooling, we can correctly identify sentences with spiked attention at important phrases, regardless of sentence lengths. For attention aggregation on the same-sentence output tokens, summation is used and can be viewed as allowing each output token to vote an attention score on all input sentences, so that the input sentence receiving the highest total score is the most relevant. We conduct trial runs of all aggregation methods on input tokens with summation for output-token aggregation for multiple generation examples, and indeed max-pooling outperforms the other two by identifying more relevant input sentences with the generated sentence.

	Gold Labels	**Gold**
0	abstract | rating summary	[this work adapts cycle GAN to the problem of decipherment with some success.]←ABSTRACT [it's still an early result, but all the reviewers have found it to be interesting and worthwhile for publication.]←RATING SUMMARY

5	weakness | rebuttal process	[The reviewers raised a number of concerns including the correctness of the proof, the lack of a simple baseline, and the presentation of the paper.]←WEAKNESS [The authors' rebuttal addressed some of these concerns, but not to the degree that the reviewers felt it should be.]←REBUTTAL PROCESS

Table 16: Generation examples of alternative control sequences on the same review inputs using the *sent-ctrl* method.

Data Split	max	med	avg
train	7276	1482	1368
validation	3762	1427	1352
test	5144	1454	1352

Table 17: Source length statistics on all data splits. Max for maximum source length, med for median source length, and avg for average source length.

length	R_1	R_2	R_L
1024	38.39	10.60	22.86
2048	**38.73**	**10.82**	**23.05**
3072	38.30	10.34	22.57

Table 18: Meta-review *sent-ctrl* generation results of different source truncation lengths.

Once we have the attention scores, we can attribute the generation of each output sentence to a few topmost relevant input sentences. Then, we can draw a color map of the input tokens in the selected sentences based on their relative attention weights.

C.6 Structure-controlled generation examples

We show examples of the generation results using alternative control sequences on another submission in Table 16. We can see the effectiveness of controlling the output structure using our proposed method.

C.7 Human evaluation

For structure similarity, we instruct the judges to label each generated sentence with the closest category. We then calculate the normalized token-level edit distance between the judge-annotated label sequence and the given control sequence, where each label is considered as a single token, and finally deduct this value from 1.

For decision correctness, we evaluate it on a binary scale where 1 indicates complete correctness and 0 otherwise. More specifically, we give 0 if the generation produces either contradictory decisions or a wrong decision, or if the generation does not show enough hints for rejection or acceptance.

Single Model Ensemble for Subword Regularized Models in Low-Resource Machine Translation

Sho Takase and **Tatsuya Hiraoka** and **Naoaki Okazaki**
Tokyo Institute of Technology
`{sho.takase@nlp., tatsuya.hiraoka@nlp., okazaki@}c.titech.ac.jp`

Abstract

Subword regularizations use multiple subword segmentations during training to improve the robustness of neural machine translation models. In previous subword regularizations, we use multiple segmentations in the training process but use only one segmentation in the inference. In this study, we propose an inference strategy to address this discrepancy. The proposed strategy approximates the marginalized likelihood by using multiple segmentations including the most plausible segmentation and several sampled segmentations. Because the proposed strategy aggregates predictions from several segmentations, we can regard it as a single model ensemble that does not require any additional cost for training. Experimental results show that the proposed strategy improves the performance of models trained with subword regularization in low-resource machine translation tasks.

1 Introduction

Subword regularizations are the technique to make a model robust to segmentation errors by using multiple subword segmentations instead of only the most plausible segmentation during the training process (Kudo, 2018; Provilkov et al., 2020). Previous studies demonstrated that subword regularizations improve the performance of LSTM-based encoder-decoders and Transformers in various machine translation datasets, especially in low-resource settings (Kudo, 2018).

However, previous subword regularizations contain the discrepancy between the training and inference. In the training process, we stochastically re-segment a given sequence into subwords based on statistics such as the uni-gram language model (Kudo, 2018). Thus, we use multiple segmentations for each input sequence. In contrast, we use only the most plausible segmentation in the inference phase. We expect that we can improve the performance by solving this discrepancy.

To solve this discrepancy, we propose an inference strategy that uses multiple subword segmentations. We construct multiple subword segmentations for an input in the same manner as that in the training process, and then aggregate the predictions from each segmentation. Therefore, our proposed inference strategy can be regarded as a single model ensemble using multiple segmentations. Figure 1 illustrates the overview of previous methods and our proposed inference strategy.

We conduct experiments on several machine translation datasets. Experimental results show that the proposed strategy improves the performance of a subword regularized model without any additional costs in the training procedure when the subword regularization significantly contributes to the performance, i.e., in low-resource settings. Moreover, we indicate that our strategy can be combined with a widely used model ensemble technique.

2 Subword Regularization

Our proposed strategy is based on a model trained with subword regularization. Thus, we briefly describe subword regularization in this section.

Kudo (2018) proposed subword regularization to improve the robustness of a neural machine translation model. Let X and Y be the source and target sentences, $\mathbf{x} = (x_1, ..., x_S)$ and $\mathbf{y} = (y_1, ..., y_T)$ be the most plausible subword segmentations corresponding to X and Y. In the vanilla training strategy, i.e., without subword regularization, we train the parameters of a neural machine translation model $\boldsymbol{\theta}$ to maximize the following log-likelihood:

$$\mathcal{L}(\boldsymbol{\theta}) = \sum_{(X,Y)\in\mathcal{D}} \log P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}), \qquad (1)$$

$$P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}) = \prod_{t=1}^{T} P(y_t|\mathbf{x}, \mathbf{y}_{<t};\boldsymbol{\theta}), \qquad (2)$$

where $\mathcal{D}$ is the training data and $\mathbf{y}_{<t} = (y_1, ..., y_{t-1})$.

Findings of the Association for Computational Linguistics: ACL 2022, pages 2536 - 2541
May 22-27, 2022

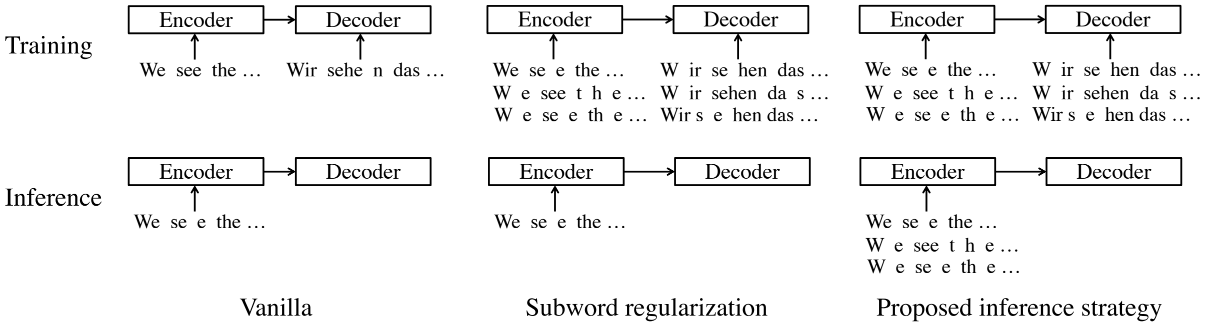

Figure 1: Overview of previous methods and the proposed inference strategy for an English-German pair “We see the ...” and “Wir sehen das ...”. In the vanilla setting, we use the most plausible segmentation only in the training and inference. In the subword regularization, we use multiple segmentations during training but use only the most plausible segmentation in the inference phase. In the proposed inference strategy, we use multiple segmentations in both the training and inference phases.

In contrast, subword regularization uses multiple subword segmentations during training. Let $P(\mathbf{x}'|X)$ and $P(\mathbf{y}'|Y)$ be segmentation probabilities for sequences X and Y, respectively. We optimize the parameters $\boldsymbol{\theta}$ with the following marginalized likelihood in subword regularization:

$$\mathcal{L}'(\boldsymbol{\theta}) = \sum_{(X,Y)\in\mathcal{D}} \mathbb{E}_{\substack{\mathbf{x}'\sim P(\mathbf{x}'|X) \\ \mathbf{y}'\sim P(\mathbf{y}'|Y)}} [\log P(\mathbf{y}'|\mathbf{x}';\boldsymbol{\theta})]. \tag{3}$$

Because the number of possible segmentations increases exponentially with respect to the sequence length, it is impractical to optimize Equation (3) exactly. Thus, Kudo (2018) approximated Equation (3) with sampled segmentations from $P(\mathbf{x}'|X)$ and $P(\mathbf{y}'|Y)$,

$$\mathcal{L}'(\boldsymbol{\theta}) \cong \sum_{(X,Y)\in\mathcal{D}} \log P(\mathbf{y}_j|\mathbf{x}_i;\boldsymbol{\theta}), \tag{4}$$

$$\mathbf{x}_i \sim P(\mathbf{x}'|X), \tag{5}$$

$$\mathbf{y}_j \sim P(\mathbf{y}'|Y). \tag{6}$$

We sample $\mathbf{x}_i$ and $\mathbf{y}_j$ for every mini-batch during training to yield a good approximation.

In the inference phase, we input the most plausible segmentation $\mathbf{x}$ and search a sequence $\mathbf{y}^*$ that maximizes the log-likelihood $\log P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta})$. In other words, we input one segmentation to the model[1] even though we use multiple segmentations during training.

Language	Vocab	Train	Dev	Test
En-De	6K	160K	7283	6750
En-Vi	4K	133K	1553	1268

Table 1: Details of each dataset.

3 Proposed Method

3.1 Proposed Inference Strategy

As described, previous subword regularizations use multiple segmentations during training but only one segmentation in the inference. To solve this discrepancy, we propose an inference strategy that uses multiple segmentations as inputs. In the proposed strategy, we search a sequence $\mathbf{y}^*$ that maximizes the following approximated marginalized likelihood:

$$\sum_{k=1}^{n} \log P(\mathbf{y}|\mathbf{x}_k;\boldsymbol{\theta}), \tag{7}$$

$$\mathbf{x}_k = \begin{cases} \mathbf{x} & k = 1 \\ \mathbf{x}_i \sim P(\mathbf{x}'|X) & \text{Otherwise.} \end{cases} \tag{8}$$

In short, we approximate the marginalized likelihood in Equation (3) with the most plausible segmentation and sampled $n-1$ segmentations.

3.2 Relation to Model Ensemble

We often apply the model ensemble technique to achieve better performance (Barrault et al., 2019). In the model ensemble, we aggregate the predictions from M models as follows:

$$\sum_{m=1}^{M} \log P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}_m), \tag{9}$$

---

[1] Kudo (2018) also proposed n-best decoding. This strategy uses n segmentations but inputs them separately. In other words, a model receives only one segment and generates the corresponding output n times in this strategy. We compare this strategy in experiments.

Method	En-De	De-En	En-Vi	Vi-En
Single Model				
Vanilla	28.89	34.87	31.09	31.43
+ w/ subword regularization (1)	29.51	35.53	31.86	**31.60**
(1) + n-best decoding	29.59	35.55	31.94	31.44
(1) + Proposed strategy	**29.72**	**35.68**	**32.16**	**31.60**
Model Ensemble				
Vanilla	30.03	36.04	32.22	32.46
+ w/ subword regularization (2)	30.83	36.83	33.22	32.83
(2) + n-best decoding	30.81	36.83	33.29	32.76
(2) + Proposed strategy	**30.86**	**36.95**	**33.44**	**33.04**

Table 2: BLEU scores on English-German and English-Vietnamese datasets.

where $\boldsymbol{\theta}_m$ denotes parameters of the m-th model.

In comparison to this model ensemble, the proposed strategy does not use multiple models but aggregates predictions from multiple segmentations. Thus, our proposed strategy can be regarded as the single model ensemble with multiple inputs. In addition, we can combine the proposed strategy with the model ensemble. We investigate the effect of this combination through experiments.

4 Experiments

4.1 Datasets

Kudo (2018) reported that subword regularization is especially effective in low-resource settings. Thus, we focus on low-resource machine translation tasks. We used IWSLT 2014 English-German (En-De) data in the same pre-processing manner as Ranzato et al. (2016)[2] because this dataset is widely-used as the low-resource setting (Sennrich and Zhang, 2019; Takase and Kiyono, 2021). In addition, we used IWSLT 2015 English-Vietnamese (En-Vi) data which were pre-processed by Luong and Manning (2015)[3].

We used SentencePiece (Kudo and Richardson, 2018) to construct a vocabulary set. We set the vocabulary sizes to 6k and 4k for En-De and En-Vi, respectively. Table 1 summarizes the dataset sizes.

4.2 Methods

We used Transformer (Vaswani et al., 2017) as our encoder-decoder architecture because Transformers are widely used as strong baselines in sequence-to-sequence problems including machine translation. We investigate the performance of the following configurations.

Vanilla: We trained Transformer (Vaswani et al., 2017) without subword regularization. For hyper-parameters, we adopted the IWSLT setting in `fairseq`[4] (Ott et al., 2019).

Subword regularization: We trained Transformer, whose hyper-parameters are identical to Vanilla, with subword regularization. We set the hyper-parameter α for sampling segmentations in subword regularization 0.2 in the same as Kudo (2018).

n-best decoding: Kudo (2018) proposed n-best decoding that generates n sequences corresponding to n-best segmentations and then outputs the most plausible sequence. We used this strategy for the model trained with subword regularization in the inference phase.

Proposed: We applied the proposed strategy to the model trained with subword regularization. To ensure fair comparison, we used the identical number, $n = 5$, for the number of sampled segmentations and n-best decoding.

4.3 Results

Table 2 shows BLEU scores of each configuration. For each configuration, we trained three models with different random seeds, and reported the averaged scores except for the proposed strategy. When we used the proposed strategy, we generated sequences three times with different random seeds for each model[5], and averaged the 9 (3 models ×

[4] https://github.com/pytorch/fairseq

[5] Because the generated sequence mainly depends on the trained model, our inference strategy generates almost the same sequences even if we vary random seeds for samplings. However, we reported the averaged BLEU of 9 sequences to make the results more reliable.

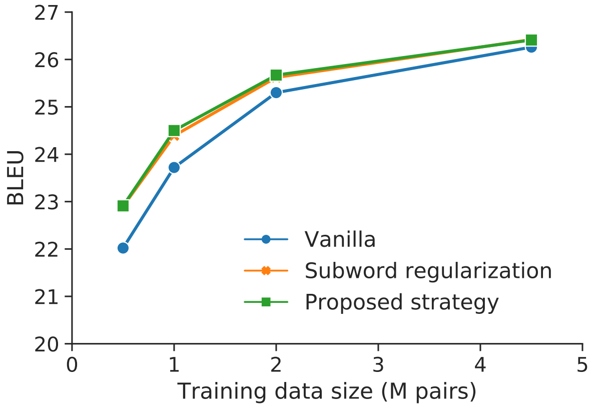

Figure 2: BLEU scores on newstest2013 when we vary the training data size.

3 sequences) scores. Table 2 also indicates BLEU scores with the ensemble of the above 3 models.

For the single model setting, Table 2 shows that subword regularization improved BLEU scores in all language pairs. In particular, subword regularization gained more than 0.5 BLEU score from Vanilla except for Vi-En. In these language pairs, the proposed strategy provided further improvements. The proposed strategy achieved better performance than n-best decoding when we used the same number of segmentations as inputs. Thus, our proposed method is more effective as the inference strategy. Moreover, our strategy maintained the score in Vi-En although n-best decoding degraded the score slightly. Therefore, the proposed strategy had no negative effect on the inference.

For the model ensemble setting, Table 2 indicates that subword regularization also improved BLEU scores in all language pairs. In this setting, the proposed strategy also provided further improvements in all language pairs. Thus, the proposed strategy is effective even if we conduct the model ensemble technique.

5 Performance in Enough Training Data

Section 4 shows the results in low-resource settings but previous studies reported that subword regularizations can improve the performance if we use sufficient training data. Thus, we investigate the performance of subword regularization and proposed strategy by varying the size of training data.

We used the WMT 2016 English-to-German training dataset, which is widely used in previous studies (Vaswani et al., 2017; Provilkov et al., 2020; Ott et al., 2018). This dataset contains 4.5M sentence pairs, that are more than 25 times as many as IWSLT datasets. We conducted pre-processing in the same manner as that in Ott et al. (2018). We trained the Transformer (base) model in Vaswani et al. (2017). For subword regularization, we set $\alpha = 0.5$ in the same as Kudo (2018). We evaluated BLEU scores on newstest2013, which is widely used as a valid data.

Figure 2 shows BLEU scores of each method for each training data size. This figure indicates that the model trained with subword regularization outperformed Vanilla in all training data sizes but the improvement decreased in accordance with the increase in the training data. The proposed strategy slightly improved the performance from subword regularization for the small training data but the improvement also decreased as the training data increased. When we used the entire training data (4.5M translation pairs), the BLEU score of the proposed strategy was identical to that of subword regularization. This result implies that the impact of the proposed strategy on the performance is small when the improvement by subword regularization is small. In other words, the proposed strategy is effective especially in low-resource settings because subword regularization probably provides much improvement in low-resource settings. However, we emphasize that the proposed strategy has no negative effect on the BLEU score for sufficient training data fortunately.

6 Related Work

In this study, we proposed the inference strategy to mitigate the discrepancy between the training and inference in subword regularizations. In experiments, we focused the subword regularization proposed by Kudo (2018) but we can apply the proposed inference strategy to variants of the subword regularization such as BPE dropout (Provilkov et al., 2020) and compositional word replacement (Hiraoka et al., 2022). Takase and Kiyono (2021) reported that simple perturbations such as word dropout are effective in a large amount of training data. Thus, we might improve the performance of the model trained with such simple perturbations if we use multiple inputs constructed by the same perturbation during the inference.

We focused on an input of a neural encoder-decoder. In contrast, Gal and Ghahramani (2016) focused on internal layers. For neural network methods, we often apply the dropout during the training but do not use it in the inference. Gal and Ghahramani (2016) proposed the variational inference to mitigate this gap on the dropout.

As described in Section 1, our proposed inference strategy can be regarded as a single model ensemble. Huang et al. (2017) and Kuwabara et al. (2020) also proposed single model ensemble methods. Huang et al. (2017) proposed the snapshot ensemble that uses multiple models in the middle of the training. Kuwabara et al. (2020) used pseudo-tags and predefined distinct vectors to obtain multiple models virtually during the training of a single model. Since these methods are orthogonal to ours, we can combine our proposed strategy.

7 Conclusion

We proposed an inference strategy to address the discrepancy between the training and inference in subword regularizations. Our proposed strategy uses multiple subword segmentations as inputs to approximate the marginalized likelihood used as the objective function during training. The proposed strategy improved the performance of the model trained with subword regularization in cases where subword regularization provided the significant improvement, i.e., in low-resource settings. Moreover, the proposed strategy outperformed the n-best decoding strategy (Kudo, 2018). Experimental results show that our proposed strategy has no negative effect on the BLEU score even if the improvement by subword regularization is small. Because the proposed inference strategy does not require any additional training cost, we encourage using the strategy to highlight the potential of models trained with subword regularization.

Ethical Considerations

Limitations: The proposed method improves the performance of encoder-decoders in the inference phase in the situation where subword regularizations are effective. Thus, if subword regularizations are ineffective, the proposed method also might be ineffective. Since subword regularizations are especially effective when the training data size is small (Hiraoka et al., 2021), the proposed method is effective in low-resource settings. In contrast, as in Section 5, the improvements of both methods are small when we have an enough training data.
Risks: Since the proposed method uses the standard neural encoder-decoder architecture without any modification, the proposed method also contains the risks of neural encoder-decoders. For example, the under translation, that ignores some information in a source sentence during the translation, might happen.

Abstract

The filtering and/or selection of training data is one of the core aspects to be considered when building a strong machine translation system. In their influential work, Khayrallah and Koehn (2018) investigated the impact of different types of noise on the performance of machine translation systems. In the same year the WMT introduced a shared task on parallel corpus filtering, which went on to be repeated in the following years, and resulted in many different filtering approaches being proposed. In this work we aim to combine the recent achievements in data filtering with the original analysis of Khayrallah and Koehn (2018) and investigate whether state-of-the-art filtering systems are capable of removing all the suggested noise types. We observe that most of these types of noise can be detected with an accuracy of over 90% by modern filtering systems when operating in a well studied high resource setting. However, we also find that when confronted with more refined noise categories or when working with a less common language pair, the performance of the filtering systems is far from optimal, showing that there is still room for improvement in this area of research.

1 Introduction

The phenomenon of noisy data in the training of machine translation (MT) systems has been studied from various angles over recent years. To outline the impact of noise, Khayrallah and Koehn (2018) specified ten common noise categories and synthetically generated noisy data samples for each of them. By adding the noisy samples to an otherwise clean training corpus they measured the effect on the resulting translation system. Their conclusion was that neural machine translation (NMT) is less robust towards noisy data than statistical machine translation and that some noise types can prove very detrimental to NMT performance. As NMT had surpassed the statistical approaches just a few years prior, this work paved the way for a spiked interest in data filtering research for machine translation.

In the same year, the Conference on Machine Translation (WMT) started to host an annual shared task on parallel corpus filtering (Koehn et al., 2018, 2019, 2020) featuring a broad mix of academic and industrial submissions. This shared task highlights the general need for well working data filtering systems and resulted in the publication of a variety of new filtering approaches (Junczys-Dowmunt, 2018; Chaudhary et al., 2019; Lu et al., 2020). The WMT evaluations simulate a real-world data filtering task on web crawled data. Each participating system is required to extract a fixed amount of parallel data and is ranked according to the performance of the translation system that was trained on the selected data. While this form of evaluation is very relevant from a practical point of view, it does not show how well a certain approach is performing on detecting specific types of noise - information that is very important when working on improving data filtering approaches.

In this work we aim to unite both viewpoints in regards to data filtering. From the work of Khayrallah and Koehn (2018) we already know how detrimental certain categories of noise are to an NMT system, so we ask the question: *How well can state-of-the-art filtering systems distinguish the synthetic noise classes proposed by Khayrallah and Koehn (2018) from clean data?*

While downstream performance might be the ultimate objective for data filtering systems, this setup allows us to investigate the strengths and weaknesses of current data filtering systems. To further investigate the challenges for a filtering system we introduce several, more refined, synthetic noise categories and use them to benchmark the performance of the aforementioned filtering systems.

2 Related Work

The task of data filtering for machine translation has attracted increasing attention in recent years, mainly for two reasons:

1. NMT models replaced the phrase based systems and it was shown that NMT models are less robust to many types of noise (Khayrallah and Koehn, 2018).

2. More and more parallel data is generated by web crawling techniques (Esplà-Gomis et al., 2019; Schwenk et al., 2019; El-Kishky et al., 2020; Schwenk et al., 2021) and this data is often quite 'noisy', making data filtering a crucial part of training competitive NMT systems.

To get an overview of existing approaches to data filtering for machine translation, a good place to start is the WMT shared task for parallel corpus filtering, which was held in 2018 (Koehn et al., 2018), 2019 (Koehn et al., 2019) and 2020 (Koehn et al., 2020). In these tasks, the participants are asked to select a fixed amount of data from a noisy parallel corpus using automatic methods. The examined language pairs were German-English (2018), Nepali-English (2019), Sinhala-English (2019), Khmer-English (2020) and Pashto-English (2020). The winning systems used a combination of language identification and language model and translation model scoring (Junczys-Dowmunt, 2018; Rossenbach et al., 2018), similarities in the cross-lingual sentence embedding space (Chaudhary et al., 2019) and even GPT-2 models (Lu et al., 2020). The only way in which data filtering systems are typically evaluated is by training a machine translation system on the selected data (Koehn et al., 2018, 2019, 2020). While this may be an intuitive evaluation criterion, it does not give many insights into the system performance regarding the detection of specific types of noise.

While much effort has been put into the building of powerful filtering systems, the same can not be said for analyzing their performance on specific types of noise. Belinkov and Bisk (2018) and Khayrallah and Koehn (2018) both examine the impact of various noise types on the performance of NMT systems but do not ask the question which types of noise can be handled reliably by data filtering systems. Xu and Koehn (2017) create synthetic noisy data to train a data filtering system with a classifier while Michel and Neubig (2018) create a 'noise translation benchmark' for NMT systems.

In this work we aim to fill this gap and systematically compare the performance of data filtering systems on specific categories of noise. We start from the categories defined in Khayrallah and Koehn (2018) and expand them further.

3 Types of Noise

We aim to investigate which noise categories can be reliably detected by state-of-the-art data filtering systems. Manual annotation of noisy corpora is expensive and tends to be very corpus and language specific, depending on the original data sources and the extraction techniques. Therefore we decide to investigate filtering systems on an array of noisy datasets mostly created synthetically from clean parallel data like it was done by Khayrallah and Koehn (2018). Most of the categories were introduced in the work of Khayrallah and Koehn (2018) (in the following marked with an asterisk (*)) but we propose two additional categories which we found to commonly occur in practice. Here we list all types of noise that we are investigating as well as our automatic and language agnostic methods of creating such noisy data. If a certain type of noise is specific to the source or target side of the data, we note the noisy side in brackets.

Misaligned Sentences* are created by shuffling the target side of a clean corpus. Hence, every source sentence get assigned a random target sentence from the same domain but (most probably) without any overlap in meaning.

Misordered Words (src|trg)* are obtained by arranging the words of either source or target sentence in a random order.

Wrong Language (src|trg)* samples are selected from a parallel corpus from a different language pair. We specify which side of the data is not fitting the intended task.

Untranslated (src|trg)* sentence pairs are created by converting a src-trg corpus into a src-src respectively trg-trg corpus via copying.

Short Segments (max. length)* are from a corpus with very short average sentence length. A segment being short does not imply that it is noisy or hurtful to the training. However we keep these categories for completeness sake in our analysis but do not emphasize on them in the experimental results.

Raw Crawled Data* is a mix of different types of noise and probably the most realistic noise category. We use data from an unfiltered web crawling corpus. Note that some sentence pairs from this category might be valid in practice and we address this in Section 5.1.

Over-/Undertranslation often times happen as a result of poor sentence splitting and alignment. To create sentence pairs in this category we remove the second half of the source sentence respectively target sentence.

Synthetic Translations can be found on an increasing number of websites and the simpler structure of synthetic translations (Edunov et al., 2018; Kim et al., 2017) can make them easier to be extracted and aligned by crawling scripts. To analyze if the the quality of the synthetic translations has an effect on detection accuracy, we extract human annotated data from the WMT shared task on news translation and group sentence pairs according to the human evaluation score.

It should be noted that most categories either distort the source or the target sentence of a pair. We keep this separation for our analysis even though many data filtering systems do not distinguish the languages direction, i.e. an X→Y filtering system can be used to clean a Y→X corpus. Hence, differences between the src- and trg-version of a noise category should best be seen as an indication of experimental variance or a dependency on the resources available for the two sides of a language pair.

4 Effect of Noise on NMT Performance

In this work we solely focus on the question how well certain types of noise can be detected by modern data filtering systems. However, an equally important question is, how detrimental a certain noise type is to the performance of an NMT system. In this section we briefly recapitulate the findings of Khayrallah and Koehn (2018), ranging the different types of noise according to their effect on NMT performance.

According to Khayrallah and Koehn (2018), the most severe noise type is the **Untranslated (trg)** category. Mixing just 20% of this type of noisy data into our clean training data results in an NMT performance drop to less than 10% BLEU, completely destroying translation performance. The authors explain this with the system learning to copy sentences rather than translating them into the correct language. The second worst type of noise is **Raw Crawled Data**, followed by **Misaligned Sentences**, **Misordered Words (src|trg)** and **Wrong Language (trg)** all leading to a significant performance degradation of the NMT system. On the other hand, Khayrallah and Koehn (2018) find that adding **Wrong Language (src)**, **Untranslated (src)** and **Short Segments (max. length)** leads to only minor performance degradation.

We additionally examine two types of noise which were not present in the work of Khayrallah and Koehn (2018), namely **Synthetic Translations** and **Over-/Undertranslation**. The latter mostly occurs as a result of bad segmentation and/or sentence splitting. We argue that in the most extreme case, this type of noise would coincide with the **Misaligned Sentences** so the impact of this category can be seen as an upper bound. In principle **Synthetic Translations** can be beneficial for NMT performance (Sennrich et al., 2016; Edunov et al., 2018; Kim et al., 2019). However, this depends heavily on the quality of the system used to generate this synthetic data and we argue that the purpose of web crawling is not to extract synthetic translation from possibly older machine translation models. Hence, we typically want to remove such samples. Therefore in this work we examine both the ability of the filtering systems to differentiate between good and bad synthetic data as well as to differentiate between synthetic and real parallel data.

We also point out that removing noise from the training data will have other benefits, aside from improved performance, such as faster convergence and less storage needs.

5 Experiments

5.1 Experimental Setup

In the following we briefly describe the filtering systems used in this study and the data conditions.

Filtering Systems

For our analysis we consider two of the strongest data filtering approaches to this date, based on either

- cross-entropy (CE) scores using translation and language models (Rossenbach et al., 2018).
- Language-Agnostic SEntence Representations (LASER) scores based on cross lin-

gual sentence embeddings (Chaudhary et al., 2019).

Both systems were among the winners of the WMT task on parallel corpus filtering in 2018 and 2019 respectively.

For the cross entropy system, we follow (Rossenbach et al., 2018) and train a source-to-target translation model $p_{s \to t}(e_1^I | f_1^J)$, a target-to-source translation model $p_{t \to s}(f_1^J | e_1^I)$ as well as two language models $p_s(f_1^J)$ and $p_t(e_1^I)$. We calculate a score for each sentence pair (f_1^J, e_1^I) with

$$\frac{1}{4}\left(\frac{1}{J}\log p_s(f_1^J) + \frac{1}{I}\log p_t(e_1^I) + \frac{1}{J}\log p_{t\to s}(f_1^J|e_1^I) + \frac{1}{I}\log p_{s\to t}(e_1^I|f_1^J)\right).$$

The language models and translation models are implemented using the RETURNN toolkit (Zeyer et al., 2018). We use a 12 layer transformer model for the language models and the base transformer model (Vaswani et al., 2017) with 6 encoder and 6 decoder layers for the translation models.

For calculating the LASER scores, we generate cross-lingual sentence embeddings using the pretrained model provided by Artetxe and Schwenk (2019). The underlying system is trained as a multilingual translation system with a multi-layer bidirectional LSTM encoder and an LSTM decoder. No additional information about the input language is given to the encoder. The output vectors of the encoder are compressed into a single embedding of fixed length using max-pooling. This is the cross-lingual sentence embedding that the LASER model is generating. This vector is the only information about the input sentence which is transferred to the decoder. The intuition is, that two sentences with the same meaning but from different languages will be mapped onto the same embedding vector, as the translations that the decoder must produce should be identical. Once the cross-lingual sentence embeddings for every source and target sentence are extracted, we calculate the LASER scores for each sentence-pair according to Chaudhary et al. (2019):

$$\frac{2k\ \cos(f,e)}{\sum_{\hat{e}\in \mathrm{NN}_k(f)} \cos(f,\hat{e}) + \sum_{\hat{f}\in \mathrm{NN}_k(e)} \cos(\hat{f},e)}$$

where f, e are the sentence embeddings for source and target sentence respectively, $\cos(\bullet)$ is the cosine distance and $\mathrm{NN}_k(\bullet)$ is the set of the k nearest embeddings from the other language. The higher the LASER score of a sentence pair, the more similar the source and target sentence are semantically, corresponding to a better quality data point for training an NMT system.

Task	Data Type	#tokens (trg)	#lines
De→En	parallel	79M	3.1M
Km→En	parallel	4.9M	270k
	Km mono	546M	11M
	En mono	419M	11M

Table 1: Data resources used for the De→En and Km→En tasks.

Many filtering systems rely on some language identification (langID) toolkit as part of the selection method. With langID, each data point gets either a score of 1.0 or 0.0, depending on whether the predicted source and target languages match the given task or not. Since langID can be seen as a 'baseline' filtering technique on its own, we address it as a separate step in the filtering pipeline and denote for each experiment whether langID scores are included or not. When combining langID with the other methods, the scores are simply multiplied. For the task of language identification we use the popular `langid.py` toolkit (Lui and Baldwin, 2012).

Data

We benchmark the performance of the filtering systems on two language pairs: German→English and Khmer→English. For an overview over the amounts of data used we refer to Table 1. For both settings we remove a section of the parallel corpus from the training data to create the synthetic noise for the following categories: Misaligned Sentences, Misordered Words, Untranslated, and Over/Under-Translation.

Following Khayrallah and Koehn (2018), the De→En data consists of Europarl, News Commentary, and the Rapid EU Press Release corpus from the WMT2017 news translation task [1]. From this clean data we select randomly 7 × 50k sentence pairs to create the aforementioned synthetic noise categories. Every sentence pair contained in a noise category is excluded from the training corpus for all components of the data filtering systems. To create the remaining noise categories we used the same corpora as Khayrallah and Koehn (2018).

Table 2: De→En Task: Accuracy of filtering methods when distinguishing different synthetic noise categories from clean, parallel data. Accuracies are reported a) in black: with knowledge of correct ratio between noisy and clean data b) in gray (oracle): with optimal noise-clean separation given the ranking of the filtering system.

For Km→En we use data from the WMT2020 parallel corpus filtering task[2]. We extract 20k sentence pairs from the clean corpus to create the synthetic noisy datasets. Since the Km→En task does not provide a lot of data to begin with, we use the same 20k sentence pairs to create the all synthetic noise categories and train the translation models for the cross-entropy filtering system on the remaining data. Since we were not able to find suitable data for the short segments and wrong language categories, we drop these for this language pair. Given that the parallel corpus is relatively small and of questionable quality, we additionally include all of the available monolingual Khmer data and subsample 11M English sentences to train the language models. To obtain raw crawled data we sample 20k sentence pairs from a web crawled corpus from the ParaCrawl project [3]. Note that this corpus also contains valid sentence pairs, however by manually annotating 150 sentence pairs, we observed that less than 10% of the sentence pairs were of acceptable quality.

5.2 Experimental Results

For each noise category described in Section 3, we generate a corresponding noisy testset. Each noisy testset is separately mixed together with an equal number of sentence-pairs sampled from a holdout set of the clean training data to create a mixed dataset where each sentence pair is labelled as either clean or noisy. To analyze the noise detection capability of the filtering systems we use either the cross-entropy or LASER approach to score each sentence-pair and sort the lines by score. For each system, a threshold-score is determined and all pairs with a score worse than the threshold are classified as noisy and all pairs with a score better than the threshold are classified as clean. This allows us to calculate the classification accuracy of the corresponding filtering system.

Two different thresholds are calculated separately for each mixed dataset:

- **Correct Ratio:** the threshold is chosen according to the true ratio between clean and noisy sentence pairs. If not denoted differently we use a 1:1 ratio.
- **Optimal (oracle):** the threshold is chosen such that we get the highest accuracy possible given the current filtering scores for the dataset. This requires knowledge of the true class and yields an upper bound of the filtering capabilities of the scoring system.

This means that if we were to rank the sentence pairs randomly, we would end up with around 50%

Table 3: Km→En Task: Accuracy of filtering methods when distinguishing different synthetic noise categories from clean, parallel data. Accuracies are reported a) in black: with knowledge of correct ratio between noisy and clean data b) in gray (oracle): with optimal noise-clean separation given the ranking of the filtering system.

classification accuracy for both thresholds. Therefore 50% accuracy can be seen as a lower bound and if a filtering system drops significantly below that, its score is negatively correlated with data quality. When just using langID, each data point is scored with either 1.0 or 0.0, so no additional threshold calculation is needed. We note that we only focus on the quality of the data filtering scores and not and the question of how to select data, i.e. how to select a threshold. It is possible that this yields a more optimistic estimation of the filtering capabilities than is achievable in practice where even the clean to noise ratio is typically unknown.

German→English

The resulting accuracy scores for the De→En setup are listed in Table 2 where the **correct ratio** score is written on the left in each cell and the **optimal** score is written on the right and grayed out.

We find that the four noise categories that involve not-fitting languages, namely 'wrong language (src, trg)' and 'untranslated (src, trg)', are almost perfectly removed thanks to the language identification. Furthermore, langID also detects most of the noise stemming from raw crawl data and very short segments. As expected, langID fails to detect any noise coming from misalignment and over-/undertranslation. The cross-entropy approach has little trouble identifying the 'short segments ($\leq$ 2)', 'misordered words (src, trg)' and 'raw crawl data' noise types. The standalone LASER system fails to detect any noise stemming from incorrect languages which is compensated for by language identification filtering. From the noise categories that are defined in Khayrallah and Koehn (2018), only 'misaligned sentences' and 'short segments ($\leq$ 5)' pose a serious detection problem. While for the latter, one could argue that it is neither harmful to the system performance (Khayrallah and Koehn, 2018) nor actually noise, the bad performance on the 'misaligned sentences' is quite surprising as this type of noise is quite severe and should be detected quite reliably in theory by both cross entropy and LASER filtering. The noise categories 'overtranslation' and 'undertranslation', which are newly added in this work, pose a serious problem for all filtering methods. In general, there is not much difference in accuracy for the combined filtering systems when detecting sentence corruptions on the German side (source) compared to the English side (target).

Regarding the selection method, we find that the cross-entropy approach is less susceptible towards different types of thresholds compared to the LASER approach. It is not clear to us why this is the case but we speculate it has to do with the fact that the CE approach is less reliant on the langID scores overall. Both cross-entropy and LASER benefit from the combination with langID.

Khmer→English

As the second language pair, we use Khmer→English, a task where the languages have very little in common in terms of syntax and data resources are scarce. The accuracy scores for the Km→En setup are listed in Table 3. As one might expect, the language identification does not perform as good for the Khmer language.

In fact in some cases the inclusion of langID is actively hurting the overall filtering performance, for example for the ‘misaligned sentences’ and ‘undertranslation’ categories. In contrast to the De→En setting, most noise categories can not be detected reliably, with the exception of the ‘untranslated (src, tgt)’, ‘misordered words (tgt)’ and ‘raw crawl data’. Most of the times, noise on the English target side can be detected more reliably than on the Khmer source side, although still not with a very good accuracy.

Synthetic Data Detection

Next, we investigate another type of noise that is often overlooked, namely synthetic data where either the source or the target side is created by MT systems. To obtain the synthetic data as well as corresponding quality annotation, we use the human-scored automatic translations of the WMT De→En news translation task from 2016 to 2019. For each year, we rank all hypotheses according to the score of the human annotators. We take the the worst 30% of translations as our noisy data. As clean data, on the one hand we take the best 30% of translations and on the other hand we take the reference translations generated by professional human translators.

In Table 4 the resulting filtering accuracy is shown for differentiating between the 30 % best scored and the 30 % worst scores translations as well as between the 30 % worst scored translations and the (human) reference translations. Interestingly the systems have a harder time differentiating between good translations of Mt systems and humans compared to differentiating between good and bad automatic translations. However, we find that the filtering systems can not reliably differentiate between synthetic and human translations, nor between a good and a bad synthetic translation from the same domain.

Adversarial Data	Filtering Accuracy Cross Entropy	 LASER
synthetic & high quality	62% / 62%	62% / 63%
references	54% / 55%	44% / 50%

Table 4: Filtering accuracy of two data filtering systems. Systems are required to distinguish synthetic translation, with poor human-rating from adversarial data. ‘synthetic & high quality’ comes from the same test set (but obtained best human scores), ‘references’ are the official references (from humans) of the same test set.

Mixed-Noise Categories

Apart from analysing the performance of the filtering systems on the individual noise categories, we briefly look at the performance on a combined dataset which consists of the concatenation of all individual noisy datasets (equal ratio of clean and noisy data).

The results for both language pairs are shown in Table 5. We again see that the systems perform better on De→En compared to Km→En which is mainly due to langID performing significantly worse on Km→En. In fact, the cross-entropy approach performs batter as a standalone system rather than in combination with langID.

Lastly we test the filtering capabilities in an extremely noisy scenario and report the results in Table 6. Note that this data set exhibits a #clean:#noise ratio of 1:12 for De→En and 1:8 for Km→En. Since this ratio is used in the filtering system (to set a filtering threshold for the ‘correct ratio’) the filtering accuracy system will always correctly classify at least a fraction of

$$\frac{\#\text{noise} - \#\text{clean}}{\#\text{noise} + \#\text{clean}}.$$

Analyzing the performance of the filtering systems using an ‘optimal’ threshold value (gray values in Table 6) we noticed that they classify all sentence pairs as noise. Since the data distribution is very biased towards noisy data we also report F1-scores for this experiments in Table 7. We find that both systems are doing a poor job at noise detection if the clean-to-noisy data ratio gets too small.

6 Conclusion

The aim of this work is to determine how well state-of-the-art data filtering systems can detect different types of noise common in parallel machine translation datasets. We create synthetic noisy datasets for all noise categories defined by Khayrallah and Koehn (2018) as well as for additional noise types that we define in this work. We find that modern data filtering systems can detect most types of noise with an accuracy of well over 90% on a German→English task, that features a medium sized, rather clean training corpus for the filtering systems.

Language Pair	Filtering Accuracy				
	Cross Entropy	LASER	Language ID Filtering		
			+none	+ CE	+ LASER
De→En	75% / 76%	49% / 50%	73%	81% / 82%	68% / 73%
Km→En	70% / 70%	46% / 51%	61%	67% / 68%	61% / 62%

Table 5: Filtering accuracy on two language pairs with a clean-noise ratio of 1:1 for De→En and Km→En by limiting the size of each noise category before ensembling all noise categories from Table 2 respectively Table 3.

Language Pair	Minimal Accuracy	Filtering Accuracy				
		Cross Entropy	LASER	Language ID Filtering		
				+none	+ CE	+ LASER
De→En	85%	89% / 92%	85% / 92%	55%	91% / 92%	87% / 92%
Km→En	78%	85% / 89%	79% / 89%	54%	86% / 89%	83% / 89%

Table 6: Filtering accuracy on two language pairs with high a clean-noise ratio of 1:12 for De→En and 1:8 for Km→En by combining all noise categories from Table 2 respectively Table 3. Note, that if these very biased distributions are accessible to the filtering system, a minimal accuracy can be guaranteed (Column 2) except for the case of pure langID filtering (since it does not rely on the data ratio).

Language Pair	F1-Score				
	Cross Entropy	LASER	Language ID Filtering		
			+none	+ CE	+ LASER
De→En	94% / 96%	92% / 96%	68%	95% / 96%	93% / 96%
Km→En	92% / 94%	88% / 94%	67%	92% / 94%	90% / 94%

Table 7: Filtering performance based on F1-score on two language pairs with high a clean-noise ratio of 1:12 for De→En and 1:8 for Km→En by combining all noise categories from Table 2 respectively Table 3.

However, well-formed but misaligned sentence pairs and over-/undertranslation can only be detected with an accuracy of less than 70%. When it comes to detecting more subtle errors like distinguishing between a good and a poor synthetic translation, the systems exhibit even worse performance. Furthermore, when switching to a less common language pair, namely Khmer→English, the performance of the filtering systems degrades significantly compared to German→English. In conclusion we find that the task of data filtering as defined by Khayrallah and Koehn (2018) is not yet solved. There is still much room for improvement, especially when going to more subtle types of noise or to less common language pairs.

For future research or when applying data filtering for a downstream task, we want to emphasize the following points:

- For high resource languages, langID is a good basis to start from. Subsequent filtering steps should specifically focus on phenomena that langID can not detect such as misaligned sentences and over-/undertranslation.
- For low resource languages, it might be beneficial to drop the langID filtering step, if the subsequent methods have their own (implicit) ways of detecting wrong language. It might be helpful to train some language classifier yourself if in-domain monolingual training data is available.
- Even when (roughly) knowing the percentage of noise in the data, removing this percentage is most of the times not the optimal choice in terms of filtering accuracy. Alternative methods such as a fixed score threshold independent of the selected percentage should also be considered.

DU-VLG: Unifying Vision-and-Language Generation via Dual Sequence-to-Sequence Pre-training

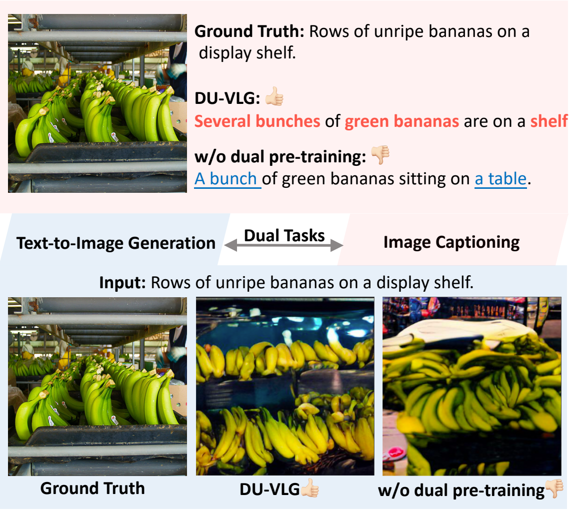
`{huangluyang,niuguocheng,liujiachen,xiaoxinyan,`
`wu_hua}@baidu.com`

Abstract

Due to the limitations of the model structure and pre-training objectives, existing vision-and-language generation models cannot utilize pair-wise images and text through bi-directional generation. In this paper, we propose **DU-VLG**, a framework which unifies vision-and-language generation as sequence generation problems. DU-VLG is trained with novel dual pre-training tasks: multi-modal denoising autoencoder tasks and modality translation tasks. To bridge the gap between image understanding and generation, we further design a novel commitment loss. We compare pre-training objectives on image captioning and text-to-image generation datasets. Results show that DU-VLG yields better performance than variants trained with uni-directional generation objectives or the variant without the commitment loss. On the image captioning task, our model reaches better performance than other pre-trained systems. On text-to-image generation datasets, our model achieves better or comparable results than previous state-of-the-art models. In addition, human judges further confirm that our model generates real and relevant images as well as faithful and informative captions.

1 Introduction

Pre-trained models for vision-and-language tasks have made remarkable progress recently (Lu et al., 2019; Su et al., 2020; Chen et al., 2020). Existing pre-trained models either focus on text-to-image synthesis or image-to-text generation (Ramesh et al., 2021; Cho et al., 2021). These models are often pre-trained with image-text pairs which are aligned in semantics. However, due to the limitations of model structure, existing models cannot be adapted to each other. In addition, pre-training objectives are designed either for text generation conditioned on the image or image generation conditioned on the text, limiting the model to learn better semantic alignment from bi-directional generation (Xu et al., 2021; Ding et al., 2021).



Ground Truth: Rows of unripe bananas on a display shelf.

DU-VLG: 👍
Several bunches of **green bananas** are on a **shelf**.

w/o dual pre-training: 👎
<u>A bunch</u> of green bananas sitting on <u>a table</u>.

Input: Rows of unripe bananas on a display shelf.

Figure 1: An example from COCO dataset. For image captioning, our system generates informative captions, with key words highlighted in **bold**. Incorrect information is <u>underlined</u>. For text-to-image generation, our system synthesizes vivid images aligned with captions.

We argue that *image-to-text and text-to-image generation appear as dual tasks, which both require strong visual and textual representations aligned in the same semantic space.* Images and text descriptions are of different information quantity and density. The images often contain more information, but are with heavy redundancy, while text descriptions are semantically condensed, but may neglect details. Uni-directional generation paradigm may induce the model to amplify this property. Take Fig.1 as an example, the uni-directional model may fail in capturing details. Inspired by this observation, we propose to utilize bi-directional generation objectives to learn better generalization of image and text representations.

To this end, we present **DU-VLG**, a framework with **DU**al sequence-to-sequence pre-training for **V**ision-and-**L**anguage **G**eneration. Under the encoder-decoder Transformer framework, our model takes text and raw images as inputs and gen-

Findings of the Association for Computational Linguistics: ACL 2022, pages 2552 - 2566
May 22-27, 2022 ©2022 Association for Computational Linguistics

erate text and images autoregressively. Concretely, images are represented as continuous patch features in the encoder and discrete visual tokens in the decoder. With the hybrid image embedding schema, DU-VLG is able to unify vision-and-language generation in a single model.

In order to utilize dualities of image-text pairs, we further propose **two pairs of dual pre-training tasks**: multi-modal denoising autoencoder task and modality translation task. For the multi-modal denoising autoencoder task, our model takes image-text pairs with some image patches or words randomly masked as inputs and learns image-text alignment through reconstruction of the corrupted modality. For modality translation tasks, we form image captioning and text-to-image generation as dual pre-training tasks, which further enhance model ability of semantic alignment. Different from existing multi-modal pre-trained models, our model learns image-text alignment through bi-directional generation objectives.

Moreover, we propose **a novel commitment loss** to drive the model to acquire better image representation. Concretely, the commitment loss is designed to connect visual embeddings in the decoder to patch-based features in the encoder. In tandem with our model design, the commitment loss aims to unify image understanding and generation in a single model, which allows for better utilization of bi-directional generation objectives.

We conduct experiments on various vision-and-language generation tasks. We first study effects of dual pre-training tasks and the commitment loss. On both image captioning and text-to-image generation tasks, DU-VLG outperforms its variant without commitment loss or the variants that only learns uni-directional generation objectives. For image captioning, we achieve better BLEU-4 and CIDER than existing pre-trained models on COCO dataset (Lin et al., 2014). For text-to-image generation, our model achieves better results than both Transformer-based and GAN-based methods on both COCO and CUB dataset (Welinder et al., 2010). Human judges confirm that our model generates captions and images with high-quality. Importantly, we test our model on a challenging vision-and-language generation task: visual commonsense reasoning (Park et al., 2020). Results demonstrate that our model is able to handle challenging multi-modal generation tasks effectively.

The main contributions of DU-VLG are as follows:

- We unifies vision-and-language generation tasks with a single model, DU-VLG. With an encoder-decoder Transformer, DU-VLG is able to handle various vision-and-language generation tasks.
- DU-VLG is pre-trained with novel dual pre-training tasks, which utilizes dualities of image-text pairs. DU-VLG yields better or comparable results than existing state-of-the-art methods on three vision-and-language generation tasks.
- We further propose a new commitment loss, which aims to bridge the gap between image understanding and generation inner with our proposed dual paradigm. Experimental results show that the ability of dual tasks is further enhanced.

The rest of the paper is organized as follows. We describe our model in § 2 and introduce our proposed pre-training task and commitment loss in § 3. Training details are presented in § 4. In § 5, we discuss experimental results. Related work is listed in § 6 and we finally draw our conclusion in § 7.

2 Model

In this section, we describe our proposed model. Overall, our model design is mainly inspired by two observations: (1) sharing parameters that play the same role boosts model performance (Xia et al., 2018) and (2) image understanding and generation require representing image features in different granularity (Cho et al., 2020). Hence, we use a standard Transformer with the encoder-decoder structure (Vaswani et al., 2017), as illustrated in Fig.2. Our model takes images and text as inputs and treats image and text generation as sequence generation problems. Importantly, we propose to use a hybrid image embedding schema in the encoder and the decoder.

2.1 Encoder

In the encoder, images and text are first passed to embedding layers to obtain text embeddings $\mathbf{x}_{\text{text}}$ and image embeddings $\mathbf{x}_{\text{image}}$. For text embedding, we follow RoBERTa and tokenize inputs into BPEs (Liu et al., 2020). Each BPE token is represented as the summation of word embedding and position embedding. Unlike text, Images are represented as pixels in a continuous semantic space. However, using pixels as image tokens results in a huge amount of computational cost since model needs to process long sequences. In order to main-

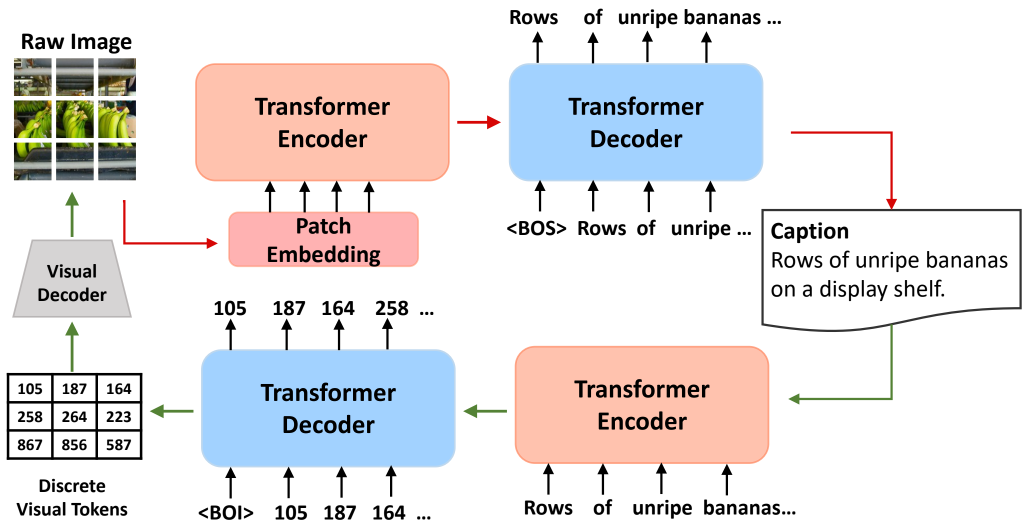


Figure 2: An overview of DU-VLG. Our model is able to take images and text as inputs and generates images and text recurrently. In order to adapt image inputs to the Transformer-based model, we use a hybrid image embedding schema in encoder and decoder. The same color indicates that model parameters are shared for both images and text. The visual decoder weights are not used during training. The symmetric structure is designed for learning better representations from dual pre-training tasks.

tain semantic information as well as reduce the computational cost, we split raw images into a grid of patches.

Image Embedding for Encoder. In the encoder, image inputs are flattened to a sequence of patches, with each patch represents the feature of $p \times p$ pixels. To obtain patch embedding, we pass input images to a trained Vision Transformer (ViT) (Dosovitskiy et al., 2021) and take hidden states of the last layer $\mathbf{x}_{\text{image}}$ as image patch embeddings.

Image and text embeddings are then concatenated and fed into the encoder self-attention layers. If either image or text is missing in the input, we use a `[IMAGEPAD]` or `[TEXTPAD]` token as the placeholder.

2.2 Decoder

In the decoder, we use two embeddings: the text embedding which shares weights with the text embedding in the encoder and the image embedding which maps discrete visual tokens to embedding vectors. To enable autoregressive generation, we add `[BOI]` and `[EOI]` token to denote the start and the end of the image sequence.

Discrete Visual Tokens for Decoder. In the decoder, the model generates a sequence of discrete visual tokens recurrently. During training, ground truth visual tokens are obtained by a Vector Quantised Variational Autoencoder (VQ-VAE) (van den Oord et al., 2017). The VQ-VAE contains two modules, an image tokenizer and a visual decoder. The image tokenizer first extracts grid features from raw images and maps into discrete tokens $\mathbf{y}_{\text{image}}$. The visual decoder reconstructs the original image from discrete visual tokens. The image tokenizer represents each $p \times p$ pixels as a visual token, with a vocabulary size of $|\mathcal{V}|$. Therefore, the number of decoder visual tokens is the same as the number of encoder patch tokens. We refer to the original paper for more details. Importantly, during testing, model first generates a sequence of image tokens recurrently and reconstruct the image with the visual decoder.

3 Dual Pre-training Tasks and Pre-training Objectives

Next, we introduce our pre-training method. Pre-training corpus consists of millions of aligned image-text pairs. In order to effectively learn vision-and-language understanding and generation, we propose dual pre-training tasks. Dual pre-training tasks drive the model to learn from reconstruction of the image or text description based on given context. We propose two pairs of pre-training tasks: (1) multi-modal denoising autoencoder task (§ 3.1) and (2) modality translation task (§ 3.2), as shown in Fig.3. In § 3.3, we formulate a commitment loss to connect image understanding and generation.

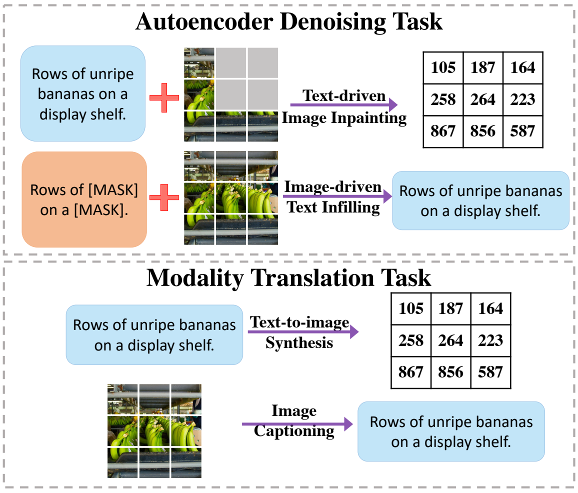

Figure 3: An illustration of our proposed dual pre-training tasks. The model reconstructs the image or text conditioned on its visual and textual context.

3.1 Multi-modal Denoising Autoencoder Task

Given an image-text pair (V, W) from the training set D, we first obtain image patch embeddings $\mathbf{x}_{\text{image}}$ computed by ViT layers and attain text embeddings $\mathbf{x}_{\text{text}}$. To encourage the model to learn cross-modal contextualized embeddings, we propose two dual tasks: 1) text-driven image inpainting task which aims to reconstruct the original image and 2) image-driven text infilling task which aims to reconstruct the original text.

Text-Driven Image Inpainting. Given image patch embeddings $\mathbf{x}_{\text{image}}$, we replace 50 percent of image patches with the same umber of trainable `[MASK]` embeddings, producing masked image sequences $\tilde{\mathbf{x}}_{\text{image}}$. We use blockwise masking algorithm (Bao et al., 2021) to randomly select patches. Meanwhile, we feed the input image to the image tokenizer and produce a sequence of visual tokens $\mathbf{y}_{\text{image}}$. The model is trained to reconstruct the image by optimizing negative log likelihood loss of the ground-truth visual tokens:

$$\mathcal{L}_{\text{image}}^{\text{DAE}} = -\sum_{(V,W)\in D} \log p(\mathbf{y}_{\text{image}} \,|\tilde{\mathbf{x}}_{\text{image}}, \mathbf{x}_{\text{text}}) \tag{1}$$

Image-Driven Text Infilling. Inspired by text infilling (Lewis et al., 2020), we randomly sample a number of text spans from a Poisson distribution ($\lambda = 3$) and replace with a single `[MASK]`. Different from text infilling, we randomly mask 50 percent of tokens since we additionally include image as visual context. The model is trained to optimize negative log likelihood loss of original text tokens:

$$\mathcal{L}_{\text{text}}^{\text{DAE}} = -\sum_{(V,W)\in D} \log p(\mathbf{x}_{\text{text}} \,|\tilde{\mathbf{x}}_{\text{text}}, \mathbf{x}_{\text{image}}) \tag{2}$$

where $\tilde{\mathbf{x}}_{\text{text}}$ represents the corrupted text sequence.

3.2 Modality Translation Task

In addition to the denoising autoencoder task, we further enhance the model with the modality translation task. The modality translation task drives the model to learn mapping from a modality to the other. Given an image-text pair, we form the modality translation task as two dual tasks: 1) image captioning and 2) text-to-image synthesis.

Image Captioning. Given an image as input, model first produces image patch embeddings $\mathbf{x}_{\text{image}}$ from ViT and encodes image features with encoder self-attentions. The decoder is trained to generate text based on image features. The loss function can be defined as:

$$\mathcal{L}_{\text{text}}^{\text{MT}} = -\sum_{(V,W)\in D} \log p(\mathbf{x}_{\text{text}} \,|\mathbf{x}_{\text{image}}) \tag{3}$$

Text-to-Image Synthesis. Given a visual description as input, model encodes the input with the encoder and the decoder generates discrete visual tokens $\mathbf{y}_{\text{image}}$ recurrently. During training, the ground truth visual tokens are computed by the image tokenizer. The loss function can be defined as:

$$\mathcal{L}_{\text{image}}^{\text{MT}} = -\sum_{(V,W)\in D} \log p(\mathbf{y}_{\text{image}} \,|\mathbf{x}_{\text{text}}) \tag{4}$$

3.3 Connecting Image Embedding between Encoder and Decoder.

In the encoder-decoder structure, text embedding is often shared among the encoder, the decoder and the token generation layer (Paulus et al., 2018). This allows the model to learn better syntactic and semantic information. For image embedding, since we use a hybrid embedding schema in the encoder and the decoder, we propose a commitment loss to connect image understanding and generation during training. Intuitively, decoder visual token embeddings $\mathbf{y}_{\text{image}}$ should commit to corresponding patch embeddings $\mathbf{x}_{\text{image}}$ in encoder. Therefore, the commitment loss uses a square loss to connect the encoder and the decoder:

$$\mathcal{L}_{\text{com}} = -\sum_{(V)\in D} \| \operatorname{sg}[\mathbf{x}_{\text{image}}] - \mathbf{y}_{\text{image}} \|^2 \tag{5}$$

where sg means stopgradient operator which is identity at forward computation but has zero partial derivatives at backward computation. The commitment loss is applied to the text-driven image inpainting objective and the text-to-image synthesis objective.

During training, for each instance, we randomly select a couple of objectives from denoising autoencoder and modality translation. We set probability of denoising autoencoder as 0.6 for all experiments. Therefore, for each batch, the pre-training loss is a combination of three losses:

$$\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{text}} + \alpha\mathcal{L}_{\text{image}} \tag{6}$$

$$\mathcal{L}_{\text{image}} = \mathcal{L}^{DAE}_{\text{image}} + \mathcal{L}^{MT}_{\text{image}} + \beta\mathcal{L}_{\text{com}} \tag{7}$$

$$\mathcal{L}_{\text{text}} = \mathcal{L}^{DAE}_{\text{text}} + \mathcal{L}^{MT}_{\text{text}} \tag{8}$$

where α and β are hyperparameters to control the scale of image loss and commitment loss.

4 Experimental Setup

4.1 Pre-training

Pre-training Corpus. We train our model on four existing datasets that consist of image-text pairs. Our pre-training datasets include 1) Common Objects in Context (COCO) (Lin et al., 2014), 2) Conceptual Captions (CC) (Sharma et al., 2018), 3) SBU Captioned Photo (SBU) (Ordonez et al., 2011) and 4) Visual Genome (VG) (Krishna et al., 2016). For Visual Genome dataset, since captions are collected for image regions, we use image regions and captions as pairs. We additionally filter captions which are fewer than five words. We end up with a collection of about 5 million image-text pairs.

Implementation Detail. We report results on two model sizes: 1) a base version with 6 layers for the encoder and decoder and 2) a large version with 12 layers for the encoder and decoder. For each model size, we report results with two different input image resolutions: 224×224 and 384×384. Following ViT, we use a patch size of $p = 16$ for all the experiments. For VQ-VAE, we take the off-the-shelf VQ-GAN (Esser et al., 2021), which is a variant of VQ-VAE. The VQ-GAN maps each 16×16 pixels as a discrete visual token, with a vocabulary size of $|\mathcal{V}| = 16384$.

For base and large model, we use `ViT-base` and `ViT-large` with a patch size of $p = 16$ to extract image patch embeddings. ViT weights are set frozen during pre-training. Since image sequences are longer than text sequences, we set $\alpha = 0.05$ and $\beta = 1$ for all experiments. For model optimization, we utilize Adam optimizer with a gradient clipping of 1.0 and a batch size equivalent of 1024.

4.2 Fine-tuning on Downstream Tasks

In order to evaluate model capability of vision-and-language generation tasks, we test on three downstream tasks: 1) text-to-image generation, 2) image captioning and 3) visual commonsense reasoning. Here we mainly introduce evaluation metrics. For additional fine-tuning details, we refer to the appendices.

Text-to-Image Generation. We experiment with two popular text-to-image generation datasets: the Caltech-UCSD Birds 200 dataset (CUB) and Common Objects in Context dataset (COCO).

The CUB dataset contains 200 bird categories with 11,788 images. Each image has ten text descriptions. We follow the standard split which uses 150 categories with 8,855 images for training and the remaining 50 categories with 2,933 images for testing. The COCO dataset contains 82,784 images for training and 40,505 for testing. Each image has five text descriptions.

We fine-tune on the pre-trained model with a learning rate of 1e-4 for 300 epoches on both datasets. Similar to Ramesh et al. (2021), we sample 16 images per caption with nucleus sampling strategy (Holtzman et al., 2020). During testing, we first sample 16 images per caption and rerank the generated images with a CLIP model (Radford et al., 2021). The CLIP model selects the best image based on its correlation with the text description.

We include two widely used evaluation metrics: 1) Inception Score (IS) (Salimans et al., 2016) and 2) Fréchet Inception Distance (FID) (Heusel et al., 2017). The IS score computes the KL-divergence between the conditional class distribution and the marginal class distribution obtained by a pre-trained Inception v3 model (Szegedy et al., 2016). The FID computes the Fréchet distance between ground-truth images and generated images based on the features obtained by the Incaption v3 model. Higher IS scores and lower FID scores denote that images synthesized by the model are of better quality. Previous work (Li et al., 2019b) reports that the IS score fails in evaluating the quality of images on COCO dataset. Hence, we do not report the IS score on COCO dataset. For fair comparison, we resize our model outputs to 256 × 256 and calculate FID and IS scores.

Image Captioning. For image captioning, we test our model on COCO dataset. We report four metrics based on word overlapping on COCO dataset: 1) BLEU-4 (Papineni et al., 2002), 2) METEOR (Lavie and Agarwal, 2007), 3) CIDEr (Vedantam et al., 2015) and 4) SPICE (Johnson et al., 2020).

For COCO dataset, we follow the Karparthy split (Karpathy and Fei-Fei, 2015) which has 113,287, 5000 and 5000 images for training, validation and test. Each image has 5 human-written captions. During inference, we generate a caption for each image and evaluate against five references.

We fine-tune on COCO dataset with a learning rate of 3e-5. Vision Transformer layers are trainable during fine-tuning. Following Li et al. (2020), we add object labels detected by the object detection model as additional text inputs. We find object labels improve CIDER and BLEU scores for at least 1 point and 0.3 points. During testing, we use beam search with a beam size of 5.

Visual Commonsense Reasoning. Besides image captioning and text-to-image generation, which only requires model to encode one modality, we further test our model on a more challenging dataset, VisualCOMET (Park et al., 2020). VisualCOMET is a visual commonsense reasoning task which provides the model with an image and the event that happens at present. The model is required to infer what may happen next, before and the people's intents at present. VisualCOMET requires the model to jointly comprehend image and text and generate reasonable inference. Similar to image captioning, we use BLEU-2, METEOR and CIDEr as metrics.

5 Results

In this section, we start with comparing our proposed pre-training objectives in § 5.1. We then conduct automatic evaluation on three vision-and-language generation tasks (§ 5.2) and further report human evaluation on both caption and synthesized image quality (§ 5.2). Finally, we investigate inference speed of our proposed model (§ 5.3).

Image -> Text	COCO Caption			
System	**BLEU-4**	**CIDER**	**METEOR**	**SPICE**
DU-VLG$_{\mathrm{B-224}}$	**38.8**	**124.8**	**29.2**	**22.0**
w/o L_{image}	36.9	118.8	28.4	20.5

w/o L_{com}	38.4	123.1	28.8	21.7

Text -> Image	CUB		COCO
System	**IS↑**	**FID↓**	**FID↓**
DU-VLG$_{\mathrm{B-224}}$	**5.14**	**23.78**	**26.82**
w/o L_{image}	4.84	25.28	36.59
w/o L_{text}	5.03	24.68	29.64
w/o L_{com}	5.08	24.44	27.92

Table 1: Ablation study on pre-training tasks and objectives. The best result per metric per dataset is **bolded**. DU-VLG$_{\mathrm{B-224}}$ yields significantly higher scores than other comparisons with approximate randomization test ($p < 0.0005$).

5.1 Comparing Pre-training Objectives

Comparisons. We first investigate whether our proposed dual pre-training tasks and commitment loss improve generation quality. We fine-tune on two downstream tasks: image captioning and text-to-image generation. We report our base model with an input image resolution of 224 × 224 (DU-VLG$_{\mathrm{B-224}}$). We compare our base model with three variants: 1) the model trained without text-driven image inpainting and text-to-image synthesis tasks (w/o L_{image}), 2) the model trained without image-driven text infilling and image captioning tasks (w/o L_{text}) and 3) the model trained without commitment loss (w/o L_{com}).

Results. As displayed in Tab.1, *our model with dual pre-training tasks performs the best on both image captioning and text-to-image generation tasks*. This demonstrates the benefit of dual pre-training tasks and the commitment loss. For image captioning, comparing with the variant without image generation objectives, our model with dual pre-training tasks significantly improves automatic metrics, which indicates that image generation objectives can boost visual understanding. For text-to-image generation, our model yields better FID and IS scores than the variant without text generation objectives on both CUB and COCO dataset. This demonstrates that using text generation objectives can guide better semantic interpretation of text content.

Moreover, our model outperforms the variant trained without the commitment loss on two downstream tasks. This further illustrates that the commitment loss improves model performance on both image understanding and generation.

5.2 Automatic Evaluation

Comparisons. We then compare our model with other vision-and-language models. For image captioning, we include state-of-the-art vision-and-language pre-trained models: (1) object-semantics aligned pre-training (OSCAR) (Li et al., 2020), (2) unified modal understanding and generation pre-training (UNIMO) (Li et al., 2021), (3) improving visual representations for vision-and-language pre-training (VinVL) (Zhang et al., 2021b) and (4) end-to-end vision-and-language pre-training (E2E-VLP) (Xu et al., 2021). For OSCAR and VINVL, we report their results with cross-entropy optimization for fair comparison.

For text-to-image generation, we include four Transformer-based models: (1) X-LXMERT, which has 228 million parameters and is trained on 9 million image-text pairs, (2) DALLE, which has 12 billion parameters and is trained on 250 million text-image pairs (Ramesh et al., 2021), (3) CogView, which has 4 billion parameters and is trained on 30 million data (Ding et al., 2021) and (4) NUWA, which has 870 million parameters and is trained on a mixture of text-image pairs and text-video pairs (Wu et al., 2021). We further compare our model with three traditional methods based on generative adversarial network (GAN): (1) DM-GAN (Zhu et al., 2019), (2) DF-GAN (Tao et al., 2020) and (3) XMC-GAN (Zhang et al., 2021a).

For visual commonsense reasoning, we include Vision-Language Transformer (V-L Transformer) (Park et al., 2020) as a baseline, which fuses region-based visual features into a pre-trained GPT-2 (Radford et al., 2019).

Results. For image captioning, our model achieves better scores than both end-to-end method and two-stage methods. In Tab.2, DU-VLG outperforms previous state-of-the-art pre-trained model VINVL, e.g., improving BLEU-4 and CIDEr by more than 1 and 3 points.

Moreover, for text-to-image generation tasks, our model achieves state-of-the-art IS and FID on CUB dataset, as displayed in Tab.3, outperforming traditional GAN-based methods. Compared with Transformer-based methods, our model yields better or comparable FID scores on COCO datasets. It is worth to note that our models are with fewer parameters and less training data compared with DALLE, CogView and NUWA. This demonstrates the effectiveness of our proposed framework.

Image -> Text	CoCo Caption			
System	**BLEU-4**	**CIDER**	**METEOR**	**SPICE**
OSCAR$_{\mathrm{B}}$	36.5	123.7	30.7	23.5
UNIMO$_{\mathrm{B}}$	38.8	124.4	29.8	22.1
VINVL$_{\mathrm{B}}$	38.2	129.3	30.3	23.6
E2E-VLP	36.2	117.3	–	–
DU-VLG$_{\mathrm{B-224}}$	38.8	124.8	29.2	22.0
DU-VLG$_{\mathrm{B-384}}$	**40.0**	**133.0**	30.2	**23.8**
OSCAR$_{\mathrm{L}}$	37.4	127.8	30.7	23.5
UNIMO$_{\mathrm{L}}$	39.6	127.7	29.5	22.4
VINVL$_{\mathrm{L}}$	38.5	130.8	30.4	23.4
DU-VLG$_{\mathrm{L-224}}$	39.2	128.1	29.8	22.8
DU-VLG$_{\mathrm{L-384}}$	**40.1**	**135.8**	**30.8**	**23.9**

Table 2: Automatic evaluation on Image Captioning datasets. We report our model and comparisons with two model sizes: the base version (B) and the large version (L) and two input image resolution: 224 × 224 and 384 × 384. Our base and large models have comparable number of parameters compared to other comparisons. The best metric of each model size is **bolded**.

In addition, we study the effect of different input image resolutions. We compare two different resolutions of the input images: 224×224 and 384×384. In Tab.2 and Tab.3, we find higher resolution as inputs leads to better results on both image-to-text and text-to-image generation tasks. This observation remarks the importance of fine-grained image representation.

We then evaluate our model on a more challenging vision-and-language task, visual commonsense reasoning. As shown in Tab.4, our model significantly outperforms V-L Transformer, which is fine-tuned based on a language model, GPT-2. This demonstrates that our model is able to jointly comprehend image and text inputs and generate informative inference.

5.3 Human Evaluation

We conduct human evaluation to analyze generation quality of images and text. For both image captioning and text-to-image generation, we select 100 samples from COCO test set and hire three annotators to rate captions and images. For image captioning, we include three systems: (1) best performed pre-trained model VINVL (2) our model that removes dual pre-training DU-VLG w/o L_{image} and

Text -> Image	CUB		COCO
System	**IS↑**	**FID↓**	**FID↓**
DM-GAN	4.75	16.09	32.64
DF-GAN	5.10	14.81	21.42
XMC-GAN	–	–	**9.33**
X-LXMERT	–	–	37.40
DALLE	–	–	27.50
COGVIEW	–	–	26.00
NUWA	–	–	12.90
DU-VLG$_{\text{B-224}}$	5.14	23.78	26.82
DU-VLG$_{\text{B-384}}$	5.26	14.60	22.41
DU-VLG$_{\text{L-224}}$	5.18	21.50	23.25
DU-VLG$_{\text{L-384}}$	**5.28**	**14.15**	14.48

Table 3: Automatic evaluation on Text-to-Image Generation datasets. For fair comparison, we resize generated images to 256×256 pixels before calculating IS and FID scores.

	VisualCOMET		
System	**BLEU-2**	**CIDER**	**METEOR**
V-L Transformer	13.5	18.2	11.5
DU-VLG$_{\text{B}-384}$	21.5	36.6	25.6
DU-VLG$_{\text{L}-384}$	**23.9**	**41.9**	**27.1**

Table 4: Automatic evaluation on visual commonsense reasoning. Our model generates informative inference compared to the baseline.

(3) our best performed model DU-VLG. For text-to-image generation, we compare three models: (1) Transformer-based model pre-trained on about 9 million data X-LXMERT, (2) our model trained without text generation objectives DU-VLG w/o L_{text} and (3) DU-VLG. For our model, we use the large version with the input image resolution of 384×384.

For image captioning, human judges are asked to rate on two aspects: **informativeness**—whether the caption covers important objects from the image and **faithfulness**—whether the caption correctly describes the image. For text-to-image generation, we consider two aspects: **fidelity**—whether the image is realistic and **relevance**—whether the image matches with the caption. All aspects are rated on a Likert scale from 1 (poor) to 5 (good).

Results. From Fig.4, we find our DU-VLG model obtains better scores in relevance, fidelity, informativeness and faithfulness than the variant that removes dual pre-training tasks. This confirms our claim that bi-directional generation objectives improve semantic alignment between images and text. Meanwhile, compared with well-performed model VINVL and X-LXMERT, our model yields better scores on four aspects. This implies that our model generates more informative captions committed to the input images and synthesizes more realistic images aligned with the captions compared to the state-of-the-art pre-trained models.

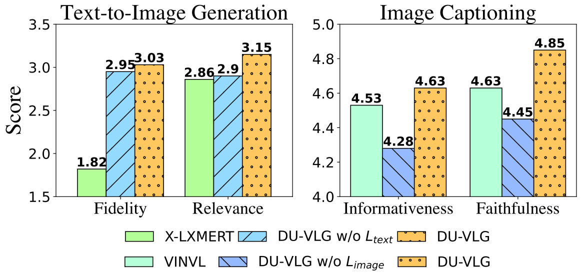

Figure 4: Human evaluation on COCO dataset.DU-VLG yields significantly higher scores than other systems on fidelity, relavance, informativeness and faithfulness ($p < 0.05$).

Interestingly, image captioning models yield higher scores than text-to-image generation models, closer to 5 (perfect). After inspection, we find that our model yields near-perfect captions compared to human written ones, while the generated images sometimes fail in synthesizing details. For example, the shape of a banana may be distorted, limiting the fidelity of the image.

5.4 Inference Efficiency

Next, we compare the inference speed and the number of model parameters with existing models. For image captioning, we compare our model with two best performed pre-trained models: the base version of UNIMO and VINVL. For text-to-image generation, we compare with two transformer-based large models DALLE and Cogview. For our model, we report the base version. We test speed on COCO test set with one 32GB NVIDIA TESLA V100. We include the visual decoder when calculating the inference speed.

In Tab.5, we find our model is roughly 7× faster than two-stage methods on image captioning. This is mainly because extracting image features with ViT is much faster than object detection. Importantly, our model has comparable parameters compared with UNIMO and VINVL.

For text-to-image generation, our model is roughly 400× faster than large model Cogview and has only 5 percent of parameters. This further confirms the importance of dual pre-training tasks.

System	Time(s)	# Param. (M)
Image Captioning		
UNIMO$_{\text{B}}$	0.88+0.12	172
VINVL$_{\text{B}}$	0.90+0.12	187
DU-VLG$_{\text{B-224}}$	0.14	228
Text-to-Image Generation		
DALLE	–	12,000
COGVIEW	300	4,000
DU-VLG$_{\text{B-224}}$	0.76	228

Table 5: Comparing inference speed (time) and number of parameters (# Param.) on different tasks. For two-stage methods UNIMO and VINVL, we report image feature extraction and beam search time respectively.

6 Related Work

Vision-and-Language Pre-training for Image-to-Text Generation Tasks. Transformer backbones have achieved great success in language pre-training (Devlin et al., 2019; Lewis et al., 2020; Liu et al., 2020). In order to adapt Transformers to multi-modal pre-training, previous work mainly focuses on (1) better image features and (2) designing pre-training tasks (Lu et al., 2019; Li et al., 2019a). To obtain high-quality image features, Image region features extracted from an object detection model are widely adopted in multi-modal pre-training (Zhou et al., 2020; Li et al., 2020; Zhang et al., 2021b). Kim et al. (2021) points out that two-stage method is time-consuming and the trained object detector may fail in the unlabeled domain (Jiang et al., 2021). To that end, Huang et al. (2020) feeds raw images to convolutional backbones such as ResNets (He et al., 2016) and takes its outputs as image features. Kim et al. (2021) uses linear projection to obtain patch-based image features. However, currently, end-to-end image feature extraction methods cannot yield comparable results compared to two-stage methods on image captioning.

To learn image-text alignment, masked token prediction, which masks a portion of text or image tokens and predicts masked positions conditioned on the context, is widely used as the pre-training task (Xia et al., 2020). Li et al. (2020) designs image-text matching task, which predicts whether the image and the text are paired or not. Li et al. (2021) proposes special self-attention masks to unify text understanding and generation. Xu et al. (2021) includes image captioning and object detection as pre-training objectives to enhance the decoder. However, current methods for generation tasks are limited to text generation and are struggled to learn fine-grained image-text alignment.

In this paper, we introduce a hybrid image embedding schema to connect image understanding and generation, which unifies image and text generation via sequence-to-sequence pre-training. Concretely, we enhance image-text alignment with novel dual pre-training tasks. Our model outperforms state-of-the-art pre-trained systems on image captioning.

Vision-and-Language Pre-training for Text-to-Image Generation Tasks. To generate images autoregressively, images are represented as discrete tokens. X-LXMERT (Cho et al., 2020) partitions image grid features into clusters and obtains visual tokens via neareast-neighbor search. However, X-LXMERT needs to train an image generator from scratch to synthesize images from visual tokens, which accumulates errors during training. Ding et al. (2021); Ramesh et al. (2021) use discrete visual tokens from a trained vector-quantised variational autoencoder (VQ-VAE) (van den Oord et al., 2017) for text-to-image generation. However, their models consist of billions of parameters and require a huge corpus to pre-train (more than 100 million image-text pairs). In this paper, we present a relative small model (about 200M parameters), with better generation quality on COCO dataset. In particular, we offer a detailed analysis on the inference speed and the model size in the appendices.

7 Conclusion

We presented a novel framework, DU-VLG, which unifies vision-and-language generation tasks with an encoder-decoder Transformer. We propose to use a hybrid image embedding schema in the encoder and decoder. In addition, we pre-train the model with novel dual pre-training tasks, along with a new commitment loss, to guide better image and text understanding and generation. Experiments show that our proposed dual pre-training objectives significantly improve performance on three vision-and-language generation tasks. Human evaluation further confirms that our model with dual pre-training tasks improves generation quality on image captioning and text-to-image generation.

9 Ethics Statement

Large models that are pre-trained on heterogeneous data can be potentially harmful to marginalized populations. Along with the improved controllability, we also recognize that our system might be misused to create offensive or fabricated content. We therefore advocate cautious usage in real-world deployment.

A Additional Evaluation

We include 5 examples on COCO dataset for image captioning and text-to-image generation tasks. In Fig.5 and Fig.6, we find that DU-VLG generates captions and images of high quality.

B Human Evaluation Guideline

In human evaluation, each annotator is presented with 100 model generated images and 100 model generated captions from 3 systems (in random order). For text-to-image generation, the human judges are asked to evaluate on fidelity and informativeness on a scale of 1 to 5 (1 being good and 5 being poor). Here are descriptions of two aspects:

- **Fidelity**: Whether the image is realistic and looks like a real photo.
- **Relevance**: Whether the image provides necessary content coverage from the text description.

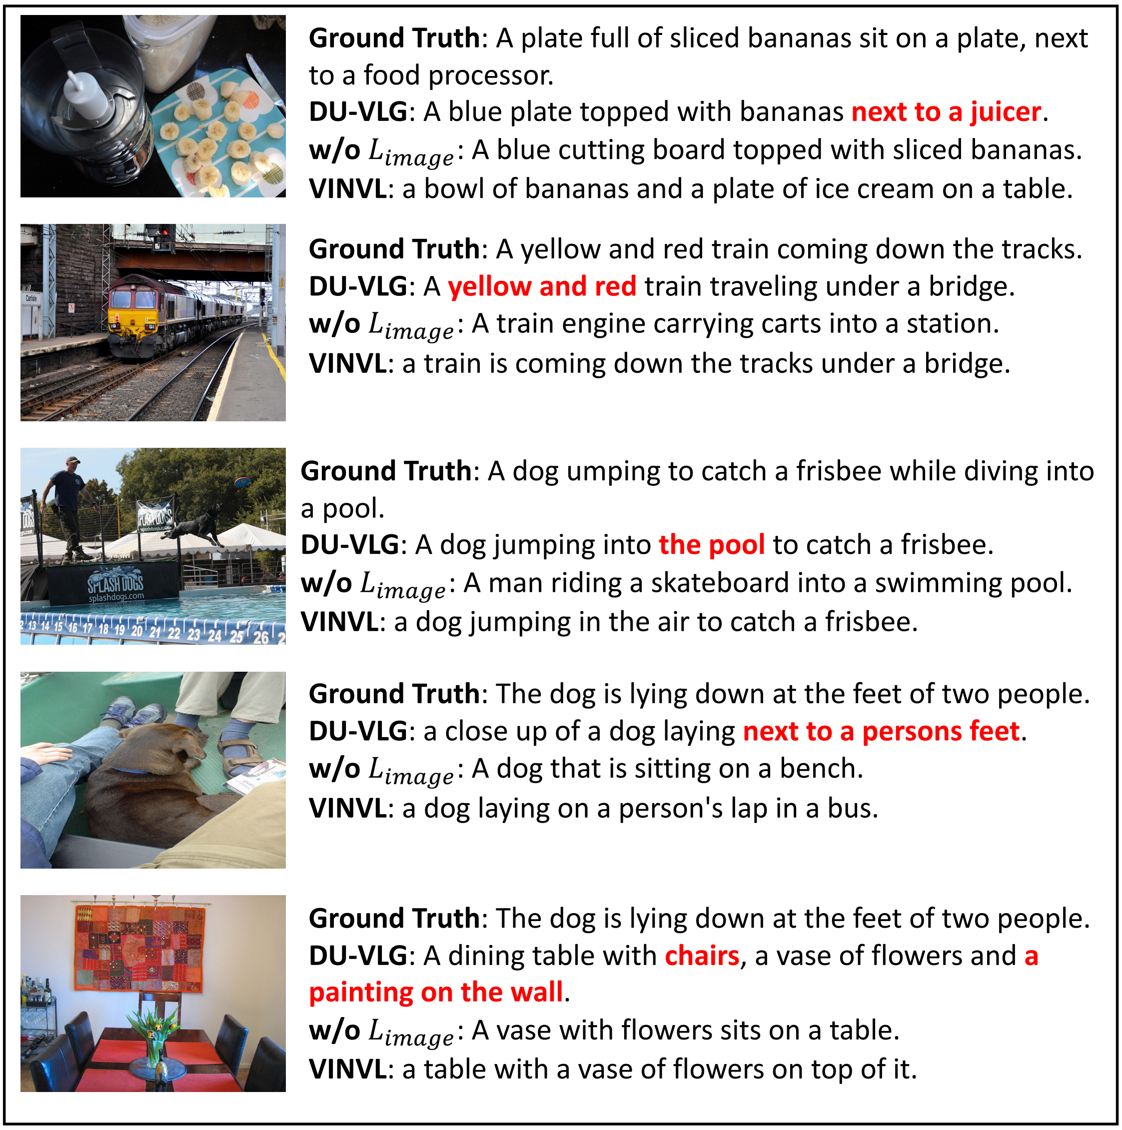
For image captioning, the human annotators are asked to evaluate on faithfulness and informativeness on a scale of 1 to 5 (1 being good and 5 being poor). Here are detailed descriptions of two aspects:

- **Faithfulness**: Whether the caption correctly describes main objects in the image.
- **Informativeness**: Whether the caption covers enough information from the image.

The definition of four aspects can be found in Tab.6.

	Image Captioning
	Informativeness:
1	Not relevant to the image.
3	Relevant, but misses the main objects of the image.
5	Successfully captures the main point of the image.
	Faithfulness:
1	The caption is full of fabricated content.
3	The caption is overall relevant to the image, but contains some fake details.
5	The caption matches with the image.
	Text-to-Image Generation
	Fidelity:
1	The image is unreal, distorted or blurred.
3	The image is overall realistic, but some details are blurred or distorted.
5	The image is vivid and looks like a real photo.
	Relavance:
1	The image does not match with the caption.
3	The image is related to the caption, but some details are hallucinated.
5	The image clearly reflects the caption.

Table 6: The definition of four aspects in human evaluation.



Ground Truth: A plate full of sliced bananas sit on a plate, next to a food processor.
DU-VLG: A blue plate topped with bananas **next to a juicer**.
w/o L_{image}: A blue cutting board topped with sliced bananas.
VINVL: a bowl of bananas and a plate of ice cream on a table.

Ground Truth: A yellow and red train coming down the tracks.
DU-VLG: A **yellow and red** train traveling under a bridge.
w/o L_{image}: A train engine carrying carts into a station.
VINVL: a train is coming down the tracks under a bridge.

Ground Truth: A dog umping to catch a frisbee while diving into a pool.
DU-VLG: A dog jumping into **the pool** to catch a frisbee.
w/o L_{image}: A man riding a skateboard into a swimming pool.
VINVL: a dog jumping in the air to catch a frisbee.

Ground Truth: The dog is lying down at the feet of two people.
DU-VLG: a close up of a dog laying **next to a persons feet**.
w/o L_{image}: A dog that is sitting on a bench.
VINVL: a dog laying on a person's lap in a bus.

Ground Truth: The dog is lying down at the feet of two people.
DU-VLG: A dining table with **chairs**, a vase of flowers and **a painting on the wall**.

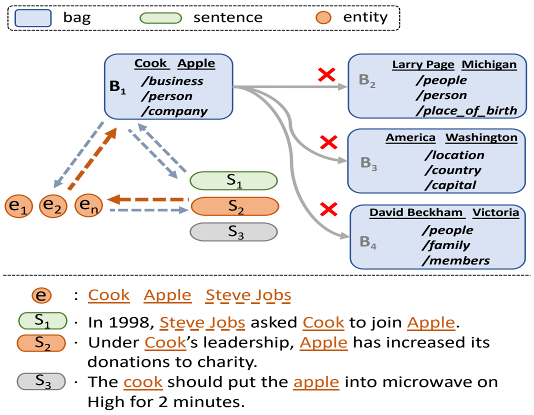
Abstract

Distant supervision assumes that any sentence containing the same entity pairs reflects identical relationships. Previous works of distantly supervised relation extraction (DSRE) task generally focus on sentence-level or bag-level denoising techniques independently, neglecting the explicit interaction with cross levels. In this paper, we propose a **Hi**erarchical **C**ontrastive **L**earning Framework for Distantly Supervised **R**elation **E**xtraction (HiCLRE) to reduce noisy sentences, which integrate the global structural information and local fine-grained interaction. Specifically, we propose a three-level hierarchical learning framework to interact with cross levels, generating the de-noising context-aware representations via adapting the existing multi-head self-attention, named Multi-Granularity Recontextualization. Meanwhile, pseudo positive samples are also provided in the specific level for contrastive learning via a dynamic gradient-based data augmentation strategy, named Dynamic Gradient Adversarial Perturbation. Experiments demonstrate that HiCLRE significantly outperforms strong baselines in various mainstream DSRE datasets.[1]

1 Introduction

Relation extraction (RE) can draw relations of two entities from unstructured text. It can be widely used in natural language processing applications such as knowledge graph construction (Khatib et al., 2020; Tang et al., 2020) and question answering (Wang and Jiang, 2019; Liu et al., 2020; Saxena et al., 2020). Existing RE works (Wei et al., 2020; Alt et al., 2020; Veyseh et al., 2020) rely on a large-scale annotated dataset, which is time-consuming and labor-intensive. DSRE (Mintz et al., 2009) attempts to address this issue via automatically generating training text samples. Obviously, this assumption introduces noisy data and may hurt the performance. Hence, multi-instance learning (MIL) (Zeng et al., 2015) is further proposed to assign a bag containing *"at least one"* correct sentence of relation triple.



· In 1998, Steve Jobs asked Cook to join Apple.

· Under Cook's leadership, Apple has increased its donations to charity.

· The cook should put the apple into microwave on High for 2 minutes.

Figure 1: Example of semantic relationships in specific levels and cross levels. The red cross means the semantic difference of two bag-level relations and the dotted arrow indicates the semantic overlapping of cross levels. (Best viewed in color).

The previous approaches of DSRE tackle the task at different granularities (i.e. sentence-level and bag-level). (1) Sentence-level. These works (Wu et al., 2019; Li et al., 2019) focus on finding the ground-truth relational labels from the internal semantics of the input sentences. (2) Bag-level. Although these works (Su et al., 2018; Beltagy et al., 2019; Chen et al., 2021a; Christopoulou et al., 2021) consider the information of sentence-level and bag-level simultaneously, but they ignore the explicit cross-level interactions, which contain plenty of knowledge to further boost the DSRE task performance. As shown in Figure 1, the rich semantic information of bag-level and sentence-

level are provided for the "Cook" and "Apple" in the entity level. For example, "Steve Jobs" in s_1 is also the co-founder of "Apple" company and the label of bag-level is the "*/business/person/company*" exactly shows the relation of this entity pair. Meanwhile, the huge semantic difference exists in a specific level such as the "*/business/person/company*" and "*/location/country/capital*" in bag level.

To overcome the challenges mentioned above, we propose a **Hi**erarchical **C**ontrastive **L**earning framework for distantly supervised **R**elation **E**xtraction (HiCLRE), which facilities semantic interactions within a specific level and cross levels:

(1) Multi-Granularity Recontextualization: To capture the cross-level structural information, we adapt the multi-head self-attention mechanism into three-level granularities, including entity-level, sentence-level and bag-level. We align the context-aware feature of each layer with the input of attention mechanism respectively. The refined representations as recontextualized interaction semantics are picked out for the corresponding level via the attention scores aggregated by the other two levels.

(2) Dynamic Gradient Adversarial Perturbation: To obtain the more accurate specific-level representations, we employ gradient-based contrastive learning (Hadsell et al., 2006; van den Oord et al., 2018) to pull the information of constructed pseudo positive samples and push the difference of negative samples. Concretely, we calculate the dynamic perturbation from two aspects, including the normalized gradient of task loss and the temporal weighted memories similarity between the last and current epoch.

To verify the effectiveness of HiCLRE, we evaluate our model on three mainstream DSRE datasets, including NYT10 (Riedel et al., 2010), GDS (Jat et al., 2017), and KBP (Ling and Weld, 2012). The experimental results show that HiCLRE significantly outperforms the state-of-the-art baselines' performance, achieving a 2.2% relative AUC increase and improving the P@M score from 77.2% to 78.2%. Furthermore, the ablation study shows the individual contributions of each module.

Accordingly, the major contributions of this paper are summarized as follows:

- We propose a hierarchical contrastive learning framework for DSRE task (HiCLRE), which fully utilizes the semantic interaction within the specific level and cross levels, reducing the influence of noisy data.
- The multi-granularity recontextualization is proposed to enhance the cross-level interaction and the dynamic gradient adversarial perturbation learns better representations within three specific levels.
- Extensive experiments show that our model outperforms the strong baseline over DSRE datasets and detailed analysis demonstrates the modules are also effective.

2 Related Work

2.1 Distantly Supervised Relation Extraction

Recently, these works are divided into two categories. (1) Human-designed Feature. (Yao et al., 2011) propose three types of LDA (i.e. Rel-LDA, Rel-LDA1, and Type-LDA) to cluster the similar triples together. MIML (Hoffmann et al., 2011; Surdeanu et al., 2012) and MIL (Zeng et al., 2015) attempt to relax the limitation of distantly supervision assumption to tackle the data generation problem. (2) Neural Networks Representation. These models automatically generate the feature representation via end-to-end learning to reduce manual intervention. (Qin et al., 2018) introduce a generative adversarial training framework that provides a cleaned dataset for RE task. (Ye and Ling, 2019) consider both inter-bag and intra-bag attention to handle the noise at sentence-level and bag-level independently. SENT (Ma et al., 2021) is a sentence-level framework to generate efficient training samples by negative training to filter the noisy data. These works generally use the partial levels' information independently to explore the relational semantics.

2.2 Contrastive Learning

Loss Function NCE (Gutmann and Hyvärinen, 2010) learns a classifier to distinguish the clean and noisy examples with the probability density function. InfoNCE (van den Oord et al., 2018) integrates the mutual information into the NCE, which can maximize similarity and minimize the difference.

Data Augmentation These works can be generally divided into three categories. (1) Data augmentation by simple text processing. EDA (Wei and Zou, 2019) proposes synonyms replace, randomly insert and randomly delete operations. CIL (Chen et al., 2021a) utilizes TF-IDF scores to insert/substitute some unimportant words to/in instance to construct positive samples. (2) Data augmentation by

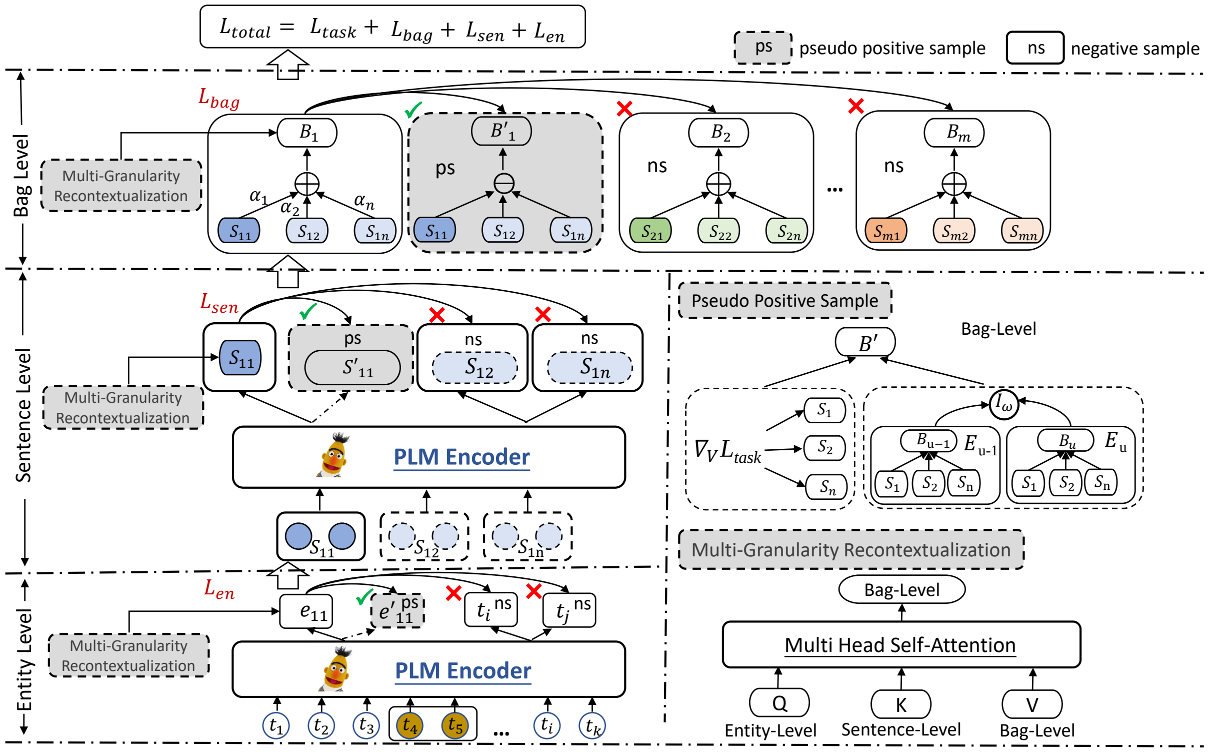

Figure 2: Model overview of HiCLRE. The left part is our model architecture and the right part shows the details on pseudo positive sample construction and multi-granularity recontextualization. (Best viewed in color).

embedding processing. ConSERT (Yan et al., 2021) explore four different data augmentation strategies (i.e. adversarial attack, token shuffling, cutoff and dropout) to generate views in BERT (Devlin et al., 2019) embedding layer. SimCSE (Gao et al., 2021) applies twice dropout in the forward process to refine the better sentence representation. (3) Data augmentation by external knowledge. ERICA (Qin et al., 2021) enumerates all the entity pairs in the training samples to link the corresponding relation from the external knowledge graph to obtain sufficient augmented data. The mentioned above methods are generally augmenting from the data aspect, ignoring the influence of the changes inside the model during the training process (Zang et al., 2020; Zou et al., 2020). Hence, we propose a hierarchical contrastive learning model to capture the global structure information and fine-grained interaction within the levels.

3 Methodology

3.1 Model Overview and Notations

The main architecture of our model is shown in Figure 2. The HiCLRE mainly includes two components. (1) Multi-Granularity Recontextualization aims to integrate the importance of cross levels to determine what valuable representation should be extracted in the target level. (2) Dynamic Gradient Adversarial Perturbation is proposed for specific levels to enhance the internal semantics via constructing the pseudo positive samples.

In HiCLRE, each sentence of input samples is consisted of certain tokens $S_{ij} = (t_{i1}, t_{i2}, \cdots, t_{ik})$, where S_{ij} denotes the i-th sentence of bag B_j. k is the total number of tokens in S_{ij} and j represents the bag's index. e_{i1} and e_{i2} are head and tail entity of sentence S_{ij} respectively. Each bag contains n sentences $B_j = (S_{1j}, S_{2j}, \cdots, S_{nj})$. Our model aims to predict the specific relation r_j of bag B_j from $|r|$ relations. d denotes the hidden state dimension of pre-trained language models (PLMs).

3.2 Hierarchical Learning Modeling

We first introduce our hierarchical learning process including sentence-level and bag-level respectively and then describe the Multi-Granularity Recontextualization and Dynamic Gradient Adversarial Perturbation specifically.

3.2.1 Sentence Representation

To be specific, the input of sentence encoder is the token sequence of sentence S_{ij} and its corresponding head entity e_{i1} and tail entity e_{i2}[2]. The textual encoder sums the token embedding, segment embedding and position embedding for each token to achieve its input embedding, and then computes context-aware hidden representations $H= \{h_{t_{i1}}, h_{t_{i2}}, \cdots, h_{e_{i1}}, \cdots, h_{e_{i2}}, \cdots, h_{t_{ik}}\}$:

$$H = \mathcal{F}\left(\{t_{i1}, t_{i2}, \cdots, t_{ik}\}\right) \tag{1}$$

where $\mathcal{F}$ is the PLMs (e.g. BERT) as our encoder and $H \in \mathbb{R}^{k \times d}$. The sentence's embedding is calculated by the hidden representations of head entity, tail entity and the $[CLS]$ tag, which is in the first position of the input sequence to denote the whole semantic of the sentence.

$$h_{S_{ij}} = \sigma([h_{e_{i1}} \parallel h_{e_{i2}} \parallel h_{[CLS]}] \cdot W_S) + b_S \tag{2}$$

where the $\parallel$ means the concatenation operation, $W_S \in \mathbb{R}^{3d \times d}$ is a weight matrix and b_S is the bias. σ denotes the non-linear function.

3.2.2 Bag Representation

In this section, we use a sentence-level attention-based mechanism (Lin et al., 2016) to yield the aggregated bag representation. Let $h_{B_j} \in \mathbb{R}^d$ denotes the bag representation, and which is computed from the sentence's attention weight α_{ij} and hidden representation $h_{S_{ij}}$.

$$h_{B_j} = \sum_{i=1}^{n} \alpha_{ij} h_{S_{ij}} \tag{3}$$

To avoid naively treating each sentence of bags equally, the selective attention mechanism assigns the importance to reduce the noise instance. Each weight α_{ij} is generated by a query-based function:

$$\alpha_{ij} = \frac{\exp\left(f_{ij}\right)}{\sum_n \exp\left(f_{ij}\right)} \tag{4}$$

where f_{ij} measures how well the input sentence S_{ij} and the predicted relation r_j matches.

$$f_{ij} = h_{S_{ij}} \mathbf{A_j} \mathbf{r_j} \tag{5}$$

where $\mathbf{A_j} \in \mathbb{R}^{d \times d}$ is a weighted diagonal matrix, and $\mathbf{r_j} \in \mathbb{R}^d$ is the representation of relation r_j which is mapped from the relation label. The final relation type of bag B_j is predicted:

$$p(r_j \mid h_{B_j}, \theta) = \frac{\exp\left(O_r\right)}{\sum_{p=1}^{|r|} \exp\left(O_p\right)} \tag{6}$$

$$O_r = \sigma(W_r \cdot h_{B_j}) + b_r \tag{7}$$

where $W_r \in \mathbb{R}^{|r| \times d}$ is trainable transformation matrix and $b_r \in \mathbb{R}^{|r|}$ is the bias. θ denotes bag encoder's parameters. $O_r \in \mathbb{R}^{|r|}$ represents the final output of our model, which is associated with all relation types. Therefore, the relation classification objective function of DSRE task is denoted as:

$$\mathcal{L}_{task} = -\sum_{j=1}^{|r|} \log p\left(r_j \mid h_{B_j}, \theta\right) \tag{8}$$

3.3 Multi-Granularity Recontextualization

The hierarchical learning process described above neglects the explicit interaction of cross levels to refine the better level's representation. Hence, after updating the hidden representations generated by the PLMs, our HiCLRE model attempts to recontextualize the enhanced representations for each level. This is accomplished using a modified Transformer layer (Vaswani et al., 2017) that substitutes the multi-headed self-attention with multi-headed attention between the target level and the other two levels' representations.

Specifically, the underlying calculation process of multi-head self-attention is defined as:

$$\text{Att.}(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right) V \tag{9}$$

where <Q, K, V> means query, key, and value respectively. d_k is the dimension of K. For example, if we focus on the enhanced bag-level representation [3], the h_{B_j} is substituted for the value, whereas the sentence-level $h_{S_{ij}}$ and entity-level h_e mean the key and query respectively[4]:

$$h'_{B_j} = \text{MLP}(\text{Att.}(h_e, h_{S_{ij}}, h_{B_j})) \tag{10}$$

where MLP is the linear multi-layer linear function. The similarity calculation (i.e. query and key) acts as the cross-level information interaction attending to the bag-level representation. After the interaction with multi-headed attention, we run a position-wise MLP similar to the standard transformer layer.

---

[2] Entity's representation is calculated by averaging all tokens hidden states of the entity.

[3] The calculation process of other modules is identical for entity level and sentence level. Hence, we take the bag level as an example in the following paper.

[4] Swapping the meaning of Q and K is also permitted.

Next, we concatenate enhanced target level representation with original hierarchical hidden state to obtain an informative level's representation:

$$h_{B_{att_j}} = \sigma([h_{B_j} \parallel h'_{B_j}] \cdot W_{att}) + b_{att} \tag{11}$$

where $W_{att} \in \mathbb{R}^{2d \times d}$ is a weight matrix and b_{att} is the bias. Finally, we leverage the three-level enhanced representation $h_{e_{att_j}}$, $h_{S_{att_j}}$ and $h_{B_{att_j}}$ to replace the hierarchical hidden representation in the following calculation process.

3.4 Dynamic Gradient Adversarial Perturbation

In addition to considering the interaction of cross levels, the semantic differences of fine-grained relations within the levels can also help models further enhance the context-aware representations. We construct a pseudo positive sample for contrastive learning (Jaiswal et al., 2020) to push the dissimilar relations away. Since the changes of specific-level gradient (Zhang et al., 2020) and the better context-aware semantic can boost the robustness representations, we devise the gradient perturbation and inertia weight memory mechanisms respectively.

3.4.1 Gradient Perturbation

The continuous gradient perturbations pt_{adv} is calculated from the gradient g of the task loss with the parameter V.

$$g_j = \bigtriangledown_V \mathcal{L}_{task}(h_{B_j}; \theta) \tag{12}$$

where V is the representation of the bag's sentences. We differentiate the entity to generate the gradient perturbation for sentence level and the token for the entity level.

$$pt_{adv_j} = \epsilon \cdot \frac{g_j}{\|g_j\|} \tag{13}$$

where $\|g\|$ is the norm of the gradient from the loss function, ϵ is a hyperparameter to control the disturbing degree.

3.4.2 Inertia Weight Memory

With the training epoch increasing, we use the time-sequential information of different granularities to further improve the robustness of internal semantics. Specifically, we add the inertia weight information (Shi and Eberhart, 1998) on the perturbation term, which takes advantage of the difference of representations between the last and the current epoch. The inertia weight information is denoted as follows:

$$I_w = \frac{T-u}{T} \operatorname{sim}\left(rep_{(u)}, rep_{(u-1)}\right) \tag{14}$$

where T is the total epoch number of the training process and u is the current epoch index. $rep_{(u)}$ can denote the entity, sentence, or bag representation respectively of the u-th epoch. rep is a embedding matrix saving the semantic memory in the order of element index, updated from the second epoch during the training process. Then, we combine the inertia weight information with gradient perturbation for bag level:

$$pt_{adv_j} = \epsilon \frac{g_j}{\|g_j\|} + \frac{T-u}{T} \operatorname{sim}\left(rep_{(u)}, rep_{(u-1)}\right) \tag{15}$$

We add pt_{adv_j} into the bag embedding, and get pseudo positive sample $h'_{B_j} = h_{B_j} + pt_{adv_j}$. Then we randomly sample a bag in the batch act as the negative sample. The positive and negative samples in InfoNCE loss (van den Oord et al., 2018) are replaced by the dynamic gradient perturbations and random bags respectively:

$$\mathcal{L}_{bag}^{info} = -\log \frac{\exp\left(cos\left(h_{B_j}, h'_{B_j}\right)/\tau\right)}{\sum_{k=1}^{m} \mathbb{1}_{[k \neq j]} \exp\left(cos\left(h_{B_j}, h_{B_{kj}}\right)/\tau\right)} \tag{16}$$

where $\mathbb{1}_{[k \neq j]}$ is an indicator function, τ is a hyper-parameter and cos is the cosine function. Due to the different granularities in the hierarchical framework, we devise different memories for entity-level, sentence-level, and bag-level, respectively.

3.5 Training Objective

In HiCLRE, our training objective contains two components, including the DSRE task loss and the contrastive learning loss. The total loss of contrastive learning is the sum of three-level infoNCE loss. Therefore, the overall objective function is formulated as follows:

$$\mathcal{L}_{total} = \lambda_1 \mathcal{L}_{en}^{info} + \lambda_2 \mathcal{L}_{sen}^{info} + \lambda_3 \mathcal{L}_{bag}^{info} + \lambda_4 \mathcal{L}_{task} \tag{17}$$

where λ_l is hyper-parameter and $\sum_{l=1}^{4} \lambda_l = 1$, denoting the weight of each components.

4 Experiments

4.1 Datasets and Baselines

We evaluate our HiCLRE model on three DSRE datasets, including NYT10 (Riedel et al., 2010),

Models	NYT10					GDS				
	AUC	P@100	P@200	P@300	P@M	AUC	P@500	P@1000	P@300	P@M
Mintz	10.7	52.3	50.2	45.0	49.2	-	-	-	-	-
PCNN-ATT	34.1	73.0	68.0	67.3	69.4	79.9	90.6	87.6	75.2	84.5
MTB-MIL	40.8	76.2	71.1	69.4	72.2	88.5	94.8	92.2	87.0	91.3
RESIDE	41.5	81.8	75.4	74.3	77.2	89.1	94.8	91.1	82.7	89.5
REDSandT	42.4	78.8	75.0	73.0	75.3	86.1	95.6	92.6	84.6	91.0
DISTRE	42.2	68.0	67.0	65.3	66.8	89.9	97.0	93.8	87.6	92.8
CIL	43.1	81.5	75.5	72.1	76.9	90.8	97.1	94.0	87.8	93.0
HiCLRE(ours)	**45.3**	**82.0**	**78.5**	74.0	**78.2**	**95.5**	**99.6**	**98.4**	**98.3**	**98.8**

Table 1: General experimental results of HiCLRE and baselines on NYT10 and GDS datasets.

GDS (Jat et al., 2017), and KBP (Ling and Weld, 2012). Table 4 shows the detailed statistics. NYT10 is annotated from the New York Times and aligned to Freebase and NYT10-M removes the noisy relation types manually from NYT10. GDS is extracted from human-judged Google Relation Extraction corpus. KBP is constructed over the newswire and web text from the corpus, which is used in the yearly TAC Knowledge Base Population challenges (Ji et al., 2010). Statistics of four datasets are showed in Appendix A.

Mintz (Mintz et al., 2009) concatenates various features of sentences to train a multi-class logistic regression classifier. PCNN-ATT (Lin et al., 2016) proposes a selective attention-based piecewise CNN to get sentence embeddings. MTB-MIL (Soares et al., 2019) proposes a Matching the Blanks method to learn the sentences' representation by the entity linked text. RESIDE (Vashishth et al., 2018) exploits the information of entity type and relation alias to add a soft limitation for relation classification. REDSandT (Christou and Tsoumakas, 2021) employs the PLMs to focus on instance embedding, aggregating the representations to the attention modules. DISTRE (Alt et al., 2019) combines the selective attention to its Transformer-based model. CIL (Chen et al., 2021a) proposes a contrastive instance learning method under the MIL framework.

4.2 Evaluation Metrics

Following the previous works (Chen et al., 2021b), we adopt the five general evaluation metrics in DSRE task to evaluate the performance, including **AUC**, **P@N** and **P@M**. Specifically, AUC (i.e. Area Under Curve) depicts the area under the ROC curve [5]. P@N refers to the P@100, P@200 and P@300 used in the metrics, denoting the top 100, top 200 and top 300 precision respectively. P@M is the mean value of the above three P@N results.

4.3 Parameter Settings

The underlying encoders of the entity level and sentence level are implemented by BERT_base (Devlin et al., 2019). The backbone encoder contains 12 Transformer layers and 12 self-attention heads, generating 768 hidden units for each token context-aware representation. During the training stage, we set the model's learning rate as {1e-5, 2e-5, 2e-7}. We choose AdamW (Loshchilov and Hutter, 2017) as our model's loss optimizer, which weight decay is 1e-5 and learning rate is 0.1. The max epoch is set to 5. We find the best hyper-parameter of temperature τ is 0.05, the λ set is {0.4, 0.4, 0.1, 0.1} and ϵ is 2. We show the important hyper parameters' searching results at Appendix C.

4.4 General Experimental Results

We first evaluate our HiCLRE model in the NYT10 and GDS that are popular used datasets in the DSRE task. Table 1 shows the overall performance on the NYT10 and GDS datasets. From the results[6], we can observe that (1) On both two datasets, the performance of our HiCLRE model outperforms all the strong baseline models significantly on the four metrics, achieving a new state-of-the-art result. (2) The performance of HiCLRE is greatly improved compared with the strongest baseline in two distantly supervised datasets (i.e. +2.2 AUC / +4.7 AUC). Meanwhile, we find the results of other four metrics are also increasing consistently. In general, it can be seen from Table 1 that the multi-granularity recontextualization for cross levels interaction and the dynamic gradient-based ad-

---

[5] ROC curve is plotted by false positive rate and true positive rate.

[6] CIL is the SOTA model in these datasets, whereas the source code is not provided so far. Hence, we reproduce the CIL model and report the performance in the test set.

versarial perturbation for specific levels can improve the performance greatly. Some general cases also prove the effectiveness in Appendix B.

The baselines and HiCLRE's overall PR-cureve is illustrated in Figure 3. From the curve, we can observe that (1) Our HiCLRE shows higher precision and recall results compared to other strong baselines. (2) Although the curve initially fluctuates quite a bit, both metrics of HiCLRE are basically stabilized at a relatively large gap during the training process. We conjecture that the difference of hierarchical context-aware representation is not obvious at the beginning of the model's training and the stored representations for inertia weight memory of specific levels do not exist in the first training epoch. During the training process, the mentioned above two learning problems tend to be stable and the performance of these two metrics is continuously performing better.

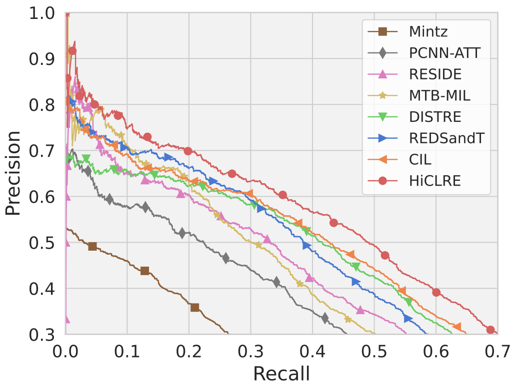

Figure 3: PR-curves of HiCLRE and other baselines on NYT10 dataset. (Best viewed in color)

Models	NYT10-M			KBP		
	AUC	F1	P@M	AUC	F1	P@M
PCNN-A	41.9	32.0	68.6	15.4	31.5	32.8
DISTRE	35.7	31.4	65.1	22.1	37.5	46.4
CIL	56.0	34.3	75.9	29.5	41.6	47.3
HiCLRE	**61.4**	**36.9**	**88.0**	**46.1**	**61.0**	**56.4**

Table 2: Experiment results on human-annotated datasets.

4.5 Evaluation on Human Annotated Dataset

Due to the inevitable annotated errors of distantly supervision assumption, we further evaluate our model on the human-annotated high-quality relation extraction datasets, including NYT10-M and KBP. The performances of baselines and HiCLRE are shown in Table 2. The result shows that HiCLRE can significantly outperform the three strong baselines especially the AUC metric reaches 46.1, which improves about 50% (29.5 ↦ 46.1) performance than CIL (Chen et al., 2021a) on the KBP dataset. This phenomenon implies that our model possesses a steady generalization ability to other analogous relation extraction datasets.

5 Detailed Analysis of HiCLRE

5.1 Ablation Study

To verify the effectiveness of various modules in our HiCLRE model, we conduct ablation study experiments on the NYT10 dataset. Specifically, we remove the following argued contributions in turn to evaluate the performance, including multi-granularity recontextualization, three-level contrastive learning loss, and the data augmentation strategies in each level. The final results are shown in Table 3. From the results, we conclude that (1) The context-aware representation interactions for cross levels and the enhanced internal semantics representations for specific level are essential, dropping -1.8% and -2.7% point on the AUC metric respectively. (2) We also find the sentence-level data augmentation skills for our HiCLRE model are the most important (e.g. -4.9% and -2.6% on AUC) compared to the other two levels. The possible reason may be that the sentence granularity is the fundamental input granularity for the DSRE task including the term "bag" is also constructed by choosing the sentences with identical entity pairs.

Methods		AUC	F1	P@M
HiCLRE		45.3	49.5	78.2
-Multi-Gra. Recon.		43.5	47.1	76.4
-Three-level CL Loss		42.6	47.9	70.8
-Bag Level	-bag gradient	43.9	48.1	75.4
	-bag memory	42.4	48.6	72.3
-Sentence Level	-sen. gradient	40.4	48.9	73.9
	-sen. memory	42.7	48.1	67.2
-Entity Level	-en. gradient	43.0	48.4	70.1
	-en. memory	43.1	46.7	73.2

Table 3: Ablation study of HiCLRE on NYT10. "-" means removing the module behind.

5.2 The Influence of Multi-Granularity Recontextualization

Figure 4 shows the comparison of final stable results and speed of convergence between the multi-granularity recontextualization and single-granularity[7] on the NYT10 dataset. we can observe that (1) multi-granularity recontextualization converges faster to not only stable but also better results. (2) When the final performance of the model converge stably, our multi-granularity recontextualization have less jitter amplitude making our model more robust.

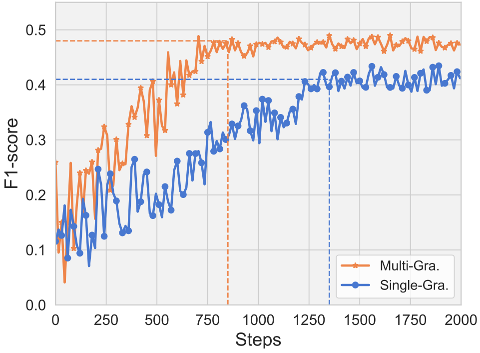

Figure 4: The comparison including convergence speed (i.e. steps) and performance (i.e. F1-score) of training process between our multi-granularity cross-level attention (Multi-Gra.) and single-granularity (Single-Gra.). (Best viewed in color)

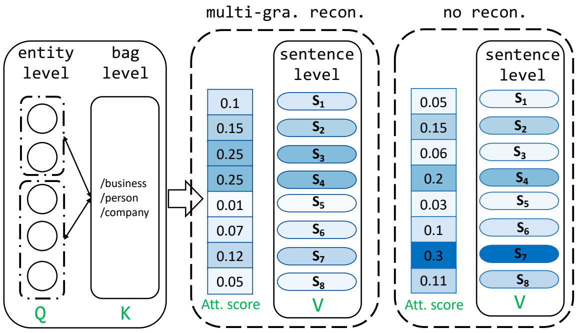
Figure 5 shows the two heat maps of the module with and without attention calculations, proving our multi-granularity recontextualization mechanism is effective for denoising the redundant sentences. For example, we take the sentence-level representations act as "V" value. Our multi-granularity recontextualization mechanism can achieve the higher attention scores (e.g. S_3 and S_4) for the important sentences in a bag, whereas the no recontextualization models incorrectly assign the highest attention score (e.g. S_7) to the noisy sentences. This phenomenon indicates that this mechanism has a better ability to filter noisy sentences.

5.3 The Influence of Gradient-based Data Augmentation

To further prove our data augmentation skill of contrastive learning is effective, we choose the other three strategies (i.e. randomly deleting a word, twice dropout, and randomly noise) to perform the evolution process of representation learning space.



bag relation: /business/person/company

S3: In 1998, Steve Jobs asked Cook to join Apple.

S4: Under Cook's leadership, Apple has increased its donations to charity.

S7: The cook should put the apple into microwave on High for 2 minutes.

Figure 5: The heat maps of our multi-headed attention mechanism (ours) and no attention mechanism (right) among cross levels. (Best viewed in color)

Following the previous works (Wang and Isola, 2020), we treat the pseudo sample as the positive instance and a randomly chosen instance from the batch as the negative instance to calculate alignment and uniformity. Then, we plot the transformation of the align-uniform points in Figure 6. The lower alignment and uniformity results indicate the better context-aware representations of the contrastive learning process. Compared to the other positive sample generation skills, our dynamic gradient adversarial perturbation module reduces the alignment and uniformity metrics steadily to the lower value and faster speed.

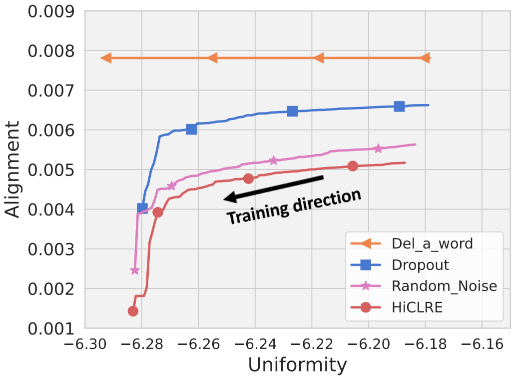


Figure 6: Results comparison of HiCLRE and other data augmentation skills in terms of alignment and uniformity. The arrows indicate the training direction. (Best viewed in color).

.

6 Conclusion

In this paper, we propose HiCLRE, a hierarchical contrastive learning framework for distantly supervised relation extraction. Multi-Granularity Recontextualization module of HiCLRE utilizes a multi-head self-attention mechanism to transmit

---

[7] The single-granularity means just facility original representation of each level without combining the multi-headed attention mechanism.

the information across three levels. Dynamic Gradient Adversarial Perturbation module combines the gradient perturbation with inertia memory information to construct better pseudo positive samples for contrastive learning. Experiments show the effectiveness of HiCLRE against the strong baseline models in various DSRE datasets.

Table 4: Statistics of four datasets. Rel.: relation, DS: distantly supervised and MA: manually annotated.

B Case Study

We enumerate several representative examples in Figure 7 to further explore why our model can work in the distantly supervised scenario. In the left part of the figure, there are two bags containing the different entity pairs (i.e. ⟨“Bill Gates”, “Microsoft” ⟩ and ⟨“Robert Walter”, “Cardinal Health” ⟩). Previous works ignore the consideration of the representation interaction in a specific levels and cross levels, which may be hard to predict similar or difficult instances. For example, sentences of bag B_1 are always classified into the relation “*major_shareholders_of*”. Although these two relations (i.e. “*major_shareholders_of*” and “*/person/-company*”) are pretty similar to each other, none of the four sentences’ semantics in B_1 represent the meaning of “*major_shareholders_of*”. In particular, after the context-aware representations interaction via cross levels and specific levels, HiCLRE can correctly predict the bag to the ground-truth label; likewise, the bag B_2 is in the same situation.

In the right part of the figure, we demonstrate an example of that HiCLRE can pull the correlated instance closely and push the uncorrelated instance away. We reduce the dimension of bag examples’ representations by t-SNE (van der Maaten and Hinton, 2008) and show the example results in the coordinate system. R^* is the target instance to be classified, the symbol “$+$” represents the degree of relevance and “$-$” represents the degree of irrelevance. HiCLRE can pull the related sample R^+ to R^{+++} (i.e. closer to R^*), while pushing the uncorrelated sample R^- to R^{--} (farther from R^*). This phenomenon is own to the design of gradient-based perturbation, which gives significant enhancement to interactions in a specific level.

C The influence of important hyper parameters

We experiment with our model on the NYT10 dataset with four important hyper-parameters, and discover a suitable parameters’ combination to reach better performance.

Bag	Sentence	Wrong Prediction	HiCLRE(ours) Prediction
B_1	- If **Bill Gates** had to worry about health insurance would he have started **Microsoft** ? - **Bill Gates** will be involved , Mr. Trump said , with a new **Microsoft** product . - **Microsoft** will invest $ 1.7 billion in India over the next four years, its chairman , **Bill Gates** , said Wednesday . - Three decades after he started **Microsoft** with the dream of placing a personal computer in every home and business , **Bill Gates** said that he would leave his day-to-day role there in two years .	/business /company_ shareholder /major_shar eholders_of	/business /person /company
B_2	- **Robert Walter** retired from **Cardinal Health** in June 2008. - **Robert Walter** is setting down his memories of **Cardinal Health**'s life. - **Cardinal Health** reported $151000 in personal aircraft use last year for **Robert Walter**.	/business /company /founders	/business /person /company

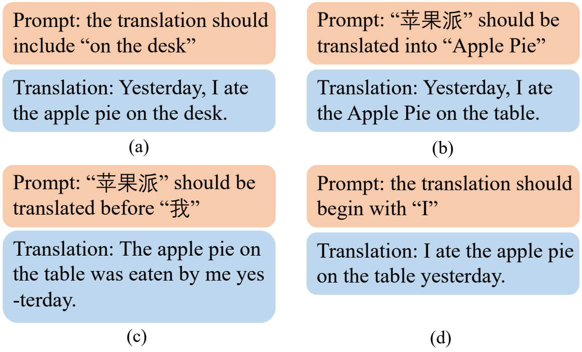
Abstract

Neural machine translation (NMT) has obtained significant performance improvement over the recent years. However, NMT models still face various challenges including fragility and lack of style flexibility. Moreover, current methods for instance-level constraints are limited in that they are either constraint-specific or model-specific. To this end, we propose prompt-driven neural machine translation to incorporate prompts for enhancing translation control and enriching flexibility. Empirical results demonstrate the effectiveness of our method in both prompt responding and translation quality. Through human evaluation, we further show the flexibility of prompt control and the efficiency in human-in-the-loop translation.



Prompt: the translation should include “on the desk”

Translation: Yesterday, I ate the apple pie on the desk.

(a)

Prompt: “苹果派” should be translated into “Apple Pie”

Translation: Yesterday, I ate the Apple Pie on the table.

(b)

Prompt: “苹果派” should be translated before “我”

Translation: The apple pie on the table was eaten by me yes -terday.

(c)

Prompt: the translation should begin with “I”

Translation: I ate the apple pie on the table yesterday.

(d)

Figure 1: A Prompt-driven NMT model outputs different translations for the sentence “昨天, 我吃了桌上的苹果派。” (English: Yesterday, I ate the apple pie on the table.) based on the given prompts. One can specify phrase translations, guarantee translation positions or alter word order by feeding the system with different prompts.

1 Introduction

Neural machine translation (NMT) has achieved much performance improvement over the recent years (Vaswani et al., 2017; Edunov et al., 2018; Hassan et al., 2018; Liu et al., 2020), yet still faces various challenges such as low cross-domain robustness (Müller et al., 2020), fragility (Li et al., 2021) and lack of style flexibility (Li and Jurafsky, 2016; Shu et al., 2019). To address these issues, a line of work considers introducing constraints to the translation outputs, typically in the form of lexical constraints (Song et al., 2019; Chen et al., 2020) and style control (Sennrich et al., 2016a; Michel and Neubig, 2018; Shu et al., 2019). For example, Song et al. (2019) ensure that polysemous words are translated to their domain-specific senses in eCommerce.

Such instance-level constraint has been shown useful for improving both the translation adequacy and readability in practical applications (Song et al., 2019; Chen et al., 2020; Jwalapuram et al., 2020; Konieczny, 2021; Chen et al., 2021a). However, they are limited in being (1) model-specific and (2) constraint-specific. For instance, lexical constraints are typically integrated into a model by either modifying the decoding process (Hokamp and Liu, 2017; Post and Vilar, 2018; Chen et al., 2021a) or introducing special post-processing (Song et al., 2019; Chen et al., 2020). Style constraints are learned through data synthesization (Sennrich et al., 2016a; Niu and Carpuat, 2020) or specialized model design (Michel and Neubig, 2018). As a result, the engineering cost of accommodating and simultaneously optimizing for various constraints and styles can be high.

We consider prompt-driven neural machine translation, a general form of introducing translation constraints. The basic idea is shown in Figure 1, where a prompt-driven NMT system can accept a source input, together with an arbitrary number of instructions, and generate a target translation in accordance. Since the translation constraints are specified in texual form, we can integrate different types of control easily into the input, such as specifying the translation of a source phrase (Figure 1b), controlling word order (Figure 1c) and laying

Findings of the Association for Computational Linguistics: ACL 2022, pages 2579 - 2590
May 22-27, 2022

out the beginning of the target sentence (Figure 1d), in addition to the traditional lexical constraints (Figure 1a). In addition, when there are no input constraints, the NMT system should give competitive performance as a unconstrained NMT model.

Without losing generality, we consider the forms of constraints in Figure 1 in this work. Building on a standard Transformer (Vaswani et al., 2017) baseline, we consider the following research questions. *First, what is the most effective system architecture for encoding both the source sentence and the prompt?* To this end, we compare various methods including concatenating source sentences with prompts, encoding prompts using a dedicated module, and incorporating prompt representations with an attention layer. The model performance is also compared with previous work on lexical constraints, a form of constraints in Figure 1 that has been much studied in the literature. *Second, can different types of constraints be effectively trained within the same model?* To this end, we design an algorithm to automatically construct different types of prompts from a standard MT training corpus, training a model with mixed prompts. *Third, can a prompt-driven NMT system accept different number of prompts, while maintaining the same level of performance compared to a Transformer baseline without constraints?* To this question, we consider a sampling-based training strategy, where the model receives random combinations of arbitrary number of prompts or no prompt at all for each sample during training. *Fourth, can the set of flexible constraints we use serve to improve the efficiency of human-in-the-loop translation?* We deploy our prompt-drive system in a real application scenario where professional translators conduct machine translation post editing (MTPE) by using prompts.

Empirical results show that the Prompt-driven Transformer (Prompt-Transformer) responds to different prompts effectively, while giving competitive performance when used as a unconstrained NMT model. In addition, prompt-driven model outperforms previous lexical constraints methods (Song et al., 2019; Chen et al., 2021b) by a large margin. Human experiments further demonstrate the control flexibility and effectiveness of our method. Through system deployment in a practical scenario, we show that the prompt-driven NMT system achieves a trade-off between translation quality and human efficiency, as compared with full NMT or NMT with human post editing. Our code is released on https://github.com/yafuly/PromptNMT.

2 Related Work

Lexical constraint has received much attention for machine translation. Some researchers incorporate the constraints into the beam search algorithm (Hokamp and Liu, 2017; Post and Vilar, 2018), and recently Chen et al. (2021b) investigate alignment-based constrained decoding methods using attention weights. Another approach focuses on data augmentation. Song et al. (2019) and Dinu et al. (2019) create a synthetic code-switching corpus. Jon et al. (2021) augment the input sentences with lemmatized constraints to correct inflection. Chen et al. (2020) propose a lexical constraint-aware Transformer model (LeCA) by concatenating constraints and source sentence. Lexical constraints is one of the application scenarios of our method. Prompt-driven model gives strong results, while also simultaneously enables structural and style constraints with the versatility of prompts.

There has been study on controlling the global output style in MT (Mima et al., 1997; van der Wees et al., 2016; Rabinovich et al., 2017; Michel and Neubig, 2018; Sennrich et al., 2016a; Niu and Carpuat, 2020). van der Wees et al. (2016) analyze the impact of dialogue specific aspects in SMT for fictional dialogues. Rabinovich et al. (2017) employ personalized SMT models for better preservation of gender traits, and Michel and Neubig (2018) propose to adapt the bias of the output softmax to different users of an NMT system. Sennrich et al. (2016a) use target-constraint T-V annotation in NMT training to control the level of politeness. Niu and Carpuat (2020) propose a formality-sensitive NMT model taking formality levels as an extra input. Our work is similar in that the output of our model can be adaptive at inference time, but different in that the control is more fine-grained and not limited to certain styles.

Human in the loop for NMT (Turchi et al., 2017; Weng et al., 2019) has been proved effective to domain adaptation. Cheng et al. (2016) propose an interactive framework which takes two human actions: picking a critical translation error and revising the translation. Petrushkov et al. (2018) propose a simple sentence-level weighting method to integrate partial chunk-based feedback into NMT. Kreutzer et al. (2018) improve NMT with explicit and implicit user feedback collected on the ecom-

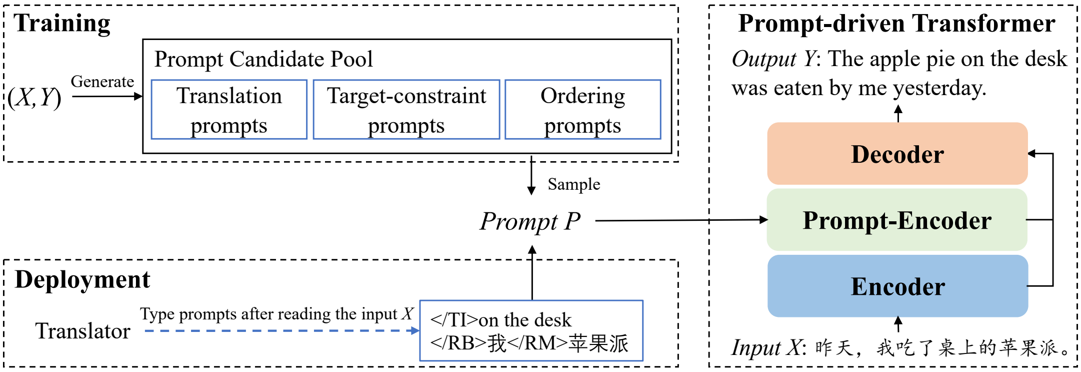


Figure 2: The overall framework of Prompt-Transformer. During training, the prompts are sampled from the prompt candidate pool, which contains all possible prompts for each sentence pair. In deployment, the translators give arbitrary prompts to control output translations according to their needs.

merce platform. Domingo et al. (2019) leverage data generated during the post-editing process. The above methods improve the performance of NMT by leveraging extra training signals from human feedback. Different from them, our method allows human to control the NMT output by training a model with mixed prompts, without the requirement of human in training.

3 Problem Definition

In neural machine translation, a set of parallel sentence pairs $D = \{(X, Y)\}$ is given where $X = (x_1, ..., x_{T_x})$ and $Y = (y_1, ..., y_{T_y})$, and the NMT systems model the conditional probability:

$$p(Y|X;\theta) = \prod_{t}^{T_y} p(y_t|y_{<t}, X;\theta), \qquad (1)$$

where θ is the set of trainable parameters. We introduce prompts $P = (P_1, ..., P_N)$ to control translation, which is defined as

$$p(Y|X, P;\theta) = \prod_{t}^{T_t} p(y_t|y_{<t}, X, P;\theta). \qquad (2)$$

The prompts can be general and flexible. In this paper, we consider the following three types of common prompts:

- **translation prompts** that indicate the specific translation of a source segment (Fig 1 (b)).
- **target-constraint prompts** including some specific segments that the translation must contain, begin or end with (Fig 1 (a) and (d)).
- **ordering prompts** that indicate a source segment should be translated before another source segment (Fig 1 (c)).

4 Approach

The overall architecture of our system is shown in Figure 2. In particular, we take a Transformer baseline (Section 4.1), discussing different ways to additionally encode prompt constraints (Section 4.2). We propose a sampling-based training framework (Section 4.4), with automatic methods for generating rich constraints from standard MT training instances (Section 4.3).

4.1 Transformer

The vanilla Transformer (Vaswani et al., 2017) is composed of an encoder and a decoder. The Transformer encoder has a stack of L identical multi-head self-attention layers, which takes the embedding of a source sentence X as input and outputs contextualized source representations. For the l-th encoder layer, the representations are computed as

$$H^l = \text{EncLayer}(H^{l-1}), \qquad (3)$$

where H^{l-1} is the output hidden state of the $(l-1)$-th layer.

The decoder introduces a cross-attention sublayer in each layer to attend to the source representations H^L, taking previously generated target tokens as input and generating the next token. For the l-th decoder layer, the hidden states of decoder are calculated as

$$S^l = \text{DecLayer}(S^{l-1}, H^L), \qquad (4)$$

where S^{l-1} is the output of the $(l-1)$-th layer.

4.2 Prompt-driven Transformer

We investigate three different approaches to incorporate prompts into the Transformer model.

(1) Separate Encoding. A straightforward way is to introduce a Prompt Encoder that is identical to the Transformer encoder, which encodes the prompt sequence separately. We concatenate the source representations and the prompt representations as the final encoder memory for the decoder:

$$H_P^L = \text{Prompt-Encoder}(P), \tag{5}$$

$$\hat{H}_L = \text{Concat}(H^L, H_P^L), \tag{6}$$

where P is a prompt sequence.

(2) Input Augmentation. We follow Chen et al. (2020) and construct pseudo source sequences by augmenting each input source sequence with the corresponding prompt sequence:

$$\hat{X} = \text{Concat}(X, P_1, P_2, ..., P_N), \tag{7}$$

where N is the number of prompts. The augmented input $\hat{X}$ is fed into the standard Transformer.

(3) Prompt Attention. On top of the concatenation method, we can also use a dedicated prompt attention sub-layer after the cross-attention module in each decoder layer. The prompt attention takes the decoder hidden representations as queries and takes the prompt representations as keys and values to perform multi-head attention:

$$\text{PromptAttn}(S^l, H_P^L) = \text{MHA}(S^{l-1}, H_P^L, H_P^L), \tag{8}$$

where MHA$(\cdot)$ is the multi-head attention mechanism (Vaswani et al., 2017).

4.3 Training Prompt Construction

Given a parallel dataset $D = \{(X, Y)\}$, we propose an automatic method to generate prompts for each sentence pair based on word alignment, resulting in a corpus $\hat{D} = \{(X, Y, \hat{P})\}$, where $\hat{P}$ is the corresponding prompt candidate pool containing all prompts. Specifically, we train an alignment tool on a parallel corpus and obtain possibly aligned phrases. For each sentence pair, we extract all possible prompts using the aligned phrases to build the prompt candidate pool.

First, we insert pre-defined symbols between source phrase segments and the corresponding aligned target segments (e.g., "</AB> menschliche gesundheit </AM> human health") to construct **translation prompts**. Second, we append pre-defined symbols before target phrase segments to construct **target-constraint prompts**: (1) "</TB>" denotes the target sequence begins with specific segments (e.g., "</TB> we know"); (2) "</TI>" denotes the target sequence includes specific segments (e.g., "</TI> the complex science"); (3) "</TE>" denotes the target sequence ends with specific segments (e.g., "</TE> we 've experienced that ."). Third, for **ordering prompts**, we find pairs of source phrases of which the aligned target phrases appear in the opposite order in the target sequence, indicating word-reordering is involved in translating these phrases. We insert pre-defined symbols between these 2 source segments (e.g., "</RB> the apple pie </RM> on the table", meaning that "on the table" should be translated before "the apple pie" in the target language).

4.4 Training

Given $\hat{D} = \{(X, Y, \hat{P})\}$, we propose a sampling based training framework to train the prompt-driven NMT model. For each instance $(X, Y, \hat{P})$, we define whether to use prompts as a discrete Bernoulli variable $u \sim \mathcal{B}(\mu)$, where μ is a hyper-parameter (*Bernoulli ratio*) and a higher μ indicates more prompt-driven samples during training. If prompt is not used, the training objective is to maximize the log-likelihood:

$$\sum_{(X,Y) \in Batch} logp(Y|X; \theta), \tag{9}$$

where $Batch$ is a mini-batch of parallel sentence pairs.

If prompt is used, we sample a certain proportion of prompts for each prompt type from the corresponding prompt candidates without replacement. In particular, we define the proportion of the sampled prompts as a continuous random variable with a uniform distribution $\mathcal{U}(0, p_u)$, where p_u is a hyper-parameter, *uniform ratio*. A larger p_u indicates more prompts are sampled for each sentence if there are. All sampled prompts are concatenated together to form the final prompt sequence P, and the training objective is to maximize the log-likelihood defined as:

$$\sum_{(X,Y,P) \in Batch} logp(Y|X, P; \theta). \tag{10}$$

The randomness in prompts enables the model to cope with complicated situations containing different prompts and output accurate translations without prompts as well.

Model	# params	BLEU		ResR
		w/o prompts	w/ prompts

Table 1: Performance of different prompt-feeding methods on IWSLT'14 De-En.

5 Experimental Settings

Setup. As a preliminary experiment, we use a small size dataset IWSLT'14 De→En to investigate the effectiveness of our model under different settings. We use the Moses tokenizer[1] and apply BPE (Sennrich et al., 2016b) with 10,000 merge operations on the merged corpus of both side. For large-scale test, we extend our method to WMT'17 En→Zh, which contains 20.6M sentence pairs after preprocessing. We use Moses tokenizer to tokenize English side and jieba segmenter[2] to tokenize Chinese side. We apply BPE with 55,000 operations on the concatenated corpus and obtain a shared vocabulary for both sides. We use fast_align (Dyer et al., 2013) to obtain word alignment, based on which we apply the algorithm in Section 4.3 to generate prompts and build the prompt candidate pool. Data statistics is presented in Appendix A. We implement the Transformer baseline and Prompt-Transformer based on THUMT (Tan et al., 2020). We use iwslt_de_en for IWSTLT'14 De→En and transformer_base for WMT'16 En→Zh. The default Prompt Encoder consists of 3 Transformer layers. We use Adam (Kingma and Ba, 2015) to optimize the network with $\beta_1 = 0.9$, $\beta_2 = 0.98$. The default Bernoulli and uniform ratios are set as 0.3 and 0.35, respectively. For inference, we set the beam width as 5 and length penalty as 0.6. Details are presented Appendix B.

Evaluation Metrics. We use both automatic and human evaluation to measure the performance of our prompt-driven NMT model, taking commonly-used BLEU scores (Papineni et al., 2002) to measure translation quality automatically. For fair comparison with previous work, we use multi-bleu.perl for De-En and sacreBLEU (Post, 2018) for En-Zh[3]. In addition, we use Response Rate (ResR) to quantify how the model responses to the given prompts, which is defined as the percentage of prompts being correctly responded. Specifically, for translation prompts, ResR denotes the ratio of prompt translations that appear in the sentence translation; for target-constraint prompts, ResR measures the ratio of prompts that exist at the beginning of, at the end of or in the translation accordingly; for ordering prompts, ResR is calculated as the ratio of translations that satisfy the word ordering information induced by the prompts.

For human evaluation, we follow Knight (2000) and ask professional translators to assign *adequacy* and *fluency* scores for each translation ranging from one to five. The five point scale for adequacy indicates how much of the meaning expressed in the reference translation is also expressed in a hypothesis translation: 5 = All, 4 = Most, 3 = Much, 2 = Little, and 1=None. The five point scale for fluency indicates how fluent the translation is: 5 = Flawless, 4 = Good, 3 = Non-native, 2 = Disfluent, and 1 = Incomprehensible.

We investigate the effectiveness of our method in the context of automatic evaluation in Section 6, where prompts are constructed towards reference translation. In Section 7, we conduct human evaluation to demonstrate the control flexibility of the Prompt-driven NMT system. Finally, in Section 8 we show an application of the method in the context of human-in-the-loop translation.

6 Experiments on the Model Design

We evaluate models under two test scenarios using IWSLT'14 De-En: inference without prompt and inference with prompt. The former is the same as the vanilla machine translation setting and is evaluated using BLEU score. For the latter, we also evaluate the model's effectiveness on responding to prompts by calculating ResR. We apply sampling strategy same to training and run on the test set once to build a deterministic prompt sets.

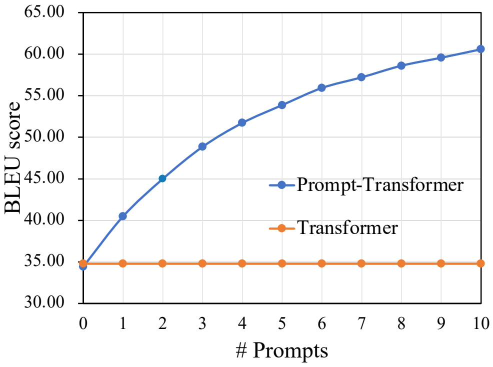

Figure 3: BLEU scores with respect to the number of prompts during inference.

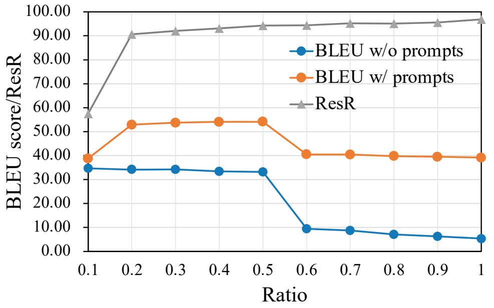

Figure 4: ResR and BLEU scores with respect to the Bernoulli ratio during training.

Number of prompts during decoding. We investigate how prompts improve translation performance by feeding different number of prompts during decoding. Specifically, we randomly select certain number of prompts from the prompt candidate pool and construct test prompts accordingly. The results are shown in Figure 3. Prompt-Transformer further achieves higher BLEU scores when there are more prompts. Given as many as 10 prompts, the BLEU reaches 60.59. We also investigate how the sampling ratio affects decoding performance, which is discussed in Appendix C.

Robustness to different prompts. We explore how the model behaves under different prompt sets, by fixing the sampling ratios but varying the seed for prompt sampling. We conduct experiments with 10 seeds, under which the model receives different prompts for translation, calculating the mean and standard deviation of BLEU scores and ResR over each seed. For each sentence, the model is provided with 1 to 8 sampled prompts. The model achieves a average BLEU score of 54.79 with a standard deviation of 0.17, and an average of 92.82 with a standard deviation of 0.14 for ResR, demonstrating that the model is stable for flexible types of prompt combinations.

Influences of model architecture. Based on the modules in Section 4.2, we compare different model architectures to incorporate prompts using a fixed prompt seed. As shown in Table 1, all prompt-driven models obtain higher BLEU scores over Transformer when provided with prompts. *Input augmentation* achieves the highest ResR, but suffers from larger performance deterioration without prompts. For the prompt encoding method, we find that reusing the sentence encoder as the prompt encoder (*Param-share Prompt Encoder*) achieves higher ResR than introducing extra parameters (*Prompt Encoder*). We attribute this pattern to the better generalization ability of the reused encoder in *Param-share Prompt Encoder*. The effects of prompt encoder depth is discussed in Appendix D. For incorporating prompt representations, introducing Prompt Attention (*Prompt Enc & Prompt Attention* and *Param-Share Prompt Enc & Prompt Attn*) is beneficial for responding effectiveness, compared with concatenating source and prompt representations for cross-attention. Overall, *Param-share Prompt Encoder* gives a balance between BLEU in unprompted cases and the response rate, without introducing extra parameters. We thus choose the model for the other experiments.

Number of prompts during training. The sampling strategy in Section 4.4 can affect the performance. We investigate how varying the Bernoulli ratio during training affects the model performance. The Bernoulli ratio indicates how many of samples in the train set are driven by prompts. For example, a Bernoulli ratio of 0.3 denotes 65.7% of the training samples are provided with prompts. The result is shown in Figure 4. We can observe that ResR grows steadily with the increasing ratio during training. The model gives a low ResR with a Bernoulli ratio of 0.1, as there are limited samples for the model to capture prompt patterns. Despite the increasing ResR, there is a sharp decline on BLEU scores when the ratio exceeds 0.5. This is because high Bernoulli ratios indicate almost all training samples are prompted (e.g., a ratio of 0.7 denotes 97.3% of training samples are provided with prompts). Therefore, the model learns to output translations by over reliance on prompts, but fails to build correspondence between source and target languages. Thus it is important to balance the learning of translation and receiving prompts.

</RB> wang zhian </RM> argued	双方在庭审中争辩 说,王志安 是否侵犯了兰玉峰的名誉权。 (English: the two sides argued in the court hearing, whether wang zhian violated the reputation right of lan yuefeng.)
</TB> 在庭审中 </RB> wang zhian </RM> argued	在庭审中 , 双方争辩 说王志安是否侵犯了兰玉峰的名誉权。 (English: in the court hearing, the two sides argued whether wang zhian violated the reputation right of lan yuefeng.)
</AB> lan yuefeng </AM> Lan Yufeng </TB> 在庭审中 </RB> wang zhian </RM> argued	在庭审中 , 双方争辩 说王志安 是否侵犯了Lan Yufeng 的名誉权。 (English: in the court hearing, the two sides argued whether wang zhian violated the reputation right of Lan Yuefeng.)

Table 2: Given different prompts, Prompt-Transformer generates different translations for the sentence “in the court hearing , the two sides argued whether wang zhian violated the reputation right of lan yuefeng.”.

Model	BLEU		CSR	ResR
	w/o P	w/ P		
TF-IWSLT	34.78	-	-	-
Code-Switch	33.88	37.15	93.69	90.21
LeCA	34.66	37.10	89.32	82.97
Prompt-TF	34.44	38.30	95.75	94.26

Table 3: Prompt-driven Transformer for lexical constraints on IWSLT’14 De-En. P denotes ‘prompts’.

Model	BLEU		ResR
	w/o prompts	w/ prompts	
TF-Base	34.06	34.06	-
Prompt-TF	33.88	48.93	91.80

Table 4: Performance on WMT’17 En-Zh.

Comparison with existing work on lexical constraints. Among the types of prompts we accommodate, lexical constraints have been investigated by existing work. We compare our method with two typical methods, i.e., CodeSwitch (Song et al., 2019) and LeCA (Chen et al., 2021b). Following Song et al. (2019) and Chen et al. (2021b), the copy success rate (CSR) is also calculated, which is the percentage of successfully generated tokens in constraints, differing from ResR which is the ratio of correctly responded prompts (i.e., phrases for lexical constraints). Compared with CodeSwitch, Prompt-Transformer maintains better performance without prompts, while also achieves a higher score of CSR and ResR. Although LeCA is slightly better in terms of BLEU without prompts, Prompt-Transformer outperforms LeCA by a large margin in terms of CSR and ResR. Performance in lexical constraints further demonstrates the effectiveness of our method for controlling translation and meanwhile maintaining performance without prompts.

Experiments on WMT. For a large scale test, we apply Prompt-Transformer on the WMT’17 En→Zh dataset. Based on the preliminary experiments, we choose the *Param-share Prompt Encoder* architecture. As shown in Table 4, Prompt-Transformer gives an improved BLEU with prompts (48.93 vs. 34.06) and a ResR of 91.80, verifying the scalability of the proposed method on large-scale datasets. We use this model for experiments in Section 7 and Section 8.

7 Experiments on Prompts

We evaluate how model responds to prompts in practical scenarios, where no “gold-standard” references are given. We sample 100 source sentences from the WMT’17 En-Zh test set and ask 2 professional translators to assign each sentence with two different prompt groups, each of which includes at least one type of prompts. In particular, for constructing translation prompts, the translators are asked to give a source segment two different valid translations (e.g., “translation-segment-1” or “translation-segment-2”); for constructing target-constraint prompts, the translators should choose two different ways to prompt the model; for constructing ordering prompts, the translators provide two opposite orderings (e.g., “source-segment1” should be translated before and after “source-segment2”, respectively). The model is expected to output two *different* and *correct* translations corresponding to the two prompt groups, respectively. We ask 3 professional translators to evaluate the *ResR* and *translation quality* based on the adequacy and fluency metrics in Section 5.

The system achieves ResR scores of 89.80, 94.74, 90.20 for translation prompts, target-constraint prompts, and ordering prompts, respectively, showing the effectiveness of our proposed model on responding to human prompts. The system obtains a competitive performance compared to the unprompted baseline in tuns of both adequacy (3.49 vs. 3.40) and fluency (3.24 vs. 3.31), demonstrating that our system can enable flexible translation style and maintain translation quality at the same time.

Table 2 shows a case study, where the system responds to different types of prompts and their combinations accurately given the same source sentence. Moreover, the system generates translations with different styles under the target-constraint prompts and ordering prompts. For instance, with the prompt "</TB> 双方" (English: </TB> the two sides), the system translates the word "argued" to "争论" (English: argued) instead of "进行了辩论" (English: launched a debate) in the unprompted case. A similar pattern can be observed when the system receives the ordering prompt "</RB> wang zhian </RM> argued", which indicates that the word "argued" should be translated before "wang zhian" in Chinese.

8 Human-in-the-loop Translation

Machine translation post-editing (MTPE) is widely used by translation companies to improve efficiency as well as ensure translation quality. Studies show that conducting post-editing over high-quality MT can increase the productivity of professional translators compared to manual translation 'from scratch' (Guerberof, 2009; Plitt and Masselot, 2010). However, MTPE still can be expensive in heavy involvement of human efforts in editing. To alleviate human labor, Prompt-driven methods can be used for a better trade-off between translation quality and efficiency.

To verify our hypothesis, we ask professional translators to compare two methods for editing on MT translations: the traditional MTPE or giving prompts based on MT translations (MTPrompt). We compare MT, MTPE and MTPrompt based on time efficiency and translation quality. MT refers to use machine translations without editing. For MTPE, translators are required to edit translations output by the WMT-trained Transformer baseline in Section 6. For MTPrompt, translators are required to observe output translation errors and give prompts to correct them. More details are presented in Appendix E.

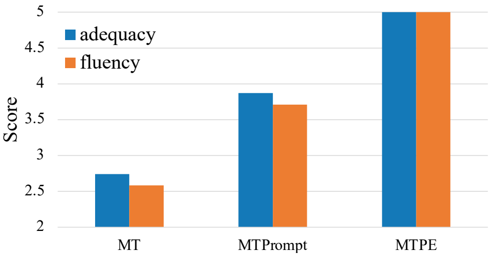

Figure 5: Translation quality based on adequacy and fluency.

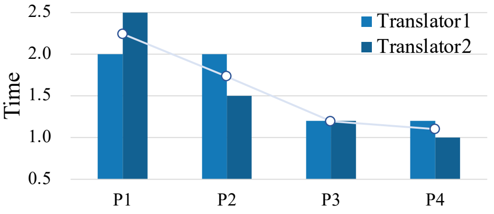

Figure 6: Time cost (hours) for MTPrompt with respect to the round of MTPrompt.

The translation quality is presented in Figure 5. MTPE achieves full marks on both adequacy and fluency, whereas the scores for MT translations are on average around 2.5. Translations with prompt obtain substantial improvement over MT translations, with both the adequacy and fluency scores being close to 4 (i.e., the translations cover most meaning and also have good fluency).

In terms of speed, the average time spent on MTPE is 3.75 hours, which is stable for more batches since the translators have strong experience in MTPE. In contrast, the time cost can be lower as they conduct more MTPrompt actions. We ask two translators to conduct multiple rounds of MTPrompt edit, with each round containing 50 translations. The time cost for each round is shown in Figure 6. We can observe that as the translators get familiar with the MTPrompt mode, they become more efficient in giving prompts. The fastest batch costs an average of 1.1 hours for MTPrompt, which is 2.4 times more efficient than MTPE, and meanwhile translation quality is maintained (adequacy: 3.87 vs. 3.84 and fluency: 3.71 vs. 3.63).

9 Conclusion

We proposed a prompt-driven Transformer model to incorporate flexible constraints on translation. Under a sampling-based training framework, the model learned prompt responding effectively and achieved competitive performance compared with both the unconstrained baseline and existing work on lexical constraints. Human experiments further demonstrated that Prompt-Transformer was able to respond to various combinations of prompts accurately, and generate versatile translations. Through deployment in an application scenario, we showed that our system could serve to improve the efficiency of human-in-the-loop translation.

10 Ethics Consideration

As mentioned, we collected our data from IWSLT and WMT that all are public to academic use, and they contain no sensitive information. The legal advisor of our institute confirms that the sources of our data are freely accessible online without copyright constraint to academic use. Our human experiments (Section 7 and Section 8) involves manual annotation. Annotators were asked to give prompts, post-edit machine translation and evalaute transations, which do not involve any personal sensitive information. We hired 4 annotators who have degrees in English Linguistics or Applied Linguistics. Before formal annotation, annotators were asked to annotate a few samples randomly extracted from the dataset, and based on average annotation time we set a fair salary (i.e., 30 dollars per hour) for them. During their training annotation process, they were paid as well.

A Data Statistics

Dataset	# sents	avg. Tr	avg. Tc	avg. O
IWSLT	160,239	41.28	41.56	0.38
WMT	20,616,247	34.69	34.69	18.24

Table 5: Data statistics with the right 4 columns accordingly denoting number of sentences, average number of translation prompts, target-constraint prompts and ordering prompts for each sentence.

B Experiment Details

We implement the Transformer baseline and Prompt-Transformer based on THUMT (Tan et al., 2020). Except for the prompt encoding modules, Prompt-Transformer shares the same settings with the Transformer baseline. The prompt encoder layer shares the same setting with the vanilla Transformer encoder layer, and the prompt attention module is the same as the Transformer cross-attention module. For IWSLT'14 De→En, we use the iwslt_de_en setting with dropout ratio 0.3. For WMT'16 En→Zh, we use the transformer_base setting with a dropout of 0.1. We use the Adam (Kingma and Ba, 2015) to optimize the network with $\beta_1 = 0.9$, $\beta_2 = 0.98$. The batch szie for training De→En models is 4,096 and 32,768 for En→Zh models. The default Bernoulli and uniform ratio is set as 0.3 and 0.35 respectively. For inference, we set the beam width as 5 and length penalty as 0.6.

C Effects of Uniform Ratio during Decoding

We investigate how prompts improve translation performance, by using the same sampling strategy during training but setting the Bernoulli ratio to 1, so that the number of prompts is only determined by the uniform ratio (Section 4.4). By varying the uniform ratio, the model receives different number of prompts for each sentence. The results are shown in Figure 7. We can observe that Prompt-Transformer behaves similarly to the Transformer baseline when the uniform ratio is 0, i.e., all sentences are translated without prompts. The translation performance is improved in a large degree when the uniform ratio is as small as 0.05. Prompt-Transformer further achieves higher BLEU scores when there are more prompts. With all prompts (0.35 ratio), the BLEU reaches 54.88, 20.06 higher than the baseline of 34.78.

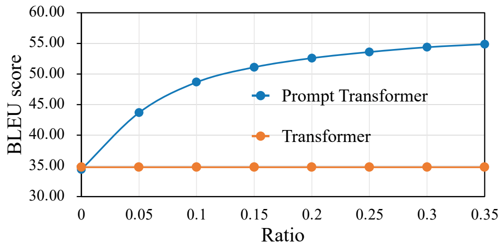

Figure 7: BLEU scores with respect to the uniform ratio during inference.

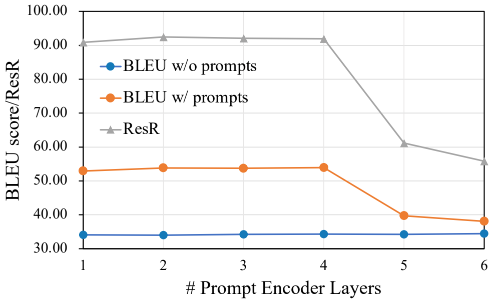

Figure 8: ResR and BLEU scores with respect to the number of prompt encoder layers.

D Effects of Prompt Encoder Depth

We investigate how the depth of the prompt encoder affects model performance. The results are shown in Figure 8. We can observe that the model performs steadily well with a prompt encoder of one to four Transformer layers. However, the ResR and BLEU score with prompts decrease sharply when the depth grows to 5 layers. This can be because that too deep prompt encoders overfit to the small scale MT dataset and thus fail to generalize to unseen prompts robustly.

E Prompt in Human-in-the-loop Translation

We sample 100 sentences from the WMT'17 En-Zh test set and ask 2 professional translators to conduct MTPE and MTPrompt on the corresponding translations. The first translator is asked to perform MTPE on the first 50 sentences and MTPrompt on the other 50 sentences, whereas the second translator is asked to do the other way around. They are required to record the time they spend with both methods. Then we ask 3 translators to evaluate translations based on adequacy and fluency mentioned in Section 5 and calculate average scores respectively.

On Controlling Fallback Responses for Grounded Dialogue Generation

Hongyuan Lu, Wai Lam, Hong Cheng, Helen M. Meng

`{hylu,wlam,hcheng,hmmeng}@se.cuhk.edu.hk`

Abstract

Dialogue agents can leverage external textual knowledge to generate responses of a higher quality. To our best knowledge, most existing works on knowledge grounded dialogue settings assume that the user intention is always answerable. Unfortunately, this is impractical as there is no guarantee that the knowledge retrievers could always retrieve the desired knowledge. Therefore, this is crucial to incorporate fallback responses to respond to unanswerable contexts appropriately while responding to the answerable contexts in an informative manner. We propose a novel framework that automatically generates a control token with the generator to bias the succeeding response towards informativeness for answerable contexts and fallback for unanswerable contexts in an end-to-end manner. Since no existing knowledge grounded dialogue dataset considers this aim, we augment the existing dataset with unanswerable contexts to conduct our experiments. Automatic and human evaluation results indicate that naively incorporating fallback responses with controlled text generation still hurts informativeness for answerable context. In contrast, our proposed framework effectively mitigates this problem while still appropriately presenting fallback responses to unanswerable contexts. Such a framework also reduces the extra burden of the additional classifier and the overheads introduced in the previous works, which operates in a pipeline manner.[1]

1 Introduction

Building knowledge grounded dialogue agents has been an important research line (Bordes et al., 2016; Young et al., 2017; Zhou et al., 2018; Chaudhuri et al., 2019; Moon et al., 2019; Dziri et al., 2021). Such incorporation of real-world knowledge (Young et al., 2017; Zhou et al., 2018) gives rise to consistent, informative and engaging response generation. Unfortunately, even with a high-quality knowledge retriever, there is no guarantee that the desired knowledge can always be retrieved. There is indeed even no guarantee for the existence of the desired knowledge in the knowledge database. Hence, presenting fallback responses is an essential ability for grounded dialogue agents. We make use of the notion of answerability that represents whether a dialogue context is answerable or not conditioned on the knowledge retrieved. Figure 1 depicts an example to illustrate the importance of answerability in grounded dialogue response generation. As in the unanswerable dialogue context, a fallback response is desirable. Conversely, as in the answerable dialogue context, the response should be as informative as possible.

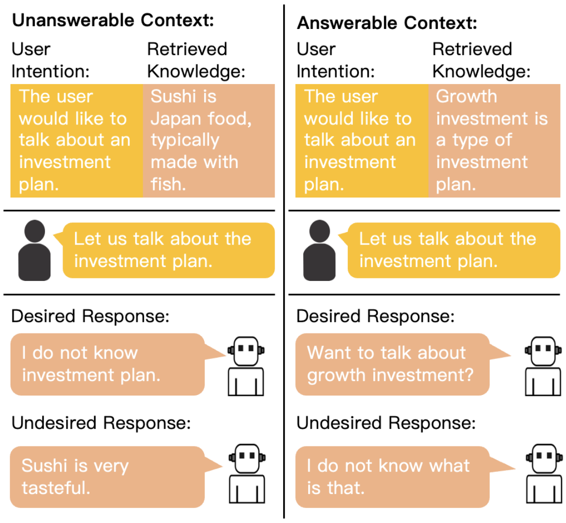

Figure 1: An illustrated example for answerable and unanswerable context conditioned on retrieved knowledge, along with corresponding desired and undesired responses. We demonstrate an easy single-turn conversation for simplicity. Better viewed in colour.

Although the concept of answerability has been well explored in other NLP areas such as Question Answering (Rajpurkar et al., 2018), it is underex-

plored in the dialogue community. Most existing knowledge grounded dialogue agents (Young et al., 2017; Chaudhuri et al., 2019; Prabhumoye et al., 2021) and knowledge grounded dialogue datasets (Zhou et al., 2018) ignore the fallback issue. However, this is almost impractical, and it is unlikely to happen in the real world that all the contexts are answerable. One recent approach has been proposed to calibrate responses with the appropriate linguistic confidence (Mielke et al., 2020); however, it overlooks informativeness, or diversity, (Li et al., 2016a; Vijayakumar et al., 2016; Fan et al., 2018; Holtzman et al., 2020; Tang et al., 2021; Wang et al., 2021), which is an important quality metric for a dialogue system. Though the previous work mentioned above (Mielke et al., 2020) employs an additional classifier for answerability, or in their case, linguistic confidence level, we demonstrate that our proposed method can achieve higher accuracy with the response generator.

Our proposed model employs controlled text generation (CTG, Niu and Bansal 2018; Mielke et al. 2020; Gehman et al. 2020; Xu et al. 2020; Baheti et al. 2021). Its central idea is to bias the generation towards a specific style by placing a control token in the input context. This control token has been investigated via two strategies: manually placed (Baheti et al., 2021) or model classified (Mielke et al., 2020). One can manually place a control token with low offensiveness to prevent the dialogue response generator from generating an offensive context (Baheti et al., 2021). One can also use a classifier to determine the linguistic confidence that the generator should present in its response generation (Mielke et al., 2020). In contrast to these works, one of our characteristics is that *while these works focus on the classification task only, our work turns the classification task into a generative manner and then exploits the classification result for the succeeding generation task within a single autoregressive generator.*

Since no existing dataset is suitable for our task, we derived a dataset by augmenting an existing dialogue dataset with unanswerable tuples of the dialogue context and the knowledge retrieved, and we conducted our experiments on the derived dataset. Our experimental results indicate that incorporating controlled text generation (Mielke et al., 2020) can capture answerability and rigorously replies with a fallback response to unanswerable contexts. However, it still undesirably hurts informativeness for answerable contexts by frequently responding with fallback responses to answerable contexts. Our method can achieve higher accuracy in classifying answerability than the traditional controlled text generation. This reduces the chance of responding with fallback to answerable contexts and thus improves the informativeness for responses to answerable contexts while still responding appropriately with fallback to unanswerable contexts.

2 Related Work

2.1 Grounded Dialogue Generation

Augmenting the dialogue agents with either table-formatted knowledge base (Bordes et al., 2016) or graph-formatted knowledge base (Moon et al., 2019) enables the dialogue agents to leverage real-world facts. This is crucial in both task-oriented dialogue (Moon et al., 2019) and chitchat dialogue (Chaudhuri et al., 2019). Dialogue agents grounded with common sense tends to be more engaging as well (Young et al., 2017). Furthermore, it also has been pointed out that using a knowledge base could reduce the problem of hallucinations (Dziri et al., 2021). Another research line tends to compress knowledge into model parameters, either by training set augmentation with template-based method (Madotto et al., 2020) or using neural architectures as domain-specific adapters (Xu et al., 2021).

2.2 Fallback Response in Dialogue Generation

Fallback response, or even answerability, remains under-explored for grounded dialogue agents. One recent close work calibrates responses with appropriate linguistic confidence (Mielke et al., 2020). Another close work parapharses fallback responses with contextualization (Shrivastava et al., 2021).

2.3 Informative Dialogue Generation

Informativeness, or diversity, plays an important role in engaging response generation. Modified decoding strategy with a dedicated objective improves diversity (Vijayakumar et al., 2016). Maximum mutual information (Li et al., 2016a) improves diversity with a diversity-promoting objective function for reranking. More recently, top-k sampling (Fan et al., 2018) and nucleus sampling (Holtzman et al., 2020) improve diversity by truncating the vocabularies or probability density to be sampled from and has shown their superiority over the traditional beam search for diverse dialogue generation.

3 Methodology

3.1 Background

We focus on the task of dialogue generation that is capable of recognizing unanswerable dialogue contexts and generating fallback response generation in an end-to-end manner. We adopt an end-to-end autoregressive language model (Zhang et al., 2020) as our neural dialogue generator. We denote this model as $\mathcal{M}$. By further denoting the knowledge retrieved as $\boldsymbol{k}$, dialogue context as $\boldsymbol{c}$ and dialogue response as $\boldsymbol{r}$, this generation task can be formulated as a mapping function that generates the dialogue response conditioned on the dialogue context and the knowledge retrieved:

$$\mathcal{M} : \boldsymbol{k}, \boldsymbol{c} \rightarrow \boldsymbol{r}$$

Unfortunately, naively approximating this function with maximum likelihood estimation might confuse the generator as the responses for the unanswerable contexts typically confess ignorance. This type of fallback response then becomes universally likely. Without an appropriate control on generating fallback responses, our generator can even give an answerable context a response that confesses ignorance. For example, a response that confesses ignorance could be templated as 'I do not know, I have not ...' where the contextualization follows. However, simply training on this instance will make 'I' to be universally likely followed by 'do'. Therefore, even for answerable user intention, the generator could fail into producing a fallback response immediately after decoding an 'I'.

3.2 Controlling Fallback Response

To effectively bias generation towards confessing ignorance for unanswerable dialogue as well as bias generation towards expressing informativeness for answerable contexts, we leverage controlled text generation. The task can be expressed as:

$$p(\boldsymbol{r} \mid \boldsymbol{k}, \boldsymbol{c}) \propto p(\boldsymbol{a} \mid \boldsymbol{k}, \boldsymbol{c})\, p(\boldsymbol{r} \mid \boldsymbol{a}, \boldsymbol{k}, \boldsymbol{c}),$$

where the answerability $\boldsymbol{a}$ in the above formula is a binary control token that is either `<|ANS|>` or `<|UNANS|>`. The former biases the succeeding dialogue response generation towards informativeness, and the latter biases the succeeding generation towards fallback. In the previous work done by Mielke et al. (2020), this control token is predicted by employing an extra classifier that outputs whether the dialogue context is answerable:

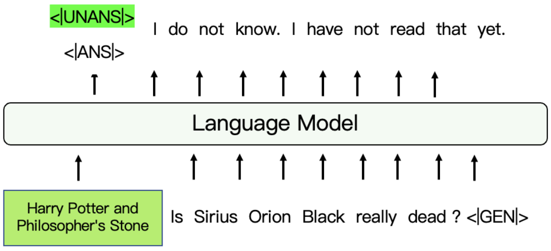

Figure 2: An illustration for the inferencing stage for our proposed framework. This dialogue is not answerable since the retrieved document does not contain the discussed user intention. Therefore, our proposed framework automatically selects a binary control token, which controls the succeeding response generation towards expressing ignorance.

$$p(\boldsymbol{r} \mid \boldsymbol{k}, \boldsymbol{c}) \propto p_{\text{classifier}}(\boldsymbol{a} \mid \boldsymbol{k}, \boldsymbol{c})\, p(\boldsymbol{r} \mid \boldsymbol{a}, \boldsymbol{k}, \boldsymbol{c})$$

This introduces extra parameters from the classifier and extra overheads for the inference. Indeed, this work has primarily focused on rephrasing responses with appropriate linguistic confidence, and their methodology requires two generators and one classifier. Our method differs as we augment the dialogue agent with the unstructured textual knowledge while theirs tests the knowledge inherently encoded in the model.[2] Their proposed method operates in a pipeline fashion that first generates a response, then obtains the control token with the classifier, and finally rephrases the generation with the second generator. An important observation is that the question or the dialogue context already contains enough information to judge the appropriate linguistic confidence level (Mielke et al., 2020). In addition, our primary goal is to directly control the fallback generation rather than maintain the semantics while calibrating the linguistic confidence. Therefore, we exclude the use of the first generator throughout our experiments.

3.3 Control Token Generation

Since a confidence level, or in our words, answerability, can be appropriately obtained even before generation, we could exploit this and remove the rephrasing generator. Furthermore, if we can further reduce the need for an answerability classifier, we can build an end-to-end system that replies with

---

[2] Previous work has employed a closed-book QA dataset as their testbed (Mielke et al., 2020).

fallback answers to unanswerable contexts. To this end, we propose a framework that incorporates the classification of control tokens into the response generation by leveraging the power of pre-trained language models to formulate language understanding tasks into a generative manner (Raffel et al., 2019; Liu et al., 2021a,b; Zhang et al., 2021). We illustrate the overall idea of our proposed framework in Figure 2. Our framework incorporates a notion called control token generation, where the control token could be automatically generated by the dialogue generator in an end-to-end manner. Firstly, we place a token of `<|GEN|>` as a prompt to signal the model to generate a binary control token, either `<|ANS|>` or `<|UNANS|>`. The former indicates the dialogue context as answerable, and the latter indicates the dialogue context as unanswerable. This then continues in an autoregressive manner for the model to complete the remaining response generation. For the control token of `<|ANS|>`, it follows a search space that is diverse and informative. In contrast, the control token `<|UNANS|>` guides into a semantical search space for fallback responses, which typically confesses ignorance, or low linguistic confidence level (Mielke et al., 2020). We thus formulate the problem as:

$$p(\boldsymbol{r} \mid \boldsymbol{k}, \boldsymbol{c}) \propto p_{\text{generator}}(\boldsymbol{a} \mid \boldsymbol{k}, \boldsymbol{c})\, p(\boldsymbol{r} \mid \boldsymbol{a}, \boldsymbol{k}, \boldsymbol{c})$$

Although previous works have formulated fallback response generation in a pipeline manner where the original response should attend (Mielke et al., 2020; Shrivastava et al., 2021), our proposed framework leverages control token to directly guide the response into either informative response or fallback response that confesses ignorance. Furthermore, our framework leverages the understanding power of large-scaled pre-trained language model (Liu et al., 2021b) and reduces the need for an extra answerability classifier by incorporating control token generation. As a result, this turns the whole system from a pipeline manner into an end-to-end manner, which drastically reduces the model size and the inference overheads.

3.4 Sequence-to-Sequence Learning

We adopt a single autoregressive Seq2Seq generator (Zhang et al., 2020) as both our control token generator as well as our dialogue response generator. Precisely, our network accepts an input concatenation of text knowledge $\boldsymbol{k}$ and dialogue context $\boldsymbol{c}$, and outputs an answerability control token $\boldsymbol{a}$ first, and then outputs the remaining dialogue response $\boldsymbol{r}$ one by one and left to right.

At the i-th timestep, the generator picks the next token r_i to be presented in the output that maximises the conditional probability:

$$r_i = \underset{r_i \in \mathcal{V}}{\operatorname{argmax}}\; p(r_i \mid r_1, ..., r_{i-1}, \boldsymbol{a}, \boldsymbol{k}, \boldsymbol{c})$$

Note that $\mathcal{V}$ in the equation above represents the vocabulary space to be decoded from.

Training To train our language model, we preprocess the original training instances to incorporate control token generation. The original training instance is the concatenation of knowledge, dialogue context, and response:

$$[\boldsymbol{k}; \boldsymbol{c}; \boldsymbol{r}]$$

We derive our new training instances as the concatenation of knowledge, dialogue context, control token, and response:

$$[\boldsymbol{k}; \boldsymbol{c}; \texttt{<|GEN|>}; \boldsymbol{a}; \boldsymbol{r}]$$

Note that `<|GEN|>` is a prompt token to signal the model to generate the succeeding answerability control token, and $\boldsymbol{a}$ is the binary control token that guides the subsequent dialogue generation.

Inferencing While our dialogue generation follows the traditional scheme where we adopt the nucleus sampling, we found in our early experiments that greedy decoding can be effective for the task of control token generation, which improves classification accuracy. We thus propose two decoding strategies:

- *Unhindered Sampling* uses nucleus sampling for both control token generation or answerability classification and dialogue response generation throughout the decoding stage.
- *Bottleneck Sampling*[3] uses greedy decoding for control token generation and nucleus sampling for dialogue response generation.

Although the former is straightforward and easy to implement, we demonstrate that the latter variant can remarkably improve the answerability classification accuracy and hence improve the succeeding response generation. Both of them can improve the response quality for the answerable contexts.

---

[3] The name is due to the fact that it has a shrunk distribution like a neck with greedy decoding at the place of control token before a flatten probability distribution for dialogue sampling.

4 Experimental Setup

Dataset Preparation Since no existing dataset is suitable for our aim, we derive our dataset based on the CMU DOCUMENT GROUNDED CONVERSATIONS DATASET (CMU DOG) dataset (Zhou et al., 2018). CMU DOG is a multi-turn dyadic dialogue dataset in which two crowdsource workers converse and find out more about a specific movie based on that particular film profile. While most of the dialogue datasets focus only on either chitchat (Zhang et al., 2018) or task-oriented dialogue (Budzianowski et al., 2018), CMU DOG interleaves chitchat and task-oriented dialogue (Zhou et al., 2018). It thus requires the agent to be both informative and knowledge grounded. Such knowledge grounded dialogue agents should appropriately respond with fallbacks to the unanswerable contexts without hurting informativeness on the responses to the answerable contexts. Therefore, CMU DOG is a suitable dataset to validate the effectiveness of our proposed framework.

We label all of the original instances as answerable conditioned on the ground truth knowledge. Indeed, the crowdsource workers converse based on the ground truth knowledge (Zhou et al., 2018). We then augment with unanswerable dialogues by sampling two instances $[\boldsymbol{k_1}; \boldsymbol{c_1}; \boldsymbol{r_1}]$ and $[\boldsymbol{k_2}; \boldsymbol{c_2}; \boldsymbol{r_2}]$ from the original dataset where $\boldsymbol{k_1} \neq \boldsymbol{k_2}$. This results into two unanswerable instances $[\boldsymbol{k_1}; \boldsymbol{c_2}; \boldsymbol{f}]$ and $[\boldsymbol{k_2}; \boldsymbol{c_1}; \boldsymbol{f}]$, where $\boldsymbol{f}$ represents the fallback responses that typically confess ignorance. This operation derives into a training / development / testing partition with 100,497 / 6,677 / 18,921 instances respectively for the CMU DOG dataset.[4]

Unlike chitchat dialogue datasets (Zhang et al., 2018) which consist of several dialogue topics that can be irrelevant to each other, the movie profiles from CMU DOG guarantees to be within the same domain. This is important as real-world retrievers can be competitive, meaning that irrelevant retrieved knowledge can make the task oversimplified into relevance classification. Fortunately, our augmentation strategy can still derive an answerability task with moderate difficulty in which the competitive classifiers report only about 82% test accuracy on the derived CMU DOG dataset.

Baseline and Comparison Model Our baseline adopts a vanilla Seq2Seq generator as a basic function mapper as described in Section 3.1 which maps the concatenation of knowledge retrieved $\boldsymbol{k}$ and dialogue context $\boldsymbol{c}$ to dialogue response $\boldsymbol{r}$ without any control over the fallback response as well as the notion of answerability. One comparison model is derived from the previous work done by Mielke et al. (2020) to employ an additional classifier to map the concatenation of knowledge retrieved $\boldsymbol{k}$ and dialogue context $\boldsymbol{c}$ to answerability control token $\boldsymbol{a}$. It then follows the classical controlled text generation procedure to feed the concatenation of the knowledge, context and control token into the generator for response generation.

Implementation Details For all the generators implemented for the baseline, comparison model and our method, we employ the state-of-the-art GPT2-based (Radford et al., 2019) dialogue response generator DIALOGPT-SMALL (Zhang et al., 2020). We also attempted on DIALOGPT-MEDIUM and DIALOGPT-LARGE. We found all three of them tend to respond inappropriately with fallbacks to the answerable dialogue contexts, and they report similar diversity measurements. Therefore, we adopt DIALOGPT-SMALL for simplicity. We use a learning rate of $5e{-}4$, $\beta_1 = 0.9$, $\beta_2 = 0.999$ and $\epsilon = 1e{-}8$. We adopt ROBERTA-BASE (Liu et al., 2019) as the answerability classifier to be used in our comparison model. We also experimented on BERT-BASE, BERT-LARGE (Devlin et al., 2019) and ROBERTA-LARGE, which led to a similar accuracy. Therefore, we adopt ROBERTA-BASE for simplicity. For the classifier, we use a learning rate of $5e{-}6$, $\beta_1 = 0.9$, $\beta_2 = 0.999$ and $\epsilon = 1e{-}8$. Since we are interested in diversity, or informativeness, we use nucleus sampling, or top-p sampling (Holtzman et al., 2020) as our decoding mechanism throughout our experiments for all our baseline, comparison model, and our method, in which we set $p = 0.95$ as the hyper-parameter as in the work done by Holtzman et al. (2020). We conduct our experiments with the TRANSFORMERS library (Wolf et al., 2020).

Evaluation Metrics In this work, we mainly focus on generation diversity for answerable contexts. We also report our investigation on fallback issues for unanswerable contexts as well as the classification accuracy. We followed previous works to adopt Distinct-n (Li et al., 2016b; Gao et al., 2019;

---

[4] All the partitions are individually processed to avoid data leakage. They contain answerable and unanswerable contexts half by half. We follow the train / dev / test split from the ParlAI platform (Miller et al., 2017). We drop some instances to match the maximum input length for BERT and ROBERTA.

Ours w/ Bottleneck Sampling	**744**	8719

Table 2: Quality measurements for fallback response generation reported on CMU DoG. FR$^+$ and FR$^-$ represents the number of fallback responses replied to answerable and unanswerable contexts respectively.

Cai et al., 2019; Lippe et al., 2020). It is the ratio of the number of unique n-grams against the total number of n-grams generated. We follow the work done by Gao et al. (2019) to calculate Distinct-n:

$$\text{Distinct-n} = \frac{\mid \bigcup_{i=1}^{N} \mathcal{R}_i \mid}{\sum_{i=1}^{N} \mid \mathcal{R}_i \mid},$$

where $\mathcal{R}_i$ represents the set of n-grams in the sample i and $\mid \mathcal{R}_i \mid$ represents the number of elements in the set. Gao et al. (2019) has employed n={1,2}, and they primarily focused on task-oriented dialogue. In contrast, we conducted our experiments on CMU DoG, which interleaves chit-chat and task-oriented dialogue. Since two tasks naturally differ, for our investigation on CMU DoG, we extend the unigrams and the bigrams to trigrams, four-grams, five-grams and six-grams, and we report Distinct-n where n={1,2,3,4,5,6} to measure phrase-level and sentence-level diversity. We also report BLEU score, which is a widely adopted sequence evaluation metrics (Papineni et al., 2002). To investigate fallback response generation, we report the number of fallback responses replied to answerable (FR$^+$) and unanswerable contexts (FR$^-$).[5] The former attains a better quality with lower values and the latter attains a better quality with higher values. For the control token generation, or answerability classification, we report the overall accuracy (Acc.), recall (Rec.), precision (Pre.), and F1-score (F1).

5 Results and Discussions

5.1 Main Results

Table 1 depicts the main results on dialogue generation. B represents BLEU scores, and D represents Distinct scores. We mainly report on the answerable dialogue contexts, i.e. the original dataset. As done in Mielke et al. (2020), we build a comparison model by incorporating the idea of controlled text generation to generate fallback responses. Incorporating controlled text generation does improve response diversity; however, it degrades the BLEU scores, which could be a side effect of naively incorporating controlled text generation. We postulate that placing an unanswerable control token makes the model more confident in outputting a fallback response even to answerable contexts. In contrast, a basic E2E model without controlled text generation can still escape from the fallback situation during the decoding phase. This leads to the conclusion that naively incorporating controlled text generation still hurts the response quality. In contrast, our proposed methods are not influenced by the side effect discussed above and report better BLEU scores than our baselines. In addition to the remarkable improvement in BLEU scores, our proposed method can improve word-level diversity (Li et al., 2016b; Gao et al., 2019; Cai et al., 2019; Lippe et al., 2020) as well as phrase-level and sentence-level diversity, which surpasses all our baseline and comparison models.

5.2 Decoding Methods

Non-deterministic sampling can improve the diversity or surprisingness of the response generation (Fan et al., 2018; Holtzman et al., 2020). One should be curious about whether such a case applies to the control token generation as well. Our

Table 3: Classification performance reported on the CMU DoG dataset with the competitive classifiers and our proposed method. Rec.$^+$ represents the recall rate for answerable dialogue contexts, and Rec.$^-$ represents the recall rate for unanswerable dialogue contexts. The precision rate (Pre.), and F1 scores follows the same convention. Acc. represents the overall accuracy.

results indicate that it is not the case. Our method with *Bottleneck Sampling* reports better diversity measurements and BLEU scores than *Unhindered Sampling* on CMU DoG. Indeed, we observe that decoding greedily on the answerability control token gives better accuracy than sampling, which could be the reason for the improved response generation. Still, *Unhindered Sampling* is straightforward to implement, and it reports a better quality in almost all of the metrics than our baselines, and the improvements with *Bottleneck Sampling* are less significant than the improvements in comparing *Unhindered Sampling* with our baselines.

5.3 Fallback Response Generation

Table 2 reports the number of fallbacks generated for answerable and unanswerable dialogue contexts on CMU DoG. As mentioned in Section 3.1, our observation is that the basic E2E model without controlled generation fails to capture the notion of answerability. Our model has a much better FR$^+$ score than our E2E baseline. For the baseline, such a failure in determining the answerability drastically affects the informativeness for answerable dialogue contexts by responding undesirably frequently with fallback. A similar phenomenon can be observed for our comparison model, though the problem is reduced, and the comparison model is better than the E2E baseline at responding with fallback to unanswerable contexts. However, our comparison model still suffers from responding with fallback to answerable contexts, which is undesirable for informative response generation for answerable contexts. In contrast, our method can reduce this problem more effectively and appropriately reply with fallback to unanswerable contexts. Note that the number reported here is not strictly the answerability classification accuracy, as we observed that a fallback response could be generated even with an answerable control token. This aligns with the fact reported in Baheti et al. (2021) that the model can generate an offensive response even with an offensiveness control token.

5.4 Answerability Classification

By prompting the dialogue response generator, our proposed methods can achieve better classification results than an external classifier that introduces extra model parameters as well as the extra classification overheads. As mentioned in Section 4, we are particularly interested in the dataset of CMU DoG, where all the knowledge for negative samples are in-domain movie profiles. This is important, as real-world retrievers are competitive, and we do not want the task to be oversimplified. Fortunately, our competitive classifiers achieve an accuracy of about 82% on the derived dataset. This fact validates that the derived task is with moderate difficulty as there was still space for improvements for the classical classification models.

Table 3 reports the classification results on CMU DoG dataset. Our proposed method has a better score on Rec.$^+$, Pre.$^-$, F1$^+$, F1$^-$ and Acc., which remarkably surpasses all the competitive classifiers. Our model also reports an on-par performance on Rec.$^-$ and Pre.$^+$ with RoBERTa-BASE. This aligns with the fact reported in Section 5.3 that our method can capture more answerable contexts and prevent the model from responding with fallback to them. Consequently, as we report in the main result in Section 5.1, it improves informativeness to the succeeding response generation to answerable contexts. *Unhindered Sampling* reports a bit lower accuracy than *Bottleneck Sampling*. This means that employing greedy decoding is desirable for classification and can improve the answerability classification accuracy. As in Table 1, such an improvement in classification accuracy

Criteria	E2E baseline	*Ours*
Appropriateness	29	71 ‡
Informativeness	30	70 ‡
Engagingness	29	71 ‡
Human-likeness	30	70 ‡

Table 4: Human evaluation results in winning percentages on CMU DoG. ‡ indicate the results as passing a two-tailed binomial significance test with $p < 0.01$.

Criteria	Mielke et al. (2020)	*Ours*
Appropriateness	43	57 †
Informativeness	40	60 ‡
Engagingness	42	58 ‡
Human-likeness	43	57 †

Table 5: Human evaluation results in winning percentages on CMU DoG. † and ‡ indicate the results as passing a two-tailed binomial significance test with $p < 0.05$ and $p < 0.01$ respectively.

correlates well with the improvements in response generation. In addition, this also aligns with the FR scores reported in Table 2, where *Bottleneck Sampling* has better FR scores than *Unhindered Sampling*. We conclude that our method is better at capturing answerable contexts than our baseline models while still achieving on-par performance on recalling unanswerable contexts and generating fallbacks to them.

5.5 Human Evaluation

We hired three experienced annotators who have degrees relevant to English Linguistics. We present 400 questions with 100 sampled answerable testing instances and ask them to conduct A/B testing. We conduct two sets of the experiment. The first set compares the baseline with our model, and the second set compares the comparison model we built as done in Mielke et al. (2020) and our model. By following previous work (Li et al., 2019; Zou et al., 2021), we adopt the following criteria:

- **(Appropriateness)**: *"Which one is more appropriate given the dialogue context?"*
- **(Informativeness)**: *"Which one presents a more informative and diverse answer?"*
- **(Engagingness)**: *"Which one would you prefer to talk with for a long talk?"*
- **(Human-likeness)**: *"Which one do you think sounds like a real person?"*

Table 4 and Table 5 report the human evaluation results. Our proposed method significantly surpasses our baseline and our comparison model in all of the four quality metrics. This phenomenon is expected and aligns with the fact presented in Section 5.1 which states that the automatic evaluation reports better diversity measurements on the response generation. This also aligns with the fact reported in Section 5.3 and Section 5.4 that the E2E baseline is unaware of the notion of answerability, and our competitive classifier employed for our comparison model has a low Rec.$^+$ on answerable contexts. In contrast, our method solidly improves the overall response quality by appropriately incorporating controlled fallback response generation in an end-to-end manner. Note that we conduct both sets of human evaluation based on our proposed method with *Bottleneck Sampling*.

6 Conclusion

Building a grounded dialogue agent is an important research line. However, most previous works have overlooked the situation when the retrieved knowledge cannot help the agent answer the dialogue. Under such a situation, fallback answers should be appropriately presented, and such incorporation should not degrade the informativeness in responses to answerable contexts. We demonstrate that a standard language model fails to handle this situation well and degrades the informativeness of responses to answerable dialogue contexts. Controlled text generation can be a solution that rigorously replies with fallback to unanswerable contexts. However, naively incorporating controlled text generation still hurts informativeness for the answerable contexts. We propose a novel end-to-end framework that leverages the understanding power of language models for answerability classification that steps into controlled response generation naturally in an autoregressive manner. Our experimental results from both automatic and human evaluation demonstrate that our method achieves higher accuracy on dialogue answerability classification than the competitive models specially designed for language understanding. This improves the informativeness for answerable dialogue contexts while still maintaining the ability to reply with fallback to unanswerable dialogue contexts.

Ethics Statement

This work conducts experiments on the well-known dialogue datasets, and the dataset pre-processing does not make use of any external textual resource. Pre-trained end-to-end dialogue generators using large-scale text corpus are also employed, which might be subjected to offensive contexts and demographic or historical biases buried in the training data. Although the model releasers have attempted their efforts to reduce offensiveness contexts and biases in their training data, the model retains the potential to generate output that triggers offensive replies and might express agreement towards offensive or unethical contexts. The reverse situation also applies, and the model might express disagreement towards ethical contexts. However, due to the fact that current state-of-the-art end-to-end pre-trained dialogue generators or pre-trained language models are mostly trained on large corpus or conversations that naturally occur, the above-mentioned issues are widely known to commonly exist for these models. Either heuristics or neural-based methods are suggested to be employed to post-process the outputs to eliminate any potential ethical issues presented by the models. Finally, we declare that any biases or offensive contexts generated from the model do not reflect the views or values of the authors.

Abstract

Humans are able to perceive, understand and reason about causal events. Developing models with similar physical and causal understanding capabilities is a long-standing goal of artificial intelligence. As a step towards this direction, we introduce CRAFT[1], a new video question answering dataset that requires causal reasoning about physical forces and object interactions. It contains 58K video and question pairs that are generated from 10K videos from 20 different virtual environments, containing various objects in motion that interact with each other and the scene. Two question categories in CRAFT include previously studied *descriptive* and *counterfactual* questions. Additionally, inspired by the Force Dynamics Theory in cognitive linguistics, we introduce a new *causal* question category that involves understanding the causal interactions between objects through notions like *cause*, *enable*, and *prevent*. Our results show that even though the questions in CRAFT are easy for humans, the tested baseline models, including existing state-of-the-art methods, do not yet deal with the challenges posed in our benchmark.

1 Introduction

Causal reasoning is a key cognitive capability that involves making predictions about physical objects and their interactions. Cognitive scientists have mainly studied causal reasoning as simple causes or chains of events (Michotte, 1963; Baillargeon, 1994; Saxe et al., 2005), rather than processing of complex causal scenes, see (Göksun et al., 2013; George et al., 2019). Referring to the interactions of multiple forces, the Force Dynamics Theory emphasizes the processing and reasoning of complex scenes, and how causal language defines the patterns of forces in causal events (Wolff, 2007).

In the past decade, though artificial learning systems have shown astonishing progress in natural language and image understanding, there are some tasks in which these systems are still significantly below human performance. One such challenging research area includes reasoning about physical actions of objects in complex causal scenes. In this paper, we explore how language and vision interact with each other in making plausible projections about causal reasoning, and analyze how well the existing neural models understand and reason about physical and causal relationships between dynamic objects in a scene through images and text.

We propose a new video question answering dataset, named CRAFT (Causal Reasoning About Forces and inTeractions), which is designed to be complex for artificial models and simple for humans. Our dataset contains synthetically generated videos of 2D scenes with accompanying questions. Its most prominent features are that it contains video clips with complex physical interactions between objects, and questions that test strong reasoning capabilities. Answering our *causal* questions needs comprehending what is being asked, identifying objects in the scene, tracking their states in relation to other objects, which in turn can be attributed to different semantic categories of causes (*cause, enable* or *prevent*) that highlight unique patterns of causal forces in events – in line with the Force Dynamics Theory. In CRAFT, there are also some *descriptive* and *counterfactual* questions, the latter requiring understanding what would have happened after an intervention, i.e. a slight change in the scene (Wolff, 2013). Figure 1 shows sample questions from different question types, which are explained in detail in the subsequent sections.

Q: "How many objects **fall to** the **ground**?" A: "2"

Q: "After **entering** the **basket**, does the **small yellow square** collide with other objects?" A: "True"

Descriptive Questions

Q: "How many objects **fall to** the **ground** if the **small yellow box** is removed?" A: "1"

Q: "Will the **small gray box enter** the **basket** if any of the other objects are removed?" A: "True"

Counterfactual Questions

Cause

Q: "Does the **small brown ball cause** the **big gray triangle** to fall to the **ground**?" A: "False"

Q: "Does the **small brown sphere cause** the **tiny yellow box** to **enter** the **basket**?" A: "True"

Enable

Q: "Does the **small brown sphere enable** the **small yellow box** to **enter** the **basket**?" A: "False"

Q: "How many objects does the **small gray block enable** to **enter** the **basket**?" A: "0"

Prevent

Q: "Does the **small yellow square prevent** the **tiny brown circle** from **entering** the **basket**?" A: "True"

Q: "How many objects does the **large cyan triangle prevent** from **entering** the **basket**?" A: "1"

Causal Questions

Figure 1: **Example CRAFT questions generated for a sample scene.** There are 48 different tasks divided into three distinct categories for 20 different scenes. Besides having tasks questioning descriptive properties, possibly needing temporal reasoning, CRAFT introduces challenges including more complex tasks requiring single or multiple counterfactual analysis or understanding object intentions for deep causal reasoning.

type of visual data, which includes either real world images (Malinowski and Fritz, 2014; Ren et al., 2015; Antol et al., 2015; Zhu et al., 2016; Goyal et al., 2017) or videos (Tapaswi et al., 2016; Lei et al., 2018), or synthetically created content (Johnson et al., 2017; Zhang et al., 2016; Yi et al., 2020). The second is at how the questions and answers are collected, which are usually done via crowdsourcing (Malinowski and Fritz, 2014; Antol et al., 2015) or by automatic means (Ren et al., 2015; Lin et al., 2014; Johnson et al., 2017). A key challenge for creating a good VQA dataset lies in minimizing the dataset bias. A model may exploit such biases and cheat the task by learning some shortcuts. In our work, we generate questions about simulated scenes using a pre-defined set of templates by considering some heuristics to eliminate strong biases. Compared to the existing VQA datasets, CRAFT is specifically designed to test models' understanding of dynamic state changes of the objects in a scene. Although some prior work focuses on temporal reasoning (Lei et al., 2018; Yu et al., 2019; Lei et al., 2020; Girdhar and Ramanan, 2020), they do not require the models to have a deep understanding of physics and/or imagine the consequence of certain actions to answer the questions, the only exceptions being TIWIQ (Wagner et al., 2018), CLEVRER (Yi et al., 2020), CLEVR_HYP (Sampat et al., 2021) and TVR (Hong et al., 2021) datasets. In these datasets, there exist hypothetical questions that require mental simulations about the consequences of performing certain actions or the lack of specific actions or objects. These datasets have received interest in developing neuro-symbolic reasoning models with physical understanding capabilities (Ding et al., 2020; Chen et al., 2021; Ding et al., 2021). CRAFT shares a similar design goal with the aforementioned datasets – but the scenes in our benchmark are temporally more complex.

Causal Reasoning in Cognitive Science. Different theories have been proposed by cognitive scientists to model how humans learn, experience, and reason about causal events, Mental Model Theory (Khemlani et al., 2014), Causal Model Theory (Sloman et al., 2009), and Force Dynamics Theory (Wolff and Barbey, 2015) to name a few. Among these, building upon the work of Talmy (1988), the Force Dynamics Theory represents a variety of causal relationships such as cause, enable, and prevent between two main entities, an affector and a patient (i.e. the object the affector acts on). The theory emphasizes that causative verbs map onto these different spatial arrays of forces within complex causal scenes. Studies with speakers of different languages such as English, Russian, and German suggest that adults distinctly represent these semantic event categories (Wolff and Song, 2003; Wolff et al., 2005). Similarly, 5- to 6-year-old children perceive the interactions of forces underlying the semantic categories of cause, enable, and prevent (Göksun et al., 2013) and make inferences about these events (George et al., 2019). To our knowledge, our work is the first attempt at integrating these complex relationships in a VQA setup to test causal reasoning capabilities of machines.

Understanding Physics in Artificial Intelligence. Lately, there has been a growing interest within the community in developing datasets and models to evaluate the ability of understanding and reasoning about the physical world. A notable amount of these efforts focuses on physical scene understanding. For instance, some researchers have explored the problem of predicting whether a set of objects are in stable configuration or not (Mottaghi et al., 2016) or if not where they fall (Lerer et al., 2016). Others have tried to estimate a motion trajectory of a query object under different forces (Mottaghi et al., 2016) or developed methods to build a stack configuration of the objects from scratch through a planning algorithm (Janner et al., 2019). Li et al. (2019) suggested to represent rigid bodies, fluids, and deformable objects as a collection of particles and used this representation to learn how to manipulate them. Recently, Bakhtin et al. (2019) and Allen et al. (2020) created the PHYRE and the Tools benchmarks, respectively, which both include different types of 2D environments. An agent must reason about the scene and predict the outcomes of possible actions in order to solve the task associated with the environment. CoPhy (Baradel et al., 2020) is another recent work, which deals with physical reasoning prediction about counterfactual interventions. Although these works involve complicated physical reasoning tasks, the language component is largely missing. As mentioned, Wagner et al. (2018), Yi et al. (2020) and Sampat et al. (2021) created VQA datasets for intuitive physics, but they lack visual variations unlike PHYRE and Tools. Though less studied, there are also some efforts in the NLP community to evaluate physical reasoning abilities of language models. Bisk et al. (2020) proposed the PIQA dataset that involves a binary choice task about daily activities regarding physical commonsense. Similarly, Aroca-Ouellette et al. (2020) presented the PROST benchmark which includes questions that are designed to probe language models in a zero-shot setting and focuses on concepts like gravitational forces, physical attributes and object affordances.

Our CRAFT dataset aims to combine the best of both worlds. In addition to the two types of questions investigated in CLEVRER (Yi et al., 2020), namely *descriptive* and *counterfactual*, CRAFT also includes questions that need reasoning about *causal* interactions through the concepts like *cause*, *enable*, and *prevent*. To succeed in these tasks, models need to learn the semantics of each verb category that specifies different kinds of object interactions and their outcomes, i.e. to gain an understanding of a kind of commonsense knowledge.

3 The CRAFT Dataset

CRAFT is built to evaluate temporal and causal reasoning capabilities of existing algorithms on video clips of 2D simulations and related questions. The dataset has approximately 57K question and video pairs, which are created from 10K videos. It is split into train, validation, and test sets with a 60:20:20 ratio per video basis, meaning that video clips in the training set are not seen in the validation or test set. Moreover, we have two different settings, an *easy setting* and a *hard setting*. They differ from each other in the way how the test split is chosen. In the hard setting, we deliberately use scene layouts that are not seen during training in picking the video and question pairs. The easy setting does not have this constraint. In the easy setting, there are 35K, 12K, and 11K question and video pairs in the train, validation and test splits, whereas in the hard setting these numbers are 35K, 11K and 12K, respectively. We provide an example set of questions from CRAFT in Figure 1.

Video Generation. We use Box2D physics simulator (Catto, 2010) to create our virtual scenes. There are 20 distinct scene layouts from which 10 seconds of video clips are collected with a spatial resolution of 256×256 pixels. Besides generating original simulation video, CRAFT scripts also generate variation videos by removing each object of the same video from the scene. These variation videos help question generation script to provide answer for certain types of questions, as explained later.

Objects. Each scene is composed of both *static scene elements* and *dynamic objects*, containing variable number of and different type of these elements and objects. There are 7 static scene elements (*ramp*, *platform*, *button*, *basket*, *left wall*, *right wall*, *ground*). These elements are all drawn in **black** color in order to differentiate them from the dynamic objects. Their attributes such as position or orientation are decided at the beginning of a simulation and then they are kept fixed throughout the video sequence. The values of these attributes are assigned randomly from sets of different intervals which are predefined for each type of scene as in Figure 2. The set of the dynamic objects contains 3 shapes (*cube*, *triangle*, *circle*), 2 sizes

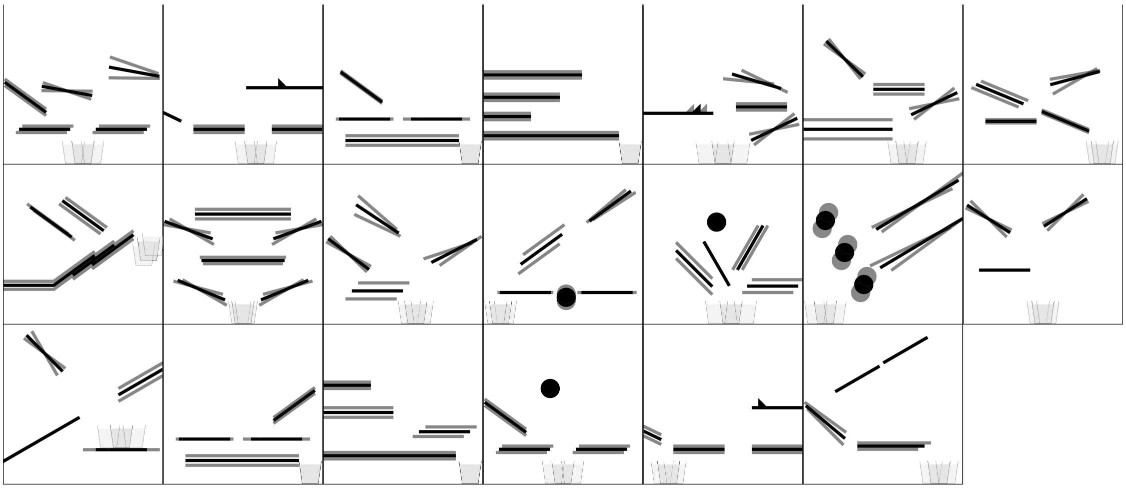

Figure 2: **Random configurations of static scene element properties for each scene.** The opaque regions show the mean value for that element, whereas the overlayed regions show the extreme values. Although these changes may seem subtle, they provide a wide variety in terms of scene dynamics.

(*small*, *large*), and 8 colors (*gray*, *red*, *blue*, *green*, *brown*, *purple*, *cyan*, *yellow*). Attributes of dynamic objects, in contrast, are in continuous change throughout the sequence due to the gravity or the interactions that they are subject to, until they rest.

Events. To formally represent the dynamical interactions in the simulations, we extract different types of events: *Start*, *End*, *Collision*, *Touch Start*, *Touch End*, and *Enter Basket*. *Start* and *End* events represent the start and the end of the simulations, respectively. Although we mainly question *Collision* events in our tasks, we want models to understand the difference between a collision and rolling on a ramp or a platform or two objects moving together. Therefore, we also extract *Touch Start*, *Touch End* events. Finally, *Enter Basket* event is triggered if the object enters the basket in the scene. All events happening a simulation are represented as a causal graph, which is also key for the question generator to extract causal relationships in an easy manner. Causal graph is a directed graph where events are represented as nodes. Each edge represents a cause relation where the source event is considered as the cause of target event because of the shared objects between them. We demonstrate the causal graph of a sample simulation in Figure 3.

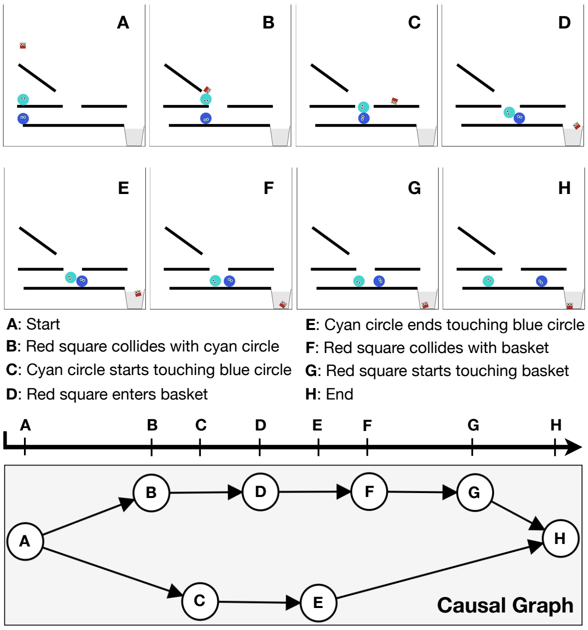

Figure 3: **A simple causal graph.** The causal graph is a graphical summary of the events that occur in a simulation. For the sake of simplicity, here we only include the interactions between the dynamic objects and the basket, and moreover, the scene is uncomplicated that there is no intermediate branching in the causal graph.

Simulation Representation. A simulation instance is represented by three different data structures, *the initial state of the scene*, *the final state of the scene*, and *the causal graph of extracted events*. The initial and final state of a scene refers to the information regarding the objects' static and dynamic attributes such as color, position, shape, and velocity at the start or at the end of the simulation, respectively. The final state is important as it bears causal relationships between the events of a simulation. Together these information sources have sufficient information to find the correct answers to CRAFT questions. Our simulation system also allows us to generate scene graphs like the ones used in CLEVR (Johnson et al., 2017), though we have not investigated it yet.

Question Generation. Each CRAFT question is expressed with a functional program as in CLEVR. We use a different set of functional modules for our programs extending the CLEVR approach. For example, our module set includes, but not limited to, functions which can filter events such as *Enter Basket* and *Collision*, and functions which can filter objects based on whether they are stationary at the start or the end of the video. List of our functional modules and some example programs are provided in Appendices A.1 and A.2 in the supplementary material, respectively. Moreover, we use different sets of word synonyms and allow question text to be paraphrased for language variety similar to CLEVR. Our preliminary analysis revealed that human performances in some questions were poor. When investigated, we figured out that these questions seem to be counter-intuitive to humans. Humans do not accurately reason about the objects for some counterfactual cases as subtle changes in the scenes result in very different outcomes. Hence, in finalizing our dataset, we applied minor random perturbations to each dynamic object in a video to verify whether the same answer can be obtained for all such cases, and excluded those questions that did not pass this verification step.

Question Types. CRAFT has 48 different question types under 3 different categories, namely *Causal, Descriptive, Counterfactual*. Among these, *Descriptive* questions mainly require extracting the attributes of objects, but some of them, especially those involving counting, need temporal analysis as well. Our dataset extends CLEVRER by Yi et al. (2020) with different types of events and multiple environments. *Counterfactual* questions require understanding what would happen if one of the objects was removed from the scene. Exclusive to CRAFT, some *Counterfactual* questions (*"Will the small gray circle enter the basket if any of the other objects are removed?"*) require multiple counterfactual simulations to be explored. As an extension to *Counterfactual* questions, *Causal* questions require grasping what is happening inside both the original video and the counterfactual video. In other words, models must infer whether an object is causing or enabling an event or preventing it by comparing the input video and the counterfactual video that should be simulated somehow. In the question text, the affector and the patient objects are explicitly specified. Some questions even include multiple patients. In particular, distinct causative verbs are mapped onto these three classes of causal events (Table 1).

Table 1: The list of causative verbs and their categories which are considered in CRAFT.

Category	**Verbs**
Prevent	*prevent, keep, hold, block, hinder*
Enable	*enable, help, allow*
Cause	*cause, stimulate, trigger*

In order to have a better understanding of the differences between *Enable*, *Cause*, and *Prevent* questions, one should understand the *intention* of the objects. We identify the intention in a simulation by examining the initial velocity of the corresponding object. Inspired by the recent findings in cognitive linguistics (Beller et al., 2020), we take having a velocity as an indication of an intention. In that regard, an affector can only enable a patient to complete the task if the patient is originally intended to do it but fails without the affector. Similarly, an affector can only cause a patient to do the task if the patient is not intended to execute it. Moreover, an affector can only prevent a patient from completing the task if the patient is intended to do it and succeeds without the affector.

Variations in Natural Language. In datasets that involve a natural language component, it is crucial to have language variety. To improve this property, CRAFT data generation scripts for questions, first allow multiple paraphrased versions of the same text to be generated to represent the same task. For a question sample, a paraphrased version of the corresponding task is chosen randomly by filling the object templates. Second, CRAFT enables synonyms of certain words to be integrated. We choose a base word and create its synonyms inside the CRAFT context. Similar to question paraphrases, the base word is replaced by a synonym randomly at run-time. All synonyms including the base word have equal chance to be included in the question text. This is handled by word suffixes and verb conjugations by preserving English grammar.

Bias Reduction. CRAFT contains simulations from different scenes to increase the variety in the visual domain. This makes reducing the dataset biases difficult because of the multiplicity in the number of the domains (textual and visual). Our data generation process enforces different simulation and task pairs to have uniform answer distributions

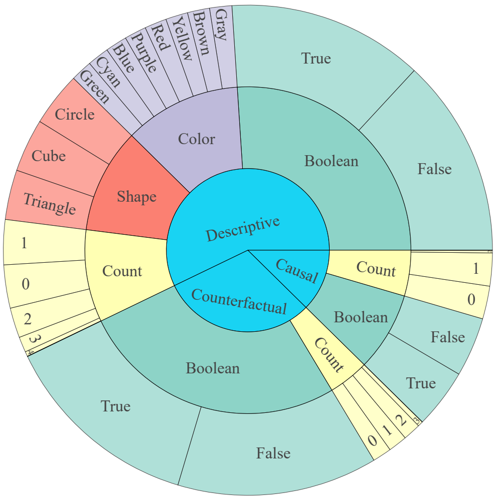

Figure 4: **Distribution of question types and answers in CRAFT.** Innermost layer represents the distribution of the questions for different task categories. Middle layer illustrates the distribution of the answer types for each task category. Outermost layer represents the distribution of answers for each answer type.

while trying to keep overall answer distribution as uniform as possible. Our aim is to make it harder for the models to find simple shortcuts by predicting the task identifier, the simulation identifier, or both, instead of understanding the scene dynamics and the question. Figure 4 shows the answer distributions for the question categories in CRAFT.

4 Experimental Analysis

In this section, we evaluate the performances of a wide range of baseline models on CRAFT. We also analyze how these performances relate with that of humans in understanding physical interactions between the objects and the environment.

4.1 Baselines

In our experiments, we consider several weak and strong baselines including some state-of-the-art visual reasoning approaches.

Heuristic models either perform random guesses or follow simple rules. **Random** model uniformly samples a random answer from the full answer space, whereas **Answer Type Based Random** model (AT-Random) makes random guesses based on the answer type (e.g. color, shape, boolean). **Most Frequent Answer** baseline (MFA) employs a simple heuristics and answers all the questions by using the most frequent answer in the training split. **Answer Type based Most Frequent Answer** model (AT-MFA) performs the same heuristics by taking the answer types into account similar to AT-Random baseline.

Text-only models ignore simulations, and do not use any visual information related to input simulations. **LSTM** model is another image-blind baseline that processes the question with an LSTM (Hochreiter and Schmidhuber, 1997), and then predicts an answer to a given question ignoring the visual input. In addition to the LSTM baseline, we experimented with **BERT** (Devlin et al., 2019) by using the `CLS` token embedding as question representation to predict answers.

LSTM-CNN baseline integrates both visual and textual cues by extending the LSTM model to additionally consider the features extracted from the a pretrained ResNet-18 model. We evaluate both (non-temporal) single frame and video versions. In the former, each video is encoded by taking into account either the first frame or the last frame, which are referred to as **LSTM-CNN-F** and **LSTM-CNN-L**, respectively. The video version, which we call **LSTM-CNN-V**, processes downsampled videos by using R3D (Tran et al., 2018) as visual feature extractor. All these three baselines concatenate the extracted visual and textual features to obtain a combined representation of the video and the question pair, feeding it to a multilayer perceptron network (MLP), followed by a linear layer generating scores for the answers.

Memory, Attention, and Composition (MAC) model (Hudson and Manning, 2018) is a compositional visual reasoning model. It decomposes the reasoning task into a series of attention-guided processing steps by isolating memory and control functions from each other. The attention mechanism considers visual and textual features jointly, which leads to robust encodings of the question and the image. Similar to the LSTM-CNN baselines, **MAC-F** looks at only the first frame, and **MAC-L** only pays attention to the last frame. **MAC-V** baseline extends the MAC model by considering the video frames sampled from the given video as the visual input. Like LSTM-CNN-V model, MAC-V also processes videos using R3D. Unlike its non-temporal variations, MAC-F and MAC-L, where the read unit originally has spatial attention over the image, this temporal variation has a read unit that applies spatio-temporal attention over the features extracted from the entire video.

TVQA is a multi-stream state-of-the-art video QA neural model (Lei et al., 2018). To adapt this model to our dataset, we only use its video stream branch and omit the answer input by generating scores for the entire answer vocabulary. In parallel with other baselines, TVQA model also extracts visual features by using ResNet-18. Different from the original implementation, our TVQA implementation uses LSTM networks with 256 units, uses a MLP network with 2 layers. Unlike the original model, we do not use GloVe word embeddings (Pennington et al., 2014) to make a fair comparison with the remaining baseline models.

TVQA+ is another multi-stream video question answering model, which is built upon TVQA model. In contrast to TVQA, TVQA+ uses convolutional networks as sequence encoder instead of LSTM networks, replaces GloVe word embeddings with BERT embeddings (Devlin et al., 2019), and implements a span proposal / prediction mechanism. We do not implement span proposal mechanism, and omit using BERT embeddings to compare TVQA+ with others more fairly as we disable GloVe embeddings in TVQA. Our TVQA+ implementation uses 256 hidden units in all submodules throughout the network, and it generates answer scores by feeding weighted average of fused multi-modal simulation-question representation into a linear layer.

G-SWM is a recenty proposed object-centric model (Lin et al., 2020), which is originally designed for simulating possible futures in a scene consisting of multiple dynamic objects. It models each frame in a video by two different latent variables encoding object and context features. We modify G-SWM to solve the reasoning tasks in CRAFT. In particular, our version of G-SWM takes in video frames resized to 64×64 pixels and extracts an object-centric representation of the input video thorough object and context features. These latent codes are then combined and concatenated with the LSTM-based question representation, similar to LSTM-CNN model, just before the final classifier layer.

LSTM-D and **BERT-D** are *oracle* text-only baselines, which take the natural language description of the causal graph of the simulation (see Figure 3) as input in addition to the question. We generate these descriptions from simplified versions of the causal graphs by only considering the *Start*, *End*, *Collision* and *Enter Basket* events, and excluding those involving certain static objects (walls, platforms, ramps, and static balls) which are not mentioned in the questions. We first sort the events by their timestamps and concatenate a template-based description of each event to generate the summary. LSTM-D uses two separate LSTM networks process the question and the description, and then a linear layer predicts the answer for the input question/description pair. BERT-D extends the BERT baseline by using the descriptions as prefixes for the input questions.

4.2 Results

In Table 2, we present the performances of the tested models for each question type, considering both the easy and the hard settings explained in Section 3. As expected, the text only models perform the worst as they completely ignore the visual information present in the videos. Moreover, the performances of the single frame methods are typically lower than those of the video models, showing the importance of the temporal aspect of the questions that a single snapshot of the simulation does not carry enough information.

As can be seen from Table 2, there exists a substantial gap between the model performances in the easy and hard settings of CRAFT. Not surprisingly, this is not the case for the text-based baselines, in which it is not important whether a scene layout has been seen before during training or not. Overall, these results suggest that our tested multimodal methods are not able to generalize well to previously unseen scenes. They cannot fully detect the physical interactions and localize the events taking place in a video.

It is worth mentioning that the performances of the models vary between different question types in CRAFT. Out of the three question types, the models consistently perform poorly on the Descriptive questions in that the accuracies are around 23.5%-48.12% in the easy setting and 23.2%-42.9% in the hard setting. The reason behind this could be attributed to the variety of the answers in this task as it includes questions covering both count, shape, and color of the object(s) (see Figure 4). On the other hand, the accuracies of the models on the remaining questions types are between 32.7% and 61.4% in the easy setting, and 30.1% and 56.2% in the hard setting.

LSTM-CNN-V baseline does reasonably well on the easy setting, but its generalization capability on the hard setting is not that good. TVQA performs worse than the LSTM-CNN-V baseline, which shows that it is more tailor-fit to video ques-

Table 2: Performances of the tested models on the test set of the CRAFT dataset on easy and hard splits. C, CF, and D columns stand for *Causal*, *Counterfactual*, and *Descriptive* tasks, respectively.

tion answering about TV clips, and its performance degrades when it does not have access to subtitles or the related concept detectors. Notably, MAC variants perform the best in the hard setting. MAC model, together with G-SWM, is a more expressive model specifically designed for compositional visual reasoning. G-SWM, however, performs poorly in our experiments, which might be because the scenes in CRAFT usually consist of many objects, thus making it harder to learn decomposing a video into objects and background. This may be resolved by switching to a two-stage framework, in which G-SWM is pretrained first to improve its decomposition ability. For now, we left this as future work.

To support our thesis that CRAFT is designed to be easy for humans, but difficult for machines, we also conducted a small human study. We asked 481 randomly selected CRAFT questions to 101 adults. We divided the questions into 5 parts with counterbalancing and every participant took one of the parts randomly. Among these 94 participants, we only considered the ones who responded at least 75% of the questions, which corresponds to 56 people. As can be seen from Table 2, there is a large gap ($>$ 29%) between human subjects and neural baselines in the hard setting.

Our oracle models, LSTM-D and BERT-D, perform better than all the tested neural models. Interestingly, the performance of BERT-D is very close to human performance, even slightly outperforming humans for the descriptive questions. Clearly, to excel in this task, a model must capture the interactions between the dynamic objects with each other and with the environment.

5 Conclusion

We have presented CRAFT, a new VQA dataset to test causal reasoning capabilities of the current models. Motivated by the Force Dynamics Theory, which highlights distinct causative verbs, CRAFT requires models to perform temporal and causal reasoning and even to imagine alternative versions of the events occurring in videos. Our results demonstrate that, while human adults can reason about the physical interactions between objects, these questions cannot be solved reliably by current models. At present, there is substantial room for improvement compared to humans. In our experiments, we did not report the results of recent neuro-symbolic models, e.g. NS-DR (Yi et al., 2020). Such approaches are very compelling and worth pursuing, but they currently require extra object-level annotations. Another exciting direction is to test object-centric methods other than G-SWM. However, it seems that they might require extra pretraining or self-supervised objectives, as explored by Ding et al. (2020). We believe that developing more effective models for CRAFT is an exciting research direction for video QA systems to mimic humans in causal reasoning about forces and interactions.

A Appendix

A.1 Functional Modules

CRAFT questions are represented with functional programs. Input and output types for our functional modules are listed in Table A.1. Lists of all functional modules are also provided in Tables A.2-A.6.

Table A.1: Input and output types of functional modules in CRAFT.

Type	**Description**
Object	A dictionary holding static and dynamic attributes of an object
ObjectSet	A list of unique objects
ObjectSetList	A list of *ObjectSet*
Event	A dictionary holding information of a specific event
EventSet	A list of unique events
EventSetList	A list of *EventSet*
Size	A tag indicating the size of an object
Color	A tag indicating the color of an object
Shape	A tag indicating the shape of an object
Integer	Standard integer type
Bool	Standard boolean type
BoolList	A list of *Bool*

Table A.2: Input functional modules in CRAFT.

Module	**Description**	**Input Types**	**Output Type**
`SceneAtStart`	Returns the attributes of all objects at the start of the simulation	*None*	*ObjectSet*
`SceneAtEnd`	Returns the atttributes of all objects at the end of the simulation	*None*	*ObjectSet*
`StartSceneStep`	Returns `0`	*None*	*Integer*
`EndSceneStep`	Returns `-1`	*None*	*Integer*
`Events`	Returns all of the events happening between the start and the end of the simulation	*None*	*EventSet*

Table A.3: Output functional modules in CRAFT.

Module	**Description**	**Input Types**	**Output Type**
`QueryColor`	Returns the color of the input object	*Object*	*Color*
`QueryShape`	Returns the shape of the input object	*Object*	*Shape*
`Count`	Returns the size of the input list	*ObjectSet*	*Integer*
`Exist`	Returns true if the input list is not empty	*ObjectSet / EventSet*	*Bool*
`AnyFalse`	Returns true if there is at least one false in a boolean list	*BoolList*	*Bool*
`AnyTrue`	Returns true if there is at least one true in a boolean list	*BoolList*	*Bool*
`IsBefore`	Returns whether the first event happened before the second event	*(Event, Event)*	*Bool*
`IsAfter`	Returns whether the first event happened after the second event	*(Event, Event)*	*Bool*

Table A.4: Object filter functional modules in CRAFT.

Module	**Description**	**Input Types**	**Output Type**
`FilterColor`	Returns the list of objects which have a color same with the input color	*(ObjectSet, Color)*	*ObjectSet*
`FilterShape`	Returns the list ofobjects which have a shape same with the input shape	*(ObjectSet, Shape)*	*ObjectSet*
`FilterSize`	Returns the list of objects which have a size same with the input size	*(ObjectSet, Size)*	*ObjectSet*
`FilterDynamic`	Returns the list of dynamic objects from an object set	*ObjectSet*	*ObjectSet*
`FilterMoving`	Returns the list of objects that are in motion at the step specified	*(ObjectSet, Integer)*	*ObjectSet*
`FilterStationary`	Returns the list of objects that are stationary at the step specified	*(ObjectSet, Integer)*	*ObjectSet*

Table A.5: Event filter functional modules in CRAFT.

Module	**Description**	**Input Types**	**Output Type**
`FilterEvents`	Returns the list of events about a specific object from an event set	*(EventSet, Object)*	*EventSet*
`FilterCollision`	Returns the list of collision events from an event set	*EventSet*	*EventSet*
`FilterCollisionWithDynamics`	Returns the list of collision events involving dynamic objects	*EventSet*	*EventSet*
`FilterCollideGround`	Returns the list of collision events involving the ground	*EventSet*	*EventSet*
`FilterCollideGroundList`	Returns the list of collision event sets involving the ground	*EventSetList*	*EventSetList*
`FilterCollideBasket`	Returns the list of collision events involving the basket	*EventSet*	*EventSet*
`FilterCollideBasketList`	Returns the list of collision event sets involving the basket	*EventSetList*	*EventSetList*
`FilterEnterBasket`	Returns the In Basket events	*EventSet*	*EventSet*
`FilterEnterBasketList`	Returns the list of In Basket event sets	*EventSetList*	*EventSetList*
`FilterBefore`	Returns the events from the input list that happens before input event	*(EventSet, Event)*	*EventSet*
`FilterAfter`	Returns the events from the input list that happened after input event	*(EventSet, Event)*	*EventSet*
`FilterFirst`	Returns the first event	*EventSet*	*Event*
`FilterLast`	Returns the last event	*EventSet*	*Event*
`EventPartner`	Returns the object interacting with the input object through the specified event	*(Event, Object)*	*Object*
`FilterObjectsFromEvents`	Returns the objects from the specified events	*EventSet*	*ObjectSet*
`FilterObjectsFromEventsList`	Returns the list of object sets from a list of event sets	*EventSetList*	*ObjectSetList*
`GetCounterfactEvents`	Returns the event list if a specific object is removed from the scene	*Object*	*EventSet*
`GetCounterfactEventsList`	Returns the counterfactual event list for all objects in an object set	*ObjectSet*	*EventSetList*

Table A.6: Auxiliary functional modules in CRAFT.

Module	**Description**	**Input Types**	**Output Type**
`Unique`	Returns the single object from the input list, if the list has multiple elements returns `INVALID`	*ObjectSet*	*Object*
`Intersect`	Applies the set intersection operation	*(ObjectSet, ObjectSet)*	*ObjectSet*
`IntersectList`	Intersects an object set with multiple object sets	*(ObjectSetList, ObjectSet)*	*ObjectSetList*
`Difference`	Applies the set difference operation	*(ObjectSet, ObjectSet)*	*ObjectSet*
`ExistList`	Applies the Exist operation to each item in the input list returning a boolean list	*ObjectSetList / EventSetList*	*BoolList*
`AsList`	Returns an object set containing a single element specified by the input object	*Object*	*ObjectSet*

A.2 Example Programs

Here we provide example functional programs for some of the sample questions provided in Figure 1, which are used to extract the correct answers using our simulation environment. Figures A.1 to A.5 provide functional program samples that are designed for CRAFT descriptive, counterfactual, cause, enable, and prevent questions, respectively.

Question: *"How many objects fall to the ground?"*

```
Count (
    FilterDynamic (
        FilterObjectsFromEvents (
            FilterCollideGround (
                Events ()
            )
        )
    )
)
```

Question: *"After entering the basket, does the small yellow square collide with other objects?"*

```
Var QueryObject = FilterShape ( FilterColor ( FilterSize ( SceneAtStart(), "Small" ) , "Yellow"), "Cube" )
Var SmallYellowCubeEvents = FilterEvents ( Events(), QueryObject )
Exist (
       FilterAfter (
              FilterCollisionWithDynamics ( SmallYellowCubeEvents ),
                     FilterFirst (
                            FilterEnterBasket ( SmallYellowCubeEvents )
                     )
              )
       )
)
```

Figure A.1: Example programs for *descriptive* questions.

Question: *"How many objects fall to the ground if the small yellow box is removed?"*

```
Var QueryObject = FilterShape ( FilterColor ( FilterSize ( SceneAtStart(), "Small" ) , "Yellow"), "Cube" )
Count (
       FilterObjectsFromEvents (
              FilterCollideGround (
                     GetCounterfactEvents ( QueryObject )
              )
       )
)
```

Question: *"Will the small gray box enter the basket if any of the other objects are removed?"*

```
Var QueryObject = FilterShape ( FilterColor ( FilterSize ( SceneAtStart(), "Small" ) , "Gray"), "Cube" )
Var OtherDynamicObjects = Difference ( FilterDynamic ( SceneAtStart() ), AsList ( QueryObject ) )
AnyTrue (
       ExistList (
              IntersectList (
                     FilterObjectsFromEventsList (
                            FilterEnterBasketList (
                                   GetCounterfactEventsList ( OtherDynamicObjects )
                            )
                     ),
                     AsList (
                            QueryObject
                     )
              )
       )
)
```

Figure A.2: Example programs for *counterfactual* questions.

Question: *"Does the small brown sphere cause the tiny yellow box to enter the basket?"*

```
Var AffectorObject = FilterShape ( FilterColor ( FilterSize ( SceneAtStart(), "Small" ) , "Brown"), “Circle” )
Var PatientObject = FilterShape ( FilterColor ( FilterSize ( SceneAtStart(), "Small" ) , "Yellow"), "Cube" )
Exist (
       FilterStationary (

       )
)
```

Figure A.5: Example program for *prevent* questions.

A.3 Implementation Details

Unless otherwise specified, all learnable baselines are trained with Adam optimizer (Kingma and Ba, 2014) with default hyperparameters. LSTM and single-frame models are trained for 75 epochs with a batch size of 64. All temporal baselines are trained for 30 epochs with a batch size of 32. G-SWM is trained for 100 epochs using a batch size of 64 with Adam optimizer and a learning rate of 0.0001. Input videos are downsampled at 5 frames per second (fps), and their frames are resized to 112 × 112 pixels. We used mixed precision strategy to train baselines more efficiently on Tesla V100 and Tesla P4 GPUs, except TVQA+, which is trained using full precision. Training single-frame models takes 2 minutes and training video models approximately 20-30 minutes per epoch. All word embeddings have a length of 256 and are randomly initialized. Pretrained convolutional video and image encoders are jointly trained with the rest of the networks. We use negative log-likelihood loss function for all models where the models predict a distribution over the set of possible answers. All models are tuned based on their performances on the validation split.

A.4 Detailed Quantitative Results

In this subsection, we share the quantitative results in more detail for different scenes and question types. Table A.7 describes the subcategories of the question types exist in CRAFT, together with a sample question. Table A.8 and Table A.9 present the results per scene on the easy and hard splits, respectively, and Table A.10 and A.11 respectively demonstrate the results per question type on the easy split and hard splits.

Table A.7: The question subcategories in the CRAFT dataset.

Subcategory	**Description**	**Sample Question**
C/A	Yes/no questions that require causal reasoning	*Does the Z C S cause the Z2 C2 S2 to enter the basket?*
C/N	Causal reasoning questions with counting	*What is the number of objects that the Z C S enables to enter the basket?*
CF/N	Counterfactual reasoning with counting	*How many objects enter the basket if the Z C S is removed?*
CF/O	Counterfactual yes/no questions	*Will the Z2 C2 S2 enter the basket if the Z C S is removed?*
D/2Q	Descriptive counting questions about the last state	*How many objects are moving when the video ends?*
D/C	Descriptive questions about the object color	*What color is the object the Z C S last collides with?*
D/C-T	Temporal yes/no questions with respect to a certain event	*Before falling to the ground, does the Z C S collide with other objects?*
D/N-T	Counting with respect to some reference event	*Before falling to the ground, does the Z C S collide with other objects?*
D/N-V	Descriptive counting questions about events	*How many objects fall to the ground?*
D/S	Descriptive questions about the object shape	*What is the shape of the object the Z C S first collides with?*
D/TO	Temporal yes/no questions about events with respect to an object	*Does the Z C S enter the basket before the Z2 C2 S2 does?*

Table A.8: Performances of the tested models per scene on the test set of the easy split of CRAFT.

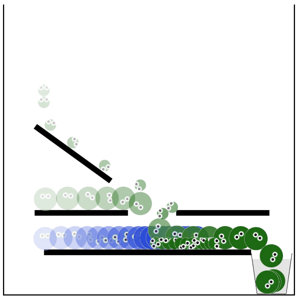
A.5 Additional Examples

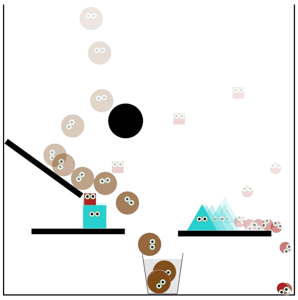
Figure A.6 provide some additional sample CRAFT questions together with the oracle descriptions and the baseline model predictions.



Description: Start. Large green circle collides with small green circle. Large blue circle collides with small green circle. Large green circle enters basket. Large green circle collides with basket. End.

Question: Are there any collisions between objects before the big green circle goes into the basket?
Answer: Yes

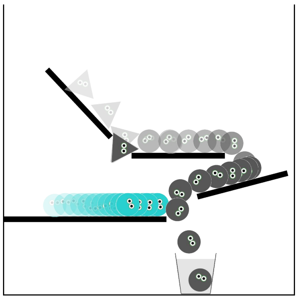
Predictions:
LSTM: Yes / **BERT:** No
Single Frame Models: No
Video Models: Yes / **TVQA+:** No
LSTM-D: No / **BERT-D:** Yes



Description: Start. Small red circle collides with large cyan triangle. Small red cube collides with large brown circle. Small red circle collides with ground. Large brown circle collides with basket. Large brown circle enters basket. Large brown circle collides with basket. End.

Question: How many objects hit the floor if the large brown circle is removed?
Answer: 1

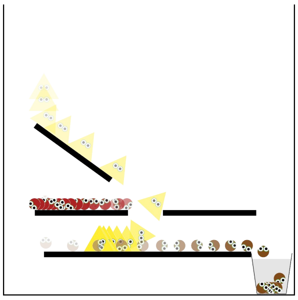
Predictions:
LSTM: 0 / **BERT:** 1
Single Frame Models: 0
LSTM-CNN-V: 1 / **MAC-V:** 1 / **TVQAs:** 2
G-SWM: 1 / **LSTM-D:** 0 / **BERT-D:** 1



Description: Start. Large gray circle collides with large gray triangle. Large cyan circle collides with large gray circle. Large gray circle enters basket. Large gray circle collides with basket. End.

Question: What color is the object the large gray triangle last collides with?
Answer: Gray

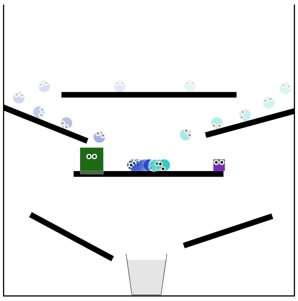
Predictions:
LSTM: Green / **BERT:** Yellow
Single Frame Models: Gray
LSTM-CNN-V: Green / **MAC-V:** Yellow
TVQA: Yellow / **TVQA+:** Blue / **G-SWM:** Brown
Oracle Models: Gray



Description: Start. Small red circle collides with large yellow triangle. Small brown circle enters basket. Small brown circle collides with basket. End.

Question: There is a small brown circle, does it block the tiny red circle from getting into the bucket?
Answer: No

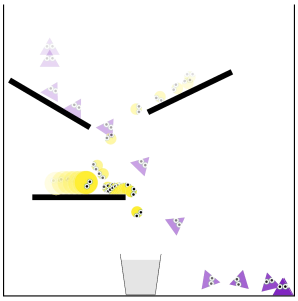
Predictions:
Text-only Models: Yes
LSTM-CNN-F: Yes / **LSTM-CNN-L:** Yes
MAC-F: No / **MAC-L:** No
Video Models: No / **TVQA+:** Yes
Oracle Models: No



Description: Start. Small blue circle collides with small cyan circle. End.

Question: How many objects are in motion at the end of the video?
Answer: 1

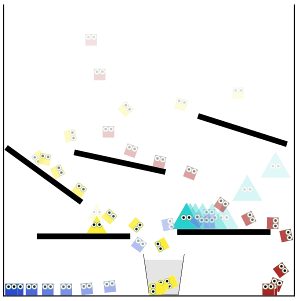
Predictions:
LSTM: 2 / **BERT:** 1
LSTM-CNN-F: 2 / **LSTM-CNN-L:** 3
MAC-F: 1 / **MAC-L:** 0 / **MAC-V:** 1
LSTM-CNN-V: 0 / **TVQA:** 0 / **TVQA+:** 2
G-SWM: 1 / **LSTM-D:** 0 / **BERT-D:** 2



Description: Start. Small yellow circle collides with large yellow circle. Small purple triangle collides with ground. End.

Question: There is a big yellow circle, does it hinder the tiny yellow circle from entering the container?
Answer: No

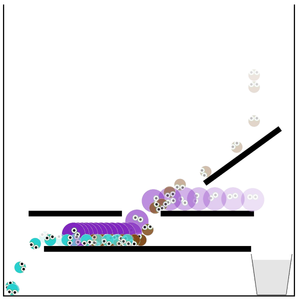
Predictions:
Text-only Models: Yes
LSTM-CNN-F: No / **LSTM-CNN-L:** Yes
MAC-F: No / **MAC-L:** Yes / **MAC-V:** No
LSTM-CNN-V: No / **TVQAs:** Yes
G-SWM: No / **LSTM-D:** No / **BERT-D:** Yes



Description: Start. Large cyan triangle collides with small blue cube. Small blue cube collides with ground. Small yellow cube enters basket. Small red cube collides with ground. Small yellow cube collides with basket. Small red cube collides with ground. Small yellow cube collides with basket. End.

Question: Are there any collisions between objects after the small blue block hits the floor?
Answer: No

Predictions:
Text-only Models: No
Single Frame Models: Yes
LSTM-CNN-V: No / **MAC-V:** No / **TVQAs:** Yes
G-SWM: Yes / **Oracle Models:** No



Description: Start. Large purple circle collides with small brown circle. Small cyan circle collide with large purple circle. Small cyan circle collide with ground. End.

Question: Will the large purple circle fall to the floor if any of the other objects are removed?
Answer: Yes

Predictions:
LSTM: No / **BERT:** Yes
LSTM-CNN-F: No / **LSTM-CNN-L:** Yes
MAC-F: No / **MAC-L:** No / **MAC-V**: Yes
LSTM-CNN-V: Yes / **TVQAs:** Yes
G-SWM: No / **Oracle Models:** No

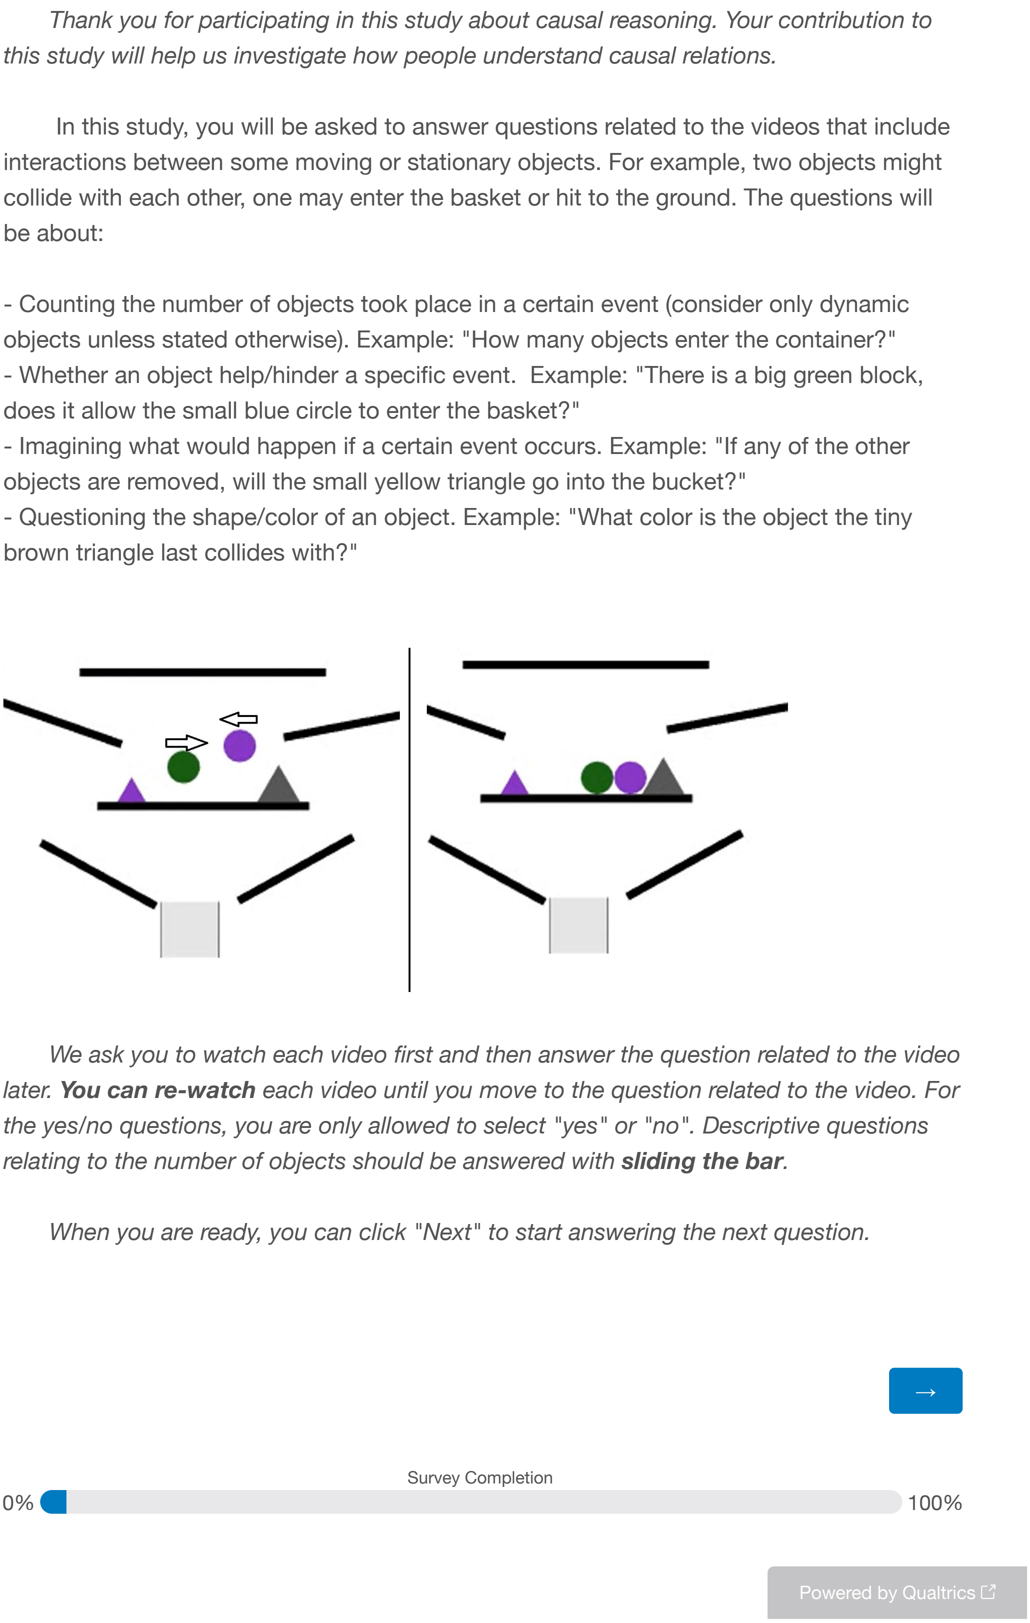
A.6 Human Evaluation

The data from human participants were collected online via Qualtrics. The approximate time to complete the study was between 20 and 30 minutes. Participants did not take any bonus or wage. They attended the study voluntarily. The personal identifying information was not obtained. There were not an expected negative outcomes of the study on participants, but they could leave the study whenever they want. Koç University's Institutional Review Board approved the study (Protocol no: 2021.164.IRB3.073).

For the human evaluation, the participants saw the videos and multiple choice questions. The instruction page that was given to participants is shown in Figure A.7.



Thank you for participating in this study about causal reasoning. Your contribution to this study will help us investigate how people understand causal relations.

In this study, you will be asked to answer questions related to the videos that include interactions between some moving or stationary objects. For example, two objects might collide with each other, one may enter the basket or hit to the ground. The questions will be about:

- Counting the number of objects took place in a certain event (consider only dynamic objects unless stated otherwise). Example: "How many objects enter the container?"
- Whether an object help/hinder a specific event. Example: "There is a big green block, does it allow the small blue circle to enter the basket?"
- Imagining what would happen if a certain event occurs. Example: "If any of the other objects are removed, will the small yellow triangle go into the bucket?"
- Questioning the shape/color of an object. Example: "What color is the object the tiny brown triangle last collides with?"

We ask you to watch each video first and then answer the question related to the video later. ***You can re-watch*** *each video until you move to the question related to the video. For the yes/no questions, you are only allowed to select "yes" or "no". Descriptive questions relating to the number of objects should be answered with* ***sliding the bar****.*

When you are ready, you can click "Next" to start answering the next question.

B Datasheet for CRAFT

This document is prepared in accordance with the guideline suggested in Datasheets for Datasets (Gebru et al., 2020), the most updated version can be found here.

Motivation

For what purpose was the dataset created?
CRAFT was created in order to facilitate research on understanding and closing the gap between the capabilities of human intelligence and artificial systems in grasping and reasoning about physical relationships between different objects in an environment through vision and language.

Who created this dataset (e.g., which team, research group) and on behalf of which entity (e.g., company, institution, organization)?
The dataset was created by Tayfun Ates, M. Samil Atesoglu, Cagatay Yigit, Erkut Erdem from Hacettepe University and Ilker Kesen, Mert Kobas, Aykut Erdem, Tilbe Goksun and Deniz Yuret from Koç University.

Who funded the creation of the dataset?
CRAFT was supported in part by GEBIP 2018 Award of the Turkish Academy of Sciences to E. Erdem and T. Goksun, BAGEP 2021 Award of the Science Academy to A. Erdem, and AI Fellowship to Ilker Kesen provided by the KUIS AI Center.

Composition

What do the instances that comprise the dataset represent (e.g., documents, photos, people, countries)?
The instances of CRAFT include a video, a question about the video, its answer, the functional program which is the ground-truth process that is used to answer the question, the states of dynamic objects and static scene elements at the start of the simulation and at the end of the simulations, causal graph of the events occurred in the video, variation videos which are created removing each dynamic object one by one, and lastly the states of objects and causal graphs for variation videos.

How many instances are there in total (of each type, if appropriate)?
CRAFT contains 58K video and question pairs that are generated from 10K videos from 20 different virtual environments.

Does the dataset contain all possible instances or is it a sample (not necessarily random) of instances from a larger set?
Please refer to Section 3 of the main paper for a detailed description of the sampling procedure used to generate questions.

What data does each instance consist of?
The video and question-answer pairs are used as the basic components for this visual question answering study. The question about the video is asked to an artificial model or a human subject. The test containing multimodal inputs question the capabilities of the subject in understanding and reasoning about physical relationships occurring in an environment. We use other instances in the dataset to find answers to questions automatically and share them for further analysis if required. Functional programs can run on object states and causal graphs to find the answer. Moreover, they can be integrated in training process for different models as well. Similarly, if ground-truth information regarding object states and causal graphs can also be extracted. Furthermore, some questions require counterfactual analysis that we define using variation videos formally. In order to evaluate effect of an object on the scene, we remove it an re-simulate the environment. We share instances regarding variations for further analysis.

Is there a label or target associated with each instance? If so, please provide a description.
Each instance consists of a ground-truth answer associated with the question about a dynamic scene.

Is any information missing from individual instances? We do not provide object-level segmentation maps.

Are relationships between individual instances made explicit (e.g., users' movie ratings, social network links)?
Instances are generated from 20 different scene layouts with some randomization.

Are there recommended data splits (e.g., training, development/validation, testing)?

We share CRAFT with two different split alternatives that we call easy and hard settings. Both of the alternatives contain non-overlapping train, validation, and test set. There are 20 distinct layouts from which we created our virtual scenes for CRAFT. In easy setting, each split might contain images from all of the scene layouts. On the other hand, in hard setting, train, validation, and test splits contain images from 12, 4, and 4 of the 20 layouts, respectively. That is, in the hard setting, the corresponding test samples are generated from unseen scene layouts.

Are there any errors, sources of noise, or redundancies in the dataset?
The process that we followed to make sure that the answers are not affected much with the slight perturbations to the initial states is described in Section 3 of the main paper.

Is the dataset self-contained, or does it link to or otherwise rely on external resources (e.g., websites, tweets, other datasets)?
The dataset is self-contained.

Does the dataset contain data that might be considered confidential (e.g., data that is protected by legal privilege or by doctor patient confidentiality, data that includes the content of individuals non-public communications)?
No.

Does the dataset contain data that, if viewed directly, might be offensive, insulting, threatening, or might otherwise cause anxiety?
No.

Does the dataset relate to people?
No.

Does the dataset identify any subpopulations (e.g., by age, gender)?
No.

Is it possible to identify individuals (i.e., one or more natural persons), either directly or indirectly (i.e., in combination with other data) from the dataset?
No.

Does the dataset contain data that might be considered sensitive in any way (e.g., data that reveals racial or ethnic origins, sexual orientations, religious beliefs, political opinions or union memberships, or locations; financial or health data; biometric or genetic data; forms of government identification, such as social security numbers; criminal history)?
No.

Collection Process

How was the data associated with each instance acquired?
All instances of CRAFT are generated automatically using a physics engine.

What mechanisms or procedures were used to collect the data (e.g., hardware apparatus or sensor, manual human curation, software program, software API)?
We use Box2D physics simulator (Catto, 2010) to create our visual scenes, extract object states and causal graphs. Furthermore, we extend the work CLEVR (Johnson et al., 2017) to create CRAFT questions and answers.

If the dataset is a sample from a larger set, what was the sampling strategy (e.g., deterministic, probabilistic with specific sampling probabilities)?
The dataset is generated from scratch and it does not depend on an already existing dataset.

Who was involved in the data collection process (e.g., students, crowdworkers, contractors) and how were they compensated (e.g., how much were crowdworkers paid)?
Authors prepared the scripts which create visual and textual data automatically.

Over what time-frame was the data collected?
Data generation scripts ran about 51 hours to create 9917 videos and 57524 questions.

Does the dataset contain all possible instances?
Although we provide all instances for this version of CRAFT, it is possible for anyone to create new samples by running the scripts provided in our code repository.

If the dataset is a sample, then what is the population?

Please refer to Section 3 of the main paper for a detailed description of the sampling procedure used to generate questions.

It is possible the enlarge CRAFT by running existing scripts to obtain huge amount of data because of the randomness existing in video generation process as described in the paper. New dynamic objects, static scene elements, events can also be created to enrich CRAFT. Moreover, it is also possible to add new types of scene layouts and question categories or types. For example, CRAFT focuses on mostly physical reasoning. It is possible to add tasks questioning different capabilities of Humans such as spatial reasoning, planning, and so on. There is actually no limit for creating datasets similar to CRAFT.

Were any ethical review processes conducted (e.g., by an institutional review board)?
Koç University's Institutional Review Board approved the user study (Protocol No: 5152021.164.IRB3.073).

Did you collect the data from the individuals in question directly, or obtain it via third parties or other sources (e.g., websites)?
The data from human participants for the user study were collected online via Qualtrics.

Were the individuals in question notified about the data collection? Yes.

Did the individuals in question consent to the collection and use of their data? The participants of the user study are asked to sign a consent form.

Has an analysis of the potential impact of the dataset and its use on data subjects (e.g., a data protection impact analysis)been conducted?
Not applicable.

Preprocessing/Cleaning/Labeling

Was any preprocessing/cleaning/labeling of the data done(e.g., discretization or bucketing, tokenization, part-of-speech tagging, SIFT feature extraction, removal of instances, processing of missing values)?
There were two preprocessing steps applied to the dataset. Firstly, after creating a video and question-answer pair, we applied simple perturbations by changing certain values of dynamic objects slightly at the start of the simulation and re-simulated the video. If the answer to the question is changed in any of the variations, then we removed the video and the question pair from the dataset. Secondly, in order to obtain a dataset which is uniform as possible in all dimensions, we removed video and question pairs whose answers are dominant after the first perturbation filter.

By collecting this dataset, we had the chance to observe that although the artificial systems have demonstrated incredible progress in the past decade, there are still areas that should be investigated for them. Therefore, CRAFT can be considered as a sample dataset which will facilitate the research in closing the gap between humans and artificial systems.

Preprocessing steps achieve two main aims of ours. Firstly, we wanted to eliminate video and question pairs whose answers are inconsistent between different variations of the same video with small perturbations. We observed that these were the cases for which humans subjects had some troubles. Secondly, we wanted to make CRAFT difficult enough for machine reasoning models by aiming at avoiding learning shortcuts by selecting the most frequent answers in answering questions. The second step of preprocessing procedure mostly achieves this aim.

Was the "raw" data saved in addition to the preprocessed/cleaned/labeled data (e.g., to support unanticipated future uses)?
The raw data were saved, but were not made public.

Is the software used to preprocess/clean/label the instances available?
We plan to publicly release the software used to generate the scenes and the questions.

Distribution

Has the dataset been used for any tasks already?
We have used the dataset to train unimodal and multimodal baselines described in the paper.

Is there a repository that links to any or all papers or systems that use the dataset?
Links to the related papers will be listed in the

project website at https://sites.google.com/view/craft-benchmark.

What (other) tasks could the dataset be used for?
Since the sample videos in our dataset include interactions between the objects themselves and the environment, they can be used in problems such as future state prediction and video generation.

Is there anything about the composition of the dataset or the way it was collected and preprocessed/cleaned/labeled that might impact future uses?
No.

Are there tasks for which the dataset should not be used?
No.

Uses

Will the dataset be distributed to third parties outside of the entity (e.g., company, institution, organization) on behalf of which the dataset was created?
CRAFT is publicly available at http://github.com/hucvl/craft/.

How will the dataset will be distributed (e.g., tarball on website, API, GitHub)?
The dataset is available through our project website and GitHub. Large dataset files are stored on Zenodo.

When will the dataset be distributed?
The dataset was first released in June 2021.
What license (if any) is it distributed under?
The dataset is released under MIT license.

Maintenance

Who is supporting/hosting/maintaining the dataset?
CRAFT will be supported and maintained by the prime authors.

Will the dataset be updated (e.g., to correct labeling errors, add new instances, delete instances)?
Extending CRAFT in different directions is planned. All versions of CRAFT will be available at http://github.com/hucvl/craft/.

A Graph Enhanced BERT Model for Event Prediction

Li Du, Xiao Ding[*], Yue Zhang, Kai Xiong, Ting Liu, and Bing Qin
Research Center for Social Computing and Information Retrieval
Harbin Institute of Technology, China
{ldu, xding, kxiong, tliu,qinb}@ir.hit.edu.cn

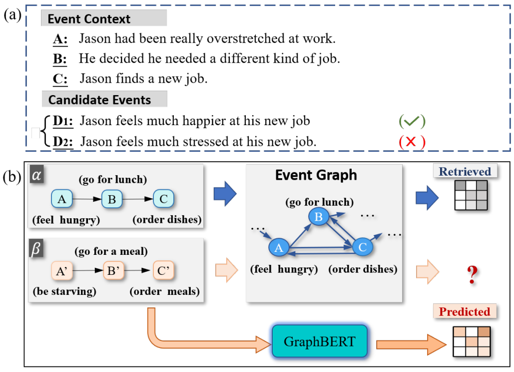
Abstract

Predicting the subsequent event for an existing event context is an important but challenging task, as it requires understanding the underlying relationship between events. Previous methods propose to retrieve relational features from event graph to enhance the modeling of event correlation. However, the sparsity of event graph may restrict the acquisition of relevant graph information, and hence influence the model performance. To address this issue, we consider automatically building of event graph using a BERT model. To this end, we incorporate an additional structured variable into BERT to learn to predict the event connections in the training process. Hence, in the test process, the connection relationship for unseen events can be predicted by the structured variable. Results on two event prediction tasks: script event prediction and story ending prediction, show that our approach can outperform state-of-the-art baseline methods.

1 Introduction

Understanding the semantics of events and their underlying connections is a long-standing task in natural language processing (Minsky, 1974; Schank, 1975). Much research has been done on extracting script knowledge from narrative texts, and making use of such knowledge for predicting a likely subsequent event given a set of context events.

A key issue to fulfilling such tasks is the modeling of event relation information. To this end, early work exploited event pair relations (Chambers, 2008; Jans et al., 2012; Granroth and Clark, 2016) and temporal information (Pichotta, 2016; Pichotta and Mooney, 2016). The former has been used for event prediction by using embedding methods, where the similarity between subsequent events and context events are measured and used for candidate ranking. The latter has been used for neural network methods, where models such as LSTMs have been used to model a chain of context events. There has also been work integrating the two methods (Wang et al., 2017).



(a)
Event Context
A: Jason had been really overstretched at work.
B: He decided he needed a different kind of job.
C: Jason finds a new job.
Candidate Events
D1: Jason feels much happier at his new job (✓)
D2: Jason feels much stressed at his new job. (✗)

Figure 1: (a) An example for event prediction. (b) Given an event sequence, retrieval-based methods lookup structural information of events from event graph. However, in the test process, part of events may be not covered by the event graph, hence their connection information is unavailable. Different from retrieval-based methods, GraphBERT is able to predict the connection strength between events.

Despite achieving certain effectiveness, the above methods do not fully model the underlying connection between context events. As shown in Figure 1 (a), given the facts that *Jason had been overstretched at work*, *He decided to change job* and *Jason finds a new job*, the subsequent event *Jason is satisfied with his new job* is more likely than *Jason feels much stressed at his new job*, which can be inferred by understanding the fact that the reason for his new job search is stress in his job. Li et al. (2018b) and Koncel et al. (2019) consider such context structure by building event evolutionary graphs, and using network embedding models to extract relational features. For these methods, event graphs serve as a source of external structured knowledge, which are extracted from narrative texts and provide prior features for event correlation.

One limitation of their methods is that the effectiveness of their methods heavily relies on the

coverage of the event graph. As shown in Figure 1 (b), Li et al. (2018b) and Koncel et al. (2019)'s methods work by looking up the event tuples in the event graph to *retrieve* the connection information between events for predicting the output. This is done by the standard knowledge graph lookup operation. However, if the context events are not in the event graph, the method cannot find relevant information. Figure 1 (b) shows an extreme case. In event sequence β, although the context events *be starving* and *go for a meal* are highly similar to the event graph content *feel hungry* and *go for lunch*, the retrieval-based methods can fail to match context events in the event graph and utilize the event graph knowledge. However, in practice, it is infeasible to construct an event graph that covers most of the possible events. As an event is the composition of multiple arguments, so the same event can correspond to various semantically equivalent expressions, such as "feel hungry" vs "be starving", or "hunger", etc. This would limit the performance of the retrieval-based systems.

To address this issue, we consider automatically predicting the event links using a graph-enhanced BERT model (**GraphBERT**). As shown in Figure 1 (b), we collect event structure information into a BERT model with graph structure extension. Given a set of event contexts, we use the GraphBERT model to construct an event graph structure by predicting connection strengths between context events, instead of retrieving them from a prebuilt event graph. Specifically, we extend the BERT model by introducing a structured variable, which captures the connection strengths between events. As shown in Figure 2, during training, both context events and external event graph information are used to train the structured variable. During testing, the structured variable which describes connection strengths between events is obtained using the context event only, which is used for finding the next event. Subsequently, we encode the predicted link strength for making a prediction.

Experimental results on standard datasets show that our model outperforms baseline methods. Further analysis demonstrates that GraphBERT can predict the connection strengths for unseen events and improve the prediction accuracy. The codes are publicly available at `https://github.com/sjcfr`.

2 Background

As shown in Figure 1 (a), the task of event prediction (Mostafazadeh et al., 2016; Li et al., 2018b) can be defined as choosing the most reasonable subsequent event for an existing event context. Formally, given a candidate event sequence $X = \{X_{e_1}, \dots, X_{e_t}, X_{e_{c_j}}\}$, where $\{X_{e_1}, \dots, X_{e_t}\}$are t context events and $X_{e_{c_j}}$ is the c_jth candidate subsequent event, the prediction model is required to predict a relatedness score $Y \in [0, 1]$ for the candidate subsequent event given the event context.

Event graphs (Li et al., 2018b) have been used to represent relationships between multiple events. Formally, an event graph could be denoted as $G = \{V, R\}$, where V is the node set, R is the edge set. Each node $V_i \in V$ corresponds to an event X_i, while each edge $R_{ij} \in R$ denotes a directed edge $V_i \rightarrow V_j$ along with a weight W_{ij}, which is calculated by:

$$W_{ij} = \frac{\mathrm{count}(V_i, V_j)}{\sum_k \mathrm{count}(V_i, V_k)} \tag{1}$$

where $\mathrm{count}(V_i, V_j)$ denotes the frequency of a bigram (V_i, V_j). Hence, the weight W_{ij} is the probability that X_j is the subsequent event of X_i.

3 Baseline System

Before formally introducing the GraphBERT framework, we first introduce a retrieval-based baseline system. As Figure 2 (a) shows, given an event sequence $X = \{X_{e_1}, \dots, X_{e_t}, X_{e_{c_j}}\}$, the baseline system retrieves the corresponding structural information for each event within X from a prebuilt event graph G, and then integrates the retrieved structural information into the BERT frame for predicting the relatedness score Y.

For an arbitrary event tuple (X_{e_i}, X_{e_j}), if it is covered by the event graph G (i.e., both X_{e_i} and X_{e_j} are nodes of G), then we can retrieve the corresponding node embeddings e_i and e_j, together with the edge weight A_{ij} by matching the event tuple in the event graph. The representation vector of the events within X further form into an embedding matrix E, and the edge weights form into an adjacency matrix A. To make use of the retrieved structural information for enhancing the prediction process, we first employ a graph neural network to combine the event representation matrix and the adjacency matrix:

$$E^{(U)} = \sigma(AEW_U) \tag{2}$$

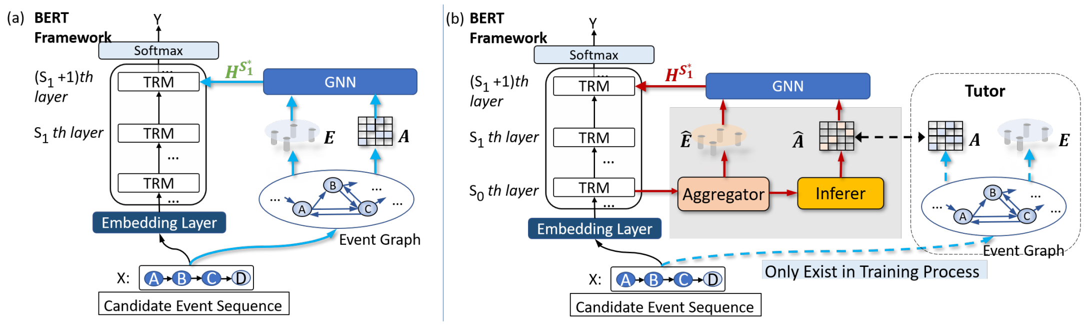

Figure 2: Model Structure. (a) Architecture of the baseline system. Given an event sequence, the baseline system retrieves event node features and connection strength from a prebulit event graph. (b) In addition to the baseline system, GraphBERT introduces an additional **aggregator** to obtain event representation from the hidden states of BERT, and learns to predict the connection strength between events in the training process using the **inferer**. So that in the test process, the connection information can be predicted for arbitrary event.

where $W_U \in \mathbb{R}^{d\times d}$ is a weight matrix; σ is a sigmoid function; $E^{(U)}$ is the event representation matrix updated by A.

Then the combined event graph knowledge can be merged into the frame of BERT for enhancing the prediction process. To this end, we employ an attention operation to softly select relevant information from the updated event representations $E^{(U)}$, and then update the hidden states of BERT. Specifically, we take the hidden states of the s_1th Transformer layer of BERT (denoted as H^{s_1}) as the query, and take the updated event representation $E^{(U)}$ as the key:

$$E^{(U)^*} = \text{MultiAttn}(H^{s_1}, E^{(U)}) \tag{3}$$

where $E^{(U)^*}$ carries information selected from $E^{(U)}$ and relevant to H^{s_1}.

Then we merge $E^{(U)^*}$ with H^{s_1} through an addition operation, and employ layer normalization to keep gradient stability:

$$H^{s_1*} = \text{LayerNorm}(E^{(U)^*} + H^{s_1}) \tag{4}$$

H^{s_1*} contains both the node feature information and the connection information between events. By taking H^{s_1*} as the input of the subsequent (s_1+1)th Transformer layers of BERT, the event prediction process is enhanced with the predicted event graph knowledge.

This retrieval-based baseline system can be regarded as the adaption of Li et al. (2018b) and Koncel et al. (2019)'s retrieval-based methods on a pretrained model BERT.

4 GraphBERT

A critical weakness of the retrieval-based baseline system is that it heavily relies on the coverage of the event graph. In other words, if an event is not covered by the event graph, then the structural information (i.e., node features and the adjacency matrix) would be absent from the constructed event graph, which further limits the model performance.

In this paper, we propose a predictive-based framework GraphBERT. GraphBERT uses the transformer layers of BERT as an encoder to obtain the representation for arbitrary events, and then learns to predict the link strength between events in the training process, so that the sparsity issues in the retrieval process can be avoided.

To this end, as Figure 2 (b) shows, in contrast to the retrieval-based baseline system, we introduce two more modules: (1) An **aggregator** to obtain event representations from the BERT framework; (2) an **inferer** to predict the link strength between events based on the event representations.

4.1 Event Encoding

Given an event sequence X, to calculate the event representations and predict the link strength for events within X, GraphBERT first encodes X into a set of *token*-level distributed representations by taking the 1st-s_0th Transformer layers of BERT as an encoder. Then an aggregator is employed to aggregate the token level representations into event representations.

Token Level Representations For an event sequence $X = \{X_1, \cdots, X_{t+1}\}$, where $X_i = \{x_1, \ldots, x_{l_i}\}$is an event within X and with l_i tokens, the s_0th Transformer layer of BERT encodes these tokens into contextualized distributed representations $H^{s_0} = \{(h_1^1, \ldots, h_{l_1}^1), \cdots, (h_1^{t+1}, \ldots, h_{l_{t+1}}^{t+1})\}$, where $h_j^i \in \mathbb{R}^{1\times d}$ is the distributed representation of the jth token of event X_i. Then we conduct the graph information prediction as well as the prediction task based on the token representations.

Event Level Representations An **aggregator module** aggregates tokens representation of events derived from the hidden states of BERT (i.e., H^{s_0}) to obtain the event level representations. For an arbitrary event $X_i \in X$, we employ a multi-head attention operation (Vaswani et al., 2017) to aggregate information from the corresponding token representations $H_i^{s_0} = (h_1^i, \dots, h_{l_i}^i)$ and obtain the vector representation of X_i. Specifically, we define the query matrix of attention operation as $q_i = \frac{1}{l_i}\sum h_l^i$, and take $H_i^{s_0}$ as the key matrix as well as the value matrix. Then the representation of X_i is calculated as:

$$\hat{e}_i = \mathrm{MultiAttn}(q_i, H_i^{s_0}, H_i^{s_0}) \tag{5}$$

where $\hat{e}_i \in \mathbb{R}^{1\times d}$.

In this way, we can obtain the representation of all events within X, which we denote as $\hat{E} = \{\hat{e}_1, \cdots, \hat{e}_{t+1}\}$, where $\hat{E} \in \mathbb{R}^{(t+1)\times d}$ is a matrix. Note that through the embedding layer of BERT, position information has been injected into the token representations. Thus $\hat{E}$ carries event order information.

Then the event representation matrix $\hat{E}$ is used for predicting the link strength between events. Hence, the performance of link strength prediction can be strongly influenced by the quality of $\hat{E}$. By deriving $\hat{E}$ from the hidden states of BERT, the abundant language knowledge within BERT can be utilized to obtain the event representations.

4.2 Link Strength Prediction

Given the event representation matrix $\hat{E}$ as node features, we employ an **inferer module** to predict the connection strength between arbitrary events within X, regardless of whether these events are seen in the training process. The output is a matrix $\hat{A} \in \mathbb{R}^{(t+1)\times(t+1)}$, where $\hat{A}_{ij}$ models the probability that event j is the subsequent event of event i.

We stack n graph attention (GAT) layers (Veličković et al., 2017) for consolidating event features. For an event X_i, the GAT layer works on the neighborhood of X_i to aggregate information. Since the connection between events are unknown a priori, we set the neighborhood set of event X_i as $\mathcal{N}_i = \{X_j\}$, where $X_j \in X, j \neq i$.

Therefore, at the kth graph attention layer, given the representation of the ith event $\hat{e}_i^k$, we calculate the attention coefficients between other events and derive deep event representation as:

$$\begin{gathered}\alpha_{ij} = \mathrm{softmax}_{j, j\in\mathcal{N}_i}(\mathrm{Relu}(u[W_\alpha \hat{e}_i^k || W_\alpha \hat{e}_j^k])) \\ \hat{e}_i^{k+1} = \sigma(\sum_{j\in\mathcal{N}_i} \alpha_{ij} \mathbf{W}_\alpha \hat{e}_j^k)\end{gathered} \tag{6}$$

where $u \in \mathbb{R}^{1\times 2d}, W_\alpha \in \mathbb{R}^{d\times d}$are trainable parameters, $\cdot||\cdot$is a concatenation operation. At the first GAT layer, $\hat{e}_i^1$is initialized by $\hat{e}_i$derived from the aggregator.

After n graph attention operations, we employ a bilinear map to calculate a relation strength score between two events within X based on their deep representations:

$$\Gamma_{ij} = \left(\hat{e}_i^n \; W_R \; \mathrm{T}(\hat{e}_j^n)\right) \tag{7}$$

where $W_R \in \mathbb{R}^{d\times d}$ are learnable parameters, $T(\cdot)$ is the transpose operation. For all $t+1$ events within X, the relation strength score between arbitrary two events forms a matrix $\Gamma \in \mathbb{R}^{(t+1)\times(t+1)}$, with each element Γ_{ij} measuring the relation strength between X_i and X_j.

Then we normalize the relation strength scores using the softmax function:

$$\hat{A}_{ij} = \mathrm{softmax}_j(\Gamma_{ij}) \tag{8}$$

After the layer normalization, $\sum_j \hat{A}_{ij} = 1$.

Hence, with the aggregator and the inferer, GraphBERT can obtain representation and connection strengths for arbitrary events, regardless of whether or not the event is covered by the event graph. Then the predicted adjacency matrix $\hat{A}$ and event representations $\hat{E}$ can be used for prediction, and the process is same as the retrieval-based baseline, as described in Eq.(2)-Eq.(4).

4.3 Training of Inferer

In the training process, we employ a **tutor module** to supervise the prediction of $\hat{A}$ using the structural information from a prebuilt event graph. Given an event sequence X, the tutor obtains an adjacency matrix A based on the edge weights of the event graph. Formally, the weights of A are initialized as:

$$A_{ij} = \begin{cases} W_{ij}, & \text{if } V_{i'} \rightarrow V_{j'} \in R, \\ 0, & \text{others.} \end{cases} \tag{9}$$

where $V_{i'}$, $V_{j'}$are nodes in the event graph corresponding to the ith and the jth event of the candidate event sequence. The same as the predicted event adjacency matrix $\hat{A}$, A is also a $\mathbb{R}^{(t+1)\times(t+1)}$matrix.

We scale A to make each row sum equals 1. Therefore, each element of A models the probability that the jth event is the subsequent event of the ith event in X. In the training process, through minimizing the distance between $\hat{A}$ and A, the inferer module is supervised by the tutor to learn to predict the event connection strength based on the event representations.

4.4 Optimization

The overall loss function is defined as:

$$L = L_{\text{Event Prediction}} + \lambda L_{\text{Graph Reconstruction}} \tag{10}$$

where $L_{\text{Event Prediction}}$ is a cross-entropy loss measuring the difference between predicted relatedness score Y and golden label, $L_{\text{Graph Reconstruction}}$ assess the difference between A and $\hat{A}$, λ is an additional hyperparameter for balancing the prediction loss with graph reconstruction loss.

For calculating $L_{\text{Graph Reconstruction}}$, we cast both A and $\hat{A}$ as a set of random variables, and employ the KL divergence to measure their difference:

$$\begin{aligned} &L_{\text{Graph Reconstruction}} = \\ &\sum_i \mathrm{KL}(\mathrm{MultiNomial}(\hat{A}_i)||\mathrm{MultiNomial}(A_i)) \end{aligned} \tag{11}$$

where i denotes the ith row, and $\mathrm{MultiNomial}(\cdot)$ denotes the multinomial distribution.

5 Experiments

We evaluate our approach on two event prediction tasks: Multiple Choice Narrative Cloze Task (MCNC) (Granroth and Clark, 2016) and Story Cloze Test (SCT) (Mostafazadeh et al., 2016) by constructing an event graph based on the training set of MCNC to train the GraphBERT model and then adapts the GraphBERT model trained on the MCNC dataset to the SCT dataset to evaluate whether GraphBERT can predict the link strength between unseen events to enhance the prediction performance.

5.1 Dataset

Multiple Choice Narrative Cloze Task The MCNC task requires the prediction model to choose the most reasonable subsequent event from five candidate events given an event context (Granroth and Clark, 2016). In this task, each event is abstracted to Predicate-GR form (Granroth and Clark, 2016), which represents an event in a structure of {subject, predicate, object, prepositional object}. Following Granroth and Clark (2016), we extract event chains from the New York Times portion of the Gigaword corpus. The detailed statistics of the dataset are shown in Table 1.

	Training	Dev.	Test
#Documents	830,643	103,583	103,805
#Event Chains	140,331	10,000	10,000
#Unique Events	430,516	44,581	47,252
#Uncovered Events	0	24,358	24,081

Table 1: Statistics of the MCNC dataset.

Story Cloze Test Task The SCT task requires models to select the correct ending from two candidates given a story context. Compared with MCNC which focuses on abstract events, the stories in SCT are concrete events and with much more details. This dataset contains a five-sentence story training set with 98,162 instances, and 1,871 four-sentence story contexts along with a right ending and a wrong ending in the dev. and test dataset, respectively. Because of the absence of wrong ending in the training set, we only use the development and the test dataset, and split the development set into 1,771 instances for finetuning models and 100 instances for the development purpose.

5.2 Construction of Event Graph

The event graph is constructed based on the training set of the MCNC dataset. Each event within the training set of MCNC is taken as a node of the event graph, and the edge weights are obtained by calculating the event bigram frequency. Note that, as shown in Table 1, although the events have been processed into a highly abstracted form to alleviate the sparsity, there are still nearly half of the events in the development and test set of MCNC remains uncovered by the event graph. In the test process, for retrieval-based methods, given a candidate event sequence with length $t + 1$, the edge weights for events not covered by the event graph are all set as $1/(t + 1)$.

5.3 Experimental Settings

We implement the GraphBERT model using pretrained BERT-base model, which contains 12 Transformer layers. We aggregate the *token* representations from the 7th Transformer layer of BERT, and merge the updated event representations to the 10th Transformer layer of BERT. The aggregator has a dimension of 768, and contains 12 attention heads. The inferer contains 1 GAT layer. The balance coefficient λ equals 0.01. During the training and testing process, we concatenate the elements of the Predicate-GRs to turn the Predicate-GRs into strings, so that the event sequences can conform to the input format of the GraphBERT model. More details are provided in the Appendix.

Baselines for MCNC

Event Pair and Event Chain Based Methods

(i) Event-Comp (Granroth and Clark, 2016) calculates the pair-wise event relatedness score using a Siamese network. **(ii) PairLSTM** (Wang et al., 2017) integrates event order information and pair-wise event relations to predict the ending event. **(ii) RoBERTa-RF** (Lv et al., 2020) enhances pre-trained language model RoBERTa with chain-wise event relation knowledge for making prediction.

Event Graph Based Methods

(i) SGNN (Li et al., 2018b) constructs a narrative event evolutionary graph (NEEG) to describe event connections, and propose a scaled graph neural network to predict the ending event based on structural information ***retrieved*** from the NEEG. **(ii) HeterEvent** (Zheng et al., 2020) encodes events using BERT, and implicitly models the word-event relationship by an heterogeneous graph attention mechanism. **(iii) GraphTransformer** (Koncel et al., 2019) ***retrieves*** structural information from event graph and introduces an additional graph encoder upon BERT to leverage the structural information.

Pretrained Language Model Based Methods

(i) BERT (Devlin et al., 2019) refers to the BERT-base model finetuned on the MCNC dataset. **(ii) GraphBERT$_{\lambda=0}$** refers the GraphBERT model optimized with the balance coefficient λ set as 0. Hence, the structural information cannot be incorporated through the graph reconstruction term.

5.3.1 Settings for SCT

To test the generality of GraphBERT, we examine whether GraphBERT can utilize the structural knowledge learned from MCNC-based event graph to guide the SCT task. To make fair comparisons, we also trained the BERT (Devlin et al., 2019), GraphTransformer (Koncel et al., 2019) on the MCNC dataset, then finetuned them on the SCT dataset. In the following sections, we use the subscript "MCNC" to denote the model which has been trained on the MCNC dataset.

However, in the finetuning and test process, GraphTransformer still relies on an event graph to provide structural information. To address this issue, we abstract each event in the finetuning set and test set of SCT into the Predicate-GR form, which is the same form with the nodes in the MCNC-based event graph. As a result, structural information for an event in SCT can be retrieved from the MCNC-based event graph using its corresponding Predicate-GR form, once the event is covered by the event graph.

In addition to the above-mentioned methods, on the SCT dataset, we also compare GraphBERT with the following **event-chain-based** baselines:

(i) HCM (Chaturvedi et al., 2017) trains a logistic regression model based on contextual semantic features. **(ii) ISCK** (Chen, 2019) integrates narrative sequence and sentimental evolution information to predict the story ending.

5.3.2 Overall Results

We list the results on MCNC and SCT in Table 2 and Table 3, respectively. From the results on MCNC (Table 2), we can observe that:

(1) Compared to event-pair-based EventComp and event-chain-based PairLSTM, event-graph-based methods (i.e. SGNN, HeterEvent, GraphTransformer, and GraphBERT) show better performance. In addition, GraphBERT outperforms event-chain based RoBERTa-RF, though RoBERTa-RF is built upon a much more powerful language model. This confirms that involving event structural information could be effective for this task.

(2) Compared to BERT and GraphBERT$_{\lambda=0}$, graph enhanced models GraphTransformer and GraphBERT further improve the accuracy of script event prediction (T-test; P-Value < 0.01). This shows that linguistic and structural knowledge can have a complementary effect.

(3) Compared to the retrieval-based method GraphTransformer, GraphBERT shows efficiency of learning structural information from the event graph (T-test; P-Value < 0.01). This indicates that GraphBERT is able to learn the structural information from the event graph in the training process, and predict the correct structural information for unseen events in the test process.

Results on the SCT dataset (Table 3) show that:

(1) Comparing GraphBERT with BERT$_{\text{MCNC}}$, GraphBERT$_{\lambda=0,\text{MCNC}}$ shows that the graph information can also be helpful for the SCT task.

(2) Though incorporated graph information, the performance of GraphTransformer is close or inferior to BERT on SCT. This could be because of the limited size of the SCT development set, which contains 1,771 samples and might be insufficient to adapt GraphTransformer to the SCT problem. However, GraphBERT shows a 1.3% absolute improvement over BERT, which indicates the efficiency of GraphBERT in predicting the link strength between unseen events for predicting the ending event.

Methods	Accuracy(%)
Random	20.00**
EventComp (Granroth and Clark, 2016)	49.57**
PairLSTM (Wang et al., 2017)	50.83**
SGNN (Li et al., 2018b)	52.45**
BERT (Devlin et al., 2019)	57.35**
GraphTransformer (Koncel et al., 2019)	58.53**
HeterEvent (Zheng et al., 2020)	58.10**
GraphBERT$_{\lambda=0}$	57.23**
RoBERTa-RF (Lv et al., 2020)	58.66**
GraphBERT	**60.72**

Table 2: Performance of GraphBERT and baseline methods on the test set of MCNC. Accuracy marked with * means p-value < 0.05 and ** indicates p-value < 0.01 in T-test.

Methods	Accuracy(%)
HCM (Chaturvedi et al., 2017)	77.6**
ISCK (Chen, 2019)	87.6**
BERT (Devlin et al., 2019)	88.1*
BERT$_{\text{MCNC}}$	88.5*
GraphTransformer$_{\text{MCNC}}$ (Koncel et al., 2019)	88.9
HeterEvent$_{\text{MCNC}}$ (Zheng et al., 2020)	88.4*
GraphBERT$_{\lambda=0,\text{MCNC}}$	88.3*
GraphBERT$_{\text{MCNC}}$	**89.8**

Table 3: Model performance on the test set of SCT. Accuracy marked with * means p-value < 0.05 and ** indicates p-value < 0.01 in T-test.

5.4 Influence of the Accuracy of the Predicted Link Strength

We investigate the relationship between the accuracy of the predicted link strengths with the model performance. However, for events in the test set, the golden event graph is unavailable. To address this issue, we split the original training set of MCNC into a new training and evaluating set, containing 120,331 and 20,000 instances, respectively. For each sample, we calculate the Pearson correlation coefficient between the predicted connection strengths and connection strengths derived from the event graph, as well as the relationship between such correlation coefficient and model performance. The results are shown in Figure 3. We observe that, in general, GraphBERT can predict the connection between arbitrary events with reasonable accuracy. Also, the model performance improves as the connection prediction accuracy increases. This confirms that correctly predicting the event connections for unseen events can be helpful for the event prediction process.

5.5 Influence of the Coverage of the Event Graph

We conduct experiments to investigate the specific influence of the sparsity of the event graph on model performance. Based on the original test set of MCNC, we build new test sets with different proportions of uncovered events, and compare the performances of the GraphBERT framework with retrieval-based method GraphTransformer (Koncel et al., 2019) on these test sets. As shown in Figure 4, as the proportion of uncovered events increase from 0 to 1, the performance of GraphTransformer shows a negative trend in general. This is because, for retrieval-based methods, with the increase of sparsity, the availability of structural information decreases. Compared to GraphTransformer, the performance of GraphBERT is more stable. These results indicate that predicting the structural information can be useful for enhancing the performance of event prediction.

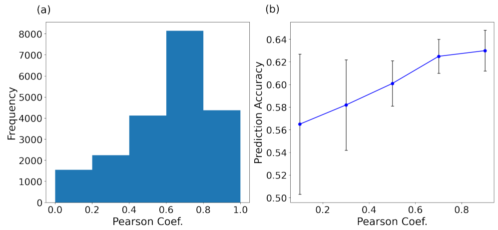

Figure 3: (a) The distribution of Pearson correlation coefficients between the predicted connection strength and connection strength derived from the event graph. (b) Relationship between correlation coefficient and model performance.

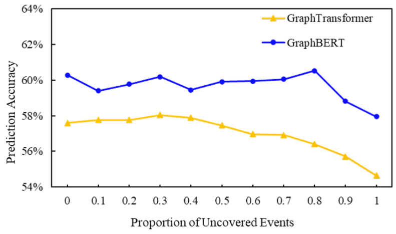

Figure 4: The performance of GraphBERT and GraphTransformer under different proportion of uncovered events.

5.6 Case Study

Table 4 provides an example of prediction results from different models on the test set of SCT. The event context describes a story that a bear appeared in the campus and policemen came to tranquilize the bear. Given the event context, GraphBERT is able to choose correct ending E_1 *The bear fell asleep*, while GraphTransformer chooses the incorrect ending E_2 *The bear became very violent*.

To correctly predict the story ending, a model should understand the relationship between *gave a tranquilizer* and *fell asleep*. However, event *gave a tranquilizer* is not covered by the event graph. Hence, the retrieval-based method GraphTransformer is unable to obtain structural information from the event graph. On the other hand, in the event graph, there is a directed edge from a node *obj. sedated* to node *subj. slept*. This indicates that,

Event Context	Candidate Subsequent Event	Model
A: I heard that my school's campus had been closed. **B:** The message said there was a bear on the grounds ! **C:** The police had to come and help get the bear away. **D:** They gave the bear a tranquilizer.	$\mathbf{E_1}$: The bear fell asleep. ($\surd$)	GraphBERT
	$\mathbf{E_2}$: The bear became very violent. ($\times$)	GraphTransformer

Table 4: An example of event predictions made by GraphTransformer and GraphBERT on the SCT dataset.

GraphBERT can learn the structural knowledge from the MCNC-based event graph, and predict the connection between *gave a tranquilizer* and *fell asleep* for instances in the SCT dataset.

6 Discussion

The GraphBERT model employs a structure variable $\hat{A}$ to capture the "is_next_event" relationship between events. By introducing more parallel structural variables $\{\hat{A}^1, \ldots, \hat{A}^k\}$, it can be extended to simultaneously learn multiple kinds of event relationships, such as temporal or causal relationship. Furthermore, previous researches demonstrate that the graph-structured relationship extensively exist between other semantic units, such as sentences(Yasunaga et al., 2017), or even paragraphs (Sonawane and Kulkarni, 2014). However, similar to the situation in event graph, it would be impractical to construct knowledge graphs that cover all possible connection relationships between all the sentences or paragraphs. This restricts the applicable of retrieval-based methods in these situations. On the contrary, our generative approach suggests a potential solution by learning the connection relationship from graph-structured knowledge base with limited size, then generalizing to the unseen cases.

7 Related Work

The investigation of scripts dates back to 1970's (Minsky, 1974; Schank, 1975). The script event prediction task models the relationships between abstract events. Previous studies propose to model the pair-wise relationship (Chambers, 2008; Jans et al., 2012; Granroth and Clark, 2016) or event order information (Pichotta and Mooney, 2016; Pichotta, 2016; Wang et al., 2017) for predicting the subsequent event. Li et al. (2018b) and Lv et al. (2019) propose to leverage the rich connection between events using graph neural network and attention mechanism, respectively.

Different from script event prediction, the story cloze task (Mostafazadeh et al., 2016) focuses on concrete events. Therefore, it requires prediction models to learn commonsense knowledge for understanding the story plot and predicting the ending. To this end, Li et al. (2018a) and Guan (2019) propose to combine context clues with external knowledge such as KGs. Li et al. (2019) finetune pretrained language models to solve the task. Compared to their works, our approach can use both the language knowledge enriched in BERT to promote the comprehension of event context, and the structural information from event graph to enhance the modeling of event connections.

A recent line of work has been engaged in combining the strength of Transformer based models with graph structured data. To integrate KG with language representation model BERT, Zhang et al. (2019) encode KG with a graph embedding algorithm TransE (Bordes et al., 2013), and takes the representation of entities in KG as input of their model. However, this line of work only linearizes KGs to adapt the input of BERT. Graph structure is not substantially integrated with BERT. Guan (2019) and Koncel et al. (2019) propose retrieval-based methods to leverage the structural information of KG. However, in the event prediction task, the diversity of event expression challenges the coverage of the event graph, and prevents us from simply retrieving events in the test instances from the event graph. We propose to integrate the graph structural information with BERT through a predictive method. Compared to retrieval-based methods, our approach is able to learn the structural information of the event graph and *generate* the structural information of events to avoid the unavailable of structural information in test instances.

8 Conclusion

We devised a graph knowledge enhanced BERT model for the event prediction task. In addition to the BERT structure, GraphBERT introduces a structured variable to learn structural information from the event graph, and model the relationship between the event context and the candidate subsequent event. Compared to retrieval-based methods, GraphBERT is able to predict the link strength between all events, thus avoiding the (inevitable) sparsity of event graph. Experimental results on

MCNC and SCT task show that GraphBERT can improve the event prediction performances compared to state-of-the-art baseline methods. In addition, GraphBERT could also be adapted to other graph-structured data, such as knowledge graphs.

10 Experimental Settings

10.1 Training Details

To conform to the input format of BERT, for an event described in the Predicate-GR form {subject, predicate, object, prepositional object}, we first concatenate each element within the predicate-GR into a string “subject predicate object prepositional object”, so that an event described in a structured form is turned into a string. Then for satisfying the requirement of BERT, the candidate event sequence is further preprocessed into the form of:

$$\texttt{[CLS]}\ e_1\ \texttt{[SEP]}\ \ldots e_t\ \texttt{[SEP]}\ \texttt{candidate}\ \texttt{[SEP]} \tag{12}$$

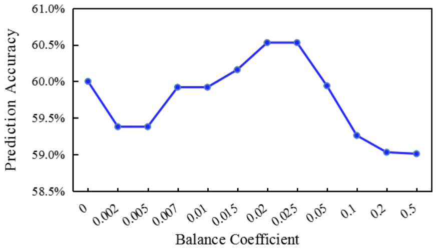

Figure 5: The performance of model trained with different balance coefficient λ.

On the MCNC dataset, the GraphBERT model is trained for 3 epochs, with a batch size of 64, and a learning rate of 2e-5. While during the finetuning process on SCT, GraphBERT is optimized with a batch size of 16, and a learning rate of 1e-5, with 5 epochs.

10.2 Searching for the Balance Coefficient

In this paper, the objective function is composed of two components. Through minimizing the graph reconstruction loss, model learns to modeling the bigram event adjacency patterns. While through minimizing the prediction loss, model is trained to choose the correct ending given an event context. These two components are balanced with a coefficient λ.

To investigate the effect of the balance coefficient, we compare the prediction accuracy of the GraphBERT model trained with different λ and show the results in Figure 5. From which we could observe that, the prediction accuracy increases as the balance coefficient increase from 0 to 0.1. This is because the additional event graph structure information is helpful for the event prediction task. However, as the λ exceeds 0.5, the model performances start to decrease. This is because the overemphasis of graph reconstruction loss would in turn decrease the model performance.

GraphBERT	60.72
RoBERTa	61.19
GraphRoBERTa	62.81

Table 6: Performance of the event graph knowledge enhanced RoBERTa model (Graph-RoBERTa) on the MCNC dataset.

10.3 Searching of Start and Merge Layer in BERT

Different transformer layers of BERT tend to concentrate on different semantic and syntactic information (Clark et al., 2019; Coenen et al., 2019). Therefore, which layer is selected in the BERT to start integrating event graph knowledge, and which layer is selected to merge graph enhanced event representations can affect the performance of the model. We study such effect in two ways: first, we fix the start layer and change the merge layer. Second, we fix the gap between start and merge layer, and change the start layer. Results are shown in Table 5. The tuple (n_1, n_2) denotes the (start, merge) layer. From which we could observe that, under the same gap between merge and start layer, employing the 7th transformer layer of BERT as the start layer can achieve the best result. While setting the merge–start gap as 2 is more efficient than other choices. Interestingly, Jawahar et al. (2019) find that the syntactic features can be well captured in the middle layers of BERT, especially in the 7–9 layer. This indicates that the middle layers of BERT focus more on sentence level information, and implicitly support the reasonableness that choosing the 7th and 10th transformer layer of BERT as the start end merge layer.

11 Enhancing Different Kinds of Pretrained Transformer-based Pretrained Language Models with Event Graph Knowledge

In this paper, we propose the GraphBERT framework, which enhances the transformer-based pertrained language model BERT with event graph knowledge through an additional structural variable $\hat{A}$. We argue that, using the structural variable, we can also equip other transformer-based pretrained language models, such as RoBERTa, with the event graph knowledge, and then enhance the event prediction process. This could be achieved by adapt the aggregator, inferer and merger module upon the other transformer-based frameworks.

Using the above-mentioned manner, we implemented a GraphRoBERTa model and examined its performance on the MCNC dataset. The results are shown in Table 6. We observe that, compared with BERT, RoBERTa and GraphRoBERTa show better performance. This is because, during the pretraining process, RoBERTa can acquire more abundant linguistic knowledge for understanding the events through the dynamic masked token prediction mechanism. Moreover, the comparison between GraphBERT with BERT, and between GraphRoBERTa with RoBERTa show the effectiveness of our approach in incorporating event graph knowledge with multiple prevailing transformer-based pretrained language models, to consistently enhancing the performance of event prediction.

Long Time No See! Open-Domain Conversation with Long-Term Persona Memory

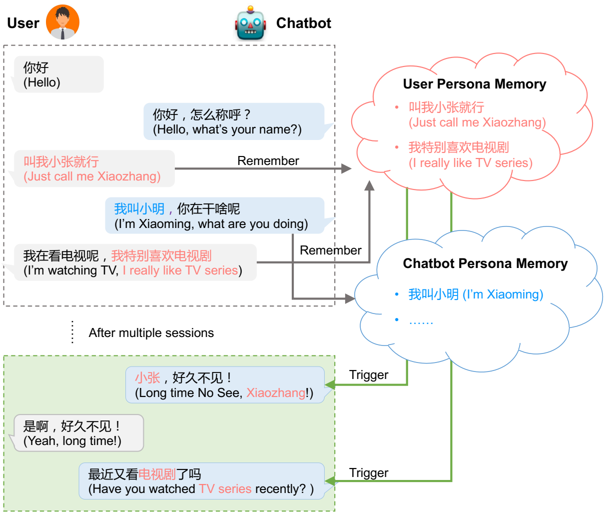
Abstract

Most of the open-domain dialogue models tend to perform poorly in the setting of long-term human-bot conversations. The possible reason is that they lack the capability of understanding and memorizing long-term dialogue history information. To address this issue, we present a novel task of **Lo**ng-ter**m** Memory **Con**versation (LeMon) and then build a new dialogue dataset DuLeMon and a dialogue generation framework PLATO-LTM with a Long-Term Memory (LTM) mechanism. This LTM mechanism enables our system to accurately extract and continuously update long-term persona memory without requiring multiple-session dialogue datasets for model training. To our knowledge, this is the first attempt to conduct real-time dynamic management of persona information of both parties, including the user and the bot. Results on DuLeMon indicate that PLATO-LTM can significantly outperform baselines in terms of long-term dialogue consistency, leading to better dialogue engagingness [1].



你好
(Hello)

你好，怎么称呼？
(Hello, what's your name?)

叫我小张就行
(Just call me Xiaozhang)

我叫小明，你在干啥呢
(I'm Xiaoming, what are you doing)

我在看电视呢，我特别喜欢电视剧
(I'm watching TV, I really like TV series)

小张，好久不见！
(Long time No See, Xiaozhang!)

是啊，好久不见！
(Yeah, long time!)

最近又看电视剧了吗
(Have you watched TV series recently?)

User Persona Memory
- 叫我小张就行 (Just call me Xiaozhang)
- 我特别喜欢电视剧 (I really like TV series)

Chatbot Persona Memory
- 我叫小明 (I'm Xiaoming)
- ……

Figure 1: A sample of long-term conversation with memory. At first, the chat partner is not familiar with each other, so the goal is to get to know each other; Then, after multiple sessions, the chatbot already has a certain understanding and memory of the user's persona and its own persona, making the deep chat possible.

1 Introduction

Persona is crucial for open-domain dialogue systems to establish long-term intimacy with users (Huang et al., 2020). Existing persona dialogue datasets such as PersonaChat (Zhang et al., 2018; Dinan et al., 2019) and models (Li et al., 2016a; Zhang et al., 2017; Qian et al., 2018) have greatly facilitated the chatbot with configurable and persistent personalities.

Nevertheless, current open-domain dialogue systems still cannot build a long-term connection with humans. The possible reason is that they lack the capability of understanding and memorizing long-term dialogue history information, which we called **long-term persona ability**. Remembering and actively utilizing the user's persona increases engagingness and contributes to long-term friendships between chatbot and user (Campos et al., 2018). Without this ability, the current state-of-the-art models, such as Meena (Adiwardana et al., 2020), Blender (Roller et al., 2021), and PLATO (Bao et al., 2020), tend to talk to people like strangers in long-term conversations.

Despite the importance and challenge of utilizing long-term persona in open-domain dialogue, as far as we know, the long-term persona ability of large-scale models is less studied due to a lack of both task design and corresponding dataset. Previous long-term persona dialogue systems (Kim et al., 2014; Bang et al., 2015) are mainly rule-based systems without large-scale pre-training models, in which researchers proposed various episodic memory architectures to extract, store and manage rel-

evant facts in prior interactions for use in future dialogs (Campos et al., 2018).

In addition, existing persona conversation datasets (Zhang et al., 2018; Dinan et al., 2019; Zheng et al., 2019) focus only on the consistency of the chatbot's own persona and ignore the memory and utilization of the user's persona. And they all set fixed persona that cannot be updated during the chat. Recently, Xu et al. (2021) proposed MSC dataset as a multi-session extension of PersonaChat, and its sessions are additionally annotated with summaries of important personal points. Similar to the previous episodic memory architecture, Xu et al. (2021) summarize and recall previous conversations for future dialogue generation. The stored documents in MSC will not be dynamically modified and will increase infinitely as the conversation progresses. Furthermore, the retrieval-augmented generative models rely on a long-session conversation dataset for training, which is expensive and difficult to annotate.

To address the limitations of existing models and the above issues, we defines the **LeMon** (**L**ong-t**e**rm **M**emory **Con**versation) task and propose a new dataset named **DuLeMon**, which focuses not only on the consistency of the bot's own persona but also on the active construction and utilization of the user's persona in a long-term interaction (ie. mutual persona). We demonstrate an example dialogue in DuLeMon in Figure 1. In DuLeMon, we assume that the two speakers have previously interacted with each other and that the chatbot remembers part of the user's persona. Besides, both the user and chatbot grounding persona are annotated in each utterance.

Based on our collected dataset, we carefully design a novel **PLATO-LTM** framework for the long-term persona dialogue setting by adding a plug-and-play long-term memory (LTM) to the state-of-the-art open-domain dialogue model (Bao et al., 2020). It enables us to study long-term persona conversations without relying on the long-session dataset. PLATO-LTM can extract both parties' persona information from the conversation in real time, write it to persona memory respectively, and retrieve both parties' persona information from memory to generate responses. The PLATO-LTM framework consists of three modules: (1) Persona Extractor (PE): The memory is updated by filtering irrelevant information and extracting persona sentences through a classifier. (2) Long-Term Memory (LTM): Two separated long-term memories store the explicit persona information of interlocutors. (3) Generation Module: We use the large-scale model and the retrieved persona sentences of the user and chatbot are directly concatenated with dialogue context as model input.

Our major contributions are as follows:

(1) We firstly propose the long-term persona chat task LeMon for Chinese long-term conversations. Our proposed DuLeMon dataset is also the largest multi-turn Chinese mutual persona chat dataset currently available.

(2) We proposed a PLATO-LTM framework that extracts and remembers both user's and the chatbot's persona in real time, enabling the chatbot to have long-term persona dialogue without training on long-session data.

(3) Automatic and human evaluation show that our method significantly improves the consistency of the state-of-the-art in long conversations, making the response more engaging while ensuring coherency.

2 Related Work

Persona Dialogue: As described in Huang et al. (2020), there is much work related to persona dialogue. Generally speaking, these works can be divided into implicit persona models and explicit persona models. In the implicit model, the persona is represented in the form of the semantic persona vector. Kim et al. (2014) proposed a retrieval-based method to integrate persona and user interests into the dialogue system. Because these models are implicit methods, they are not easy to interpret and control in target response generation. In Qian et al. (2018), an explicit persona model is proposed to generate consistent responses for given persona information. The persona information of the machine includes name, gender, hobbies, and so on. In this way, the given persona information can be better used for model generation. There are also many persona chat datasets that have been constructed to develop models, as shown in Table 1. In particular, the introduction of the PersonaChat (Zhang et al., 2018; Dinan et al., 2019) dataset has extensively promoted the development of this field where the crowd-workers are simply asked to "chat with the other person naturally and try to get to know each other." However, the user's persona was unknown

Dataset	Persona	Mutual	# Dialogues	Language	Multi-turn

Table 1: Comparison of our dataset DuLeMon with other datasets.

to the bot, so the dialogue was like strangers exchanging information. In contrast, our proposed DuLeMon dataset requires the chatbot to actively remember and use the user's persona to improve conversational engagements and increase the intimacy between interlocutors in long-term interactions.

Dialogue Model with External Memory: As described in Lim (2012), there are various memory models used by the rule-based dialogue systems. In Bang et al. (2015), user-related information is memorized and used to rewrite the response. In Elvir et al. (2017), a unified episodic memory architecture for Embodied Conversational Agents (ECAs) is proposed. They describe a process that determines the prevalent contexts in the conversations obtained from the interactions. In Campos et al. (2018), the authors introduce an agent that uses its conversational memory to revisit shared history with users to maintain a coherent social relationship over time. However, they find it challenging to leverage the shared history with individual users and hard to accommodate expected conversational coordination patterns. Apart from studies in rule-based dialogue systems mentioned above, Xu et al. (2021) shows how large-scale pre-training generative dialogue models trained on existing datasets perform poorly in the long-term conversation setting and proposes a new extended English conversation dataset, entitled Multi-Session Chat (MSC). Different from them, our novel dataset DuLeMon does not rely on long sessions with high collection costs to study long-term memory problems in the persona chat, with significant differences in task design and data collection.

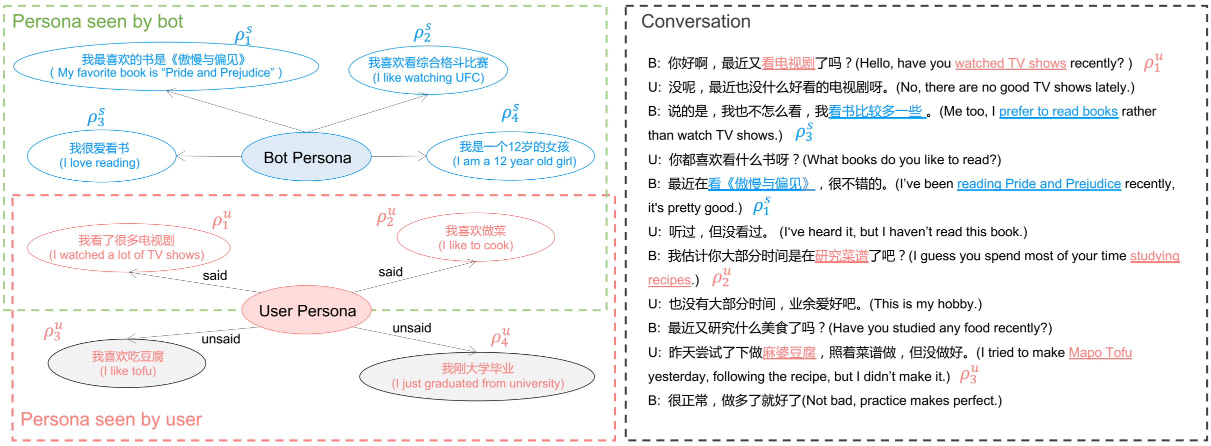
3 Data Collection

Task Definition. Given dialogue context $c = \{u_1, s_1, u_2, s_2, ..., u_{t-1}, s_{t-1}, u_t\}$, where u and s represent the user and the chatbot respectively. Each speaker has its corresponding persona description that consists of a set of sentences, we define the user persona as $\rho^u = \{\rho^u_1, \rho^u_2, ..., \rho^u_m\}$, and the chatbot persona as $\rho^s = \{\rho^s_1, \rho^s_2, ..., \rho^s_n\}$. Given the dialogue context c, user persona ρ^u and chatbot persona ρ^s, we are interested in finding the corresponding persona and predicting the chatbot response s_t.

To support our task, we collect and release a new dataset, entitled DuLeMon. In DuLeMon, the chatbot actively remembers and reasonably uses what the user has said about their persona while maintaining consistency in its persona, allowing the conversation to proceed more deeply. In a nutshell, our DuLeMon dataset has two essential features: During the conversation, the chatbot can see the persona of both parties; the other is that the persona associated with the response is explicitly annotated in our dataset. Unlike the PersonaChat dataset, the setting in DuLeMon is that one speaker plays the role of a chatbot, and the other plays the user's role. We elaborate on the construction process of the dataset as the following.

(1) Persona collection: The persona is mainly from the translation and rewriting of persona in PersonaChat. The chatbot's persona is only visible to itself, and the chatbot can use its persona information to chat with the user, as shown in Figure 2. The user's persona contains two parts: persona that the chatbot already knows and persona that the chatbot does not know. The first part is the user's persona that the chatbot has learned through historical conversations. This part is randomly selected from multiple personas of each user. The chatbot needs to use this information to guide the conversation during the chat process. It should be noted that in order to simulate the situation at the beginning of the chat, this part may be empty.

(2) Dialogue collection: For each dialogue, two crowd-workers (one plays the chatbot, the other plays the user) are randomly paired and given random persona. They are required to organize a di-



B: 你好啊，最近又看电视剧了吗？(Hello, have you watched TV shows recently?) ρ_1^u
U: 没呢，最近也没什么好看的电视剧呀。(No, there are no good TV shows lately.)
B: 说的是，我也不怎么看，我看书比较多一些 。(Me too, I prefer to read books rather than watch TV shows.) ρ_3^s
U: 你都喜欢看什么书呀？(What books do you like to read?)
B: 最近在看《傲慢与偏见》，很不错的。(I’ve been reading Pride and Prejudice recently, it's pretty good.) ρ_1^s
U: 听过，但没看过。 (I‘ve heard it, but I haven’t read this book.)
B: 我估计你大部分时间是在研究菜谱了吧？(I guess you spend most of your time studying recipes.) ρ_2^u
U: 也没有大部分时间，业余爱好吧。(This is my hobby.)
B: 最近又研究什么美食了吗？(Have you studied any food recently?)
U: 昨天尝试了下做麻婆豆腐，照着菜谱做，但没做好。(I tried to make Mapo Tofu yesterday, following the recipe, but I didn’t make it.) ρ_3^u
B: 很正常，做多了就好了(Not bad, practice makes perfect.)

Figure 2: Example of our proposed DuLeMon dataset with both chatbot’s and user’s persona. It has two important features: one is that during the conversation, the chatbot can see the persona of both parties; the other is that the persona information associated with the response is explicitly labeled in our dataset which is shown as the ρ^u and ρ^s in the figure.

alogue based on the given persona. The chatbot should think more about chatting to make it go on. It should utilize the known user’s persona to conduct the in-depth chat. The user will act as an ordinary user to cooperate with the conversation. The content of the chat can be selected from the given persona. It must not be irrelevant for the given information, nor can it conflict with the given persona.

(3) Persona Grounding Labeling: This part annotates whether the current response uses the given persona information and whether the current sentence is a persona sentence. For each utterance, we first let the annotators label whether it uses persona or not. Furthermore, the annotator should label the grounding persona (from chatbot or user) being used in the response. Therefore, through this process, the direct relationship between the response and the persona can be given. Then, for sentences that use the persona, we further annotate whether the utterance is a persona sentence or not.

To scale the amount of data, we also collected conversations where the user’s persona was not visible to the bot, following the PersonaChat (Zhang et al., 2018). Finally, our DuLeMon dataset consists of two parts. In DeLeMon-SELF, the bot only knows its own persona, while in DuLeMon-BOTH, it also knows part of the user’s persona (as described above). The overall statistics of the DuLeMon are shown in Table 2.

Category	**SELF**	**BOTH**
# Dialogues	24500	3001
# Utterances	400472	48522
Avg. # turns	16.3	16.2
Avg. length of utterances	19.7	21.2
Avg. # bot persona	4.0	4.0
Avg. # user persona (seen)	0	4.4
Avg. # user persona (unseen)	4.0	1.3

Table 2: Statistics of DuLeMon.

4 Model Architecture

In this work, we propose a long-term memory dialogue system based on an explicit memory read-write mechanism. It includes three parts: persona extractor, long-term persona memory, and generation module. Through the read and write operations of the long-term memory module, the user’s and chatbot’s persona can be stored, updated, and read. The overall framework is shown in Figure3.

4.1 Persona Extractor

Given an utterance or text span as input, our persona extractor can assign each input a label to indicate if it contains persona information. Here we train an ERNIE-CNN network architecture in a supervised way on an annotated persona-utterance dataset as this persona extractor. Specifically, the ERNIE-CNN network employs a pre-trained ERNIE[2] (Sun et al., 2019) network for sentence representation, and another CNN model (Kim, 2014)

(a) Dialogue Flow

(b) System Pipeline

(c) Models

Figure 3: Illustration of our system PLATO-LTM. (a) shows the dialogue flow. (b) describes the modules and pipeline of our system. It consists of a persona extractor (PE), a long-term persona memory, a retriever, and a generator. ① The long-term memory contains both user persona and chatbot persona extracted from the dialogue history by PE . ② The retriever uses context as query to retrieve related personas in memory ③ concatenates the retrieved text to the context and use the generator to produce the generated response. (c) details our generator PLATO-2 and ranker CPM (Context Persona Matching).

for classification.

Training procedure. First, we collect the first-version training dataset, in which there are 6k utterances (from the DuLeMon corpus and Chinese social forum corpus) being human-annotated with positive or negative class labels. Second, using the aforementioned dataset, we train five ERNIE-CNN network (with different pre-training parameter versions) based models (called pc-stage1). Third, we employ these five models to automatically annotate 1.4 million utterances with labels, where these utterances are collected from the DuLeMon and the online Chinese social forum. We then refine this augmented dataset as the final-version dataset with the following steps: (a) Given an utterance, if there are at least two of the above five models identifying it as a positive sample, then it is attached with a positive label, (b) otherwise it is attached with a negative label. Finally, we train the five models on the final-version dataset and select the one with the best performance as our persona extractor (named pc-stage2).

Inference procedure. First, given an utterance, we segment it into clauses with the use of punctuation marks. Second, we use the persona extractor mentioned above to classify each clause with a label and then collect the clause with a positive label as persona sentences.

4.2 Long-Term Memory

The long-term memory (LTM) module maintains memories to store the historical persona information from the user and the chatbot, respectively. The most critical operations are reading and writing based on the context persona matching (CPM) model. We use context encoder $E_c(\cdot)$ to encode the current context c, and use persona encoder $E_\rho(\cdot)$ to encode the persona ρ_i. $E(\cdot)$ is the encoder's output on the first input token (`[CLS]`), corresponding to the input's pooled representation.

The encoder E_c and E_ρ is initialized with the ERNIE model and then trained on our DuLeMon corpus. For each training sample, we define the positive persona as the persona used in the current user's utterance and the bot's response (including bot persona and user persona seen by bot), and the negative persona as the remaining persona of the current session. Given context c, a positive persona ρ^+, and a negative persona ρ^-, we use triplet loss to tune the network as:

$$\max\left(sim(c,\rho^{+}) - sim(c,\rho^{-}) + \alpha, 0\right)$$

We set the margin $\alpha = 0.2$ in our experiments. Below we describe the specific read and write process of the long-term memory module.

Write: We use the PE module to identify the persona in the dialogue history as the candidate information to be written. It needs to eliminate duplicates before writing. Specifically, calculate the cosine similarity with the persona in memory to get the most approximate persona ρ_j. When the similarity between ρ_i and ρ_j exceeds the given duplication threshold s_{dup}, replace ρ_j in memory with ρ_i; otherwise, write ρ_i directly into the memory. When writing to memory, save $\{\rho_i, E_\rho(\rho_i)\}$ pair for the subsequent reading. We measure the distance with the cosine similarity as:

$$sim(\rho_i,\rho_j) = \cos(E_\rho(\rho_i), E_\rho(\rho_j)) \tag{1}$$

Read: The reading process can be regarded as the retrieval process from memory. First, we use the efficient similarity search of dense vectors to select candidates. Then a matching model is utilized to score the relevance of the candidates to the current context. The similarity between the context and the persona using cosine similarity:

$$sim(c,\rho_i) = \cos(E_c(c), E_\rho(\rho_i)) \tag{2}$$

The top k persona candidates ρ^u in the user memory and top k candidates ρ^s in the chatbot memory are used for response generation. To model persona sparsity in dialogue, we filter out the persona, whose similarity score is lower than the similarity threshold s_c.

4.3 Generation Module

We trained our model on the basis of the PLATO-2 (Bao et al., 2020) architecture which adopts the generic transformer language model (Vaswani et al., 2017) and leverages a stack of masked multi-head self-attention layers to train on massive dialogue data [3].

Given the conversation context $c = \{u_1, s_1, u_2, s_2, ..., u_{t-1}, s_{t-1}, u_t\}$, the corresponding user persona ρ^u and chatbot persona ρ^s, the ground truth response as $r = \{x_{m+1}, x_{m+2}, ..., x_N\}$, the conditional probability of $p(r|c,\rho^u,\rho^s)$ can be written as the product of a series of conditional probabilities:

$$p(r|c,\rho^u,\rho^s) = \prod_{t}^{N} p(r_t|c,\rho^u,\rho^s,r_{<t}) \tag{3}$$

Therefore, we need to minimize the following negative log-likelihood (NLL) loss:

$$\begin{aligned}\mathcal{L}_{NLL} &= -\mathbb{E}\log p(r|c,\rho^u,\rho^s)\\ &= -\mathbb{E}\sum_{t=1}^{T}\log p(r_t|c,\rho^u,\rho^s,r_{<t})\end{aligned} \tag{4}$$

where T is the length of the target response r and $r_{<t}$ denotes previously generated words. Since the response generation is a uni-directional decoding process, each token in the response only attends to those before it. As for the context, bi-directional attention is enabled for better natural language understanding.

We added two strategies to distinguish different roles in the dialogue and prevent the confusing use of persona information.

- Role Embedding (Bao et al., 2021): different role embedding is used to distinguish the persona of different chat parties, abbreviated role_embed.
- Role Token: splicing "system persona" before the chatbot persona and "user persona" before the user persona, abbreviated role_token.

5 Experiments

In this section, we present the baselines, experiment settings, model comparisons, and results of experiments.

5.1 Compared Methods

As baselines, we select state-of-the-art methods to compare with our method.

- PLATO-2 (Bao et al., 2020): The SOTA open-domain dialogue model.
- PLATO-FT: The PLATO-2 model fine-tuned on our proposed DuLeMon dataset.
- PLATO-LTM: The PLATO-FT model with our proposed long-term memory (LTM).

---

[3] There are two stages within the PLATO-2 model, the first stage conduct candidate responses generation and the second stage conduct responses selection. We only implement our work on the first stage of PLATO-2.

- PLATO-LTM w/o PE: PLATO-LTM without the persona extractor (PE) module, which stores all history utterances (user and bot separately) into memory without persona extraction.

5.2 Experiment Settings

Automatic Evaluation Metrics. We use Precision, Recall and F1 to evaluate the persona classification model. For the long-term memory module, we use the AUC and recall@k to evaluate the ranking model. We evaluate responses generated by the models using PPL, BLEU (Papineni et al., 2002), and F1 with reference to the human-annotated responses and DISTINCT-1/2 (Zhao et al., 2017). More recently, Adiwardana et al. (2020) has shown the correlation between perplexity and human judgment in open-domain chit-chat models.

Human Evaluation Metrics. In human evaluation, we employ three utterance-level metrics, including coherence, consistency, engagingness. Three crowd-sourcing workers are asked to score the response/dialogue quality on a scale of [0, 1, 2]. The higher score, the better. These criteria are discussed as follows:

- Coherence: an utterance-level metric, measuring whether the response is relevant and consistent with the context.
- Consistency: an utterance-level metric, evaluating whether the response is consistent with the persona in the dialogue history.
- Engagingness: an utterance-level metric, assessing whether the annotator would like to talk with the speaker for each response in the long-term conversation.

5.3 Results

In this part, we first analyze the effects of each module and then analyze the results of the manual evaluation of our entire system, PLATO-LTM.

5.3.1 Results of Persona Extractor

We measure the performance of the persona extractor. To measure the performance of different models, we manually annotated the test set (the number of test sets is 200). We select the best of the first and second stages. The result is shown in Table 3. The pc-stage2 model is better than that of the pc-stage1 model. The F1 of the model exceeds 0.9, which shows that our model can effectively recognize the persona information from the dialogue history and ensure that the persona information can be correctly stored in the long-term memory. Therefore, the pc-stage2 model is adopted in our system to recognize the persona in the dialogue history.

Model	ACC	Precision	Recall	F1
pc-stage1	0.91	0.96	0.84	0.90
pc-stage2	0.92	0.95	0.87	0.91

Table 3: Comparison of two-stage models of our persona classifier.

5.3.2 Selection of Generative Models

The generative model utilizes the current context and persona information retrieved from long-term memory to generate the response. We first evaluate the effect of the CPM model on retrieval persona information. The AUC on the automatic test set is 0.76, recall@5 is 0.83, which shows that our model can efficiently retrieve relevant persona from the long-term memory.

The effect of the generative model reflects the model's ability to use the content of long-term memory to generate the response. Therefore, we select the best generative model to utilize better the retrieved persona information to generate. The result is shown in Table 4. We use the 12L model to conduct experiments to compare different models. The experiment results show that PLATO-FT + role_embed + role_token is the best. Compared to PLATO-FT, the PPL can decrease to 13.377, showing that both strategies are effective. In order to further improve the model, we increased the model size and further trained with the 32L model. Experiment results have shown that the PPL of the 32L model is lower than the 12L model by 4.4 and F1 increased by 2.5, which can further improve the generative model. Therefore, PLATO-FT 32L + role_embed + role_token model is adopted in our system.

5.3.3 Human Evaluation

Self-chat has been widely used in the evaluation of dialogue systems (Li et al., 2016b; Roller et al., 2021; Bao et al., 2020), where the model plays the roles of both parties in the dialogue. To better control variables, we use our proposed PLATO-LTM as a user simulator in our experiments and ask all chatbots (including PLATO-LTM) to chat sepa-

Model	PPL	BLUE-1/2	DISTINT-1/2	F1
PLATO-FT 12L	13.641	0.190/0.081	0.061/0.277	21.02
PLATO-FT 12L + role_embed	13.387	0.180/0.080	0.062/0.274	20.98
PLATO-FT 12L + role_token	13.553	0.193/0.081	0.060/0.272	21.28
PLATO-FT 12L + role_embed + role_token	**13.377**	**0.194/0.081**	0.060/0.267	**21.59**
PLATO-FT 32L + role_embed + role_token	9.380	0.194/0.087	0.068/0.296	22.61

Table 4: Comparison of automatic evaluation metric results among different generative models.

Model	Coherence	Consistency	Engagingness
PLATO-2	**1.70**	0.13	1.46
PLATO-FT	1.59	0.40	1.40
PLATO-LTM	1.67	**0.87**	**1.54**
PLATO-LTM w/o PE	1.57	0.49	1.43

Table 5: Comparison of human evaluation metric results on self-chat dialogues among our model and baselines. All the above generation models are 32L. The PLATO-FT is with role embedding and role token strategies.

rately with the user simulator. After that, the crowd-sourcing workers evaluate only the responses generated by the chatbots other than the simulator. The details are as follows.

Each chatbot chats with the user simulator for 10 episodes, each containing 4 long sessions, and each session contains 16 rounds. As in Bao et al. (2020), we do not impose any restrictions on the chats except for specifying session openings. We pre-select some session openings from the DuLeMon test set, start the interactive conversation with these openings, and ask the two bots to perform chats given the context.

The results are shown in Table 5, from which we can get the following key results:

(1) The long-Term Memory mechanism can significantly improve dialogue consistency. As shown in Table 5, in terms of dialogue consistency, our two models, PLATO-LTM and PLATO-FT, can achieve scores of 0.87 and 0.40, respectively, which is significantly better than the baseline model PLATO-2. Furthermore, when we compare the performance of PLATO-LTM with PLATO-FT, it can be seen that the use of Long-Term Memory and persona extractor can boost the performance of PLATO-FT with a relative improvement of 118%. Moreover, the model of PLATO-LTM w/o PE can achieve a score of 0.49, which is still better than the PLATO-FT model. It indicates that long-term memory without a persona extractor is still effective in improving persona consistency.

(2) With the long-term memory mechanism, the use of persona extractor can significantly improve persona consistency and dialogue engagingness. As shown in Table 5, in terms of dialogue consistency, the two models, PLATO-LTM (using PE) and PLATO-LTM w/o PE, can achieve scores of 0.87 and 0.49 respectively, indicating that the use of persona extractor can significantly improve dialogue consistency. In terms of dialogue engagingness, PLATO-LTM can obtain a score of 1.54, outperforming the baseline model PLATO-2. In addition, when we remove PE from PLATO-LTM, its performance drops from 1.54 (the score of PLATO-LTM) to 1.43 (that of PLATO-LTM w/o PE), indicating that the use of persona extractor can improve the performance of PLATO-FT.

(3) Fine-tuning on the small-scale dataset will slightly hurt the performance of pre-trained dialogue models in dialogue coherence. In terms of dialogue coherence, the PLATO-FT model (fine-tuned on our dataset) achieve a score of 1.59, which is lower than that of the baseline model PLATO (not finetuned on our dataset). The possible reason is that during the self-play procedure for system evaluation, their dialogs usually cover a wide range of topics, and then it is challenging to generate appropriate or coherent responses when given these open-domain topics in contexts. The finetuning procedure might hurt the capability of the pre-trained dialogue model in terms of response appropriateness or dialogue coherence, leading to the inferior performance of PLATO-LTM and its variants.

6 Conclusion

In this paper, We present a novel LeMon (Long-term Memory Conversation) task and then build the corresponding dataset DuLeMon, introducing long-term persona modelling into large-scale generative dialogue models. We further propose a Long-Term Memory (LTM) as a plug-in component of state-of-the-art large-scale generative dialogue models. LTM consists of user memory and chatbot memory, where the user memory is for understanding and memorizing persona information mentioned by the user, and the chatbot memory attempts to keep its persona information to be continuously updated over time. Experiment results show that our system PLATO-LTM can make effective use of both parties' persona information from dialogue history to enhance dialogue consistency and engagingness when conducting a long-term conversation. In the future, we will further study the possibility of using reinforcement learning with human feedback signals to help long-term conversation.

7 Ethical Considerations

We are sure that DuLeMon has been collected in a manner that is consistent with the terms of use of any sources and the intellectual property and privacy rights of the original authors of the texts. Meanwhile, our project is approved by an IRB. Finally, we also provide details on the characteristics of DuLeMon and steps taken to ensure the potential problems with the quality of the dataset do not create additional risks.

A Details of Data Collection

The collection processes of DuLeMon are as follows.

- The crowdworkers enter the chat interface in pairs, and role 1 initiates a conversation;
- The chat content can include opening greetings, self-introduction, chatting content that conforms to the persona information, asking the other party's questions, answering the other's questions, and so on. The information used in the chat must be consistent with the given personal information;
- The dialogue contains at least 8 turns (each person speaks at least 8 utterances);

At the same time, we also let the crowdworkers pay attention to the follows: 1. Use as many words as possible, and do not repeat them. The overall dialogue strives to be natural, smooth, and not embarrassing. 2. Do not simply copy and paste the sentences in the personal information and express them as richly as possible. If it is found that 50% of the fragments of any given sentence appear in the conversation, it is a non-compliant conversation. 3. When using persona information, do not copy it entirely, and talk about relevant content around the persona. For example, if the persona setting contains the sentence *"I am a painter"*, the response can be that *"I have painted many beautiful paintings and held several exhibitions"*; 4. If the question raised by the other speaker is not covered in the given personal information, the reply can be freely used; if there is any reference or related information in the given personal information, reply according it.

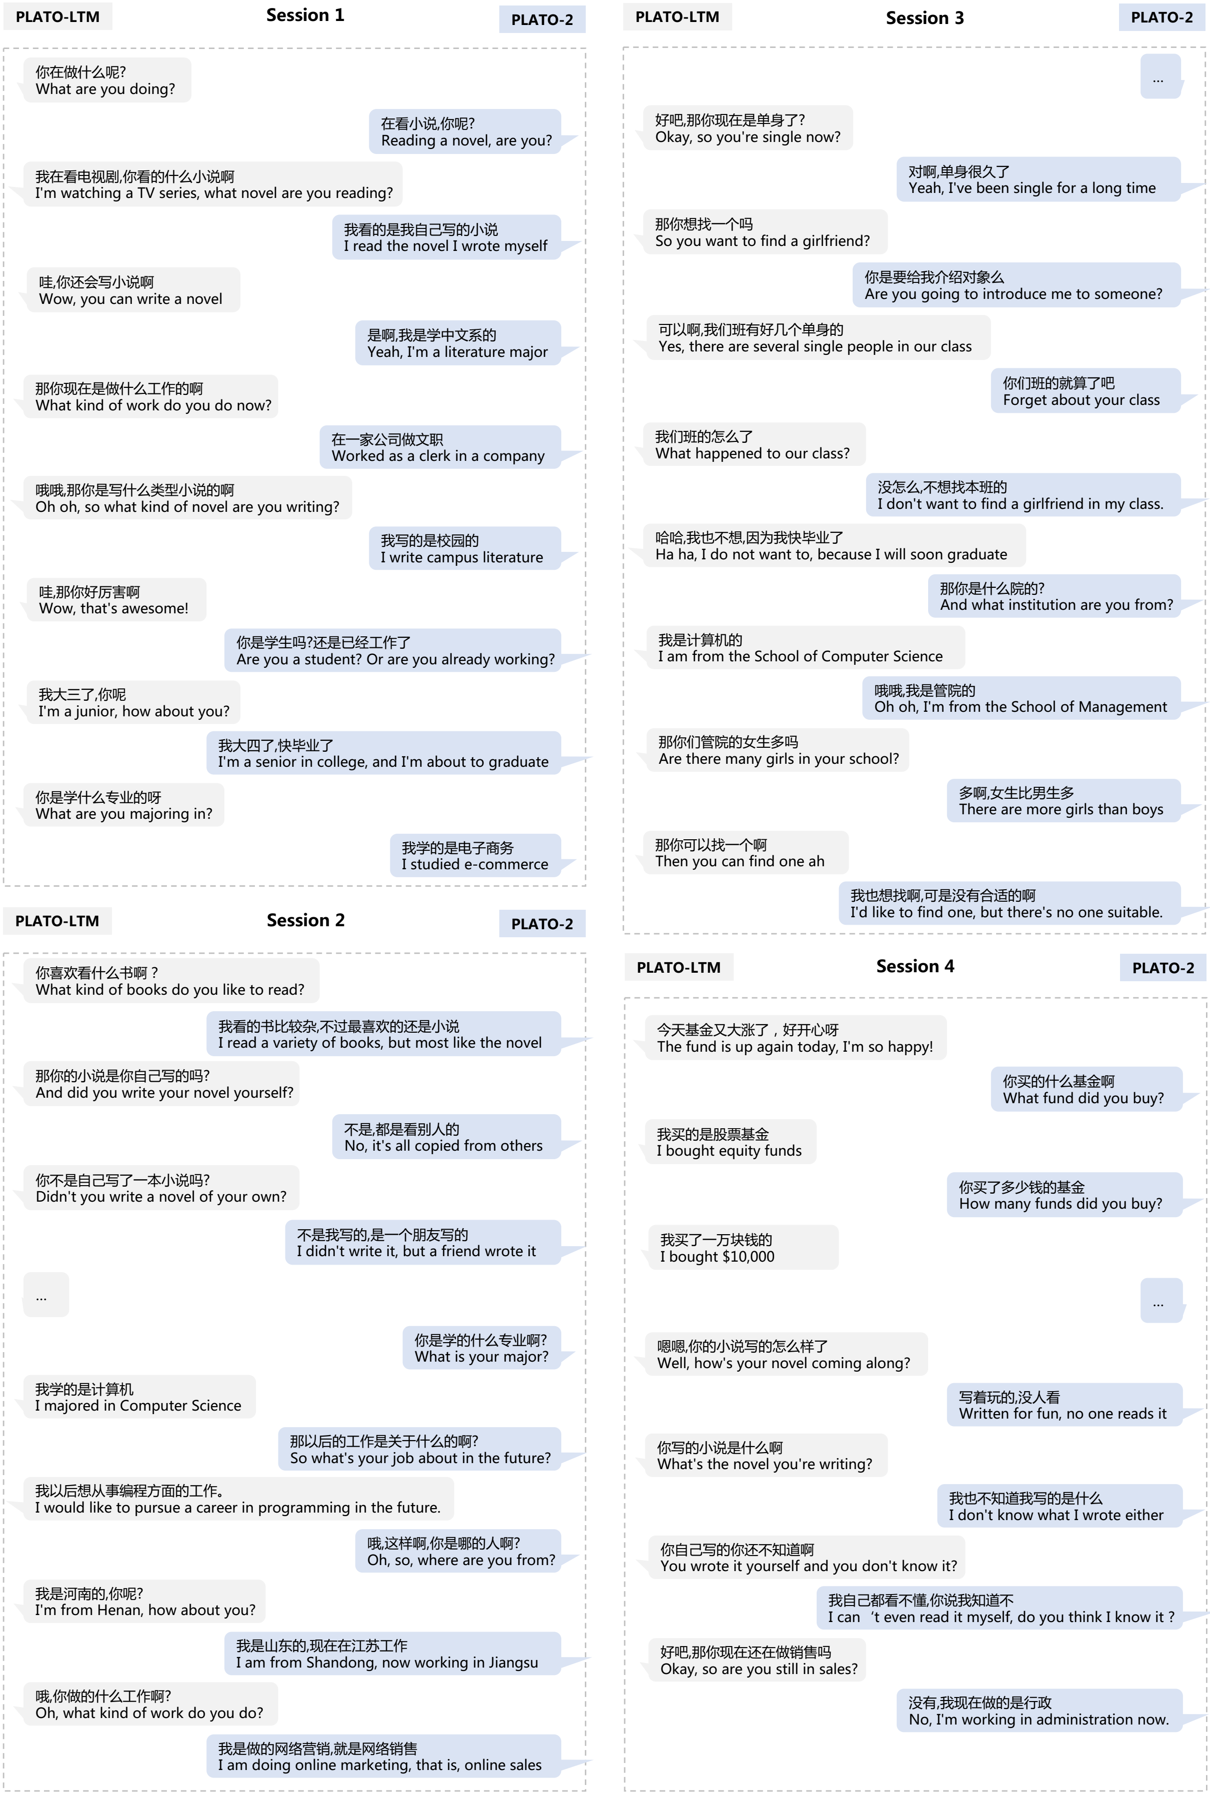
B Details of Models

Generation Model For the Generation model, We follow PLATO-2 (Bao et al., 2020). The maximum length of context, user persona, and chatbot persona are set to 384, 76, and 52, respectively. The vocabulary contains 30K Chinese BPE tokens. We optimize all models using Adam (Kingma and Ba, 2015) with every batch of $B = 16384$ tokens and learning rate of $lr = 5e - 5$. We conduct all experiments on NVIDIA V100 32GB and A100 48GB GPUs.

Long-term Memory For both user memory and chatbot memory, we set duplication threshold $s_{dup} = 0.95$, number of candidates $K = 5$, and similarity threshold $s_c = 0.7$. Due to the persona sparsity of dialogue and the efficiency of our persona storage, we do not limit the memory capacity.

C Cases of PLATO-LTM

To concretely demonstrate the long-term persona ability in a long-term conversation, we further provide a cherry-picked example of one episode conversation (between PLATO-LTM and PLATO-2) in Figure 4.



Session 1

你在做什么呢?
What are you doing?

在看小说,你呢?
Reading a novel, are you?

我在看电视剧,你看的什么小说啊
I'm watching a TV series, what novel are you reading?

我看的是我自己写的小说
I read the novel I wrote myself

哇,你还会写小说啊
Wow, you can write a novel

是啊,我是学中文系的
Yeah, I'm a literature major

那你现在是做什么工作的啊
What kind of work do you do now?

在一家公司做文职
Worked as a clerk in a company

哦哦,那你是写什么类型小说的啊
Oh oh, so what kind of novel are you writing?

我写的是校园的
I write campus literature

哇,那你好厉害啊
Wow, that's awesome!

你是学生吗?还是已经工作了
Are you a student? Or are you already working?

我大三了,你呢
I'm a junior, how about you?

我大四了,快毕业了
I'm a senior in college, and I'm about to graduate

你是学什么专业的呀
What are you majoring in?

我学的是电子商务
I studied e-commerce

Session 2

你喜欢看什么书啊？
What kind of books do you like to read?

我看的书比较杂,不过最喜欢的还是小说
I read a variety of books, but most like the novel

那你的小说是你自己写的吗?
And did you write your novel yourself?

不是,都是看别人的
No, it's all copied from others

你不是自己写了一本小说吗?
Didn't you write a novel of your own?

不是我写的,是一个朋友写的
I didn't write it, but a friend wrote it

...

你是学的什么专业啊?
What is your major?

我学的是计算机
I majored in Computer Science

那以后的工作是关于什么的啊?
So what's your job about in the future?

我以后想从事编程方面的工作。
I would like to pursue a career in programming in the future.

哦,这样啊,你是哪的人啊?
Oh, so, where are you from?

我是河南的,你呢?
I'm from Henan, how about you?

我是山东的,现在在江苏工作
I am from Shandong, now working in Jiangsu

哦,你做的什么工作啊?
Oh, what kind of work do you do?

我是做的网络营销,就是网络销售
I am doing online marketing, that is, online sales

Session 3

...

好吧,那你现在是单身了?
Okay, so you're single now?

对啊,单身很久了
Yeah, I've been single for a long time

那你想找一个吗
So you want to find a girlfriend?

你是要给我介绍对象么
Are you going to introduce me to someone?

可以啊,我们班有好几个单身的
Yes, there are several single people in our class

你们班的就算了吧
Forget about your class

我们班的怎么了
What happened to our class?

没怎么,不想找本班的
I don't want to find a girlfriend in my class.

哈哈,我也不想,因为我快毕业了
Ha ha, I do not want to, because I will soon graduate

那你是什么院的?
And what institution are you from?

我是计算机的
I am from the School of Computer Science

哦哦,我是管院的
Oh oh, I'm from the School of Management

那你们管院的女生多吗
Are there many girls in your school?

多啊,女生比男生多
There are more girls than boys

那你可以找一个啊
Then you can find one ah

我也想找啊,可是没有合适的啊
I'd like to find one, but there's no one suitable.

Session 4

今天基金又大涨了，好开心呀
The fund is up again today, I'm so happy!

你买的什么基金啊
What fund did you buy?

我买的是股票基金
I bought equity funds

你买了多少钱的基金
How many funds did you buy?

我买了一万块钱的
I bought $10,000

...

嗯嗯,你的小说写的怎么样了
Well, how's your novel coming along?

写着玩的,没人看
Written for fun, no one reads it

你写的小说是什么啊
What's the novel you're writing?

我也不知道我写的是什么
I don't know what I wrote either

你自己写的你还不知道啊
You wrote it yourself and you don't know it?

我自己都看不懂,你说我知道不
I can ‘t even read it myself, do you think I know it ?

好吧,那你现在还在做销售吗
Okay, so are you still in sales?

没有,我现在做的是行政
No, I'm working in administration now.

Abstract

Word embeddings are powerful dictionaries, which may easily capture language variations. However, these dictionaries fail to give sense to rare words, which are surprisingly often covered by traditional dictionaries. In this paper, we propose to use definitions retrieved in traditional dictionaries to produce word embeddings for rare words. For this purpose, we introduce two methods: Definition Neural Network (DefiNNet) and Define BERT (DefBERT). In our experiments, DefiNNet and DefBERT significantly outperform state-of-the-art as well as baseline methods devised for producing embeddings of unknown words. In fact, DefiNNet significantly outperforms FastText, which implements a method for the same task-based on n-grams, and DefBERT significantly outperforms the BERT method for OOV words. Then, definitions in traditional dictionaries are useful to build word embeddings for rare words.

1 Introduction

Words without meaning are like compasses without needles: pointless. Indeed, meaningless words lead compositionally to meaningless sentences and, consequently, to meaningless texts and conversations. Second language learners may grasp grammatical structures of sentences, but, if they are unaware of the meaning of single words in these sentences, they may fail to understand the whole sentences, especially when there is an insufficient context for unfamiliar words. This is why a large body of natural language processing research is devoted to devising ways to capture word meaning.

As language is a living body, distributional methods (Turney and Pantel, 2010; Mikolov et al., 2013; Pennington et al., 2014) are seen as the panacea to capture word meaning as opposed to more static models based on dictionaries (Fellbaum, 1998) and other lexical resources (Baker et al., 1998; Kipper et al., 2000). Distributional methods may easily capture new meaning of existing words and, eventually, can easily assign meaning to emerging words. In fact, the different methods can scan corpora and derive the meaning of these new words by observing them in context (Harris, 1954; Firth, 1950; Wittgenstein, 1953). Words are then represented as vectors – now called word embeddings – which are then used to feed neural networks to produce meaning for sentences (Bengio et al., 2003; İrsoy and Cardie, 2014; Kalchbrenner et al., 2014; Tai et al., 2015) and meaning for whole texts (Joulin et al., 2017; Lai et al., 2015).

Distributional methods have a strong limitation: word meaning can be assigned only for words where sufficient contexts can be gathered. Rare words are not covered and become the classical out-of-vocabulary words, which may hinder the understanding of specific yet important sentences. To overcome this problem, n-grams based distributional models have emerged (Joulin et al., 2016) where word meaning is obtained by composing *"meaning"* of character n-grams forming a word. These n-grams act as proto-morphemes and, hence, meaning of unknown words can be obtained by composing meaning of proto-morphemes.

Traditional dictionaries can offer a solution to find meaning of rare words. They have been put aside since they cannot easily adapt to language evolution and they cannot easily provide distributed representations for neural networks.

In this paper, we propose to use definitions in dictionaries to compositionally produce distributional representations for out-of-vocabulary (OOV) words. Trying to reproduce in a distributional setting the compositional properties that hold between symbols is a debated task since compositional dis-

Findings of the Association for Computational Linguistics: ACL 2022, pages 2651 - 2662
May 22-27, 2022

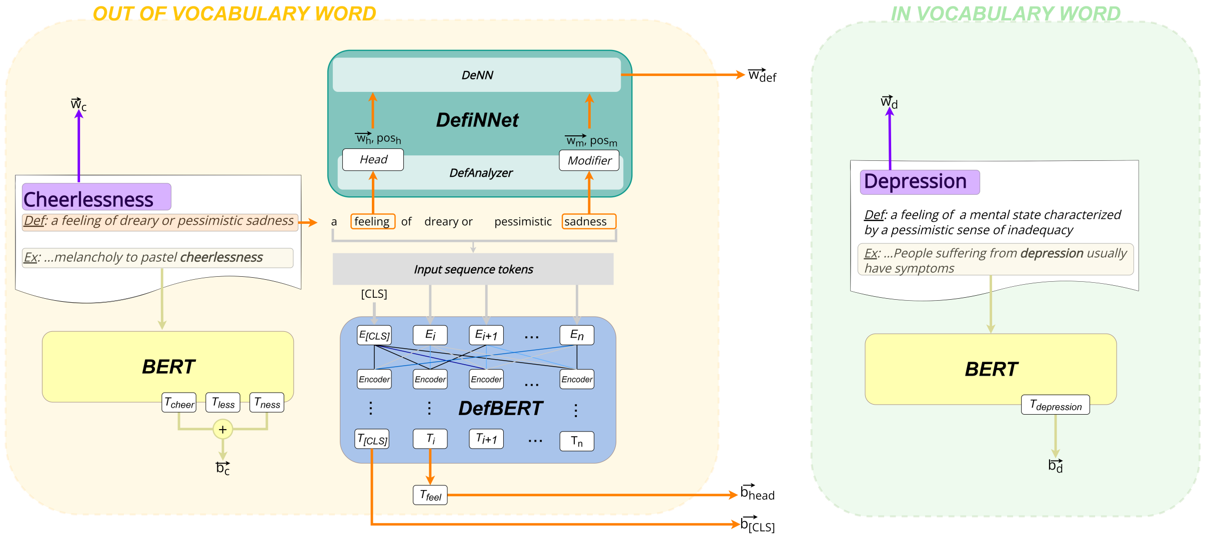

Figure 1: Exploiting definitions for out-of-vocabulary words: the DefiNNet and the DefBERT models.

tributional models were proposed (Mitchell and Lapata, 2008; Baroni and Zamparelli, 2010; Zanzotto and Dell'Arciprete, 2011; Paperno et al., 2014; Ferrone and Zanzotto, 2020). Definitions in dictionaries are intended to describe the meaning of a word to a human reader. Then, we propose two models to exploit definitions to derive the meaning of OOV words: (1) Definition Neural Network (DefiNNet), a simple neural network; (2) DefBERT, a model based on pre-trained BERT. We experimented with different tests and datasets derived from WordNet (Fellbaum, 1998). Firstly, we determined if DefiNNet and DefBERT can learn to derive word meaning from definitions. Secondly, we aimed to establish whether DefiNNet and DefBERT can cover OOV words, which are not covered by word2vec (Mikolov et al., 2013) or by the BERT pre-trained encoder, respectively. In our experiments, DefiNNet and DefBERT significantly outperform state-of-the-art as well as baseline methods devised for producing embeddings of unknown words. In fact, DefiNNet significantly outperforms FastText (Joulin et al., 2016), which implements a method for the same task-based on n-grams, and DefBERT significantly outperforms the BERT method for OOV words. Then, definitions in traditional dictionaries are useful to build word embeddings for rare words.

2 Background and Related Work

Out-of-vocabulary (OOV) words have been often a problem as these OOV words may hinder the applicability of many NLP systems. For example, if words are not included in a lexicon of a Probabilistic Context-Free Grammar, interpretations for sentences containing these words may have a null probability. Hence, solutions to this problem date back in time.

In the context of word embeddings, three families of solutions have been proposed: (1) context-based methods, (2) form-based methods, (3) combination of previous. The first family includes methods addressing the issue of learning new terms from tiny data either tuning existing models (Herbelot and Baroni, 2017) or performing a linear transformation on the average of all context word embedding (Khodak et al., 2018). In form-based methods, the most common solution is to use word n-grams (Joulin et al., 2016) or word pieces of variable length (Wu et al., 2016) as proxies to model morphemes. Embeddings are learned for 3-grams as well as for word pieces. In Joulin et al. (2016) these 3-grams are then combined to obtain the embedding for the entire word. For example, the word *cheerlessness*, which contains 3 morphemes (*cheer*, *less* and *ness*), is modeled by using embeddings for $\vec{che}$, $\vec{hee}$, ..., $\vec{ess}$ in the 3-gram approach and by using embeddings for $\vec{cheer}$ and $\vec{lessness}$ in the word pieces approach. These embeddings are possibly capturing information about the related morphemes. In this way, OOV word embeddings are correlated with meaningful bits of observed words. These models are our baselines. The last family includes methods taking into account both contextual and morphological information (Schick and Schütze, 2019; Hu et al., 2019; Schick and Schütze, 2020).

Deriving word embeddings for OOV words from dictionary definitions is an alternative approach. This approach has shown to be competitive in low resource scenarios in Bahdanau et al. (2017) where an LSTM model was fed with the definition. Dictionary definitions have been used in early attempts to train rudimentary compositional distributional semantic models (Zanzotto et al., 2010), which aimed to build embeddings for sequences of two words. In the word embedding field, several algorithms using definitions were proposed to build new embeddings matrices (Hill et al., 2016; Tissier et al., 2017; Bosc and Vincent, 2018). However, those methods are alternatives to the corpus-based distributional ones while our method is focused on tackling the OOV words problem, complementing existing word embedding spaces. Lexical resources have been also used exploiting their underlying semantic graph as an additional source of information (Pilehvar and Collier, 2017; Prokhorov et al., 2019). However, models based on those semantic graphs rely on a stronger assumption than models based on definitions only.

Universal sentence embedders (USEs) (Conneau et al., 2018) can play an important role in this novel approach. In fact, definitions are particular sentences aiming to describe meaning of words. Therefore, USEs should obtain an embedding representing the meaning of a word by composing embeddings of words in the definition.

Moreover, deriving word embeddings from definitions can be seen as a semantic stress test of universal sentence embedders. Generally, the ability of USEs (Devlin et al., 2019; Yang et al., 2020; Clark et al., 2020) to semantically model sentences is tested with end-to-end downstream tasks, for example, natural language inference (NLI) (Jiang and de Marneffe, 2019a; Raffel et al., 2020; He et al., 2021), question-answering (Zhang, 2019) as well as dialog systems (Wu et al., 2020). USEs such as BERT (Devlin et al., 2019) are encoding semantic features in hidden layers (Jawahar et al., 2019; Miaschi et al., 2020). However, USEs' success in downstream tasks may be due to superficial heuristics (as supposed in McCoy et al. (2019) and Ranaldi et al. (2022)) and not to deep modeling of semantic features. Therefore, our study can contribute to this debate. In fact, to the best of our knowledge, it is the first study aiming to investigate if USEs can model meaning by producing embedding for words starting from their definitions.

3 Model

This section introduces our proposals to use definitions in generating embeddings for out-of-vocabulary words: Definition Neural Network (DefiNNet) and BERT for Definitions (DefBERT). Section 3.1 describe the basic idea to process WordNet definitions. Section 3.2 describes the definition of the feed-forward neural network DefiNNet. Finally, Section 3.3 describes how we used the Universal Sentence Embedder BERT in producing embeddings for definitions.

3.1 Basic Idea

Our model stems from an observation: when someone steps into a rare unknown word while reading, definitions in traditional dictionaries are the natural resource used to understand the meaning of this rare, out-of-one's-personal-dictionary word. Then, as people rely on dictionaries in order to understand meanings for unknown words, learners of word embeddings could do the same.

Indeed, definitions in dictionaries are conceived to define compositionally the meaning of target words. Therefore, these are natural candidates for deriving a word embedding of an OOV word by composing the word embeddings of the words in the definition. The hunch is that universal sentence embedders can be used for this purpose.

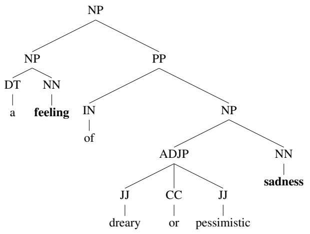
Moreover, these definitions have a recurrent structure, which can be definitely used to derive a simpler model. Definitions for words w are often organized as a particular sentence that contains the super-type of w and a modifier, which specializes the super-type (Amsler, 1980). For example (Fig. 1), *cheerlessness* is defined in WordNet as *a feeling*, which is the super-type, and *of dreary and pessimistic sadness*, which is the modifier. By using this structure, we propose a simpler model for composing meaning.

In the following sections, we propose two models: (1) DefiNNet, a model that exploits the structure of the definitions to focus on relevant words; and (2) DefBERT, a model that utilizes BERT as universal sentence embedder to embed the definition in a single vector.

3.2 DefiNNet: a feed-forward neural network to learn word embedding from definitions

The Definition Neural Network (DefiNNet) is our first model and has two main components (see Figure 1). The first component, *DefAnalyzer*, aims to spot the two important words of the definition: the super-type w_h and the main word w_m of the modifier of the super-type. The second component, *DeNN*, is a feed-forward neural network that takes in input the embeddings, $\vec{w}_h$ and $\vec{w}_m$, of the two selected words and produces the embedding for the target word $\vec{w}_{def}$.

To extract the two main words from a given definition, *DefAnalyzer* exploits the recurrent structure of definitions by using their syntactic interpretations. In our study, we use constituency parse trees and correlated rules to extract the super-type w_h and its closest modifier w_m. Basically, the simple algorithm is the following: given a definition s, parse the definition s and select the main constituent. If the main constituent contains a semantic head and a modifier, then those are the two target words. In the other case, select the semantic head of the main constituent as the super-type w_h and the semantic head of the first sub-constituent as the relevant modifier w_m. For example, the parse tree for the definition of $cherlessness$ in Fig. 1 is the following:



In this case, the main constituent is the first NP: the selected w_h is the word feeling which is semantic head of the first NP; w_m is noun sadness which is the semantic head of PP. The semantic heads are computed according to a slightly modified version of the semantic heads defined by Collins, 2003.

The second component is *DeNN* that, given the words embeddings $\vec{w}_h$ and $\vec{w}_m$ from the Word2Vec embedding space for respectively w_h and w_m from the definition, their POS tag p_h, p_m and the target's POS tag p_c as additional information, outputs the embedding $\vec{w}_c$ for the target word w_c. The input of DefiNNet is illustrated in Fig.1. The general equation for *DeNN* is:

$$\vec{w}_c = \mathbf{DeNN}(\vec{w}_h, \vec{w}_m, p_h, p_m, p_c)$$

The $\mathbf{DeNN}$ function can be described starting from three simpler subnets: (1) $\mathbf{FF}_w$ processes word embeddings $\vec{w}_h$ and $\vec{w}_m$; (2) $\mathbf{FF}_p$ embeds and processes p_h, p_m and p_c; finally, (3) $\mathbf{FF}$ processes the joint information from the previous steps.

The equation describing the subnet $\mathbf{FF}_w$ that takes as input $\vec{w}_h$ and $\vec{w}_m$ is the following:

$$\vec{s} = \mathbf{FF}_w(\vec{w}_h, \vec{w}_m) = \sigma(\mathbf{W}_s\sigma(\mathbf{W}_h\vec{w}_h + \mathbf{W}_m\vec{w}_m)) \tag{1}$$

where $\mathbf{W}_h$, $\mathbf{W}_m$ and $\mathbf{W}_s$ are dense layers and σ is the LeakyReLU activation function.

The subnet $\mathbf{FF}_p$ processes POS tags: p_h, p_m, p_c. Each p_i for $i \in \{h, m, c\}$ is firstly fed into an embedding layer ϵ which weights are learned from scratch. The resulting embedding $\epsilon(p_i)$ is then fed into a dense layer $\mathbf{W}_i$. Hence $\vec{p_i}$ is defined as follows:

$$\vec{p_i} = \mathbf{W}_i\epsilon(p_i)$$

The resulting $\vec{p}_h$, $\vec{p}_m$, $\vec{p}_c$ are then concatenated ($\oplus$) and fed into a dense layer $\mathbf{W}_p$. The following equation describes the subnet $\mathbf{FF}_p$:

$$\vec{p} = \mathbf{FF}_p(p_h, p_m, p_c) = \sigma(\mathbf{W}_p(\vec{p}_h \oplus \vec{p}_m \oplus \vec{p}_c) \tag{2}$$

The $\vec{s}$ resulting from Equation 1 and the $\vec{p}$ from Equation 2 are then concatenated ($\oplus$):

$$\vec{h} = \vec{s} \oplus \vec{p}$$

As final step $\vec{h}$ is fed into a feed-forward subnet $\mathbf{FF}$ composed of the dense layers $\mathbf{W}_1$, $\mathbf{W}_2$ and $\mathbf{W}_3$ as follows:

$$\mathbf{FF}(\vec{h}) = \mathbf{W}_3\sigma(\mathbf{W}_2(\sigma(\mathbf{W}_1\vec{h}))) \tag{3}$$

Hence the following:

$$\vec{w}_c = \mathbf{FF}(\mathbf{FF_w}(\vec{w}_h, \vec{w}_m), \mathbf{FF_p}(p_h, p_m, p_c))$$

describes how *DeNN* computes the embedding $\vec{w}_c$ for an OOV word having as input $\vec{w}_h$, $\vec{w}_m$, p_h, p_m from *DefAnalyzer* and p_c.

For comparative purposes, we defined two additional baseline models: an hypernym model ($Head$) and an additive model ($Additive$) (Mitchell and Lapata, 2008). The $Head$ model derives the embedding for the OOV word c by using the embedding for its hypernym h in WordNet, that is, $\vec{w}_c = \vec{w}_h$. The $Additive$ model instead adds the embeddings of the two words in the definition used by DefiNNet, that is, $\vec{w}_c = \vec{w}_h + \vec{w}_m$.

3.3 DefBERT: Transforming definitions in word embeddings

DefBERT aims to use BERT's ability to process sentences to use directly the definition for w_c in order to produce its embedding $\vec{w}_c$. DefBERT$_{[CLS]}$

and DefBERT$_{Head}$ are the approaches followed in exploiting the definition.

DefBERT$_{[CLS]}$ is the first of these approaches: in this case, the definition of w_c is given in input to a pretrained BERT-base model and, as shown in Figure 1, $\vec{b}_{[CLS]}$, the embedding for the [CLS] token, is taken as sentence embedding in the USE acceptation of BERT.

DefBERT$_{Head}$ is the second approach and in this case is selected $\vec{b}_{head}$, which is contextual embedding of $\vec{w_h}$ from the definition. Since BERT's embedding are contextual, $\vec{b}_{head}$ could benefit from the definition being the input sentence. A BERT pretrained model as USE in DefBERT$_{[CLS]}$ and its ability in producing contextualized word embeddings in DefBERT$_{Head}$ definition can hence be exploited in producing embeddings for OOV.

For comparative purposes, we also define BERT$_{wordpieces}$ and BERT$_{Head-Example}$. BERT$_{wordpieces}$ is used to see if our model outperforms the classical behavior of BERT when it encounters OOV words. In this case, BERT is fed with a sample sentence containing the target OOV word, for example *"... melancholy to pastel cheerlessness"* for the target OOV *"cheerlessness"* (see Figure 1). Then, the word is divided into word pieces. To obtain the embedding for the target word, we sum up vectors of these word pieces. BERT$_{Head-Example}$ instead is used to determine if definitions are really useful for modeling meaning of the head word. BERT$_{Head-Example}$ is similar to DefBERT$_{Head}$ but the input is different. BERT$_{Head-Example}$ has a random sentence that contains the head word. Hence, comparing DefBERT$_{Head}$ with BERT$_{Head-Example}$ gives intuition if the head in definition really absorbs its meaning.

4 Experiments

Experiments aim to investigate three issues: (1) if DefiNNet and DefBERT word embeddings are reasonably better than baseline models for indirectly generating embeddings; (2) the highly debated question whether similarity measures over WordNet are correlated with word embeddings (Lastra-Díaz et al., 2019); (3) finally, if DefiNNet and DefBERT word embeddings for out-of-vocabulary words obtained are good word representations in terms of their correlation with similarity measures on WordNet. Clearly, issue (2) is necessary to investigate issue (3).

The rest of the section is organized as follows. Section 4.1 introduces the general settings of our experiments. Section 4.2 presents results and it is organized in four subsections, which address the above three issues. If needed, these subsections introduce additional settings for the experiments.

4.1 Experimental set-up

Our experiments are defined around WordNet (Fellbaum, 1998) and around the two word embedding spaces of Word2Vec (Mikolov et al., 2013) (W_{w2v}) and of BERT (Devlin et al., 2019) (W_{BERT}). WordNet (Fellbaum, 1998) is the source of word definitions, it is used to collect testing sets of pairs of similar and dissimilar words and similarity measures over WordNet are used to rank them.

Then, IV_{w2v} and IV_{BERT} are WordNet words in the target embedding matrices W_{w2v} and W_{BERT}, respectively, and OOV_{w2v} and OOV_{BERT} are WordNet words outside these matrices.

Additionally, IV_{BERT} and OOV_{BERT} are restricted to words with usage example in WordNet as these examples are needed for applying DefBERT. The datasets derived from those sets are described in Table 1.

Word2Vec (Mikolov et al., 2013) and BERT (Devlin et al., 2019) offer instead large pre-trained word embedding spaces. Indeed, Word2Vec's embedding space (Mikolov et al., 2013) is pre-trained on part of Google News dataset (about 100 billion words) and the BERT's word embedding space (Devlin et al., 2019) is pre-trained on lower-cased English text from BooksCorpus (800M words) (Zhu et al., 2015) and English Wikipedia (2,500M words) as described by Devlin et al. (2019).

Dataset	Subset of	Size	
$Train_{w2v}$	IV_{w2v}	31,471 (train) 7,867 (val)	
$Test_{w2v}$	IV_{w2v}	9,931	
$Test_{BERT}$	IV_{BERT}	3,218	
Dataset	Subset of	Size	# Sublists
$Pairs_{IV_{w2v}}$	$IV_{w2v} \times IV_{w2v}$	14,000	2,000
$Pairs_{IV_{BERT}}$	$IV_{BERT} \times IV_{BERT}$	560	80
$Pairs_{IV_{fasttext}}$	$IV_{fasttext} \times IV_{fasttext}$	14,000	2,000
$Pairs_{w2v}$	$OOV_{w2v} \times IV_{w2v}$	4,500	600
$Pairs_{BERT}$	$OOV_{BERT} \times IV_{BERT}$	3,500	450
$Pairs_{w2v \cap BERT}$	$Pairs_{w2v} \cap Pairs_{BERT}$	450	60

Table 1: Datasets defined over WordNet

To investigate the first issue described at the beginning of this section, we introduced $Train_{w2v}$, $Test_{w2v}$, and $Test_{BERT}$. $Train_{w2v}$ is DefiNNet training set: this dataset contains definition for IV_{w2v} words since they are needed as target of

DefiNNet. $Test_{w2v}$ is a test dataset and it is completely analogous to $Train_{w2v}$ (Sec, 4.2.1). Since DefBERT$_{[CLS]}$ is not trained, $Test_{BERT}$ is the dataset prepared. Benchmarks on similarity and relatedness are also introduced in Sec 4.2.2

DefiNNet and DefBERT are also tested to assess their ability to produce embeddings for OOV that may replicate some similarity measure between words in pairs. The investigated pairs consist of WordNet "sister terms": two words are sister if they are both immediate hyponyms of the same node. In WordNet sister terms are definitely positive examples of similar words as well as negative example pairs can be generated by selecting pairs of words uniformly at random. $Pairs$ datasets are composed of positive or negative examples of sister terms. To address the second issue presented in Sec 4, $Pairs_{IV_{w2v}}$, $Pairs_{IV_{BERT}}$, $Pairs_{IV_{fasttext}}$ datasets are generated. In this datasets both w_1 and w_2 are IV words. Then, we collected two sets of pairs of words $Pairs_{w2v}$ and $Pairs_{BERT}$: those datasets are used to test if the correlation with similarity measures holds with OOV word embedding derived from DefiNNet or DefBERT. To capture different degrees of similarity among pairs of words in WordNet, we selected three similarity measures defined over WordNet: $path$ (Rada et al., 1989), wup (Wu and Palmer, 1994) and res (Resnik, 1995). To correctly apply Spearman's correlation between our systems and the expected rank on the list of pairs induced by a similarity measure, we divided $Pairs$ datasets into lists of 7 pairs. Pairs in the list are selected to have 7 clearly different values of the selected similarity ($path$, wup and res) between the two words. The final Spearman's correlation is a distribution of correlation over these lists.

To comparatively investigate our DefiNNet and DefBERT, we used FastText (Bojanowski et al., 2016) as realized in Grave et al. (2018) along with: (1) Additive and Head defined in Section 3.2; (2) BERT$_{wordpieces}$ and BERT$_{Head-Example}$ defined in Section 3.3. FastText defines embeddings unknown words c by combining embeddings of 3-grams, for example, the embedding for the OOV word *cheerlessness* is represented as the vector $\vec{f_c} = \vec{che} + \vec{hee} + ... + \vec{ess}$.

As final experimental setting, definitions are parsed using Stanford's CoreNLP probabilistic context-free grammar parser (Manning et al., 2014). NLTK (Loper and Bird, 2002) is used to access WordNet and compute similarity measures over it.

4.2 Results and discussion

For clarity, this section is organized around the three issues we aim to investigate: the ability of proposed methods to build embeddings of words starting from dictionary definitions (Sec. 4.2.1, Sec. 4.2.2); the debated relation between similarity over word embeddings and similarity in WordNet (Sec. 4.2.3); and, finally, the ability of the proposed methods to produce embeddings for OOV words (Sec. 4.2.4).

4.2.1 Word Embeddings from Dictionary Definitions

The first issue to investigate is whether our methods produce word embeddings from dictionary definitions that are similar with respect to word embeddings directly discovered. We then studied the cosine similarity between the two kinds of embeddings, for example, between the embedding of *cheerlessness* and the embedding of the definition *a feeling of .... sadness*. For the diffent methods, the comparison is on their own space, that is, $sim(\vec{w}_c, \vec{w}_{def})$ for DefiNNet and $sim(\vec{b}_c, \vec{b}_{[CLS]})$ or $sim(\vec{b}_c, \vec{b}_{head})$ for DefBERT$_{[CLS]}$ and DefBERT$_{Head}$, respectively (see Fig. 1). Experiments are conducted on In-Vocabulary words for both spaces by using the $Test_{w2v}$, $Test_{BERT}$ and $Test_{w2v \cap BERT}$ datasets.

		nouns	**verbs**
Dataset	*Model*	*sim*	*sim*
$Test_{w2v}$	Additive	$0.25(\pm0.17)^{\circ}$	$0.29(\pm0.19)^{\circ}$
	Head	$0.26(\pm0.21)^{\star}$	$0.29(\pm0.25)^{\star}$
	DefiNNet	$\mathbf{0.39}(\pm\mathbf{0.18})^{\circ\star}$	$\mathbf{0.46}(\pm\mathbf{0.14})^{\circ\star}$
$Test_{BERT}$	DefBERT$_{Head}$	$\mathbf{0.46}(\pm\mathbf{0.13})^{\dagger\ddagger}$	$\mathbf{0.41}(\pm\mathbf{0.14})^{\dagger\ddagger}$
	DefBERT$_{[CLS]}$	$0.32(\pm0.08)^{\dagger}$	$0.30(\pm0.09)^{\dagger}$
	BERT$_{Head-Example}$	$0.41(\pm0.12)^{\ddagger}$	$0.39(\pm0.12)^{\ddagger}$
$Test_{w2v \cap BERT}$	DefBERT$_{Head}$	$\mathbf{0.47}(\pm\mathbf{0.13})^{\dagger\triangle}$	$0.42(\pm0.15)^{\dagger\triangle}$
	DefBERT$_{[CLS]}$	$0.28(\pm0.09)^{\dagger\diamond}$	$0.30(\pm0.09)^{\dagger\diamond}$
	DefiNNet	$0.33(\pm0.13)^{\triangle\diamond}$	$\mathbf{0.47}(\pm\mathbf{0.13})^{\triangle\diamond}$

Table 2: Cosine similarity between word embeddings and embeddings of their definitions. The marking signs $\star$, $\circ$, $\dagger$, $\ddagger$ and $\diamond$ indicate pairs of models results for which the higher result is statistically significant better than the other (with a 95% confidence level) according to the one-sided Wilcoxon signed-rank test.

Definitions seem to be better sources of word embeddings instead of baseline methods and other solutions. In fact, both DefiNNet and DefBERT$_{Head}$ outperform different methods in their respective tests for both nouns and verbs (see Table 2). For nouns, DefiNNet has an average cosine similarity of $0.39(\pm0.18)$, which is well above that of Additive $(0.25(\pm17))$ and Head $(0.26(\pm21))$.

In the same syntactic category, DefBERT$_{Head}$ outperforms BERT$_{Head-Example}$, $0.46(\pm 0.13)$ vs. $0.41(\pm 0.12)$. For verbs, DefiNNet has an average cosine similarity of $0.46(\pm 0.14)$, which is well above the Additive and the Head. In the same category, DefBERT$_{Head}$ slightly outperforms BERT$_{Head-Example}$. Finally, in the common test, that is, $Test_{w2v\cap BERT}$, definition-based models outperform simpler models. DefBERT$_{Head}$ has a better similarity for nouns and DefiNNet has a better similarity for verbs.

For BERT, the embedding related to the token [CLS] does not seem to represent the good token where to take semantics of the sentence in terms of a real composition of the meaning of component words. DefBERT$_{[CLS]}$ performs poorly with respect to DefBERT$_{Head}$ and also with respect to BERT$_{Head-Example}$ in both syntactic categories for $Test_{BERT}$ (see Table 2). This is confirmed in the restricted set $Test_{w2v\cap BERT}$. Therefore, even if the embedding in token [CLS] is often used as universal sentence embedding for classification purposes (Devlin et al., 2019; Adhikari et al., 2019; Jiang and de Marneffe, 2019b), it may not contain packed meaning whereas it may contain other kinds of information regarding the sentence.

4.2.2 Standard Relatedness and Similarity Tests

In this section, DefiNNet embeddings are evaluated by measuring their ability to capture similarity and relatedness of words pairs. The used benchmarks contain words pairs and a score of similarity for each pair assigned by human assessors. If the similarity among embeddings correlates with the assigned similarity score, then the embeddings are considered capable of capturing similarity and relatedness. In this scenario, the first word's embedding of each pair is computed according to the examined method, the second embedding comes from the Word2Vec embedding space. The obtained Spearman's coefficients are presented in Table 3. Head and Additive baseline models are also tested.

DefiNNet achieves better correlation with all the tested relatedness benchmarks: `MEN` (Bruni et al., 2014), `MTurk-287` (Radinsky et al., 2011) and `MTurk-771` (Halawi et al., 2012). Among the similarity benchmarks, DefiNNet outperforms the Additive and Head baseline in different tasks. With `RareWords` (Luong et al., 2013), composed of words with low occurrences, DefiNNet significantly outperforms both baselines. The correlation coefficients calculated with `SimLex999` (Hill et al., 2015) are instead closer and relatively lower. Head achieves the best results with the smaller `RG-65` (Rubenstein and Goodenough, 1965) and its subset `MC-30` (Miller and Charles, 1991). DefiNNet achieves a higher Spearman's coefficient in `SimVerb-3500` (Gerz et al., 2016), `Verb-143` (Baker et al., 2014) and `YP-130` (Yang and Powers, 2006) which assess similarity on verbs pair.

Benchmark	DefiNNet	Head	Additive
`MEN`	$\mathbf{0.48}(\pm\mathbf{0.01})^{\diamond\dagger}$	$0.37^{\diamond}$	$0.39^{\dagger}$
`MTurk-287`	$\mathbf{0.46}(\pm\mathbf{0.02})^{\diamond\dagger}$	$0.39^{\diamond}$	$0.39^{\dagger}$
`MTurk-771`	$\mathbf{0.37}(\pm\mathbf{0.01})^{\diamond\dagger}$	$0.33^{\diamond}$	$0.33^{\dagger}$
`RareWords`	$\mathbf{0.32}(\pm\mathbf{0.01})^{\diamond\dagger}$	$0.20^{\diamond}$	$0.02^{\dagger}$
`SimLex999`	$0.18(\pm 0.01)^{\diamond\dagger}$	$0.15^{\diamond}$	$\mathbf{0.19}^{\dagger}$
`RG-65`	$0.43(\pm 0.04)^{\diamond}$	$\mathbf{0.63}^{\diamond}$	0.41
`MC-30`	$0.27(\pm 0.07)^{\diamond\dagger}$	$\mathbf{0.71}^{\diamond}$	$0.33^{\dagger}$
`SimVerb-3500`	$\mathbf{0.27}(\pm\mathbf{0.01})^{\diamond\dagger}$	$0.22^{\diamond}$	$0.22^{\dagger}$
`Verb-143`	$\mathbf{0.41}(\pm\mathbf{0.02})^{\diamond\dagger}$	$0.25^{\diamond}$	$0.26^{\dagger}$
`YP-130`	$\mathbf{0.43}(\pm\mathbf{0.02})^{\diamond\dagger}$	$0.27^{\diamond}$	$0.27^{\dagger}$

Table 3: Spearman's correlation coefficients on similarity and relatedness benchmarks. Mean and standard deviation results in DefiNNet are obtained from 10 runs. The symbols ◇ and † indicate a statistically significant difference between two results (with a 95% confidence level) according to the one-sided Wilcoxon signed-rank test.

4.2.3 Word Embedding Spaces and WordNet

WordNet and its correlated similarly metrics can be an interesting opportunity to extract testsets for assessing whether our methods can be used to derive embeddings of OOV words. However, it is a strongly debated question whether similarities in WordNet are correlated with similarities over word embeddings (Lastra-Díaz et al., 2019).

Model	*Dataset*	*Measure*	*Spearman*
Word2Vec	$Pairs_{IV w2v}$	*path*	$0.25(\pm 0.39)$
		wup	$0.25(\pm 0.38)$
		res	$0.50(\pm 0.31)$
FastText	$Pairs_{IV fasttext}$	*path*	$0.31(\pm 0.38)$
		wup	$0.40(\pm 0.35)$
		res	$0.52(\pm 0.29)$
BERT	$Pairs_{IV BERT}$	*path*	$0.09(\pm 0.41)$
		wup	$0.30(\pm 0.39)$
		res	$0.28(\pm 0.38)$

Table 4: Average Spearman's coefficient measuring correlation on cosine similarity among embedding and similarity over WordNet taxonomy.

The aim of this section is to select WordNet

Dataset	*Model*	*Corr(path)*	*Corr(wup)*	*Corr(res)*
$Pairs_{w2v}$	Additive	$\mathbf{0.24}(\pm\mathbf{0.40})^{\circ}$	$0.46(\pm0.32)^{\circ}$	$0.44(\pm0.34)^{\circ}$
	Head	$0.23(\pm0.37)^{\star}$	$0.49(\pm0.30)$	$0.49(\pm0.31)^{\star}$
	FastText	$0.07(\pm0.40)$	$0.43(\pm0.36)^{\diamond}$	$0.41(\pm0.35)^{\diamond}$
	DefiNNet	$0.03(\pm0.42)^{\circ\star}$	$\mathbf{0.50}(\pm\mathbf{0.31})^{\circ\diamond}$	$\mathbf{0.51}(\pm\mathbf{0.31})^{\circ\star\diamond}$
$Pairs_{BERT}$	DefBERT$_{Head}$	$\mathbf{0.27}(\pm\mathbf{0.36})^{\ddagger\bullet}$	$\mathbf{0.33}(\pm\mathbf{0.37})^{\dagger\ddagger\bullet}$	$\mathbf{0.31}(\pm\mathbf{0.36})^{\dagger\ddagger\bullet}$
	DefBERT$_{[CLS]}$	$0.26(\pm0.36)$	$0.17(\pm0.37)\dagger$	$0.11(\pm0.39)^{\dagger}$
	BERT$_{Head-Example}$	$0.15(\pm0.41)^{\ddagger}$	$0.25(\pm0.38)^{\ddagger}$	$0.19(\pm0.40)^{\ddagger}$
	BERT$_{wordpieces}$	$0.09(\pm0.37)^{\bullet}$	$0.19(\pm0.37)^{\bullet}$	$0.23(\pm0.38)^{\bullet}$
$Pairs_{w2v\cap BERT}$	DefBERT$_{Head}$	$0.12(\pm0.44)^{\diamond}$	$0.33(\pm0.36)^{\bullet}$	$0.27(\pm0.39)^{\bullet}$
	DefiNNet	$\mathbf{0.31}(\pm\mathbf{0.37})^{\diamond\triangle}$	$\mathbf{0.39}(\pm\mathbf{0.33})^{\triangle}$	$\mathbf{0.35}(\pm\mathbf{0.36})^{\triangle}$
	FastText	$0.19(\pm0.42)$	$0.35(\pm0.36)$	$0.32(\pm0.37)$
	BERT$_{wordpieces}$	$0.11(\pm0.37)^{\triangle}$	$0.14(\pm0.42)^{\bullet\triangle}$	$0.18(\pm0.34)^{\bullet\triangle}$

Table 5: Average Spearman's coefficient from the sister terms investigation. The marking signs $\star$, $\circ$, $\bullet$, $\dagger$, $\ddagger$, $\triangle$ and $\diamond$ indicate pairs of models results for which the higher result is statistically significant better than the other (with a 95% confidence level) according to the one-sided Wilcoxon signed-rank test.

similarity measures that can be used to investigate the quality of embeddings generated for OOV words. For this experimental session, we used the $Pairs_{IV_{w2v}}$, $Pairs_{IV_{BERT}}$ and $Pairs_{IV_{fasttext}}$ datasets defined in Section 4.1, which are composed of sister terms in WordNet.

Sister terms may be very similar or less similar. For example, *cheerlessness* and *depression* (see Figure 1) are sister terms and are definitely similar. On the contrary, *house* and *architecture* are sister terms but are less similar with respect to the previous pair of words. In WordNet, this difference in similarity is captured by using many different metrics.

We investigated three different WordNet similarity measures: $path$ (Rada et al., 1989), wup (Wu and Palmer, 1994) and res (Resnik, 1995). The measure $path$ uses the length of the path connecting two synsets over the WordNet taxonomy. The measure wup is still based on the length of path between the synsets related to the two words and takes into account the number of edges from synsets to their Least Common Subsumer (LCS) and the number of links from the LCS up to the root of the taxonomy. Finally, the measure res belongs to another family of measures as it is based on the Information Content. In res, the similarity between synsets of the related words is a function of the Information Content of their LCS. In this case, a more informative LCS (a rare as well as a specific concept) indicates that the hyponym concepts are more similar.

The best correlated WordNet measure is res. In fact, it is highly correlated for two spaces out of three, Word2Vec and FastText, and it is on par with wup in the BERT space (see 4). The average Spearman's correlation between the word embedding spaces of Word2Vec and res is $0.50(\pm0.31)$, which is well above $path$ and wup. The same happens for the space FastText where the correlation is $0.52(\pm0.29)$.

As a final consideration, for our purposes, word embedding spaces are correlated and the best measure that captures this correlation is res.

4.2.4 Testing over out-of-vocabulary words

The final analysis is on real OOV words for Word2Vec and for BERT. These last experiments are carried out by considering the positive relation between WordNet similarity measures and the word embedding spaces.

Using definitions for deriving word embeddings for OOV words seems to be the good solution compared to alternative available approaches.

In its space, DefiNNet achieves very important results for the correlation with the two WordNet similarity measures wup and res (see Table 5). In both cases, it outperforms FastText, which is a standard approach for deriving word embeddings for OOV words (0.51 ± 0.31 vs. 0.41 ± 0.35 for res and 0.50 ± 0.30 vs. 0.43 ± 0.36 for wup). Moreover, DefiNNet outperforms Head, a baseline method based on WordNet, and Additive, the simplest model to use WordNet definitions.

The same happens for DefBERT$_{Head}$ in its space (see Table 5). DefBERT$_{Head}$ significantly outperforms BERT$_{wordpieces}$, showing that DefBERT$_{Head}$ is a better model to treat OOV with respect to that already included in BERT. Results on DefBERT$_{Head}$ confirm that the output related to the token representing the head carries better information than the output related to the token [CLS]. Moreover, the definition has is a positive effect on shaping the word embedding of the head word towards the defined word. In fact, DefBERT$_{Head}$ and BERT$_{Head-Example}$ are applied on the same head word and DefBERT$_{Head}$ transforms better the meaning than BERT$_{Head-Example}$, which is applied to a random sentence containing the head word. Indeed, also for BERT, definitions are important in determining embeddings of OOV words.

The final comparison is between DefiNNet and DefBERT$_{Head}$ and it is done on the small dataset $Pairs_{w2n \cap BERT}$. DefiNNet achieves better results than DefBERT$_{Head}$ for all the three WordNet measures (see Table 5) but statistical significance between them cannot be asserted with the fixed p-value (0.05).

5 Conclusions and Future Work

Building word embedding for rare out-of-vocabulary words is essential in natural language processing systems based on neural networks. In this paper, we proposed to use definitions in dictionaries to solve this problem. Our results show that this can be a viable solution to retrieve word embedding for OOV rare words, which work better than existing methods and baseline systems.

Moreover, the use of dictionary definitions in word embedding may open also another possible line of research: a different semantic probe for universal sentence embedders (USEs). Indeed, definitions offer a definitely interesting equivalence between sentences and words. Hence, unlike existing semantic probes, this approach can unveil if USEs are really changing compositionally the meaning of sentences or are just aggregating pieces of sentences in a single representation.

Finally, this paper promotes responsible Artificial Intelligence as intended in Human-in-the-Loop Artificial Intelligence (Zanzotto, 2019). In fact, it gives the possibility to track how human knowledge is used by learning algorithms.

Acknowledgments

This work is partially funded by the 2019 BRIC INAIL ID32 SfidaNow project. We would like to thank Giorgio Gambosi, Arianna Patrizi and Aria Nourbakhsh for the useful discussions.

Abstract

Existing news recommendation methods usually learn news representations solely based on news titles. To sufficiently utilize other fields of news information such as category and entities, some methods treat each field as an additional feature and combine different feature vectors with attentive pooling. With the adoption of large pre-trained models like BERT in news recommendation, the above way to incorporate multi-field information may encounter challenges: the shallow feature encoding to compress the category and entity information is not compatible with the deep BERT encoding. In this paper, we propose a multi-task learning framework to incorporate the multi-field information into BERT, which improves its news encoding capability. Besides, we modify the gradients of different tasks based on their gradient conflicts, which further boosts the model performance. Extensive experiments on the MIND news recommendation benchmark show the effectiveness of our approach.

1 Introduction

Online News platforms such as Google News and MSN News have become a prevalent way for users to access news information (Das et al., 2007). To alleviate information overload and improve the reading experience, personalized news recommendation has become an essential part of these platforms (Liu et al., 2010; Phelan et al., 2011).

Traditional Recommendation models focus on modeling feature interactions (Rendle, 2012; Cheng et al., 2016; Guo et al., 2017; Wang et al., 2017). Accurate modeling of news and users is critical for news representation. Previous neural methods usually learn news representation vectors solely based on news titles and then learn a user representation by aggregating the previously browsed news via sequential or attentive models (Okura et al., 2017; An et al., 2019; Wu et al., 2019d). Though effective, these methods only utilize the title information and neglect other valuable news information such as categories and entities, which we call multi-field information. To fully utilize this information, as shown in Figure 1, existing methods usually transform each field of information (e.g., title, category, and entities) into a feature vector and combine different representations via attentive multi-field learning (Wu et al., 2019a, 2021a).

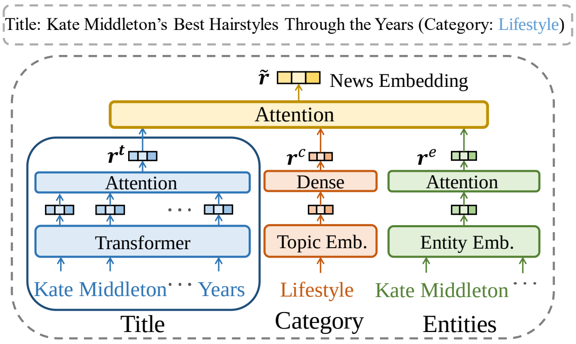

Figure 1: Traditional way to incorporate multi-field news information with attentive multi-field learning.

With the widespread use of large pre-trained language models, news recommendations start to adopt BERT (Devlin et al., 2019) as the cornerstone to encode news contents (e.g., encoding title as the blue box in Figure 1). However, when employing the above attentive way to combine other fields of information, we may encounter challenges: the shallow feature encoding to compress the category and entity information is *not compatible* with the deep BERT encoding for the title. Consequently, the ineffective adaption of multi-field information arises when we employ large pre-trained models in news recommendation.

In this paper, we propose a novel multi-task learning (Collobert and Weston, 2008; Stickland and Murray, 2019; Li et al., 2019) framework over BERT for news recommendation, named *MTRec*,

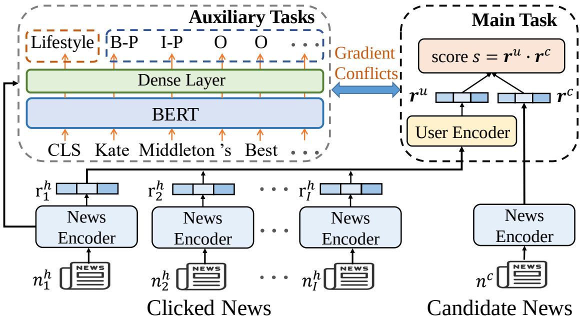

Figure 2: The overall framework of *MTRec*. We employ BERT as the news encoder and additive attention as the user encoder. In addition to the main task of news recommendation, we design two auxiliary tasks (i.e., category classification and NER) to further incorporate the category and entity information.

to effectively incorporate the multi-field information. Specifically, we use BERT to encode the news title as news embedding, and design two auxiliary tasks on top of BERT, i.e., category classification and named entity recognition (NER). The two auxiliary tasks are trained together with the main news recommendation task. We believe such a multi-task way can help BERT better capture the news semantics. To further improve the model performance, we adopt the recently proposed *gradient surgery* technique (Yu et al., 2020) which eliminates the gradient conflicts among different tasks during the multi-task training. While Zhang et al. (2021) study homogeneous multi-field news information including titles, abstracts and bodies, we study titles, categories and entities, which are heterogeneous thus can provide valuable information from different perspectives.

Finally, we find that combining the proposed multi-task learning and traditional attentive multi-field learning can further boost the performance of our model. Extensive experiments on the real-world MIND (Wu et al., 2020) news recommendation dataset show that *MTRec* can effectively improve the accuracy of news recommendation.

2 Method

Given I historical clicked news of a user $N^h = [n_1^h, n_2^h, ..., n_I^h]$ and a set of candidate news $N^c = [n_1^c, n_2^c, ..., n_J^c]$. Our goal is to calculate the user interest score s_j of each candidate news according to the historical behavior of the user, then the candidate news with the highest interest score is recommended to the user. For each news, we have its title text T, category label p^c, and entity set $\mathcal{E}$.

2.1 News Recommendation Framework

As shown in Figure 2, there are three main components in news recommendation framework, i.e., a *news encoder*, a *user encoder*, and a *click predictor*.

News Encoder For each news n, we encode its title with pre-trained BRET (Devlin et al., 2019). Specifically, we feed the tokenized text T into the BERT model and adopt the embedding of [CLS] token as the news representation $\mathbf{r}$. We denote the encoded vectors of historical clicked news N^h and candidate news N^c as $\mathbf{R}^h = [\mathbf{r}_1^h, \mathbf{r}_2^h, ..., \mathbf{r}_I^h]$ and $\mathbf{R}^c = [\mathbf{r}_1^c, \mathbf{r}_2^c, ..., \mathbf{r}_J^c]$, respectively.

User Encoder To gain a user representation from the representations of historical clicked news, existing methods usually employ sequential (An et al., 2019) or attentive models (Wu et al., 2019d; Li et al., 2018). In this paper, we adopt additive attention as the user encoder to compress the historical information $\mathbf{R}^h$. The user representation $\mathbf{r}^u$ is then denoted as:

$$\mathbf{r}^u = \sum_{i=1}^{I} a_i^u \mathbf{r}_i^h, \ \ a_i^u = \mathrm{softmax}(\mathbf{q}^u \cdot \tanh(\mathbf{W}^u \mathbf{r}_i^h)), \tag{1}$$

where $\mathbf{q}^u$ and $\mathbf{W}^u$ are trainable parameters.

Click Predictor For each candidate news, we obtain its interest score s_j by matching the candidate news vector $\mathbf{r}_j^c$ and the user representation $\mathbf{r}^u$ via dot product:

$$s_j = \mathbf{r}_j^c \cdot \mathbf{r}^u. \tag{2}$$

Loss Function Following previous work (Huang et al., 2013; Wu et al., 2019d), we employ the NCE loss to train the main ranking model. Then the main task loss $\mathcal{L}_{Main}$ is the negative log-likelihood of all positive samples in the training dataset $\mathcal{D}$:

$$\mathcal{L}_{Main} = -\sum_{i=1}^{|\mathcal{D}|} \log \frac{\exp(s_i^+)}{\exp(s_i^+) + \sum_{j=1}^{L} \exp(s_i^j)}, \tag{3}$$

where s^+ denotes the interest scores of positive news, L indicates the number of negative news.

2.2 Multi-Field Information

Besides the contents of news (e.g., titles), there is also other valuable information available in news recommendation, for example, category labels and entity annotations, which we call multi-field information. To fully utilize the multi-field information, existing methods usually treat them as additional input features (Wu et al., 2019a, 2021a). As the example in Figure 1, each field of information (i.e., title, category, and entities) is firstly transformed into vectors via embedding lookup and attention mechanisms. Then the representations $\mathcal{R} = \{\mathbf{r}^t, \mathbf{r}^c, \mathbf{r}^e\}$ for title, category and entities are combined as the final news representation $\widetilde{\mathbf{r}}$ via attentive multi-field learning[1]:

$$\widetilde{\mathbf{r}} = \sum_{\mathbf{r}_i \in \mathcal{R}} w_i \mathbf{r}_i, \;\; w_i = \mathrm{softmax}(\mathbf{q}^r \cdot \tanh(\mathbf{W}^r \mathbf{r}_i)), \tag{4}$$

where $\mathbf{q}^r$ and $\mathbf{W}^r$ are trainable parameters.

Though effective with traditional text encoding, attentive multi-field learning may not work well with deep BERT encoding. Since the shallow feature encoding to compress the category and entity information may not be in the same feature space with the deep BERT encoding, directly combining them together may cause *incompatibility* problem thus ineffective use of multi-field information.

2.3 Multi-Task Learning

To effectively utilize the multi-field information with the BERT news encoder, we propose to employ multi-task learning with two auxiliary tasks on top of BERT: category classification and named entity recognition, as illustrated in Figure 2.

Category Classification To incorporate the news category information, we design a classification task on top of BERT, which uses the [CLS] embedding to predict the category distribution of news n_i:

$$\hat{\mathbf{p}}_i^c = \mathrm{softmax}(\mathbf{W}^c \mathbf{r}_i + \mathbf{b}^c), \tag{5}$$

where $\mathbf{b}^c$ and $\mathbf{W}^c$ are trainable parameters. Then the loss function of category classification task is:

$$\mathcal{L}_{\text{Category}} = -\frac{1}{I} \sum_{i=1}^{I} \sum_{k=1}^{K^c} p_{i,k}^c \log(\hat{p}_{i,k}^c)), \tag{6}$$

where K^c is the number of categories.

Named Entity Recognition We also design a NER task (Lample et al., 2016) on top of BERT, so that the model can recognize important entities in the title thus better matching interested news. Specifically, we locate the given entities in the news title according to exact match and use "B" to indicate the beginning word of an entity, "I" to indicate the internal words. The other non-entity words in the title are denoted as "O". Then a tag prediction task is performed based on the BERT output embeddings:

$$\hat{\mathbf{p}}_{t_i}^n = \mathrm{softmax}(\mathbf{W}^n \mathbf{r}^{t_i} + \mathbf{b}^n), \tag{7}$$

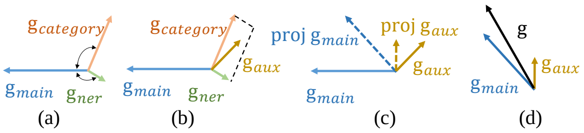

Figure 3: Illustration of the Gradient Surgery (GS).

where $\mathbf{r}^{t_i}$ is the output embedding of i-th token, $\mathbf{b}^n$ and $\mathbf{W}^n$ are trainable parameters. The loss function of the NER task is thus formulated as:

$$\mathcal{L}_{\text{NER}} = -\frac{1}{I} \sum_{i=1}^{I} \sum_{l=1}^{l_i} \sum_{k=1}^{K^n} p_{l,k}^n \log(\hat{p}_{l,k}^n)), \tag{8}$$

where K^n is the number of all NER tags, l_i is the title length of i-th news.

We optimize the loss function of the main task, category classification, and NER task simultaneously, which derives the final loss function:

$$\mathcal{L}_{\text{MTRec}} = \mathcal{L}_{\text{Main}} + \mathcal{L}_{\text{Category}} + \mathcal{L}_{\text{NER}}. \tag{9}$$

Multi-Task Learning with Gradient Surgery Yu et al. (2020) find that multi-task learning is not always beneficial, since there may exist *gradient conflicts* among different tasks. The problem means that the gradient directions of different tasks form an angle larger than 90° thus harm each other, as shown in Fig. 3(a). To alleviate this issue, Yu et al. (2020) propose a technique called Gradient Surgery (GS) that projects the gradient of the i-th task $\mathbf{g}_i$ onto the normal plane of another conflicting task's gradient $\mathbf{g}_j$:

$$\mathbf{g}_i = \mathbf{g}_i - \frac{(\mathbf{g}_j \cdot \mathbf{g}_i)}{\|\mathbf{g}_j\|^2} \cdot \mathbf{g}_j. \tag{10}$$

Though GS is effective to some degree, our task is a little different from the ordinary multi-task learning as Yu et al. (2020): we aim to use auxiliary tasks to boost the main task performance rather than treating them equally. Therefore, it would be beneficial to apply fewer gradient modifications to the main task. To this end, we slightly *revise* the original GS by firstly merging the gradients of auxiliary tasks, then adopt factor λ to scale them (Fig. 3(b)):

$$\mathbf{g}_{aux} = \lambda(\mathbf{g}_{category} + \mathbf{g}_{ner}), \tag{11}$$

where λ is empirically set to 0.3. Then we apply GS between the gradients of the main task and the merged auxiliary task (Fig. 3(c)) and derive the final gradient $\mathbf{g}$ (Fig. 3(d)).

---

[1] Concatenation is another option but generally performs worse than attentive pooling.

3 Experiment

3.1 Dataset and Settings

We evaluate our approach on a real-world news recommendation dataset MIND (Wu et al., 2020), and we use the small version for quick experiments. Following previous work (Wu et al., 2019b; Qi et al., 2021), we utilize users' most recent 50 clicked news as historical behavior and each positive news is paired with 4 negative news. More details about the settings are in the Appendix A.

We compare our approach against several competitive baselines including NAML (Wu et al., 2019a), LSTUR (An et al., 2019), NRMS (Wu et al., 2019d), HieRec (Qi et al., 2021). While the above methods all adopt shallow text encodings, we also employ BERT as the news encoder, implementing a BERT baseline. Further, we reproduce two best-performing BERT-based methods (Wu et al., 2021b), denoted as LSTUR+BERT and NRMS+BERT. We also combine attentive multi-field learning to incorporate the multi-field information with the BERT baseline and MTRec, denoted as BERT+AMF and MTRec+AMF respectively.

3.2 Results

The main experimental results are listed in Table 1, from which we have the following observations. Firstly, the news recommendation system clearly performs better when BERT is utilized as the news encoder. For example, LSTUR+BERT and NRMS+BERT, for which we only replace the news encoder with BERT in LSTUR and NRMS, surpass their shallow versions significantly. Secondly, BERT+AMF performs better than the BERT baseline, which proves the value of the multi-field information. Different users prefer different categories and entities of news and this information is beneficial for the system to make personalized recommendations. Thirdly, MTRec performs significantly better than BERT+AMF, indicating the effectiveness of the multi-task learning strategy. It's worth noting that the attentive multi-field learning applies Glove (Pennington et al., 2014) and TransE (Bordes et al., 2013) embeddings to vectorize the information of categories and entities respectively. We claim that these feature encodings may not be in the same feature space as the deep BERT encoding, thus causing the insufficient use of multi-field information in BERT+AMF. Finally, MTRec+AMF achieves the best results. Ruder (2017) proposes that multi-task learning can be regarded as a kind of regularization. Thus, we deduce that the attentive multi-field learning, which augments the news representation directly, is not in conflict with the multi-task learning in MTRec.

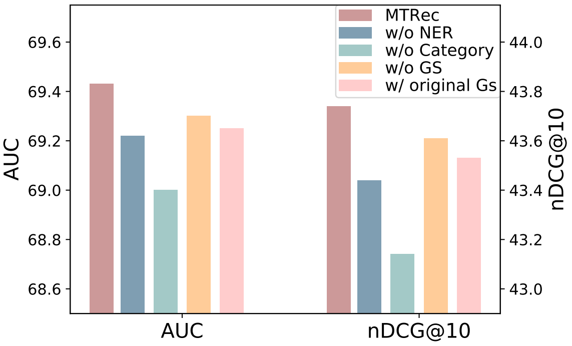

Figure 4: Ablation study to show the effectiveness of auxiliary tasks and gradient surgery (GS).

3.3 Ablation Study

Auxiliary Tasks Firstly, we drop the category classification and NER tasks respectively to explore their impacts on the system. As shown in Figure 4, the model performances decrease to varying degrees when only introducing a single auxiliary task. But their performances are still better than the BERT baseline, which proves that both auxiliary tasks contribute additional information to BERT. Wu et al. (2019c) only utilizes the title and category, which is denoted as w/o NER in Figure 4. Note that the performance drops the most when we remove the category classification task, possibly due to that categories are document-level labels and contain richer information than entities.

Gradient Surgery Further, we remove the Gradient Surgery technique in MTRec. As shown in Figure 4, the model performance drops greatly, which verifies the benefits to alleviate the gradient conflicts among different tasks. When we apply the original Gradient Surgery as Yu et al. (2020) in MTRec, the performances even get worse. The reason is that we aim to use auxiliary tasks to boost the main task performance rather than treating them equally, which is different from the ordinary multi-task learning. We also record and plot the gradient cosine similarity between the main and merged auxiliary task during training in the Appendix B.

4 Conclusion

We propose a novel multi-task learning framework over BERT for news recommendation, named MTRec, to effectively incorporate the multi-field information. We also modify the Gradient Surgery technique to reduce gradient conflicts and further improve the model performance. Finally, we find that combining multi-task learning with traditional attentive multi-field learning achieves the best results. Extensive experiments on the MIND dataset show the effectiveness of our approach. In the future, we will also combine MTRec with more advanced user modeling methods (Li et al., 2022).

A Dataset and Settings

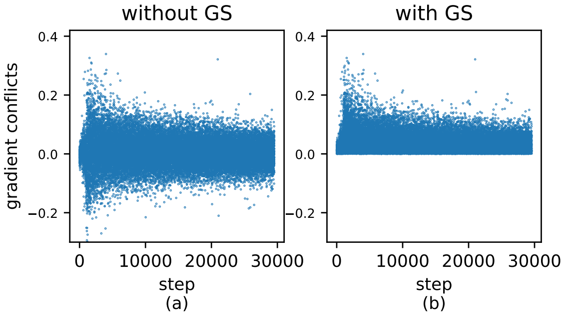

Figure 5: The fluctuation of cosine similarity for the main task and the merged auxiliary task. 'GS' indicated the gradient surgery.

Dataset We evaluate our approach on a real-world news recommendation dataset MIND (Wu et al., 2020), which is collected from the user behavior logs of Microsoft News. There are two versions of the dataset, namely MIND-large and MIND-small. The MIND-large contains more than 15 million impression logs generated by 1 million users, from which the MIND-small randomly samples 50,000 users. An impression log records the clicked and non-clicked news that are displayed to a user at a specific time and his historical news click behaviors before this impression. Besides, MIND contains off-the-shelf category labels and a set of entities of each news.

Settings Following previous work (Wu et al., 2019b; Qi et al., 2021), we utilize users' most recent 50 clicked news as historical behavior. We use *bert-base-uncased* pre-trained model as the news encoders. Only news title is used as the model input in this paper and the maximum length is set to 20. The dimension of the query vector in the additive attention is set as 200. Following previous work (Wu et al., 2019b; Qi et al., 2021), we apply Glove (Pennington et al., 2014) and TransE (Bordes et al., 2013) embeddings to vectorize the information of categories and entities respectively. The total number of news categories is 19 and 22 entity classes are identified in this paper. The embeddings dimension of the entities and categories are 100, and both are finetuned during model training. For the embedding of categories and entities, we also apply a dense layer to align the feature dimensions with the corresponding title encodings. The negative sampling rate L is set to 4 during training, i.e., each positive news is paired with 4 negative news. The learning rate is set to $2e^{-5}$ and linearly decayed with 10% warmup steps. We employ Adam (Kingma and Ba, 2015) as the optimization algorithm. As previous work (Wu et al., 2020), we employ four ranking metrics, i.e., AUC, MRR, nDCG@5, and nDCG@10, for evaluation.

B Gradient Conflicts

As shown in the Figure 5, we record and plot the gradient cosine similarity between the main and merged auxiliary task $\frac{\mathbf{g}_{main} \cdot \mathbf{g}_{aux}}{\|\mathbf{g}_{main}\| \|\mathbf{g}_{aux}\|}$ in each step. It's easy to find that there are often conflicts (negative points) between the main task and the merged auxiliary task before applying the gradient modification (Fig. 5(a)). Contrastively, our method eliminate these conflicts (Fig. 5(b)). There is no doubt that it is great internal consumption for optimization if the gradient directions among different tasks are opposite. Without alleviating the gradient conflicts, the model cannot balance multiple tasks well. In this case, the multi-filed auxiliary tasks are even harmful to the performance of the recommendation system.

Cross-domain Named Entity Recognition via Graph Matching

Abstract

Cross-domain NER is a practical yet challenging problem since the data scarcity in the real-world scenario. A common practice is first to learn a NER model in a rich-resource general domain and then adapt the model to specific domains. Due to the mismatch problem between entity types across domains, the wide knowledge in the general domain can not effectively transfer to the target domain NER model. To this end, we model the label relationship as a probability distribution and construct label graphs in both source and target label spaces. To enhance the contextual representation with label structures, we fuse the label graph into the word embedding output by BERT. By representing label relationships as graphs, we formulate cross-domain NER as a graph matching problem. Furthermore, the proposed method has good applicability with pre-training methods and is potentially capable of other cross-domain prediction tasks. Empirical results on four datasets show that our method outperforms a series of transfer learning, multi-task learning, and few-shot learning methods.

1 Introduction

Named entity recognition (NER) is a crucial component in many language understanding tasks (Shaalan, 2014; Nadeau and Sekine, 2007) and is often applied in various domains. Due to the data scarcity in the real-world scenario, obtaining adequate domain-specific data is usually expensive and time-consuming. Hence, cross-domain NER, which is capable of adapting NER models to specific domains with limited data, has been drawing increasing attention in recent years.

However, one of the primary challenges of cross-domain NER is the mismatch between source and target domain labels (Yang and Katiyar, 2020). For example, the label sets between ATIS (Hakkani-Tür et al., 2016) and CoNLL 2003 are non-overlapping.

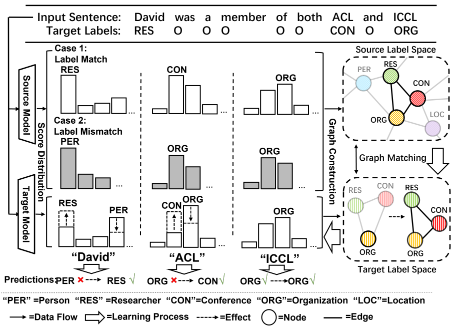

Figure 1: A demonstration of graph matching. In both two cases, our model learns graph structures from the source label space and makes correct predictions. In two label spaces, each node is a target label and the matching nodes and edges are opaque.

To address this issue, some approaches utilize multi-task learning (Jia and Zhang, 2020; Wang et al., 2020) for transferring knowledge across domains. However, these methods require full training on both source and target domain data when adapting to each new domain. Since the source domain dataset is usually much larger than the target domain dataset, the multi-task learning methods are inefficient when adapting to low-resource domains.

Recently, as Pre-trained Language Models (PLMs) such as BERT (Devlin et al., 2019) have shown remarkable success in NER, transfer-learning-based methods also show effectiveness for cross-domain NER. A typical approach is to first train a NER model initialized with PLM on rich-resource domain (*e.g.,* CoNLL 2003 (Sang and Meulder, 2003)), and then fine-tune the entire model with a new task-specific linear classifier (*pre-train fine-tune*) (Lee et al., 2018; Rodríguez et al., 2018). Despite its simplicity, this approach provides strong results on several benchmarks (Huang et al., 2020), and we serve it as the baseline in our research.

Inspired by the idea in You et al. (2020), where labels across domains are connected by probability

May 22-27, 2022

distributions, we propose a novel approach, **L**abel **S**tructure **T**ransfer for cross-domain **NER** (**LST-NER**) to address the label mismatch problem. By modeling the label relationships as *label graphs*, we transfer the label structure from the source model (*i.e.,* the NER model trained on source domain) to the target model (*i.e.,* fine-tuned model). We are the first to capture label graph structures for cross-domain NER to our best knowledge. In this study, we focus on enhancing cross-domain ability based on *pretrain-finetune* training paradigm, with **only** target domain labeled data for domain adaptation. Therefore, pre-training (Liu et al., 2021) and self-training (Huang et al., 2020) based methods, which leverages massive unlabeled data, are not considered.

To explicitly capture the connections between two domains labels, we construct a *label graph* by probability distributions of target labels estimated by the source NER model. In the *label graph*, graph nodes refer to target labels, and edges refer to the relationships between labels. We represent each node as the probability distribution and add an edge between two nodes if the labels have similar distributions. By representing label relationships as *label graphs* in both source and target label spaces, the label knowledge can be transferred via graph matching. We introduce Gromov-Wasserstein distance (GWD) for aligning two *label graphs* because of its capability of capturing edge similarity.

We show an example in Fig 1 to demonstrate how graph matching works. In the example, "ACL" is a "Conference" named entity in the target domain. When label sets between source and target domains match perfectly, the source NER model naturally predicts "Conference" with the highest probability. Then, the target model straightforward learns this property from the source domain. When two label sets are mismatching, the source NER model may predict "ACL" as an "Organization" since the label "Organization" is seen in the source domain. By score distributions of "ICCL" and "David" in the source domain, we can model their relationships with "ACL" as graph structures. Then, the target model learns label structures via graph matching and predicts "ACL" as "Conference" correctly. In this way, the label relationships can be learned even when two domain label sets are different.

Furthermore, we enhance the contextual representation by fusing the constructed *label graph* into the word embedding by Graph Convolutional Network (GCN), where an auxiliary task is introduced for better extracting label-specific components for each entity type.

We performed extensive experiments on eight different domains in both rich- and low-resource settings. Empirical results show that our method outperforms a series of competitive baselines.

2 Related Work

Cross-domain NER. In recent years, cross-domain NER has received increasing research attention. There is a line of research based on multi-task learning (Yang et al., 2017). Some approaches proposed adding auxiliary tasks Liu et al. (2020a); Wang et al. (2020), while some approaches proposed new model architecture (Jia et al., 2019; Jia and Zhang, 2020) for improving target domain NER model by jointly training on both source and target domain data. Jia and Zhang (2020) presented a multi-cell compositional LSTM (Multi-Cell LSTM) structure where modeled each entity type as a separate cell state, and it reaches the state-of-the-art (SOTA) performance for cross-domain NER. These methods require training on massive source domain data when adapting to each domain and thus inefficient.

Another line of research is based on transfer learning. Except from the *pretrain-finetune* paradigm, some approaches proposed adding adaption layers Lin and Lu (2018) or adapter modules Houlsby et al. (2019) to the backbone network. Compared with them, our method constructs *label graphs* dynamically and performs label semantic fusion via attention mechanism, and thus has fewer parameters for training. Besides, our method is built on word contextual embedding by PLM. Therefore, our model can combine with various backbone networks and thus has better applicability.

Few-shot NER. Few-shot NER aims at recognizing new categories in a highly low-resource scenario (Feng et al., 2018), which also shows good cross-domain ability. Tong et al. (2021) induced different undefined classes from the "Others" class to alleviate the over-fitting problem. Yang and Katiyar (2020) proposed NNShot and StructShot based on the nearest neighbor classifier, and StructShot further applies the Viterbi algorithm when decoding. The few-shot learning methods focus on building models that can generalize from very few examples. Unlike these methods, our approach aims to enhance domain adaptation ability in both low-resource and rich-resource scenarios.

3 Methodology

3.1 Problem Formulation

We focus on only one source and one target domain in this study. Given a NER model f_0 pre-trained on a source dataset $\mathcal{D}_s = \{(x_s^i, y_s^i)\}_{i=1}^{m_s}$, we aims to fine-tune f_0 by a target dataset $\mathcal{D}_t = \{(x_t^i, y_t^i)\}_{i=1}^{m_t}$. Following You et al. (2020), we assume that only $\mathcal{D}_t$ and f_0 are available when fine-tuning since $\mathcal{D}_s$ is often large-scale.

Because the source label set $\mathcal{Y}_s$ and target label set $\mathcal{Y}_t$ may be mismatching, f_0 can not be applied to target data directly. A common practice is to split f_0 into two parts: a backbone network for learning general representation and task-specific layers for mapping representation to label space. We adopt BERT as our backbone model and Fully-Connected (FC) layer as the task-specific layer throughout our research. We show a demonstration of our model in Fig. 2.

3.2 Label Graph Construction

In this part, we construct *source graph* and *target graph* with the probabilistic outputs of source and target NER models respectively.

Typically, the target labels are fine-grained and domain-specific, while the source labels are coarse-grained and more general. Similar to the idea of You et al. (2020), we map each target label as a probability distribution of the source labels. A straightforward method for obtaining this mapping (*i.e.* conditional distribution) $p(y_s|y_t = y)$ is to average the predictions of the source model over all samples for each target entity type. Formally, we have

$$\begin{aligned} p(y_s|y_t = y) &\approx |\mathcal{D}_t^y|^{-1}\Sigma_{(x_t,y_t)\in\mathcal{D}_t^y} f_0'(x_t) \\ f_0'(x_t) &= softmax(f_0(x_t)/T) \\ \mathcal{D}_t^y &= \{(x_t, y_t) \in \mathcal{D}_t | y_t = y\}, \end{aligned} \tag{1}$$

where y_s/y_t denotes source/target label, T denotes the temperature parameter for smoothing the probability distribution and $|\mathcal{D}_t^y|$ is the number of target domain training samples [1] with ground-truth label y. The pre-trained model f_0 is regarded as a probabilistic model for approximating the probability distribution $p(y_s|x_t)$ over source labels $\mathcal{Y}_s$.

Next, we build *source graph* $\mathcal{G}_s(\mathcal{V}_s, \mathcal{E}_s)$ where nodes refer to target labels and edges refer to semantic similarity between nodes. As illustrated in Fig 1, two labels with similar semantic meanings (*i.e.,* "Conference" and "Organization") have the similar probability distribution. Based on this feature, we represent the graph node with label y as

$$\begin{aligned} \widetilde{\boldsymbol{v}}_s^y = \Big[p(y_s^{(1)}|y_t = y), \cdots, p(y_s^{(i)}|y_t = y)\Big] \\ y_s^{(i)} \in \mathcal{Y}_s, i \in \{1, \cdots, |\mathcal{Y}_s|\} \end{aligned} \tag{2}$$

where $\widetilde{\boldsymbol{v}}_s^y \in \mathbb{R}^{|\mathcal{Y}_s|}$ is the node representation and $|\mathcal{Y}_s|$ is the number of source labels. To eliminate the influence of scales of different dimensions, we normalize the graph nodes by dividing the average distance of node pairs, and $l2$ distance is used as the distance metric. Then, the graph node representation for label y is calculated as

$$\boldsymbol{v}_s^y = \frac{\widetilde{\boldsymbol{v}}_s^y * |\mathcal{Y}_t|^2}{\sum_{y_1,y_2} l2(\widetilde{\boldsymbol{v}}_s^{y_1}, \widetilde{\boldsymbol{v}}_s^{y_2})}, \tag{3}$$

where $\boldsymbol{v}_s^y \in \mathcal{R}^{|\mathcal{Y}_s|}$ is the normalized node representation, $|\mathcal{Y}_t|$ is the number of target labels and $l2$ is the distance function. Then, we add edge between two nodes if and only if their distance is smaller than a threshold δ.

$$\boldsymbol{e}_s^{y_1,y_2} = \begin{cases} l2(\boldsymbol{v}_s^{y_1}, \boldsymbol{v}_s^{y_2}), & \text{if } l2(\boldsymbol{v}_s^{y_1}, \boldsymbol{v}_s^{y_2}) < \delta; \\ \infty, & \text{else.} \end{cases} \tag{4}$$

In a similar way as *source graph*, we construct *target graph* $\mathcal{G}_t(\mathcal{V}_t, \mathcal{E}_t)$ by the fine-tuned model f where probability distribution $p(y_t|x)$ over target labels $\mathcal{Y}_t$ are estimated. In *target graph*, nodes refer to target labels, and edges refer to semantic similarity measured in target label space.

3.3 Label Semantics Fusion

Commonly in NER, the ground-truth label of a named entity is related to the context (*e.g.,* label "Researcher" can be inferred by label "Conference" as the example shown in Fig 1). In this part, we fused the learned graph structure into the word contextual embedding output by BERT to model the sentence's semantic label relationships.

Given a sentence $X = [x_1, \cdots, x_{n_s}]$ with ground-truth label sequence Y, the contextual representation $\boldsymbol{h}_j \in \mathbb{R}^{d_h}$ for each token can be obtained by backbone network. Then, we randomly initialize the *label representation* $\boldsymbol{c}_i \in \mathbb{R}^{d_c}$ before

---

[1] The training sample refers to one token and its ground-truth label

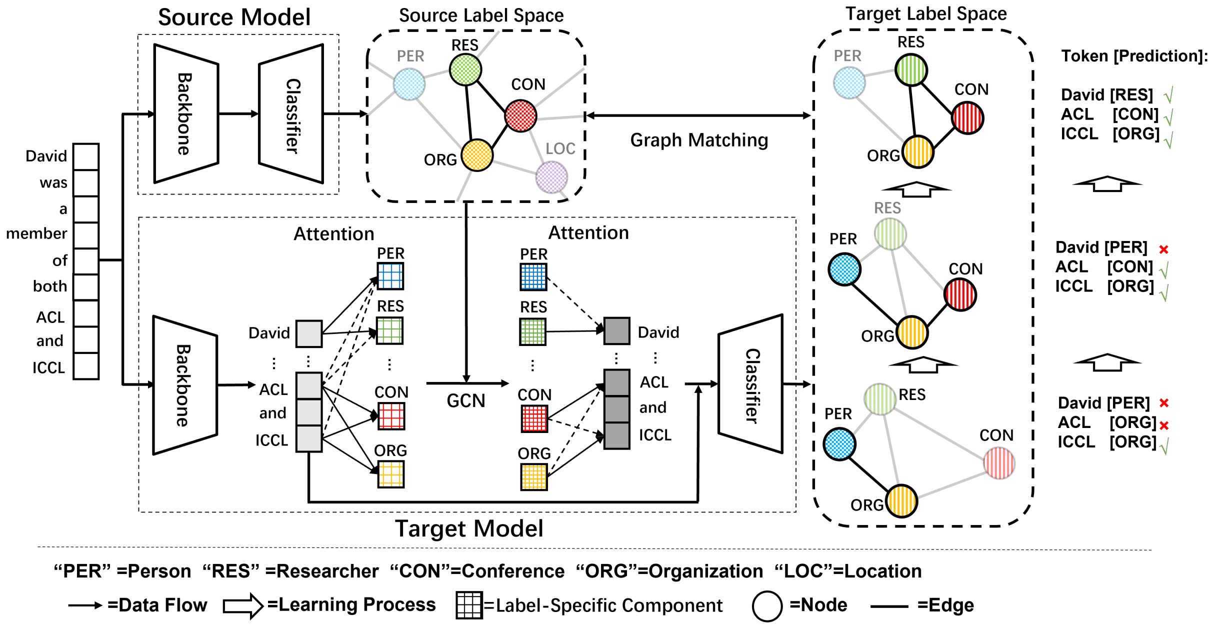

Figure 2: A demonstration of the proposed model. First, the label graph from source label space is incorporated into the contextual representation by GCN. Then, the target model transfers graph structures from the source model via graph matching. Finally, the target model makes correct predictions with the learned label structures.

fine-tuning. The *label representation* represents the semantic meanings for each entity type, and it is learned during fine-tuning. For the sentence X, we apply a label-guided attention mechanism to extract the *label-specific components* as follow:

$$\begin{aligned} \boldsymbol{q}_j &= \boldsymbol{h}_j \mathbf{W}_p + \boldsymbol{b}_p, \\ \alpha_{ij} &= \frac{\exp(\boldsymbol{q}_j \boldsymbol{c}_i^T)}{\sum_j \exp(\boldsymbol{q}_j \boldsymbol{c}_i^T)}, \\ \boldsymbol{u}_i &= \sum_j \alpha_{ij} \boldsymbol{q}_j, \end{aligned} \tag{5}$$

where $\boldsymbol{q}_j \in \mathbb{R}^{d_p}$ is the *label-related embedding* for the j-th token in the sentence, $\mathbf{W}_p \in \mathbb{R}^{d_h \times d_p}$ and $\boldsymbol{b}_p \in \mathbb{R}^{d_p}$ are the weight and bias for projection respectively. $\boldsymbol{u}_i \in \mathbb{R}^{d_p}$ denotes the *label-specific component* for the i-th label in $\mathcal{Y}_t$ and α_{ij} indicates how informative the j-th token to the i-th label. For each sentence, *label-specific components* modeling its semantic relevance to each entity type.

And then, by replacing the node representation of *source graph* from probability distribution $\boldsymbol{v}_s$ to *label-specific component* $\boldsymbol{u}$, we obtain the graph representation of *label-specific components*. Next, we utilize GCN (Kipf and Welling, 2017) to enhance the representations of each *label-specific component* by propagating messages between neighboring nodes.

$$\boldsymbol{u}' = GCN(\boldsymbol{u}) \tag{6}$$

$\boldsymbol{u}' \in \mathbb{R}^{d_p}$ denotes the aggregated node representation of the *label-specific component* and *GCN* denotes the graph convolution operations where details are omitted for simplicity. As shown in Fig. 2, label structure from *source graph* is fused into *label-specific components* by GCN.

Last, we utilize the token-guided attention mechanism to fuse the aggregated *label-specific component* into the contextual representation for each word:

$$\begin{aligned} \beta_{ji} &= \frac{\exp(\boldsymbol{q}_j \boldsymbol{u}_i'^T)}{\sum_i \exp(\boldsymbol{q}_j \boldsymbol{u}_i'^T)} \\ \boldsymbol{h}_j' &= \boldsymbol{h}_j + (\sum_i \beta_{ji} \boldsymbol{u}_i') \mathbf{W}_p' + \mathbf{b}_p'. \end{aligned} \tag{7}$$

$\boldsymbol{h}_j' \in \mathbb{R}^{d_h}$ is the *label-fused embedding* for the j-th token and $\mathbf{W}_p' \in \mathbb{R}^{d_p \times d_h}$,$\mathbf{b}_p' \in \mathbb{R}^{d_h}$ are the weight and bias for projection respectively. In Eq. 7, we map the weighted sum of $\boldsymbol{u}'$ into the same space of $\boldsymbol{h}_j$ and add them together to allow information fusion. Followed by the task-specific FC layer, the classification loss for NER tasks can be calculated:

$$\mathcal{L}_{cls} = CE(FC(\boldsymbol{h}'), Y) \tag{8}$$

where *CE* denotes the Cross-Entropy loss.

Besides, we introduce an auxiliary task to ensure the *label-specific components* focus on correct entity types. Concretely, the model predicts what entity types appear in the sentence, which is a multi-label classification task. The loss for the auxiliary task is calculated as

$$\mathcal{L}_{aux} = BCE(FC_{aux}(Cat([\boldsymbol{h}'_1, \cdots, \boldsymbol{h}'_{n_s}])), Y') \tag{9}$$

where *BCE* is the Binary-Cross-Entropy loss, FC_{aux} is the FC layer for auxiliary task, *Cat* is the concatenation operation for last dimension and Y' is the ground-truth label for the sentence. Different from $\mathcal{L}_{cls}$, $\mathcal{L}_{aux}$ encourages model to extract correct *label-specific components* for each sentence.

3.4 Graph Structure Matching

Since *source graph* $\mathcal{G}_s$ is constructed by the pre-trained LM f_0, it naturally contain priori knowledge from rich-resource domain. In this part, we utilize the *label graphs* built in different label spaces for graph matching to exploit the semantic relations among labels from *source graph*.

Gromov-Wasserstein distance (GWD) is proposed for distributional metric matching by Peyré et al. (2016). Since its capability of capturing edge similarity between graphs, GWD has been applied to graph matching (Vayer et al., 2019; Chowdhury and Mémoli, 2019) and domain alignment (Chen et al., 2020). Naturally, we can adopt GWD for matching the edges (relationships) between two *label graphs*.

Following Alvarez-Melis and Jaakkola (2018); Chen et al. (2020), we convert each graph to a discrete distribution with uniform mass on each node. Let $\boldsymbol{\mu}$,$\boldsymbol{\nu}$ denote two discrete distributions corresponding to $\mathcal{G}_s, \mathcal{G}_t$ respectively. Then, we define the GWD between $\boldsymbol{\mu}$ and $\boldsymbol{\nu}$ as:

$$\begin{aligned} &\mathbf{D}_{gw}(\boldsymbol{\mu}, \boldsymbol{\nu}) \\ &= \inf_{\gamma \in \prod(\boldsymbol{\mu}, \boldsymbol{\nu})} \mathbb{E}_{(\boldsymbol{v}_s, \boldsymbol{v}_t) \sim \gamma, (\boldsymbol{v}'_s, \boldsymbol{v}'_t) \sim \gamma} [L(\boldsymbol{v}_s, \boldsymbol{v}_t, \boldsymbol{v}'_s, \boldsymbol{v}'_t)] \\ &= \min_{\hat{\mathbf{T}} \in \prod(\boldsymbol{u}, \boldsymbol{v})} \sum_{i, i', j, j'} \hat{\mathbf{T}}_{ij} \hat{\mathbf{T}}_{i'j'} L(\boldsymbol{v}_s^i, \boldsymbol{v}_t^j, \boldsymbol{v}_s^{i'}, \boldsymbol{v}_t^{j'}), \end{aligned} \tag{10}$$

where $\prod(\boldsymbol{\mu}, \boldsymbol{\nu})$ denotes all the joint distributions $\boldsymbol{\gamma}(\boldsymbol{v}_s, \boldsymbol{v}_t)$ with marginals $\boldsymbol{\mu}(\boldsymbol{v}_s)$ and $\boldsymbol{\nu}(\boldsymbol{v}_t)$. $\prod(\boldsymbol{u}, \boldsymbol{v})$ represents the space of all valid transport plan, where the weight vector $\boldsymbol{u} = \{u_i\}_{i=1}^n, \boldsymbol{v} = \{v_i\}_{i=1}^m$ is the n- and m-dimensional simplex for distribution $\boldsymbol{\mu}$,$\boldsymbol{\nu}$. The matrix $\mathbf{T}$ is the transport plan, where $\mathbf{T}_{ij}$ represents the amount of mass shifted from u_i to v_j. $L(\cdot)$ is the cost function evaluating the intra-graph structural similarity between two pairs of nodes $(\boldsymbol{v}_s^i, \boldsymbol{v}_s^{i'})$ and $(\boldsymbol{v}_t^j, \boldsymbol{v}_t^{j'})$, and it is defined as follow in the proposed method:

$$L(\boldsymbol{v}_s^i, \boldsymbol{v}_t^j, \boldsymbol{v}_s^{i'}, \boldsymbol{v}_t^{j'}) = |l2(\boldsymbol{v}_s^i, \boldsymbol{v}_s^{i'}) - l2(\boldsymbol{v}_t^j, \boldsymbol{v}_t^{j'})| \tag{11}$$

By projecting the edges into nodes, the learned transport plan $\hat{\mathbf{T}}$ helps align the edges in different graphs (van Lint and Wilson, 1992). Then, label relationships (edges) can be learned from *source graph* to *target graph* by minimizing $\mathbf{D}_{gw}$ with Sinkhorn algorithm (Cuturi, 2013; Peyré et al., 2019). In Fig. 2, the fine-tuned model learns the structure between labels (*i.e.,* "Conference", "Organization" and "Researcher") , and makes correct predictions with the learned label relationships. When fine-tuning, *target graph* evolves dynamically through the update of the parameters of NER model f, while *source graph* and the source model f_0 are frozen.

3.5 Total Learning Objective

Finally, the total loss can be formulated as

$$\mathcal{L} = \mathcal{L}_{cls} + \lambda_1 \mathcal{L}_{aux} + \lambda_2 \mathbf{D}_{gw}, \tag{12}$$

where the loss of auxiliary task and GWD are weighted by λ_1 and λ_2 respectively.

4 Experiments

4.1 Experimental Settings

Datasets. We take five public publicly available datasets for experiments, including CoNLL 2003 (Sang and Meulder, 2003), CrossNER (Liu et al., 2021), ATIS (Hakkani-Tür et al., 2016), MIT Restaurant (Liu et al., 2013a) and MIT Movie (Liu et al., 2013b). Table 1 presents detailed statistics of these datasets.

Baseline models. We first consider three approaches built on bi-directional LSTM structure (Hochreiter and Schmidhuber, 1997), including traditional NER system BiLSTM-CRF (Lample et al., 2016) together with two improved methods Coach (Liu et al., 2020b) and Multi-Cell LSTM (Jia and Zhang, 2020).

We also compare several BERT-based NER systems. BERT-tagger (Devlin et al., 2019) is the BERT-based baseline model which fine-tunes the BERT model with a label classifier (*i.e., pretrain-finetune*). NNShot and StructShot (Yang and Katiyar, 2020) are two metric-based few-shot learning approaches for NER. Different from the above approaches, TemplateNER (Cui et al., 2021) is a

template-based prompt method through a generative pre-trained LM, BART (Lewis et al., 2020), and it also shows effectiveness in few-shot NER.

In the experiments, we don't include approaches requiring extra unlabeled data for comparison, such as noisy supervised pre-training, self-training (Huang et al., 2020) and domain-adaptive pre-training (Liu et al., 2021).

Implementation Details. Throughout the experiments, we use BERT-based model(Devlin et al., 2019) as our backbone model. The models were implemented in Pytorch (Paszke et al., 2019) on top of the BERT Huggingface implementation (Wolf et al., 2019), and training was performed on two GeForce RTX 2080 Ti GPU.

The hyperparameters in our model are set as follows: temperature parameter $T = 4$; dimensional parameters $d_h = d_p = 768$; edge threshold $\delta = 1.5$; weight parameters $\lambda_1 = 0.1, \lambda_2 = 0.01$.

Evaluation. For evaluation, we use the standard evaluation metrics for NER (*i.e.,* micro averaged F1 score) and report the average results of five independent runs. Besides, we use BIO tagging schema for evaluation.

In the low-resource setting, we construct the target domain training set by sampling K entities for each entity types following existing studies in few-shot NER (Yang and Katiyar, 2020; Cui et al., 2021). Different from sentence-level few-shot tasks, in NER, simply sampling K sentences for each entity type will result in far more entities of frequent types than those of less frequent types (Yang and Katiyar, 2020). Therefore, we apply greedy sampling strategy (Yang and Katiyar, 2020) to construct a few-shot training set. Due to the randomness of few-shot sampling, we will release all sampled data along with the codes for reproducibility.

4.2 Cross-Domain Experiments

Cross-Domain Settings. Following Huang et al. (2020); Liu et al. (2021), we use CoNLL 2003 as the source domain datasets and evaluate the cross-domain performance on other datasets with different domains. The MIT Movie, MIT Restaurant, and ATIS are three NER benchmark datasets. However, these three datasets lack domain-specialized entity types or do not focus on a specific domain (*e.g.,* "Opinion", "Relationship",etc), leading to a less effective cross-domain evaluation (Liu et al., 2021). Thus, we additionally use CrossNER datasets (with five different domains) for the experiments. For each domain in CrossNER, it contains domain-specialized entity types as well as the four entity types in CoNLL 2003[2]. Since the target domain contains far more entity types than the source domain, there is a mismatch between different domain label sets. Considering the statistics of the datasets, we perform experiments on movie reviews, restaurant reviews, and dialogue domains for the rich-resource setting (we use all samples for training) and all eight domains for the low-resource setting ($K = 20, 50$). If an entity has a smaller number of samples than the fixed number to sample K, we use all of them for training.

Training Details. Based on the two baseline methods BiLSTM-CRF and BERT-tagger, we jointly train on both source and target domain samples to obtain two more baselines (*i.e.,* BiLSTM-CRF-joint and BERT-tagger-joint, respectively) for better comparison. Following Liu et al. (2021), we up-sample target domain samples for balancing two domain data. When training BiLSTM-CRF and Coach, we use word-level embedding from Pennington et al. (2014) and char-level embedding from Hashimoto et al. (2017) as input. For Multi-Cell LSTM, BERT representation, as well as word-level and char-level embedding, are utilized.

Apart from the approaches based on multi-task learning (*i.e.,* BiLSTM-CRF-joint, Coach, Multi-Cell LSTM, and BERT-tagger-joint), we train the NER model on CoNLL 2003 for ten epochs before adapting to the target domain. For NNShot and StructShot, we further perform fine-tuning in the target domain since we find that they only yield better results than fine-tuning when only very few data are available (Huang et al., 2020). We summarize the results of cross-domain evaluation as well as the ablation study in Table 2 and 3, where methods are grouped together based on the backbone model (BiLSTM, BERT, BART from top to down respectively).

Result Analysis. Results show that our model consistently outperforms all the compared models in both low- and rich-resource settings. Our method shows significant improvements in the rich-resource setting on the baseline BERT-tagger (2.76% on Movie Review; 2.03% on Restaurant Review; 0.29% on Dialogue). Even though the multi-task-learning-based methods (*e.g.,* Multi-Cell LSTM) are trained on more data and show competitive results, the proposed method has superior performance with only target domain data.

Results also suggest that jointly training pretrained LM (*e.g.,* BERT) on both domains data may not have better performance on target domain compared with *pretrain-finetune* paradigm. We think that the reason may be the semantic discrepancy of the same label from two domains. Different from them, the proposed method captures both similarity and discrepancy between source and target labels through probability distributions. Therefore, our model benefits from the broad knowledge from the source NER model and alleviates the requirement to target domain data.

Ablation Study. We consider three settings in the ablation study, the final loss without (1) loss of auxiliary task $\mathcal{L}_{aux}$, (2) GWD for graph matching $\mathcal{D}_{gw}$ and (3) both of them. One should note that the model trained in case (3) is not the same as BERT-tagger, which has label semantic fusion layers.

The results suggest that both the graph matching mechanism and label semantic fusion are beneficial for learning a better NER model. When training only with classification loss, the model shows tiny improvement on fine-tuning. Combined with learned graph structure (*i.e., source graph*), the label semantic fusion part becomes more effective when auxiliary task is added. Moreover, the model trained with graph matching consistently yields better results, indicating that transferring the graph structure of labels is critical and beneficial for cross-domain NER.

Table 4: Comparison of different methods combined with DAPT. In each domain, we use **all** samples for training. ‡ indicates the results are from Liu et al. (2021).

4.3 Additional Experiments

Combined with Domain-Adaptive Pre-Training. Liu et al. (2021) proposed to use integrate the entity- and task-level unlabeled corpus and span-level masking strategy in Domain-Adaptive Pre-Training (DAPT) for the NER domain adaptation.

---

[2] person, location, organization and miscellaneous

We conduct experiments to combine DAPT with ours model and Multi-Cell LSTM, respectively. The results are shown in Table 4.

By pre-training on a massive domain-related corpus, our method further improves the F1-score by 3.48% on average. Compared with Multi-Cell LSTM, our method benefits from rich knowledge learned by pre-train LM directly and shows better performance when combined with DAPT. Therefore, we believe that our method can be incorporated with self-training and noisy supervised pre-training methods to achieve superior results.

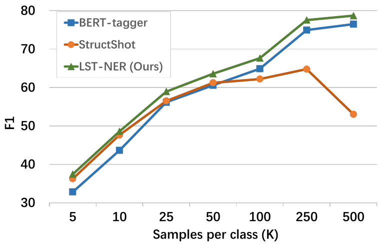

Figure 3: Comparisons when utilizing different amounts of data for training in "Restaurant Reviews" domain.

Performance with Different Amounts of Data. We evaluate the performance of our model with different amounts of target domain labeled data on the "Restaurant Reviews" domain and make comparisons with two baselines BERT-tagger and StructShot. We use the same few-shot sampling strategy as in the low-resource setting. From results in Fig 3, we find that even when in a highly low-resource scenario ($K = 5, 10$), the proposed model shows competitive performance with the few-shot NER model StructShot. When more data are available, our model consistently outperforms both BERT-tagger and StructShot. In contrast, StructShot becomes ineffective when data are relatively sufficient (K>50). We think the reason may be that StructShot is based on nearest neighbor learning, which is susceptible to noisy data. The results indicate that our method enhances domain adaptation capability in a more general scenario compared with few-shot NER methods.

Hyperparameter Discussion. We explore the impact of edge threshold δ, temperature parameter T and weight parameter λ_1,λ_2 on the performance. We show the result in Fig. 4 and Fig. 5. Temperature T controls the smoothness of the score distribution. The edge threshold δ controls the number of edges for matching. We find that T and δ have a relatively small influence on the f1 score when $T > 3$ and $\delta > 1.0$, suggesting the stability of our model. In the experiments, we choose the best value as the default setting (*i.e.*, $T = 4$, $\delta = 1.5$, $\lambda_1 = 0.1$ and $\lambda_2 = 0.01$).

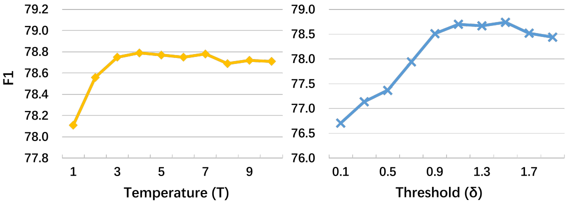

Figure 4: The impact of temperature T and edge threshold δ to the performance in "Restaurant Reviews" domain.

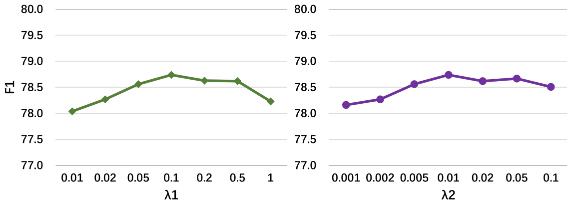

Figure 5: The impact of weight parameters λ_1 and λ_2 to the performance in "Restaurant Reviews" domain.

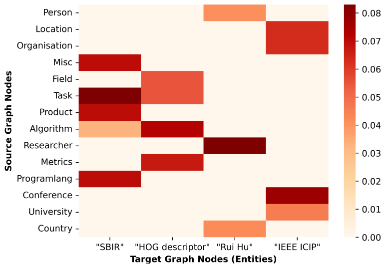
Sentence:	At the IEEE International Conference on Image Processing (IEEE ICIP), Rui Hu extended the HOG descriptor for use in sketch based image retrieval (SBIR).
BERT-tagger:	IEEE ICIP [Conference], Rui Hu [Person], HOG descriptor [Algorithm], SBIR [Misc]
Multi-Cell LSTM:	IEEE ICIP [Conference], Rui Hu [Researcher], HOG descriptor [Algorithm], SBIR [Misc]
LST (Ours):	IEEE ICIP [Conference], Rui Hu [Researcher], HOG descriptor [Algorithm], SBIR [Task]

(a) Example



(b) Transport plan

Figure 6: (a) An example from the AI domain test set. Green and Red represent correct and incorrect entity respectively. (b) The transport plan corresponds to the example. A higher value represents more attention between nodes.

Case Study. In the example shown in Fig.6, the model constructs *source graph* with all target data where all target labels are contained. The transport plan demonstrates how label structures (edges) are learned via graph matching from all target entity types to the named entity in the sentence. Compared with BERT-tagger and Multi-Cell LSTM, our method correctly predicts "Rui Hu" as "Researcher" and "SBIR" as "Task".

5 Conclusion

This paper proposes a novel and lightweight transfer learning approach for cross-domain NER. Our proposed method learns graph structure via matching *label graphs* from source to target domain. Through extensive experiments, we demonstrated the effectiveness of our approach, reporting better results over a series of transfer learning, multi-task learning, few-shot learning methods. In conclusion, our approach is general, which can be combined with domain-adaptive pre-training and potentially applied to other cross-domain prediction tasks. Besides, there are some limitations of our approach. For example, when the target domain entity types are fine-grained and largely different from the source domain entity types (e.g., in ATIS dataset), our approach shows limited improvement on the *pretrain-finetune* paradigm. To this end, future directions include investigations on employing multi-task learning for modeling the semantic discrepancy of labels across domains and fusing hierarchical label relationships into the *label graphs*.

Assessing Multilingual Fairness in Pre-trained Multimodal Representations

Jialu Wang and **Yang Liu** and **Xin Eric Wang**

Abstract

Recently pre-trained multimodal models, such as CLIP (Radford et al., 2021), have shown exceptional capabilities towards connecting images and natural language. The textual representations in English can be desirably transferred to multilingualism and support downstream multimodal tasks for different languages. Nevertheless, the principle of multilingual fairness is rarely scrutinized: do multilingual multimodal models treat languages equally? Are their performances biased towards particular languages? To answer these questions, we view language as the fairness recipient and introduce two new fairness notions, multilingual individual fairness and multilingual group fairness, for pre-trained multimodal models. Multilingual individual fairness requires that text snippets expressing similar semantics in different languages connect similarly to images, while multilingual group fairness requires equalized predictive performance across languages. We characterize the extent to which pre-trained multilingual vision-and-language representations are individually fair across languages. However, extensive experiments demonstrate that multilingual representations do not satisfy group fairness: (1) there is a severe multilingual accuracy disparity issue; (2) the errors exhibit biases across languages conditioning the group of people in the images, including race, gender and age.

1 Introduction

Recently pre-trained vision-and-language representations (Lu et al., 2019; Tan and Bansal, 2019; Su et al., 2020; Li et al., 2020a; Chen et al., 2020; Li et al., 2020b; Gan et al., 2020; Yu et al., 2021; Desai and Johnson, 2021; Radford et al., 2021; Cho et al., 2021) have received a surge of attention. Such pre-trained multimodal representations have shown great capabilities of bridging images and natural language on the downstream tasks, including image captioning (Laina et al., 2019), image retrieval (Vo et al., 2019), visual QA (Zhou et al., 2020), text-to-image generation (Ramesh et al., 2021), etc. While it is commonly recognized that the multimodal representations trained on English corpora can be generalized to multilingualism by cross-lingual alignment (Lample and Conneau, 2019; Conneau et al., 2020), recent studies criticize that the multilingual textual representations *do not* learn equally high-quality representations for all the languages (Wu and Dredze, 2020), especially for low-resource languages. Hu et al. (2020) emphasize the need for general-purpose representations to seek equal performance across all languages. However, there is still a lack of a nuanced understanding of how multilingual representations fare on vision-and-language benchmarks.

This paper provides a novel perspective for analyzing the principles of multilingual fairness in multimodal representations from two aspects. First, existing frameworks for measuring multilingual biases usually emulate text sources in different languages, which may have ambiguous meanings in varied contexts (González et al., 2020). In contrast, we leverage visual grounding as the anchor to bridge text in different languages—text snippets in different languages but with similar semantics should be equitably relevant to the same images. Second, we equate a language as an aggregated group of individuals (e.g., French as a group of French sentences) in the terminology of fairness. As Choudhury and Deshpande (2021) has pointed out, "*each language has a distinct identity, defined by its vocabulary, syntactic structure, its typological features, amount of available resources, and so on.*" The notions of fairness, such as individual fairness (Dwork et al., 2012) and group fairness (Zemel et al., 2013; Chouldechova, 2017; Hardt et al., 2016; Zhu et al., 2022), can be naturally adapted by comparing the multimodal model's treatment across languages.

Therefore, we introduce two fairness notions:

Findings of the Association for Computational Linguistics: ACL 2022, pages 2681 - 2695
May 22-27, 2022

multilingual individual fairness presumes similar outcomes between similar language expressions grounding on the same images; *multilingual group fairness* postulates that multimodal models should induce similar predictive performance across different languages. These fairness notions are formalized to *compare the multimodal model's treatment of one language versus another* for either the individual target or the aggregated group.

Our contributions are as follows:

- We formally define the individual fairness and group fairness notions in the multilingual and multimodal setting (see Section 3 and Section 4).
- We theoretically investigate the extent to which pre-trained multilingual vision-and-language representations are individually fair. However, our negative result demonstrates that individual fairness does not suffice to prevent accuracy disparity at the group level (see Section 5.1).
- Extensive experimental results reveal the accuracy disparity across different languages. Our results also imply that the choice of visual representations affects the group fairness metrics (see Section 5.2).
- We further demonstrate the prevalence of group rate disparity when language is coupled with multi-dimensional groups associated with images, such as race, gender, and age (see Section 5.3). Our empirical exploration provides new directions for mitigating biases under the multilingual setting.

2 Background

Notation. Throughout the paper, we use the uppercase letter I to denote images and T to denote text. We use the superscript (L) in $T^{(L)}$ to represent the text is in language L. When we are jointly using $T^{(L)}$ and $T^{(L')}$ for two languages L and L', we often assume that they share the same semantic meanings. Lowercase letters $\boldsymbol{v}$ and $\boldsymbol{t}$ are used to denote the visual and textual representation vectors encoded by model M, respectively. To simplify the presentation, we use $S(\cdot,\cdot)$ to generally represent the similarity between images and text. Specifically, $S(I,T)$ refers to the similarity scores predicted by the model M between the image I and text T, while $S(\boldsymbol{v},\boldsymbol{t})$ refers to the cosine similarity between vectors $\boldsymbol{v}$ and $\boldsymbol{t}$.

2.1 Multilingual CLIP

Our work is established on the multimodal setting. The universal framework for matching images and text (Mogadala et al., 2021) is to encode them into representation vectors in a shared representation space, such that the distance between visual and textual vectors can measure the similarity between images and text. Throughout this paper, our analysis mainly focuses on CLIP (Contrastive Language-Image Pre-training Radford et al., 2021), a representative pre-trained multimodal representation model that achieves state-of-the-art performances on zero-shot transfer tasks.

CLIP is a multimodal model trained on large-scale images with natural language supervision collected from the internet. It comprises an image encoder and a text encoder that can embed images and text into visual and textual representation vectors. One desirable property is that the CLIP model takes the cosine similarity between image and text features to measure the log-odds of the corresponding image-text pairs, and is trained to maximize their similarity by a contrastive learning objective. In light of this capability, CLIP can predict the similarity, denoted by $S(I,T)$, between arbitrary images I and natural language text snippets T.

In order to adapt the flexible CLIP model to multilingualism, Multilingual CLIP (Carlsson and Ekgren, 2021) uses a pre-trained multilingual language model, such as M-BERT (Devlin et al., 2019), to take over the original text encoder in English, and fine-tune the textual representation vectors by cross-lingual alignment (Lample and Conneau, 2019; Conneau et al., 2020). In this setting, we use $S(I,T^{(L)})$ to represent the similarity between image I and text $T^{(L)}$ in language L. Though the empirical evaluations in this paper mainly focus on Multilingual CLIP, the experimental approaches we adopt to arrive at the observations can be generalized to other pre-trained multilingual vision-and-language representations.

2.2 Fairness Notions

The multilingual fairness notions developed in this work is inspired by multiple fairness definitions (Narayanan, 2018; Dwork et al., 2012) in the algorithmic fairness literature. We will briefly introduce these fairness notions in fair decision making and instantiate them in the domain of multilingual vision-and-language learning later.

Individual fairness, initiated by Dwork et al.

(2012), requires that individuals who are similar with respect to a task-specific similarity metric have similar decision outcomes.

Group fairness definitions seek to provide fairness guarantees based on group-level statistical constraints, in the sense that they are evaluated and enforced without reference to similarity measures. In the fairness literature, group fairness is commonly framed in terms of *protected groups* G, such as race, gender, and age. For instance, demographic parity (Zafar et al., 2017) requires that the outcomes are independent of the group membership, and equalized odds (Hardt et al., 2016) essentially requires equal true positive and false positive rates between different groups.

Principally, these fairness criteria are formulated by comparing the treatment of one individual or one group versus another. Our work will instantiate the standard fairness notions by viewing language as the recipient — we compare *how the treatment of one language differs from another*.

2.3 Fairness in NLP

Many recent works (Choudhury and Deshpande, 2021; Hu et al., 2020; Pires et al., 2019; González et al., 2020; Ross et al., 2021) scrutinize the ethical issues raised in multilingual settings, albeit with varying degrees of success. For instance, Zhao et al. (2020) quantifies the presence of representational biases in multilingual word embeddings by calculating the distance between targets corresponding to different sensitive attributes. Huang et al. (2020) evaluate group fairness violations among demographic groups on the task of hate speech detection, but do not explicitly regard language as unique group membership. Burns et al. (2020) studies the performance degradation when multimodal models are trained to support additional languages, and tries to address the multilingual accuracy disparity on the task of image-sentence retrieval. Our work complements the fairness discourse in multilingual NLP to the extent that we provide a novel perspective of studying multilingual fairness by viewing language as the recipient of fairness notions.

Our work is also closely relevant to prior studies on biases in vision-and-language tasks, including visual semantic role labeling (Zhao et al., 2017), image captioning (Burns et al., 2018; Tang et al., 2021), and image search (Wang et al., 2021). Notably, Srinivasan and Bisk (2021) investigates the gender bias associated with entities for pre-trained representations. Compared to these works, we focus on generic fairness measures for multimodal models and use visual grounding to bridge different languages.

3 Multilingual Individual Fairness

For an ideal multilingual vision-and-language model, text descriptions in different languages referring to similar semantic meanings should be equally similar or dissimilar to the same grounding images. We note that there are no language expressions that are perfectly identical to each other in real-world scenarios due to linguistic features. Nevertheless, at least in a normal vision-and-language task, multilingual models are desired to impose equal treatment to different languages. For instance, “this is a cat” (in English) and “das ist eine Katze” (in German) should be similarly related to an image of a cat in image-text retrieval. This intuition aligns with individual fairness in a multilingual manner. In this section, we investigate to what degree multilingual representations are individually fair.

Individual fairness requires that similar people should be treated similarly (Dwork et al., 2012). In our multilingual setting, we require that the text snippets expressing similar semantics in different languages should be similarly related to the same images. Taking the Euclidean distance function to measure the distance between text features, we can define α-multilingual individual fairness by:

Definition 1 (Multilingual Individual Fairness)**.** Given a set of image-text pairs $\{(I, T)\}$, a multimodal model M satisfies α-multilingual individual fairness if for all (I, T), for languages L and L':

$$|S(I, T^{(L)}) - S(I, T^{(L')})| \leq \alpha \|\boldsymbol{t}^{(L)} - \boldsymbol{t}^{(L')}\|$$

where $\boldsymbol{t}^{(L)}$ is the textual representation vector yielded by M in language L.

Here, α is a parameter to control the ratio of similarity gap to the text feature vectors' distance, and smaller α indicates the model is individually fairer. Note that the similarity gap is at most 2, because the range of cosine similarity is $[0, 1]$. In general settings, $S(I, T)$ is measured by the cosine similarity between the encoded visual vector $\boldsymbol{v}$ and textual vector $\boldsymbol{t}$.

Lemma 1. *Denote* $\mathcal{O}_\rho(\boldsymbol{t}) = \{\boldsymbol{x} \mid \|\boldsymbol{x} - \boldsymbol{t}\| \leq \rho\}$ *to be a closed ball of radius* $\rho > 0$ *and center* $\boldsymbol{t}$*. Then* *for any visual representation vector* $\boldsymbol{v}$*,*

$$\sup_{\substack{\boldsymbol{t}^{(L')} \in \mathcal{O}_\rho(\boldsymbol{t}^{(L)}) \\ 0 \le \rho < \|\boldsymbol{t}^{(L)}\|}} |S(\boldsymbol{v}, \boldsymbol{t}^{(L')}) - S(\boldsymbol{v}, \boldsymbol{t}^{(L)})| \le \sqrt{2(1 - \sqrt{1 - (\frac{\rho}{\|\boldsymbol{t}^{(L)}\|})^2})} \quad (1)$$

where $S(\cdot, \cdot)$ *denotes the cosine similarity,* $\boldsymbol{t}^{(L)}$ *and* $\boldsymbol{t}^{(L')}$ *are textual representation vectors for languages* L *and* L'*, respectively.*

We defer the proof to Appendix A.1. Lemma 1 implies that when the distance between multilingual textual representation vectors is bounded, the similarity with images can be bounded in terms of their distance. It is worth noting that the bounds are independent of the visual representation vectors. Nevertheless, the form of upper bound in Theorem 1 is a bit sophisticated, and can be simplified when $\rho \ll \|\boldsymbol{t}^{(L)}\|$.

Theorem 2. *When* $\|\boldsymbol{t}^{(L')} - \boldsymbol{t}^{(L)}\| \ll \|\boldsymbol{t}^{(L)}\|$*,*

$$|S(\boldsymbol{v}, \boldsymbol{t}^{(L')}) - S(\boldsymbol{v}, \boldsymbol{t}^{(L)})| \lessapprox \frac{\|\boldsymbol{t}^{(L')} - \boldsymbol{t}^{(L)}\|}{\|\boldsymbol{t}^{(L)}\|}.$$

Theorem 2 is a direct application of Lemma 1 when the distance between multilingual vectors is small enough, and extends in many natural cases to approximate the multilingual individual fairness with $\alpha \approx \frac{1}{\|\boldsymbol{t}^{(L)}\|}$. The proof can be found in Appendix A.2. Theorem 2 implicates to what degree the multimodal model satisfies individual fairness when text snippets are well aligned between different languages.

4 Multilingual Group Fairness

Distinct from individual fairness, multilingual group fairness appeals to the idea that multimodal models should achieve equivalent predictive performance across different languages. From the perspective of representations, it is hard to carry out this demand without well-defined tasks and metrics. Hence it is natural to ask how to define group fairness in this scenario properly? In this section, we shall answer this question by equating language as a unique dimension of group membership relating to the text modality. We formulate the criteria by equalizing the accuracy rates over different languages. We also observe that images are often connected to people in protected or unprotected groups. Given the image-text pairs, we consider the accuracy disparity across different languages conditioning the subgroup of images.

4.1 Equality of Accuracy across Languages

Given a dataset $\mathcal{D}$ consisting of ground-truth image-text pairs $\{(I_i, T_i)\}$ and each text can be in different languages. The goal of a multimodal model M is to predict the similarity $S(I_i, T_j)$ for any image I_i and text T_j. Then the model matches $\hat{T}_i$ for images I_i by selecting the text with highest similarity scores, i.e., $\hat{T}_i = \arg\max_j S(I_i, T_j)$.

$$\texttt{Acc}(M) = \frac{1}{|\mathcal{D}|} \sum_{\mathcal{D}} \mathbb{1}[\hat{T}_i = T_i] \quad (2)$$

We use the superscript (L) to indicate the accuracy $\texttt{Acc}^{(L)}$ is evaluated in language L. Next, we take language as group membership and define multilingual accuracy parity by equalizing accuracy across languages.

Definition 2 (multilingual accuracy parity)**.** A multimodal model M satisfies *multilingual accuracy parity* if $\texttt{Acc}^{(L)}(M) = \texttt{Acc}^{(L')}(M)$ for all languages L, L'.

In practice, it is impossible to achieve accuracy parity for all languages. Following (Hu et al., 2020), we use

$$\texttt{Gap}_M(L, L') = |\texttt{Acc}^{(L)}(M) - \texttt{Acc}^{(L')}(M)| \quad (3)$$

to represent the cross-lingual gap for model M.

4.2 When Language Meets Groups in Images

The above discussion on group fairness considers language as the sole group membership. In the real-world image and text applications, the people portrayed in the images are often associated with protected groups. For instance, the face attribute dataset (Liu et al., 2015) contains sensitive attributes, such as race, age and gender. Let G denote the group membership of images and $\mathcal{D}_a$ denote the subset of data examples $\mathcal{D}$ given $G = a$. The accuracy of a multimodal model evaluated on the images of subgroup a is defined as

$$\texttt{Acc}_a(M) = \frac{1}{|\mathcal{D}_a|} \sum_{\mathcal{D}_a} \mathbb{1}[\hat{T}_i = T_i] \quad (4)$$

When language is connected to images of different groups, we can define accuracy disparity between group a and group b with respect to model M within language L as

$$\texttt{Disp}_M^{(L)}(a, b) = |\texttt{Acc}_a^{(L)}(M) - \texttt{Acc}_b^{(L)}(M)| \quad (5)$$

Disp represents the group rate gap in a single language. Mirroring *multilingual accuracy parity*, we can define the *multilingual group rate parity* as below.

Definition 3 (multilingual group rate parity)**.** A multi-modal model M satisfies multilingual group rate parity if $\texttt{Disp}_M^{(L)}(a,b) = \texttt{Disp}_M^{(L')}(a,b)$ with respect to groups a, b associated with images for all languages.

Definition 2 and Definition 3 evaluate the fairness of multilingual representations from diverse aspects. More broadly, we may be interested in the accuracy gap between different combinations of languages and groups. A common case is that there are only two protected groups (e.g. female and male, young and old). Let $p_a = \frac{|\mathcal{D}_a|}{|\mathcal{D}|}$ and $p_b = \frac{|\mathcal{D}_b|}{|\mathcal{D}|}$ represent the population proportions of group a and group b respectively, satisfying $p_a + p_b = 1$. Then we can decompose the cross-lingual cross-group accuracy disparity as below:

Proposition 3. *When there are only two protected groups a and b, the following inequality holds for any two languages L and L'*

$$|\texttt{Acc}_a^{(L)} - \texttt{Acc}_b^{(L')}| \leq \texttt{Gap}(L, L') \\ + p_b \cdot \texttt{Disp}^{(L)}(a,b) + p_a \cdot \texttt{Disp}^{(L')}(a,b) \quad (6)$$

The proof can be found in Appendix A.3. Proposition 3 guarantees that the accuracy disparity between any combinations of languages and protected groups can be upper bounded by a variety of factors, and implicates that we only need to focus on cross-lingual gap and group rate gap measures to assess multilingual group fairness. In what follows, we will take a closer look at how the multilingual CLIP model performs with compositions of languages and protected groups under these fairness criteria.

5 Evaluations

In this section, we work with the pre-trained multilingual CLIP (Carlsson and Ekgren, 2021) model to study multilingual fairness. We validate the extent to which the model is individually fair across different languages in Section 5.1. We characterize the prevalence of multilingual group unfairness on human faces in Section 5.2 and Section 5.3. These empirical evaluations shed light on potential directions for mitigating unfairness in multilingual multimodal representations.

5.1 Multilingual Individual Fairness

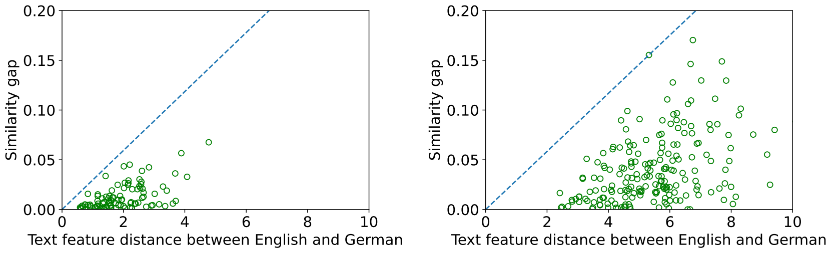
The theoretical analysis on multilingual individual fairness posed in Section 3 implies that the ratio of similarity difference to their text feature distance can be bounded by the reciprocal of the length of text feature vectors. To verify the implication, we conduct experiments on the Multi30K dataset (Elliott et al., 2016).

Dataset. The Multi30K dataset (Elliott et al., 2016) contains 31,014 Flickr30K (Young et al., 2014) images and composes the *translation* and the *independent* portions of English-German caption pairs. The German translations were collected from professional English-German translators by translating the English captions without seeing the images, one per image. The independent portion was independently annotated by German crowd-workers after seeing the images instead of English captions, five per image. Hence, the translated captions are strongly aligned in both languages, while the independent descriptions may have distinct context. We use 1,000 test images for our evaluation. For the independent portion, we select the first English caption and the first German caption of the five to pair with the image for a fair comparison.

Results. We embed each English-German caption pair into textual representation vectors and the corresponding image into visual representation vectors. We compute the Euclidean distance between English-German text features, as well as the cosine similarity with respect to the image features. We plot their cross-lingual gap on the translation and the independent portions in Fig. 1a and Fig. 1b, respectively. For both portions, the blue dashed lines represent the empirical upper bounds of the ratio between similarity gap and text feature distance.

Unsurprisingly, we find out that the English-German captions are more closely aligned on the translation portion (the average textual feature distance is 1.86) than the independent portion (average distance is 5.69). The similarity gaps regarding the translation portion are below 0.06 in general, and those regarding the independent portion are above 0.10 for many instances. The reason is apparent: translated captions have more similar semantics owning to the professional text-to-text translations, while independent captions have more diverse expressions of the same images, even if they might refer to the same content.

On the other hand, we observe that the slopes



(a) Translation

(b) Independent

	translation	independent
en	50.4	59.2
de	45.6	36.3
`Gap`	4.8	22.9

(c) Accuracy disparity

Figure 1: **We empirically examine how does the multilingual CLIP fare on the translation and the independent portions.** Fig. (a) and (b): the x-axis represents the distance between English and German captions, the y-axis represents the gap between their corresponding similarity scores, and the slope of blue dashed lines represents the empirical α for multilingual individual fairness. Fig. (c): we evaluate the accuracy for image-text matching, and find out that the independent portion incurs huge accuracy disparity compared with the translation portion.

of blue dashed lines in Fig. 1a and Fig. 1b are approximate to each other, i.e., the empirical α for both portions are similar. This fact implies that the multilingual CLIP model evaluated on two different text corpora share a similar level of individual fairness, even though the cross-lingual similarity gaps are quite different. We also note that the empirical upper bound of α are much smaller than the theoretical upper bound $\frac{1}{\|\boldsymbol{t}^{(L)}\|}$ in Theorem 2.

Although we have verified that multilingual multimodal representations satisfy similar individual fairness, we demonstrate that they violate group fairness by evaluating their image-text matching accuracy. As shown in Fig. 1c, English captions dominate the Top-1 image-text matching accuracy over German captions, with 4.8% higher on the translation portion and 22.9% higher on the independent portion. This observation delivers an important message for researchers who are interested in learning fair representations (Ruoss et al., 2020): individual fairness *does not* flatly prevent accuracy disparity among different languages (Binns, 2020).

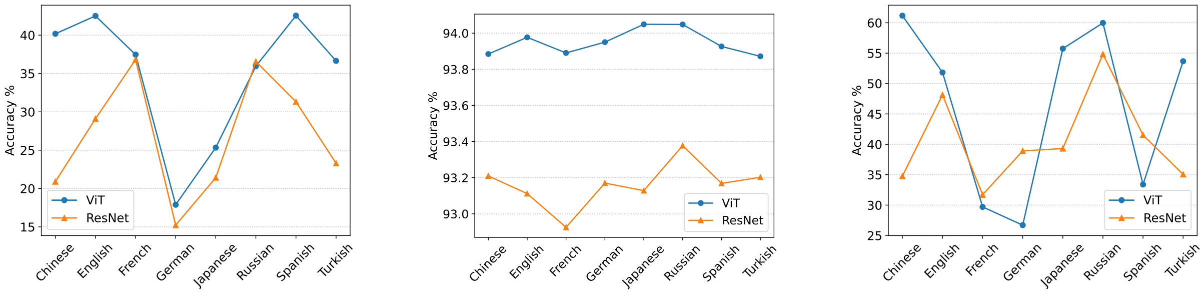
5.2 Multilingual Accuracy Disparity

Dataset. FairFace (Karkkainen and Joo, 2021) is a face attribute dataset for the balanced race, gender, and age groups. It categorizes gender into two groups, including female and male, and race into seven groups, including White, Black, Indian, East Asian, Southeast Asian, Middle Eastern, and Latino. For ages, we categorize the raw labels into five groups: infants (0–2), children and adolescents (2–19), adults (20–49), middle age adults (50–69), and seniors (more than 70). We follow their original data split and select the validation set consisting of 10,940 face images for evaluation.

Languages. We analyze the multilingual group fairness for 8 languages: Chinese (zh), English (en), French (fr), German (de), Japanese (ja), Russian (ru), Spanish (es), and Turkish (tr). We select English as the pivot language and write natural language prompts in English. Then we translate them into other languages: we first use Google Translate and then recruit native speakers to rate the prompts and fix any potential errors on Amazon Mechanical Turk (see Appendix D for more details). The rationale for only using English as the pivot language is that the multilingual CLIP (Carlsson and Ekgren, 2021) selects English as the pivot language for aligning multilingual text embeddings.

Text Prompts. Following Radford et al. (2021), we construct the text prompt by the template "A photo of a `{label}` person". Concretely, for gender classification, we construct the text prompt "A photo of a woman" when the gender attribute is female, and construct "A photo of a man" otherwise. For race classification, we construct the text prompt by "A photo of a(n) {race} person". Note that Indian actually refers to South Asian ethnic groups in the Fairface race taxonomy (Karkkainen and Joo, 2021) but it can refer to Native Americans as well. To avoid ambiguity, we replace "Indian" by "South Eastern" to construct the prompts. For age classification, we notice that the age attributes in Fairface dataset are numeric values and use the template "A photo of a person aged `{age}` years" to construct text prompts.

Results. We probe the multilingual accuracy disparity for race classification, gender classification, and age classification, as shown in Fig. 2. We use two different pre-trained image encoders for extracting visual representation vectors, including



(a) Race classification (b) Gender classification (c) Age classification

Figure 2: **Race, gender, and age classification accuracy across different languages.** The languages are in alphabetical order. Two different vision encoders for encoding image features are evaluated, including Vision Transformer (ViT) (Dosovitskiy et al., 2021) and ResNet-50 (ResNet) (He et al., 2016).

Vision Transformer (Dosovitskiy et al., 2021) and ResNet-50 (He et al., 2016). We observe that:

- **Cross-lingual gap varies across different protected groups.** The predictive accuracy for gender classification is consistently higher than 90% across all the languages. In contrast, the multimodal model has relatively poor performance and more considerable variance for race and age classification. Furthermore, race classification yields 24.66% accuracy disparity and age classification yields 34.47% accuracy disparity for Vision Transformer. This implies that the huge disparity may result from the poor predictive performance of the model.
- **Visual representations affect accuracy disparity.** For race classification, Vision Transformer features generally achieve higher accuracy across all languages than ResNet-50 (34.82% *vs.* 26.83% on average) except for Russian. The standard deviation of Vision Transformer is higher than ResNet-50 (8.18% *vs.* 7.34%). The maximal accuracy gap for Vision Transformer is 30.40% between German and Spanish, while the maximal accuracy gap for ResNet-50 is 23.12% between German and French. For gender classification, Vision Transformer dominantly achieves higher accuracy and incurs less accuracy gap. For age classification, the accuracy is moderately low for all languages. However, Vision Transformer has 63.1% accuracy in Chinese while only 25.8% accuracy in German, exaggerating the accuracy gap between languages.

In Table 1, we present the complete results of Fig. 3 by compositions of gender and race groups across different languages.

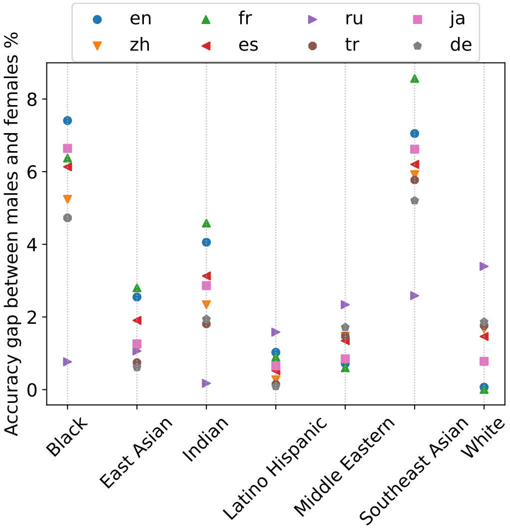


Figure 3: **Gender accuracy gap across different languages and racial groups.** Black and Southeast Asian people face significant larger gender gaps than other racial groups in most languages.

5.3 Multilingual Group Rate Disparity

We evaluate multilingual group rate disparity for gender classification on Fairface dataset. We follow the same setup as described in Section 5.2 and measure the gender gap given by Eq. (5), where a is the composition of male and various race groups, b is the composition of female and various race groups. We defer the complete results to Table 1 in Appendix B. We try to answer the following research questions:

- **How do gender gaps differ across protected groups?** We plot the gender accuracy gap across different languages and racial groups in Fig. 3. It is clearly shown that Black and Southeast Asian groups dominantly exhibit larger gender gaps than other groups. We also observe that French has a similar performance with English. We con-

Table 1: **Gender classification accuracy of FairFace images by race groups across different languages.** We note the maximal gender gap across races with underline and the maximal gender gap across languages in **bold**. Taking English as the pivot language, we also highlight any amplified gap compared to English in red and any mitigated gap in green.

Language	Gender	White	Black	Indian	East Asian	Southeast Asian	Middle Eastern	Latino	Average
English	Female	95.1	90.9	94.5	95.2	96.0	96.0	94.2	94.6

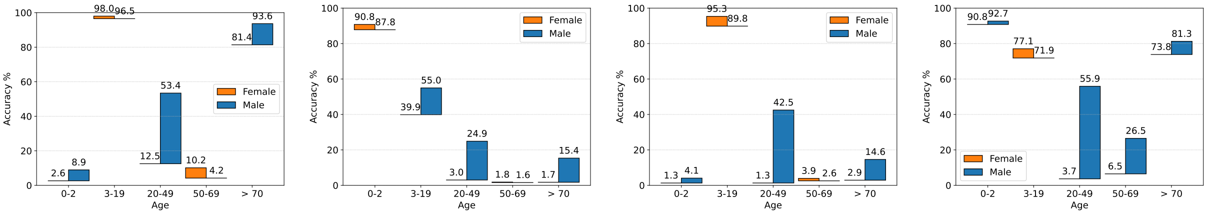
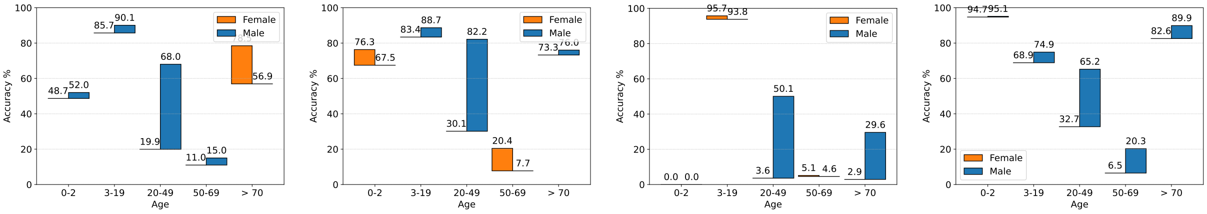
jecture this is because English and French share the same alphabet and similar syntactic structures. Besides, as shown in Table 1, English and French have the largest race inequality regarding gender gap—nearly zero gender gaps for White but near the maximal gaps for Black.

- **Are gender gaps amplified for different languages when compared with English?** We report the accuracy gap on gender classification of FairFace images by race groups across different languages in Table 1. We take English as the pivot language and examine whether the accuracy gaps by race groups are amplified for other languages. Compared with English, accuracy gaps for White and Middle Eastern groups are generally amplified for other languages. On the other hand, accuracy gaps are generally mitigated for groups including Black, Indian, East Asian, Southeast Asian, and Latino groups. The averaged cross-lingual gaps are mitigated for all the languages except for French.

We also evaluate multilingual group rate disparity for age classification. We composite gender and age as the group membership. We plot the age classification accuracy by female and male groups across different languages in Fig. 4. The blue bars indicate that the male group has higher accuracy than the female group, while the orange bars indicate that the female group has higher accuracy than the male group. The heights of bars represent the accuracy gaps between male and female groups. In general, the male group has higher accuracy than the female group. Especially, adults (20–49 years old) consistently suffer huge gender gaps across all the languages, with the largest gap 52.2% for Japanese. It is worth noting that the numerals to express ages are identical in text prompts for different languages, e.g., "a person aged 20 to 49 years" in English versus "eine Person im Alter von 20 bis 49 Jahren" in German. This controlled experiment



(a) English (b) German (c) French (d) Japanese



(e) Turkish (f) Russian (g) Spanish (h) Chinese

Figure 4: **Age classification accuracy across female and male groups for different languages.** The blue bars indicate that the male group has higher accuracy than the female group, while orange bars indicate that the female group has higher accuracy. The heights of bars represent the accuracy gaps between male and female groups.

helps us better understand whether the identical numeric digits have distinct meanings in multilingual contexts. As shown in Fig. 4, although text prompts in different languages share the same numerals of ages, the yielding accuracy exhibits significant disparity across languages. One prominent example is that the predictive accuracy for infants (0–2 years old) is 5.8% for English and 2.6% for French, but 89.4% for German and 91.6% for Japanese, implying the presence of significant cross-lingual accuracy gaps.

6 Conclusion and Limitation

Our work extends a growing body of fairness discourse in multilingual and multimodal learning to explore how the multilingual fairness notions, characterized by individual fairness and group fairness, are formulated on the multimodal representations. We stress that multimodal representations are individually fair, but do not prevent accuracy disparity across groups. Our extensive experimental results reveal the negative impacts caused by carelessly applying pre-trained general-purpose multimodal representations. Just one example of this, as discussed in Section 5.3, is the significant disparities between cross-lingual gender gaps occurred in age classification. We believe the findings and insights gained through this work can encourage future work to investigate how to mitigate multidimensional biases in representation learning and prevent disparities in the downstream decision-making process.

Our work also has limitations. This work does not provide a thorough explanation on whether the biases and disparities result from the multilingual model itself, or from the datasets it is pre-trained on. However, to give a convincing explanation, it requires either access to large amounts of training data with privacy concerns (the complete datasets for training CLIP are not released yet), or ample computational resources for reproducing the training process. This research question itself is important and worth investigating further.

Broader Impact

This work provides insights into fairness in the context of multilingual and multimodal representations. We recognize potential ethical concerns that may arise in the evaluation and address them below.

Firstly, the empirical evaluation for multilingual group fairness adopts the categories of protected groups introduced in the FairFace dataset (Karkkainen and Joo, 2021). We are aware that gender can be non-binary, and individuals can be self-identified outside male and female. Some terms of race attributes in the dataset, such as Latino and Hispanic, are rooted in culture and ethnicity and should not be treated as racial categories. In addition, facial images of low population groups, including Hawaiian and Pacific Islanders and Native Americans, are discarded during data collection. The sensitive attributes in the original FairFace datasets are identified and annotated by human crowd workers. It is possible that the labels of gender, race, and age contain implicit biases and noises. However, these ethical concerns arise from the data collection of the FairFace dataset per se. We anticipate that the methodology we adopted to study multilingual fairness can still be generalized to other data source when more inclusive data collections are available.

Secondly, image classification on the FairFace dataset relies on human-crafted text prompts. The fashion of prompt engineering can be dated from pre-training image and text representations with natural language supervision (Li et al., 2017; Radford et al., 2021). To avoid offensive and harmful speech towards certain protected groups, we construct the text prompts in a descriptive intent and a neutral tone.

Finally, the intention for performing classification with sensitive attributes is to validate the presence of biases in pre-trained representations rather than to acquire the personal information of people in the images. Both the evaluated pre-trained models and the benchmark datasets are publicly accessible, and we carefully follow their licenses and agreements for usage. In this sense, we do not foresee any data privacy or information security issues.

Acknowledgements

A Omitted Proofs

A.1 Proof of Lemma 1

Proof. Given by the definition of cosine similarity, we have

$$\begin{aligned} &|S(\boldsymbol{v}, \boldsymbol{t}^{(L)}) - S(\boldsymbol{v}, \boldsymbol{t}^{(L')})| \\ =\ & |\frac{\boldsymbol{v} \cdot \boldsymbol{t}^{(L)}}{\|\boldsymbol{v}\|\|\boldsymbol{t}^{(L)}\|} - \frac{\boldsymbol{v} \cdot \boldsymbol{t}^{(L')}}{\|\boldsymbol{v}\|\|\boldsymbol{t}^{(L')}\|}| \\ =\ & \frac{|\boldsymbol{v} \cdot (\|\boldsymbol{t}^{(L')}\|\boldsymbol{t}^{(L)} - \|\boldsymbol{t}^{(L)}\|\boldsymbol{t}^{(L')})|}{\|\boldsymbol{v}\|\|\boldsymbol{t}^{(L)}\|\|\boldsymbol{t}^{(L')}\|} \end{aligned} \tag{7}$$

From the definition of dot product,

$$\begin{aligned} &|\boldsymbol{v} \cdot (\|\boldsymbol{t}^{(L')}\|\boldsymbol{t}^{(L)} - \|\boldsymbol{t}^{(L)}\|\boldsymbol{t}^{(L')})| \leq \\ &\qquad \|\boldsymbol{v}\| \cdot \|(\|\boldsymbol{t}^{(L')}\|\boldsymbol{t}^{(L)} - \|\boldsymbol{t}^{(L)}\|\boldsymbol{t}^{(L')})\| \end{aligned} \tag{8}$$

We plug Eq. (8) into Eq. (7) and eliminate the variable $\boldsymbol{v}$

$$\begin{aligned} &|S(\boldsymbol{v}, \boldsymbol{t}^{(L)}) - S(\boldsymbol{v}, \boldsymbol{t}^{(L')})| \leq \\ &\qquad \frac{\|(\|\boldsymbol{t}^{(L')}\|\boldsymbol{t}^{(L)} - \|\boldsymbol{t}^{(L)}\|\boldsymbol{t}^{(L')})\|}{\|\boldsymbol{t}^{(L)}\|\|\boldsymbol{t}^{(L')}\|} \end{aligned} \tag{9}$$

Let θ denote the angle between $\boldsymbol{t}^{(L)}$ and $\boldsymbol{t}^{(L')}$, i.e.,

$$\cos\theta = \frac{\boldsymbol{t}^{(L)} \cdot \boldsymbol{t}^{(L')}}{\|\boldsymbol{t}^{(L)}\|\|\boldsymbol{t}^{(L')}\|},$$

the square of numerator in Eq. (9) expands as

$$\begin{aligned} &(\|\boldsymbol{t}^{(L')}\|\boldsymbol{t}^{(L)} - \|\boldsymbol{t}^{(L)}\|\boldsymbol{t}^{(L')})^2 \\ &\qquad = 2\|\boldsymbol{t}^{(L)}\|^2\|\boldsymbol{t}^{(L')}\|^2(1 - \cos\theta) \end{aligned} \tag{10}$$

Substituting the square root of Eq. (10) into Eq. (9), we eliminate the denominator and obtain

$$|S(\boldsymbol{v}, \boldsymbol{t}^{(L)}) - S(\boldsymbol{v}, \boldsymbol{t}^{(L')})| \leq \sqrt{2(1 - \cos\theta)} \tag{11}$$

Recall that $\boldsymbol{t}^{(L')} \in \mathcal{O}_\rho(\boldsymbol{t}^{(L)})$, we can bound θ by the law of sines

$$\sup_\theta |\sin\theta| = \sup_{\boldsymbol{t}^{(L')}} \frac{\|\boldsymbol{t}^{(L')} - \boldsymbol{t}^{(L)}\|}{\|\boldsymbol{t}^{(L)}\|} = \frac{\rho}{\|\boldsymbol{t}^{(L)}\|} \tag{12}$$

Taking supremums on both sides of Eq. (11) and combining Eq. (12), we complete the proof

$$\begin{aligned} &\sup_{\substack{\boldsymbol{t}^{(L')} \in \mathcal{O}_\rho(\boldsymbol{t}^{(L)}) \\ 0 \leq \rho < \|\boldsymbol{t}^{(L)}\|}} |S(\boldsymbol{v}, \boldsymbol{t}^{(L')}) - S(\boldsymbol{v}, \boldsymbol{t}^{(L)})| \\ \leq\ & \sup_\theta \sqrt{2(1 - \sqrt{1 - sin^2\theta})} \\ =\ & \sqrt{2(1 - \sqrt{1 - (\frac{\rho}{\|\boldsymbol{t}^{(L)}\|})^2})} \end{aligned}$$

□

A.2 Proof of Theorem 2

Proof. Due to Half-Angle Identities, Eq. (11) derives as

$$|S(\boldsymbol{v}, \boldsymbol{t}^{(L')}) - S(\boldsymbol{v}, \boldsymbol{t}^{(L)})| \leq 2|\sin\frac{\theta}{2}| \tag{13}$$

For sufficiently small θ, i.e., $\|\boldsymbol{t}^{(L')} - \boldsymbol{t}^{(L)}\| \ll \|\boldsymbol{t}^{(L)}\|$, we take the first-order Taylor approximation

$$2|\sin\frac{\theta}{2}| \approx |\theta| \approx |\sin\theta| = \frac{\|\boldsymbol{t}^{(L')} - \boldsymbol{t}^{(L)}\|}{\|\boldsymbol{t}^{(L)}\|} \tag{14}$$

Combining Eq. (13) and Eq. (14) we complete the proof. □

A.3 Proof of Theorem 3

Proof. Expanding $|\mathtt{Acc}_a^{(L)} - \mathtt{Acc}_b^{(L')}|$ by triangle inequality we have

$$\begin{aligned} &|\mathtt{Acc}_a^{(L)} - \mathtt{Acc}_b^{(L')}| \\ =\ & |\mathtt{Acc}_a^{(L)} - \mathtt{Acc}^{(L)} + \mathtt{Acc}^{(L)} \\ &\qquad - \mathtt{Acc}^{(L')} + \mathtt{Acc}^{(L')} - \mathtt{Acc}_b^{(L')}| \\ \leq\ & |\mathtt{Acc}_a^{(L)} - \mathtt{Acc}^{(L)}| + |\mathtt{Acc}^{(L)} - \mathtt{Acc}^{(L')}| \\ &\qquad + |\mathtt{Acc}^{(L')} - \mathtt{Acc}_b^{(L')}| \end{aligned} \tag{15}$$

Noticing that $\mathtt{Acc}^{(L)} = p_a \cdot \mathtt{Acc}_a^{(L)} + p_b \cdot \mathtt{Acc}_b^{(L)}$ and $p_a + p_b = 1$, we have

$$\begin{aligned} &|\mathtt{Acc}_a^{(L)} - \mathtt{Acc}^{(L)}| \\ =\ & p_b \cdot |\mathtt{Acc}_a^{(L)} - \mathtt{Acc}_b^{(L)}| \\ =\ & p_b \cdot \mathtt{Disp}^{(L)}(a, b) \end{aligned} \tag{16}$$

Similarly,

$$\begin{aligned} &|\mathtt{Acc}^{(L')} - \mathtt{Acc}_b^{(L')}| \\ =\ & p_a \cdot |\mathtt{Acc}_a^{(L')} - \mathtt{Acc}_b^{(L')}| \\ =\ & p_a \cdot \mathtt{Disp}^{(L)}(a, b) \end{aligned} \tag{17}$$

Substituting Eq. (3), Eq. (16), and Eq. (17) into Eq. (15) we complete the proof. □

B Additional Experimental Results

B.1 Empirical Evaluation with Dissimilar Images and Text

We note that the theoretical analysis posed in Theorem 2 does *not* presume how the images are similar to the text. However, the evaluation in Section 5.1 only focuses on similar images and text. To complement for evaluation on dissimilar images and text, we measured to what extent the pre-trained model satisfies multilingual individual fairness for dissimilar images and captions in the Appendix B.1. Specifically, we randomly shuffle the images in the data set such that each image is paired with a random pair of English and German captions. Then we compare the similarity gaps between English and German captions with the images in terms of the encoded textual vector distance between English and German. We observe the same trends for dissimilar images and text: (1) The translation portion generally induces a smaller similarity gap than the independent portion. (2) The CLIP model evaluated on both text corpora has similar empirical α values.

C Computation Infrastructure

We use a GPU server with 4 NVIDIA RTX 2080 Ti GPUs for evaluation.

D Human Evaluation of the Quality of Machine Translated Text Promts

We recruited crowd workers at Amazon Mechanical Turk (AMT)[1] to evaluated the quality of text prompts generated in Section 5.2. The crowd workers were supposed to speak both the original language and the translated language to be qualified for completing the tasks. Each task contained one pair of text prompts in the original language (English) and the translated language and was assigned to at least five crowd workers. Each crowd worker was asked to rate the quality of translation from adequacy and fluency on a scale of 1–5. Specifically, we asked the crowd workers the following questions:

- **Adequacy:** does the translated text adequately expresses the meaning in the original text in English?
- **Fluency**: how good the translated language is?

We also asked the workers to point out and fix any potential problems in the prompts. We collected and visualized the crowdsourced ratings in Fig. 6. For Chinese, French, German, and Japanese, the crowd workers considered the translated text can adequately express all the meanings retained in the English prompts and is flawless. For Japanese, Russian, and Turkish, the crowd workers considered the translations can convey most of the message in the English prompts and are good in fluency.

Abstract

Traditionally, Latent Dirichlet Allocation (LDA) ingests words in a collection of documents to discover their latent topics using word-document co-occurrences. Previous studies show that representing bigrams collocations in the input can improve topic coherence in English. However, it is unclear how to achieve the best results for languages without marked word boundaries such as Chinese and Thai. Here, we explore the use of retokenization based on chi-squared measures, *t*-statistics, and raw frequency to merge frequent token ngrams into collocations when preparing input to the LDA model. Based on the goodness of fit and the coherence metric, we show that topics trained with merged tokens result in topic keys that are clearer, more coherent, and more effective at distinguishing topics than those of unmerged models.

1 Introduction

Latent Dirichlet allocation (LDA) models provide useful insights into themes and trends in a large text collection through the unsupervised inference of *topics*, or probability distributions over unigram word types in the corpus (Blei et al., 2003). Topics from these models are often interpreted based on their highest-probability words, with documents expressed as vectors of proportions of each topic. Unfortunately, the context in which these tokens arise can be obscured in the bag-of-words rendering of text as unigram counts in documents. For instance, a topic with high probabilities of both "coffee" and "table" is tempting to interpret as focusing on the furniture item "coffee table", but both words could be frequent in a discussion of cafes containing no coffee tables. This problem is amplified in languages without marked word boundaries, such as Chinese and Thai: while existing tokenizers in these languages can segment characters into words, there is always a question about to what extent the tokenizers should group words together. Words that have been segmented by tokenizers may not express the concept of the original text if they were found as parts of collocations. Meaningful interpretation of topics can be lost without careful recombination of these words.

We hypothesize that the morphology of the language should play an important role in determining the suitable pre-processing steps that would improve the results of topic models. The main morphological types we consider are *synthetic language* and *analytic language*. Synthetic languages use many morphemes to compose a word and can be further divided into fusional and agglutinative languages. Fusional languages such as German differ from agglutinative languages such as Korean and Japanese: a single morpheme in fusional languages can code for many morphosyntactic features. On the other hand, analytic languages such as Thai and Chinese convey meanings by relating many words together, and morphological devices are more rarely used. Under our hypothesis, analytic languages should benefit from token merging, but synthetic languages might not because the meaning is conveyed by inflection (through bound morphemes) and agglutination (through free morphemes).

In this project, we investigate the effects of token merging as a pre-processing step, and study how those effects vary based on the writing systems and the morphological features of the languages. We evaluate three measures to determine when to merge multiple adjacent words into conceptually-unified phrasal tokens prior to LDA model training: chi-squared statistics, *t*-statistics, and raw frequency counts of phrases. We test these merging strategies on English, German, Chinese, Japanese, Korean, Thai, and Arabic. This set of languages is drawn from various writing systems and different morphological typology to see which type of

language favors which type of merging strategy.

The main contributions of this paper are as follows:

- We determine through empirical studies that a *t*-statistic and raw-frequency approach to token merging improves the topic modeling results across all language types and writing systems for the corpora that do not differ much from the collocation training data.
- We also show the positive consequences of token merging: the percentage of merged tokens in the LDA training data is correlated with the quality of the topic modeling results.
- Finally, we provide evidence that the popular approach of applying a χ^2measure to token merging tends to overfit to the collocation training data and result in a low percentage of merged tokens in a number of languages, making it a less suitable general-purpose approach than *t*-statistics.

2 Related Work

Pre-processing steps can substantially alter the results of the LDA models even in languages with good tokenization heuristics such as English (Schofield and Mimno, 2016; May et al., 2016). We believe that languages that do not have clear tokenization standards deserve investigation into what kind of processing is appropriate. Many works recognize that LDA results can be improved when input are including phrases (Lindsey et al., 2012; Lau et al., 2013; Yu et al., 2013; El-Kishky et al., 2014; Wang et al., 2016; Bin et al., 2018; Li et al., 2018). We consider it valuable to specifically assess approaches to determining these phrases.

Despite their popularity in analyzing large amounts of text data, LDA models are notoriously complex to evaluate. One must evaluate both the statistical fit of a model and the human-registered thematic coherence of the words found to arise in the high-probability words, or *keys*, of a topic, which may not correlate (Chang et al., 2009). Analyses often combine evaluations of fit (Wallach et al., 2009) and automated approximations of human judgments of coherence (Bouma, 2009; Mimno et al., 2011) based on mutual information, even with the expectation these may only somewhat correlate with true human judgments (Lau et al., 2014). A limitation of these existing approaches, however, is that they expect the vocabulary and tokenization to remain constant between the two models. For our evaluation, we use a normalized log-likelihood approach to capture fit while accounting for changes in vocabulary (Schofield and Mimno, 2016).

3 Collocations as LDA Token

Collocations consist of two or more words that express conventional meaning, which can convey information about multi-word entities, context, and word usage. We hypothesize that the introduction of multi-word tokens, which capture collocations as bigrams or trigrams by way of concatenation of adjacent tokens, can help achieve more useful and coherent topic models. For languages without clear word boundaries, there is a possible additional benefit to multi-word tokens: it can be hard to intuit whether inferred word boundaries will have a large impact on the final results. Merging adjacent words into 'multi-word' tokens may help remedy the potential problem of a segmentation that is not optimal for topic modeling purposes.

Many methods are possible to select collocations to merge from tokenized text (Manning and Schutze, 1999). In this paper, we evaluate the chi-squared statistics (χ^2), the *t*-statistic and raw frequency as approaches to develop a threshold for merging collocations into multi-word tokens prior to topic model training. The chi-squared measure $\chi^2(w_1, w_2)$ and $t(w_1, w_2)$ *t*-statistic for two adjacent tokens w_1 and w_2 are defined as:

$$\chi^2(w_1, w_2) = \frac{(P(w_1, w_2) - P(w_1)P(w_2))^2}{P(w_1)P(w_2)} \quad (1)$$

$$\begin{aligned} t(w_1, w_2) &= \frac{\bar{x} - \mu}{\frac{s^2}{N}} \\ &\approx \frac{P(w_1, w_2) - P(w_1)P(w_2)}{\sqrt{\frac{P(w_1, w_2)}{N}}} \end{aligned} \quad (2)$$

We first compute the collocation measures for all bigrams on a large collocation training corpus. Then we select the top bigrams that score the highest on the collocation measures and add those to our lexicon. After we tokenize and pre-process the collection of documents on which we would like to train LDA, we retokenize the data based on the collocation training corpus. We find all of the bigrams in the LDA training data that are also found in the top bigram lexicons that we obtain from the collocation training corpus. Then, the LDA training process proceeds as usual but with some of the original tokens merged into multi-word tokens as defined from the collocation training data.

4 Evaluation Metrics

We consider two primary evaluation metrics for exploring the effect of merging tokens: one based on log-likelihood, and one based on silhouette coefficients.

Held-Out Likelihood. When multi-word phrases are converted to individual tokens, the number of tokens in the document decreases while the size of the corpus vocabulary increases. It is therefore illogical to compare the likelihoods of the word-token model and collocation-token model directly. In order to normalize the scores between the two models that do not have the exact same vocabulary and tokens, we use the log-likelihood ratio between the LDA model likelihood and the null (unigram) likelihood for each model. In other words, we normalize the LDA model likelihood ($\mathcal{L}_{\text{model}}$) by dividing it with the unigram likelihood ($\mathcal{L}_{\text{unigram}}$) as introduced by Schofield and Mimno (2016). Therefore, the normalized loglikelihood per token ($\text{PTLL}_{\text{norm}}$) is

$$\text{PTLL}_{\text{norm}} = \frac{\log \mathcal{L}_{\text{model}} - \log \mathcal{L}_{\text{unigram}}}{N} \quad (3)$$

where N is the number of tokens. Since likelihood per token has been normalized by the unigram likelihood per token, the higher the PTLL, the better the model.

Concatenation-based Embedding Silhouette (CBES) Previous measures of topic coherence rely on statistics from the training data and assume that the vocabularies are identical for both models, which is not the case for our settings. To address this, we propose a new application of the silhouette coefficients (Rousseeuw, 1987), a common clustering evaluation metric to measure topic coherence.

A good topic should have all of its topic keys close to each other and away from other words that do not belong in the same topic. Therefore, the word embeddings of these topic keys should have shorter cosine distances within the same topic, and longer distances to the topic keys in other topics. When words are represented as a vector, this is exactly what the silhouette coefficients measure. To compute them, we first compute the $a(i)$, which is the mean cosine distance between topic-key i and other topic-keys in the same topic.

$$a(i) = \frac{1}{\mid C_i \mid -1} \sum_{j \in C_i, i \neq j} d(i,j) \quad (4)$$

where $d(i,j)$ is the distance between ith and jth topic-key and $\mid C_i \mid$ is the number of topic-keys in topic i. Then for each other topic, we compute the mean of the distance of topic-key i to topic-keys in that other topic. And $b(i)$ is the smallest of such mean among other topics.

$$b(i) = \min_{k \neq i} \frac{1}{\mid C_k \mid} \sum_{j \in C_k} d(i,j) \quad (5)$$

After obtaining $a(i)$ and $b(i)$, the silhouette coefficient for topic-key i is defined as:

$$s(i) = \frac{b(i) - a(i)}{\max(a(i), b(i))}, \text{if} \mid C_i \mid > 1 \quad (6)$$

and

$$s(i) = 0, \text{if} \mid C_i \mid = 1 \quad (7)$$

The silhouette coefficient for the entire model is the average $s(i)$ over all i. The larger silhouette coefficient means that topic-keys are relatively similar within their topic and different from other topics.

In order to compare the distances among words merged by different criteria, all compared word embeddings must be in the same space. Since merged tokens will modify the vocabulary of the corpus, we create four versions of the word embedding training corpus: the original version and the three other versions where tokens are merged based on χ^2, *t* and frequency collocation measures. We train the word embeddings on these four versions of the corpus so we can then compare word embeddings on a consistent vocabulary in each retokenization scheme.

5 Experiments

We hypothesize that morphology should play an important role in determining the suitable preprocessing steps. We test our methods on one fusional language (German), two agglutinative languages (Japanese and Korean), three analytic languages (Chinese, Thai, and Arabic), and English, which can be thought of as either analytic or fusional. These languages also represent languages drawn from all writing systems: logograms (Chinese), syllabic system (Japanese), featural system (Korean), abugida (Thai), abjad (Arabic), and true alphabets (English and German).

Arabic	1.22	1.20	66.89

Table 2: The percentage of overlapping merged tokens between two methods of retokenization computed on the retokenization training data. t and χ^2yield similar results for all languages.

The English corpora are drawn from The New York Times (Sandhaus, 2008), the Yelp Dataset[1], and United States State of the Union addresses (1790 to 2018) divided into paragraphs[2]. The German data come from Ten Thousand German News Articles Dataset[3]. The Chinese data come from three corpora: the news articles from Chinanews[4], restaurant reviews from Dianping[5], and the movie reviews from Douban[6]. The Japanese data is from the Webhose's Free Datasets[7]. The Korean data come from the KAIST Corpus[8]. The Thai data come from the news articles in Prachathai[9], the restaurant reviews from Wongnai[10], the BEST corpus[11], and the Thai National Corpus (Aroonmanakun, 2007). The Arabic data come from the Antcorpus (Chouigui et al., 2017). Each corpus is separated into 75% training documents and 25% test documents (Table 1).

We train the χ^2, t, and frequency-based tokenizers for each language on Wikipedia articles for that language. For all languages, we use the reduced version of Wikipedia database, except for English we use the filtered Wiki103 dataset (Merity et al., 2016). English, German, Chinese, Japanese, Korean, Thai and Arabic documents are tokenized with NLTK (Bird, 2006), SoMaJo (Proisl and Uhrig, 2016), Stanford Word Segmenter (Tseng et al., 2005), Fugashi (McCann, 2020), KoNLPy (Park and Cho, 2014), Attacut (Chormai et al., 2020) and Camel-tools (Obeid et al., 2020) respectively. For each criterion, we create a list of 50,000 top bigrams that have the highest scores. These lists of top bigrams will be used to merge words in the input of the LDA, effectively training a new tokenizer.

To train word embeddings, we use the `gensim` (Řehůřek and Sojka, 2010) implementation with the Continuous Bag-of-Word (CBOW) algorithm (Mikolov et al., 2013) to obtain word embeddings. The training corpora and their collocation versions are prepared based on the tokenizers that we discuss above. We preprocess the word embedding training data and the LDA training data the same way. For English, we lemmatize and lowercase the data. For Korean, Japanese, and Arabic, we lemmatize the data. For German, Chinese, and Thai, we do not do any normalization.

We use `MALLET` (McCallum, 2002) implementation of LDA with the default hyperparameters to train and evaluate topic models in both word and multi-word (collocation) documents with 10, 50, 100 topics. We run the experiment 3 times for each combination of corpus, type of retokenization (no retokenization, χ^2, t or frequency) and number of topics to compute the means of the normalized held-out likelihood and CBES, discussed in section 4.

6 Results and Discussion

The normalized log-likelihood per token of the t and frequency-based retokenization is significantly higher than the baseline for English, German, Chinese, Japanese, Korean, and Arabic for all text collections and the number of topics except EN-Yelp, TH-BEST, and TH-TNC (Table 3). Frequency-

Table 3: Normalized unigram log-likelihood per token (top) and Concatenation-based Embedding Silhouette (CBES) scores (bottom) for between the baseline and retokenization models: χ^2 , textitt, and raw frequency. Shaded cells mean that the results are inferior to the baseline, while bolded cells show the best results for each corpus and number of topics.

based retokenization gives the best results for most settings but not significantly higher than *t* retokenization. However, we observe mixed results from χ^2retokenization for some languages. This is quite surprising because raw frequency was previously found to be an inferior measure of collocation. This suggests that *t* and frequency-based retokenization might be a more reliable method for improving the goodness of fit of the LDA model. This also suggests that Japanese and Korean might have some specific quality that interacts well with all three types of retokenization.

Similarly, we observe a general improvement in coherence for the *t* and frequency retokenization (Table 3). The higher CBES score indicates that topic-keys are more semantically coherent and topics are more distinct. The coherence improves after *t* and frequency-based retokenization for English, Japanese, Korean, and Arabic corpora regardless of the number of topics. The improvement for Thai is spotty, and Chinanews is the only Chinese corpus in which we see improvement. This suggests that the choice of retokenization strategy might depend on the language types or the content of corpora itself. Consistent with the normalized log-likelihood results, Japanese and Korean corpora interact well with all three types of retokenization, suggesting that the morphology or typology of these two languages consistently benefit from collocation before training LDA models.

What could account for this discrepancy across languages and corpora? First, we observe a large variation of percentages of merged tokens across corpora. Because we fix the number of bigrams types to merge during the tokenizer training process to 50,000 for all three criteria (Table 1), we can use this analysis to find trends in the relative frequency of merged tokens. We see that χ^2 retokenizer only merges barely 1% of all the tokens before training the LDA models for English, Chinese,

Figure 1: The top 20 collocations from each retokenization methods. χ^2 favor proper names (bold-faced) more heavily than the other two methods.

German, Arabic, and Thai corpora, possibly introducing noise in the data that yield the results similar to or worse than the baseline. In contrast, the *t* and frequency-based retokenizers merge around 8%- 15% of all the tokens for English, German, and Chinese. Arabic has seen the highest merging percentage of 26%-27%. Notably, around 20 % of tokens are retokenized by all three retokenizers in Japanese and Korean. The truncation of the top χ^2bigrams list might cause this different behavior. The number of χ^2collocations that pass the hypothesis testing is significantly larger than that of *t* collocations. For example, there are 3.73 million χ^2collocations versus 231 thousand *t* collocations in Thai for the same significance level $\alpha = 0.005$. This full list of χ^2collocations includes all the top collocations from the *t* score and frequency treatments, implying that were we to use this significance threshold, the percentage of merged word would be at least as high as the two methods. However, the large vocabulary that the χ^2approach induces is impractical in many applications, suggesting it is an inefficient approach if the goal is primarily to merge frequent ngrams.

Another possible effect these results may show is that the writing system or the morphology could account for this notable discrepancy in retokenization percentage across languages. For English, the top 20 χ^2collocations are primarily specific named entities, but the *t* and frequency-based retokenizers yield more general compound nouns and common phrases (Figure 1). As the top 50,000 χ^2collocations contain primarily rare words, these are expected to co-occur rarely enough that even a few co-occurrences can trigger significance. Therefore, when we use this truncated list of rarely-occurring χ^2collocations, we generally see a very low merged token percentage.

The quality of retokenization impacts both the goodness of fit the model, as indicated by the normalized log-likelihood score, and the coherence of the model, as indicated by the CBES score. Within the same language, news corpora have higher percentages of merged words when merged with *t* and frequency collocations, while corpora containing restaurant and movie reviews tend to see lower percentages (Table 1). This could be because the news corpora are in a similar domain to that of the Wikipedia which we use to build the list of co-occurring words. A good retokenizer (in our cases, trained on Wikipedia data) should generalize well and recognize many collocations in a new corpus, which differs somewhat from the retokenizer training data. We found a significant positive correlation between merge percentage and the margin of improvement over the baseline (the difference between the PTLL of the model without retokenization and the PTLL or CBES of the model

Figure 2: Topic keys comparison in languages.

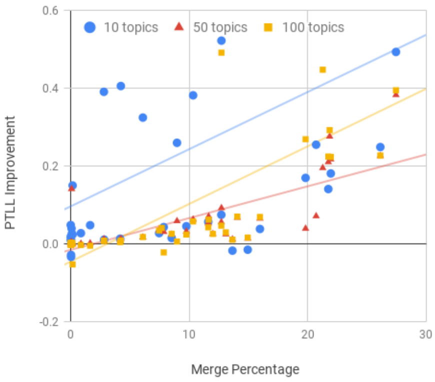

Figure 3: PTLL improvement vs. merged percentage.

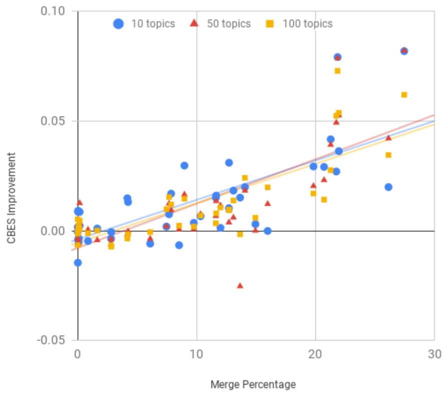

Figure 4: CBES improvement vs. merged percentage.

with retokenization). Pooling across all languages and corpora, we found the correlation coefficients of 0.41, 0.77, and 0.68 for the models with 10, 50, and 100 topics respectively for PTLL. As for the coherence metric, we found the correlation coefficients of 0.73, 0.76, and 0.79 for the models with 10, 50, and 100 topics respectively for CBES. This means the models with higher merge percentages are better than their corresponding word models in reproducing the statistics of the held-out data. This suggests that the quality of the LDA models depends on the generalizability of the retokenizers.

The LDA model results become more understandable when certain tokens are retokenized. We see merged tokens in the topic key sets of almost all topics in all corpora when retokenized based on *t* or raw frequency. Many of these represent non-compositional meanings that might have been lost without retokenization: for example, the collocation "social security" is not fully represented by the individual tokens "social" or "security" separately. More strikingly, the collocation '*kōn sŭa dāng*' refers to a political movement group in Thailand. When it is separated into *kōn* (people) *sŭa* (shirt) *dāng* (red), the key meaning is totally lost. When we compare by looking at the topic-keys of the word and multi-word models, we can come up with similar topics because we as a human who understands English and has general knowledge of the world can make the connection based on surrounding topic-keys even though they are not explicitly merged. However, if we want to use these topic keys as input to other downstream tasks such as information retrieval or text classification, the merged tokens help retain the specificity of the "red shirt people" as a meaningful entity distinct from the phrase's constituting parts.

7 Conclusion

In this work, we improve the quality of LDA models by better processing the input text before training the model. We found that the retokenizers trained based on *t* statistics and raw frequency yield an improvement across all languages considered in this study, while the χ^2approach was a less efficient approach that focuses more on rare named entities than common noun phrases. Using retokenizers ensures that LDA models can fit better to the data, the topic keys are more coherent, and the topics are more distinct. Outputs from retokenization with *t* statistics and frequency approaches yield common noun phrases in the most frequent terms of topics that represent a significant aid to both direct topic interpretation and expected utility of these topics in downstream tasks.

Abstract

Data modification, either via additional training datasets, data augmentation, debiasing, and dataset filtering, has been proposed as an effective solution for generalizing to out-of-domain (OOD) inputs, in both natural language processing and computer vision literature. However, the effect of data modification on adversarial robustness remains unclear. In this work, we conduct a comprehensive study of common data modification strategies and evaluate not only their in-domain and OOD performance, but also their adversarial robustness (AR). We also present results on a two-dimensional synthetic dataset to visualize the effect of each method on the training distribution. This work serves as an empirical study towards understanding the relationship between generalizing to unseen domains and defending against adversarial perturbations. Our findings suggest that more data (either via additional datasets or data augmentation) benefits both OOD accuracy and AR. However, data filtering (previously shown to improve OOD accuracy on natural language inference) hurts OOD accuracy on other tasks such as question answering and image classification. We provide insights from our experiments to inform future work in this direction.

1 Introduction

Deep neural networks have emerged as a widely popular architectural choice for modeling tasks in multiple domains such as (but not limited to) computer vision (Yuille and Liu, 2021), natural language processing (Hochreiter and Schmidhuber, 1997; Vaswani et al., 2017), and audio (Hannun et al., 2014). While these models are highly capable of learning from training data, recent studies show that they are quite prone to failure on new test sets or under distribution shift (Taori et al., 2020), natural corruptions (Hendrycks and Dietterich, 2019), adversarial attacks (Goodfellow et al., 2015), spurious correlations (Beery et al., 2018), and many other types of "unseen" changes that may be encountered after training. This shortcoming stems from the *i.i.d.* assumption in statistical machine learning which guarantees good performance only on test samples that are drawn from an underlying distribution that is identical to the training dataset. For instance, digit recognition models trained on the black-and-white MNIST training images are almost perfect ($> 99\%$ accuracy) on the corresponding test set, yet their performance on colored digits and real-world digits from street number plates is less than 75%. Similarly, state-of-the-art NLP models have been shown to fail when negation is introduced in the input (Kassner and Schütze, 2020). These findings pose a significant challenge to the practical adoption of these models and their reliability in the real-world.

To test model performance beyond the traditional notion of in-domain (ID) generalization, two prominent ideas have emerged: out-of-domain (OOD generalization) *a.k.a.* domain generalization[1], and adversarial robustness. The OOD generalization objective expects a model which is trained on distribution $\mathcal{D}$ to perform reliably on unseen distributions $\mathcal{D}_e, e \in \{1, \dots, n\}$, that differ from $\mathcal{D}$. For a trained classifier f^*, OOD accuracy on previously unseen distribution $\mathcal{D}_e$ is defined as:

$$\text{acc}^e_{\text{OOD}} = \mathop{\mathbb{E}}_{(\mathbf{x},\mathbf{y})\sim\mathcal{D}_e} [\mathbb{I}(f^*(\mathbf{x}) = \mathbf{y})] \qquad (1)$$

To define adversarial robustness, consider an input $\mathbf{x}$ and a true label $\mathbf{y}$. For a classifier loss function ℓ, a loss-maximizing perturbation δ^* within Δ_ϵ (an ϵ-bounded neighborhood of $\mathbf{x}$) is defined as:

$$\delta^*_{\mathbf{x}} = \max_{\delta\in\Delta_\epsilon} \ \ell(f^*(\mathbf{x}+\delta), \mathbf{y}). \qquad (2)$$

The second idea is that of adversarial robustness. Recent work on adversarial examples has revealed

---

[*] Equal Contribution

[1] In this paper we use these two terms interchangeably.

Findings of the Association for Computational Linguistics: ACL 2022, pages 2705 - 2718
May 22-27, 2022

the vulnerability of deep neural networks against small perturbations of the original data. Adversarial robustness in such under this setting is defined as the accuracy of the classifier on adversarial samples $\mathbf{x}+\delta_{\mathbf{x}}$, where the perturbation lies within an ℓ_p norm bound: $||\delta_{\mathbf{x}}||_p < \epsilon$.

$$\text{acc}_{rob} = \mathop{\mathbb{E}}_{(\mathbf{x},\mathbf{y})\sim\mathcal{D}} \mathbb{I}(f^*(\mathbf{x}+\delta_{\mathbf{x}}) = \mathbf{y}). \quad (3)$$

In the context of text classification, the norm-bound can also be in the form of small character-level or word-level perturbations such as swapping, inserting, or deleting characters or words. In essence, adversarial robustness measures the invariance of the classifier to small perturbations of the input.

Various methods have been developed that either improve OOD generalization or improve adversarial robustness. Notable among these are techniques that modify the distribution of the training dataset. In this paper, we focus on three major data modification techniques – the use of additional datasets (also known as multi-source training), data augmentation, and data filtering; in addition we also consider model-based debiasing techniques which do not alter the data distribution explicitly. We study the performance of these methods on three representative tasks – natural language inference (NLI), extractive question answering (QA), and image classification (IC).

Our first aim in this paper is to understand whether the increase or decrease in OOD generalization by each method over the naive baseline (standard training on the source dataset) is consistent across tasks. To further conduct fine-grained analysis, we also analyze the effect of these methods on in-domain (ID) accuracy on the test set for each task, since in the ideal case improvement in OOD performance should not come at the cost of in-domain accuracy.

Recent work seeks to understand the relationships between in-domain and out-of-domain performance: for instance, Miller et al. (2021) empirically show that ID and OOD performance are strongly correlated, Raghunathan et al. (2020); Yang et al. (2020) show a trade-off between robustness and accuracy for adversarially trained models. However it is not clear how methods *designed for OOD generalization* affect robustness. This is largely because work on domain generalization reports only IID and OOD metrics, and work on robustness reports only ID and robustness metrics. Our second aim is to understand the effect of these generalization methods on adversarial robustness.

In addition to our experiments on NLP and vision tasks, we also provide an experiment on a synthetic binary classification dataset where points lie in a 2-dimensional feature space and are separated by concentric circles into class labels. This setting allows us to visualize the effect of data modification techniques on the training distribution and the resulting performance.

Our findings can be summarized as follows:

- More data benefits OOD generalization,
- Data filtering hurts OOD generalization, and
- Data filtering significantly hurts adversarial robustness on all benchmarks.

These findings and our additional analysis raise new questions for robustness and domain generalization research. Significant among these are the importance of both diversity and number of training samples for inductive bias and generalization guarantees, the problems associated with data filtering in terms of robustness, and the importance of a comprehensive set of evaluation metrics that could be adopted for future work.

2 Categorization of Domain Generalization Methods

In this section, we provide a categorization of methods that are typically used as baselines for domain generalization. We briefly explain the method and provide relevant related work in which these ideas are used as methods for domain generalization. Throughout this paper, we will refer to the original training distribution as the *“source”* and the out-of-distribution datasets as the *“targets”*.

Single-Source Training (`SS`) refers to the “vanilla” baseline which is trained only on the source dataset, without any dataset modification. `SS` utilizes no other information apart from the single source dataset $\mathcal{D}$ and updates parameters θ of classifier f to minimize the risk on the source using approaches such as ERM (Vapnik and Chervonenkis, 1991).

$$\underset{\theta}{\text{minimize}} \mathop{\mathbb{E}}_{(\mathbf{x},\mathbf{y})\sim\mathcal{D}} \ell(f(\mathbf{x};\theta),\mathbf{y}). \quad (4)$$

Multi-Source Training (`MS`). This method is identical to `SS` except that additional training datasets $\mathcal{D}'$ are used for risk minimization.

$$\underset{\theta}{\text{minimize}} \mathop{\mathbb{E}}_{(\mathbf{x},\mathbf{y})\sim\mathcal{D}\cup\mathcal{D}'} \ell(f(\mathbf{x};\theta),\mathbf{y}). \quad (5)$$

Usually $\mathcal{D}'$ are designed for the same task as $\mathcal{D}$ but may have different styles, characteristics, or sources of collection. For instance, while both SNLI (Bowman et al., 2015) and MNLI (Williams et al., 2018) are datasets for natural language inference with identical class labels, SNLI was collected from image captions, while MNLI was collected from Open American National Corpus[2].

Gulrajani and Lopez-Paz (2020) provide an extensive comparitive study of models trained for multi-source domain generalization for image classification and surprisingly find that if multiple source domains are available, ERM is empirically the best approach as compared to specially designed DG methods such as meta-learning (Li et al., 2018a), learning domain-invariant features (Ganin et al., 2016), invariant risk minimization (Arjovsky et al., 2019), etc. These findings have also been observed on text classification experiments in (Koh et al., 2021). Hendrycks et al. (2020a) show that pre-training transformer architectures on diverse data leads to higher OOD accuracies on multiple tasks such as semantic textual similarity, sentiment classification, reading comprehension and natural language inference.

Data Augmentation (`DA`). When additional training distributions are not directly available, transformations of samples in $\mathcal{D}$ using pre-defined augmentation functions can be used to create $\mathcal{D}'$ and train the model. Such data augmentation functions are typically derived from existing knowledge about the invariance of the task w.r.t. certain transformations. For instance, for image classification, addition of small noise, small translations, scaling, etc. are common data augmentation functions, since they do not change the true label for the image. Similarly, for text inputs, synonyms of words are commonly used since they do not change the semantics of the sentence. NLP data augmentation techniques include UDA (Xie et al., 2020), EDA (Wei and Zou, 2019), and back-translation for question answering (Longpre et al., 2019).

Data Filtering (`DF`). Dataset filtering has been previously explored for quality control, such as, removing noise and artifacts to curate and improve publicly sourced datasets. However, there has been recent interest in considering `DF` as a method for bias reduction and generalization. This idea can be traced back to work by Zellers et al. (2018, 2019), that proposed `DF` as an algorithmic method to avoid annotation artifacts and spurious correlations during dataset construction. AFLite (Bras et al., 2020) extended this idea to a generic filtering methodology that can work without any pre-defined rules or strategies. Instead, AFLite operates by utilizing several weak learners (such as support-vector machines) trained over small subsets to identify samples that are easy to classify. It is argued that such samples are more likely to carry biases, and as such, could be removed. AFLite suggests that reduction of a dataset to even 10% of the original size can boost OOD accuracy on NLI. In the vision domain, similar ideas have been proposed concurrently, including REPAIR (Li and Vasconcelos, 2019) and RESOUND (Li et al., 2018b), in which instead of completely removing samples, biased samples are assigned smaller weights. However these methods require a prior knowledge of the bias variable. Liu et al. (2021) have recently proposed a simple approach which upweights samples which have higher loss – this is shown to improve worst-group accuracy without having access to the bias variable.

Model De-biasing (`DB`). Methods under this category do not directly alter the training dataset, but instead resort to changes in the modeling technique – these changes can be in terms of the optimization function, regularization, additional auxiliary costs, etc. The main idea in `DB` is to utilize known biases (or identify unknown biases) in the data distribution, model these biases in the training pipeline, and use this knowledge to train robust classifiers (Clark et al., 2019; Wu et al., 2020; Bhargava et al., 2021). In the image classification literature, there is growing consensus on enforcing a consistency on different views (or augmentations) of an image in order to achieve debiasing (Hendrycks et al., 2020c; Xu et al., 2020; Chai et al., 2021; Nam et al., 2021). Unlike `DF`, model de-biasing does not directly alter the training distribution, but instead allows the model to learn which biases to ignore.

3 Toy Example: Concentric Circles

We begin with a simple two-dimensional example to illustrate our experimental setting and to show how each method affects the distribution of the training set. Consider the set of points shown in Figure 1 where the points belong to two class labels (either `0` or `1`) and are seen to lie on concentric circles. Points with label `0` are closer to the origin,

---

[2] `https://www.anc.org/`

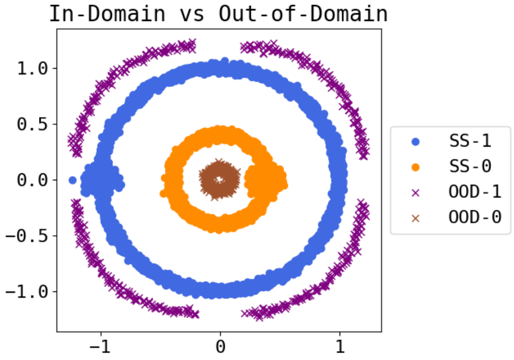

Figure 1: Our toy experimental setting consists of points in $\mathbb{R}^2$ belonging to two classes (0/1). This illustration shows the discrepancy between the source dataset (`SS`) and the out-of-domain dataset (`OOD`).

while points with label `1` are closer to a distance of `1` from the origin. Our aim is to start with the single source dataset and train the model to generalize on the out-of-domain (OOD) dataset. An important thing to note here is that the source dataset contains a subset of points with label `0` (orange) clustered around $(0.4, 0.0)$ and a subset with label `1` clustered around $(-1, 0.0)$. This implies that class-`0` is biased towards $x > 0$, while class-`1` is biased towards $x < 0$. In total, our `SS` dataset consists of 10000 samples, of which 20% are biased.

We apply three data modifications: additional source (`MS`), gaussian data augmentation (`DA`) $\sim\mathcal{N}(0, 0.1)$, and data filtering (AFLite) which reduces the dataset size to 10%. Note that we do not show model debiasing (`DB`) here, since it does not alter the data distribution. Figure 2 shows the effect on the data distribution. The most striking is the effect of `DF` which removes all samples previously in the biased clusters near $(0.4, 0.0)$ and $(-1.0, 0.0)$.

Equipped with these resulting datasets, we train a linear SGD classifier with log-loss and evaluate the robustness of each model in terms of in-domain and OOD accuracies. We also evaluate adversarial robustness by using standard PGD attacks. Results are shown in the textboxes in Figure 2. It can be seen that data filtering significantly hurts both OOD generalization and robustness. This finding motivates our experiments to understand the effect of each method for NLP and vision tasks.

4 Experiments

In this section, we present three tasks and their corresponding experimental setup, evaluation protocol and our findings. A summary of methods belong to each category is provided in Table 1 and the abbreviations `SS`, `MS`, `DA`, `DB`, `DF` are used henceforth.

4.1 Natural Language Inference (NLI)

NLI is the task of determining whether a *hypothesis* is true (entailment), false (contradiction), or undetermined (neutral) given a *premise*.

Methods. We use RoBERTa as the backbone model for each method and SNLI (Bowman et al., 2015) as our source training corpus. A model trained with expected risk minimization (ERM) on SNLI alone, forms our single-source (`SS`) baseline. A model trained with a combination of SNLI and MNLI (Williams et al., 2018) forms our multi-source (`MS`) baseline. We apply EDA (Wei and Zou, 2019) to augment our training dataset with 100% of additional data to train a `DA` model. The LMH debiasing method from Clark et al. (2019) represents our `DB` model. For data filtering, we use AFlite (Bras et al., 2020) to filter out 90% of the SNLI training data, and use the remaining 10% data to train our `DF` model – this setting is based on the experiments from (Bras et al., 2020).

Evaluation Protocol. We report accuracy on the SNLI test set (IID), and to evaluate generalization, we report accuracy on NLI diagnostics (Wang et al., 2018), Stress test evaluation (Naik et al., 2018a) and HANS (McCoy et al., 2019a). We use two metrics for evaluating robustness:

- *model-based robustness* uses BAE adversarial attack (Garg and Ramakrishnan, 2020), implemented using TextAttack (Morris et al., 2020), and reports robustness as number of queries (sequential perturbations) needed to fool the model.
- *model-free robustness* uses six pre-defined operations to transform SNLI test inputs into adversarial examples. These six methods are: CLARE (Li et al., 2021a), character-swap (Pruthi et al., 2019), Checklist (Ribeiro et al., 2020), EDA (Wei and Zou, 2019), counter-fitted embeddings (Emb) (Alzantot et al., 2018a).

Results. Table 2 shows the performance of each method in terms of in-domain and out-of-domain accuracy. We observe that four methods all improve the generalization performance on average but decrease the in-domain performance. Especially, `DF` method is the best in terms of OOD accuracy, but is the worst in terms of in-domain performance. We also see a trend that four methods improve the generalization in all sets of NLI-

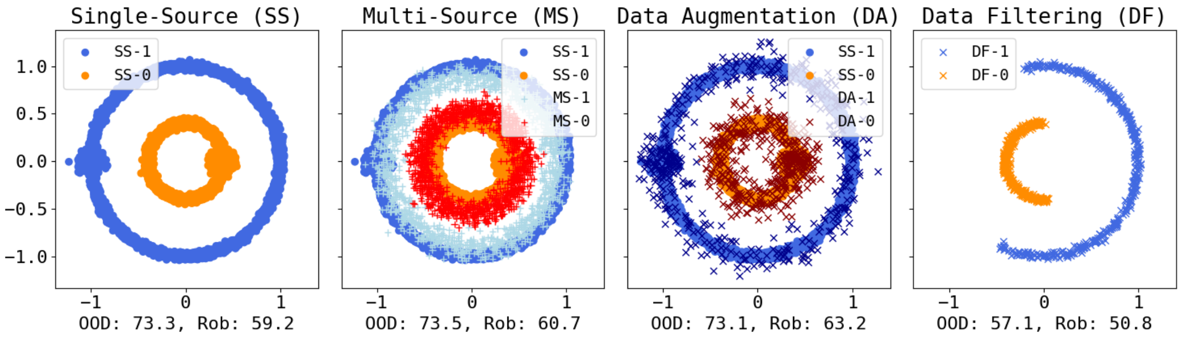

Figure 2: This figure illustrates the effect of data modification techniques on the training distribution. The leftmost figure shows the training distribution in the single-source setting. The introduction of a second dataset or Data-augmentation (done using small perturbations of source samples with Gaussian noise) makes the distribution more diverse in the multi-source (`MS`) and data augmentation (`DA`) setting respectively. On the other hand, data filtering, in order to remove spurious correlations from the dataset, removes points from certain sectors of the distribution. The effect of each strategy on OOD generalization and robustness is shown below each plot.

Method Category	**Tasks**		
	Natural Language Inference	Question Answering	Image Classification
`SS` (Single-Source ERM)	SNLI	NQ (Kwiatkowski et al., 2019)	MNIST
`MS` (Multi-Source ERM)	SNLI + MNLI	NQ + SQuAD+NQA+HQA+SQA+TQA	MNIST + USPS
`DA` (Data Augmentation)	EDA (Wei and Zou, 2019)	QG (Chan and Fan, 2019)	M-ADA (Qiao et al., 2020)
`DB` (Model De-biasing)	LMH (Clark et al., 2019)	Mb-CR(Wu et al., 2020)	RandConv (Xu et al., 2020)
`DF` (Data Filtering)	AFLite (Bras et al., 2020)	AFLite (adapted for QA)	AFLite

Table 1: List of method categories and specific methods that we use under each task setting in nour experiments. Details for each can be found in Section 4 for the corresponding task.

Diagnostics and HANS, while all four methods do not show improvement on generalization on Distraction and Noise sets of Stress dataset.

Table 3 shows the robustness evaluation. We see that except for `DF`, all methods improve the robustness under both model-based and model-free evaluation. `MS` improves the robustness in all transformations except for EDA. `DA` achieves the best robustness by model-based evaluation but is not consistent in terms of different transformations of model-free evaluation. `DB` improves the robustness in terms of every transformation and achieves the best robustness in terms of average of model-free evaluation. `DF` significantly hampers the model-free robustness with a drop in all transformations.

4.2 Question Answering (QA)

We focus on extractive QA. Given a passage (or "context") and a question, the task is to extract the answer span from the passage.

Methods. We use BERT (Devlin et al., 2019) as the backbone model for each method. We use MRQA (Fisch et al., 2019) which is a collection of 12 publicly available multi-domain QA datasets – with Natural Questions (NQ) (Kwiatkowski et al., 2019) as the source dataset. SQuAD, NewsQA, HotpotQA, SearchQA, and TriviaQA are used as additional datasets for multi-source training. Similar to NLI, we use EDA for `DA` by applying EDA on the question. We apply the augmentation to all samples in the training set and combine them with the original set to train a `DA` model. For model debiasing (`DB`), we use Mb-CR approach (Wu et al., 2020), where a teacher and bias models are trained *a* priori, and are used for debiasing.

We modify AFLite for our QA task of span prediction, since AFLite was originally designed for classification tasks. To do so, we first randomly divide the training set into 10 subsets (or folds) $S_{1:10}$. For $k \in \{1, \ldots, 10\}$, we pick S_k as the held-out test set, and train models on the rest, and obtain 10 such models. At test time, models are used for predicting an answer by only looking at the context (without access to the question) – this allows us to identify strong spurious correlations in the dataset. Based on the predictions, samples are sorted on the basis of their F1 score. A higher F1 score implies that the model is more likely to answer the question

Method	**In-Domain Acc. (%)**	**OOD Acc. (%)** NLI-Diagnostics				Stress Test			HANS			**Avg**
		Kno.	Lex.	Log.	PAS	Comp.	Distr.	Noise	Lex.	Subs.	Consti.	
`SS`	**89.6**	51.8	65.7	57.8	72.6	77.9	73.5	79.8	88.4	28.2	21.7	61.74

`DF`	62.6	53.9	66.5	58.7	68.9	79.1	72.0	79.5	94.1	46.3	38.5	**65.75**

Table 2: NLI Result: In-domain (IID) accuracy and out-of-domain generalization (OOD) on the NLI benchmark using SNLI as source dataset. [3] *See Table 1 for method abbreviations.*

Method	**Model Based #Num Queries**	**Model Free Accuracy (%)** CharSwap	EasyData	Embedding	WordNet	CheckList	CLARE	**Avg**
`SS`	53.56	81.3	72.0	81.9	77.0	89.4	76.3	79.65
`MS`	54.44	81.5	71.6	82.0	78.2	89.2	77.5	80.00
`DA`	**55.06**	77.7	74.1	80.7	80.2	86.6	80.5	79.97
`DB`	54.82	81.5	72.4	82.3	78.0	89.2	77.0	**80.07**
`DF`	51.13	65.2	56.8	66.2	62.5	72.3	62.5	64.25

Table 3: NLI Result: Comparison of robustness in terms of model-based evaluation (number of queries needed to fool the model) and model-free (accuracy on adversarial transformations). [2] *See Table 1 for method abbreviations.*

without even knowing the question. We retain 10% samples with the lowest F1 scores – these represent the task since the model is not likely to predict the correct answer without knowing the question.

Evaluation Protocol. We report exact-match (EM) accuracy for MRQA. To evaluate the generalization performance, we use six OOD development sets from MRQA: DROP, RACE, BioASQ, TextbookQA, RelationExtraction, and DuoRC. For robustness, we use the "Morphues" attack (Tan et al., 2020) on the question as the model-based evaluation, the attack method is similar to NLI. Model-free methods are the same as NLI.

Results. Table 4 shows the performance of each method in terms of in-domain and out-of-domain accuracy. We observe that two methods, `MS` and `DB`, improve the generalization performance on each out-of-domain dataset and also improve the in-domain performance. The improvement of `MS` is larger than `DB`. `DA` improves on some out-of-domain datasets but not all, and it also improves the in-domain performance. `DF` dramatically reduces both out-of-domain and in-domain datasets.

Table 5 shows that except for `DF`, all methods improve over `SS` for both model-based and model-free robustness evaluation. `MS`, `DA`, and `DB` improve the robustness in all transformations of model-free evaluation as well as the model-based evaluation, where `MS` achieves the best performance in model-based and model-free evaluation. `DF` significantly hampers the model-free robustness with drop in all transformations, meanwhile, the model-based robustness also drops.

4.3 Image Classification

We conduct our experiments on the standard domain generalization benchmark "Digits", which is a collection of handwritten digit classification datasets belonging to 10 classes (digits 0–9). Following standard practice(Volpi et al., 2018), we train models on 10000 images from MNIST (LeCun et al., 1998) as the source, and use SVHN (Netzer et al., 2011), SYN and MNIST-M (Ganin and Lempitsky, 2015) as the OOD datasets.

Methods. We use DigitNet (Volpi et al., 2018) as our backbone image classifier architecture. Our `SS` baseline uses MNIST for training; `MS` uses MNIST and USPS (Denker et al., 1988). For data augmentation we rely on M-ADA (Qiao et al., 2020) which is a perturbation-based min-max algorithm to create augmented data. Our debiasing method is RandConv (Xu et al., 2020) which utilizes a random convolutional layer to generate novel views of each input image, and a KL-divergence based loss function that encourages the classifier to predict consistent predictions for each version of the image. This leads to the model being debiased on spurious features like background, texture, or color of digits. We use AFLite as our `DF` method.

Method	In-Domain EM. (%)	OOD EM. (%)						
		DROP	RACE	BioASQ	TBQA	R.E.	DuoRC	**Avg**
`SS`	63.76	20.09	19.29	33.91	28.61	62.82	32.71	32.91
`MS`	65.07	26.88	27.45	45.01	40.52	72.86	43.44	**42.69**

`DB`	98.86	87.67	54.95	63.37	68.66
`DF`	95.27	51.04	22.07	27.83	33.65

Table 6: Source (in-domain) accuracy and domain generalization (OOD accuracy) on the Digits benchmark with MNIST-10k as source dataset.[2]

Evaluation Protocol. We report IID accuracy on the MNIST test set and generalization as the accuracy on our OOD datasets. For evaluating adversarial robustness we use Foolbox (Rauber et al., 2017) and use 10 attack methods (both ℓ_2 and ℓ_∞ versions of FGSM, PGD, BIM, AUN, and DeepFool). Robustness is calculated as the accuracy for 20 values of ϵ between $[0, 2]$, and is plotted as robustness curves for visualization, along with the average values for area under the curve (AUC).

Results. Table 6 shows the performance of each method in terms of in-domain and OOD accuracy. `MS`, `DA` and `DB`, improve the generalization performance on each OOD dataset and also improve the in-domain performance, where `DB` displays best generalization capacity. `DF` dramatically reduces the OOD performance with significant reduction across all datasets; the in-domain accuracy also decreases. Figure 3 shows robustness (accuracy) and area under the curve (AUC) for each plot. It can be observed that `DF` is worse than `SS` for all 10 attack variants. We observe that `DA` and `DB` are better than `SS`, and the drop for `DF` is the largest.

5 Analysis

Based on the results of three tasks, we have the following observations about the performance of each method compared to the `SS` baseline:

- `MS` increases OOD accuracy on all three tasks and robustness on two tasks (NLI and QA).
- `DA` increases OOD on two tasks (NLI and IC) and robustness on all three tasks.
- `DB` increases OOD on three tasks and robustness on two tasks (NLI and QA).
- `DF` decreases OOD on two tasks (QA and IC) and robustness on all three tasks.

Decrease in NLI in-domain accuracy is seen for all methods, even though these lead to increase in OOD accuracy. This suggests that the training dataset (SNLI) has a large shift w.r.t. OOD datasets.

More data implies more OOD generalization: While this trend is observed for both `MS` and `DA`, there is one anomaly – `DA` for the QA task leads to marginal decrease compared to `SS` (a difference of 0.56%). This finding is aligned with Longpre et al. (2019), who report no significant effect of data augmentation (back translation) on OOD performance for question answering. This points to the need for improving data augmentation techniques in QA.

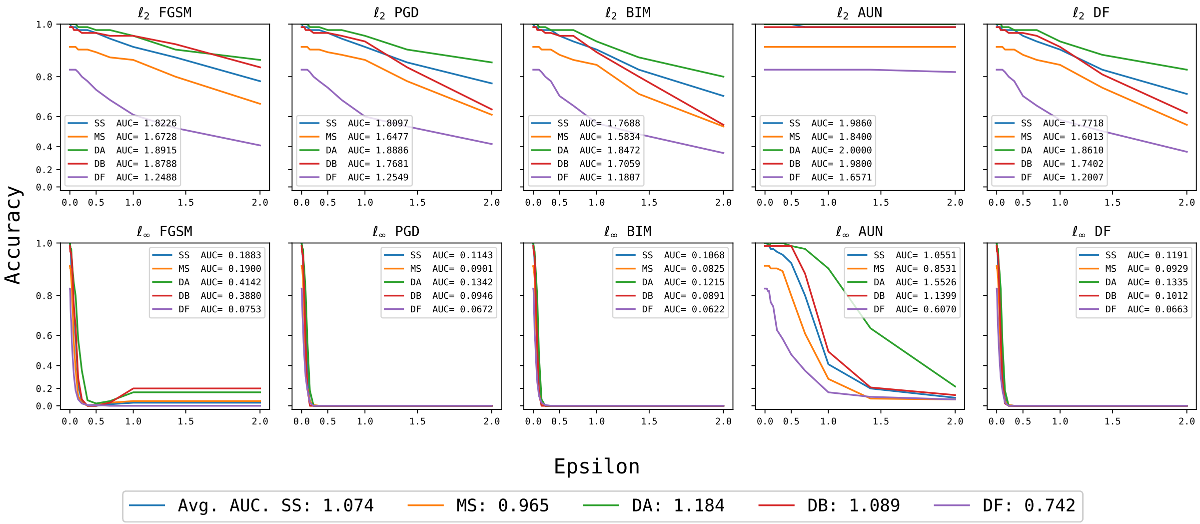

Figure 3: Evaluation of adversarial robustness (using 10 attack methods) for MNIST10k.

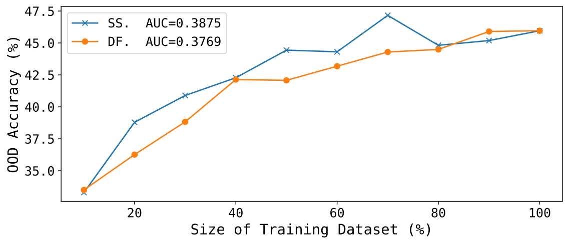

Figure 4: Comparison between SS and DF models trained with different percentages of MNIST10k.

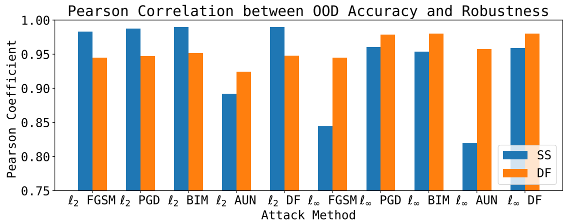

Figure 5: Pearson Correlation between OOD accuracy and robustness for SS and DF models on MNIST10k.

On the other hand, the performance drop due to DF is significantly large for QA (11.53%).

Decrease in MNIST robustness: For MNIST, the DA method (M-ADA (Qiao et al., 2020)) is the best in terms of robustness and also improves OOD accuracy. M-ADA is an "adversarial data augmentation" method, i.e., it uses a min-max objective to find loss-maximizing perturbations and uses these perturbations as augmented data. It is therefore intuitive that such a method would do well on the adversarial robustness metric (although robustness evaluation was not reported by Qiao et al. (2020)).

Marginal Improvement on Robustness: From the results, it is easy to see that the improvement on OOD is more noticeable than robustness, for example, MS improves OOD performance by $\sim$10%, but improves only by $\sim$1% under model-free evaluation. While this observation is reasonable since each method is designed to improve the generalization, new methods that improve both generalization and robustness should be encouraged.

5.1 Correlation between Adversarial Robustness and OOD Generalization

Our experiments reveal the alarming finding that across the board, DF reduces adversarial robustness. To investigate further, we conduct an analysis on the Digits benchmark and compare SS and DF when trained with equal amounts of data ($\{10\%, 20\%, \ldots, 100\%\}$). Note that for SS the data are sampled randomly, while for DF the data are obtained via AFLite data filtering. Results are shown in Figure 4. It can be observed that the OOD accuracy increases as the size of the dataset increases, and is greater for SS than DF. To understand how an increase in OOD accuracy affects robustness, we also compute the robustness values at each size of training data, and compute the Pearson correlation coefficient for each attack method – positive correlation implies that as OOD accuracy increases, robustness also increases. Figure 5 shows clear evidence in favor of positive correlation; interestingly, SS has higher correlation for ℓ_2 attacks, while DF is higher for ℓ_∞ attacks. The evidence is clear: OOD generalization increases with the size of the dataset and adversarial robustness is positively correlated with OOD generalization.

Our experiments show that the size of the training set directly affects both robustness and generalization. While removing 90% data increased OOD accuracy in NLI, the effect was the exact opposite for QA and MNIST. The key idea in domain generalization is that the test distributions are unknown and little information about them is available apart from the fact that there is no task shift. Without this prior knowledge, deciding whether (or how much) to filter a dataset is a challenging task.

6 Related Work

In Section 2 we have provided relevant work that falls into one of our five modeling categories. Here, we discuss additional literature on robustness and generalization and new efforts towards dataset creation, benchmarks, and evaluation.

Generalization Benchmarks. Hendrycks et al. (2020b) have constructed a robustness benchmark for multiple language understanding tasks by splitting training sets from existing benchmarks according to topics, styles, and vocabulary; this has been subsequently used to study robustness of model rankings (Mishra and Arunkumar, 2021). Benchmarks have also been constructed to study dataset artifacts and generalization capabilities of models (Mishra et al., 2020a,b; Mishra and Sachdeva, 2020). MRQA (Fisch et al., 2019) is a benchmark for evaluating domain generalization of question answering (reading comprehensive) models. MRQA contains 6 datasets each for training, development, and evaluation. For image classification, many benchmarks have been proposed to evaluate domain generalization, such as PACS (Li et al., 2017), OfficeHome (Venkateswara et al., 2017), Digits (Volpi et al., 2018), and WILDS (Koh et al., 2021) which is a compendium of domain generalization bechmarks for tasks such as image classification, text sentiment and toxicity prediction.

Corruption Robustness. Hendrycks and Dietterich (2019) introduced ImageNet-C and CIFAR-C to test robustness along corruptions such as weather, noise, blur, and digital artifacts, and ImageNet-P which tests robustness against small tilts and changes in brightness. MNIST-C was introduced by Mu and Gilmer (2019) for similar corruptions of handwritten digit images.

Adversarial and Contrastive Sets. Generation of adversarial examples (Jia and Liang, 2017; Ribeiro et al., 2018; Iyyer et al., 2018; Alzantot et al., 2018b) and approaches to defend against word substitution (Jia et al., 2019) have been explored. Contrastive examples have been introduced as a means for evaluation, for example, manually crafted contrast sets for textual entailment (Gardner et al., 2020) or template-based (McCoy et al., 2019b; Glockner et al., 2018; Naik et al., 2018b). Model-in-the-loop dataset creation methods have also been proposed for various NLP tasks (Nie et al., 2020; Arunkumar et al., 2020; Kiela et al., 2021) and visual question answering (Sheng et al., 2021; Li et al., 2021b).

7 Discussion

Recently, Miller et al. (2021) have empirically shown linear trends between in-distribution and out-of-distribution performance on multiple image classification tasks, across various model architectures, hyper-parameters, training set size, and duration of training. They also show that there are certain settings of domain shift under which the linear trend does not hold. Our work empirically shows that while data filtering may benefit OOD generalization on the NLI benchmark, this does not hold for other tasks such as image classification and question answering. This suggests that data filtering may benefit generalization in certain types of domain shift, but not on others. Concurrently, Yi et al. (2021) have theoretically shown that models robust to input perturbations generalize well on OOD distribution within a Wasserstein radius around the training distribution. Our empirical observations in this paper in both vision and language domains, agree with the theory of Yi et al. (2021).

In this work, we conduct a comprehensive study of methods which are designed for OOD generalization on three tasks: NLI, QA, and IC. We evaluate each method on in-domain, OOD, and adversarial robustness. [4] Our findings suggest that more data typically benefits both OOD and robustness. Data filtering hurts OOD accuracy on two out of three tasks, and also hurts robustness on all three tasks. In context of our findings and work by Miller et al. (2021); Yi et al. (2021), we recommend that methods designed either for robustness or generalization should be evaluated on multiple aspects and not on the single metric that they are optimized for.

Broader Impact

One underlying assumption behind using large datasets for training (or pre-training) vision and language models is that larger datasets increase the likelihood of obtaining a diverse set of samples to reduce overfitting. However, recent studies (Bender et al., 2021; Stanovsky et al., 2019) serve as cautionary tales when employing uncurated internet data to train large language models, and discuss how large data does not necessarily imply that models will learn the dievrse distribution. At the same time, the inverse (small data aids diversity) is also not true (as shown by this paper) and comes with its own problems – for instance, Figure 2 shows that dataset filtering can lead to much larger changes in the data distribution beyond notions of proportionality and fairness. As such, the decision on how many and what samples to remove can also introduce its own set of biases. Data curation is a challenging problem and needs further task-specific study since the concepts of bias and fairness often depend on the task definition and specifications of ideal outcomes. Insights from this paper could help researchers and practitioners in choosing appropriate approaches for improving generalization and robustness.

ASSIST: Towards Label Noise-Robust Dialogue State Tracking

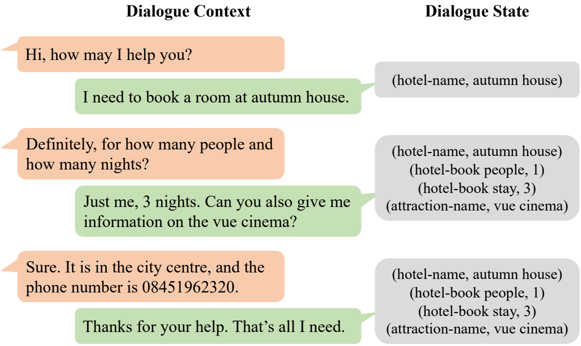
Fanghua Ye and **Yue Feng** and **Emine Yilmaz**
University College London
London, UK
{fanghua.ye.19, yue.feng.20, emine.yilmaz}@ucl.ac.uk

Abstract

The MultiWOZ 2.0 dataset has greatly boosted the research on dialogue state tracking (DST). However, substantial noise has been discovered in its state annotations. Such noise brings about huge challenges for training DST models robustly. Although several refined versions, including MultiWOZ 2.1-2.4, have been published recently, there are still lots of noisy labels, especially in the training set. Besides, it is costly to rectify all the problematic annotations. In this paper, instead of improving the annotation quality further, we propose a general framework, named ASSIST (l**A**bel noi**S**e-robu**S**t d**I**alogue **S**tate **T**racking), to train DST models robustly from noisy labels. ASSIST first generates pseudo labels for each sample in the training set by using an auxiliary model trained on a small clean dataset, then puts the generated pseudo labels and vanilla noisy labels together to train the primary model. We show the validity of ASSIST theoretically. Experimental results also demonstrate that ASSIST improves the joint goal accuracy of DST by up to 28.16% on MultiWOZ 2.0 and 8.41% on MultiWOZ 2.4, compared to using only the vanilla noisy labels.

1 Introduction

Task-oriented dialogue systems play an important role in helping users accomplish a variety of tasks through verbal interactions (Young et al., 2013; Gao et al., 2019). Dialogue state tracking (DST) is an essential component of the dialogue manager in pipeline-based task-oriented dialogue systems. It aims to keep track of users' intentions at each turn of the conversation (Mrkšić et al., 2017). The state information indicates the progress of the conversation and is leveraged to determine the next system action and generate the next system response (Chen et al., 2017). As shown in Figure 1, the dialogue state is typically represented as a set of (*slot*, *value*) pairs (Williams et al., 2014; Henderson et al., 2014).



Hi, how may I help you?

I need to book a room at autumn house.

(hotel-name, autumn house)

Definitely, for how many people and how many nights?

Just me, 3 nights. Can you also give me information on the vue cinema?

(hotel-name, autumn house)
(hotel-book people, 1)
(hotel-book stay, 3)
(attraction-name, vue cinema)

Sure. It is in the city centre, and the phone number is 08451962320.

Thanks for your help. That's all I need.

(hotel-name, autumn house)
(hotel-book people, 1)
(hotel-book stay, 3)
(attraction-name, vue cinema)

Figure 1: An example dialogue spanning two domains. On the left is the dialogue context with system responses shown in orange and user utterances in green. The dialogue state at each turn is presented on the right.

Therefore, the problem of DST is defined as extracting the values for all slots from the dialogue context at each turn of the conversation.

Over the past few years, DST has made significant progress, attributed to a number of publicly available dialogue datasets, such as DSTC2 (Henderson et al., 2014), FRAMES (El Asri et al., 2017), MultiWOZ 2.0 (Budzianowski et al., 2018), CrossWOZ (Zhu et al., 2020), and SGD (Rastogi et al., 2020). Among these datasets, MultiWOZ 2.0 is the most popular one. So far, lots of DST models have been built on top of it (Lee et al., 2019; Wu et al., 2019; Ouyang et al., 2020; Kim et al., 2020; Hu et al., 2020; Ye et al., 2021b; Lin et al., 2021).

However, it has been found out that there is substantial noise in the state annotations of MultiWOZ 2.0 (Eric et al., 2020). These noisy labels may impede the training of robust DST models and lead to noticeable performance decrease (Zhang et al., 2016). To remedy this issue, massive efforts have been devoted to rectifying the annotations, and four refined versions, including MultiWOZ 2.1 (Eric et al., 2020), MultiWOZ 2.2 (Zang et al., 2020), MultiWOZ 2.3 (Han et al., 2020b), and MultiWOZ 2.4 (Ye et al., 2021a), have been released. Even so, there are still plenty of noisy and inconsistent la-

Findings of the Association for Computational Linguistics: ACL 2022, pages 2719 - 2731

bels. For example, in the latest version MultiWOZ 2.4, the validation set and test set have been manually re-annotated and tend to be noise-free. While the training set is still noisy, as it remains intact. In reality, it is costly and laborious to refine existing large-scale noisy datasets or collect new ones with fully precise annotations (Wei et al., 2020), let alone dialogue datasets with multiple domains and multiple turns. In view of this, we argue that it is essential to devise particular learning algorithms to train DST models robustly from noisy labels.

Although loads of noisy label learning algorithms (Natarajan et al., 2013; Han et al., 2020a) have been proposed in the machine learning community, most of them target only multi-class classification (Song et al., 2020). However, as illustrated in Figure 1, the dialogue state may contain multiple labels, which makes it unstraightforward to apply existing noisy label learning algorithms to the DST task. In this paper we propose a general framework, named ASSIST (l**A**bel noi**S**e-robu**S**t d**I**alogue **S**tate **T**racking), to train DST models robustly from noisy labels. ASSIST first trains an auxiliary model on a small clean dataset to generate pseudo labels for each sample in the noisy training set. Then, it leverages both the generated pseudo labels and vanilla noisy labels to train the primary model. Since the auxiliary model is trained on the clean dataset, it can be expected that the pseudo labels will help us train the primary model more robustly. Note that ASSIST is based on the assumption that we have access to a small clean dataset. This assumption is reasonable, as it is feasible to manually collect a small noise-free dataset or re-annotate a portion of a large noisy dataset.

In summary, our main contributions include:

- We propose a general framework ASSIST to train robust DST models from noisy labels. To the best of our knowledge, we are the first to tackle the DST problem by taking into consideration the label noise.
- We theoretically analyze why the pseudo labels are beneficial and show that a proper combination of the pseudo labels and vanilla noisy labels can approximate the unknown true labels more accurately.
- We conduct extensive experiments on MultiWOZ 2.0 & 2.4. The results demonstrate that ASSIST can improve the DST performance on both datasets by a large margin.

2 Problem Definition

In this section, we first provide the conventional definition of DST and then extend the definition to the noisy label learning scenario.

2.1 Conventional Dialogue State Tracking

Let $\mathcal{X} = \{(R_1, U_1), \ldots, (R_T, U_T)\}$ denote a dialogue of T turns, where R_t and U_t represent the system response and user utterance at turn t, respectively. The dialogue state at turn t is defined as $\mathcal{B}_t = \{(s, v_t) | s \in \mathcal{S}\}$, where $\mathcal{S}$ denotes the set of predefined slots and v_t is the corresponding value of slot s. Following previous work (Lee et al., 2019; Hu et al., 2020; Ye et al., 2021b), a slot in this paper refers to the concatenation of the domain name and slot name so as to include the domain information. For example, we use "*hotel-name*" to represent the slot "*name*" in the hotel domain.

In general, the issue of DST is defined as learning a dialogue state tracker $\mathcal{F} : \mathcal{X}_t \rightarrow \mathcal{B}_t$ that takes the dialogue context $\mathcal{X}_t$ as input and predicts the dialogue state $\mathcal{B}_t$ at each turn t as accurately as possible. Here, $\mathcal{X}_t$ represents the dialogue history up to turn t, i.e., $\mathcal{X}_t = \{(R_1, U_1), \ldots, (R_t, U_t)\}$.

2.2 Dialogue State Tracking with Noisy Labels

Conventionally, all the state labels are assumed to be correct. However, this assumption may not hold. In practice, dialogue state annotations are error-prone (Han et al., 2020b). There are a couple of reasons. First, the states are usually annotated by crowdworkers to improve the labelling efficiency. Due to limited knowledge, crowdworkers cannot annotate all the states with 100% accuracy, which naturally incurs noisy labels (Han et al., 2020a). Second, the dialogue may span multiple domains, which also increases the labelling difficulty. Apparently, the noisy labels are harmful and likely to lead to sub-optimal performance. Therefore, it is crucial to take them into consideration so as to train DST models more robustly.

Let $\tilde{\mathcal{B}}_t = \{(s, \tilde{v}_t) | s \in \mathcal{S}\}$ denote the noisy state annotations, where $\tilde{v}_t$ is the noisy label of slot s at turn t. We use $\mathcal{B}_t = \{(s, v_t) | s \in S\}$ to denote the noise-free state annotations. Here, v_t represents the true label of slot s at turn t, which is unknown. In fact, existing DST approaches are only able to learn a sub-optimal dialogue state tracker $\tilde{\mathcal{F}} : \mathcal{X}_t \rightarrow \tilde{\mathcal{B}}_t$ rather than the optimal state tracker $\mathcal{F} : \mathcal{X}_t \rightarrow \mathcal{B}_t$, as none of them have considered the influence of noisy labels. In this work, we aim to learn a robust state tracker $\mathcal{F}^*$ that can better approximate $\mathcal{F}$ from the noisy state annotations $\tilde{\mathcal{B}}_t$.

3 Proposed Approach

We introduce a general framework ASSIST, aiming to train DST models robustly from noisy labels. We assume that a small clean dataset is accessible. Based on this dataset, ASSIST first trains an auxiliary model $\mathcal{A}$. Then, it leverages $\mathcal{A}$ to generate pseudo labels for each sample in the noisy training set. The pseudo state annotations are represented as $\breve{\mathcal{B}}_t = \{(s, \breve{v}_t) | s \in \mathcal{S}\}$, where $\breve{v}_t$ denotes the pseudo label of slot s at turn t. Afterwards, both the generated pseudo labels and vanilla noisy labels are exploited to train the primary model $\mathcal{F}^*$. That is, we intend to learn $\mathcal{F}^* : \mathcal{X}_t \rightarrow C(\breve{\mathcal{B}}_t, \tilde{\mathcal{B}}_t)$, where $C(\breve{\mathcal{B}}_t, \tilde{\mathcal{B}}_t)$ is a combination of $\breve{\mathcal{B}}_t$ and $\tilde{\mathcal{B}}_t$.

Essentially, any existing DST models can be employed as the auxiliary model. However, these models may lead to overfitting due to the small size of the clean dataset. To tackle this issue, we propose a new simple model as the auxiliary model[1].

3.1 Auxiliary Model Architecture

Figure 2 shows the architecture, which consists of a dialogue context semantic encoder, a slot attention module, and a slot-value matching module.

Dialogue Context Semantic Encoder

Similar to (Lee et al., 2019; Kim et al., 2020; Ye et al., 2021b), we utilize the pre-trained language model BERT (Devlin et al., 2019) to encode the dialogue context $\mathcal{X}_t$ into contextual semantic representations. Let $Z_t = R_t \oplus U_t$ be the concatenation of the system response and user utterance at turn t, where $\oplus$ denotes the operator of sequence concatenation. Then, the dialogue context $\mathcal{X}_t$ can be represented as $X_t = Z_1 \oplus Z_2 \oplus \cdots \oplus Z_t$.

We also concatenate each slot-value pair and denote the representation of the dialogue state at turn t as $B_t = \bigoplus_{(s,v_t) \in \mathcal{B}_t, v_t \neq \texttt{none}} s \oplus v_t$, in which only non-`none` slots are included. B_t can serve as a compact representation of the dialogue history. In view of this, we treat the previous turn dialogue state B_{t-1} as part of the input as well, which can be beneficial when X_t exceeds the maximum input length of BERT. The complete input sequence to the encoder module is then denoted as:

$$I_t = [CLS] \oplus X_{t-1} \oplus B_{t-1} \oplus [SEP] \oplus Z_t \oplus [SEP],$$

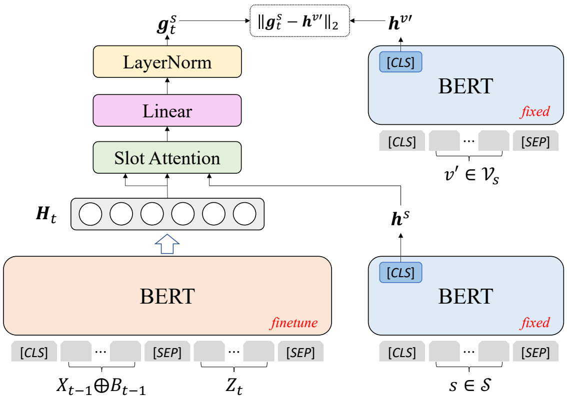


Figure 2: Overall architecture of the auxiliary model. The parameters of the BERT used to encode slots and values are fixed during the training process.

where $[CLS]$ and $[SEP]$ are the two special tokens introduced by BERT.

Let $\boldsymbol{H}_t \in \mathbb{R}^{|I_t| \times d}$ be the semantic matrix representation of I_t. Here, $|I_t|$ and d denote the sequence length of I_t and the BERT output dimension, respectively. Then, we have:

$$\boldsymbol{H}_t = \texttt{BERT}_{finetune}(I_t),$$

where $\texttt{BERT}_{finetune}$ means that the BERT model will be fine-tuned during the training process.

For each slot s and its candidate value $v' \in \mathcal{V}_s$, we employ another BERT to encode them into semantic vectors $\boldsymbol{h}^s \in \mathbb{R}^d$ and $\boldsymbol{h}^{v'} \in \mathbb{R}^d$. Here, $\mathcal{V}_s$ denotes the candidate value set of slot s. Unlike the dialogue context, we leverage the pre-trained BERT without fine-tuning to embed s and v'. Besides, we adopt the output vector corresponding to the special token $[CLS]$ as an aggregated representation of slot s and value v', i.e.,

$$\boldsymbol{h}^s = \texttt{BERT}_{fixed}^{[CLS]}([CLS] \oplus s \oplus [SEP]),$$
$$\boldsymbol{h}^{v'} = \texttt{BERT}_{fixed}^{[CLS]}([CLS] \oplus v' \oplus [SEP]).$$

Slot Attention

The slot attention module is exploited to retrieve slot-relevant information for all the slots from the same dialogue context. The slot attention is a multi-head attention (Vaswani et al., 2017). Specifically, the slot representation $\boldsymbol{h}^s$ is regarded as the query vector, and the dialogue context representation $\boldsymbol{H}_t$ is taken as both the key matrix and value matrix. The slot attention matches $\boldsymbol{h}^s$ to the semantic vector of each word in the dialogue context and calculates the attention score, based on which the slot-specific information can be extracted. Let $\boldsymbol{a}_t^s \in \mathbb{R}^d$ denote

---

[1] We adopt existing DST models as the primary model.

a d-dimensional vector representation of the related information of slot s at turn t, we obtain:

$$\boldsymbol{a}_t^s = \texttt{MultiHead}(\boldsymbol{h}^s, \boldsymbol{H}_t, \boldsymbol{H}_t).$$

$\boldsymbol{a}_t^s$ is expected to be close to the semantic vector representation of the true value of slot s.

Considering that the output of BERT is normalized by layer normalization (Ba et al., 2016), we also feed $\boldsymbol{a}_t^s$ to a layer normalization layer, which is preceded by a linear transformation layer. The final slot-specific vector $\boldsymbol{g}_t^s \in \mathbb{R}^d$ is calculated as:

$$\boldsymbol{g}_t^s = \texttt{LayerNorm}(\texttt{Linear}(\boldsymbol{a}_t^s)).$$

Slot-Value Matching

The slot-value matching module is utilized to predict the value of each slot s. It first calculates the distance between the slot-specific representation $\boldsymbol{g}_t^s$ and the semantic representation of each candidate value $v' \in \mathcal{V}_s$, i.e., $\boldsymbol{h}^{v'}$. Then, the candidate value with the smallest distance is selected as the prediction. The ℓ_2 norm is adopted to compute the distance. Denoting $\hat{v}_t$ as the predicted value of slot s at turn t, we have:

$$\hat{v}_t = \underset{v' \in \mathcal{V}_s}{\operatorname{argmin}} \|\boldsymbol{g}_t^s - \boldsymbol{h}^{v'}\|_2.$$

3.2 Auxiliary Model Training

We leverage a small clean dataset to train the auxiliary model. Since the true labels are available, the auxiliary model is directly trained to maximize the joint probability of all slot values. The probability of the true value v_t of slot s at turn t is defined as:

$$p(v_t|\mathcal{X}_t, s) = \frac{\exp\left(-\|\boldsymbol{g}_t^s - \boldsymbol{h}_t^v\|_2\right)}{\sum_{v' \in \mathcal{V}_s} \exp\left(-\|\boldsymbol{g}_t^s - \boldsymbol{h}^{v'}\|_2\right)},$$

where $\boldsymbol{h}_t^v$ is the semantic representation of v_t. Maximizing the joint probability $\Pi_{(s,v_t)\in\mathcal{B}_t} p(v_t|\mathcal{X}_t, s)$ is equivalent to minimizing the following objective:

$$\mathcal{L}_{aux} = \sum_{(s,v_t)\in\mathcal{B}_t} -\log p(v_t|\mathcal{X}_t, s).$$

3.3 Pseudo Label Generation

Our approach depends on the auxiliary model $\mathcal{A}$ to generate pseudo labels $\breve{\mathcal{B}}_t = \{(s, \breve{v}_t)|s \in \mathcal{S}\}$ for each sample in the noisy training set. In this work, we treat each dialogue context $\mathcal{X}_t$ rather than the entire dialogue as a training sample. Without loss of generality, the pseudo label generation process is denoted as follows:

$$\breve{\mathcal{B}}_t = \mathcal{A}(\mathcal{X}_t, \mathcal{S}),$$

where $\mathcal{X}_t$ belongs to the noisy training set.

3.4 Primary Model Training

To reduce the influence of noisy labels, we combine the generated pseudo labels and vanilla noisy labels to train the primary model.

Let $\breve{\boldsymbol{v}}_t$ and $\tilde{\boldsymbol{v}}_t$ be the one-hot representation of the pseudo label $\breve{v}_t$ and vanilla noisy label $\tilde{v}_t$, respectively. Then, we can define the combined label as:

$$\boldsymbol{v}_t^c = \alpha\breve{\boldsymbol{v}}_t + (1-\alpha)\tilde{\boldsymbol{v}}_t,$$

where $\alpha (0 \leq \alpha \leq 1)$ is a parameter to balance the pseudo labels and vanilla labels. We calculate the probability of $\boldsymbol{v}_t^c$ as below:

$$p(\boldsymbol{v}_t^c|\mathcal{X}_t, s) = p(\breve{v}_t|\mathcal{X}_t, s)^{\alpha} p(\tilde{v}_t|\mathcal{X}_t, s)^{(1-\alpha)}.$$

Here, $p(\breve{v}_t|\mathcal{X}_t, s)$ and $p(\tilde{v}_t|\mathcal{X}_t, s)$ correspond to the probability of $\breve{v}_t$ and $\tilde{v}_t$, respectively.

Let $C(\breve{\mathcal{B}}_t, \tilde{\mathcal{B}}_t) = \{(s, \boldsymbol{v}_t^c)|s \in \mathcal{S}\}$ represent the combined state annotations. The training objective of the primary model is then defined as:

$$\begin{aligned}
\mathcal{L}_{pri} &= \sum_{(s,\boldsymbol{v}_t^c)\in C(\breve{\mathcal{B}}_t,\tilde{\mathcal{B}}_t)} -\log p(\boldsymbol{v}_t^c|\mathcal{X}_t, s) \\
&= \alpha \sum_{(s,\breve{v}_t)\in\breve{\mathcal{B}}_t} -\log p(\breve{v}_t|\mathcal{X}_t, s) \\
&\quad + (1-\alpha) \sum_{(s,\tilde{v}_t)\in\tilde{\mathcal{B}}_t} -\log p(\tilde{v}_t|\mathcal{X}_t, s) \\
&= \alpha\mathcal{L}_{pseudo} + (1-\alpha)\mathcal{L}_{vanilla},
\end{aligned}$$

where $\mathcal{L}_{pseudo}$ and $\mathcal{L}_{vanilla}$ correspond to the training objective of using only the pseudo labels and using only the vanilla noisy labels, respectively. By minimizing $\mathcal{L}_{pri}$, the primary model is trained to learn from the vanilla noisy labels and at the same time imitate the predictions of the auxiliary model.

3.5 Theoretical Analysis

Since the pseudo labels are generated by the auxiliary model that has been trained on a small clean dataset, it can be expected that the combined labels are able to serve as a better approximation to the unknown true labels. Let $\boldsymbol{v}_t$ denote the one-hot representation of the unknown true value v_t of slot s at turn t. We adopt the mean squared loss to define the approximation error of any corrupted labels $\ddot{\boldsymbol{v}}_t$ associated with the noisy training set $\mathcal{D}_n$ as:

$$Y_{\ddot{\boldsymbol{v}}} = \frac{1}{|\mathcal{D}_n||\mathcal{S}|} \sum_{\mathcal{X}_t\in\mathcal{D}_n} \sum_{s\in\mathcal{S}} E_{\mathcal{D}_c}[\|\ddot{\boldsymbol{v}}_t - \boldsymbol{v}_t\|_2^2],$$

where the expectation ranges over different choices of the clean dataset $\mathcal{D}_c$, and $|\cdot|$ returns the cardinality of a set.

Next, we show that the approximation error of the combined labels can be smaller than that of both the vanilla noisy labels and the generated pseudo labels. The details are presented in Theorem 1.

Theorem 1. *The optimal approximation error with respect to the combined labels* $\boldsymbol{v}_t^c$ *is smaller than that of the vanilla labels* $\tilde{\boldsymbol{v}}_t$ *and pseudo labels* $\breve{\boldsymbol{v}}_t$*, i.e.,*

$$\min_{\alpha} Y_{\boldsymbol{v}^c} < \min\{Y_{\tilde{\boldsymbol{v}}}, Y_{\breve{\boldsymbol{v}}}\}.$$

By setting $\alpha = \frac{Y_{\breve{\boldsymbol{v}}}}{Y_{\tilde{\boldsymbol{v}}}+Y_{\breve{\boldsymbol{v}}}}$, $Y_{\boldsymbol{v}^c}$ *reaches its minimum:*

$$\min_{\alpha} Y_{\boldsymbol{v}^c} = \frac{Y_{\tilde{\boldsymbol{v}}} Y_{\breve{\boldsymbol{v}}}}{Y_{\tilde{\boldsymbol{v}}} + Y_{\breve{\boldsymbol{v}}}}.$$

Proof. The proof is presented in Appendix A. ☐

Theorem 1 indicates that if α is set properly, the combined labels can approximate the unknown true labels more accurately. Hence, we can potentially train the primary model more robustly. Note that we cannot calculate the optimal value of α directly.

4 Experimental Setup

4.1 Datasets

We adopt MultiWOZ 2.0 (Budzianowski et al., 2018) and MultiWOZ 2.4 (Ye et al., 2021a) as the datasets in our experiments. MultiWOZ 2.0 is one of the largest publicly available multi-domain task-oriented dialogue datasets, including about 10,000 dialogues spanning seven domains. MultiWOZ 2.4 is the latest refined version of MultiWOZ 2.0. The annotations of its validation set and test set have been manually rectified. While its training set remains intact and is the same as that of MultiWOZ 2.1 (Eric et al., 2020), in which 41.34% of the state values are changed, compared to MultiWOZ 2.0.

Since the *hospital* domain and *police* domain never occur in the test set, we use only the remaining five domains {*attraction*, *hotel*, *restaurant*, *taxi*, *train*} in our experiments. These domains have 30 slots in total. Considering that the validation set and test set of MultiWOZ 2.0 are noisy, we replace them with the *counterparts* of MultiWOZ 2.4[2]. We preprocess the datasets following (Ye et al., 2021b). We use the validation set as the small clean dataset.

4.2 Evaluation Metrics

We exploit joint goal accuracy and slot accuracy as the evaluation metrics. The joint goal accuracy is defined as the proportion of dialogue turns in which the values of all slots are correctly predicted. It is the most important metric in the DST task. The slot accuracy is defined as the average of all individual slot accuracies. The accuracy of an individual slot is calculated as the ratio of dialogue turns in which its value is correctly predicted.

We also propose a new evaluation metric, termed as joint turn accuracy. We define joint turn accuracy as the proportion of dialogue turns in which the values of all *active* slots are correctly predicted. A slot becomes active if its value is mentioned in current turn and is not inherited from previous turns. The advantage of joint turn accuracy is that it can tell us in how many turns the turn-level information is fully captured by the model.

4.3 Primary DST Models

To verify the effectiveness of the proposed framework, we apply the generated pseudo labels to three different primary models.

SOM-DST: SOM-DST (Kim et al., 2020) is an open vocabulary-based method. It treats the dialogue state as an explicit fixed-sized memory and selectively overwrites this memory at each turn.

STAR: STAR (Ye et al., 2021b) is a predefined ontology-based method. It leverages a stacked slot self-attention mechanism to capture the slot dependencies automatically.

AUX-DST: We also test using the proposed auxiliary model as the primary model. For the sake of description, we refer to this model as AUX-DST.

4.4 Implementation Details

For the auxiliary model, the pre-trained BERT-base-uncased model is utilized as the dialogue context encoder. Another pre-trained BERT-base-uncased model with fixed weights is employed to encode the slots and their candidate values. The maximum input length of the BERT model is set to 512. The number of heads in the slot attention module is set to 4. The output dimension of the linear transformation layer is set to 768, which is the same as the dimension of the BERT outputs. Recall that the previous turn dialogue state is treated as part of the input. The ground-truth one is used during training, and the predicted one is used during testing[3].

---

[2] Despite this change, we still call the dataset MultiWOZ 2.0 in this paper for ease of exposition.

Table 1: Performance comparison on MultiWOZ 2.0 and MultiWOZ 2.4. Note that MultiWOZ 2.0 and MultiWOZ 2.4 share the same test set in our experiments. The best scores are highlighted in bold.

We train the auxiliary model on the clean validation set and the primary model on the noisy training set. When training the auxiliary model, the noisy training set is leveraged to choose the best model. For all primary models, the parameter α is set to 0.6 on MutliWOZ 2.0 and 0.4 on MultiWOZ 2.4. More training details can be found in Appendix B.

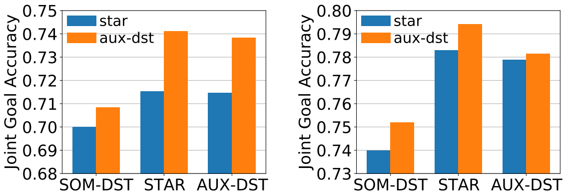
5 Experimental Results

5.1 Main Results

Table 1 presents the performance scores of the three different primary DST models on the test sets of MultiWOZ 2.0 & 2.4 when they are trained using our proposed framework ASSIST. For comparison, we also include the results when only the vanilla labels or only the pseudo labels are used to train the primary models.

As can be seen, ASSIST consistently improves the performance of the three primary models on both datasets. More concretely, compared to the results obtained using only the vanilla labels, ASSIST improves the joint goal accuracy of SOM-DST, STAR, and AUX-DST on MultiWOZ 2.0 by 25.69%, 25.82%, and 28.16% absolute gains, respectively. On MultiWOZ 2.4, ASSIST also leads to 8.41%, 5.79%, and 7.77% absolute joint goal accuracy gains. From Table 1, we further observe that the performance improvements on MultiWOZ 2.4 are lower than on MultiWOZ 2.0. This is because the training set of MultiWOZ 2.4 is the same as that of MultiWOZ 2.1 (Eric et al., 2020), in which lots of annotation errors have been fixed. We also observe that all the primary models demonstrate relatively good performance when only the pseudo labels are used. From these results, it can be concluded that the pseudo labels are beneficial and they can help us train DST models more robustly.

Another observation from Table 1 is that SOM-DST tends to show comparable or even higher joint turn accuracy compared to STAR and AUX-DST, although its performance is worse in terms of joint goal accuracy and slot accuracy. This is because SOM-DST focuses on turn-active slots and copies the values for other slots from previous turns, while both STAR and AUX-DST predict the values of all slots from scratch at each turn. These results show that the joint turn accuracy can help us understand in more depth how different models behave.



(a) MultiWOZ 2.0 (b) MultiWOZ 2.4

Figure 3: Performance comparison on MultiWOZ 2.0 and MultiWOZ 2.4 by adopting STAR as the auxiliary model. We use lowercase letters in the legend to show that the models are taken as the auxiliary model.

5.2 Applying STAR as the Auxiliary Model

Although any existing DST models can be adopted as the auxiliary model, we chose to propose a new simple one to reduce overfitting. In order to verify the superiority of the proposed model, we also apply STAR as the auxiliary model and compare their performance in Figure 3. We chose STAR due to its good performance, as shown in Table 1. From Figure 3, we observe that all three primary

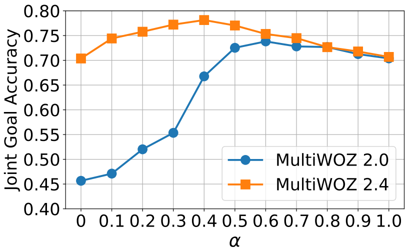


Figure 4: Effects of the parameter α. A larger α indicates that more emphasis is put on the pseudo labels.

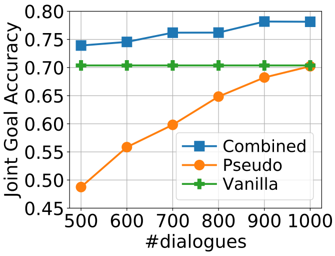

Figure 5: Effects of the size of the clean dataset. We include "Pseudo" and "Vanilla" for comparison.

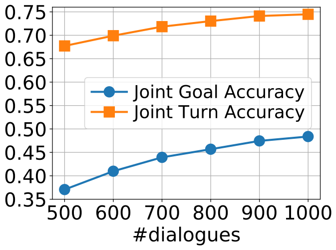

Figure 6: Performance of the auxiliary model evaluated on the noisy training set of MultiWOZ 2.4.

models demonstrate higher performance on both datasets when using the proposed auxiliary model than using STAR as the auxiliary model. The results indicate that the proposed auxiliary model is able to generate pseudo labels with higher quality.

5.3 Effects of Parameter α

The parameter α adjusts the weights of the pseudo labels and vanilla labels in the training phase. Here, we study the effects of α by varying its value in the range of 0 to 1 with a step size of 0.1. Figure 4 shows the results of AUX-DST. As can be seen, α plays an important role in balancing the pseudo labels and vanilla labels. The best performance is achieved when α is set to 0.6 on MultiWOZ 2.0 and 0.4 on MultiWOZ 2.4. Since the training set of MultiWOZ 2.0 has more noisy labels than that of MultiWOZ 2.4, more emphasis should be put on its pseudo labels to obtain the best performance. It is also noted that the performance difference between MultiWOZ 2.0 and MultiWOZ 2.4 dwindles away as α increases. This is because the vanilla labels will contribute less to the training of the primary model when α is set to be larger.

5.4 Effects of the Size of the Clean Dataset

Considering that our proposed framework ASSIST relies on a small clean dataset to train the auxiliary model that is further leveraged to generate pseudo labels for the training set, it is valuable to explore the effects of the size of the clean dataset on the performance of the primary model. For this purpose, we vary the number of dialogues in the clean dataset from 500 to 1000[4] to generate different pseudo labels. We then combine these different pseudo labels with the vanilla labels to train the primary model AUX-DST. The results on MultiWOZ 2.4 are reported in Figure 5. For comparison, we also include the results when only the pseudo labels or only the vanilla labels are used to train the primary model. As can be seen, the size of the clean dataset has a great impact on the performance of the primary model. Apparently, fewer clean data will lead to worse performance. Nevertheless, as long as the pseudo labels are combined with the vanilla labels, the primary model can consistently demonstrate the strongest performance.

5.5 Analyses on Pseudo Labels' Quality

The previous experiments have proven the effectiveness of the generated pseudo labels in training robust DST models. In this part, we provide further analyses on the quality of the pseudo labels to gain more insights into why they can be beneficial.

5.5.1 Quantitative Analysis

We first investigate whether the pseudo labels are consistent with the true labels. To achieve this goal, we can compute the joint goal accuracy and joint turn accuracy of the auxiliary model on the training set. However, the true labels of the training set are unavailable. As an alternative, we treat the vanilla noisy labels as true labels (note that only a portion of the vanilla labels are noisy). In this experiment, we also vary the number of clean dialogues to train the auxiliary model. Figure 6 presents the results. As shown in Figure 6, the auxiliary model achieves higher performance when more clean dialogues are utilized to train it. If the entire validation set is used, it achieves around 50% joint goal accuracy and around 75% joint turn accuracy. Given that the vanilla noisy labels are regarded as the true labels, we can conjecture that the true performance is actually higher. This experiment shows that the pseudo labels are consistent with the unknown true labels to some extent and can serve as a good complement to the vanilla noisy labels.

---

[4] There are 1000 dialogues in total in the validation set.

Dialogue Context	Vanilla Labels	Pseudo Labels
[sys]: Sure, da vinci pizzeria is a cheap Italian restaurant in the area. **[usr]:** Would you mind making a reservation for Thursday at 17:15?	(restaurant-name, da vinci pizzeria)	(restaurant-book day, thursday) (restaurant-book time, 17:15) (restaurant-name, da vinci pizzeria)

Table 2: Four dialogue snippets with their vanilla labels and the generated pseudo labels. These dialogue snippets are chosen from the training set of MultiWOZ 2.4. To save space, we only present turn-active slots and their values.

5.5.2 Qualitative Analysis

To intuitively understand the quality of the pseudo labels, we show four dialogue snippets with their vanilla labels and the generated pseudo labels in Table 2. As can be seen, the vanilla labels of the first two dialogue snippets are incomplete, while all the missing information is presented in the pseudo labels. For the third dialogue snippet, the vanilla labels contain an unmentioned slot-value pair "*(train-arriveby, 13:03)*". This error has also been fixed in the pseudo labels. For the last dialogue snippet, the vanilla labels are correct. However, the pseudo labels introduce an overconfident prediction of the value of slot "*hotel-area*". This case study has verified again that the pseudo labels can be utilized to fix certain errors in the vanilla labels. However, the pseudo labels may bring about some new errors. Hence, we should combine the two types of labels so as to achieve the best performance.

Settings	MultiWOZ 2.0	MultiWOZ 2.4
T	45.66	71.80

T+C+P	74.96	78.92

Table 3: The joint goal accuracy (%) of AUX-DST on MultiWOZ 2.0 & 2.4 under different training settings. T: the noisy training set. C: the small clean dataset. P: the generated pseudo labels of the original training set. The reported scores are the best ones on the test set.

5.6 Pseudo Labels vs. Simple Combination

Aiming to better validate the effectiveness of the proposed framework, we also report the results when the small clean dataset is directly combined with the large noisy training set to train the primary model. We adopt AUX-DST as the primary model and show the results in Table 3. Since the clean dataset (i.e., the validation set in our experiments) is combined with the training set, all the results in Table 3 are the best ones on the test set. As can be observed, a simple combination of the noisy training set and clean dataset can lead to better results. However, the performance improvements are lower, compared to using pseudo labels (especially on MultiWOZ 2.0 due to its noisier training set). It is also observed that when both the clean dataset and the pseudo labels are utilized to train the model, even higher performance can be achieved. These results indicate that our proposed framework can make better use of the small clean dataset to train the primary model.

5.7 Error Analysis

We further investigate the error rate with respect to each slot. We adopt AUX-DST as the primary model and use AUX-DST(w/o p) to denote the case when only the vanilla labels are employed to train the model. The results on the test set of MultiWOZ 2.4 are illustrated in Figure 7, from which we can observe that the slot "*hotel-type*" has the highest error rate. Even though the error rate is reduced with the aid of the pseudo labels, it is still the highest one among all the slots. This is because the labels of this slot are confusing. It is also observed that the "*name*"-related slots have relatively high error rates. However, when the pseudo labels are used, their error rates reduce remarkably. Besides, we observe that the error rates of some slots are higher when the pseudo labels are leveraged. This is probably due to the fact that we have used the same parameter α to combine the pseudo labels and vanilla labels of all slots. In practice, the noise rate with respect to each slot in the vanilla labels may not be exactly the same. This observation in-

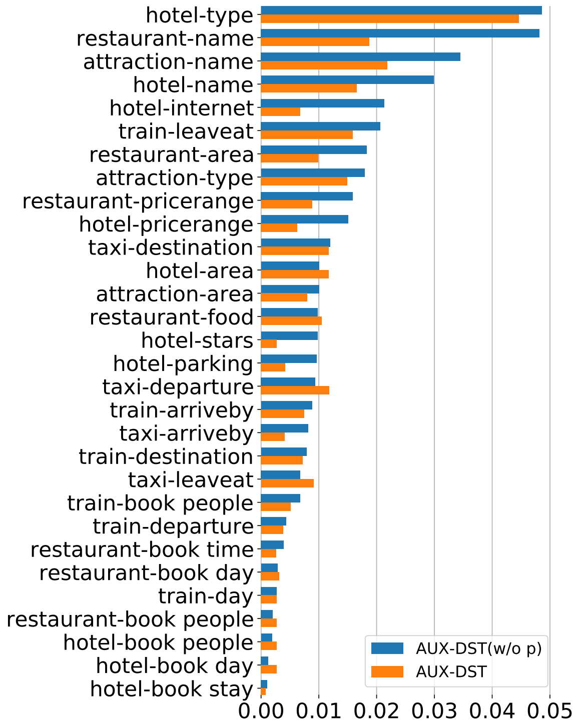

Figure 7: The error rate of each slot on MultiWOZ 2.4.

spires us that more advanced techniques should be developed to combine the pseudo labels and vanilla labels, which we leave as our future work.

6 Related Work

In this section, we briefly review related work on DST and noisy label learning.

6.1 Dialogue State Tracking

Recently, DST has got an enormous amount of attention, thanks to the availability of multiple large-scale multi-domain dialogue datasets such as MultiWOZ 2.0 (Budzianowski et al., 2018), MultiWOZ 2.1 (Eric et al., 2020), RiSAWOZ (Quan et al., 2020), and SGD (Rastogi et al., 2020). The most popular datasets are MultiWOZ 2.0 and MultiWOZ 2.1, and lots of DST models have been built on top of them (Lee et al., 2019; Wu et al., 2019; Ouyang et al., 2020; Hosseini-Asl et al., 2020; Kim et al., 2020; Hu et al., 2020; Feng et al., 2020; Ye et al., 2021b; Lin et al., 2021; Liang et al., 2021).

These recent DST models can be grouped into two categories: predefined ontology-based models and open vocabulary-based models. The predefined ontology-based models treat DST as a multi-label classification problem and tend to demonstrate better performance (Chen et al., 2020; Zhang et al., 2020; Shan et al., 2020; Ye et al., 2021b). The open vocabulary-based models leverage either span prediction (Heck et al., 2020; Gao et al., 2020) or sequence generation (Wu et al., 2019; Feng et al., 2020; Hosseini-Asl et al., 2020) to extract slot values from the dialogue context directly.

Although these DST models have made a huge success, they can only achieve sub-optimal performance, due to the lack of handling noisy labels. To the best of our knowledge, we are the first to take the noisy labels into consideration when tackling the DST problem.

6.2 Noisy Label Learning

Addressing noisy labels in supervised learning is a long-term studied problem (Frénay and Verleysen, 2013; Song et al., 2020; Han et al., 2020a). This issue becomes more prominent in the era of deep learning, as training deep models generally requires a lot of well-labelled data, but it is expensive and time-consuming to collect large-scale datasets with completely clean annotations. This dilemma has sparked a surge of noisy label learning methods (Hendrycks et al., 2018; Zhang and Sabuncu, 2018; Song et al., 2019; Wei et al., 2020). Even so, these methods mainly focus on multi-class classification (Song et al., 2020), which makes it not straightforward to apply them to the DST task.

7 Conclusion

In this work, we have presented a general framework ASSIST, aiming to train DST models robustly from noisy labels. ASSIST leverages an auxiliary model that is trained on a small clean dataset to generate pseudo labels for the large noisy training set. The pseudo labels are combined with the vanilla labels to train the primary model. Both theoretical analysis and empirical study have verified the validity of our proposed framework. In the future, we intend to explore more advanced techniques to combine the pseudo labels and vanilla noisy labels in a better way.

A Proof of Theorem 1

Proof. Our proof is based on the bias-variance decomposition theorem[5]. For any sample $\mathcal{X}_t$ in the noisy training set $\mathcal{D}_n$, the approximation error with respect to the pseudo label $\breve{v}_t$ of slot s is defined as $E_{\mathcal{D}_c}[\|\breve{\boldsymbol{v}}_t - \boldsymbol{v}_t\|_2^2]$, which, according to the bias-variance decomposition theorem, can be decomposed into a bias term and a variance term, i.e.,

$$E_{\mathcal{D}_c}[\|\breve{\boldsymbol{v}}_t - \boldsymbol{v}_t\|_2^2] = (\texttt{Bias}_{\mathcal{D}_c}[\breve{\boldsymbol{v}}_t])^2 + \texttt{Var}_{\mathcal{D}_c}[\breve{\boldsymbol{v}}_t],$$

where

$$\begin{aligned}\texttt{Bias}_{\mathcal{D}_c}[\breve{\boldsymbol{v}}_t] &= \|E_{\mathcal{D}_c}[\breve{\boldsymbol{v}}_t] - \boldsymbol{v}_t\|_2,\\ \texttt{Var}_{\mathcal{D}_c}[\breve{\boldsymbol{v}}_t] &= E_{\mathcal{D}_c}[\|E_{\mathcal{D}_c}[\breve{\boldsymbol{v}}_t] - \breve{\boldsymbol{v}}_t\|_2^2].\end{aligned}$$

In our approach, the auxiliary model is a BERT-based model, which has more than 110M parameters. Such a complex model is expected to be able to capture all the samples in the small clean dataset $\mathcal{D}_c$. Therefore, we can reasonably assume that the bias term is close to zero. Then, we have:

$$\texttt{Bias}_{\mathcal{D}_c}[\breve{\boldsymbol{v}}_t] \approx 0 \Rightarrow E_{\mathcal{D}_c}[\breve{\boldsymbol{v}}_t] \approx \boldsymbol{v}_t.$$

Considering that the pseudo labels are generated by the auxiliary model that is trained on an extra small clean dataset and this clean dataset is independent of the noisy training set, we can regard the pseudo labels and vanilla labels as independent of each other. Consequently, we obtain:

$$\begin{aligned}&E_{\mathcal{D}_c}[(\tilde{\boldsymbol{v}}_t - \boldsymbol{v}_t)^T(\breve{\boldsymbol{v}}_t - \boldsymbol{v}_t)]\\ &\quad= [E_{\mathcal{D}_c}[\tilde{\boldsymbol{v}}_t - \boldsymbol{v}_t]]^T E_{\mathcal{D}_c}[\breve{\boldsymbol{v}}_t - \boldsymbol{v}_t]\\ &\quad= [E_{\mathcal{D}_c}[\tilde{\boldsymbol{v}}_t - \boldsymbol{v}_t]]^T E_{\mathcal{D}_c}[\breve{\boldsymbol{v}}_t - E_{\mathcal{D}_c}[\breve{\boldsymbol{v}}_t]]\\ &\quad= [E_{\mathcal{D}_c}[\tilde{\boldsymbol{v}}_t - \boldsymbol{v}_t]]^T \mathbf{0} = 0.\end{aligned}$$

Based on the formula above, we can now calculate the approximation error with respect to the combined label $\boldsymbol{v}_t^c$ of slot s as below:

$$\begin{aligned}&E_{\mathcal{D}_c}[\|\boldsymbol{v}_t^c - \boldsymbol{v}_t\|_2^2]\\ &\quad= E_{\mathcal{D}_c}[\|\alpha\breve{\boldsymbol{v}}_t + (1-\alpha)\tilde{\boldsymbol{v}}_t - \boldsymbol{v}_t\|_2^2]\\ &\quad= E_{\mathcal{D}_c}[\|\alpha(\breve{\boldsymbol{v}}_t - \boldsymbol{v}_t) + (1-\alpha)(\tilde{\boldsymbol{v}}_t - \boldsymbol{v}_t)\|_2^2]\\ &\quad= \alpha^2 E_{\mathcal{D}_c}[\|\breve{\boldsymbol{v}}_t - \boldsymbol{v}_t\|_2^2]\\ &\qquad+ (1-\alpha)^2 E_{\mathcal{D}_c}[\|\tilde{\boldsymbol{v}}_t - \boldsymbol{v}_t\|_2^2],\end{aligned}$$

where the last equality holds because of $E_{\mathcal{D}_c}[(\tilde{\boldsymbol{v}}_t - \boldsymbol{v}_t)^T(\breve{\boldsymbol{v}}_t - \boldsymbol{v}_t)] = 0$. Then, we have:

$$\begin{aligned}Y_{\boldsymbol{v}^c} &= \frac{1}{|\mathcal{D}_n||\mathcal{S}|}\sum_{\mathcal{X}_t\in\mathcal{D}_n}\sum_{s\in\mathcal{S}} E_{\mathcal{D}_c}[\|\boldsymbol{v}_t^c - \boldsymbol{v}_t\|_2^2]\\ &= \frac{\alpha^2}{|\mathcal{D}_n||\mathcal{S}|}\sum_{\mathcal{X}_t\in\mathcal{D}_n}\sum_{s\in\mathcal{S}} E_{\mathcal{D}_c}[\|\breve{\boldsymbol{v}}_t - \boldsymbol{v}_t\|_2^2]\\ &\quad+ \frac{(1-\alpha)^2}{|\mathcal{D}_n||\mathcal{S}|}\sum_{\mathcal{X}_t\in\mathcal{D}_n}\sum_{s\in\mathcal{S}} E_{\mathcal{D}_c}[\|\tilde{\boldsymbol{v}}_t - \boldsymbol{v}_t\|_2^2]\\ &= \alpha^2 Y_{\breve{\boldsymbol{v}}} + (1-\alpha)^2 Y_{\tilde{\boldsymbol{v}}}.\end{aligned}$$

$Y_{\boldsymbol{v}^c}$ reaches its minimum when $\alpha = \frac{Y_{\tilde{\boldsymbol{v}}}}{Y_{\tilde{\boldsymbol{v}}}+Y_{\breve{\boldsymbol{v}}}}$, and

$$\min_{\alpha} Y_{\boldsymbol{v}^c} = \frac{Y_{\tilde{\boldsymbol{v}}}Y_{\breve{\boldsymbol{v}}}}{Y_{\tilde{\boldsymbol{v}}}+Y_{\breve{\boldsymbol{v}}}},$$

which concludes the proof. □

B Training Details

Note that the proposed auxiliary model is also applied as one primary model in our experiments. In both cases, AdamW (Kingma and Ba, 2014) is adopted as the optimizer, and a linear schedule with warmup is created to adjust the learning rate dynamically. The peak learning rate is set to 2.5e-5. The warmup proportion is fixed at 0.1. The dropout (Srivastava et al., 2014) probability and

---

[5] `https://en.wikipedia.org/wiki/Bias-variance_tradeoff`

word dropout (Bowman et al., 2016) probability are also fixed at 0.1. When taken as the auxiliary model, the model is trained for at most 30 epochs with a batch size of 8. When taken as the primary model, the batch size and training epochs are set to 8 and 12, respectively. The best model is chosen according to the performance on the validation set. We apply left truncation when the input exceeds the maximum input length of BERT.

For SOM-DST and STAR, the default hyperparameters are adopted when they are applied as the primary model (except setting *num_workers = 0*).

C Additional Experimental Results

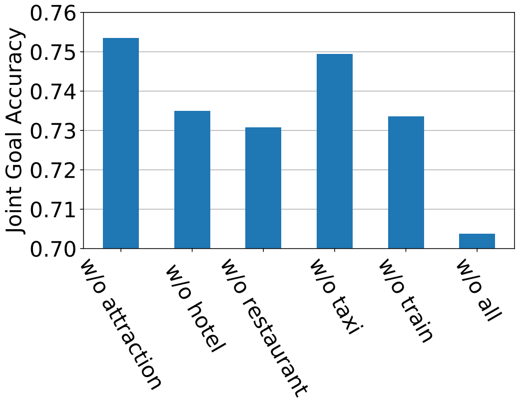

Figure 8: Analyses on the effects of the distribution of the clean dataset by removing all the dialogues related to each domain. "w/o all" means no clean data is used.

C.1 Effects of the Distribution of the Clean Dataset

Except for the size of the clean dataset, the distribution of the clean dataset may also affect the performance of the primary model, especially when the clean dataset has a significantly different distribution from the training set. Thus, it is important to study the effects of the distribution of the clean dataset. However, we are short of clean datasets with different distributions. It is also challenging to model the distribution explicitly since the dialogue state may contain multiple labels. To address this issue, we propose to remove all the dialogues that are related to a specific domain and use only the remaining ones as the clean dataset. As thus, we can create multiple clean datasets with different distributions. The results of AUX-DST on MultiWOZ 2.4 are shown in Figure 8. As can be observed, although different clean datasets indeed lead to different performance, compared to the situation where no clean data is used (i.e., only the vanilla labels are used to train the model), all these clean datasets still bring huge performance improvements.

Graph Refinement for Coreference Resolution

Abstract

The state-of-the-art models for coreference resolution are based on independent mention pairwise decisions. We propose a modelling approach that learns coreference at the document-level and takes global decisions. For this purpose, we model coreference links in a graph structure where the nodes are tokens in the text, and the edges represent the relationship between them. Our model predicts the graph in a non-autoregressive manner, then iteratively refines it based on previous predictions, allowing global dependencies between decisions. The experimental results show improvements over various baselines, reinforcing the hypothesis that document-level information improves conference resolution.

1 Introduction

Current state-of-the-art (SOTA) solutions for coreference resolution such as (Toshniwal et al., 2020; Xu and Choi, 2020; Wu et al., 2020) formulate the problem in an end-to-end manner where the models jointly learn to detect mentions and link coreferent mentions. The objective is to predict the antecedent of each mention-span in a document, so the model performs pair-wise decisions of all mentions. After having the model predictions, related mentions are grouped into clusters. Under this scenario, each decision (i.e., whether two mentions are related to the same entity or not) is independent. Lee et al. (2018) proposed an iterative method to update the representation of a mention with information of its probable antecedents. However, the final decisions are still made locally.

We propose a modeling approach that learns coreference at the document-level and takes global decisions. We propose to model mentions and coreference links in a graph structure where the nodes are tokens in the text, and the edges represent the relationships between them. Figures 1 and 2 show a short example taken from the CoNLL 2012 dataset (Pradhan et al., 2012) showing the graph in two perspectives. Figure 1 shows how the token nodes in a text are connected with edges drawn with arrows. We differentiate the connections between words in a coreference mention, '*mention links*', and the ones among mentions in a cluster, '*coreference links*' (see Sec. 4). Figure 2 shows the same graph in a matrix representation, where the number in a cell indicates the type of relation between the row and the column. Our model receives a document as input then predicts and iteratively refines the graph of mentions and coreference links.

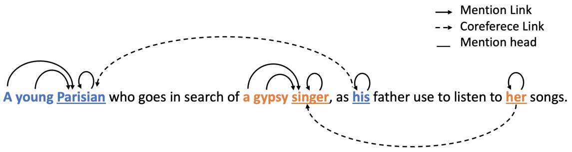

Figure 1: Example of a graph structure for coreference. Mention spans are shown in bold, and colors represent entity clusters. The mention heads are underlined.

We follow a similar approach to the Graph-to-Graph Transformer (G2GT) proposed in (Mohammadshahi and Henderson, 2021, 2020) for syntactic parsing, but instead of encoding sentences, we en-

code documents. Our model predicts the graph in a non-autoregressive manner, then iteratively refines it based on previous predictions. This recursive process introduces global dependencies between decisions. Unlike (Mohammadshahi and Henderson, 2021), we define different structures for input and output graphs, to reflect the different roles of these graphs. To ensure that locality in the input graph reflects all the relevant relationships, the input graph encodes relations for all mention tokens. This makes the encoding process easier. To provide a unique specification of the target graph, the output only encodes a minimal set of connections. This facilitates prediction. We initialize the Transformer with pre-trained language models, either BERT (Devlin et al., 2019), or SpanBERT (Joshi et al., 2020).

Another difference with (Mohammadshahi and Henderson, 2021) is that our model predicts two levels of representation. While they predict the whole graph at each iteration, during the first iteration our model only predicts edges that identify mention-spans. This is because mention detection is a sentence-level phenomenon whose outputs are required as inputs to coreference resolution, which is a discourse-level phenomenon. But we do not organise these two tasks in a pipeline. Starting at the second iteration, the model predicts the complete graph. This allows the model to refine mention decisions given coreference decisions, and vice versa. In this way, we propose to use iterative graph refinement as an alternative to pipeline architectures for multi-level deep learning models. The iterative process finishes when there are no more changes in the graph or when a maximum number of iterations is reached.

Ideally, the whole document should be encoded at once, but in practice there is a limit on the maximum length. In order to deal with this issue, we propose two strategies: overlapping windows and reduced document. In the first strategy, we split documents into overlapping windows of the maximum allowed size K. The segments overlap for a length $K/2$. At decoding time, segments are input in order, and we construct the final graph by joining all graphs from different segments. In the second strategy, we use two networks. The mention-span network is the previously described overlapping model, and we use it for predicting the first graph. For the second network, we reduce the document by including only the tokens of candidate mention-spans, separated by a special token. This network refines the initial graph for the following iterations.

The experiments show improvements over the relevant baselines and state-of-the-art. They also indicate that the models reach the best solution in a maximum of three iterations. Given that we predict the graph at once for each iteration, our model's complexity is lower than the baselines. Our contributions are the following:

- We propose a novel modeling approach to coreference resolution using a graph structure and multi-level iterative refinement.
- We propose two iterative graph refinement models that can predict the complete entity coreference structure of a document.
- We show improvements over baseline models and the relevant state-of-the-art.

The rest of the paper is organized as follows. Section 2 presents a summary of coreference resolution approaches related to this paper. Section 3 briefly describes the fundamentals of state-of-the-art approaches. In Section 4, we define entity mentions and their coreference links as a graph, and fomulate the task as a sequence-to-graph problem. In Section 5, we present our iterative refinement solution to global modelling of the coreference graph, and in Section 6, we present two proposed architectures to address the resulting computational issues. Sections 7, 8 and 9 contain the experimental setup, results and discussion, respectively. Finally, Section 10 draws the conclusions of this paper.

2 Related Work

The first approaches to coreference resolution (CR) were rule-based systems (Lappin and Leass, 1994; Manning et al., 2014), but eventually, they were outperformed by machine learning approaches (Aone and William, 1995; McCarthy, 1995; Mitkov, 2002) due to annotated corpora's creation. In genral, there are three coreference approaches : mention-pair, entity-mention, and ranking models. Mention-pair models set coreference as a binary classification problem. The initial stage is the mention detection, where the input is raw text, and the output is the locations of each entity mention in the text. Mention detection is done as an independent task in a pipeline model (Soon et al., 2001) or as part of an end-to-end model (Lee et al., 2017). The next stage is the classification of mention pairs. At first, the best classifiers were decision trees (Soon et al., 2001; McCarthy, 1995; Aone and William, 1995), but later, neural networks became the SOTA. The final stage is reconciling the pair-wise decisions to create entity chains, usually by utilizing greedy algorithms or clustering approaches. Entity-mention models focus on maintaining single underlying entity representation for each cluster, contrasting the independent pair-wise decisions of mention-pair approaches (Clark and Manning, 2015, 2016). Ranking models aim at ranking the possibles antecedent of each mention instead of making binary decisions (Wiseman et al., 2016). An alternative modeling approach is to perform clustering instead of classification (Fernandes et al., 2012).

SOTA models for CR are mostly based on Lee et al. (2017). They introduced the first end-to-end model that jointly optimizes mention detection and coreference resolution tasks. These neural network-based models also simplify the mention input representation to be word embedding vectors, instead of the traditional pipeline of different linguistic feature extraction tools such as part-of-speech (POS) tagging and dependency parsing. The following models proposed improvements over this work. (Lee et al., 2018) improved the previous model by introducing higher order inference so the entity's mention representation will get iteratively updated with the weighted average of antecedent representations, where the weights are the predictions from the model at the previous iteration. This contrasts with our approach in that we iterate over the whole coreference link graph and we perform discrete decisions at each iteration. Fei et al. (2019) use reinforcement learning to directly optimize the model on the evaluation metrics. Joshi et al. (2019) uses BERT embeddings (Devlin et al., 2019) as input. Joshi et al. (2020) introduced a new SpanBERT embedding model, which is shown to outperform BERT for the CR task. Xu and Choi (2020) showed that higher order inference has low impact on strong models such as SpanBERT. Toshniwal et al. (2020) proposed a bounded memory model trained to manage limited memory by learning to forget entities. Finally, Wu et al. (2020) formulated the problem of coreference resolution as question-answering and trained a model for span prediction. This model has the advantage of being pretrained with larger data-sets from the question-answering task.

3 Baseline: Neural Coreference Resolution

Neural coreference resolution, as formulated in (Lee et al., 2017, 2018), is a mention-pair approach. It uses an exhaustive method defining mentions as any text span of any size in a document. There, a document D represents a sequence of tokens of size N. The objective is to assign an antecedent y_i to each of the M text spans m_i in D. The set of possible antecedents of the span m_i is denoted as $\mathrm{Y}(i)$. This set contains all text spans with index less than i, plus a null antecedent ϵ, $\mathrm{Y}(i) = \{\epsilon, m_1, ..., m_{i-1}\}$. The null antecedent is assigned when: (a) the span is not an entity mention, (b) the span is the first mention of an entity in the document. The final mention clusters are constructed greedily by grouping connected spans based on the model predictions during decoding time.

The model is trained to learn a conditional probability distribution over documents $p(y_1, ..., y_n|D)$, assuming independence among each decision of antecedent assignment y_i, as follows:

$$p(y_1, ..., y_M|D) = \prod_{i=1}^{M} p(y_i|D) \tag{1}$$

In (Lee et al., 2018), the probability distribution $p(y_i|D)$ is inferred over T iterations of the model over the same input document. At each iteration t, the span representations are updated with the weighted average of all possible antecedents at time $t-1$ where the weights are given by the probability distribution of the model at time $t-1$. They called this model high-order coreference resolution since each mention representation considers information from its probable antecedents.

The training optimization is done using cross-entropy. Given that a mention-span m_i can have more than one true antecedent, the loss considers the sum of probabilities of all true antecedents in the annotated data:

$$log \prod_{i=1}^{M} \sum_{y_i \in \mathrm{Y}(i) \cap \mathrm{C}(i)} p(y_i|D) \tag{2}$$

where $\mathrm{C}(i)$ indicates the cluster of mention-spans that includes m_i in the annotated data. If the span does not belong to any cluster or all its antecedents have been pruned, then the span is assigned to the null cluster $\mathrm{C}(i) = \{\epsilon\}$.

This model's complexity is of the order $\mathcal{O}(N^4)$, where N is the document length. The complexity is computed by considering all possible text spans M of the document, so $\mathcal{O}(M) = \mathcal{O}(N^2)$. Then, it considers all possible combinations of span-antecedents $\mathcal{O}(M^2)$. The model prunes spans and candidate antecedents to predetermined maximum numbers in order to maintain computational efficiency.

4 Graph Modeling

We propose to model the set of coreference links of a document in a graph structure where the nodes are tokens[1] and the edges are links of different types. Given a document $D = [x_1, ..., x_N]$ of size N, the coreference graph is defined as the matrix $G \subset \mathbb{N}^{N\times N}$ of links between tokens. Here, the relation type between two tokens, x_i and x_j, is encoded with integers and is denoted as $g_{i,j} \in \{0, 1, 2\}$. We define three relation types: (0) no link, (1) mention link, and (2) coreference link, as illustrated in Figure 2.

Mention links This type of link serves to identify mentions. We define mention links in two different manners depending on whether the graph is an input or output of the model, for functional reasons. When the graph is an input G^{in}, there is a directed link from each mention's token to the mention head, including the head to itself. When the graph is the model's output G^{out}, there is only one directed link from the last token of the mention-span to the first token. Both encoding methods define a mention-span uniquely, even when having nested mentions; every mention has a unique start-end combination and a unique head. The model utilizes the output for prediction, so it is simpler to predict one single link, whereas, in the input, the model uses links to all tokens to provide a more direct representation of the role of every token in the mention.

Mention heads We simplified the head identification process by considering the first token of a mention span as the head. Although this method is naive, experiments show that this approximation works well enough in practice. However, as some spans can potentially have the same first token in case of nested mentions, we fix this issue by assigning the next token as the head if the first is already the head of any other mention. Investigating alternative approaches to mention head identification is future work.

Coreference links This type of link defines the relationship between a mention and each of its antecedents. We also define coreference links in two different manners depending on whether the graph is an input or output of the model. When the graph is input, there is a link from a mention head token to the head of each mention in the same cluster. When the graph is a model's output, the mention should be connected to at least one of its antecedents. If the mention has no antecedent, or corresponds to the first mention of an entity in the text, then it is connected to a null antecedent ϵ. We use all possible connections between mentions in an entity cluster for the input so that the model receives a direct input for each coreference relationship. On the other hand, we consider that predicting at least one connection of the mention to its cluster is sufficient to specify the output graph.

The objective is to learn the conditional probability distribution $p(G|D)$. This distribution is initially approximated by assuming independence among each relation $g_{i,j}$ as:

$$p(G|D) = \prod_{i=1}^{N}\prod_{j=1}^{i} p(g_{i,j}|D) \tag{3}$$

The probability $p(g_{i,j}|D)$ is split in two cases: one for mention links p_m and the other for coreference links p_c. The mention link probability is defined as:

$$p_m(g_{i,j}{=}1|D) = \sigma(W_m \cdot [h_i, h_j]) \tag{4}$$

where W_m is a parameter matrix, and h_i and h_j are the hidden state representations of the tokens x_i and x_j respectively. This probability indicates whether there is a mention starting at position j and ending at position i of the document D. The optimization is done using binary-cross-entropy $loss_m$.

The coreference link probability is defined as:

$$p_c(g_{i,j}{=}2|D) = \frac{exp(W_c \cdot [h_i, h_j])}{\sum_{j' \in \mathrm{A}(i)} exp(W_c \cdot [h_i, h_{j'}])} \tag{5}$$

where W_c is a parameter matrix, and h_i and h_j are the hidden state representations of the tokens x_i and x_j respectively. Similar to the baseline, we denote $\mathrm{A}(i)$ as the set of all candidate antecedents of x_i. This set contains all mention heads with

---

[1] The tokenization of the words in the document, and thus the nodes of the graph, are defined by the input format of the relevant pre-trained Transformer model.

an index less than i, plus a null head ϵ, $\mathrm{A}(i) = \{\epsilon, x_k \mid k < i \text{ and } x_k \in \mathrm{H(D)}\}$, and H(D) is the set of all candidate mention heads in the document. The optimization is done with cross-entropy loss. Given that a mention-span m_i can have more than one true antecedent, the loss considers the sum of probabilities of all true antecedents in the annotated data (as in Equation(2)):

$$loss_c = log \prod_{i \in \mathrm{H}(D)} \sum_{j \in \mathrm{Y}(i) \cap \hat{\mathrm{C}}(i)} p_c(g_{i,j}|D) \quad (6)$$

where $\hat{\mathrm{C}}(i)$ indicates the annotated cluster of mention-spans that includes m_i in the annotated data. If the mention does not belong to any cluster, then the span is assigned to the null cluster $\hat{\mathrm{C}}(i) = \{\epsilon\}$. The final loss is the sum of $loss_m$ and $loss_c$.

The token's hidden state representations $\{h_1, .., h_N\}$ are the last hidden layer of a Transformer model. We use various pre-trained Transformer models to initialize the weight parameters, then fine-tune for the coreference task.

5 Iterative Refinement

The strong independence assumption made in Equation (3) does not reflect the real scenario and could lead to poor performance. Therefore, we use an iterative refinement approach to model interdependencies between relations, similar to G2GT (Mohammadshahi and Henderson, 2021). Under this approach, the model makes T iterations over the same document D. At each iteration t, the predicted coreference graph G_t is conditioned on the previously predicted one G_{t-1}. The model's conditional probability distribution is now defined as follows:

$$p(G^t|D, G^{t-1}) = \prod_{i=1}^{N} \prod_{j=1}^{i} p(g_{i,j}|D, G^{t-1}) \quad (7)$$

This means that the graph should be input to the Transformer model (Vaswani et al., 2017). Following (Mohammadshahi and Henderson, 2021), the graph is encoded by inputting an embedding for the type of each relation into the self-attention function of the Transformer :

$$\mathsf{Attention}(Q, K, V, L_k, L_v) = \\ \text{softmax}(\frac{Q \cdot (K + L_k)^{\intercal}}{\sqrt{d}}) \cdot (V + L_v) \quad (8)$$

$$\text{where} \quad L_v = E(G_{t-1}) \cdot W_v \\ L_k = E(G_{t-1}) \cdot W_k$$

where E is a matrix of embeddings which encode the types of links in the graph, as illustrated in Figure 2. Thus, the relationship between a pair of tokens is encoded as an embedding vector which is input when computing the attention function for that pair of tokens. W_k, W_v are weight matrices that serve to specialize $E(G_{t-1})$ to be either *key* or *value* vectors. The complexity of our model is of the order of $\mathcal{O}(N^2 \times T)$, where N is the document length, and T is the number of refinement iterations of the model.

To illustrate the iterative refinement of a graph, Figure 3 shows an example of two iterations of the model. The mention links are indicated with solid line arrows and the coreference links with dotted arrows. The initial graph matrix G_0^{in} is full of zeros, so no connections are drawn. The first predicted graph G_1^{out} only has mention-links because initially there were no mention heads to be connected. This graph is transformed to serve as input G_1^{in} for the next iteration. Finally, during the second iteration, the model predicts the coreference graph G_2^{out}. The model can continue iterating for a maximum of T times.

6 Architectures

There exists in practice a maximum length for encoding a document due to limited hardware memory. In this section, we describe two strategies to manage this issue: overlapping windows and reduced document. In the experiments we also report results for a naive strategy of truncating the documents at the maximum segment length of K for both training and testing.

6.1 Overlapping Windows

Here, we split the documents into overlapping segments of the maximum size K, with an overlap of $K/2$ tokens. The segments are encoded individually in our G2GT model. During training, each segment is treated as an independent sample. However, during decoding, the segments are decoded in order. The subgraph corresponding to the overlapping part is input to the next segment. The union of the segmented graphs forms the final graph.

6.2 Reduced Document

This model has two parts; one to detect mentions and the other to perform coreference resolution.

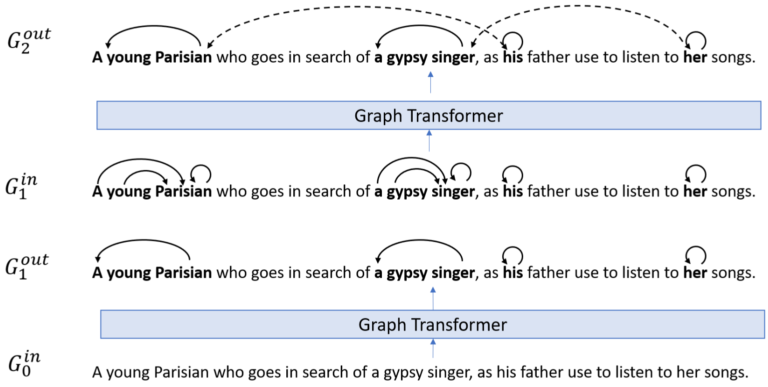

Figure 3: Example of iterations with G2GT.

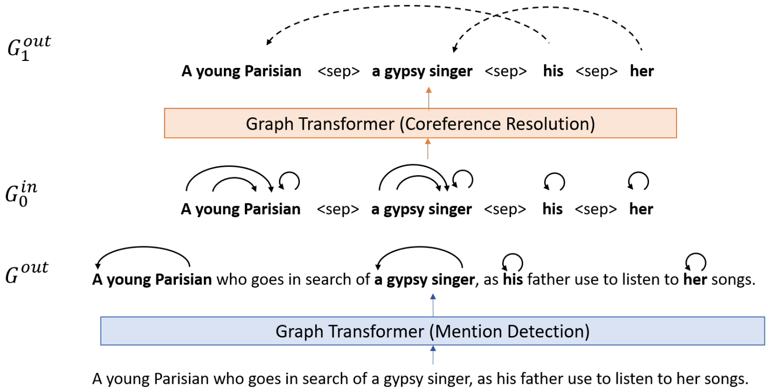

Figure 4: Example of iterations with G2GT in two stages.

The mention detection is similar to the previously described model. The coreference resolution part receives a shorter version of the document as input. The complete model is described in the following:

Mention Detection This Transformer is non-iterative so it corresponds to the definition in Equation (3). To encode the document, we apply overlapping windows, as in the previous section. For prediction, we used the *soft-target* method proposed in (Miculicich and Henderson, 2020). This method enables the model to increase the recall of detection. Given that the candidate mentions will be fixed for the coreference resolution part, we need to detect most of them here.

Coreference Resolution This part is a G2GT with iterative refinement. The input is a shorter version of the document obtained by concatenating the tokens from candidate mention-spans with a separation token in between and removing all other tokens. To maintain coherence in the document, we modify the token input representation to the sum of three vectors: (a) a token embedding, (b) an embedding of the token's position in the original document, so we retain information of distance between mentions, and (c) the token's contextualized representation obtained from the mention detection part where the original document is encoded. This second part predicts only coreference links, but the input graph contains both candidate mentions and coreference links. The set of candidate mentions remains the same across all iterations of this second part, but the mentions are refined in the sense that the final output only includes the mentions which are involved in the final coreference links.

Figure 4 shows an example of this architecture with one iteration over a document. The mention links are indicated with solid line arrows and the coreference links with dotted arrows. The first model predicts the graph of mention-spans G^{out}. This graph is transformed into the input format for the next model G_0^{in}. Then, the second model predicts the graph of coreference G_1^{out}. Note that this coreference resolution model can continue iterating for T times. The final coreference graph is the output after the final iteration of the second model. The final set of mentions is only a subset of the mention candidates output by the first

	Train	Dev.	Test	Total

model, namely those mentions which participate in coreference links.

7 Experimental Setting

7.1 Dataset

We use the CoNLL 2012 corpus (Pradhan et al., 2012). It contains data from diverse domains e.g., newswire, magazines, conversations. We experiment only with the English part. Table 1 shows the statistics of the dataset; the average length per document does not exceed 500 words. We pre-process the text to extract sub-word units (Sennrich et al., 2016) with BERT tokenizer (Wu et al., 2016). We map the positional annotation of mentions from words to sub-words and retain this mapping for back transformation during evaluation.

7.2 Model configuration

We use the implementation of Wolf et al. (2019)[2] of ‘BERT-base’, ‘BERT-large’ (Joshi et al., 2019) and ‘SpanBERT-large’ (Joshi et al., 2020). All hyper-parameters follow this implementation unless specified otherwise.

Training The G2GT considers an independent loss for each different refinement iteration. There is no back-propagation between refinement iterations because the model makes discrete decisions when predicting the graph for the next refinement step. There are two stopping criteria for the refinement: (a) when a maximum number of iterations T is reached, or (b) when there are no more changes in the graph, $G_t = G_{t-1}$. This criterion is for both training and testing. Our models are trained with a maximum segment length of $K = 512$ and a batch size of 1 document. We use Adam (Kingma and Ba, 2014; Wolf et al., 2019) optimizer with a base learning rate of $2e{-}3$ and no warm-up. As our graphs are directed, we use only the lower triangle of G for predictions. The components of the reduced models are trained independently. The coreference resolution follows the currently described training schema. The mention detection model has no iterative refinement step and follows the training schema of the *span scoring soft-target* approach described in (Miculicich and Henderson, 2020), with $\rho = 0.1$.

Model	Iter.	MUC	B^3	CEAF$_{\phi_4}$	Avg. F1

	$T=5$	81.9	70.1	71.2	74.4

Table 2: Refinement iterations T on the development set (CoNLL 2012).

Evaluation At evaluation time, we map back all sub-word units to words and reconstruct the document in CoNLL 2012 format. We use the precision, recall, and F1 score calculated in three different manners: MUC that counts the number of links between mentions, B^3 that counts the number of mentions, and CEAF that counts the entity clusters. We did paired bootstrapping re-sampling for significance test following (Koehn, 2004).

8 Results Analysis

This section describes the results of various baselines and our models. First, we analyze the optimum number of refinement iterations, and then we show results using the best models.

Table 2 shows the performance of our G2GT models when varying the maximum number of refinement iterations T from 2 to 5 (T=1 is mention detection only). The results are in terms of the F1 score of the three coreference metrics and the average. All three implementations shown in the table perform the best when using T=4. There is a significant decrease in performance when the graphs are not refined, T=2, showing the importance of modelling the interdependencies between coreference relations.

Table 3 shows the evaluation results on the test set in terms of precision (P), recall (R), and F1 score for each metric. The last column displays the average F1 of the three metrics. The first section

of the table exhibits scores of different coreference resolution systems from the literature. The second section shows the result of the 'Baseline' (Lee et al., 2018) system described in Section 3. This model uses ELMo (Peters et al., 2018) instead of BERT to obtain token representations. Baseline plus 'BERT-base', 'BERT-large' (Joshi et al., 2019) and ' SpanBERT-large' (Joshi et al., 2020) correspond to the baseline using those pretrained representations. We copy all these values from the original papers. The last section of the table presents scores of our graph-to-graph models with iterative refinement. '*truncated*' is our model with no special treatment for document length; the documents are truncated at the maximum segment length of K. '*overlap*' and '*reduce*' are the models described in Section 6.

As expected, pre-training with SpanBERT results in better scores than with BERT, and BERT-large is better than BERT-base. Not surprisingly, 'G2GT BERT-base truncated' and 'G2GT BERT-large truncated' perform poorly in comparison to the baseline because their information is incomplete. For BERT-base, both the '*overlap*' and '*reduce*' models have better scores than the comparable baseline. For BERT-large and SpanBERT, the '*overlap*' model has similar scores to the baseline, but the '*reduce*' model consistently improves over the baseline.

Preliminary experiments with G2GT '*overlap*' in a pipeline approach, where mention detection is performed before coreference, showed that it is not better than in a joint approach showed here. Overall, our G2GT '*reduce*' method consistently shows the highest scores across all the models for each pre-trained model. Our models do not surpass SOTA (Wu et al., 2020) (shown in grey), but as mentioned before, this SOTA model is also trained on the much more abundant data from the question-answering task, and so it is not directly comparable to our model. We leave the issue of incorporating additional data into the training of our model to future work.

9 Discussion

These results support our claim that coreference resolution benefits from making global coreference decisions using document-level information. First, refinement of coreference decisions using global information about other coreference decisions clearly improves accuracy, as indicated by the improved scores for models with more than one coreference iteration in Table 2. Second, the model which is able to combine information from the entire document, G2GT '*reduce*', is clearly better than the model which performs the task on large windows of text and then merges the results, G2GT '*overlap*'. We believe that the benefits of full-document iterative refinement will extend to other discourse-level phenomena, and that the G2GT architecture will be an effective way to achieve this benefit.

One issue with our method is the necessity to iteratively pass the input through an expensive encoder model more than once. However, the number of iterations needed is small, and results in significant improvement.

The length management methods would not be necessary if we had more efficient pre-trained Transformer models or larger-memory GPU hardware which could handle longer sequences. However, the computational cost of very large Transformers will always be an issue, so in general there is a need to address the issue of how to reduce the number of inputs when modelling phenomena which require large contexts, such as coreference resolution. This paper contributes towards addressing this general issue.

10 Conclusion

We proposed a G2GT model with iterative refinement for coreference resolution. For this purpose, we define a graph structure to encode coreference links contained in a document. That enables our model to predict the complete coreference graph at once. The graph is then refined in a recursive manner, iterating the model conditioned on the document and the graph prediction from the previous step. This allows global modelling of all coreference decisions using all document-level information, but it introduces computational issues for longer documents. We experimented with two methods to manage long documents and maintain computational efficiency. The first method encodes the document in overlapping segments. The second method reduces the set of tokens which are input.

The evaluation shows that both methods can outperform a comparable baseline, and that the second method has better performance than the first one and than all other comparable models. This experiment shows that global decisions and document-level information are useful to improve coreference and thus should not be ignored. It also shows that the models can benefit from increasingly powerful pre-trained language models, BERT-base (Devlin et al., 2019), BERT-large (Devlin et al., 2019), and SpanBERT (Joshi et al., 2020).

By empirically showing the benefits of making global decisions and using document-level information in coreference resolution, this work motivates further work on this topic. In addition, the model designs developed in this work provide a viable approach to addressing the related issues. Addressing the computational issues with modelling large documents in Transformers is an area of active research, and our proposed methods could be improved in future work.

Abstract

Events are considered as the fundamental building blocks of the world. Mining event-centric opinions can benefit decision making, people communication, and social good. Unfortunately, there is little literature addressing event-centric opinion mining, although which significantly diverges from the well-studied entity-centric opinion mining in connotation, structure, and expression. In this paper, we propose and formulate the task of event-centric opinion mining based on event-argument structure and expression categorizing theory. We also benchmark this task by constructing a pioneer corpus and designing a two-step benchmark framework. Experiment results show that event-centric opinion mining is feasible and challenging, and the proposed task, dataset, and baselines are beneficial for future studies.

1 Introduction

Events are the fundamental building blocks of the world (Russell, 1927; Ong, 1969). We express, share and propagate our opinions about events with personal understandings, emotions and attitudes in our daily life. People can better understand, communicate and interact with each other by mining, sharing and exchanging event-centric opinions. And being exposed to event-centric opinions from different angles can debias people's own emotions and attitudes about social issues (Karamibekr and Ghorbani, 2013). Therefore, mining event-centric opinions have huge social and personal impacts.

Figure 1: An illustration of event-centric opinions. Given an event, people can express their **judgements**, **beliefs**, **attitudes** and **suggestions**. The opinions oriented to an event may not directly target at itself, but can target at its related subevents or entities.

Unfortunately, there is little literature addressing *event-centric opinion mining*, and most of current opinion mining studies focus on entity-centric opinions, which significantly diverge from the concerning event-centric ones. First, entity-centric opinions mostly focus on sentimental polarity of the holder (Liu, 2012), meanwhile event-centric opinions care more about the content such as non-sentimental judgments, predictions or suggestions. Second, due to the rich interactions between events, entities, and people, event-centric opinions have a complicated structure. Given an event, people can express their opinions about the event itself, as well as its subevents, related events, and the involved entities. Third, the expressions of event-centric opinions are unique. The targets of event-centric opinions are frequently implicitly referred to, which often don't appear in the opinion expressions. Moreover, event-centric opinions are usually widely spread in long news and passages, which are mixed up with facts and non-opinion information. By contrast, entity-centric opinions mainly appear in short and focused reviews or comments individually. The above connotation, structure, and

expression divergences make event-centric opinion mining a novel task, which cannot be resolved using current entity-centric mining techniques.

In this paper, we formally formulate the task of event-centric opinion mining. Specifically, inspired by the expression categorizing theory (Asher et al., 2009), we define 5 types of event-centric opinions, and a text snippet is considered as an event-centric opinion if it contains judgments, attitudes, beliefs, sentiments or suggestions of the opinion holder. Then we formulate the targets of event-centric opinions as an *event-arguments opinion structure* by extending the widely-used event-arguments structure (Pustejovsky, 1991). In this way, an opinion can target an event itself, or its specific arguments including subevents or involved entities. For example in Figure 1, given an event "Samsung wins appeal in patent dispute with Apple", an opinion towards this event may target at the `wins appeal` event itself, the related subevent `patent dispute`, as well as the involved entity `Samsung` and `Apple`. Consequently, event-centric opinion mining can be formulated as identifying opinion snippets from event-related documents and then recognizing the target argument of the opinion snippet.

Based on the task formulation, we create Event-Centric Opinion Bank (ECO Bank), a pioneer corpus for learning and evaluating event-centric opinion mining models. ECO Bank contains nearly 1K events from real-world event trending services, as well as 5K documents about these events in English and Chinese. Each document is aligned to one event. Given a document and its related event, we manually annotated the opinion segments corresponding to the event in the document, and align them to correct target arguments of the event. Consequently, we obtain nearly 18K opinion segments from 5K documents, which target more than 4K different arguments of 1K events.

Finally, we propose a new framework to tackle event-centric opinion mining and benchmark the task on ECO Bank. The overall architecture of the framework is shown in Figure 2. Specifically, we decouple event-centric opinion mining into a two-step pipeline. Step 1 is *event-oriented opinion extraction (EOE)*, which detects the snippets containing event-oriented opinions in each document given the concerning event. Step 2 is *opinion target extraction (OTE)*, which recognizes the corresponding target arguments in the event given identified opinion snippets. We then provide two baselines for each step. For event-oriented opinion extraction, we formulate it as either a sentence-level sequential labeling task or a binary sentence classification task. For opinion target extraction, we resolve it based on a span ranking model or an MRC model. By comparing and analyzing the performance of different baselines, we figure out the critical challenges and bottlenecks of current methods to event-centric opinion mining, which can shed some light on the future research directions in this field.

Generally, the contributions[1] of this paper are:

- We propose, define and formulate the task of event-centric opinion mining based on event-argument structure and expression categorizing theory. To the best of our knowledge, this is the first work that tries to formally formulate event-centric opinions and the task of event-centric opinion mining.
- We construct Event-Centric Opinion Bank (ECO Bank), a pioneer corpus for learning and benchmarking event-centric opinion mining models in both English and Chinese. To the best of our knowledge, this is the first public benchmark focusing on event-centric opinions.
- We design a two-step framework to tackle event-centric opinion mining, and propose several baseline approaches to identify and analyze the challenges and bottlenecks of the task.

2 Event-Centric Opinion Mining

This section first defines the connotation and targets of event-centric opinions. Then we will formulate

---

[1] ECO Bank and the source code are available at e-com.ac.cn.

the task of event-centric opinion mining.

2.1 Connotation of Event-Centric Opinions

The connotations of event-centric opinions are complicated and cannot be simply summarized based on sentimental tendencies. For example, towards a *Trade War* event, one may express the personal judgment opinion by commenting "*I do believe this is a turning point of the relationships between two countries*", which is without explicit sentiments. Therefore, we need to define broader connotations for event-centric opinions than entity-centric ones. To this end, we formulate the connotations of event-centric opinions according to the divergence between facts and opinions (Banfield, 1984; Hackett, 1984). An event-centric opinion is defined as a statement that expresses views about an event or related issues, which 1) cannot be proved or disproved with currently available information and 2) varies from person to person (Schauer, 1978; Wiebe et al., 2005; Corvino, 2014).

Specifically, inspired by expression categorizing theory (Asher et al., 2009), we define the connotation of event-centric opinion as a text snippet that expresses the following 5 kinds of information, including: 1) **Judgements**, such as speculations, interpretations, and predictions about things in the future, e.g., *Trump's plan will not work*; 2) **Attitudes**, such as positions on controversial issues and evaluations of people, places, and things, e.g., *Apple describes the ruling as total political crap*; 3) **Sentiments**, which express feelings like fear and sadness, e.g., *I am so happy to see the Act passed*; 4) **Beliefs**, which can not be proved or disproved, e.g. *I believe aliens definitely exist*; 5) **Suggestions**, which is about personal advice to the readers, e.g., *We advise Samsung Galaxy Note 7 owners to turn off their devices during flights*.

2.2 Targets of Event-Centric Opinions

Entity-centric opinions mostly directly target the entity or its attributes (which is referred as *aspects*). By contrast, when talking about events, people can talk about their related events, entities and concepts, and these opinions may not direct to the event itself. For example, given the *Trade War* event, an opinion holder may express their opinion like *Trump always made bad decisions*, which actually targets on *Trump* rather than the event because the holder will not change the opinion no matter whether the *Trade War* event happens.

To formulate the target of event-centric opinions, we introduce event-arguments opinion structure. Event-arguments structure (Pustejovsky, 1991) is a widely used event formulation in many event-related tasks where arguments refer to a set of critical elements about how an event realized (Doddington et al., 2004; Hovy et al., 2013). Based on this structure, the opinions about a specific event target at one of the following arguments: 1) **Event**, which means that the opinion is directly targeting the entire event; 2) **Subevents**, which means that the opinion does not target at the entire event, but on its subevent or related event. For example in Figure 1, an opinion towards the *patent dispute* in the event *Samsung wins appeal in patent dispute with Apple*; 3) **Entities**, which means that the opinion directly targets one of the involved entities regardless of the event, e.g., commenting *Apple is a great company* on the event in Figure 1.

2.3 Task Formulation for Event-Centric Opinion Mining

Based on the formulated connotation and targets, we define event-centric opinion mining as the task of extracting (opinion, argument) pairs from a document and an event descriptor. Formally, let $e = \{w_1, w_2, ..., w_m\}$ denote an event descriptor with m tokens and $d = \{s_1, s_2, ..., s_n\}$ denote a document with n sentences. Event-centric opinion mining aims to identify (opinion, argument) pairs $T = \{..., (o_k, a_k), ...|e, d\}$, where $o = \{s_i, s_{i+1}, ..., s_j|s \in d\}$ is a continuous opinion segment in d targeting at the same argument, and $a = \{w_t, w_{t+1}, ..., w_l|w \in e\}$ is the target argument of the opinion o in the event descriptor e. For example in Figure 1, given the event *Samsung wins appeal in patent dispute with Apple*, there are 4 (opinion,argument) pairs, two of whom target at the entire event, one target at subevent *patent dispute* and one target at entity *Apple*.

3 Event-Centric Opinion Bank

Based on the task formulation, this paper creates Event-Centric Opinion Bank (ECO Bank), a new event-centric opinion mining corpus in both English and Chinese. In the following, we describe how we construct ECO Bank and report the statistics of ECO Bank.

3.1 Dataset Construction

Event Descriptor Collection. To construct ECO Bank, we collect event descriptors from real-world event trending services. For the English portion of ECO Bank, we collect event descriptors from the W2E dataset (Hoang et al., 2018), a worldwide event dataset for topic detection and tracking. We select highly discussed topics as event descriptors and manually shorten them into meaningful texts if necessary. For the Chinese portion, we collect manually-maintained event trending from widely-used social networks, WeChat Top Topics. We then filter out items in the trending corresponding to events as event descriptors. Because the trending is manually created, it is already of sufficient quality and therefore no more modification is required. Finally, we construct 988 high-quality event descriptors, where 821 in the Chinese and 167 in the English.

Document Collection. Given the event descriptor, we collect related documents that may contain the opinions towards the event. For the Chinese portion of ECO Bank, we collect related documents by retrieving relevant documents from WeChat Search. Specifically, We retrieve top 10 articles for each event descriptor, and then manually filter out the redundant, low-quality and irrelevant documents. For the English portion, because each topic in W2E dataset is already linked to several related articles from more than 50 prominent mass media channels. We therefore directly applied these documents except filtering out the redundant ones. Finally, we preserve 3000 Chinese documents and 2000 English documents for further annotation.

Event-Centric Opinion Annotation. Given the documents and their corresponding event descriptors, we hired annotators to annotate the (opinion, argument) pairs. Specifically, the annotation is conducted in a two-step paradigm. First, annotators are asked to identify opinions related to the event described in the descriptor. Then, given the event descriptor, an identified opinion and the source document, the annotators were asked to link the opinion to its target in the descriptor. To ensure the high quality of annotations, each document is annotated by two annotators. If there is a disagreement between the original annotators, three more professional annotators will relabel the document independently, and produce the final annotations by voting between them. Finally, to facilitate further research, we also ask annotators to recognize all possible arguments in the event descriptor that can serve as an opinion target. All annotators are fairly paid according to their workload.

Statistics on ECO Bank		**Chinese**	**English**
Document	Number	3000	2000
	Avg. Sents	15.2	20.3
	Avg. Opinion	2.6	4.5
Opinion	Number	7742	9058
	Ratio (%)	32.0	28.1
	Avg. Sents	1.9	1.3
Event	Number	821	167
	Avg. Tokens	6.4	7.7
Arguments	Events (%)	30.6	34.4
	Subevents (%)	24.9	11.7
	Entities (%)	44.5	53.9

Table 1: Overall statistics of ECO Bank dataset.

3.2 Dataset Analysis

Table 1 shows the main statistics of ECO Bank. We can observe many unique characteristics of event-centric opinion mining. First, the distribution of event-centric opinions is very sparse. Only about 30% of the sentences in both English and Chinese dataset express opinions. This is because event-centric articles usually mix massive factual snippets with opinionated snippets. By contrast, entity-centric opinions are densely distributed in comments and reviews. Second, the targets of event-centric opinions are highly diversified. We notice that only 30% of opinions directly target the event, leaving 24.9% on subevents and 44.5% on entities (ECO-ZH), and 11.7% on subevents and 53.9% on entities (ECO-EN). This verifies the necessity of defining an event-specified opinion structure. Furthermore, we find that targets of event-centric opinions are often implicit. To show this we randomly select 50 documents with 151 opinions. Among them, there are 80 opinions on events/subevents, where 25% opinions target implicit arguments, and 28% opinions are with event co-reference and therefore its target event cannot be directly recognized without more contexts. By contrast, this proportion is much lower in opinions on entity arguments, where we only find 8% implicit arguments and 7% entity co-reference. These results demonstrate that the target of event-centric opinions cannot be identified locally, which is one of the most significant divergences between event-centric and entity-centric opinion mining.

4 Benchmarking Event-Centric Opinion Mining

This section benchmarks event-centric opinion mining with a two-step framework. Two feasible solutions are proposed for each step, and therefore lead to 4 different benchmark architectures.

4.1 Step 1: Event-Oriented Opinion Extraction

Given an event descriptor e and a related document d, the goal of event-oriented opinion extraction (EOE) is to extract text snippets o in d which contain opinions about event e. To this end, we propose two architectures, one formulates EOE as a pair-wise classification task and the other formulates it as a sentence-level sequential labeling task.

4.1.1 Pair-wise Classification

A basic solution for EOE is to build binary classifier for all (sentence, event) pairs. Specifically, given an event e and a sentence s in document d, we identify whether s is an opinion to e using a BERT-based binary classifier (Devlin et al., 2019). The classifier takes the concatenation $\mathcal{X} = \{[\text{CLS}], e, [\text{SEP}], s\}$ as input, where [CLS] and [SEP] represent the beginning of input and the separator between s and e respectively. We then use BERT as the encoder, then conduct binary classification on [CLS] token to identify the relation between e and s:

$$\mathcal{H} = \text{BERT}(\mathcal{X}), \quad p = \text{sigmoid}(\mathcal{H}_{[\text{CLS}]}), \quad (1)$$

where $\mathcal{H}_{[\text{CLS}]}$ is the representation at [CLS] token, and p is the probability of s containing an opinion to e. Then we regard sentences with $p \leq 0.5$ as the opinion sentences, and concatenates all continuous opinion sentences to form opinion snippets.

4.1.2 Sentence-level Sequential Labeling

Because an opinion may contain more than one sentence, sentence-level classification to identify opinion snippets may result in opinion boundary ambiguity. To this end, we propose sentence-level sequential labeling architecture (Cheng et al., 2020) for EOE. Specifically, given a document $d = \{s_1, s_2, ..., s_n\}$ and an event descriptor e, we first concatenate e and each sentence in d to form the input $\mathcal{X}$, using [CLS] as the separators between each sentence. We then fed $\mathcal{X}$ into BERT-based encoder to obtain context-aware representations. The representations at [CLS] tokens $\mathcal{H}_{[\text{CLS}]}$ are used to represent the sentences after them. To leverage the deep interaction between different sentences, we further apply BiLSTM layer upon $\mathcal{H}_{[\text{CLS}]}$ and learn the interacted sentence representations $\mathcal{S} = \text{BiLSTM}(\mathcal{H}_{[\text{CLS}]})$. Finally, we apply a Conditional Random Field (Lafferty et al., 2001) upon $\mathcal{S}$ to label each sentence to obtain the sentence-level tagging output $\mathcal{Y} = \text{CRF}(\mathcal{S})$ encoded in BIO schema (Sang and Buchholz, 2000).

4.2 Step 2: Opinion Target Extraction

Given an event descriptor $e = \{w_1, ..., w_n\}$ and an opinion snippet o identified in Step 1, Opinion Target Extraction (OTE) aims to recognize a span in e corresponding to the target argument of o. To this end, we build two baselines of OTE by taking it as either a span ranking problem or a MRC problem.

4.2.1 Span Ranking for Opinion Target Extraction

Given an opinion o, the span ranking approach directly enumerates all spans in e, and selects the best span as o's target argument. Formally, given a span a in e, we concatenate a with o to form the model input. Then similar to the pair-wise EOE classifier in Equation (1), we send the concatenation into a BERT-based encoder, and then obtain the score of the span a being the opinion target of o via a sigmoid classifier. Finally, the span with highest score is regarded as the target of the opinion o.

4.2.2 MRC for Opinion Target Extraction

Recent advances (Cui et al., 2020; Sugawara et al., 2020) have shown that pointer network style machine reading comprehension models (Wang and Jiang, 2016) can effectively resolve the span spotting problems. Therefore, we apply an MRC architecture similar to Devlin et al. (2019) for OTE, which regards the opinion o as the query and the event descriptor $e = \{w_1, w_2, ..., w_n\}$ as the document to identify argument a from e.

Specifically, given an event descriptor e and opinion o, we first represent the input o and e as a single packed sequence $\mathcal{X} = \{[\text{CLS}], o, [\text{SEP}], e\}$. We use BERT encoder to get token representations $\mathcal{H} = \text{BERT}(\mathcal{X})$. We then introduce a start vector $\mathcal{S}$ and an end vector $\mathcal{E}$. The probability of word w_i being the start or end of the argument span is computed as a dot product between $\mathcal{H}_\text{i}$ and $\mathcal{S}$ or $\mathcal{E}$ followed by a softmax over all of words in e:

$$p_s = \frac{e^{\mathcal{S}\mathcal{H}_i}}{\sum_j e^{\mathcal{S}\mathcal{H}_j}}, \quad p_e = \frac{e^{\mathcal{E}\mathcal{H}_i}}{\sum_j e^{\mathcal{E}\mathcal{H}_j}}. \quad (2)$$

	ECO-ZH		ECO-EN	
	Accuracy	Overlap-F1	Accuracy	Overlap-F1
SpanR	49.21	77.83	26.50	53.31
MRC	64.89	84.89	54.29	76.98

Table 4: The performance on OTE given golden opinion snippets.

5 Experiments

5.1 Benchmark Settings

Dataset Split. We split both English and Chinese portion of Event-Centric Opinion Bank into roughly 7:1:2 for train/dev/test respectively. To ensure no information leakage, the same event descriptor will not be sampled into different sets. Finally, for English portion, there are 112/16/39 event descriptors with 1402/198/400 documents for train/dev/test. And for Chinese portion, there are 590/78/153 event descriptors with 2100/299/601 documents for train/dev/test. This ECO Bank split can be viewed as a standard benchmark for evaluating event-centric opinion mining models.

Evaluation Criteria. To evaluate the event-centric opinion mining performance, we design several evaluation metrics for the task as well as its two sub-tasks. Specifically, given golden (opinion,argument) pair set $\mathcal{T} = \{(o_1^T, a_1^T), ..., (o_n^T, a_n^T)\}$ and the predicted (opinion,argument) pair set $\mathcal{P} = \{(o_1^P, a_1^P), ..., (o_n^P, a_n^P)\}$, where $o_i = \{s_{i1}, ..., s_{ik}\}$ contains continuous sentences from documents and $a_i = \{w_{i1}, .., w_{il}\}$ contains continuous words from the event descriptors, we design the following evaluation metrics:

1. End2End Evaluation, which measures the end-to-end performance of event-centric opinion mining. We propose to use F_1 score at opinion segment-level or sentence-level to evaluate the overall performance. Segment-level F_1 is the F_1 score calculated by directly comparing $\mathcal{T}$ and $\mathcal{P}$. And sentence-level F_1 is calculated by first splitting (o,a) pairs in $\mathcal{T}$ and $\mathcal{P}$ into sentence-level pairs $\{(s_1, a), .., (s_k, a)\}$ and then combining them to form the sentence-level golden annotation set $\mathcal{T}'$ and prediction set $\mathcal{P}'$. Finally, sentence-level F_1 is calculated between $\mathcal{T}'$ and $\mathcal{P}'$.

2. EOE Evaluation. We also consider both segment-level and sentence-level metrics when evaluating the Step 1 EOE. The only difference is that we only evaluate the performance of extracting opinion snippets without considering corresponding opinion targets in EOE evaluation.

3. OTE Evaluation. To evaluate how well the Step 2 OTE works, we further use the golden annotated opinion snippets as input to evaluate OTE performance. We use two evaluation metrics for OTE: 1) Accuracy, which measures whether the extracted argument can be exactly the same as the annotated one; 2) Overlap-F_1, which measures the overlap between extracted and golden arguments using F_1. Specifically, let $a^T = \{w_1^T, .., w_l^T\}$ denotes the golden argument and $a^P = \{w_1^P, .., w_k^P\}$ as the predicted argument, Overlap-F_1 is calculated by micro-averaged F_1 on all (a^T, a^P) pairs.

5.2 Overall Results

The performance of 4 different architectures on the end2end, EOE and OTE evaluation are shown in Table 2, 3 and 4. We also listed the human end2end performance in Table 2, which is summarized from the divergences between the annotations from the first two annotators and the final annotations. From these tables, we can see that:

1) The proposed formulation for event-centric opinion mining is a feasible task for human beings. From Table 2, we can see that human can reach high agreements on both ECO-ZH and ECO-EN. This demonstrates that the proposed opinion connotation and structure are applicable for event-centric opinions.

2) Event-centric opinion mining is a challenging task. The best benchmark system Seq-MRC can only achieve 28.01 and 18.15 segment-level F_1 on Chinese and English respectively. The performance gap between machine and human is huge, which indicates that more effective architectures and task-specialized approaches are needed.

3) Seq-MRC architecture achieved the best performance among 4 baseline architectures. We believe this is because the architecture is a more natural design for event-centric opinion mining. Naturally, EOE is a sentence-level sequential labeling problem given the event, and OTE is a span extraction problem given the opinion. As a result, Seq-MRC is more suitable for solving these two tasks compared with PairCls and SpanR.

4) The main bottleneck for event-centric opinion mining is to identify completed continuous opinion snippets from documents. From Table 3, we can see that current sentence-level sequential labeling can only achieve 44.33% and 34.84% segment-level F_1 score, which is the main reason for the low end2end performance. By contrast, we can see that the sentence-level evaluation results are much better than segment-level evaluation results. We believe the reason behind is that current architectures can not well identify the structural relations at sentence-level, and leveraging such structure requires strong discourse-level knowledge.

5) ECO-EN dataset is more challenging than ECO-ZH. Even with similar training document size and opinion numbers, the performance of ECO-EN is significantly worse than that of ECO-ZH. We believe this is because 1) English opinions are often more implicit than Chinese ones. Therefore, even human annotators made more disagreements on ECO-EN; 2) ECO-EN is with much fewer event descriptors than ECO-ZH, which make the training of EOE models may overfit on the events in the training data.

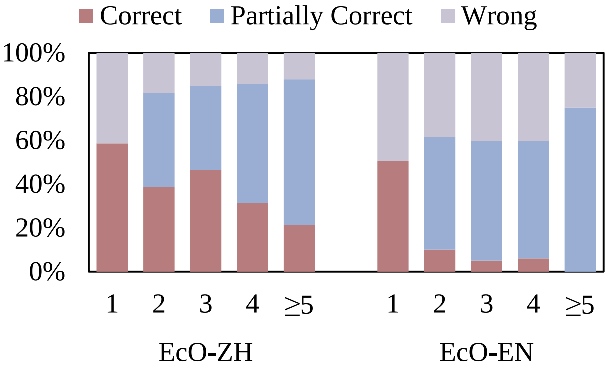

Figure 3: Performance of *Seq* on EOE with different opinion lengths.

5.3 Effects of Opinion Length to EOE

To investigate whether opinion length will impact the performance of EOE, we categorize the model's prediction on golden opinion snippets into: 1) Correct; 2) Partially Correct, which means that at least one sentence in the opinion segment is identified; 3) Wrong. Figure 3 shows the results of *Seq* approach. We can see that the correct prediction ratio drops when opinion length increases. This is easy to understand because opinions with more sentences are more difficult to recognize. However, we can see that the wrong prediction ratio also drops along with the increase of opinion length. This indicates that for longer opinions, the chance of at least one sentence can be correctly identified is relatively high. Therefore, if we can jointly consider the predictions of multiple sentences by leveraging discourse knowledge, we may reduce such partial labeling errors and improve the performance.

5.4 Effects of Argument Type to OTE

	Subevents	Entities	Events
ECO-ZH	76.80	54.40	72.92
ECO-EN	25.00	48.48	70.85

Table 5: Performance of *MRC* on different kinds of arguments.

Table 5 shows the opinion target extraction performance of *MRC* on different types of arguments. For both ECO-ZH and ECO-EN dataset, the performance on whole events is better than that on arguments. In particular, it performs poorly on subevents in ECO-EN. This may be because the amount of event descriptors is not enough for the model to learn to extract the exact boundaries of subevent arguments.

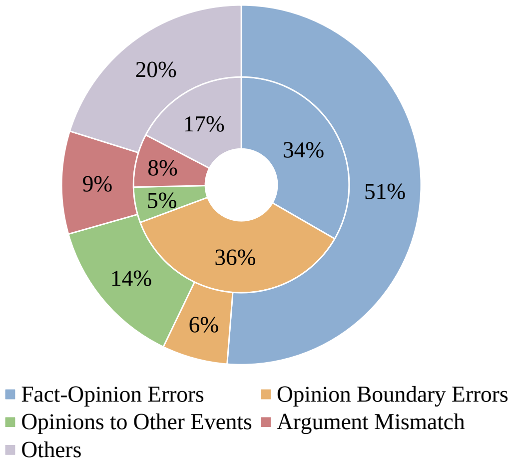

Figure 4: Proportions of error causes on ECO of *Seq-MRC*. Inner circle refers to performance on ECO-ZH and outer circle corresponds to ECO-EN dataset.

5.5 Error Analysis & Discussion

To better understand the challenge and bottlenecks of event-centric opinion mining, we further randomly sampled 50 annotated documents from ECO-ZH and ECO-EN respectively. We then categorized the errors made by Seq-MRC model to figure out the critical issues to resolve. From Figure 4, we can see that:

1) The confusions between facts and opinions are one of the most critical EOE errors for both English and Chinese portions. 51% errors in English and 34% errors in Chinese portion stem from fact-opinion confusion. This corresponds to the nature of the task because event-centric opinions are frequently mixed up with many facts and non-opinion information. And a sentence can contain both opinion and fact at the same time, which makes it very difficult to identify.

2) Opinion boundary errors are more significant in Chinese portion than English portion. Compared with 6% boundary errors in English portion, the percentage in Chinese portion is a much higher 36%. We believe this is because the average length of opinions in Chinese is longer than that in English, which is shown in Table 1. As a result, more opinion boundary errors are introduced in EOE. Furthermore, by looking into the error cases, we find that such errors mainly occur in cases where two continuous opinions refer to different arguments, which is very challenging.

3) OTE errors are more severe in English portion than Chinese portion. We find that such errors happened more frequently on the opinions with implicit targets. Furthermore, there are notable 14% errors in English portion that comes from identifying opinions not corresponding to the given event. This usually happens when models are confused by strong opinion marker words like *say* and *believe*, and similar arguments such as World War I and World War II. We believe that this is because event descriptors in the English portion are much less than Chinese portion. As a result, models overfit on some spurious features and can not sufficiently capture the correct event-oriented information. To alleviate this problem, we will enlarge the English portion of ECO Bank in the future.

6 Related Work

Previous opinion mining (OM) researches focus on entity-centric opinions (Liu, 2007), which mainly categorizes the holder's sentiments towards entities and their attributes at document-level (Turney, 2002; Moraes et al., 2013; Sharma et al., 2014; Tang et al., 2015; Paredes-Valverde et al., 2017), sentence-level (Hatzivassiloglou and Wiebe, 2000; Riloff and Wiebe, 2003; Hu and Liu, 2004; Riloff et al., 2006; Sayeed et al., 2012; Alessia et al., 2015) and aspect-level (Jin et al., 2009; Li et al., 2010; Qiu et al., 2011; Liu, 2012; Mitchell et al., 2013; Liu et al., 2015; Wang et al., 2017; Zhao et al., 2020; Peng et al., 2020; Cai et al., 2021; Mao et al., 2021).

There are also some researches working on event-related opinions (Karamibekr and Ghorbani, 2012; Zhou et al., 2013; Deng and Wiebe, 2015b,a; Qian et al., 2016; Maynard et al., 2017). Generally speaking, these studies commonly regard event as a special type of entity, neglecting the unique characteristics of event-centric opinions. However, events are very different from entities, and therefore event-centric opinions have different connotations and targets which have not been exploited yet.

For the evaluation resource of OM, most of current studies are based on the Semeval Challenges datasets (Pavlopoulos, 2014; Pontiki et al., 2015, 2016) and its extension (Wang et al., 2017; Fan et al., 2019; Peng et al., 2020), which consist of entity-centric customer reviews about target entities from 7 domains. To the best of our knowledge, the constructed ECO Bank is the first publicly available event-centric opinion mining benchmark from news domain, which definitely can benefit future research in this direction.

7 Conclusions and Future Work

In this paper, we propose and formulate ***event-centric opinion mining***, a new task that aims to mine a broader range of opinions oriented to specific events from documents. An Event-Centric Opinion Bank corpus is constructed and a two-step framework is proposed. Experiments demonstrate the challenges and advantages of mining event-centric opinions. The focus of this paper is the introduction of the new task and datasets. The proposed four baseline systems are relatively simple and leave much room for further improvements. In future work, we will try to build end-to-end models that directly extract opinion triples in an end-to-end fashion and enrich the current opinion structure.

8 Ethics Consideration

In consideration of ethical concerns, we provide the following detailed description:

1. All of the collected documents and event descriptors come from publicly available sources. The legal advisor of our institute and/or the original dataset constructor confirms that the sources of our data are freely accessible online without copyright constraint to academic use.

2. ECO Bank contains 5000 annotated documents with 988 event descriptors. After double-checking, we guarantee that ECO Bank doesn't contain samples that may cause ethic issues. The dataset does not involve any personal sensitive information. All references in the annotated data are double-checked for plausibility and grammaticality by different human annotators. All documents and event descriptors are also manually checked to ensure they are informative and logically coherent. We manually check the content of each piece of data in ECO Bank to ensure that it does not contain any hate speech or attacks on vulnerable people.

3. We hired 5 annotators who have bachelor degrees. Before formal annotation, annotators were asked to annotate 20 samples randomly extracted from the dataset, and based on average annotation time we set a fair salary (i.e., 35 dollars per hour) for them. During their training annotation process, they were paid as well.

Abstract

Embedding-based methods have attracted increasing attention in recent entity alignment (EA) studies. Although great promise they can offer, there are still several limitations. The most notable is that they identify the aligned entities based on cosine similarity, ignoring the semantics underlying the embeddings themselves. Furthermore, these methods are shortsighted, heuristically selecting the closest entity as the target and allowing multiple entities to match the same candidate. To address these limitations, we model entity alignment as a sequential decision-making task, in which an agent sequentially decides whether two entities are matched or mismatched based on their representation vectors. The proposed reinforcement learning (RL)-based entity alignment framework can be flexibly adapted to most embedding-based EA methods. The experimental results demonstrate that it consistently advances the performance of several state-of-the-art methods, with a maximum improvement of 31.1% on Hits@1.

1 Introduction

Entity alignment (EA) is one of the most crucial tasks in knowledge graph (KG) studies. It aims to seek the potentially aligned entity pairs between two KGs, such that distributed knowledge can be linked for better supporting downstream applications. Generally, a fact in a KG can be represented by a triplet (e^1_x, r^1, e^1_y), where e^1_x, e^1_y denote the head and tail entities in the first KG $\mathcal{G}_1$. r^1 is the relation connecting them. With a small number of known alignment pairs as anchors, embedding-based entity alignment (EEA) methods can learn the representations of entities belonging to respective KGs in a unified space and exploit the underlying aligned pairs based on the embedding distance. For example, e^2_x will be chosen as target entity for e^1_x if its embedding is closest to the embedding of e^1_x in vector space.

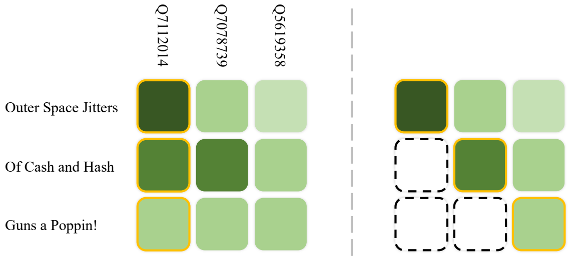

Figure 1: Different evaluation strategies. The ranking strategy (left) heuristically selects the candidate with the largest similarity. The sequential strategy (right) allows each candidate to be matched only once. Deeper color indicates higher similarity. Diagonals are correct matches. Cells with yellow borders are the selected entities, while those with dotted borders denote the excluded entities.

Although recent EEA methods (Chen et al., 2017; Sun et al., 2017, 2018; Guo et al., 2019; Wu et al., 2019; Tang et al., 2020; Wang et al., 2020; Sun et al., 2020a) have made great performance improvement, they rarely consider the evaluation process. For example, in Figure 1, all three films are directed by Jules White and have similar casts. This makes the EEA methods confused to discriminate the true aligned entities from other candidates. Current ranking strategy heuristically chooses the nearest entities without considering that some entities have already been matched before. An entity with the largest similarity is not always the true target, especially when this candidate has been matched with other entities. In contrast, we can model entity alignment as a sequential decision-making task, where the agent sequentially decides whether a candidate embedding is aligned with the input one. Then, the environment will exclude the matched candidates in the subsequent decisions.

One issue with the sequential strategy is the accumulated errors. Due to the heterogeneity of KGs, a pair of underlying aligned entities may not share

May 22-27, 2022

an identical neighborhood. This makes their embeddings not as similar as desired with each other (e.g., “Guns a Poppin!” in Figure 1). But semantics in the embeddings may still indicate the actual target. It is worth estimating the alignment score directly from their embeddings. It is also important to negate a most likely candidate for maximizing the long-term rewards.

In this paper, we draw on the insights of reinforcement learning (RL) that has recently received great attention in many fields (Mnih et al., 2015; Lillicrap et al., 2016; Silver et al., 2016). With the trained embeddings of any existing EEA models as raw input, we train an agent to find as many alignment pairs as possible to maximize the reward. Meanwhile, we adopt a curriculum learning (Elman, 1993) strategy for the environment to provide candidate entity pairs as observations of increasing difficulty. In sum, our contributions are three-fold:

- We propose to model entity alignment as a sequential decision-making task. To the best of our knowledge, this is the first method that provides a general solution to improve the evaluation strategy for the EEA task.
- We implement an end-to-end RL-based entity alignment (RLEA) framework to solve the sequential EEA problem[1]. We elaborate an entity alignment environment to sample candidate pairs as observations efficiently. Besides, we design a policy network that takes self-embedding, neighborhood, and long-term rewards into account.
- We conduct extensive experiments to show that RLEA can significantly and consistently improve the state-of-the-art EEA methods.

2 Related Work

2.1 Embedding-based Entity Alignment

We divide the exiting EEA methods into two categories. The first is based on the well-known KG embedding method TransE (Bordes et al., 2013). TransE models a triplet (e_x^1, r^1, e_y^1) as $\mathbf{e}_x^1 + \mathbf{r}^1 \approx \mathbf{e}_y^1$, with the boldfaced as the corresponding embeddings. Many methods use TransE as the KG embedding model for the EA task: MTransE (Chen et al., 2017) sets a learnable matrix to project the entity embeddings from the source KG to the space of the target KG. Then, the distance among entity embeddings from different KGs can be used to estimate the similarity. This idea is extended by later works, e.g., KDCoE (Chen et al., 2018), SEA (Pei et al., 2019a), and OTEA (Pei et al., 2019b). Specifically, KDCoE learns the triplet embedding model and the description embedding model in a co-training fashion. SEA leverages adversarial learning to learn better projection matrix. It also considers the attribute information. OTEA makes use of optimal transport theories to advance the learning process of MTransE. On the other hand, JAPE (Sun et al., 2017) and IPransE (Zhu et al., 2017) adopt a mapping strategy that utterly different from MTransE. They directly set two entities in a known alignment pair to one embedding vector. Therefore, the vector spaces of two KGs are naturally connected. For example, given a known alignment (e^1, e^2), e^1, e^2 will be mapped to one embedding vector $\mathbf{e}$.

The other line of EEA research focuses on the design of embedding models. Great efforts were put into graph convolutional networks (GCNs) (Kipf and Welling, 2017), e.g., GCN-Align (Wang et al., 2018), RDGCN (Wu et al., 2019), and graph attention networks (GATs) (Velickovic et al., 2018), e.g., MuGNN(Cao et al., 2019), AliNet (Sun et al., 2020a). Most of them adopt the mapping strategy to map entities in each known pair to one vector to connect two KGs. Therefore, these methods center on the design of different graph network structures, which is out of the discussion of this paper. We refer the readers to (Sun et al., 2020b; Wang et al., 2017) for details.

One unique method, BootEA (Sun et al., 2018), iteratively labels likely entity alignment as training data. BootEA is a powerful method that greatly improved the performance of the basic AlignE model. This bootstrapping method is closely related to RLEA as it also assumes that a candidate entity should not be matched more than once. However, BootEA does not have a learning process, similar to its followers (Xu et al., 2020; Zeng et al., 2020; Zhu et al., 2021). The entity alignment pairs are computed based on the cosine similarity and further threshed by a hyper-parameter to filter out those with low similarity. On the other hand, the bootstrapping algorithm must run with the embedding model iteratively, making BootEA more sensitive to parameter settings. Nevertheless, there is no contradiction in integrating RLEA with BootEA to achieve better performance (see Section 4.6).

---

[1] https://github.com/guolingbing/RLEA

The above methods have different objectives and investigate diverse techniques. However, RLEA only needs their trained embeddings as input data, which is sufficient to achieve much better performance on several datasets.

2.2 Deep Reinforcement Learning for Knowledge Graphs

One most relevant work to this paper is CEAFF (Zeng et al., 2021), which also leverages RL algorithms and believes in 1-to-1 alignment. But CEAFF focuses more on generating and integrating different entity features. The RL part is less explored. From its experimental results (Zeng et al., 2021), we can find that RL-based CEAFF only outperformed its heuristic version slightly. Moreover, CEAFF does not provide a general solution for sequential EEA task. It is not applicable to most existing EEA methods.

DeepPath (Xiong et al., 2017) and its followers (Das et al., 2018; Wan et al., 2020) are also well-known RL-based KG embedding methods. They leverage RL agents to continually extend paths for multi-hop reasoning. There are two major differences. First, DeepPath focuses more on the design of the reward function. It takes accuracy, diversity, and efficiency into consideration when estimating an action's reward. However, the design of the environment is relatively straightforward, as the next state is certain after receiving an edge as action. By contrast, the reward in our sequential EA task can be simply assigned by comparing the output action (i.e., *match* or *mismatch*) with the actual label; nevertheless, any valid entity pair can be set as next state. Therefore, we focus more on formalizing this problem and building a proper environment where the agent can explore efficiently.

Additionally, some methods like KAGAN (Qu et al., 2019) only use the policy gradient algorithm (Williams, 1992) to update their network parameters. They do not really learn a policy to solve a sequential decision-making problem. Therefore, we do not review them in this paper.

3 Methodology

3.1 Preliminaries

Let $\mathcal{G}_1 = \{\mathcal{E}_1, \mathcal{R}_1, \mathcal{T}_1\}$ and $\mathcal{G}_2 = \{\mathcal{E}_2, \mathcal{R}_2, \mathcal{T}_2\}$ be the source and target KGs, with $\mathcal{E}$, $\mathcal{R}$, $\mathcal{T}$ denoting the entity, relation, and triplet sets respectively. The proposed RL-based framework consists of two modules, i.e., the agent and the environment. We use the trained entity embeddings $\mathbf{E}_1$, $\mathbf{E}_2$ of any EEA models as input for the agent. The training set, same to the existing works, is still a small number of known entity alignment $\mathcal{S} \subset \mathcal{E}_1 \times \mathcal{E}_2$ provided by the dataset.

In each training episode, the states and actions are generated by the environment and the agent in an alternative order, i.e., $s_1, a_1, s_2, a_2, ..., s_i, a_i$. We define a state s as a pair of arbitrary entities $[e_x, e_y]$ belonging to respective KGs (we rewrite $[e_x^1, e_y^2]$ as $[e_x, e_y]$ for readability, the same below). An action $a \in \{0, 1\}$ represents the decision of the agent that indicates *match* or *mismatch* for $[e_x, e_y]$. Each state also has a label $l \in \{0, 1\}$, implying the right decision. It is worth noting that an action may still have a positive effect even if it is not equal to the label. For example, an incorrect *match* action can also exclude two wrong entities correctly.

In the following sections, we call the case of $a = 0 \wedge l = 0$ a *true mismatch*, $a = 0 \wedge l = 1$ a *false mismatch*, $a = 1 \wedge l = 0$ a *false match*, and $a = 1 \wedge l = 1$ a *true match*. Therefore, the number of correct aligned entity pairs equals to that of *true match*, which is proportional to the Hits@1 result in the conventional EEA task.

3.2 Agent

We start by introducing the agent module, which is modeled by neural networks.

State A state $s = [e_x, e_y]$ is given by the environment. We take the following features into consideration: (1) the embeddings of two entities $\mathbf{e}_x$, $\mathbf{e}_y$; (2) the neighbor embedding sets of two entities $\mathbf{N}_x$, $\mathbf{N}_y$; (3) the opponent entity embedding set $\mathbf{O}_y$ of e_y. We term the k-nearest candidates to e_x except e_y "opponent entities", as they are also possible aligned entities to e_x. These entities can provide additional information for refusing or accepting the input entity pair $[e_x, e_y]$.

Action An action a is a binary number that represents the agent's choice. The binary schema has two advantages. First, the corresponding best policy can be an easier function to be approximated. Selecting one entity from multiple candidates is significantly more complex than judging a pair of entities, especially for the case of existing thousands of different candidates. On the other hand, the binary schema enables the agent to suspend the current candidate pair. For example, if the agent chooses *mismatch*, the source entity still has a chance to be correctly matched in the following interactions.

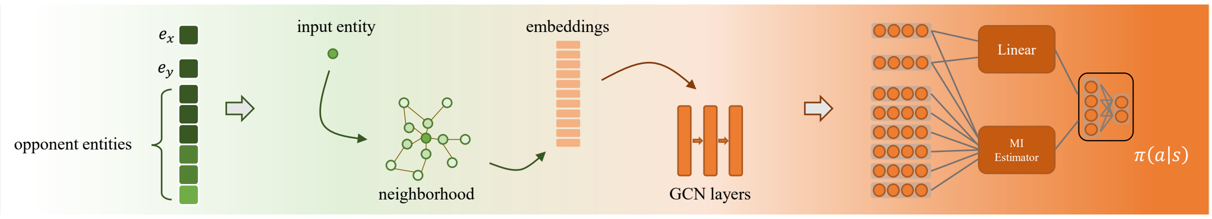

Figure 2: Overview of the policy network. We first use a GNN model to aggregate the neighbor embeddings of each entity. The output representations of e_x, e_y are then fed into a linear layer that maps features to an unnormalized estimation of the alignment score. We also leverage a mutual information estimator, which takes the opponent entity representations as negative examples. We combine the output of two types of estimations to obtain the final action distribution.

By contrast, in the classification schema, the agent must select one entity as the final choice.

Policy The policy $\pi(a|s,\theta)$ is parameterized by graph neural networks (GNNs), where θ denotes the parameter set. We illustrate its architecture in Figure 2. Given a state $s = [e_x, e_y]$, we first extract the features by a multi-layer GNN. Here, we use vanilla GCN (Kipf and Welling, 2017) for graph convolution, but other GNN models like GATs (Velickovic et al., 2018) can also be employed. The output embedding of e_x at layer k is defined as:

$$\mathbf{g}_x^k = \sigma\Big(\sum_{e_i \in N(e_x)\cup\{e_x\}} \frac{1}{c_x}\mathbf{W}_g^k \mathbf{g}_i^{k-1}\Big) \tag{1}$$

where g_x^k denotes the output hidden of layer k for e_x. c_x is the normalization constant. $\mathbf{W}_g^k$ is the weight matrix at layer k. $\sigma(\cdot)$ is the activation function (ReLU (Nair and Hinton, 2010) in our implementation). For the first layer, we set $\mathbf{g}_i^0 = \mathbf{e}_i$, where $\mathbf{e}_i$ denotes the input embedding of e_i. GCNs efficiently aggregate the neighborhood and self-information into a single vector, which is supposed to be more robust and informative than directly using the trained embeddings. Furthermore, GCNs also allow RLEA to reweight entity embeddings for sequential EEA. For simplicity, we denote the output of the last GCN layer by $\mathbf{g}_x$.

Next, we use a linear layer to combine the output embeddings $\mathbf{g}_x$, $\mathbf{g}_y$, which can be written as follows:

$$\mathbf{h}_{e_x,e_y} = \sigma(\mathbf{W}_h(\mathbf{g}_x || \mathbf{g}_y) + \mathbf{b}_h), \tag{2}$$

where $||$ is the concatenation operator to concat $\mathbf{g}_x$, $\mathbf{g}_y$ to one hidden vector. $\mathbf{W}_h$ and $\mathbf{b}_h$ are the weight matrix and bias vector, respectively.

We also take the mutual information $I(e_x, e_y)$ (Belghazi et al., 2018) as an additional feature. Unlike the cosine similarity that weights the difference of two vectors at each dimension, mutual information values more on the high-level correlations. Therefore, it is especially appropriate for the EEA task, where two aligned entities may not have identical neighborhoods due to the heterogeneity. Following (van den Oord et al., 2018), we leverage a neural function $f(\mathbf{g}_x, \mathbf{g}_y)$ to estimate the density ratio:

$$f(\mathbf{g}_x, \mathbf{g}_y) = \exp(\mathbf{g}_x^T \mathbf{W}_f \mathbf{g}_y), \tag{3}$$

where $\mathbf{W}_f$ is the weight matrix. As aforementioned, we consider opponent entities a kind of future information to aid the agent in making decisions. This idea can be naturally reified by viewing the opponents as negative examples:

$$\hat{I}_{e_x,e_y} = \frac{f(\mathbf{g}_x, \mathbf{g}_y)}{\sum_{e_i \in O_y \cup \{e_y\}} f(\mathbf{g}_x, \mathbf{g}_i)}. \tag{4}$$

The above equation has a similar form to that used in InfoNCE (van den Oord et al., 2018). But from another aspect, $\hat{I}_{e_x,e_y}$ can be also understood as the probability of outputting the action *match* based on the mutual information estimator (MIE).

Finally, we concatenate all estimates to obtain the final action distribution:

$$\begin{aligned}\mathbf{p}_{e_x,e_y} &= \mathit{Softmax}(\mathbf{W}_p(\mathbf{h}_{e_i,e_j} || \hat{I}_{e_x,e_y})),\\ &= \pi(a|s,\theta)\end{aligned} \tag{5}$$

where $\mathbf{p}_{e_x,e_y}$ is the normalized action distribution . $\mathbf{W}_p$ is the weight matrix.

Reward We assign the reward for the given output action a by the following equation:

$$r = \begin{cases} 1, & \text{a } \textit{true match}, \\ -10, & \text{a } \textit{false mismatch}, \\ 0, & \text{elsewise}. \end{cases} \tag{6}$$

The goal of the agent is to maximize the overall reward, i.e., output 1 as much as possible for aligned pairs. Therefore, we set a positive reward for $a = l$ when the input pair match and a severe penalty (-10 is most efficient in our implementation) for a *false mismatch*. For other cases, the agent will receive a reward 0, as they do not directly increase or decrease the number of alignment pairs.

Optimization We use the policy gradient algorithm REINFORCE (Williams, 1992) to find the parameters leading to a larger reward. To reduce the variance, we employ a baseline function for comparison. Therefore, the gradient at i-step in an episode is:

$$\nabla\theta = \alpha\gamma^i\delta\nabla \ln \pi(a|[e_x, e_y]), \tag{7}$$

where α is the learning step-size. γ is the discount factor. δ is the relative advantage of policy $\pi(a|[e_x, e_y])$ than the baseline, i.e., how much better the output action a is than mean or random. It can be defined as follows:

$$\begin{aligned} \delta &= G - \hat{v}([e_x, e_y]) \\ &= \sum_{k=i+1}^{T} \gamma^{k-i-1} r_k - \hat{v}([e_x, e_y]), \end{aligned} \tag{8}$$

where G is the return based on the future rewards. T denotes the episode length. The baseline function $\hat{v}([e_x, e_y])$ in this paper is an estimate of the state value.

3.3 Environment

Generally, the environment for an RL task should conform with three basic properties: dependency, dynamics, and difficulty.

Dependency The output action may change the later states. For sequential entity alignment, a *true match* will not only yield a correct alignment, but also exclude some plausible candidates for the following judgments, contributing to higher overall reward. Even a *false match* also has its value in filtering out two wrong entities. Therefore, we should consider the long-term dependencies.

To this end, for each entity e_x in $\mathcal{G}_1$, its k-nearest entities $e_1, e_2, ..., e_k$ in $\mathcal{G}_2$ are selected as candidates. Those entities are then concatenated with e_x to form k candidate pairs $[e_x, e_1], [e_x, e_2], ..., [e_x, e_k]$. The environment maintains a sequence $c_1, c_2, ..., c_j$, in which each element is such a candidate pair. At the i-th step, the environment pops a candidate pair $[e_x, e_y]$ as s_i. If it receives an action $a_i = 1$ from the agent, all candidate pairs containing e_x or e_y will be removed from the sequence.

Dynamics The environment is usually dynamic. The state-action sequences are different in different episodes. A dynamic environment makes the agent capable of capturing the general rules of the game, which is crucial to avoid overfitting. For the EEA task, if the state sequence is constant at each training episode, the agent will fit this sequence. However, the states are entirely different at the testing phase.

To ensure the dynamic property, we set a skip rate p_s. The environment randomly skips a candidate pair with probability p_s and then pops the next pair. Therefore, the length and elements of the state sequence change in each episode.

Difficulty Often, the difficulty of a game is improved gradually as step number grows. For example, the health and speed of enemies in video games usually increase over game time. On the other hand, it is also a general strategy to break down complex knowledge by a sequence of learning episodes of increasing difficulty, which is known as curriculum learning (Elman, 1993).

For sequential entity alignment, the difficulty of a candidate pair can be estimated based on the cosine similarity of the two entities and their label, which can be written as follows:

$$\begin{aligned} d(e_x, e_y) = & l(C_{e_x,e_{max}} - C_{e_x,e_y}) \\ & + (1-l)(\tau - C_{e_x,e_{max}} + C_{e_x,e_y}) \end{aligned} \tag{9}$$

where C_{e_x,e_y} is the cosine similarity between e_x and e_y. e_{max} denotes the entity with the largest similarity to e_x. We use the difference between $C_{e_x,e_{max}}$ and C_{e_x,e_y} as the basis to estimate the extent, and the label l as the sign. When $l = 1$, i.e., the first term in Eq. (9), a large difference between C_{e_x,e_y} and $C_{e_x,e_{max}}$ will result in high difficulty because e_x, e_y may be too dissimilar with each other. The situation is reversed for $l = 0$. We add a hyper-parameter τ to balance difficulty scores between these two cases.

Then, we can sort candidate pairs by the difficulty in ascending order, such that the agent will always start from the relatively easier states. However, this operation is inapplicable to the testing set where the label information is unknown. To mitigate this problem, we propose a curriculum

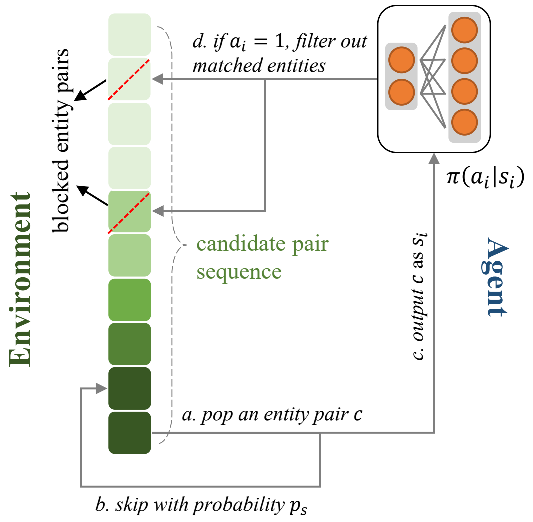

Figure 3: Illustration of how the environment interacts with the agent in RLEA.

learning strategy. We do not directly sort the candidate pairs by difficulty score. Instead, we sort them based on the cosine similarity and re-weight the skip rate p_s for each pair by its normalized difficulty score. Therefore, for each episode, the agent will start from pairs with high similarity, and the more difficult states will be skipped with larger probabilities. As the policy is optimized, we gradually decrease p_s to approximate the testing environment. The final state sequence shall have a similar arrangement to that at the testing phase.

The skip rate $p_s^{i,t}$ at the i-th step in episode t can be written as:

$$p_s^{i,t} = max(p_s^{min}, \eta^{t-1} p_s d_i), \tag{10}$$

where p_s^{min} is the minimal skip rate to ensure the dynamic property. p_s is the basic skip rate. d_i denotes the difficulty of state s_i at i-th step. As episode number grows, $p_s^{i,t}$ decreases with discount factor η exponentially until it meets the lower bound p_s^{min}.

We illustrate how the environment collaborates with the agent in Figure 3: a. the environment pops an entity pair c from the candidate pair sequence; b. this entity pair may be skipped with probability p_s (Equation (10)); c. the non-skipped pair is outputted by the environment as s_i; d. the agent takes s_i as input, and its output action changes the candidate pair sequence reversely. The detailed implementation can be found in Appendix A.

4 Experiment

We conducted experiments to verify the effectiveness of the proposed RL-based framework. The trained entity embeddings were obtained from the OpenEA project [2].

4.1 Dataset Settings

We used the 15K benchmark proposed by OpenEA. It consists of four subsets: EN-FR, EN-DE, D-W, and D-Y. The former two are cross-lingual datasets, where EN, FR, DE denote English, French, and German versions of DBpedia, respectively. The latter two are cross-source datasets, where D, W, Y denote DBpedia (Auer et al., 2007), WikiData (Vrandečić and Krötzsch, 2014), and Yago (Fabian et al., 2007), respectively. We used "V1" subsets that has similar distributions to original KGs. Please refer to (Sun et al., 2020b) for detailed statistics.

4.2 Compared Methods

We select the following methods as baselines:

- JAPE (Sun et al., 2017), which learns attribute embeddings and relational embeddings jointly for EEA.
- SEA (Pei et al., 2019a), which adopts adversarial learning to learn the projection matrix.
- RSN (Guo et al., 2019), which leverages recurrent neural networks (RNNs) (Williams and Zipser, 1989) to learn KG embeddings.
- RDGCN (Wu et al., 2019), which uses GCNs to capture the neighborhood information into entity embeddings.

We also design a basic sequential strategy called *Seq* for comparison. We follow the algorithm used in BootEA (Sun et al., 2018) to implement it. Entity pairs with similarity above a predefined threshold are regarded as *match*, or the algorithm randomly chooses actions based on cosine similarity.

4.3 Main Results

The results on four datasets are shown in Table 1. Orig denotes the original results of the EEA methods. We can observe that RLEA significantly improved the performance of all baseline methods, including the best-performing one, RDGCN. Therefore, we believe that RLEA provides a better way

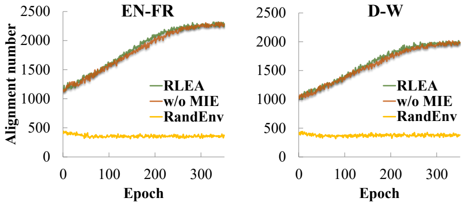

Figure 5: Alignment number w.r.t. episode number, on EN-FR and D-W datasets.

to exploit aligned entity pairs from embeddings than the widely-used heuristic strategy.

Specifically, the performance improvement of JAPE is most notable, with 30.4% and 31.1% increases on EN-FR and D-Y, respectively. Although RSN has minimal performance increase, the difference is still significant. Similarly, RDGCN also achieved better performance, leading to a new state-of-the-art on the benchmark.

With the basic sequential strategy Seq, four baseline methods also achieved better Hits@1 results on most datasets except D-W. This observation empirically proves the advantages of modeling EA as a sequential decision-making task.

Note that RLEA also has its limitations. We find there exists a dataset bias. The performance improvement on EN-FR dataset is notable, but that on D-W is less significant. We believe that the sequential evaluation process might cause this bias. For instance, Seq also got worse performance than the original method SEA on D-W. We leave how to mitigate this problem in future work.

4.4 Influence of Candidate Number

In RLEA, the candidate number for each entity is an important hyper-parameter as it decides the length of the candidate sequence. A large value means covering more correct alignment pairs as well as more plausible pairs. Therefore, it is necessary to study how this hyper-parameter influences the performance of RLEA.

We used the embeddings of the best-performing method RDGCN as input in this experiment. As shown in the left of Figure 4, the Hits@1 results on four datasets gradually increase with candidate number from 1 to 5, but converge after 10. When candidate number was set to 1, for each entity, only the pair with the highest similarity was added to the sequence, resulting in similar or even worse results compared with the original method. For example, on D-W, the hits@1 of RLEA is 0.478, significantly below that of the original RDGCN (0.541). As the candidate number increased, more aligned pairs were added to the sequence, the performance improved steadily. It then gets saturated due to more unaligned pairs were also added to the sequence. On the right of Figure 4, we show the runtime of one testing episode w.r.t. candidate number, which, however, grows exponentially. This observation suggests that setting a large candidate number is computationally expensive. Therefore, we decide to use the top-10 candidates in our implementation, for sake of performance and efficiency.

4.5 Effectiveness of Modules

We conducted experiments to verify the effectiveness of mutual information estimator (MIE) and the proposed environment. We developed two variants of RLEA: (1) RLEA without MIE (denoted as w/o MIE), and (2) RLEA with a random environment (RandEnv). The random environment still maintains a candidate pair sequence but does not have the difficulty and skipping settings. All candidate pairs in the sequence are randomly reset at the start of each episode.

We compare the results in Figure 5, from which we find that the agent does not work in the random environment on all datasets. The alignment num-

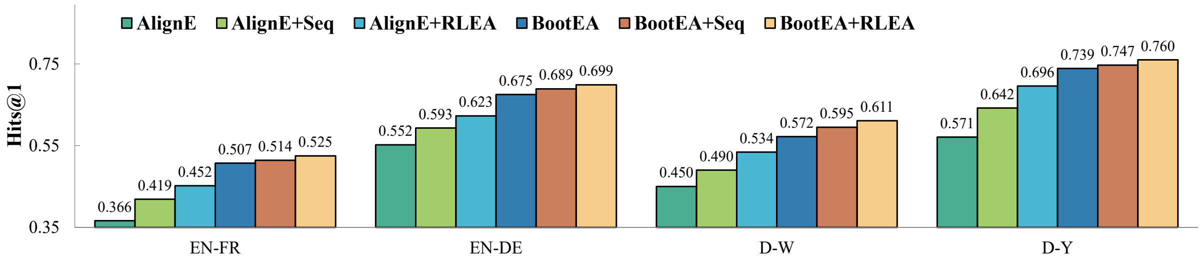

Figure 6: A comparison between RLEA and BootEA.

ber even slowly decreases during training. This is because that the state sequence in the random environment changes irregularly. The agent fails to establish an effective policy to maximize the reward for all episodes. Furthermore, the random environment does not have a curriculum learning strategy to help the agent study from easy to hard. Therefore, the agent is not able to capture the general rules in the random environment.

On the other hand, we find that MIE slightly improves the performance. It does not have a significant advantage over the final reward or alignment number. This may be because that the output embeddings of GNNs have already included sufficient information to judge entity pairs. Nevertheless, the estimation provided by MIE helps the agent find the best policy rapidly, which is crucial when applying to larger datasets. A more detailed version of Figure 5 is shown in Appendix B, from which we can obtain the consistent observations.

4.6 A Comparison of RLEA and BootEA

BootEA (Sun et al., 2018) is a bootstrapping method that iteratively labels possible entity alignment as training data. Like RLEA, BootEA assumes a candidate entity should not be aligned twice. Therefore, it is interesting to compare and discuss these two methods.

We illustrate the experimental results on four datasets in Figure 6. AlignE is a variant of BootEA without bootstrapping process. We first compare the left four columns. Obviously, BootEA (4th column) has a better effect in improving the performance of AlignE, as it directly participates in training AlignE by iteratively adding plausible alignment pairs. In contrast, Seq (2nd column) and RLEA (3rd column) only use the trained embeddings as input and do not modify the embeddings or training procedure. They are thus more extensible and applicable to arbitrary EEA methods.

In fact, it is no contradiction to integrate these two types of methods. The performance improvement (5th and 6th columns) is still significant and consistent on all four datasets.

4.7 Competing with Conventional Methods

There has always been an argument about the practical use of EEA. Most EEA methods are end-to-end and easy to be deployed. The performance also improves when new models are developed. However, a significant performance gap still exists between EEA methods and those conventional methods like Paris (Suchanek et al., 2012) and LogMap (Jiménez-Ruiz and Grau, 2011). We show in Table 2 that RLEA with the embeddings of best EEA methods as input can narrow this gap and even outperform the conventional methods on some datasets. As shown in Table 2, PARIS is the best method that outperformed others on all datasets except D-Y. However, The second method changed from LogMap to RLEA. We can find that RLEA not only outperformed LogMap on EN-FR, but also achieved the best performance on D-Y.

We should notice that the alignment pairs exploited by EEA methods and conventional methods are not all overlapped (Sun et al., 2020b). It is possible to integrate them to achieve better performance (Sun et al., 2017, 2020b). In this sense, RLEA is also the best choice to be combined with conventional methods.

5 Conclusion and Future Work

In this paper, we proposed an RL-based entity alignment framework, which can advance most existing EEA methods without modifying their parameter settings or infrastructures. Our experiments demonstrate consistent and significant improvement on all baseline methods. We plan to study how to jointly train EEA methods and RLEA for further improvement in future work.

A Implementation

A.1 Algorithm

We show the training procedure of RLEA by Algorithm 1. The input is two KGs, trained embeddings of an arbitrary EEA method, and parameter settings. If the EEA method has projection matrices (Chen et al., 2017; Pei et al., 2019a), the embeddings of $\mathcal{G}_2$ should be projected to the space of $\mathcal{G}_1$ by the corresponding matrix before the training starts. We first initialize all parameters of the policy network. The episode sequence and candidate pair sequence will be reset at the start of each episode. After that, the agent interacts with the environment, which generates a state-action sequence. We then use REINFORCE algorithm to update the policy network with the generated sequence.

Algorithm 1: RLEA

```
Input: Two KGs $\mathcal{G}_1$, $\mathcal{G}_2$, entity embeddings
       $\mathbf{E}_1$, $\mathbf{E}_2$, and number of episodes $N$.
Output: The policy $\pi(a|s, \theta)$.
Initialize the policy parameter $\theta$;
for t=1:N do
    Reset episode sequence to empty and
      initialize candidate pair sequence;
    repeat
        Pop a candidate pair $c$ from
          candidate pair sequence;
        Calculate the skip rate $p_s$ with
          Equation (10);
        $\mu \leftarrow \mathrm{RandInt}(0, 1, p_s)$;
        if $\mu = 1$ then continue ;
        else $s \leftarrow c$ ;
        $a \sim \pi(a|s, \theta)$;
        if $a = 1$ then Update candidate pair
          sequence according to $c$ ;
        Add $s, a$ to episode sequence;
    until All entities are matched or
      candidate pair sequence is empty.;
    for each step in the episode sequence do
        Update the policy parameter $\theta$
          according to Equation (7).
    end
end
Output $\pi(a|s, \theta)$.
```

A.2 Parameter Settings

For each EEA method, we directly used their trained entity embeddings as input and did not modify these vectors during training. The embedding-size was identical to that used in OpenEA (Sun et al., 2020b). The number of training episodes was set to 500, and the learning step-size was set to 0.0001. The candidate pair number for each entity was set to 10.

B Detailed Results of Ablation Study

The detailed results of RLEA and its two variants are shown in Figure 7. Overall, the full RLEA still has the best performance and training speed, especially on D-Y dataset. The method without MIE also have competitive performance on four datasets, which demonstrates the effectiveness of the RL-based sequential EEA.

From the bottom sub-figures, we find that the agent tries to find a policy to achieve high rewards in the random environment. However, 0 is almost the best reward it can get. The agent fails to establish a good policy in this dynamic environment.

C Results on OpenEA 100K datasets

As shown in Table 3, the Hits@1 results on OpenEA 100K datasets are consistent with those on 15K datasets. RLEA still outperformed the baselines on four datasets. We did not consider RDGCN and RSN in this experiment, as they can only be trained on CPUs (confirmed from the authors of OpenEA).

Table 3: Hits@1 results on OpenEA 100K datasets.

Abstract

While multilingual training is now an essential ingredient in machine translation (MT) systems, recent work has demonstrated that it has different effects in different multilingual settings, such as many-to-one, one-to-many, and many-to-many learning. These training settings expose the encoder and the decoder in a machine translation model with different data distributions. In this paper, we examine how different varieties of multilingual training contribute to learning these two components of the MT model. Specifically, we compare bilingual models with encoders and/or decoders initialized by multilingual training. We show that multilingual training is beneficial to encoders in general, while it only benefits decoders for low-resource languages (LRLs). We further find the important attention heads for each language pair and compare their correlations during inference. Our analysis sheds light on how multilingual translation models work and enables us to propose methods to improve performance by training with highly related languages. Our many-to-one models for high-resource languages and one-to-many models for LRL outperform the best results reported by Aharoni et al. (2019).

1 Introduction

Multilingual training regimens (Dong et al., 2015; Firat et al., 2016; Ha et al., 2016) are now a key element of natural language processing, especially for low-resource languages (LRLs) (Neubig and Hu, 2018; Aharoni et al., 2019). These algorithms are presumed to be helpful because they leverage syntactic or semantic similarities between languages, and transfer processing abilities across language boundaries.

In general, English is used as a central language due to its data availability, and three different multilingual training settings are considered: (1) *one-to-many*: training a model with languages pairs from English to many other languages. (2) *many-to-one*: training a model with languages pairs from many languages to English (3) *many-to-many*: training a model with the union of the above two settings' data. (1) and (3) can be used for English to other (En-X) translation, while (2) and (3) can be used for other to English (X-En) translation.

However, multilingual training has not proven equally helpful in every setting. Arivazhagan et al. (2019) showed that many-to-one training improves performance over bilingual baselines more than one-to-many does. In this paper, we consider this result from the point of view of the components of the MT model. In the many-to-one setting, the model's inputs are from different language distributions so the encoder can be considered a multi-domain model, whereas the decoder is trained on a single distribution. In the one-to-many setting, it is the opposite: the encoder shares data, and the decoder is multi-domain. While there are recent studies analyzing multilingual translation models (Kudugunta et al., 2019; Voita et al., 2019a; Aji et al., 2020; Mueller et al., 2020), in general, they do not (1) examine the impact of different multilingual training settings such as one-to-many and many-to-one, and (2) they do not examine the different components, such as the encoder and the decoder, separately.

This motivates us to ask *"how do various types of multilingual training interact with learning of the encoder and decoder?"* To answer this question, we set up controlled experiments that decouple the contribution to the encoder and the decoder in various training settings. We first train multilingual models using many-to-one, one-to-many, or many-to-many training paradigms. We then compare training bilingual models with and without initializing the encoder or the decoder with parameters learned by multilingual training. We find that, for LRLs, multilingual training is beneficial to both the encoder and the decoder. However, surprisingly, for high-resource languages (HRL), we found mul-

Findings of the Association for Computational Linguistics: ACL 2022, pages 2766 - 2780

Size (K)	6	5	10	61	214	168	212	205

Table 1: Training data size.

tilingual training only beneficial to the encoder but not to the decoder.

To further analyze the result, we examine *"to what degree are the learned parameters shared across languages?"*. We use the head importance estimation method proposed by Michel et al. (2019) as a tool to identify the important attention heads in the model, and measure the consistency between the heads sets that are important for different language pairs. The results suggest that the encoder does share parameters across different languages in all settings. On the other hand, the decoder can treat the representation from the encoder in a language-agnostic way for X-En translation, and less parameter sharing is observed for En-X translation. Our analyses on parameter sharing also provide a possible explanation to Kudugunta et al. (2019)'s observation that the representation from the encoder is target-language-dependent.

Our investigation of how multilingual training works leads us to a method for improving MT models. With the comprehensive experiments in multilingual settings, for translations in HRL (Ar-En, De-En, He-En, It-En), we discover that fine-tuning multilingual model with target bilingual data outperforms the best results in Aharoni et al. (2019) by 2.99 to 4.63 BLEU score. With the analysis of the parameter sharing in the decoder, we are able to identify related languages. Fine-tuning jointly with the identified related languages boosts low-resource translation (En-Az, En-Be, En-Go, En-Sk) over the best results in Aharoni et al. (2019) by 1.66 to 4.44 BLEU score. Compared to Neubig and Hu (2018), our method does not require linguist knowledge, and thus may be more useful for less-studied low-resource languages.

In sum, our contributions are three-fold. First, our experiments can be used as a diagnostic tool for multilingual translation to investigate how an encoder and a decoder benefit from multilingual training. Second, our results provide insights into how multilingual translation works. Third, we improve the translation models based on the findings from our analysis, showing a promising path for future research on multilingual machine translation.

2 Experimental Settings for Multilingual Training

Before stepping into our analysis, we first explain our experimental setup. Following the setting in Aharoni et al. (2019) and Neubig and Hu (2018), we use the publicly available TED Talks Dataset (Qi et al., 2018) is used to train all our machine translation models. Following Neubig and Hu (2018), we break words into subwords with BPE jointly learned over all source languages using the `sentencepiece` toolkit. The vocabulary size is 32,000. We perform experiments with the Transformer architecture (Vaswani et al., 2017) using the hyperparameters same as in (Arivazhagan et al., 2019) [1]. All models are implemented and trained using *Fairseq* 0.10.0 (Ott et al., 2019). We trained multilingual translation models with 60 different languages on the TED Talks Dataset with the three settings described in Section 1: *one-to-many*, *many-to-one* and *many-to-many*. For *one-to-many* and *many-to-many* settings, we add a special language token to the input of the encoder to indicate the target language. Following Aharoni et al. (2019), we evaluate our models with BLEU score (Papineni et al., 2002; Post, 2018) on the selected 8 languages. They are representative of different language families (Qi et al., 2018). The size of the training is shown in Table 1.

3 How Multilingual Training Benefits Each Component

Previous studies have shown that the multilingual training results are generally stronger than the bilingual training (Arivazhagan et al., 2019). To understand how multilingual training benefits NMT, we analyze the effect of multilingual training on different components of an NMT model, specifically, the encoder and decoder.

3.1 Experiments Design

To study how multilingual training benefits each component, we train models on bilingual data with components initialized differently as follows:

- **Bilingual Only:** Models trained from scratch with no components initialized with parameters learned from multilingual training.

Table 2: Results of translating to English. **All** in the model name refers to using all 59 languages.

- **Load encoder/decoder:** Models with trainable parameters of either encoder or decoder initialized with parameters learned from multilingual training.
- **Load both:** Models with parameters of both encoder and decoder initialized with parameters learned from multilingual training. This can be seen as fine-tuning the multilingual model on bilingual data.

The motivation for this paradigm is that if multilingual training is beneficial to a component, then initializing the parameters of that component should result in improvements over random initialization and training on only bilingual data. If *load encoder* outperforms *bilingual only*, then we can say that multilingual training is beneficial for the encoder, and if *load decoder* outperforms we can make the analogous conclusion for the decoder. Thus comparing these models reveals how each component benefit from multilingual training.

We also consider a *load and freeze* setting (Thompson et al., 2018), where we initialize a component from a multilingual model and freeze its weights when fine-tuning on bilingual data. For example, in the *load decoder* setting, we train the loaded decoder with a randomly initialized encoder. We suspect that learning with randomly initialized component might ruin the other component which is well-trained with multilingual data, especially in the beginning of the training. Thus, we additionally experiment with this *load and freeze* setting to ensure the multilingual-trained component is not deteriorated.

3.2 Results and Discussion

The overall results of X-En and En-X are shown in Table 2 and Table 3, respectively. The difference between the numbers reported in Aharoni et al. (2019) and ours is due to the different batch size and learning rate schedule we use. In the following section we will discuss the results of our study. Because they are highly dependent on the training data size (Table 1), we discuss the results in two groups: high-resource languages (HRL; referring to *ar*, *de*, *he*, and *it*) and low-resource languages (LRL; referring to *az*, *be*, *gl*, *sk*).[2]

3.2.1 Low-Resource Language Results

For LRLs, we find that multilingual training is generally beneficial to both the encoders and the decoders in all three multilingual models. Both *load encoder* and *load and freeze decoder* can achieve performance better than the bilingual baseline. This suggests that the parameters in the encoder and the decoder learned by multilingual training do contain information that is not effectively learned from the smaller bilingual data.

The results also suggest that multilingual training is more beneficial for the encoders than decoders. In all cases, either *load encoder* or *freeze encoder* outperforms both *load decoder* and *load and freeze decoder*. However, multilingual training of the encoder and the decoder are complementary; loading both the encoder and the decoder can usually improve the performance over loading only one component.

---

[2] *sk* has intermediate size, and its behavior is not always consistent with the other LRL.

	Load All	6.1	13.0	26.4	23.2	17.0	30.3	27.9	34.6

Table 3: Results of translating from English. **All** in the model name refers to using all 59 languages.

3.2.2 High-Resource Language Results

On HRLs, we find that multilingual training is generally beneficial to the encoders in all three multilingual models, while it is not beneficial for the decoders in some settings. *Load encoder* consistently outperforms the baseline models, but for the All-En model on X-En translation, and the All-All model on En-X translation, neither *load decoder* nor *load and freeze decoder* outperform the baseline model.

We also observe that multilingual training is generally more beneficial to the encoders than decoders. In all cases, *load encoder* can achieve performance competitive to *load both* (better or less by within 1 BLEU score). However, in all cases, both *load decoder* and *load and freeze decoder* have worse performance than *load both*. Therefore, multilingual training is not as beneficial to the decoders as to the encoders.

3.3 Discussion

For LRL, because the size of bilingual training data is small, it is not surprising that multilingual training is beneficial for both the encoder and the decoder. However, our results are somewhat more surprising for HRL — it is not trivial that multilingual training is not as beneficial. In the next section, we focus on explaining the phenomena observed on HRL by investigating how parameters are shared across languages.

4 How Multilingual Parameters are Shared in Each Component

Given the previous results, we are interested in exactly *how* parameters are shared among different language pairs. Given that we are using the Transformer architecture, for which multi-head attention is a fundamental component, we use the attention heads as a proxy to analyze how multilingual models work differently when translating between different languages. Specifically, we analyze our models by identifying the attention heads that are important when translating a language pair. Measuring the consistency between the sets of important attention heads for two language pairs gives us hints on the extent of parameter sharing.

4.1 Head Importance Estimation

First, we provide some background on head importance estimation, specifically the method proposed by Michel et al. (2019).

Given a set of multi-head attention modules, each of which can be written as

$$\mathrm{MHAtt}(x) = \sum_{h=1}^{N_h} \xi_h \mathrm{Att}_{W_q^{(h)}, W_k^{(h)}, W_v^{(h)}}(x), \quad (1)$$

where N_h is the number of attention heads, and $\xi_h = 1$ for all h.

The importance of a head can be estimated as

$$\tilde{I}_h = \mathbb{E}_{x \sim X} \left| \frac{\partial L(x)}{\partial \xi_h} \right|. \quad (2)$$

given a loss function L and input X. Then, the importance score of each head in an attention module is normalized

$$I_h = \frac{\tilde{I}_h}{\sqrt{\sum_i^{N_h} I_h^2}}. \tag{3}$$

Note that when the input X is different, the estimated importance score can be different. Therefore, when different language pairs are fed in, the important heads identified can be different. We denote the set of attention head scores estimated on translation from language l_a to language l_b as $H(l_a, l_b)$. We denote the scores of attention heads in a component by using superscript. For example, H^{enc} represents the scores of the heads in a encoder.

4.2 Measuring Parameter Sharing by Correlation of Head Scores

With the attention head importance scores estimated by Equation 3, we can investigate how parameters are shared across languages. For each of the En-All, All-En, All-All multilingual models, we estimated a set of head-importance scores $H(l_a, l_b)$ for each language pair (l_a, l_b) in the training setting. We calculate the head scores with the training loss function (MLE with label smoothing) and 100K randomly sampled sentences in the training set.

To investigate how much parameters are shared by two pairs of languages (l_a, l_b) and (l_c, l_d), we measure the agreement between $H(l_a, l_b)$ and $H(l_c, l_d)$. If a head is important for both of (l_a, l_b) and (l_c, l_d), then important parameters for translating are shared. Thus high agreement suggests high parameter sharing.

To quantify the agreement between two score sets, we use Spearman's rank correlation (Spearman, 1987). A rank-based correlation metric is used because the importance estimation was originally proposed to order attention heads in a model. Higher correlation implies higher agreement and thus implies higher parameter sharing. For each of the En-All, All-En, All-All models, we calculate the correlation between $H(l_a, l_b)$ and $H(l_c, l_d)$ for all language pairs (l_a, l_b) and (l_c, l_d) that are used to train the model. The detailed correlation computation process can be found in Appendix A. We plot the correlation matrices of the head scores (included in appendix) and summarize them in Table 4. We also compare the top-10 most important heads for every language pairs with F1 scores, and observe similar results. We include the statistics in appendix.

Model	Lang. Pair	H^{enc}	H^{dec}
All-En	X-En	.871 (.086)	.973 (.023)
En-All	En-X	.806 (.153)	.720 (.150)
All-All	X-En	.898 (.073)	.967 (.029)
All-All	En-X	.813 (.126)	.762 (.141)

Table 4: Correlation between the attention head scores when estimated using different language pairs.

4.3 How Multilingual Translation Models Share

Results in Table 4 combined with Section 3 provides the insights into how multilingual translation models work with respect to cross-lingual sharing:

Encoder for En-X: It is natural that the encoder from En-X likely benefit from multilingual training because it can generate representations tailored for different target languages with shared parameters. En-X is a set of language pairs where the source language is always English. Therefore, if the prepended target language token is ignored, the inputs of the encoders for all pairs in En-X are from one identical distribution. This is in contrast to X-En pairs, where the inputs are in different languages. However, for the encoders, we observe from Table 4 that the average correlation scores of En-X pairs (0.806 and 0.813), are lower than the correlation scores of X-En pairs (0.871 and 0.898). Kudugunta et al. discovers that the representation of the encoder is target-language-dependent. Thus we conjecture that some parameters may be used to generate representation tailored for the target languages. At the same time, since the inputs are from a single distribution (English) for different target languages, a large portion of parameters may still be shareable across target languages. Therefore, in this case, multilingual training is beneficial.

Encoder for X-En: For X-En language pairs, the input of the encoder is multilingual, which means the input from different X-En language pairs has distinct distribution. However, the correlation between different source languages is still high. It shows that high parameters sharing in the encoder is possible.

Decoder for En-X: The decoders for En-X have the lowest correlation. From the correlation matrix, we do see some parameter sharing between some language pairs. However, larger model capacity might be required for a model to be proficient in all the languages.

Decoder for X-En: The decoder have average correlation as high as 0.973 and 0.967 for All-En and All-All models respectively. This suggests that to decode intermediate representation encoded by the encoder, the decoder use almost the same set of parameters. However, Kudugunta et al. shows that the representation encoded by the encoder is not language-agnostic. A possible explanation is that the important parameters of the decoder are highly determined by the target output, which is always in English. Therefore, even though the encoder representation is not language-agnostic, it is still difficult to learn parameters reflecting the difference. It suggests why multilingual training does not benefit the decoder in the X-En setting. The set of English sentences is almost the same for all the HRL pairs in the TED Talks dataset, so multilingual training can hardly provide more unique English sentences than bilingual training does. If the decoder is dedicated for generation, multilingual training cannot expose the decoder to more diverse data. Therefore the multilingually trained decoder does not perform better than the bilingual one.

5 Improving Translation Based on the Degree of Parameter Sharing

Insights from the previous section provide us with a new way to choose languages for multilingual training. In previous work (Lin et al., 2019; Oncevay et al., 2020), choosing on languages with similar linguistic properties is a popular practice. However, Mueller et al. (2020) found the effect is highly language-dependent. Sometimes training with similar languages might be worse than training on a set of unrelated languages. Here we otherwise propose an entirely model-driven way to find related languages to improve multilingual translation models. We explore choosing languages where parameters can be better shared.

5.1 Improving X-En by Related En-X Pairs

In the All-All model, we notice low parameter sharing between En-X and X-En pairs. The average correlation between $H^{enc}(En, X)$ and $H^{enc}(X, En)$ is 0.44 (std: 0.17). The average correlation between $H^{dec}(En, X)$ and $H^{dec}(X, En)$ is 0.49 (std: 0.13). It provides a possible explanation why training with both the En-X and the X-En pairs only brings little improvement over training with only En-X alone or with X-En alone.

The low correlation combined with results in Section 3 motivate us to experiment on improving X-En with related En-X pairs. Section 3 shows that the multilingual decoder has less advantage than the encoder. This may suggest the inefficiency of parameter sharing in the decoder. Therefore we experiment on choosing a set of related languages based on the degree of parameter in the decoder. We choose the language set L such that for all $l \in L$, the average correlation $\frac{1}{60}\sum_{l_i=1}^{60} \mathrm{Corr}(H^{dec}(En, l), H^{dec}(l_i, En))$ is higher than 0.60.

Results are shown in Table 5. Even though fine-tuning on related languages improves the overall performance, it is not better than fine-tuning on the All-En pairs only. Also, the average correlation between $H^{dec}(En, l_a)$ and $H^{dec}(l_b, En)$ is not improved. Our experiment demonstrates the difficulty of sharing parameters between All-En pairs and En-All pairs. We leave this problem for future work.

5.2 Improving En-X by Language Clusters

The low correlation between attention head scores of language pairs motivates us to improve the performance of En-X using related language pairs. As shown in Table 4, the decoders have the lowest correlation scores. We conjecture that it is due to the difficulty of sharing parameters between distant languages. Thus, we seek for finding related language sets, in each of which parameters can be shared.

Again, we resort to the attention head importance scores to find the related languages. Our intuition is that related languages would share many parameters in between and training a model on related languages would be helpful. As a sanity check of our idea, we first use t-SNE (Maaten and Hinton, 2008) to reduce the dimension of head-importance scores $H(l_a, l_b)$. We only focus on heads in the decoders, because the correlation score between $H_{(\mathrm{En}, l_c)}$ and $H_{(\mathrm{En}, l_d)}$ is lower in average for the decoders. The result visualized in Figure 1 illustrates that, the distance between $H_{(\mathrm{En}, l_c)}$ and $H_{(\mathrm{En}, l_d)}$ tend to be shorter if languages l_c and l_d are linguistically related. Hence, determining related languages with head score $H_{(\mathrm{En}, l)}$ should be reasonable.

We then fine-tune multilingual models on related language clusters. Related languages clusters are determined by k-mean++ (Arthur and Vassilvitskii,

Model	az	be	gl	sk	ar	de	he	it
All-All	8.1	12.6	22.8	24.6	21.7	27.1	26.1	31.1
+ f.t. on All-En	10.5	17.5	29.7	28.1	25.9	31.3	30.5	34.0
+ f.t. on All-En & related	10.5	17.4	28.3	27.0	25.1	30.0	29.9	32.7

Table 5: Performance of All-All model fine-tuned on All-En pairs and fine-tuned on the union of All-En pairs and related En-All languages.

Model	az	be	gl	sk	ar	de	he	it
En-All (Aharoni et al., 2019)	5.1	10.7	26.6	24.5	16.7	30.5	27.6	35.9

Load En-All w/ f.t. on closest	7.8	**15.2**	**28.6**					

Table 6: Performance of En-All model without and with fine-tuning on language clusters.

2007) with $k = 5$. We consider clusters that cover all of the four low-resource languages. For the All-All model, one of the cluster we consider contains Be, Gl, De, He, It, and the other one contains Az. For the En-All model, we also experiment with two clusters. One includes Ar, De, He, It, and the other includes Az, Be, Gl, Sk. As a baseline, we also experiment with random groups. They are groups generated by randomly splitting the 59 target languages.

The results are shown in Table 6. For both the En-All and the All-All model, except En-Gl, fine-tuning on clusters can improve performance on all the considered language pairs consistently. For LRLs, fine-tuning on related language clusters is also better than fine-tuning on random groups in general. To verify whether this improvement is brought by increased parameter sharing in the decoders, we check the correlation between H^{dec} after fine-tuning. The results shown in Table 7 shows improvements after fine-tuning on the clusters.

For low-resource language pairs En-Az, En-Be, En-Sk on the En-All model, we notice that only few languages are highly correlated with them (with correlation > 0.80). Therefore, we also experiment with fine-tuning the En-All model with only the language pairs with high correlation scores (> 0.80) for each of the three pairs , which boosts the performance of En-Be to 15.2 and En-Sk to 28.6.

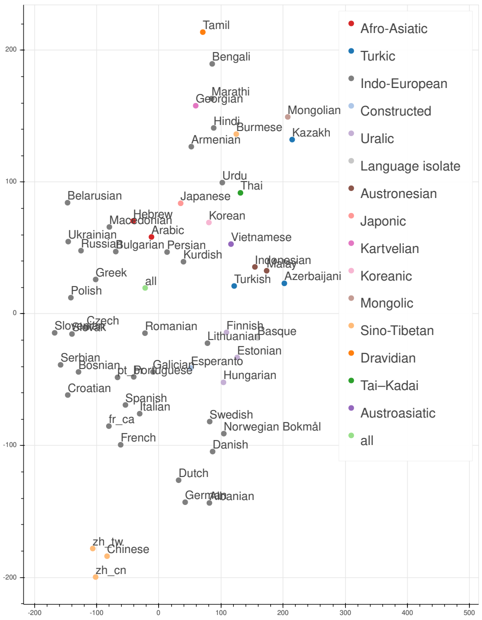

Figure 1: Visualization of the En-All decoder head scores of languages by t-SNE.

Model	H^{dec} w/o f.t.	H^{dec} w/ f.t.
All-All	.762 (.141)	.894 (.069)
En-All (HL)	.855 (.066)	.866 (.065)
En-All (LL)	.826 (.096)	.834 (.091)

6 Related Work

The early attempts of multilingual training for machine translation use a single model to translate between multiple languages (Dong et al., 2015; Firat et al., 2016; Ha et al., 2016). Those works find multilingual NMT models are appealing because they not only give us a simple paradigm to handle mapping between multiple languages, but also improve performance on low and zero-resource languages pairs (Gu et al., 2018). However, how multilingual training contributes to components in the translation model still remains unknown.

There are some attempts at analyzing and explaining the translation models. Thompson et al. (2018) analyze the contribution of different components of NMT model to domain adaptation by freezing the weights of components during continued training. Arivazhagan et al. (2019) provide an comprehensive study on the state-of-the-art multilingual NMT model in different training and testing scenarios. Sachan and Neubig (2018) experiment with different parameter sharing strategies in Transformer models, showing that sharing parameters of embedding, key and query performs well for *one-to-many* settings. Artetxe et al. (2020) shows the strong transferability of monolingual representation to different languages. The intermediate representation of BERT can be language-agnostic if we freeze the embeddings during training. The deficiency of the *one-to-many* setting is explored in (Johnson et al., 2017). They find only the *many-to-one* setting consistently improves the performance across languages. Wang et al. (2018) also explore problems of the *one-to-many* setting, and show language-specific components are effective to improve the performance. Voita et al. (2019a) analyzes how generated sentences of NMT models are influenced by context in the encoder and decoder. The attempt to investigate encoder and decoder separately is similar to our work. Rothe et al. (2020) explores how pretrained checkpoints can benefit the encoder and the decoder in a translation model. Zhang et al. (2021) investigate the trade-off between language-specific and shared capacity of layers in a multilingual NMT model.

Multi-head attention has been shown effective in different NLP tasks. Beyond improving performance, multi-head attention can help with subject-verb agreement (Tang et al., 2018), and some heads are predictive of dependency structures (Raganato and Tiedemann, 2018). Htut et al. (2019) and Clark et al. (2019) report that heads in BERT attend significantly more to words in certain syntactic position. They show some heads seem to specialize in certain types of syntactic relations. Michel et al. (2019), Voita et al. (2019b), and Behnke and Heafield (2020) study the importance of different attention heads in NMT models, and suggest that we can prune those attention heads which are less important. Brix et al. (2020) also shows pruning NMT models can improve the sparsity level to optimize the memory usage and inference speed.

However, all previous works do not directly investigate how encoder and decoder of NMT models benefit from multilingual training, which is the key question of why multilingual training works. To our best knowledge, we are the first to tackle the question, and our analysis can be used to further improve multilingual NMT models.

7 Conclusion

In this work, we have the following findings: 1) In Section 3, we examine how multilingual training contributes to each of the components in a machine translation model. We discover that, while multilingual training is beneficial to the encoders, it is less beneficial to the decoders. 2) In Section 4, our analysis of important attention heads provides insight into the behavior of multilingual components. Results suggest that the encoder in the En-All model may generate target-language-specific representation, while the behavior of the decoder of the All-En model may be source-language-agnostic. In addition, in the All-All model, we observe indications of lower parameter sharing between X-En pairs and En-X pairs. 3) In Section 5, we explore approaches to improve the model based on our findings. On En-X translation, we outperform the best results in (Aharoni et al., 2019). With our proposed analysis as diagnostic tools, future work may further improve the multilingual systems.

Table 8: Languages in the Ted Talk Dataset

A Correlation of Head Scores

Here we detail the computation of the correlation of head scores for two pairs of languages (l_a, l_b) and (l_c, l_d). The steps are as follow:

1. The two language pairs' head importance scores $H(l_a, l_b)$ and $H(l_c, l_d)$ are estimated with Equation 3. Since there are many heads in a Transformer model, both $H(l_a, l_b)$ and $H(l_c, l_d)$ are vectors.

2. We flatten the scores in $H(l_a, l_b)$ and $H(l_c, l_d)$ into two arrays of scalars. We treat the two arrays as the observations of two variables. Then, we use Spearman correlation to compute the correlation between the two variables. In other words, the input of the Spearman correlation function is the two arrays.

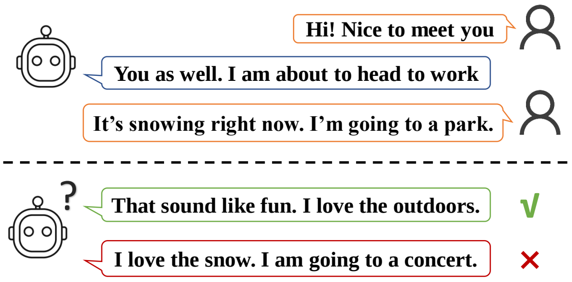
Abstract

Chatbot models have achieved remarkable progress in recent years but tend to yield contradictory responses. In this paper, we exploit the advantage of contrastive learning technique to mitigate this issue. To endow the model with the ability of discriminating contradictory patterns, we minimize the similarity between the target response and contradiction related negative example. The negative example is generated with learnable latent noise, which receives contradiction related feedback from the pretrained critic. Experimental results show that our method helps to avoid contradictions in response generation while preserving response fluency, outperforming existing methods on both automatic and human evaluation.

1 Introduction

In recent years, with the advent of large training corpora and pretrain technology, chatbot models have evolved considerably in open domain (Bao et al., 2020; Roller et al., 2021). Current chatbots have achieved surprising results in generating fluent, engaging, informative responses, but still occasionally generate responses that are contradictory with history when interacting with human (Li et al., 2021b). Such contradiction issues are often jarring and severely disrupt communication. Therefore, it is essential to reduce contradiction for chat-bots in multi-turns dialogues.

Previous work (Li et al., 2016; Song et al., 2020) proposes to use the paradigm of RL to mitigate the gap between the training and contradiction avoiding objective. However, the RL-based methods are easy to degrade in deep neural network (Parisotto et al., 2020), leading to the decoder generates responses that deviate from human language (Lewis et al., 2017; Kottur et al., 2017). Other method (Li et al., 2020) aims to address dialogue logical contradictions via unlikelihood training (Welleck et al., 2019). While they reduce the probability of the labeled contradicting responses, it is less generalizable to different conversation scenarios with the limited coverage of labeled contradicting data.



Hi! Nice to meet you

You as well. I am about to head to work

It's snowing right now. I'm going to a park.

That sound like fun. I love the outdoors. ✓

I love the snow. I am going to a concert. ✗

Figure 1: The similarity between correct and contradictory response is 0.9315 in blenderbot embedding space.

We argue that one of the reasons behind contradiction is that model lacks the ability to identify contradictory behavior clearly. As shown in Fig.1, the large pretrained chatbot blenderbot (Roller et al., 2021) still has high similarity between the correct and contradictory responses in embedding space. Chatbots are likely to cause contradictions when probed with unusual conversations during inference (Roller et al., 2021), while they are commonly trained to mimic human context-response pairs under the teacher-forcing algorithm (Williams and Zipser, 1989). Without being exposed to incorrect and contradictory context-response pairs, chatbots fail to learn the ability that discriminating contradictory response patterns directly, which hurts its robustness to avoid contradiction.

To tackle this challenging issue, we propose a novel method to Mitigate Contradiction via Contrastive Learning, namely MCCL. Our method explicitly perceives the difference between the self-contradiction negative example and semantic-aligned positive example. Instead of utilizing well-labeled contradicting examples (Li et al., 2020), we generate a self-contradiction negative example with a learnable latent noise. To capture contradic-

tion actions, we employ the policy gradient method for rewarding the latent noise based on the feedback from a pre-trained critic. Furthermore, we construct an additional positive example by adding a small perturbation. The positive example has aligned semantic with the original context, which devotes to the training stability and robustness.

Overall, our contributions are summarized as follows: 1) To mitigate contradictions in dialogue, we propose a novel method named MCCL, which contrasts target response with negative pairs, to make chatbot models discriminate and refrain from contradictory response patterns. 2) Experiment results show that our method performs better than baselines in automatic metrics and manual evaluation, especially in contradiction score.

2 Related work

2.1 Consistent Conversation

It has been a long-standing goal of artificial intelligence to build an intelligent conversational system that passes the Turing test (Turing, 1950). Researchers improve chatbots intelligence according to dialogue consistency-related information like style (Wang et al., 2017), topic (Dziri et al., 2019) or persona fact (Zhang et al., 2018). Despite showing improvements in guided response generation based on consistency modeling, the issue of contradiction still remains challenging (Nie et al., 2021).

2.2 Contrastive Learning

The concept of contrastive learning has been widely used adopted in many tasks. SimCLR (Chen et al., 2020) shows that contrastive learning can boost the performance of self-supervised and semi-supervised learning in computer vision tasks. In recent years, contrastive learning has been been widely investigated for many NLP tasks, including language modeling (Gao et al., 2021; Li et al., 2021a), text summarization (Liu and Liu, 2021) and machine translation (Pan et al., 2021).

3 Approach

3.1 Encoder-decoder Architecture

Similar to conventional chatbots model (Roller et al., 2021; Bao et al., 2020), our response generation model employs the encoder-decoder architecture. Given the context history C and target response $Y = (y_1, \dots, y_T)$, the encoder first transforms C into a sequence of hidden representations M. After that, the decoder predicts Y at word level. The decoding process at each time step t can be formalized as follows:

$$\begin{aligned} h_t &= Decoder(M, y_{t-1}) \\ P(y_t|y_{<t}, C) &= softmax(W_d h_t + b_d) \end{aligned} \tag{1}$$

where h_t is the hidden representation of y_t (the t-th word in the response). We maximize the conditional log likelihood for a given N observation $(C^{(i)}, Y^{(i)})_{i=1}^{N}$ as follows:

$$\mathcal{L}_{MLE} = -\sum_{i=1}^{N}\sum_{t=1}^{T} logP(y_t^{(i)}|y_{<t}^{(i)}, C^{(i)}) \tag{2}$$

3.2 Contrastive Learning Framework

In order to tackle the contradiction problem, we exploit contrastive learning framework to expose various incorrect dialogue pairs. Following (Chen et al., 2020), we can train the model to learn the response representation by contrasting the positive pairs with the negative pairs. A straightforward approach is to treat randomly selected responses from different conversations as semantic negative examples (Sinha et al., 2020). Then we have the base contrastive learning objective as follows:

$$\mathcal{L}_c = -\sum_{i=1}^{N} \log \frac{f(M^{(i)}, H^{(i)})}{\sum_{m \in S} f(m, H^{(i)})} \tag{3}$$

where $S = \{M^{(j)}\}_{j=1}^{N}$ is a set of context hidden representations randomly sampled from the same batch, $H = [h_1, ..., h_T]$ is the the concatenation of the hidden representations of the target tokens. The function $f(\cdot, \cdot)$ calculates the correlation between context and response as follows:

$$\begin{aligned} c &= Pool(\phi_x(M)) \\ z &= Pool(\phi_y(H)) \\ f(M, H) &= exp(sim(c, z)/\tau) \end{aligned} \tag{4}$$

where ϕ_x and ϕ_y are two fully connected layers with RELU activation and $Pool$ is the average pooling function, sim is the inner product between two vectors, τ is the temperature hyperparameter. Such contrastive learning objective guides chatbot model to learn a more accurate representation of the target response sequence, by identifying which features make the output positive or negative.

3.3 Self-contradiction Negative Example

However, there is no explicit contradiction relationship between the randomly selected non-aligned context and target response. To expose the chatbot model with a contradiction-related negative example, we learn a latent noise ζ based on the input context. Inspired by (Zhao et al., 2019), we decouple the latent noise learning process from response generation. The latent noise ζ is taken as the form of continuous isotropic Gaussian distribution (Serban et al., 2017). We first determine the distribution of latent noise as follows:

$$\begin{aligned} \mu, log(\sigma^2) &= \pi(M) \\ P(\zeta|M) &= N(\mu, \sigma^2) \end{aligned} \tag{5}$$

where π is a feed forward network that projects M into μ and σ. The contradiction negative context representation $\hat{M}$ is formulated as follows:

$$\hat{M} = M + \epsilon\zeta \tag{6}$$

where ϵ is the balanced factor. After that, we sample a negative response $\hat{Y}$ from the decoder successively using the pseudo-Gibbs Markov chain (Ng et al., 2020). To capture the high-level contradiction action for the multi-turns context, we use the policy gradient theorem (Williams, 1992) to train the latent noise generation network, whose gradient can be estimated as follows:

$$\nabla_{\theta_{la}} J(\theta_{la}) = \mathbb{E}[R \cdot logP(\zeta|M, \theta_{la})] \tag{7}$$

where θ_{la} is the parameters in latent noise generation network, R is contradiction probability between C and $\hat{Y}$ measured by the external critic. We apply a pretrained MNLI [1] (Williams et al., 2018) model as critic in practice. With the help of the perturbed negative representation $\hat{M}$, we can augment the contrastive learning loss as follows:

$$\mathcal{L}_{cn} = -\sum_{i=1}^{N} \log \frac{f(M^{(i)}, H^{(i)})}{\sum_{m \in \{S \cup \hat{M}^{(i)}\}} f(m, H^{(i)})} \tag{8}$$

3.4 Semantic-aligned Positive Example

Moreover, we construct an additional positive example to improve the training robustness with a small, approximately worst-case perturbation. Following (Goodfellow et al., 2015), we obtain a perturbation with the linear approximation and generate our positive example $\tilde{M}$ as follows:

$$\begin{aligned} g &= \nabla_M logP(Y|C) \\ \tilde{M} &= M - \eta\frac{g}{||g||^2} \end{aligned} \tag{9}$$

where η is the balanced hyperparameter. We can argument the contrastive learning loss as follows:

$$\mathcal{L}_{cp} = -\sum_{i=1}^{N} \log \frac{f(\tilde{M}^{(i)}, H^{(i)})}{\sum_{m \in \{S \cup \tilde{M}^{(i)} \cup \hat{M}^{(i)}\}} f(m, H^{(i)})} \tag{10}$$

To ensure the positive examples can have aligned semantic, we also minimize the KL divergence between perturbed conditional distribution and the original conditional distribution as follows:

$$\mathcal{L}_{KL} = \sum_{i=1}^{N} KL[P(Y^{(i)}|M)||P(Y^{(i)}|\tilde{M})] \tag{11}$$

3.5 Training Objective

The overall training objective for the response generation model can be formulated as follows:

$$\mathcal{L}_{tot} = \mathcal{L}_{MLE} + \alpha\{\mathcal{L}_{cn} + \mathcal{L}_{cp}\} + \beta\mathcal{L}_{KL} \tag{12}$$

where α and β are balanced hyperparameters. We alternate the optimization of response generation model and the policy update of latent noise generation network (Lewis et al., 2017).

4 Experiment

4.1 Datasets

BST. (Smith et al., 2020) It is a crowdsourced dataset that blends three dialogue skills (engaging personality, empathy, and knowledge). Each conversation is collected with a guided and unguided human speaker. It contains 76k utterances, each with about 16 tokens on average. We use this dataset to finetune the response generation models.

DECODE. (Nie et al., 2021) This dataset offers a new domain for NLI. It contains human-written dialogues, which are labeled as "contradiction" or "non-contradiction". This dataset has 27,184/4,026/4,216 pairs for train/validation/test. To explore the contradiction situation, we only select the context in contradiction pairs from the validation/test sets, namely *DECODE-C*.

---

[1] `https://huggingface.co/roberta-large-mnli`

4.2 Implement Details

We use the Blender (Roller et al., 2021) as our backbone chatbot model. We choose the 400M-distill version [2], whose hidden dimension is 1,280. We employ Adam to optimize the model parameters, with the learning rate of 1e-5. For contrastive learning, the temperature τ is set as 0.1, the perturbation factor ϵ is set to 0.4 and η is set to 3. For the hyperparameters in the overall objective, We set α as 0.5 and β as 1. During the inference stage, we use beam search of width 10 to generate the target responses. All the methods are trained in 10 epochs with an NVIDIA Tesla V100.

4.3 Baselines

We compare our method against state-of-the-art baselines: **Blender** (Roller et al., 2021): a pretrained model that maximizes log likelihood. **PersonaCat** (Zhang et al., 2018): a method that prepends all possible persona texts to the input message. **R3F** (Aghajanyan et al., 2021): a method that minimizes the negative log likelihood and symmetric KL-divergence. **CLASP** (Lee et al., 2021): a method that minimizes the similarity between the output sequence and adversarial negative sample, which is generated by adding a small perturbation. **LaRL** (Zhao et al., 2019): a flexible latent variable RL-based method that uses the positive consistent score as reward.

4.4 Evaluation Metrics

The evaluation of logical consistent conversation is mainly about two aspects: contradiction performance and text generation metrics. For contradiction performance, we calculate the contradiction score (C.S) following (Nie et al., 2021). We reimplement the structured utterance-based approach, which finetunes the pretrained RoBERTa (Liu et al., 2019) on DECODE training set, to detect contradictions automatically. Our re-implementation achieves accuracy of 92.33% on test set, which is aligned with the reported accuracy 93.19%. The C.S is calculated as follows:

$$C.S = \frac{\sum_{i=1}^{D} P_i}{D} \tag{13}$$

where D denotes the size of test set, P_i is the label of the i_{th} test case (0: non-contradiction, 1: contradiction). To evaluate the fluency and relevance of responses, we adopt PPL (Adiwardana et al., 2020), BLEU-1/2 (Papineni et al., 2002) and Embedding Greedy metrics (E.grd) (Liu et al., 2016).

Table 1: Automatic evaluation results for compared methods in BST dataset. "B" indicates the BLEU metrics. Bold scores are the best overall.

	C.S(%) ↓	B1 ↑	B2 ↑	PPL ↓	E.grd ↑
Blender	13.81	16.13	5.93	10.96	69.04
Persona	12.69	16.27	6.03	10.99	69.00
CLASP	13.13	16.23	5.88	9.97	69.53
R3F	12.23	16.08	5.88	10.58	69.01
LaRL	11.72	16.37	6.12	10.13	69.37
MCCL	**10.88**	16.42	6.09	9.59	**69.93**
naive	11.70	16.30	6.01	9.86	69.41
+ pos	11.64	**16.51**	**6.21**	**9.45**	69.63
+ neg	11.31	16.29	6.08	9.62	69.70

4.5 Results and Analysis

Table.1 shows that our method outperforms all baselines on BST dataset. We also compare with ablation study about contrastive learning objective. **naive** only maximizes the naive objective from Eq 3; **+ pos/neg** utilizes additional positive or negative examples solely. As we can see, the performance of the **naive** model is not outstanding. When we integrate the **pos** module and the **neg** module, the performance achieves the best.

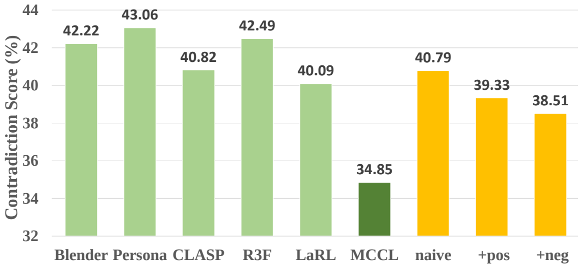

Figure 2: C.S of compared methods on DECODE-C.

Furthermore, MCCL is mainly designed for solving the contradiction problem in dialogue. To verify the effectiveness of the self-contradiction negative component in our method, we take experiment on DECODE-C dataset which is hard for chatbots to generate consistent responses. We only shows the contradiction score since DECODE-C lacks the consistent ground truth while PPL, BLEU and E.grd are reference-based metrics. The results are shown in Fig.2. From this result, we can get some observations. First, our method has a significant advantage (>10%) on contradiction score compared

---

[2] `https://huggingface.co/facebook/blenderbot-400M-distill`

Table 2: Manual Evaluation Comparison results.

	Ours Win(%)	Tie(%)	Ours Lose(%)
Blender	25.3	65.3	9.3
CLASP	32.7	54.0	13.3
R3F	25.3	57.3	17.3

with all baselines. Secondly, we find that Persona model has a high contradiction score. This indicates that only adding personal profile information is not enough to resolve dialogue contradiction problem. Lastly, the ablated methods suffer from the ablations on contradiction score which proves that every component is essential for our method.

We further randomly select 50 conversation examples and ask 3 annotators to compare the contradiction performance. As shown in Table 2, our method performs better than other baselines, which is consistent with automatic evaluation results. The kappa score (Fleiss, 1971) is 0.478, showing moderate agreement between the annotators.

5 Conclusion

In this paper, we propose a new method named MCCL to mitigate the contradiction problem in open domain chatbots. Our method minimizes the similarity between the target response and self-contradiction negative example, and maximizes the similarity with semantic-aligned positive example. Experiment results show that our contrastive loss helps to avoid contradiction and obtain better response generation metrics on two different datasets. In the future, we will investigate how to improve the interpretability of negative examples.

A Appendix

A.1 Case Analysis

Case study is shown in Table 3 and Table 4. The gray text indicates the speaker role. The context history consists of the utterances between two different speakers, interleaving with each other. The chatbot models need to generate the next response for the speaker2. Table 3 shows the case 1. The context talks about the dangers of drinking alcohol. The speaker2 is a sober and claims that he don't drink at all. The baseline chatbots fail to avoid contradiction by talking about the last drinking time. Table 4 shows the case 2. From the context, we can know that the speaker2 is afraid of getting bodily injury in sports. The baseline chatbots generate contradictory responses by speaking "not worried about ...", while there are no contradictions in our response.

A.2 Type of Latent Noise

To generate additional self-contradiction negative example, we add a learnable latent noise to the context representation. The latent noise is optimized based on policy gradient method under the feedback from a MNLI (Williams et al., 2018) model. To verify the effectiveness of our method, we sample a random noise as latent noise from Gaussian distribution. This method can get a contradiction score of 39.82% which is far worse than our model (34.85%). This indicates that the contradiction reward is essential for the generation of self-contradiction negative example.

Table 3: Generated Results 1.

Context	[S2] I don’t drink alcohol at all, I’m all about sobriety. [S1] Thats a good choice. Alcohol is just never the answer for anything. [S2] I agree with you! Sobriety is such a natural state of a human being given at birth. [S1] Yes, unfortunately many mothers drink alcohol during pregnancy which can cause the baby to have some health issue. [S2] Gosh that’s so horrible! my father used to be an alcoholic so i’m pretty traumatized, that’s why i all for sobriety and i want everybody i care about to be sober. [S1] Sorry to hear about your trauma. I once drank alcohol and hit my friend in a drunken rage. I have vowed to be sober since then. [S2] Good for you! Stay sober, my friend! because someone who abstains from alcohol but wants to start drinking again isn’t truly sober. [S1] I suppose that is one way to see it, when was your last drink?
Blender	about a month ago, and i still want to be a part of it but i just don’t want to go through with it.
Persona	about a month ago, but i want to stay sober for as long as possible. i don’t want to relapse.
CLASP	The last time I had a beer was in December of this year. I don’t drink as much now that I’m sober.
R3F	about a month ago, and i’ve been sober for almost a year now. i used to drink all the time, but now i just don’t drink at all.
LaRL	about a month ago, but i’m trying to stay sober for as long as i can.
MCCL	i don’t drink so i can’t say when it was, but i know it’s bad for me.

Table 4: Generated Results 2.

Context	[S1] I was so happy to watch my friend do a backflip [S2] I’ve always been too scared to do a backflip. I always worry I’m going to break my neck or something. Did it take him a long time to get it right?And did he get hurt? [S1] I think he just took gymnastics classes. He luckily did not get hurt! [S2] Oh, that makes sense. And I’m glad to hear that. I always worry about that sort of thing. You ever think about trying to do it netx? [S1] no, i never tried to so it netx. Are you worry about your neck or some of your body parts?
Blender	I’m not too worried about my body parts, but I do worry about my balance.
Persona	I’m not really worried about my body parts, but I do worry about my neck. It’s something that I worry about a lot.
CLASP	I’m not worried about my body parts, I’m more concerned about my neck.
R3F	I’m not really worried about my body parts, but I do worry about my balance.
LaRL	I’m not worried about my body parts, but I do worry about things like my balance, balance, and coordination.
MCCL	I’m not sure what you mean by body parts. Do you mean the bones, organs, and skin?

ELLE: Efficient Lifelong Pre-training for Emerging Data

Abstract

Current pre-trained language models (PLM) are typically trained with static data, ignoring that in real-world scenarios, streaming data of various sources may continuously grow. This requires PLMs to integrate the information from all the sources in a lifelong manner. Although this goal could be achieved by exhaustive pre-training on all the existing data, such a process is known to be computationally expensive. To this end, we propose ELLE, aiming at efficient lifelong pre-training for emerging data. Specifically, ELLE consists of (1) function preserved model expansion, which flexibly expands an existing PLM's width and depth to improve the efficiency of knowledge acquisition; and (2) pre-trained domain prompts, which disentangle the versatile knowledge learned during pre-training and stimulate the proper knowledge for downstream tasks. We experiment ELLE with streaming data from 5 domains on BERT and GPT. The results show the superiority of ELLE over various lifelong learning baselines in both pre-training efficiency and downstream performances. The codes are publicly available at `https://github.com/thunlp/ELLE`.

1 Introduction

Pre-trained language models (PLM) have broken the glass ceiling for various natural language processing (NLP) tasks (Radford et al., 2018; Devlin et al., 2019; Han et al., 2021). However, most of the existing PLMs are typically trained with a static snapshot of the web information, ignoring that in real-world scenarios, streaming data from various sources may continuously grow, e.g., the gatherings of literary works (Zhu et al., 2015), news articles (Zellers et al., 2019) and science papers (Lo et al., 2020). In addition, the distribution of incoming data may also vary over time. This requires PLMs to continually integrate the information from all the sources to grasp the versatile structural and semantic knowledge comprehensively, so that PLMs could utilize the proper knowledge to boost the performance in various downstream tasks.

A simple yet effective way to integrate all the information is to pre-train PLMs on all the existing data exhaustively. However, such a process is computationally expensive (Schwartz et al., 2019), especially under the information explosion era when tremendous data is continually collected. This leaves us an important question: with limited computational resources, how can we efficiently adapt PLMs in a lifelong manner? We formulate it as the *efficient lifelong pre-training* problem. Similar to conventional lifelong learning, PLMs are expected to continually abosrb knowledge from emerging data, and in the meantime, mitigate the catastrophic forgetting (McCloskey and Cohen, 20p) on previously learned knowledge.

In addition, efficient lifelong pre-training poses two new challenges: (1) **efficient knowledge growth**. When the overall data scale accumulates to a certain magnitude, packing more knowledge into a fixed-sized PLM becomes increasingly hard, which significantly impacts the efficiency of PLM's knowledge growth. This is because larger PLMs show superior sample efficiency and training efficiency over their smaller counterparts (Kaplan et al., 2020; Li et al., 2020) due to overparameterization (Arora et al., 2018). That is, larger PLMs learn knowledge in a more efficient way. Therefore,

Findings of the Association for Computational Linguistics: ACL 2022, pages 2789 - 2810
May 22-27, 2022

timely model expansions are essential for efficient knowledge growth; (2) **proper knowledge stimulation**. During pre-training, various knowledge from all domains is packed into PLMs hastily. However, a certain downstream task may largely require the knowledge from a specific domain. Thus it is essential for PLMs to disentangle different kinds of knowledge and properly stimulate the needed knowledge for each task.

In this paper, we propose ELLE, targeting at **E**fficient **L**ife**L**ong pre-training for **E**merging data. Specifically, (1) to facilitate the efficiency of knowledge growth, we propose the **function preserved model expansion** to flexibly expand an existing PLM's width and depth. In this way, we increase PLM's model size and thus improve its training efficiency. Before being adapted to a new domain, the expanded PLM performs a function recovering warmup to regain the functionality of the original PLM; (2) for proper knowledge stimulation, we pre-implant **domain prompts** during pre-training to prime the PLM which kind of knowledge it is learning. Therefore, versatile knowledge from multiple sources can be disentangled. During downstream fine-tuning, we could further utilize these implanted prompts and manipulate the PLM to stimulate the proper knowledge for a specific task.

To demonstrate the effectiveness of ELLE, we simulate the scenario where streaming data from 5 domains sequentially comes. We pre-train two typical PLMs (BERT and GPT) and expand their model sizes each time when the new data is available. We experiment when the number of parameters is sequentially grown from both 30M to 125M and 125M to 355M. The experimental results show the superiority of ELLE over multiple lifelong learning baselines in both pre-training efficiency and downstream task performances. In addition, we conduct sufficient experiments to verify the effectiveness of each component of ELLE. In general, we provide a promising research direction and hope this work could inspire more future attempts towards efficient lifelong pre-training.

2 Related Work

Lifelong Learning for PLMs. Lifelong learning aims at incrementally acquiring new knowledge, and in the meantime, mitigating the catastrophic forgetting issue. Numerous efforts have been spent towards this goal, including (1) memory-based methods (Rebuffi et al., 2017; Rolnick et al., 2019), which perform experience replay with authentic data (de Masson d'Autume et al., 2019), automatically generated data (Sun et al., 2020), or previously computed gradients (Lopez-Paz and Ranzato, 2017) conserved in the memory, (2) consolidation-based methods (Kirkpatrick et al., 2017; Aljundi et al., 2018), which introduce additional regularization terms to consolidate the model parameters that are important to previous tasks, and (3) dynamic architecture methods (Rusu et al., 2016; Yoon et al., 2018), which fix trained network architectures in old tasks and dynamically grow branches for new tasks. Lifelong learning is also a hot topic for PLMs. Some target at domain adaptation through continual pre-training (Gururangan et al., 2020), parameter-efficient adapters (He et al., 2021) and sparse expert models (Gururangan et al., 2021). Others focus on the incremental acquisition of factual knowledge that changes over time (Dhingra et al., 2021; Jang et al., 2021). However, the existing works seldom consider our lifelong learning setting where streaming data from multiple sources is sequentially gathered. Recently, researchers have also conducted a series of empirical studies on the continual learning of PLMs (Wu et al., 2021; Jin et al., 2021).

Efficient Pre-training in NLP. Many attempts have been made towards improving the efficiency of pre-training, such as designing novel pre-training tasks (Clark et al., 2020), model architectures (Zhang and He, 2020), optimization algorithms (You et al., 2020) and parallel architectures (Shoeybi et al., 2019; Shazeer et al., 2018). Until recently, researchers propose to "back distill" the knowledge from existing PLMs to accelerate large PLMs' pre-training (Qin et al., 2021a). Another line of work proposes *progressive training* to dynamically expand an existing PLM's size through parameter recycling (Gong et al., 2019; Gu et al., 2021; Chen et al., 2021). However, these methods typically focus on training PLMs on one static corpus, and thus cannot be directly applied to our lifelong pre-training setting.

3 Methodology

3.1 Preliminaries

Background for PLM. A PLM $\mathcal{M}$ generally consists of an embedding layer and L Transformer (Vaswani et al., 2017) layers. Given an input $\mathbf{x}$ consisting of a series of tokens, i.e.,

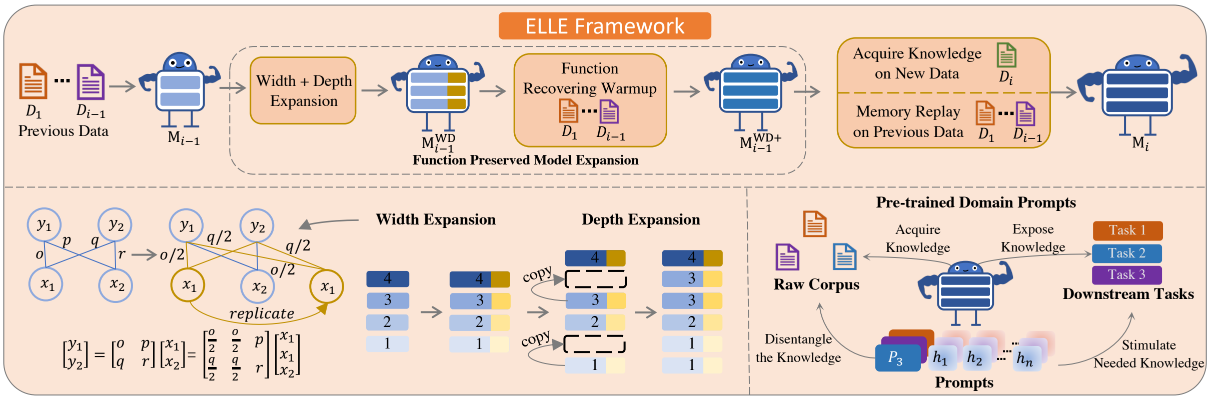

Figure 1: Illustration of ELLE when adapting an existing PLM $\mathcal{M}_{i-1}$ trained on previous data $\overline{\mathcal{D}}_{i-1}$ to a new corpus $\mathcal{D}_i$. We also visualize the mechanism of width / depth expansion and pre-trained domain prompts.

$\mathbf{x} = \{w_1, \ldots, w_{|\mathbf{x}|}\}$, $\mathcal{M}$ first converts the input into embeddings $\{\mathbf{h}_1^0, \ldots, \mathbf{h}_{|\mathbf{x}|}^0\}$, which are sequentially processed by each Transformer layer into contextualized hidden representations $\mathbf{H}^l = \{\mathbf{h}_1^l, \ldots, \mathbf{h}_{|\mathbf{x}|}^l\}$, where $1 \le l \le L$.

Task Definition. Assume a stream of corpus $\overline{\mathcal{D}}_N$ from N domains (e.g., news articles, web content and literary works) is sequentially gathered, i.e., $\overline{\mathcal{D}}_N = \{\mathcal{D}_1, \ldots, \mathcal{D}_N\}$, where $\mathcal{D}_i = \{\mathbf{x}_i^j\}_{j=1}^{|\mathcal{D}_i|}$. The whole training process can be partitioned into several stages. Initially, we have a PLM $\mathcal{M}_1$, which has been well trained on $\mathcal{D}_1$, and for the i-th stage ($i > 1$), we obtain a new collection of data $\mathcal{D}_i$. Assume in this stage, we only have limited computational resources $\mathcal{R}_i$, our goal is to continually pre-train the existing PLM $\mathcal{M}_{i-1}$ to learn new knowledge on $\mathcal{D}_i$, and obtain a new PLM $\mathcal{M}_i$. Meanwhile, we expect the adapted PLM $\mathcal{M}_i$ should not forget the previously learned knowledge of $\overline{\mathcal{D}}_{i-1}$.

Overall Framework. As illustrated in Figure 1, starting from $\mathcal{M}_{i-1}$, which is trained on previous data $\overline{\mathcal{D}}_{i-1}$, we first expand $\mathcal{M}_{i-1}$'s width and depth and construct an enlarged PLM $\mathcal{M}_{i-1}^{\text{WD}}$ to improve its training efficiency. Then we perform function recovering warmup and train $\mathcal{M}_{i-1}^{\text{WD}}$ to inherit the knowledge of $\mathcal{M}_{i-1}$ to obtain $\mathcal{M}_{i-1}^{\text{WD+}}$. The above procedures are dubbed as **function preserved model expansion** (§ 3.2). After that, we continually pre-train $\mathcal{M}_{i-1}^{\text{WD+}}$ to gain new knowledge on $\mathcal{D}_i$. To mitigate the catastrophic forgetting on the previously learned knowledge, we employ data-based memory replay on a subset of previously gathered data $\overline{\mathcal{D}}_{i-1}^{sub} = \{\mathcal{D}_1^{sub}, \ldots, \mathcal{D}_{i-1}^{sub}\}$ conserved in the memory, where $\mathcal{D}_k^{sub} = \{x_k^1, \ldots, x_k^B\} \in \mathcal{D}_k$ ($1 \le k \le i-1$) and B is the constrained memory size for each domain. To help PLMs disentangle the knowledge during pre-training and also stimulate the needed knowledge for each downstream task, we implant **domain prompts** into PLMs during the whole training process (§ 3.3).

3.2 Function Preserved Model Expansion

To accumulate knowledge more efficiently, each time when a new corpus $\mathcal{D}_i$ comes, we expand both $\mathcal{M}_{i-1}$'s width and depth to attain the superior sample efficiency and fast convergence brought by larger model capacity (Li et al., 2020).

Width Expansion. For width expansion, we borrow the function preserving initialization (FPI) from Chen et al. (2021). For a brief introduction, FPI expands the matrices of all modules of a Transformer layer to arbitrary larger sizes and constructs an enlarged PLM $\mathcal{M}_{i-1}^{\text{W}}$. $\mathcal{M}_{i-1}^{\text{W}}$ is initialized using the corresponding matrices of the original $\mathcal{M}_{i-1}$ through parameter replication. For example, as visualized in Figure 1, the core principle of FPI is to divide the product of $o \times x_1$ into multiple partitions, e.g. $\frac{o}{2} \times x_1 + \frac{o}{2} \times x_1$. Formally, FPI expands a matrix $\boldsymbol{W} \in \mathbb{R}^{h_1 \times h_2}$ of $\mathcal{M}_{i-1}$ to an enlarged matrix $\boldsymbol{W}' \in \mathbb{R}^{(h_1 + \Delta_{h_1}) \times h_2}$ of $\mathcal{M}_{i-1}^{\text{W}}$ as follows:

$$
\begin{aligned}
m(i) &= \begin{cases} i & i \in [1, h_1] \\ U(\{1, \ldots, h_1\}) & i \in (h_1, h_1 + \Delta_{h_1}], \end{cases} \\
C_i &= \sum_{i'=1}^{h_1+\Delta_{h_1}} \mathbb{I}(m(i') = m(i)), \\
\boldsymbol{W}'_{(i,*)} &= \frac{1}{C_i} \cdot \boldsymbol{W}_{(m(i),*)} + \mathbb{I}(C_i > 1) \cdot \boldsymbol{\delta}_i,
\end{aligned}
\tag{1}
$$

where $U(\cdot)$ denotes a uniform sampling function, $m(\cdot)$ denotes the mapping function between two matrices, $\mathbb{I}(\cdot)$ is an indicator function, C_i counts how many partitions a specific neuron is splitted and $\boldsymbol{\delta}_i \in \mathbb{R}^{h_2}$ is a random gaussian noise. FPI ensures that both $\mathcal{M}_{i-1}^{\mathrm{W}}$ and $\mathcal{M}_{i-1}$ have approximately the same functionality, i.e., both models have almost the same output given the same input. Besides function preservation, the initialized model could serve as a good starting point for further optimization. We refer readers to Chen et al. (2021) for more details about width expansion. Different from Chen et al. (2021), we additionally introduce random noises $\boldsymbol{\delta}_i$ into the newly copied parameters of $\boldsymbol{W}'$ during initialization. These slight noises would break the symmetry after the replication and accelerate later pre-training.

Depth Expansion. For depth expansion, previous works generally resort to stacking all the original PLM layers into $2\times$ layers through parameter replication (Gong et al., 2019). Such initialization is demonstrated to improve training efficiency.

However, the above *layer stacking* method restricts the number of layers of the enlarged PLM $\mathcal{M}_{i-1}^{\mathrm{D}}$ to be integer multiples of that of the original PLM $\mathcal{M}_{i-1}$, which is not flexible for practical uses. To improve the expansion flexibility so that $\mathcal{M}_{i-1}$ could be expanded with arbitrary number of layers, we propose a novel *layer insertion* method to construct a new PLM $\mathcal{M}_{i-1}^{\mathrm{D}}$ with $L + L'$ layers, where $1 \leq L' \leq L$. Specifically, we randomly select L' layers from $\mathcal{M}_{i-1}$, copy each layer's parameters and insert the replication layer right before / after the original layer. We found empirically that inserting the copied layer into other positions would cause a performance drop, and the reason is that it will violate the processing order of the original layer sequence and break the PLM's original functionality. At each expansion stage when new data comes, since different layers have different functionalities, we always choose those layers that have not been copied before to help PLMs develop in an all-around way, instead of just developing a certain kind of functionality. Since both width expansion and depth expansion are compatible with each other, we simultaneously expand both of them to construct an enlarged model $\mathcal{M}_{i-1}^{\mathrm{WD}}$, which inherits $\mathcal{M}_{i-1}$'s knowledge contained in the parameters.

Function Recovering Warmup. Since the above model expansion cannot ensure exact function preservation and inevitably results in functionality loss and performance drops, we pre-train the initialized PLM $\mathcal{M}_{i-1}^{\mathrm{WD}}$ on the previous corpora $\overline{\mathcal{D}}_{i-1}^{sub}$ conserved in the memory to recover the language abilities lost during model expansion, which is dubbed as function recovering warmup (FRW). After the warmup, we obtain $\mathcal{M}_{i-1}^{\mathrm{WD+}}$, which successfully inherits the knowledge from $\mathcal{M}_{i-1}$ and is also well-prepared for the next training stage.

3.3 Pre-trained Domain Prompt

Instead of training a separate model for each domain, we expect a single compact PLM to integrate the knowledge from all the sources. When confronted with a downstream task from a specific domain, the PLM needs to expose the proper knowledge learned during pre-training. To facilitate both knowledge acquisition during pre-training and knowledge exposure during fine-tuning, we resort to prompts as domain indicators and condition the PLM's behavior on these prompts. Soft prompts have been demonstrated excellent task indicators (Qin et al., 2021b) and have non-trivial transferability among tasks (Su et al., 2021).

Specifically, during pre-training, to disentangle the knowledge from different sources, we implant a soft prompt token into the input to prime the PLM which kind of knowledge it is learning. The prompt of domain i is a tunable vector $\mathbf{p}_i$. We prepend $\mathbf{p}_i$ before the original token embeddings $\mathbf{H}^0 = \{\mathbf{h}_1^0, \ldots, \mathbf{h}_{|\mathbf{x}|}^0\}$ for an input $\mathbf{x} \in \mathcal{D}_i$, resulting in the modified input $\mathbf{H}^{0*} = \{\mathbf{p}_i; \mathbf{h}_1^0, \ldots, \mathbf{h}_{|\mathbf{x}|}^0\}$, which is then processed by all the Transformer layers. Each $\mathbf{p}_i$ is optimized together with other parameters of the PLM during pre-training. During fine-tuning, when applying the PLM on a similar domain of data seen before, we could leverage the trained domain prompt and prepend it before the input of downstream data. In this way, we manually manipulate the PLM to stimulate the most relevant knowledge learned during pre-training.

4 Experiments

4.1 Experimental Setting

Data Streams. We simulate the scenario where streaming data from 5 domains is gathered sequentially, i.e., the concatenation of WIKIPEDIA and BOOKCORPUS (WB) (Zhu et al., 2015), NEWS ARTICLES (NS) (Zellers et al., 2019), AMAZON REVIEWS (REV) (He and McAuley, 2016), BIOMEDICAL PAPERS (BIO) (Lo et al., 2020) and COMPUTER SCIENCE PAPERS (CS) (Lo et al., 2020). For each corpus $\mathcal{D}_i$, we roughly sample $3,400$M tokens, and the quantity for each $\mathcal{D}_i$ $(1 \leq i \leq 5)$ is comparable to the pre-training data

Table 1: Average perplexity (AP) and average increased perplexity (AP$^+$) of PLMs trained by different lifelong learning methods with the same train wall time. PLMs are trained with streaming data from WB, NS, REV, BIO and CS domain sequentially. We evaluate the performance each time when PLMs finish training on one domain.

of BERT (Devlin et al., 2019). In addition, considering that in practice, the expense of storage is far cheaper than the computational resources for pre-training, we maintain a relatively large memory compared with conventional lifelong learning settings by randomly sampling 200M tokens ($\mathcal{D}_i^{sub}$) for each corpus $\mathcal{D}_i$.

Evaluated Models. We mainly follow the model architectures of BERT and GPT (Radford et al., 2018). We use byte-level BPE vocabulary to ensure there are few unknown tokens in each corpus. We experiment with the initial PLM $\mathcal{M}_1$ of 6 layers and hidden size of 384 (around 30M parameters, denoted as BERT$_{L6\_D384}$ / GPT$_{L6\_D384}$), and linearly enlarge the PLM's number of parameters for 4 times, to the final PLM $\mathcal{M}_5$ of 12 layers and hidden size of 768 (around 125M parameters, denoted as BERT$_{L12\_D768}$ / GPT$_{L12\_D768}$). We also experiment on a larger model size, i.e., growing the PLM from BERT$_{L12\_D768}$ (125M) to BERT$_{L24\_D1024}$ (355M). Details of each $\mathcal{M}_i$'s architecture are listed in appendix B. We also discuss the effect of expanded model size at each stage in appendix A.

Training Details. We train our model for $62,500$ steps for the first corpus. For the following domain i ($i > 1$), after the model expansion, we perform function recovering warmup for $5,000$ steps, then train the resulting PLM for $20,000$ steps on the new data together with memory replay. Following Chaudhry et al. (2019b), we jointly train PLMs on a mixture samples from both $\mathcal{D}_i$ and $\overline{\mathcal{D}}_{i-1}^{sub}$ in each batch, and the sampling ratio of $\mathcal{D}_i$ and $\overline{\mathcal{D}}_{i-1}^{sub}$ is set to $9:1$ in every batch. Adam (Kingma and Ba, 2015) is chosen as the optimizer. All the experiments are conducted under the same environment of 8 V100 GPUs with a batch size of $2,048$. More training details of pre-training are left in appendix B. We also experiment with fewer computational budgets and memory budgets in appendix G, and find that within a reasonable range, both of the two factors would not significantly influence the performance of ELLE.

Evaluation Metrics. We deem one algorithm to be more efficient if it could achieve the same performance with other methods utilizing fewer computations. For PLM, this is equivalent to achieving better performance using the same computations since pre-training with more computations almost always results in better performance (Clark et al., 2020). We evaluate the PLM's performance during both pre-training and downstream fine-tuning.

Specifically, for pre-training, we propose two metrics to evaluate how PLMs perform on the learned domains following Chaudhry et al. (2019a): (1) average perplexity (AP) and (2) average increased perplexity (AP$^+$). We record the train wall time (Li et al., 2020) during pre-training. For a model checkpoint at time step T when learning the j-th domain, we measure the checkpoint's per-

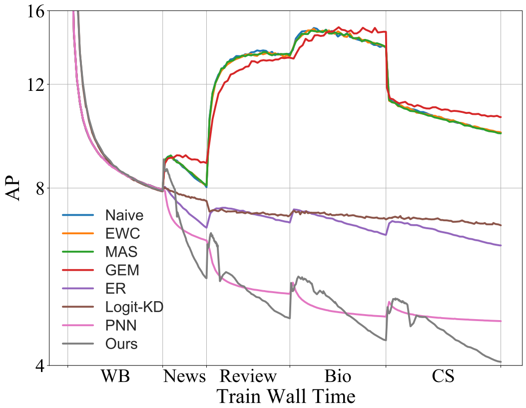

Figure 2: Average perplexity (AP) of different lifelong learning methods with $\text{BERT}_{\text{L6\_D384}}$ as the initial PLM. The trend curves for AP^+ and other PLMs are left in appendix D.

plexity $\text{PPL}_{T,i}$ on the validation set of each domain i. Let $\text{PPL}^f_{i,i}$ be the perplexity on the i-th domain when the PLM finishes training on the i-th domain, the above metrics are calculated as follows:

$$\begin{aligned} \text{AP} &= \exp\left(\frac{1}{j}\sum_{i=1}^{j}\log \text{PPL}_{T,i}\right), \\ \text{AP}^+ &= \frac{1}{j-1}\sum_{i=1}^{j-1}(\text{PPL}_{T,i} - \text{PPL}^f_{i,i}), \end{aligned} \tag{2}$$

where AP measures the average performance on all the seen data $\{\mathcal{D}_1, \ldots, \mathcal{D}_j\}$. Lower AP indicates the PLM generally learns more knowledge from existing domains; AP^+ measures the influence of current data $\mathcal{D}_j$ on previous data $\overline{\mathcal{D}}_{j-1}$. Lower AP^+ means PLMs forget less knowledge learned before.

To evaluate PLMs' performance in downstream tasks, for each domain, we select a representative task that is relatively stable, i.e., MNLI (Williams et al., 2018), HYPERPARTISAN (Kiesel et al., 2019), HELPFULLNESS (McAuley et al., 2015), CHEMPROT (Kringelum et al., 2016) and ACL-ARC (Jurgens et al., 2018) for WB, NS, REV, BIO and CS, respectively. Training details for fine-tuning are left in appendix C.

Baselines. Keeping most of the experimental settings the same, we choose the following baselines for comparison: (1) **Naive**, which is a naive extension of Gururangan et al. (2020) to continually adapt PLMs for each domain and can be seen as the lower bound; (2) **EWC** (Schwarz et al., 2018), which adopts elastic weight consolidation to add L_2 regularization on parameter changes; (3) **MAS** (Aljundi et al., 2018), which estimates parameter importance via the gradients of the model outputs; (4) **ER** (Chaudhry et al., 2019b), which alleviates forgetting by jointly training models on a mixture samples from new data $\mathcal{D}_i$ and the memory $\overline{\mathcal{D}}^{sub}_{i-1}$. ELLE is based on ER and additionally introduces the model expansion and pre-trained domain prompts. For ER, we set the sampling ratio of $\mathcal{D}_i$ and $\overline{\mathcal{D}}^{sub}_{i-1}$ to be $9:1$ in every batch same as ELLE; (5) **A-GEM** (Chaudhry et al., 2019a), which constrains the new parameter gradients to make sure that optimization directions do not conflict with gradients on old domains; (6) **Logit-KD**, which prevents forgetting by distilling knowledge from the previous model $\mathcal{M}_{i-1}$ using the old data in the memory; (7) **PNN** (Rusu et al., 2016), which fixes the old PLM $\mathcal{M}_{i-1}$ to completely avoid knowledge forgetting and grows new branches for learning new knowledge. For a fair comparison, we control the total train wall time of ELLE and all the baselines to be the same at each training stage, so that each method consumes the same computational costs.

Table 2: Final downstream performance (F1) of BERT on each domain after finishing pre-training on all domains. Experiments of NS domain are repeated for 10 times with different seeds and others are repeated for 5 times. More detailed results at different pre-training stages are illustrated in appendix C.

4.2 Main Results

Table 1 summarizes the pre-training performance each time when the PLM finishes training on a specific domain. Figure 2 depicts the trend of AP for BERT w.r.t. train wall time, other trend curves are illustrated in appendix D. We also report the final downstream performance for discriminative PLMs (BERT) on each domain after finishing the whole pre-training in Table 2. The intermediate downstream performance each time when the PLM finishes training on one domain is left in appendix C.

Table 3: AP and AP^+ of different combinations of strategies when growing $\text{BERT}_{\text{L6\_D384}}$ to $\text{BERT}_{\text{L12\_D768}}$.

Superiority of ELLE. (1) From the results in Table 1, we observe that, compared with all the baselines, ELLE achieves the lowest AP and satisfying AP^+ after finishing training on each domain. This demonstrates that, given limited computational resources, ELLE could acquire more knowledge and in the meantime, mitigate the knowledge forgetting problem. (2) We also observe from Figure 2 that the AP of ELLE descends the fastest, showing the superior training efficiency of ELLE over all baselines. (3) Besides, ELLE performs the best on all downstream tasks, indicating that the knowledge learned during pre-training could be properly stimulated and leveraged for each downstream task. (4) The superiority of ELLE is consistently observed on the larger model size, i.e., $\text{BERT}_{\text{L24\_D1024}}$ and other model architectures, i.e., $\text{GPT}_{\text{L12\_D768}}$. This shows that ELLE is agnostic to both the model size and the specific PLM model architecture chosen. We expect future work to apply ELLE on other PLM architectures and extremely large PLMs.

Comparisons with Baselines. (1) First of all, consolidation-based methods (EWC and MAS) perform almost comparable with the naive baseline in either pre-training or downstream tasks. This means that parameter regularization may not be beneficial for PLMs' knowledge acquisition. (2) Among memory-based methods, gradient-based reaply (A-GEM) exhibits poorer performance in pre-training, on the contrary, data-based replay (ER and Logit-KD) achieve lower AP and AP^+ than the naive baseline, demonstrating that replaying real data points could more efficiently mitigate the knowledge forgetting problem. Meanwhile, all of the memory-based methods perform comparable or worse than the naive baseline in downstream performance. (3) PNN achieves significantly lower AP than non-progressive baselines, and is immune to knowledge forgetting ($\text{AP}^+ = 0$). It also performs better on the downstream tasks than other baselines. This indicates that enlarging the network is an effective way for lifelong pre-training and also benefits downstream tasks.

5 Analysis

In this section, we conduct analyses to investigate the effect of ELLE's components. We follow the setting in § 4 by choosing $\text{BERT}_{\text{L6\_D384}}$ as the initial model and continually growing it to $\text{BERT}_{\text{L12\_D768}}$. Specifically, we investigate the effect of (1) width expansion (WE), (2) depth expansion (DE), (3) function recovering warmup (FRW), (4) the random noises added into the newly constructed parameters during model expansion (δ_N) and (5) the pre-trained domain prompts (PT). We test ELLE under different combinations of the above components and compare the results. The experimental results of pre-training and downstream tasks are summarized in Table 3 and Table 4, respectively. Detailed trend curves for AP and AP^+ are illustrated in appendix D.

Effect of Width / Depth Expansion. First, we compare the differences of conducting only width expansion (WE+FRW), only depth expansion (DE+FRW) and expansion on both width and depth (WE+DE+FRW) before function preserving warmup. For a fair comparison, we keep the total number of $\mathcal{M}_i$'s increased parameters for the above three strategies almost the same at each stage i. The specific model architectures are listed in appendix F. The results show that: (1) compared with the non-expanding baseline, all these three strategies achieve better pre-training and downstream performance, showing that with the growth of model size, the sample efficiency and training efficiency are extensively increased. Therefore, PLMs could gain more knowledge with limited computational resources and perform better in downstream tasks; (2) compared with expanding only width or depth, expanding both of them is

Table 4: $\text{BERT}_{\text{L12\_D768}}$'s downstream performance (F1) on each domain after being continually pre-trained on all domains with different combinations of strategies.

more efficient and can also achieve better downstream performance on almost all domains, except the Ns domain. This is also aligned with previous findings that PLM's growth favors compound scaling (Gu et al., 2021). We also conclude from the trend curves in appendix D that only expanding depth will make the training process unstable.

Effect of Function Recovering Warmup. We compare the performance of the model expansion w/ and w/o FRW, i.e., WE+DE and WE+DE+FRW. For a fair comparison, we keep the total train wall time for either strategy the same, in other words, for WE+DE, PLMs can be trained for more steps on the new domain due to the removal of FRW. However, the results show that WE+DE achieves worse AP and AP^+, indicating that without FRW, PLM would learn new knowledge slower and also forget more previous knowledge. The trend curve in appendix D also shows that AP and AP^+ decrease faster with FRW. This demonstrates the necessity of the warmup after model expansion, i.e., PLMs could better recover the knowledge lost during model expansion and also get prepared for learning new knowledge. Meanwhile, WE+DE+FRW performs slightly better than WE+DE in most of the downstream tasks, except the Ns domain.

Effect of Random Noises. Different from the original FPI (Chen et al., 2021), ELLE additionally adds random noises into the newly copied parameters after expanding the width of PLMs as mentioned in § 3.2. By comparing the model performance w/ and w/o this trick, i.e., WE+DE+FRW and WE+DE+FRW+δ_N, we can see that the added noises significantly speed up pre-training and also conduce to improving PLM's overall downstream performance. This validates our hypothesis that random noises are useful for breaking the symmetry of the copied parameters, thus providing a better initialization that further optimization favors.

Table 5: $\text{BERT}_{\text{L12\_D768}}$'s downstream performance (F1) on each domain when no prompt / a wrong prompt is prepended in the input.

Effect of Pre-trained Domain Prompts. To investigate the effect of pre-trained domain prompts, we first compare the performance w/ and w/o them, i.e., WE+DE+FRW+δ_N and WE+DE+FRW+δ_N+PT. From the results we can conclude that when aided with domain prompts, PLMs achieve lower AP and AP^+ during pre-training, showing that domain prompts could accelerate pre-training and alleviate catastrophic forgetting by disentangling the knowledge from different sources. Furthermore, domain prompts generally improve downstream performance by stimulating the proper knowledge needed for each task.

To rigorously investigate how domain prompts stimulate the knowledge during fine-tuning, for a PLM pre-implanted with prompts during pre-training, we test its downstream performance when (1) no prompt is prepended in the input (i.e., ELLE-$\text{PT}_{\text{fine-tune}}$) during fine-tuning and (2) a prompt from a random wrong domain is prepended in the input (i.e., ELLE + $\neg\text{PT}_{\text{fine-tune}}$). The results in Table 5 show that both of the above strategies have lower downstream performance than prepending the right prompt (ELLE). We hypothesize the reasons are two-fold: (1) firstly, for ELLE- $\text{PT}_{\text{fine-tune}}$, there exists a great gap between the formats of input during pre-training and fine-tuning, and such a gap would hinder the successful knowledge transfer; (2) secondly, for ELLE + $\neg\text{PT}_{\text{fine-tune}}$, although the above gap disappears, the PLM is primed with a wrong domain prompt, and thus cannot properly stimulate the knowledge that is most relevant to the downstream task. Although manually deciding the most relevant domain prompt for a specific downstream task is relatively easy and fast, such a process can also be automated by training a domain discriminator, which is left as future work.

Attention Pattern Visualization of a Stream of PLMs. Through the function preserved model expansion, PLMs inherit the knowledge of their "ancestors" contained in the parameters. Intuitively,

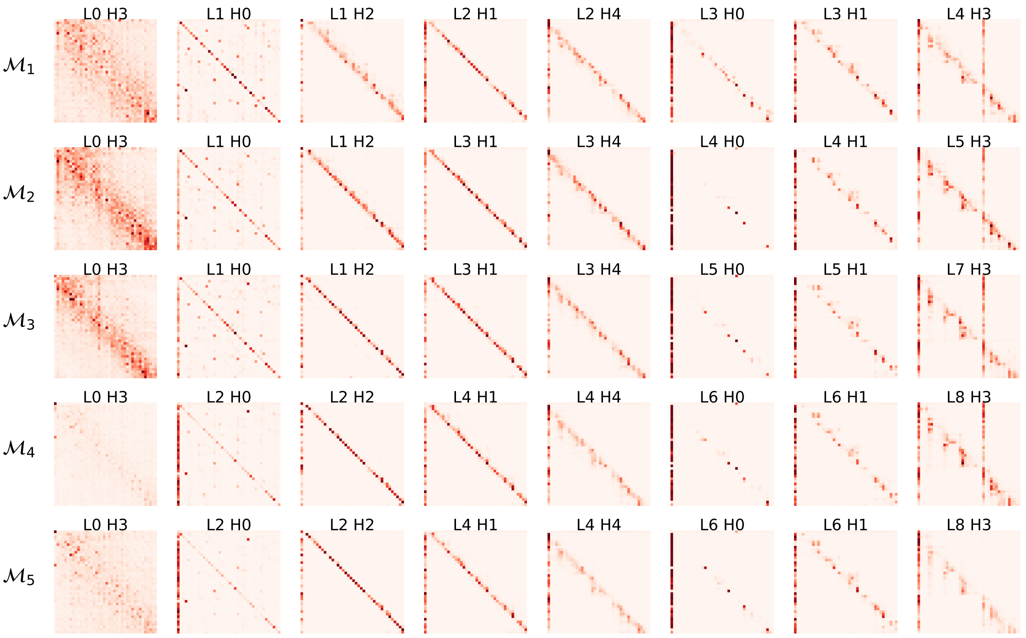

Figure 3: The visualization of the attention patterns of different attention heads in $\mathcal{M}_1$ (BERT$_{\text{L6\_D384}}$), $\mathcal{M}_2$ (BERT$_{\text{L8\_D512}}$), $\mathcal{M}_3$ (BERT$_{\text{L10\_D640}}$), $\mathcal{M}_4$ (BERT$_{\text{L11\_D708}}$) and $\mathcal{M}_5$ (BERT$_{\text{L12\_D768}}$) after finishing training on the new corpus $\mathcal{D}_i$. Note that in this figure, all the attention heads of a PLM $\mathcal{M}_i$ are expanded from all its ancestors $\{\mathcal{M}_1, \ldots, \mathcal{M}_{i-1}\}$ in the same column. We observe similar attention patterns between the descendant PLM and the ancestor PLM, demonstrating the descendant PLM successfully preserves the functionality of its ancestors.

the descendant PLM (the expanded larger PLM) should have similar functionalities to the ancestor PLM (the original PLM before model expansion). We thus investigate such functionality similarity through the lens of attention patterns of each attention head in the Transformer layer.

Specifically, we visualize the attention patterns of a stream of PLMs ($\{\mathcal{M}_1, \ldots, \mathcal{M}_5\}$) trained by ELLE when growing from BERT$_{\text{L6\_D384}}$ to BERT$_{\text{L12\_D768}}$. We checkpoint each PLM $\mathcal{M}_i$ when it finishes training on the emerging data $\mathcal{D}_i$. We input the same data into these checkpoints to derive the attention patterns. The results are illustrated in Figure 3, from which we observe that the attention patterns of a head in a descendant PLM are surprisingly similar to those of its "ancestors", even if the descendant PLM is further trained on the new data and enlarged many times. This indicates that the expanded PLM by ELLE successfully inherits the knowledge from its "ancestor", and thus exhibits similar functionality to some extent.

6 Conclusion

In this paper, we present the efficient lifelong pre-training problem, which requires PLMs to continually integrate the information from emerging data efficiently. To achieve our goal, we propose ELLE and progressively expand PLMs to acquire knowledge efficiently and mitigate the knowledge forgetting. We also pre-implant domain prompts during pre-training and use them to stimulate the needed knowledge for downstream tasks. The experimental results show the superiority of ELLE over various lifelong learning baselines in both pre-training efficiency and downstream performances.

Appendices

A Additional Analysis on Function Preserved Model Expansion

In addition to the analyses of function preserved model expansion conducted in our main paper, in this section, we further analyze the effect of (1) the expanded model size at each training stage and (2) the choice of copied layer during depth expansion. We experiment on the combination of WE+DE+FRW as mentioned in § 5 and choose $\text{BERT}_{\text{L6\_D384}}$ as the initial PLM $\mathcal{M}_1$. Other settings are kept the same as § 5.

Effect of Expanded Model Size. In our main experiments, we assume that the data size of each emerging corpus is the same and linearly enlarge the model size when conducting model expansion. In this section, we explore the effect of expanded model size given limited computational resources. We conduct experiments on a stream of data from 3 domains, i.e., WB, NS and REV domain. We start from the initial PLM $\text{BERT}_{\text{L6\_D384}}$ and continually adapt it to new corpora. Under the same training environment, we control the computational costs (train wall time) of each domain to be 7200 seconds. We compare the performances when the PLM expands 0, 2, 4, and 6 layers and heads for each domain, respectively. Note the PLMs expanded with a larger size would be trained with fewer steps to control the train wall time.

The results are shown in Table 6, from which we can conclude that the best performance is obtained when the model expands 2 layers and heads at each expansion stage, and expanding more or fewer parameters leads to a performance drop. The reasons are two-fold: (1) firstly, as mentioned before, expanding the model size improves the sample efficiency (Kaplan et al., 2020; Li et al., 2020), which is beneficial for PLMs' knowledge acquisition; (2) secondly, when increasing the expanded model size, the benefits from inheriting the knowledge of a small PLM would become less and less evident. To sum up, expanding with an intermediate size strikes the best trade-off between the above two reasons, and there may exist an optimal expanded size when performing model expansion.

Intuitively, the optimal expanded model size may be influenced by many factors, e.g., the computational budgets, the amount of emerging data, the PLM's model architecture, etc. And systematically analyzing the effects of all these factors is beyond the scope of this paper, thus we expect future works to design algorithms to accurately estimate the optimal expanded size for model expansion.

Choice of Copied Layer. As mentioned in § 3.2, each time when we conduct width expansion, we choose those layers that have not been copied before. To demonstrate the benefit of this trick, we compare three expansion strategies: (1) always replicating those layers that have not been copied before (WE+DE+FRW); (2) always replicating the first layer ($\text{WE+DE}_{\text{first}}\text{+FRW}$) and (3) always replicating the last layer ($\text{WE+DE}_{\text{last}}\text{+FRW}$).

The results in Figure 4 show that AP and AP^+ descend the fastest when we always replicate those layers that have not been copied before (i.e., WE+DE+FRW). This demonstrates that, since different layers have different functionalities, choosing those layers that have not been expanded before would help PLMs develop in an all-around way, instead of just developing a certain kind of functionality. Furthermore, we find empirically that when pre-training PLMs continually on multiple domains, if we always choose those layers that have not been expanded before at each depth expansion stage, then the final performance is not sensitive to choosing which layers to expand first.

B Pre-training Hyper-parameters

In Table 7, we list the architectures and the hyper-parameters for the PLMs we pre-trained with ELLE in this paper, including the total number of trainable parameters (n_{params}), the number of layers (n_{layers}), the number of units in each bottleneck layer (d_{model}), the number of attention heads (n_{heads}), the inner hidden size of FFN layer (d_{FFN}), the learning rate (lr), the training steps of FRW (SF), the training steps of adaptation after FRW (STF) when learning the new corpus, the ratio of learning rate warmup (RW), and the total train wall time (TWT). We set the dropout rate for each model to 0.1, weight decay to 0.01 and use linear learning rate decay for BERT and inverse square root decay for GPT. We adopt Adam (Kingma and Ba, 2015) as the optimizer. The hyper-parameters for the optimizer is set to $1 \times 10^{-6}, 0.9, 0.98$ for $\epsilon, \beta_1, \beta_2$, respectively. We reset the optimizer and the learning rate scheduler each time when the PLM finishes FRW or the training on new corpus. All experiments are conducted under the same computation environment with 8 NVIDIA 32GB V100 GPUs. All the pre-training implementations are based on

Domain	WB		News		Review	
Metrics	AP	AP^+	AP	AP^+	AP	AP^+

Table 8: Hyper-parameters for fine-tuning on downstream tasks of each domain. As mentioned in the main paper, for each domain, we select a representative task that is relatively stable, i.e., MNLI (Williams et al., 2018), HyperPartisan (Kiesel et al., 2019), Helpfullness (McAuley et al., 2015), ChemProt (Kringelum et al., 2016) and ACL-ARC (Jurgens et al., 2018) for WB, Ns, Rev, Bio and CS, respectively.

C Implementation Details and Additional Experiments for Downstream Fine-tuning

Implementation Details. Table 8 describes the hyper-parameters for fine-tuning PLMs on downstream tasks of each domain. The implementations of MNLI are based on `fairseq`[2] (Ott et al., 2019) (MIT-license). The implementations of HyperPartisan, Helpfulness ChemProt, and ACL-ARC are based on (Gururangan et al., 2020)[3].

Additional Experiments. Figure 5 visualizes the specific F1 on each downstream tasks and the average F1 of PLMs trained with Naive, A-GEM, EWC, MAS, ER, Logit-KD, PNN and ELLE after finishing training on each domain when we choose $\text{BERT}_{\text{L6\_D384}}$ as the initial PLM $\mathcal{M}_1$. The average F1 when finishing training on the i-th domain is calculated as follows:

$$\text{F1}^{i}_{avg} = \frac{1}{N}\sum_{j=1}^{N} \text{F1}^{j}_{\mathcal{M}_i} \tag{3}$$

where $\text{F1}^{j}_{\mathcal{M}_i}$ is the F1 score of $\mathcal{M}_i$ evaluated on the downstream task of the j-th domain. We also list the detailed numerical results for each task in Table 9, covering all PLMs trained by each lifelong learning method.

The results show that ELLE outperforms all the lifelong learning baselines after finishing training on each domain, demonstrating that ELLE could properly stimulate the learned knowledge during pre-training and boost the performance in downstream tasks.

D Trend Curves for AP and AP$^+$

For the experiments in § 4, the trend curves of average perplexity (AP) and average increased perplexity (AP$^+$) w.r.t train wall time are shown in Figure 7 (growing from $\text{BERT}_{\text{L6\_D384}}$ to $\text{BERT}_{\text{L12\_D768}}$), Figure 8 (growing from $\text{BERT}_{\text{L12\_D768}}$ to $\text{BERT}_{\text{L24\_D1024}}$), and Figure 9 (growing from $\text{GPT}_{\text{L6\_D384}}$ to $\text{GPT}_{\text{L12\_D768}}$). Each figure illustrates the performance of different lifelong learning methods. The above results reflect that, compared with all the baselines, AP and AP$^+$ of ELLE descend with the fastest speed, demonstrating that ELLE could acquire knowledge and mitigate the knowledge forgetting on previous domains more efficiently. Thus given limited computational resources, PLMs trained by ELLE could integrate more information from different domains.

For the analysis in § 5, we visualize the trend curves of AP and AP$^+$ when choosing different combinations of strategies. Specifically, we investigate (1) the effect of width / depth expansion in Figure 10 (comparing WE+FRW, DE+FRW and WE+DE+FRW); (2) the effect of function recovering warmup in Figure 11 (comparing WE+DE and WE+DE+FRW); (3) the effect of random noises added into the newly initialized parameters during model expansion in Figure 11 (comparing WE+DE+FRW and WE+DE+FRW+δ_N) and (4) the effect of pre-trained domain prompts in Figure 12 (comparing ELLE and ELLE-PT). All of the above results again demonstrate the effectiveness of ELLE's each component.

E Representational Similarity of a Stream of PLMs

We investigate the representational similarity (Abnar et al., 2019) of a descendant PLM and its ancestors. Representational similarity measures how similar two PLMs represent the data. Specifically,

Table 11: Final downstream performance (F1) of BERT on each domain after finishing pre-training on all domains with half train wall time on Ns, Rev, Bio, CS domains and smaller memory containing 34M tokens for each domain. Experiments of Ns domain are repeated for 10 times with different seeds and others are repeated for 5 times.

where KL denotes the Kullback-Leibler divergence between two probability distributions. Higher ARS$_j$ means the representations of $\mathcal{M}_j$ and its ancestors are more similar. To some extent, ARS$_j$ could reflect how much knowledge / functionality of the ancestors is preserved by $\mathcal{M}_j$.

We compare ARS of PLMs trained by Naive, MAS, ER, Logit-KD and ELLE and illustrate the results in Figure 6, from which we observe that Logit-KD has the highest ARS. This is because the training objective of knowledge distillation in Logit-KD is highly correlated with ARS. In addition, ELLE takes second place. We also find that, with PLMs continually absorbing new knowledge, the ASR generally decreases.

F Model Architectures for the Analysis of Model Expansion

In Table 12, we list the model architectures of all the investigated PLMs when conducting analysis of model expansion in § 5. Specifically, three strategies are investigated, including WE+FRW, DE+FRW and WE+DE+FRW. As mentioned in our main paper, for a fair comparison, we keep the total number of $\mathcal{M}_i$'s increased parameters for the above three strategies almost the same at each stage i.

G Performance of ELLE with Fewer Computational Budgets and Storage Budgets

To investigate the performance of ELLE under limited (1) computational budgets and (2) storage budgets, in this section, we take an initial step to investigate the effect of (1) training resources (train

Model	n_{params}	n_{layers}	d_{model}	n_{heads}	d_{FFN}	lr

wall time) and (2) memory size for ELLE. Following the experimental setting in § 4, we continually grow $\text{BERT}_{\text{L6\_D384}}$ to $\text{BERT}_{\text{L12\_D768}}$ on a stream of data from 5 domains. We test the performance of ELLE and a series of lifelong learning baselines (MAS, ER, Logit-KD and PNN), by (1) reducing the train wall time by half (for NS, REV, BIO and CS domain) and (2) randomly sample only 34M tokens (1% of the full corpus) as the memory $\mathcal{D}_i^{sub}$ for each corpus i, compared with the memory size 200M in § 4.

The experimental results for the above two settings are listed in Table 10 (pre-training) and Table 11 (fine-tuning), respectively. We also illustrate the trend curves of AP and AP^+ in Figure 13 and Figure 14. From the above results, we find that: (1) when given fewer computational budgets and storage budgets, ELLE still outperforms all the lifelong learning baselines in both pre-training and downstream performance, which demonstrates the superiority of ELLE; (2) for ELLE, when PLMs are trained with fewer computational budgets, we observe significant performance drops in both pre-training (higher AP and AP^+) and downstream tasks (lower average F1). This shows that pre-training with fewer computations would harm PLMs' knowledge acquisition; (3) for ELLE, when there are fewer memory budgets, although we also observe slight performance drops in pre-training (higher AP and AP^+), the performance in downstream tasks is generally not influenced, with the average F1 score keeping almost the same (77.8). This shows the **data-efficiency** of PLMs, i.e., PLMs could easily recall the learned knowledge by reviewing small-scale data conserved in the memory (as few as 1%). As mentioned before, considering that for pre-training, the expense of storage (e.g., hard disks) is far cheaper than the computational resources (e.g., GPUs), the storage space problem for memory seldom needs to be considered.

H Details of Baselines

We tried different hyper-parameters for baselines, including the regularization parameter λ for EWC and MAS, and the memory size for A-GEM, to derive and report their best performance. Their AP and AP^+ curves are shown in Figure 15, 16 and 17. From the results we can see that none of these hyperparameters works well. For EWC and MAS, when the regularization parameter λ is small, the pre-training performance is not obviously better than that of naive method. However, if we slightly increase λ, the performance would become worse than baseline. For A-GEM, the case with bigger memory also doesn't clearly outperform cases with smaller memory and naive case. Specially, we observed that during A-GEM pre-training, 99.9% of the inter-products of current gradient and replay gradient are positive, implying that pre-training on different domains is similar to each other to a large extent. This might indicate that EWC, MAS, and A-GEM cannot deal with the subtle difference of various domains.

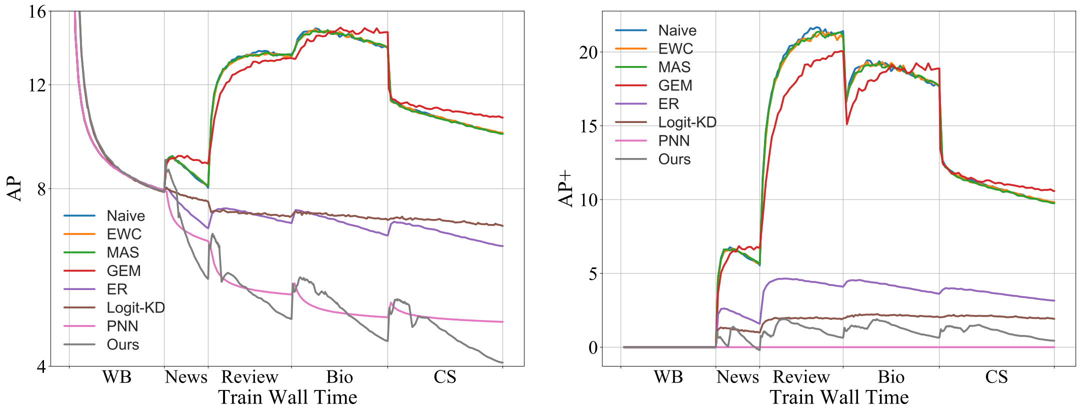

Figure 7: AP and AP^+ of different lifelong learning methods with $\mathrm{BERT}_{\mathrm{L6\_D384}}$ as the initial PLM w.r.t train wall time. ELLE continually grows $\mathrm{BERT}_{\mathrm{L6\_D384}}$ to $\mathrm{BERT}_{\mathrm{L12\_D768}}$.

EnCBP: A New Benchmark Dataset for Finer-Grained Cultural Background Prediction in English

Weicheng Ma, Samiha Datta, Lili Wang, and **Soroush Vosoughi**
Department of Computer Science, Dartmouth College
{weicheng.ma.gr, samiha.datta.23, lili.wang.gr, soroush.vosoughi}@dartmouth.edu

Abstract

While cultural backgrounds have been shown to affect linguistic expressions, existing natural language processing (NLP) research on culture modeling is overly coarse-grained and does not examine cultural differences among speakers of the same language. To address this problem and augment NLP models with cultural background features, we collect, annotate, manually validate, and benchmark EnCBP, a finer-grained news-based cultural background prediction dataset in English. Through language modeling (LM) evaluations and manual analyses, we confirm that there are noticeable differences in linguistic expressions among five English-speaking countries and across four states in the US. Additionally, our evaluations on nine syntactic (CoNLL-2003), semantic (PAWS-Wiki, QNLI, STS-B, and RTE), and psycholinguistic tasks (SST-5, SST-2, Emotion, and Go-Emotions) show that, while introducing cultural background information does not benefit the Go-Emotions task due to text domain conflicts, it noticeably improves deep learning (DL) model performance on other tasks. Our findings strongly support the importance of cultural background modeling to a wide variety of NLP tasks and demonstrate the applicability of EnCBP in culture-related research.

1 Introduction

Psychological research has revealed that people from different cultural background behave differently in the ways they think (Nisbett et al., 2001), talk (Kim, 2002), write (Krampetz, 2005; Almuhailib, 2019; Kitano, 1990), and express emotions (Hareli et al., 2015; Sun et al., 2021; Acheampong et al., 2020). NLP researchers have applied cultural background information to model differences in linguistic expressions across culture groups especially for psycholinguistic tasks [1], e.g., distributional perspective identification (Tian et al., 2021) and sentiment analysis (Sun et al., 2021). In prior research, culture groups are usually defined by official language (Tian et al., 2021) (e.g., US, UK, and India are considered part of the same culture group) or, even more coarse-grained, by ideology (Imran et al., 2020) (e.g., “Western" countries and “Eastern" countries). These settings typically overlook the nuanced cultural differences across or within countries, and they do not provide useful information for modeling different language use behavior in mono-lingual contexts.

To study culture-specific linguistic expressions in the same language and to apply culture-related knowledge to other NLP tasks, we build EnCBP, a cultural background prediction dataset in English. Following (Tambassi, 2018), we assume that language use patterns are more consistent inside each country or each district in a large country, e.g., states in the US. As such, we first construct news corpora by sampling news articles covering five frequently discussed and controversial topics from major news outlets in five English-speaking countries and four geographically dispersed states in the US. We then break the articles down to paragraphs and annotate them with the country and state codes of the news outlets to construct the country- and district-level subsets of EnCBP. We refer to the two subsets as EnCBP-country and EnCBP-district. To ensure annotation quality, we randomly sample 20 instances from each culture group and have them validated manually by local residents using Amazon Mechanical Turk (MTurk). The annotation accuracies and inter-validator agreement rates are both high for all the validation sets, supporting the correctness of the labels and demonstrating the differences in writing style across culture groups. In addition, we benchmark EnCBP for cultural background prediction with three widely-used NLP model architectures, namely BiLSTM, BERT (Vaswani et al., 2017), and RoBERTa (Liu et al.,

---

[1] In this paper, we refer to NLP tasks reflecting the psychological states of people, e.g., sentiments and emotions, as psycholinguistic tasks.

Findings of the Association for Computational Linguistics: ACL 2022, pages 2811 - 2823
May 22-27, 2022

2019). Among the three models, the roberta-base model achieves the best overall performance, scoring 82.96 in F1-macro on the EnCBP-country and 73.96 on EnCBP-district. The better performance of BERT and RoBERTa over BiLSTM implies the importance of deep neural network architectures and large-scale pre-training for the challenging text-based cultural background prediction task.

We conduct both quantitative and qualitative analyses on EnCBP to show the differences in linguistic expressions across culture groups. For the quantitative analysis, we fine-tune a BERT model on the corpus with each cultural background label and evaluate it on the corpora of all the culture groups. Results show that all the fine-tuned models are more compatible with the cultural domains of their training corpora and less compatible with the those of other corpora, with perplexity differences ranging from 0.43 to 14.90. For the qualitative analysis, we manually analyze sentence structures and the choices of words or phrases in instances randomly sampled from EnCBP to illustrate culture-specific English expressions.

Furthermore, we evaluate a BERT model on nine psycholinguistic (sentiment analysis and emotion recognition), syntactic (named entity recognition), and semantic (paraphrase identification, natural language inference, semantic textual similarity, and text entailment) tasks to examine how modeling culture-specific English writing styles benefits the performance of NLP models. The models that incorporate cultural background information perform noticeably better on the named entity recognition (NER) task, most semantic tasks, and the sentiment analysis (SA) tasks. In our emotion recognition (ER) evaluation on the Go-Emotions dataset, however, the performance is slightly harmed by incorporating cultural background information. This is likely due to the imbalanced cultural background distribution in the dataset, as the evaluation performance of BERT clearly improves on Emotion, another ER dataset. On the paraphrase identification (PI) task, while the model performs better with cultural information incorporated, the improvement is lower than those on SA and NER tasks. This result suggests that differentiating linguistic expressions with the same semantic meaning may introduce additional noise to semantic tasks.

Our analyses and evaluations support the importance of cultural background modeling for a wide range of NLP tasks and show that EnCBP can contribute to future culture-related NLP research.

The contributions of this paper are three-fold:

- we construct, manually validate, and benchmark EnCBP, a mono-lingual news-based cultural background prediction dataset;
- we qualitatively and quantitatively examine the distinctions in writing style from different culture groups; and
- we show the effect of introducing cultural background information to nine downstream NLP tasks to showcase the importance of cultural information in natural language understanding.

2 Dataset Construction

This section introduces the construction, validation, and benchmarking of the EnCBP dataset. The EnCBP dataset adopts a multi-class classification objective. The labels are country codes of news outlets for the coarse-grained subset (EnCBP-country) and US state codes for the finer-grained subset (EnCBP-district).

2.1 Data Collection and Annotation

Our work relies on the hypothesis that news articles from mainstream news outlets of a country or district reflect the local language use patterns. Thus, we construct 5 text corpora with news articles posted by New York Times, Fox News, and the Wall Street Journal in the US, BBC in UK, Big News Network - Canada in Canada (CAN), Sydney Morning Herald in Australia (AUS), and Times of India in India (IND) for EnCBP-country. For EnCBP-district, we construct 4 corpora from Coosa Valley News, WJCL, and Macon Daily in Georgia (GA), Times Union, Gotham Gazette, and Newsday in New York (NY), NBC Los Angeles, LA Times, and San Diego Union Tribune in California (CA), and Hardin County News, Jasper Newsboy, and El Paso Times in Texas (TX). We stream news articles from Media Cloud [2], a platform that collects articles from a large number of media outlets, using its official API.

To maintain consistent mentions of events and named entities (NEs) in the corpora, we limit the articles to those under five frequently discussed topics, namely “global warming", “abortion", “immigration", “social safety net", and “mandatory vaccination". 1,000 news articles published between Jan. 1, 2020 and Jun. 30, 2021 are sampled from each news outlet to form our corpora.

---

		Topics					Splits			
		Global Warming	Abortion	Immigration	Social Safety Net	Mandatory Vaccination	Total	Train	Dev	Test
Labels	US	332	455	253	336	624	2,000	1,600	200	200
	UK	648	129	383	456	384	2,000	1,600	200	200
	AUS	532	188	439	402	439	2,000	1,600	200	200
	CAN	418	379	430	315	458	2,000	1,600	200	200
	IND	478	171	540	371	440	2,000	1,600	200	200
	NY	206	134	443	704	513	2,000	1,600	200	200
	CA	274	242	473	556	455	2,000	1,600	200	200
	GA	245	384	214	389	768	2,000	1,600	200	200
	TX	365	328	468	585	254	2,000	1,600	200	200

Table 1: Number of documents associated with each label and under each topic in EnCBP. For each country or district label, the documents under each topic are randomly sampled into the training, development, and test sets with a 80%/10%/10% split.

After data collection, we remove duplicates and overly short documents (less than 100 words) to ensure data quality. We also replace the mentions of countries and districts with the “[country]" and “[district]" special tokens. Then, we chunk the remaining news articles into paragraphs and label the documents with the country or district codes of the news outlets by which they are posted. We adopt paragraph-level annotations since asking the validators to read an overly-long document may cause them to lose track of culture-specific information when they are making judgments. Most state-of-the-art DL models also have input length limits that are not capable of encoding full-length news article. To avoid overly simplifying the task, we remove paragraphs containing NE mentions that are mainly used by news media in specific countries or districts. We quantify the specificity of NEs using inverse document frequency (IDF) scores.

From the filtered news paragraphs, we sample 2,000 paragraphs from the corpus of each culture group to form the annotated dataset. Table 1 provides the statistics of the label and topic distribution of the instances in EnCBP.

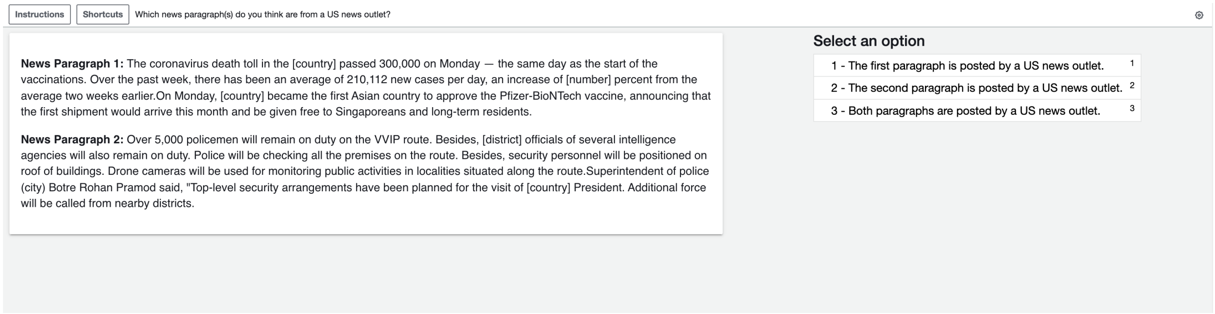
2.2 Manual Validation

To ensure that the cultural background labels in EnCBP correlate with writing styles, we randomly sample 50 instances from each class and manually validate them on MTurk. In each questionnaire, we pair the sampled instance with another random news paragraph from EnCBP and ask three annotators whether the first, second, or both paragraphs are posted by media outlets in a specific country or district. We manually check the instances to ensure there are no country- or district-specific mentions remaining to avoid potential information leakage. For quality control purposes, we only hire crowdsourcing workers from the country or US state matching the label of the instances sampled for validation.

Culture Groups	ACC (%)	IAA
US	64.00	0.61
UK	76.67	0.73
AUS	74.00	0.71
CAN	58.67	0.57
IND	61.43	0.61
NY	81.33	0.78
CA	64.67	0.59
GA	70.00	0.66
TX	72.00	0.68

Table 2: Validation results of the EnCBP dataset. ACC and IAA refer to validation accuracy and inter-annotator agreement rate in Fleiss’ κ, respectively.

To ensure the quality of annotations in EnCBP, we hire crowdsourcing workers from MTurk to validate randomly sampled data points. Since all the news articles are written by native English speakers and the culture groups are not strictly separated from each other, it is difficult for a validator to identify whether a news paragraph is written by a journalist from the same cultural background as them. Instead, we provide each validator with a news paragraph posted by an international or do-



Which news paragraph(s) do you think are from a US news outlet?

News Paragraph 1: The coronavirus death toll in the [country] passed 300,000 on Monday — the same day as the start of the vaccinations. Over the past week, there has been an average of 210,112 new cases per day, an increase of [number] percent from the average two weeks earlier.On Monday, [country] became the first Asian country to approve the Pfizer-BioNTech vaccine, announcing that the first shipment would arrive this month and be given free to Singaporeans and long-term residents.

News Paragraph 2: Over 5,000 policemen will remain on duty on the VVIP route. Besides, [district] officials of several intelligence agencies will also remain on duty. Police will be checking all the premises on the route. Besides, security personnel will be positioned on roof of buildings. Drone cameras will be used for monitoring public activities in localities situated along the route.Superintendent of police (city) Botre Rohan Pramod said, "Top-level security arrangements have been planned for the visit of [country] President. Additional force will be called from nearby districts.

2 - The second paragraph is posted by a US news outlet. 2
3 - Both paragraphs are posted by a US news outlet. 3

Figure 1: An example of the questionnaire used for validating the annotations in EnCBP.

mestic news outlet in the country or district they live in (MTurk allows for filtering based on location) and a randomly selected news paragraph from our dataset. The validators are asked to compare the two news paragraphs and decide which of the two paragraphs (or both) were written by their local news outlets through analyzing the use of words, phrases, and sentence structures. To avoid information leak and bias in the validation process, the mentions of countries and districts are replaced with “[country]" and “[district]" special tokens at the pre-processing stage of the dataset. An example questionnaire is shown in Figure 1.

We display the validation accuracy (ACC), i.e., the proportion of the validators’ answers that match the labels of those instances in EnCBP, and inter-annotator agreement rate (IAA) in Table 2. Since we have three options in each of the questionnaires, the ACC of random guess is around 33% for each culture group. We quantify IAA with Fleiss’ κ (Fleiss, 1971), a widely used metric for evaluating IAA. The Fleiss’ κ in Table 2 range from moderate (> 0.40) to substantial agreement (> 0.60). We infer from the relatively high ACC and IAA that: 1) news writing styles are affected by the cultural backgrounds of journalists and 2) writing styles in each culture group are identifiable by local residents. Since we removed country- or state-specific NEs and mentions of countries or states from the paragraphs, and as the distributions of topics and sentiments are balanced across corpora, the chance that the validators make their judgments based on these external information is low.

2.3 Dataset Benchmarking

After data validation, we divide both EnCBP-country and EnCBP-district into training, development, and test sets with a 80%/10%/10% split and a random state of 42. To show the predictability of cultural background labels with NLP models, we benchmark the EnCBP-country and EnCBP-district separately with BiLSTM, bert-base-cased, and roberta-base models. We train the BiLSTM model for 20 epochs with a learning rate of 0.25 and fine-tune the other models for five epochs with a learning rate of 1e-4 on both subsets.

Model	EnCBP-country	EnCBP-district
BiLSTM	50.89 (0.98)	44.53 (1.39)
BERT	78.13 (0.67)	72.09 (1.84)
RoBERTa	82.96 (0.89)	73.96 (1.01)

Table 3: Benchmark performance of BiLSTM, bert-base-cased (BERT), and robert-base (RoBERTa) models on EnCBP-country and EnCBP-district. Average F1-macro scores over five runs with different random seeds are reported and standard deviations are shown in parentheses.

Table 3 displays the average F1-macro scores across five runs with different random seeds for model initialization. For all the models, the standard deviations of the five runs are at most 0.98 on EnCBP-country and 1.84 on EnCBP-district, indicating that randomness does not severely affect the predictions of models, and that the culture-specific writing styles can be modeled by DL models. Both the BERT and RoBERTa models outperform the BiLSTM model with large margins, which suggests the importance of deep neural network architectures and large-scale pre-training for the task. We also note that all the three models perform worse on EnCBP-district, which may be caused by both the more difficult task setting and the higher level of noise in EnCBP-district, since local news outlets target audiences from all over the country. In the rest of this paper, we use the bert-base-cased model for the analyses and discussions since it is less resource-consuming than the roberta-base model, while the findings potentially apply to other model architectures as well.

3 Cultural Domain Compatibility

This section examines whether linguistic expressions are clearly separable across culture groups in EnCBP through LM evaluations. We also manually examine representative linguistic expressions associated with each label to illustrate the differences in linguistic expression across cultures.

3.1 Language Modeling Analysis

Since all the documents in EnCBP come from news articles, we assume they are well-written and grammatically correct. In addition, LMs trained on a grammatical corpus should produce similar perplexities on the corpus with each label if the writing styles are consistent across corpora. Thus, to examine culture-specific differences in writing styles, we fine-tune a bert-base-cased model on the training corpus of each class in EnCBP with the MLM objective and evaluate perplexity of the fine-tuned models on all the test corpora.

As Table 4 shows, BERT models usually produce the lowest perplexities on the test portions of their training corpora, and the cross-corpus perplexities are usually considerably higher. This supports our hypothesis that English writing styles are culture-dependent, and that the writing styles across cultures are different enough to be detected by LMs. Meanwhile, we find that the cultural domain compatibility differs for different pairs of corpora, e.g., the IND corpus is more compatible with the UK corpus than other countries or districts. The relations are not symmetric either, e.g., while the LM trained on the CAN corpus well adapts to the US corpus, the US LM performs the worst on the CAN corpus among the five countries. These potentially result from the effects of geographical, geo-political, and historical backgrounds on the formation of cultural backgrounds. For instance, the US could be said to have greater influence on Canadian culture than vice versa. Potentially for similar reasons, compared to TX and GA, NY has a more consistent writing style with CAN. We also note clear cultural domain compatibility gaps between liberal (NY and CA) and conservative states (GA and TX), which, agreeing with Imran et al. (2020), shows that ideologies and policies of a district potentially has an effect on its culture-specific writing styles. We provide additional topic-level LM analysis in Appendix A.

3.2 Topic and Sentiment Distributions

To verify if the different expressions across classes in the EnCBP datasets are triggered by cultural differences, we analyze the distributions of topics and sentiment scores for each class. Specifically, we model the topics of each corpus using BERTopic (Grootendorst, 2020) and analyze sentiments of text using Stanza (Qi et al., 2020).

We apply two-sided Kolmogorov-Smirnov (KS) tests on the topic distributions of each pair of classes to see whether the topic distributions for each country or state are similar. For all pairwise comparisons, the null hypothesis (which is that the distributions are identical) cannot be rejected using the KS test, with all p-values being above 0.1, and most in fact being above 0.7. This potentially results from both topic control at the data collection phase and data filtering eliminating paragraphs containing NEs with high IDF scores. Additionally, the sentiment score distribution is relatively consistent across classes (28.02% to 34.97% instances with negative sentiments). Since the classes in EnCBP contain documents that are similar in topics and sentiments, it is likely that the differences in linguistic expressions across classes are caused by cultural differences.

3.3 Manual Analysis

In addition to automatic evaluations, we manually examine distinguishable English expressions for each culture group in EnCBP. Specifically, we extract phrases with high TF-IDF values for each corpus in EnCBP, retrieve news paragraphs that contain these phrases, and examine sentence structures and phrase usages in these representative instances.

From our analyses, we find that the different writing styles of countries and districts in EnCBP are affected by the choice of words or phrases, the ordering of phrases, and degrees of formality. For example, the phrases “in the wake of", “in the lead up to", and “the rest of the world" are much more frequently used by AUS news outlets than the others. Also, the use of auxiliaries, especially the word “may", is more frequent in the UK corpus, in the context of politeness. The US corpus is in general more colloquial than the other corpora, as the journalists often write subjective comments in the news articles. Additionally, the ways of referencing speeches differ across corpora, e.g., the quoted text usually appears prior to the “[name] said" in the UK corpus but reversely in the US corpus. In the

		Evaluation Corpus

Table 4: Perplexity of LMs fine-tuned on the training corpora of EnCBP with the MLM objective and evaluated on the test corpora. The lowest perplexity for each fine-tuned LM is in bold and the highest perplexity is underlined.

EnCBP-district subset, the sentence structures are more consistent across corpora, while the mentions of NEs and wordings differ more. For example, the word “border" appears frequently in the TX corpus but less in the other corpora when discussing the “immigration" topic. Though the observations summarized from EnCBP may not be universally applicable to other datasets or text domains, they are validated by native speakers of English to be accounting for the high ACC in manual validations.

4 Experiments and Analyses

Since cultural background labels are expensive to annotate, most NLP models forego the use of this information to opt for larger training data amount. For example, BERT is trained on Wikipedia text written in styles from mixed cultural backgrounds without access to cultural background information of the writers. Using the EnCBP dataset we constructed, this section examines the relatedness between the cultural background prediction task and multiple other NLP tasks via model probing. We also examine the effectiveness of cultural feature augmentation, i.e., augmenting DL models on downstream NLP tasks with culture-specific writing style information. Specifically, we evaluate a bert-base-cased model with two common information injection methods, namely two-stage training and MTL, on nine syntactic, semantic, and psycholinguistic tasks.

4.1 Tasks and Datasets

The datasets used in our evaluations are:

PAWS-Wiki (Zhang et al., 2019) is a PI dataset containing English Wikipedia articles. Each instance in PAWS-Wiki consists of a pair of sentences and a label indicating whether the two sentences are paraphrase (1) or not (0). There are 49,401 training instances, 8,000 development instances, and 8,000 test instances in this dataset.

CoNLL-2003 English NER dataset (Tjong Kim Sang and De Meulder, 2003) contains news articles from Reuters news only, so the dataset has a more consistent UK writing style, compared to the other datasets we utilize. Each word in the documents is annotated with persons (PER), organizations (ORG), locations (LOC), or miscellaneous names (MISC) NE label in the IOB-2 format. We adopt the official data split of the CoNLL-2003 dataset in the experiments, where there are 7,140, 1,837, and 1,668 NEs in the training, development, and test sets, respectively.

Go-Emotions (Demszky et al., 2020) is an ER dataset containing 58,009 English Reddit comments. Instances in this dataset are labeled with 28 emotion types including neutral, in the multi-label classification form. We split the dataset into training, development, and test sets with a 80%/10%/10% split using 42 as the random seed. To be consistent with other evaluations, we switch the annotations to the multi-class classification form by duplicating the data points associated with multiple labels and assigning one emotion label to each copy. This results in an ER dataset containing 199,461 training instances, 35,057 development instances, and 34,939 test instances after removing instances with no labels.

Stanford Sentiment Treebank (SST-5) (Socher et al., 2013) is a document-level SA dataset containing sentences from movie reviews. The documents are annotated with sentiment scores, which are turned to fine-grained (5-class) sentiment labels after pre-processing. Using the official data split, we divide the dataset into training, development, and test splits containing 156,817, 1,102, and 2,211 instances, respectively. Note that the training set of SST-5 contains a mixture of phrases and sentences, while the development and test sets contain only complete sentences.

SST-2 is the coarse-grained SST-5 dataset, in which each document is labeled with positive (1) or negative (0) sentiments. There are 67,349 training instances, 872 development instances, and 1,821 test instances in this dataset.

QNLI (Wang et al., 2019) is a natural language inference (NLI) dataset with a question answering background. Each instance in QNLI contains a question, a statement, and a label indicating whether the statement contains the answer to the question (1) or not (0). There are 104,743 training instances, 5,463 development instances, and 5,463 test instances in this dataset.

STS-B (Cer et al., 2017) is a benchmarked semantic textual similarity (STS) dataset. Each instance in STS-B is a pair of sentences manually annotated with a semantic similarity score from 0 to 5. The dataset contains 5,749 training instances, 1,500 development instances, and 1,379 test instances.

RTE is a textual entailment (TE) dataset. Each instance in RTE contains a pair of sentences and a label indicating whether the second sentence is an entailment (1) or not (0) of the first sentence. The RTE dataset we use is a combination of RTE1 (Dagan et al., 2005), RTE2 (Bar-Haim et al., 2006), RTE3 (Giampiccolo et al., 2007), and RTE5 (Bentivogli et al., 2009) datasets, which contains 2,490 training instances, 277 development instances, and 3,000 test instances.

Emotion (Saravia et al., 2018) is a Twitter-based ER dataset labeled with six emotion types, i.e., sadness (0), joy (1), love (2), anger (3), fear (4), and surprise (5). There are 16,000 training instances, 2,000 development instances, and 2,000 test instances in this dataset.

4.2 Feature Augmentation

4.2.1 Experimental Settings

We use the Huggingface (Wolf et al., 2020) implementation of BERT in all our evaluations. On each task, we fine-tune a bert-base-cased model for five epochs with different random seeds, and we report the average evaluation score on the test sets of downstream tasks over the five runs to avoid the influence of randomness. Each experiment is run on a single RTX-6000 GPU with a learning rate of 1e-4 and a batch size of 32.

4.2.2 Two-Stage Training

We first explore the two-stage training method which successively fine-tunes the pre-trained BERT model on a cultural background prediction dataset and the target task. We use EnCBP-country here to examine the efficacy of coarse-grained cultural feature augmentation, and we study the effect of using EnCBP-district in Section 4.2.4.

As Table 5 shows, the two-stage training strategy brings noticeable performance improvements to the SA models. This agrees with prior psychological research (Sun et al., 2021), since the expressions of sentiments and attitudes differ across culture groups. Similarly, since NEs are usually mentioned differently across cultures, training the model to distinguish culture-specific writing styles helps resolve the conflict between the training domain of BERT and that of the CoNLL-2003 dataset and improves the performance of the NER model. On the PI task, while two-stage training has a positive effect on the performance of the model, the score improvement is not as significant as those on SA and NER tasks. The same trend holds for two other semantic tasks (QNLI and STS-B), where two-stage training brings only marginal performance improvements. We attribute this to the additional noise introduced by the cultural background labels for a semantic task, since expressions with the same semantic meaning can be associated with different cultural background labels in EnCBP. To verify this assumption, we conduct an additional experiment by applying the MLM objective instead of the classification objective in the first training stage. The model performance on PI is raised to 94.11 in F1-macro score, outperforming the previous two-stage training model by 2.44. The two-stage training performance also improves by 0.81 and 0.49/0.53 for QNLI and STS-B when using the MLM objective at the first fine-tuning stage. These results imply that while the cultural background labels are noisy for semantic tasks, enhancing the LM with English expressions from multiple cultural backgrounds is beneficial. Quite differently, however, two-stage training brings noticeable performance improvements to the RTE model. One possible explanation is, as is supported by the large standard deviations of evaluation scores in five runs, that the RTE dataset is too small and the performance tend

	PAWS-Wiki (PI)	CoNLL-2003 (NER)	Go-Emotions (ER)	SST-5 (SA)

Table 6: The performance of BERT model without cultural feature augmentation (BERT-orig), and models with cultural feature augmentation via two-stage training and multi-task learning. The **EnCBP-district** is used as the auxiliary dataset. We report accuracy for QNLI, RTE, and SST-2, Pearson's and Spearman's correlations for STS-B, and F1-macro for the other tasks. The average score and standard deviation (in parentheses) in five runs with different random seeds are reported for each experiment

to be affected more greatly by other issues such as model initialization. Unlike the other tasks, the performance of BERT drops on Go-Emotions in our evaluations, which is counter-intuitive since expressions of emotion are culture-specific (Hareli et al., 2015). We hypothesize that the negative effect of cultural feature augmentation is mainly caused by the imbalanced distribution of users' cultural backgrounds in the Go-Emotions dataset, as the dataset is constructed over a Reddit [3] corpus and nearly 50% Reddit users are from the US [4]. Supporting our hypothesis, cultural feature augmentation on the Emotion dataset notably improves the performance of BERT, despite the domain differences between the EnCBP-country (news domain) and Emotion (social media domain) datasets.

4.2.3 Multi-Task Learning

We further explore MTL methods for cultural feature augmentation when training the BERT model on downstream tasks. Specifically, we use EnCBP-country as the auxiliary task and train the model alternatively on the primary and auxiliary tasks.

According to Table 5, introducing cultural background information via MTL improves the performance of BERT on all the datasets except for Go-Emotions, similar to the two-stage training method. However, the performance on NER is noticeably lower with MTL than with two-stage training. This

---

[4] https://www.statista.com/statistics/325144/reddit-global-active-user-distribution/

potentially results from the mono-cultural nature of the CoNLL-2003 dataset, which is constructed on Reuters news, a UK news outlet. While the information and expressions in countries other than UK fade gradually during the second training stage, the MTL method strengthens the irrelevant information in the entire training process and harms the evaluation performance of the model more severely. To validate our hypothesis, we generate a binary cultural background prediction dataset by treating the UK documents as positive instances and the others as negative instances, and we re-run the MTL evaluation on the CoNLL-2003 dataset. The performance of BERT under this setting is raised to 93.97 in F1-macro score, which implies the importance of careful text domain selection for cultural feature augmentation on DL models.

4.2.4 Finer-Grained Feature Augmentation

We repeat the two-stage training and MTL evaluations on the nine downstream tasks using EnCBP-district to examine the effects of cultural feature augmentation with cultural background information with different granularity levels. The evaluation results are shown in Table 6. While the scores are very consistent with those in Table 5, we observe better MTL performance on CoNLL-2003 and Emotion and worse performance with both two-stage training and MTL on SST-5. Based on our analysis of EnCBP-country and EnCBP-district, the larger gaps in writing style among countries than those across states are likely the cause of the lower NER evaluation performance. In EnCBP-district, the linguistic expressions are more consistent since they all come from news outlets in the US, which relieves the problem and improves the MTL performance on CoNLL-2003. On the contrary, the lower diversity in expressions potentially negatively affects the performance of the SST-5 model since the SA task benefits from identifying culture-specific linguistic expressions, and since the corpus of SST-5 contains writings from all over the world. In addition, using EnCBP-district does not relieve the problem on the Go-Emotions dataset either, which suggests the limitation of cultural feature augmentation: trying to distinct expressions in different cultural backgrounds may introduce unexpected noise into models especially when the cultural background of a dataset is mostly the same. The performance of BERT on the Emotion dataset which consists of writings from more diverse cultural backgrounds, for example, is subject to comparable or even greater improvements when the model is augmented using the finer-grained EnCBP-district dataset.

To summarize, while cultural feature augmentation using EnCBP is beneficial for a wide range of NLP tasks, the necessity of conducting cultural feature augmentation has to be carefully evaluated. We also examine the effect of feature augmentation with less auxiliary data in Appendix B, showing that the size of the auxiliary data has an affect on the performance of DL models.

5 Conclusion and Future Work

This paper presents EnCBP, a mono-lingual news-based cultural background prediction dataset containing country-level (coarse-grained) and district-level (finer-grained) cultural background labels. Through manual validation on MTurk and cultural domain compatibility evaluations, we find that writing style clearly differs across countries and districts, confirming that cultural background has a substantial effect on writing style even in the same language. We also benchmark the dataset with state-of-the-art NLP models to show that, though challenging, different English expressions across cultural backgrounds can be identified and classified into culture categories by DL models. Additionally, our evaluations on downstream NLP tasks of various types show that cultural feature augmentation is able to improve the performance of DL models on various semantic, syntactic, and psycholinguistic tasks. While the performance of the BERT model is negatively affected by introducing cultural background information on an ER dataset, the imbalanced distribution of cultural backgrounds in its corpus may account for the performance drop. Our results demonstrate that cultural feature augmentation with EnCBP is a practical way of improving the performance of DL models on various NLP tasks, as long as the text domains of EnCBP and the downstream tasks are not too divergent.

Future work can extend our research to examine cultural differences in social media writings, which reflect even finer-grained cultural distinctions and are much noisier and difficult to annotate or validate than news articles.

6 Acknowledgement

We thank Mr. Aadil Islam for conducting additional evaluations on QNLI, STS-B, RTE, SST-2, and Emotion to respond to the reviewers' comments.

7 Ethics Statement

This paper presents and releases a news-based cultural background prediction dataset. The dataset is constructed on publicly available news outlets using the public API of Media Cloud and the labels are generated based on the country and district codes of the media outlets. Thus, there is no sensitive or private information in the dataset. Additionally, since we use mainstream news outlets for our data collection we believe there is less risk of overtly unethical information (though we cannot be sure given the current sociopolitical climate). Given the relatively large size of our dataset, we cannot manually examine all articles, however, the publicly released dataset will warn users of the possibility of the dataset containing unethical information and will allows users to flag unethical articles in our dataset. We also hired annotators from MTurk to validate the quality of annotations for a sample instances from our dataset. To ensure the quality of dataset validation, we require the annotators to be native English speakers from the same country or district as the label of each instance to be validated. The annotators were given clear instructions to choose the news paragraph(s) written by journalists in their countries or districts from a pair of paragraphs. We payed \$0.14 (USD) for validating each instance, which translates to over \$25 per hour since each data point takes no more than 1 minute to validate. This hourly rate is considerably higher than the federal minimum wage in the US. The entire annotation process was anonymized and the annotators were not asked for their personally identifiable information, so there was not any risk of harm associated with their participation.

This paper presents one of the first attempts at tailoring NLP models to the writing styles of specific regions, thus reducing the out-sized influence of the linguistic style of larger countries in these models.

A Language Modeling Analysis Based on Topic

We study the cultural domain compatibility across news topics in EnCBP by repeating the LM evaluations with the news paragraphs grouped by their topics. As Table A1 shows, for the topics “Immigration" and “Social Safety Net", the LMs do not achieve the lowest perplexities on their training topics. We speculate that this reflects the more controversial nature of these two topics, since linguistic expressions are heavily affected by attitudes and stances. In addition, since each country or state news outlet has a relatively stable attitude towards each topic, the discrepancy between each trained LM and the test set in the cultural domain of its training set implies that the EnCBP dataset is constructed over diverse culture groups. The diverse writing styles in EnCBP make it appropriate for improving DL models on downstream tasks via cultural feature augmentation, since EnCBP does not bias extremely towards the writing styles of a single culture group.

B Feature Augmentation with Less Data

We repeat the joint modeling and two-stage training experiments on PAWS-Wiki, CoNLL-2003, Go-Emotions, and SST-5 datasets with randomly downsampled EnCBP-country and EnCBP-district training datasets to examine the effect of auxiliary data size. Specifically, we randomly reduce 20%, 40%, and 80% of training instances from EnCBP-country and EnCBP-district with a random seed of 42 and use the reduced datasets in the evaluations. The experimental results are shown in Table B1 (EnCBP-country) and Table B2 (EnCBP-district).

While removing 20% of the training instances from EnCBP-country and EnCBP-district generally does not greatly affect the feature augmentation evaluation results, there is noticeable performance gap on all the tasks when over 40% of the training instances are eliminated. This may be due to the poorer predictability of cultural background labels from the much smaller training datasets, as the BERT performance drops greatly from 78.13 to 60.92 (on EnCBP-country) and from 72.09 to 60.03 (on EnCBP-district) when 40% of the training data is removed (see Table 3 for the original BERT performance results). On the other hand, though using more training data from EnCBP has positive overall effects on the performance of feature-augmented models, the improvements become gradually smaller when the training data amount increases.

In brief, through these experiments we hypothesize that a cultural background prediction dataset of a moderate size such as EnCBP is sufficient for cultural feature augmentation. Even if datasets larger in size could potentially lead to better performance improvements, the gains are likely to be small compared to the effort required for constructing a larger dataset.

Abstract

Prompting language models (LMs) with training examples and task descriptions has been seen as critical to recent successes in few-shot learning. In this work, we show that finetuning LMs in the few-shot setting can considerably reduce the need for prompt engineering. In fact, one can use *null prompts*, prompts that contain neither task-specific templates nor training examples, and achieve competitive accuracy to manually-tuned prompts across a wide range of tasks. While finetuning LMs does introduce new parameters for each downstream task, we show that this memory overhead can be substantially reduced—finetuning only the bias terms can achieve comparable or better accuracy than standard finetuning while only updating 0.1% of the parameters. All in all, we recommend finetuning LMs for few-shot learning as it is more accurate, has relatively stable performance across different prompts, and can be made nearly as efficient as using frozen LMs.

1 Introduction

Few-shot learning—the ability to learn tasks with limited examples—is an important academic and practical challenge (Lake et al., 2015). In state-of-the-art NLP, few-shot learning is performed by reformulating tasks as natural language “prompts” and completing those prompts with pre-trained language models (Brown et al., 2020; Schick and Schütze, 2021a). Prompts that are well-designed can substantially improve accuracy (Zhao et al., 2021; Lu et al., 2021). However, finding these prompts is difficult: it requires a non-trivial combinatorial search over the prompt’s wording (a.k.a. its pattern or template), whether and how to include training examples, and how to convert language model probabilities into class predictions. Consequently, prompts are often designed using human intuition that is hard to replicate and apply in a principled manner (Perez et al., 2021).

In this work, we seek to mitigate prompt engineering by identifying a class of simple prompts that are effective across many tasks for masked language models (LMs). We find that, when using prompt-based finetuning (Schick and Schütze, 2021a; Gao et al., 2021), the prompt requires less optimization than previously thought; in fact, the pattern and training examples can be completely cut out (e.g., Figure 1, right). These *null prompts*—simple concatenations of the inputs and the [MASK] token—achieve comparable accuracy to manually-written patterns while drastically simplifying prompt design: users only need to decide the label names (a.k.a. the verbalizer) and where to place the [MASK] token. The effectiveness of null prompts also challenges the common wisdom that the success of few-shot learning is due to inductive biases present in the prompt.

A key drawback of prompt-based finetuning is that it has large memory requirements for each new downstream task at inference time (Figure 1, left). In contrast, in-context learning (Brown et al., 2020) allows reusing the large-scale LM across tasks, but it requires significant prompt engineering. To determine whether memory efficiency and simple prompt selection can be *simultaneously* achieved, we experiment with either: (1) making prompts for in-context learning similarly easy to create, or (2) making prompt-based finetuning more memory efficient. For (1), we simplify prompt engineering for in-context learning by automatically tuning the prompt’s tokens or embeddings, an approach that has been successful in the non-few-shot setting (Shin et al., 2020; Lester et al., 2021). For (2), we study lightweight finetuning alternatives that update a smaller set of parameters: BitFit (Ben-Zaken et al., 2021), Adapters (Houlsby et al., 2019), and calibration layers (Zhao et al., 2021).

Figure 1: **Different Methods of Few-Shot Learning.** Right: We visualize different types of prompts for QQP. We denote the input fields using curly brackets {}, the manually-written pattern using magenta, and the verbalizers using green. We show that *null prompts*, ones that do not contain training examples or task-specific patterns, can achieve competitive accuracy. Left: We compare different methods for model finetuning. Unlike standard prompt-based finetuning, we propose to update only the masked LM's bias terms (BitFit). This achieves competitive accuracy while only updating 0.1% of the parameters.

We show that the latter approach—prompt-based finetuning with lightweight updates—is considerably more successful. In particular, learning only the model's bias terms (BitFit) can achieve competitive or better few-shot accuracy than standard finetuning while only requiring switching out 0.1% of the parameters at inference time to perform different tasks. On the other hand, automated prompt tuning for in-context learning generally fails to find prompts that are competitive with manual ones. Taken together, our results show that prompt-based finetuning is preferable because it is more accurate, works well for different types of prompts, and can be made nearly as efficient as using frozen LMs.

2 Prompting Language Models

We use masked LMs for few-shot learning. Following Schick and Schütze (2021a), we have:

- a pre-trained masked LM, with T denoting its vocabulary and T^* the set of all token sequences.
- a small set of training inputs $x_i \in X$ and their corresponding labels $y_i \in Y$.
- a *pattern* $P : X \rightarrow T^*$ that maps inputs to cloze questions containing a single [MASK] token. Additionally, a *verbalizer* $v : Y \rightarrow T$ that maps each label to a single vocabulary token. We call the pattern and verbalizer together the *prompt*.

In our work, we consider different ways of constructing the prompt (Section 2.1) and updating the masked LM's parameters (Section 2.2). Table 1 contains an overview of existing prompting methods and the settings they are evaluated in.

2.1 Constructing the Prompt

The prompt is important: in some settings, different prompts can cause accuracy to vary from near chance to near state-of-the-art (Zhao et al., 2021). However, finding good prompts can be difficult. Prompt construction requires a non-trivial combinatorial search over the prompt's wording, whether to include training examples, and how to convert LM probabilities to class predictions. As a consequence, prompts are either designed using human intuition that is hard to replicate and apply in a principled manner (Perez et al., 2021), or using automated methods (Shin et al., 2020; Gao et al., 2021; Lu et al., 2021). These methods search for elements such as: (1) the text of the pattern, (2) the tokens in the verbalizers, and (3) whether and how training examples are prepended before the test input. Although automated prompt search can match the accuracy of manual tuning, it introduces its own complexities. For example, the prompts from Gao et al. (2021) achieve comparable results to manually-designed prompts but are found using generative models and careful validation.

In this paper, we show that prompt-based finetuning (see Section 2.2) can considerably reduce the importance of the prompt. This does not contradict past work—the extreme importance of the prompt is only true when models are *not finetuned*.

2.2 Prompting Approaches for Few-Shot Learning

In-Context Learning An increasingly popular strategy for few-shot learning is prompting frozen

Method	Finetuned Params	Prompt Design	Few-shot
AUTOPROMPT (Shin et al., 2020)	None	Learned (Discrete)	✗
Prompt Tuning (Lester et al., 2021)	Prompt Token Embeds	Learned (Continuous)	✗

P-Tuning (Liu et al., 2021)	All + Prompt Token Embeds	Learned (Continuous)	✓
Null Prompts + Bitfit (Ours)	Bias Terms	None	✓

Table 1: **Overview of Existing Work on Prompting**. *Finetuned Params* indicates the parameters altered during training. *Prompt Design* indicates how prompts are created; we use *null prompts*. *Few-Shot* indicates using few-shot training and validation sets.

LMs (Brown et al., 2020). This strategy relies solely on *in-context learning* (a.k.a. priming), where the LM learns by conditioning on the prompt rather than updating its parameters. In-context learning has been shown to be successful when using very large (e.g., billions of parameters) LMs, as these models better leverage the prompt.

Prompt-Based Finetuning Rather than using frozen LMs, *prompt-based finetuning* methods finetune all of the LM's parameters (Schick and Schütze, 2021a; Le Scao and Rush, 2021; Gao et al., 2021). For masked LMs, this is done by constructing training examples that contain a [MASK] token and finetuning the masked LM to generate the correct verbalizer token in that position.

The main advantage of prompt-based finetuning over in-context learning is that it achieves higher accuracy, especially when the LM is relatively small, e.g., millions of parameters (Schick and Schütze, 2021b). The main downside is that the same model can no longer be reused across different tasks, thus reducing efficiency. The efficiency is impacted in two ways. First, it requires large amounts of disk space at test time because numerous model checkpoints must be stored. Second, during training time, it requires large amounts of GPU memory to perform updates on massive LMs.

In this paper, we will show an additional benefit to prompt-based finetuning—it makes prompt engineering easier. We will also show that the memory inefficiency of prompt-based finetuning can be drastically mitigated using lightweight finetuning alternatives. These lightweight methods allow one to switch out only a small subset of model parameters at inference time in order to solve multiple tasks, and also drastically reduce training-time memory costs. Moreover, in many cases these lightweight methods also improve model accuracy. Our work is related to Le Scao and Rush (2021), who show that different manually-written patterns lead to similar accuracy for prompt-based finetuning.

3 Experimental Setup

3.1 Datasets and Hyperparameter Tuning

We use the following classification datasets from GLUE (Wang et al., 2019b) and SuperGLUE (Wang et al., 2019a): BoolQ, CB, MNLI, MRPC, QNLI, QQP, RTE, and SST-2.[1]

To build few-shot datasets, past work collects K examples from each label for training and K examples from each label for development (Gao et al., 2021). Despite this setup often being denoted as K-shot learning, it effectively uses $2K$ examples and splits the examples evenly into train and development. We instead propose to use cross validation to perform more principled model selection. Concretely, we sample $2K$ examples from each label and use 4-fold cross validation to determine the best hyperparameters. After finding the best hyperparameters, we train on the first K examples and early stop on the second K examples. We use $K = 16$ following past work (Gao et al., 2021).

We sample our examples from each dataset's original training set. Since transformers' performance in few-shot settings can be highly dependent on weight initialization (Dodge et al., 2020), we initialize the weights with 10 different random seeds and report the mean and variance of the model performance. We use each dataset's original development set for our final evaluation and use the standard evaluation metrics (accuracy or F_1) associated with each dataset. We do not check the

---

[1] We also evaluated on WiC and WNLI. We omit these results because all models achieved near-random accuracy.

Figure 2: **How # Wins are Computed**. For a given dataset, we perform a Welch's t-test to determine if there is a significant difference in accuracy for each pair of methods. The method which performs better than most other methods (i.e., the row with the most yellow squares; BitFit in this case) is considered the "winner" of the task, and its *# Wins* is incremented by 1. In the figure above, we show a subset of methods evaluated on a single dataset.

final evaluation metrics during any tuning of the hyperparameters to ensure that we are doing "true" few-shot learning (Perez et al., 2021).

3.2 Masked Language Models

Following past work (Schick and Schütze, 2021b), we use the RoBERTa (large, 330M params, Liu et al., 2019) and ALBERT (xxl-v2, 223M params, Lan et al., 2020) masked LMs provided by the HuggingFace transformers library (Wolf et al., 2020). Training and evaluation were performed on a heterogeneous compute cluster with the following minimum specs: 2xNVIDIA GeForce GTX 1080 Ti's, 8-core Intel Core i7 CPU, 64 GB RAM.

3.3 Comparing Few-Shot Methods by # Wins

The results for different few-shot learning methods can be quite different across datasets and seeds for the training set (Zhao et al., 2021; Schick and Schütze, 2021a). To compare different methods at a high level, we use a metric denoted as *# Wins*: the number of datasets that a given method performs significantly better than all other methods on. We compute this metric for a given dataset by first performing a Welch's t-test to determine if there is a significant difference in accuracy for each pair of methods. The method which performs better than most other methods is considered the "winner" of the task and its *# Wins* is incremented by 1. There are multiple winners in the case of a tie. See Figure 2 for a demonstration.

4 Simplifying Prompt Engineering

In this section, we run prompt-based finetuning and ablate different elements of the prompt. We consider the following ablations:

- **Manual Prompt (Prior)**: We use manually-written prompts from Schick and Schütze (2021a,b), and Gao et al. (2021). We show the patterns and verbalizers in Appendix A1.
- **Manual Prompt (w/o Engineering)**: We simulate standard prompt design by manually writing one prompt for each task using our intuition. We show the prompts in Appendix A2.
- **Prompt Tuning**: Inspired by Liu et al. (2021) and Lester et al. (2021), we use the pattern from Manual Prompt (Prior) but randomly initialize the embeddings of the pattern tokens and learn them using gradient-based optimization. This ablates the gains from human-designed patterns.
- **Null Prompt**: We use the same verbalizer as Manual Prompt (Prior) but use a pattern that consists of only the input fields and a `[MASK]` token (Appendix A3). This ablates the pattern entirely.
- **Null Verbalizer**: We use the same pattern as Manual Prompt (Prior) but—following Opitz (2019) and Le Scao and Rush (2021)—select random tokens for the verbalizer. This ablates the gains from a human-designed verbalizer.
- **Null Prompt + Verbalizer**: We use both null prompts and random tokens for the verbalizer.

In all cases, we finetune all of the masked LM parameters. We show the accuracy of the above prompts as well as traditional finetuning (using a `[CLS]` token and a classification head) in Figure 3.[2]

Manual Prompts Perform Best The manually-written prompts from prior work perform best on average for both models. On the other hand, our manual prompts (w/o Engineering) are noticeably worse than the ones from prior work and are outperformed by many other methods.

Null Prompts Are Competitive In many cases, prompt tuning and null prompts perform comparably to manually-written prompts, especially for RoBERTa. For instance, both of these methods outperform manual prompts (w/o Engineering) in

---

[2] For fair comparison we use the finetuning recommendations of Mosbach et al. (2021) to improve stability.

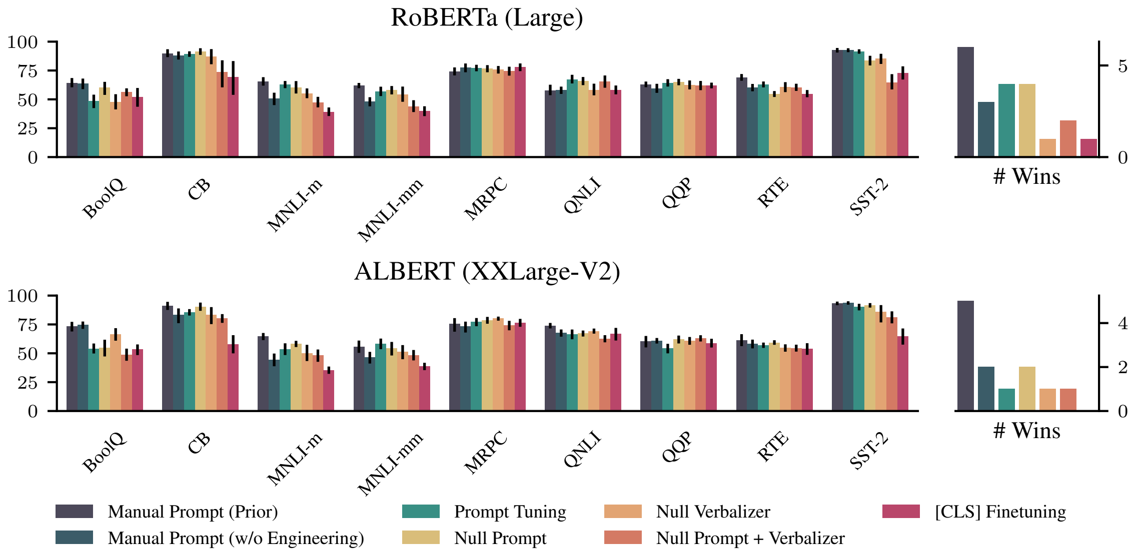

Figure 3: **Simplifying the Selection of Prompts**. We apply prompt-based finetuning in conjunction with six different types of prompts. We report accuracy or F_1 on each dataset. Manually-designed prompts from prior work achieve the best accuracy but require manual tuning on validation sets. On the other hand, null prompts and prompt tuning both perform competitively without requiring any tuning of the pattern.

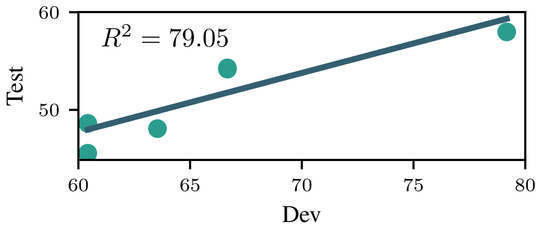

Figure 4: **Correlation of Dev and Test Performance of Null Prompts on MNLI**. The only decision to make when using null prompts is which order to concatenate the mask token and the input fields. One can choose the best option using a tiny held-out development set. We show the results for MNLI, with the few-shot development set accuracy on the x-axis.

terms of # Wins. These results are exciting from a practical perspective as they show that one can achieve competitive few-shot results without resorting to any tuning of the prompt.

From an analysis perspective, these results also show that effective few-shot learning can be accomplished without any inductive bias from a manually-written pattern. In fact, combining null prompts with null verbalizers, which involves no human design at all, still significantly outperforms standard [CLS] finetuning for numerous tasks (3 for RoBERTa and 5 for ALBERT at $p = 0.05$). This shows that some of the effectiveness of prompt-based finetuning is due to its basic setup, i.e., predicting on a [MASK] token with an MLM head.

Null Prompts or Prompt Tuning? Both null prompts and prompt tuning achieve competitive results without resorting to manual prompt design. We advocate for using null prompts over prompt tuning because they are easier to use. Null prompts only require choosing which order to concatenate the input fields and the [MASK] token. Prompt tuning requires choosing the number of embeddings, their placement, their initialization, etc.

Null Prompts Simplify Prompt Search One complication that arises in standard prompt-based finetuning is that prompts become a hyperparameter of the finetuning procedure, and have a combinatorially large search space. On the other hand, determining the concatenation order for null prompts is trivial by just trying all of the few possible options and choosing which one works best on the validation set. To see this, in Figure 4 we plot the accuracy on the few-shot development set and the full test set for different concatenation orders for RoBERTa on MNLI.[3] The development and test accuracy is strongly correlated ($R^2 = 79.05$), which demonstrates that tuning the concatenation order is easy even when validation data is scarce.

Impact of Dataset Size We next investigate whether the observations made in the previous para-

---

[3] We use MNLI because the concatenation order has a large impact on performance.

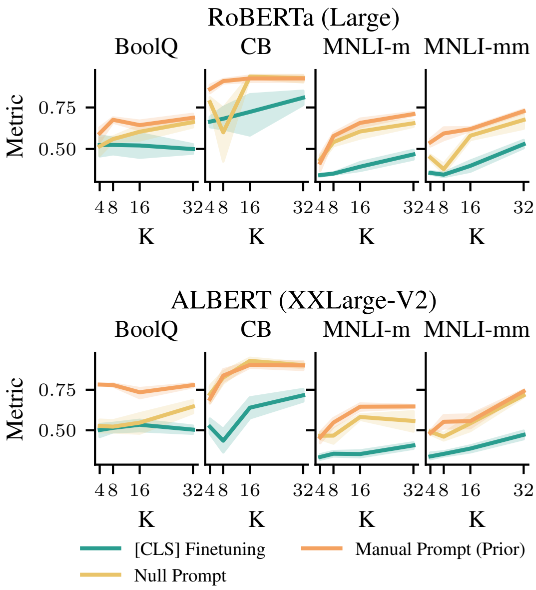

Figure 5: **Impact of Dataset Size**. We plot a subset of learning curves for $K \in \{4, 8, 16, 32\}$ (results for all datasets are provided in Appendix A1). Shaded regions indicate the range of performance across 10 different random seeds. In general, we find that as K increases the accuracy of prompt tuning with null prompts tends to be close to that of manual prompts, and substantially better than traditional finetuning.

graphs hold across different dataset sizes. Intuitively, when the amount of data is small, manual prompts may outperform other approaches because the inductive bias provided by the prompt has the most impact when there is little data to learn the task at hand. In Figure 5 we compare the accuracy of prompt-based finetuning using manually-written prompts and null prompts to traditional finetuning, using the same setup described in Section 3.1 but varying $K \in \{4, 8, 16, 32\}$. Full results for all datasets are provided in Appendix A1. Although there is some instability at lower values of K, we find that the accuracy of both prompt-based finetuning approaches tends to be similar, and is either substantially better or on-par with traditional finetuning. In other words, null prompts are competitive with manual prompts, even when K is small.

5 Achieving Simplicity *and* Efficiency

Thus far, we have shown that prompt-based finetuning can simplify prompt engineering at the cost of memory inefficiency—a new set of parameters must be learned for each task. This is in contrast to in-context learning, which holds all model weights fixed but is heavily influenced by small prompt modifications (Zhao et al., 2021; Lu et al., 2021). In this section, we investigate how to achieve *both* memory efficiency and simple prompts. Concretely, in Section 5.1 we try to simplify prompt engineering for in-context learning by tuning the prompt, and in Section 5.2, we reduce the number of learned parameters for prompt-based finetuning.

5.1 Simplifying In-Context Learning With Prompt-Only Tuning

Here, we try to make prompt engineering for in-context learning as simple as prompt-based finetuning by automatically finding the prompt. Concretely, we focus on the emerging class of methods that do *prompt-only tuning*: learning the prompt while keeping the rest of the model fixed (Shin et al., 2020; Lester et al., 2021). We consider:

- **AUTOPROMPT**: Following Shin et al. (2020), we search for discrete tokens to use in the input instead of manually-designed patterns. Search is performed using the original hyperparameters.
- **Prompt Tuning (Short)**: We use the same prompt tuning approach described in the previous section but we keep the masked LM fixed.
- **Prompt Tuning (Long)**: Based on the advice of Lester et al. (2021), we increase the number of learned prompt embeddings to 20 in order to expand the learning capacity.

For reference, we also report the results from prompt-based finetuning with null prompts. We show the results for RoBERTa in Figure 6. We find that only tuning the prompt is relatively unsuccessful. First, on average it fails to match the performance of manually-designed prompts. Second, all methods struggle to match the accuracy of prompt-based finetuning. In fact, for many of the datasets, prompt-only methods perform worse by a wide margin (e.g., 40% absolute difference in F_1 score on CB). This shows that finetuning masked LMs in the few-shot setting leads to substantially higher accuracy than prompt-only tuning.

Our Results versus Recent Prompt Tuning Work We find that only tuning the prompt performs substantially worse than finetuning the entire LM. This is in contrast to recent work, which argues that prompt-only tuning is competitive with finetuning (Lester et al., 2021; Li and Liang, 2021). We believe these are not contradictions but rather differences in the models and settings. Li and Liang

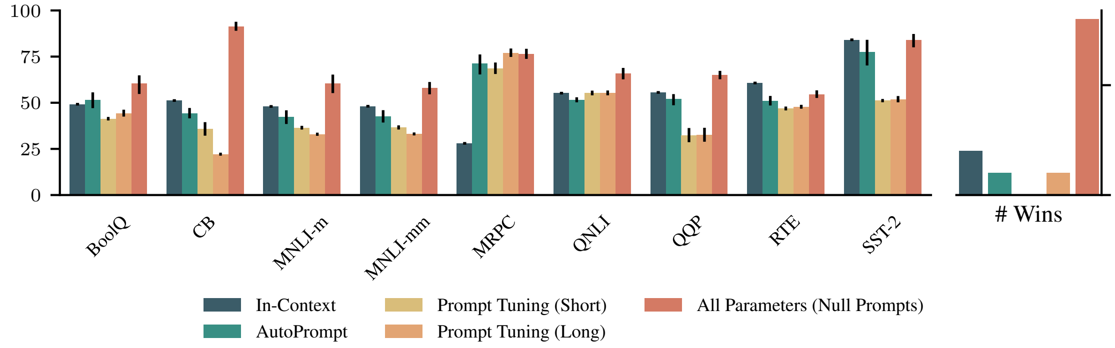

Figure 6: **Prompt-Only Tuning**. We try to simplify prompt engineering for in-context learning (i.e., using frozen models) by directly learning the prompt. The performance (accuracy/F_1) for prompt-only tuning is substantially lower than finetuning the LM parameters for RoBERTa-large. Thus, we recommend finetuning over in-context learning in the few-shot setting.

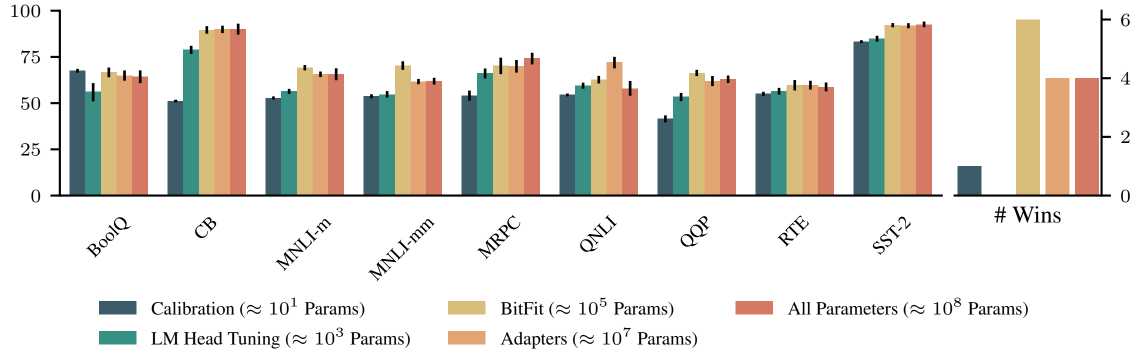

Figure 7: **Parameter-Efficient Prompt-Based Finetuning**. We perform prompt-based finetuning using different lightweight finetuning schemes. We show the accuracy or F_1 on each dataset for RoBERTa-large. BitFit achieves the highest accuracy on average and only modifies 0.1% of the parameters.

(2021) focus on *left-to-right* LMs for *generation* tasks, whereas we focus on masked LMs for classification tasks. They also finetune additional parameters in intermediate layers of the model. These differences may explain the difference in prompting accuracies. Moreover, Lester et al. (2021) show that prompt-only tuning becomes less competitive as models get smaller; we use even smaller models than evaluated in their work. Consequently, although we find that finetuning a masked LM is superior to prompt-only tuning, there may be other settings in which they fair similarly.

5.2 Memory-Efficient Finetuning

Given the inadequacies of prompt-only tuning, we next study if prompt-based finetuning can be made memory-efficient. To do so, we focus on reducing the number of trainable parameters, taking inspiration from recent work in the non-few-shot setting. The benefits of these methods is that they: (1) reduce storage costs at test time when running many tasks (one can store only the modified parameters for each task), and (2) reduce memory costs at training time, as fewer optimized parameters means much smaller statistics in optimizers like Adam. We consider four lightweight finetuning methods:

- **Adapters**: We use Adapters (Houlsby et al., 2019), neural networks layers that are inserted between the feedforward portion of the Transformer architecture. We use the default Adapters hyperparameters from Houlsby et al. (2019) (≈ 10^7 parameters per task).
- **BitFit**: Following Ben-Zaken et al. (2021), we only update the bias terms inside the Transformer (≈ 10^5 parameters per task).
- **LM Head Tuning**: We update the embeddings in the MLM output layer that are associated with the verbalizer tokens (≈ 10^3 parameters per task).
- **Calibration**: Following Zhao et al. (2021), we learn an affine transformation on top of the log-

		BoolQ (acc)	CB (F_1)	MNLI (acc)	MRPC (F_1)	QNLI (acc)	QQP (F_1)	RTE (acc)	SST-2 (acc)	Wins (#)

Table 2: **Final Few-Shot Results** from representative methods. Wins are computed on a per-datasets basis and the "winners" of the different approaches are highlighted in bold. Prompt-based finetuning significantly outperforms in-context learning and traditional [CLS] finetuning, even without any tuning of the prompt (*null prompt*). Moreover, prompt-based finetuning can be highly memory efficient using bias-only finetuning (*BitFit*). We show matched and mismatched results for MNLI.

its associated with the verbalizer tokens ($\approx 10^1$ parameters per task).

We run prompt-based finetuning for each method with the prompts from Manual Prompts (Prior). We also report the accuracy of finetuning all of the parameters for reference.

Results We show the results in Figure 7. There are diminishing returns as the parameter count is increased. In particular, substantial gains are made when going from calibration to LM head tuning to BitFit, however, there is either a marginal improvement or even a decrease in performance when going to Adapters or All Parameters. The BitFit method provides the best accuracy-efficiency trade-off, and even outperforms finetuning all of the parameters in terms of # Wins. This suggests that updating all of the LM's hundreds of millions of parameters on only 16 data points is suboptimal.

5.3 Putting Everything Together

We finally combine null prompts and memory-efficient finetuning. We show the results from this method, as well as the other best few-shot methods, in Table 2. Overall, we recommend finetuning with null prompts and BitFit: it achieves competitive accuracy, is simple to set up, and introduces small memory costs for each new task.

6 Conclusion and Future Work

Two high-level methods exist in few-shot prompting: using a frozen LM (in-context learning) and finetuning the LM on the few training examples (prompt-based finetuning). In this work, we demonstrate two new advantages of prompt-based finetuning. First, we show that it performs comparably across different prompt choices. In fact, there is a simple class of prompts—null prompts—that can be flexibly applied to different tasks without degrading performance relative to manually-written and learned prompts. Second, we demonstrate that prompt-based finetuning can be made memory efficient: finetuning only the bias terms (BitFit) achieves comparable or better accuracy than finetuning all the parameters while being 1000x more memory efficient. Taken together, using null patterns with BitFit is an approach that is efficient, simple-to-tune, and competitive in accuracy. Code and instructions for reproducing our results is available at: `https://github.com/ucinlp/null-prompts`.

Our results motivate future *analysis* of few-shot learning methods. Concretely, we show that the success of prompt-based finetuning is not solely explained by carefully-chosen patterns or verbalizers. This suggests that the gains from prompt-based finetuning are partially due to its low-level setup, i.e., predicting on a [MASK] token with a pre-trained MLM head. More generally, we hope to further analyze why and how small changes to different few-shot learning methods can lead to wildly different accuracies. We also hope to extend our findings to both *very large* and *left-to-right* LMs, as our current results are for masked LMs that are relatively small by modern standards.

Acknowledgements

We would like to thank Danqi Chen, Timo Schick, and Hinrich Schütze for their careful corrections to an earlier version of this manuscript. We also would like to thank the reviewers for their thoughtful feedback. uFACT: Unfaithful Alien-Corpora Training for Semantically Consistent Data-to-Text Generation

Tisha Anders, Alexandru Coca, Bill Byrne
Department of Engineering, University of Cambridge, United Kingdom
anderstisha@gmail.com ac2123@cam.ac.uk wjb31@cam.ac.uk

Abstract

We propose UFACT (Un-Faithful Alien Corpora Training), a training corpus construction method for data-to-text (d2t) generation models. We show that d2t models trained on UFACT datasets generate utterances which represent the semantic content of the data sources more accurately compared to models trained on the target corpus alone. Our approach is to augment the training set of a given target corpus with *alien* corpora which have different semantic representations. We show that while it is important to have faithful data from the target corpus, the faithfulness of additional corpora only plays a minor role. Consequently, UFACT datasets can be constructed with large quantities of unfaithful data, minimising the need for faithful data. We show how UFACT can be leveraged to obtain state-of-the-art results on the WebNLG benchmark using METEOR as our performance metric. Furthermore, we investigate the sensitivity of the generation faithfulness to the training corpus structure using the PARENT metric, and provide a baseline for this metric on the WebNLG (Gardent et al., 2017) benchmark to facilitate comparisons with future work.

1 Introduction

Data-to-text (d2t) generation is the task of generating *fluent text* t given a set of information units, linearised into *data source* string d (Table 1).

d	{(name, Einstein), (born, 1879), (profession, physicist)}
t	Einstein was a physicist, born in 1879.

Table 1: Example of d2t system input (d) and output (t)

Training high quality generation models requires corpora whose reference texts are faithful to the data sources representing their semantic content, i.e. the reference texts t_r should have perfect information overlap with d. Most corpora are, however, noisy, with imperfect fact overlap between data d and reference text t_r (Dhingra et al., 2019a). The quality of the training data in that case negatively impacts the performance of a d2t generator trained on it, as well as making it difficult to estimate the true accuracy of a generation t_g, given t_r (Parikh et al., 2020). Faithful examples are however expensive to obtain, and usually only available in small quantities. In the context of this scarcity, we propose the UFACT training set construction method. UFACT allows a generator to learn a more accurate d2t generation model from a mixture of faithful and unfaithful corpora, which reduces the need for vast quantities of faithful examples. For instance, our best-performing UFACT dataset contains 88692 examples, of which only $20,000$ (24.34%) examples (the ones from the target corpus) are guaranteed to be faithful. We find that our approach leads to significant improvement in PARENT (Dhingra et al., 2019b) and METEOR (Banerjee and Lavie, 2005) compared to the conventional approach of training a d2t generator on one large unfaithful corpus. We conclude that even unfaithful examples from other corpora can contribute to fluency and faithfulness. Our UFACT-trained T5 surpasses state-of-the-art performance for METEOR on the WebNLG dataset.

2 Related work

Early approaches (Reiter and Dale, 1997) formalize d2t generation as three subtasks: content determination, structuring/grouping of information, and surface realisation. A handcrafted system is designed to solve each task. Recently, the focus has shifted towards end-to-end neural approaches, incorporating each of the subtasks into one system (Ferreira et al., 2019, Puduppully et al., 2018, Harkous et al., 2020).

A number of end-to-end approaches to increasing faithfulness in d2t generation are *curative*, i.e. address generation quality post-hoc. For instance, Harkous et al. (2020) and Dušek and Kasner (2020)

Findings of the Association for Computational Linguistics: ACL 2022, pages 2836 - 2841
May 22-27, 2022

produce candidate generations first, and then judge faithfulness with a separate model, by checking entailment between d and t_g. Another approach to enhance faithfulness is to alter the generation model. Chen et al. (2020b) propose a generation model comprised of a copy-generate gate within an LSTM positional encoder. The gate acts as a soft switch between a copy-from-data mode and a language-generation mode. Kale (2020) utilise transfer learning to enhance their generation model, through pre-training on a large unsupervised, task-agnostic corpus.

A different line of research focuses on *preventative* approaches, where the typical aim is to obtain a better model by improving the training data quality. Chen et al. (2020a) apply a unigram-based dataset selection process, by removing examples for which t_r is not sufficiently related to d. Parikh et al. (2020) also investigate this approach, releasing the noise-free ToTTo dataset, to ensure the training data does not encourage unfaithful generation. Filippova (2020) look for hallucinative examples in their dataset, either considering word-overlap, or comparing how strongly a language model vs. a conditional language model anticipates subsequent text. Dhingra et al. (2019b) develop the PARENT metric, a faithfulness-quantifying F-score that takes into account the data source in addition to the potentially divergent reference, providing a more robust assessment of the d2t mapping.

In their work on model-agnostic meta-learning, Finn et al. (2017) note that training on different instances of a required task (e.g., training on different corpora) can facilitate learning a particular task. Inspired by this approach, we add other corpora with different semantic representations to the training dataset. We find not only that adding corpora boosts the semantic faithfulness of the d2t generator, but also that said corpora need not necessarily satisfy stringent faithfulness requirements, unlike the target corpus.

3 Constructing a uFACT dataset

Typically, a d2t generation model is obtained by task-specific fine-tuning, where a large-scale pre-trained model such as T5 (Raffel et al., 2019) is fine-tuned on a small corpus. uFACT however, as an instance of *mixed-corpus training*, takes a different approach: examples from multiple corpora which do not share semantic representations, are linearised and tagged to form a large training corpus. A uFACT dataset is comprised of a *target* dataset for which we desire to maximise d2t generation fidelity and *alien* corpora. The latter are d2t corpora that may differ thematically and structurally from the target corpus and whose role is to improve generation fidelity on the target corpus.

3.1 Corpora included in the uFACT dataset

The uFACT datasets we experiment with are constructed from from three corpora which differ significantly in size, vocabulary, intended purpose, and linearisation technique. Figure 1 displays the relative sizes of the uFACT datasets (FU and FUU), their faithful counterparts (FF and FFF), as well as other dataset compositions examined.

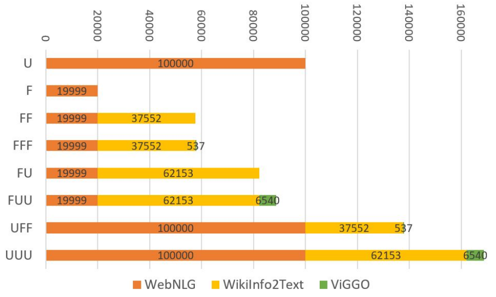

Figure 1: **Dataset sizes** The target corpus is WebNLG. Here U denotes *unfaithful*, describing a dataset that has not been curated while F stands for *faithful*, indicating a dataset that has been filtered to increase the faithfulness of the references to the data sources. See Appendix A for dataset curation approaches.

WebNLG examples consist of up to seven RDF-triplets (subject-predicate-object), which are atomic entities of a knowledge graph, linearised into a string. 15 topics appear, of which 10 are seen in training.

WikiInfo2Text[1] is based on slot-value pairs, imitating a table. Our WikiInfo2Text set (a subset of the original) comprises five topics (`UK_place`, `Book`, `Automobile`, `Military_conflict` & `French_commune`).

ViGGO (Juraska et al., 2019), a gaming dialogue corpus, has simple vocabulary, with 9 dialogue acts and 14 video game attributes available. The semantic representation consists of one dialogue act and 1-8 video game attributes, expressed as slot-value pairs that allow for lists of multiple values.

Table 2 shows a sample training point from each corpus. It also shows that in the joint dataset the data source of every example, d, is prepended with

---

[1] `https://github.com/hitercs/WikiInfo2Text`

d	**webnlg:** <s> Einstein <p> born <o> 1879 ; <s> Einstein <p> job <o> physicist
t	*Einstein was a physicist, born in 1879.*
d	**wikiinfo:** <name> H for Homicide && <author> S. Grafton && <series> Alpha Mysteries
t	*H for Homicide, by S. Grafton, is part of the Alpha Mysteries series.*
d	**viggo:** <request_explanation> (<rating>:[excellent], <genres>:[shooter, RTS]>)
t	*What is it about shooter and RTS games that you find so great?*

Table 2: **Examples of the three d2t corpora.** *WebNLG* consists of subject-predicate-object triplets, marked as such with `<s>`, `<p>`, `<o>`. *WikiInfo2Text* has slot-value pairs, with slot-names in angle brackets, and pairs separated by `&&`. *ViGGO* has limited vocabulary, but the hierarchical structure of a dialogue act (e.g., `request_explanation`) parametrized by slot-value pairs (e.g., `<rating>:[excellent]`).

a dataset-specific tag (`webnlg:, wikiinfo:, viggo:`). Tags are usually task-based, (e.g., `translate eng-to-ger:`) and have been shown to be particularly effective with Transformer models (Ribeiro et al., 2021). Treating each dataset as a different instance of the d2t task as in the meta-learning approach, the tags reveal an example's affiliation with a dataset.

3.2 Assembling a uFACT dataset

In summary, a uFACT dataset is a mixed corpus comprising a *target* (WebNLG) and *alien* datasets (WikiInfo2Text & ViGGO). The next section shows that while the target corpus should obey a maximum degree of faithfulness, the faithfulness of alien datasets plays a subordinate role. Therefore, in a uFACT dataset, the target corpus obeys the *quality-over-quantity* principle, whereas alien corpora prioritise *quantity over quality*.

4 Experiments

4.1 Experimental setup

We fine-tune the pre-trained T5-base (Raffel et al., 2020) from HuggingFace[2] for one epoch with batch size 8. We report averages of 5 values, obtained from training the model with 5 different seeds. We measure METEOR, BLEU (up to 4-grams) and PARENT (Dhingra et al., 2019b), a metric specifically developed for d2t-generation, considering both the reference text and the data source. PARENT uniquely assesses the faithfulness of the generation to the data source. For computing PARENT, we use both the word-overlap (P(w)) and co-occurrence (P(c)) entailment models. All models are tested on the WebNLG test set, as in Harkous et al. (2020), to provide a fair comparison. The dataset compositions for different experiments are given in Figure 1.

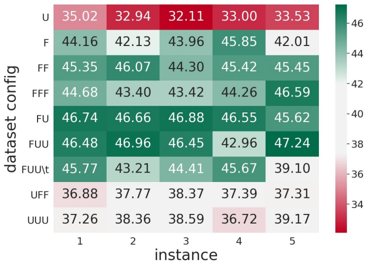

Figure 2: **T5 instance PARENT scores** for each model instance (i.e. data configuration). 'FUU\t' is a uFACT dataset without tags.

4.2 Effect of training dataset structure

Table 3 and Figure 2 show the effect of the training set structure on the model performance.

	Web.	**Wik.**	**ViG.**	**P(w)↑**	**P(c)↑**	**M↑**	**B↑**
1	U	-	-	33.32	44.43	48.28	18.89
2	F	-	-	**43.62**	**55.57**	**60.28**	**42.03**
3	F	F	-	**45.32**	**58.19**	**61.36**	39.1
4	F	F	F	44.47	56.17	60.13	**40.61**
5	F	U	-	**46.49**	**58.95**	**61.81**	**41.48**
6	F	U	U	46.02	58.54	61.59	40.88
7	F\t	U\t	U\t	43.63	59.32	60.06	33.71
8	U	F	F	37.54	48.70	51.02	**25.16**
9	U	U	U	**38.07**	**51.04**	**52.31**	18.85

Table 3: **Experimental results for T5, with different dataset configurations.** PARENT, METEOR and BLEU scores are measured for dataset configurations involving WebNLG (target), WikiInfo2Test (alien) & ViGGO (alien), respectively.{F,U}\t=no tags. All numbers reported are averages of the score of 5 models.

Training on single datasets *(Table 3, rows 1-2)* When training on the target dataset alone (i.e., WebNLG) a large performance boost is obtained on all metrics from using the faithful dataset WebNLG[F], despite the fact that it contains only 20% of the examples in WebNLG[U] (Figure 1). This demonstrates the detrimental effect of unfaithful target datasets, which are commonly used, on d2t generation faithfulness. The METEOR score of 48.28 on WebNLG[U] is comparable to the range of ∼ 39 - 46 reported in previous work (Ribeiro et al., 2021). Using faithful in-domain data has a large positive effect on all metrics (row 2).

Addition of faithful alien corpora *(rows 3-4)* When augmenting the target corpus with faithful

---

[2] https://huggingface.co/t5-base

alien corpora (i.e. F-F & F-F-F), the training corpus size increases by factors of 1.88 and 1.90, respectively. As expected, performance increases on PARENT and METEOR, compared to faithful single-corpus training (F). However, F-F (i.e. just one alien dataset) outperforms F-F-F (two alien datasets). This may be due to the fact that ViGGO has a complex semantic representation diverging from the tuple/triplet representation in the other datasets, differs considerably in domain[3] from WebNLG and WikiInfo2Text, and only represents 0.92% of the F-F-F dataset (Figure 1). Therefore, it may act as too strong a regulariser during the training phase. The decrease in BLEU coupled with increases in METEOR and PARENT suggests that the generation model stays more faithful to the table, while also phrasing the sentence in its own way.

Training on uFACT datasets *(rows 5-6)* Training on uFACT datasets F-U and F-U-U improves generator perfomance compared to training with the faithful counterparts (F-F & F-F-F) (rows 3-4). This increase shows that the faithfulness of alien datasets WikiInfo2Text and ViGGO plays a subordinate role, and the model instead benefits from the sheer number of fluent examples. However, with the addition of ViGGO[U] (row 6 vs. row 5), no metric score is boosted, suggesting a constraint on alien datasets in terms of how much domains and, potentially, semantic representation can differ.

uFACT without tags *(row 7)* Training on the largest mixed corpus (F-U-U) without dataset-specific tags reduces every metric's score, with the exception of P(c) which increases by 1.33%. Coupled with the decrease in P(w) and BLEU this suggests that the generated text contains less lexical overlap with the references.

Can the target corpus be unfaithful? *(rows 8-9)* We have seen that the large unfaithful target corpus WebNLG[U] alone is the worst-performing dataset configuration. The addition of alien corpora in this case, unlike in previous experiments, does not lead to state-of-the-art-like performance. Metric scores stay significantly below any dataset with a faithful target corpus, including the uFACT datasets. The low performance in unfaithful-target-corpus configurations shows that the straightforward addition of alien corpora does not automatically result in desirable scores, and therefore justifies uFACT's quality-over-quantity principle for the target corpus.

4.3 Analysis of uFACT efficacy

The above results indicate that faithfulness in the target corpus should not be compromised, not even to gain a larger training set (see largest dataset U-U-U vs. smallest dataset F, or simply F vs. U). Furthermore, faithful alien corpora cannot compensate for unfaithful target corpora (e.g. U-F-F vs. F).

While faithful examples are also desirable in alien datasets, the trade-off between performance and effort for faithful examples is such that faithfulness is not worth pursuing at any cost, seeing that F-U / F-U-U outperform F-F / F-F-F.

The uFACT-method however insists on the target corpus being faithful.

Models trained with $N = 2$ corpora outperform those with $N = 3$ in this paper, suggesting that adding corpora with significantly different domain coverage and semantic representations may be counterproductive when those corpora make up a tiny portion of the dataset. Subsequently, the regularising effect is mitigated in F-U-U, since the portion of ViGGO is higher (7.37%).

Both METEOR, a reference-based metric and PARENT(c/w), which both take the reference *and* the data source into account, increase when training on uFACT datasets compared to conventional training (row 6 vs. 1). These increases suggest the data source is more accurately represented in the generated text. Therefore, uFACT provides a method of training better d2t models, with increased semantic faithfulness. The efficacy of mixed-corpus training shows that pretrained language models are powerful enough to learn and benefit from several tasks at once, provided the tasks are similar enough and sufficiently represented among the training set.

On WebNLG, uFACT achieves a new state-of-the-art result of 61.81 on METEOR (Ribeiro et al., 2021) (Table 4).

Author	Model/Method	M	B
Castro Ferreira et al. (2019)	UPF-FORGe	39.00	38.65

our paper	uFACT	**61.81**	41.84

Table 4: **State-of-the-art results on WebNLG** for METEOR and BLEU.

---

[3] ViGGO has gaming-related chatbot-like utterances, whereas WebNLG and WikiInfo2Text center around geography, history, culture and public life.

The comparatively low BLEU scores, in combination with high METEOR scores, are arguably desirable, since n-gram precision metric BLEU rewards simply copying from potentially unfaithful t_r, whereas METEOR can also reward semantically equivalent rephrasings of t_r. METEOR and BLEU results thus suggest high semantic overlap without copying. Meanwhile, UFACT datasets F-U-U and F-U achieve the highest PARENT scores (Table 3, rows 5-6), ensuring semantic overlap with both reference *and* data source.

5 Conclusion

We have presented the UFACT-method, which boosts the faithfulness of data-to-text generation models by appropriately constructing the training corpus. Training T5 on a mixture of d2t corpora results in strong semantic accuracy increase, as long as and the target corpus remains faithful. UFACT's lax constraints on the majority of the training set mitigates the scarcity problem in finding faithful d2t corpora, thus making faithful d2t generation more practically feasible. The new state-of-the-art METEOR score proves that language models alone, if trained with a carefully constructed dataset, can be highly effective data-to-text generators.

A Obtaining faithful versions of the corpora

A.1 WebNLG & ViGGO

For WebNLG and ViGGO, faithful examples were retrieved from Harkous et al. (2020)[4], by selecting semantic fidelity classifier training examples labelled `accurate`.

A.2 WikiInfo2Text

Slot-value pairs with slot names which are by default irrelevant to the text (*e.g.* `img_size`, or other website-specific meta-data) were excluded from the respective example.

To be included in the training dataset, WikiInfo2Text examples had to obey two hand-crafted rules:

1. Generation-to-data-source length ratio:
   - To prevent references from giving information beyond the data source, the number of characters in the generation was restricted, given the number of semantic components in the data source:
     `len(ref) < tau*num_datapts`
2. Overall reference text length:
   - To avoid hallucinative reference texts, the number of characters in the reference was restricted:
     `len(ref) < lambda`

Values for τ and λ can be found in the table below. For WikiInfo2Text, we still perform some superficial cleaning to prevent extremely long examples from overloading the GPU.

	τ	λ
WikiInfo2Text[F]	60	800
WikiInfo2Text[U]	150	1500

Table 5: WikiInfo2Text cleaning parameter settings

Good Night at 4 pm?! Time Expressions in Different Cultures

Vered Shwartz
Department of Computer Science, University of British Columbia
`vshwartz@cs.ubc.ca`

Abstract

We propose the task of culture-specific time expression grounding, i.e. mapping from expressions such as “morning” in English or “manhã” in Portuguese to specific hours in the day. We propose 3 language-agnostic methods, one of which achieves promising results on gold standard annotations that we collected for a small number of languages. We then apply this method to 27 languages and analyze the similarities across languages in the grounding of time expressions.

1 Introduction

Natural language understanding requires the ability to map language such as color descriptions (McMahan and Stone, 2015), spatial instructions (Chen et al., 2019), and gradable adjectives (Shivade et al., 2016) to real-world physical properties. This paper focuses on temporal grounding, particularly mapping time expressions such as “morning” and “evening” to hours in the day. Temporal commonsense reasoning has been gaining traction lately (Zhou et al., 2019; Qin et al., 2021), and this important capability can benefit various temporal tasks such as event ordering and duration prediction.

One of the challenges in grounding time expressions to standard times is that such expressions may be interpreted with some variation by different people. Reiter and Sripada (2002) found that human-written weather forecasts exhibited significant individual differences between forecasters in the interpretation of time expressions. One factor for this variation is cultural differences. Vilares and Gómez-Rodríguez (2018) analyzed the time of day in which people from 53 countries posted time-specific greetings such as “good morning” and “good evening” on Twitter. They showed variation in greeting times across languages and cultures, which they connected to known facts and published statistics about cultural differences, such as differences in average wake and sleep times.

We propose to re-frame the research question posed by Vilares and Gómez-Rodríguez (2018) as a task of time expression grounding: given a time expression, the goal is to map it to a range of hours during the day. For example, what is the range of hours an Italian speaker refers to when saying pomeriggio (afternoon)? Such a grounding model can provide cultural context to machine translation systems (de Medeiros Caseli et al., 2010), language learning apps (Teske, 2017), and user-centered dialogue systems (Miehle et al., 2016).

We collected gold standard interpretations from four countries, which indeed exhibited some variation. We then proposed 3 language-agnostic methods based on either a corpus or a language model (LM). The corpus-based method performed well across languages, outperforming the method proposed by Vilares and Gómez-Rodríguez (2018) on 3 out of 4 languages. Encouraged by the performance on the labelled languages, we applied the method to additional 23 unlabelled languages, and analyzed the differences predicted by the models.

In the future, we plan to incorporate this method into NLP systems that may benefit from temporal grounding. Areas of future work involve testing our methods on low-resource languages, as well as researching ways to overcome reporting bias (Gordon and Van Durme, 2013): the under-representation of trivial facts in written text. We hope this work would be another small step in the long-term goal of developing culturally-aware NLP models (Hovy and Yang, 2021).[1]

2 Data

We collected gold standard annotations for the start and end times of five time expressions: morning, noon, afternoon, evening, and night. The annotations were collected in Amazon Mechanical Turk (AMT) for English, Hindi, Italian, and Portuguese.

Findings of the Association for Computational Linguistics: ACL 2022, pages 2842 - 2853
May 22-27, 2022

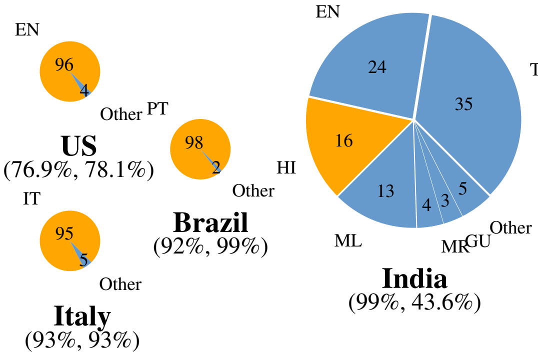

Figure 1: Percents of native languages collected from each country. India is the only country where the majority native language differs from the language used in Wikipedia and BERT (Hindi). Numbers in brackets: (1) percents of native speakers of the target language (in orange) living in this country (López, 2015); and (2) percents of the country's population that speaks this language at home (from Wikipedia).

We describe the rationale behind the choice of languages (§2.1), the HIT (Human Intelligence Task) and annotation guidelines (§2.2), and the observations from the collected data (§2.3).

2.1 Choice of Languages

The languages in our dataset are not meant to be a representative sample of all languages. We selected these languages based on the following criteria.

Availability of AMT Workers. By and large, AMT does not facilitate filtering workers by the languages in which they are fluent.[2] We thus treated country as a proxy for language, e.g. assuming that most workers in Brazil speak Portuguese, while asking workers about their native language. AMT is available at select countries, and the number of workers in each country varies. We got the most responses from US and India (100 each), in line with published analyses of demographics (Difallah et al., 2018) and language demographics in AMT (Pavlick et al., 2014). We collected 91 responses from Brazil and 58 from Italy.

The Interplay between Country and Language. We focused on pairs of country and language where most of the country's population speaks that language, and most of the L1 speakers of the language reside in that country. For instance, 78.1% of US residents speak English at home, and 76.9% of L1 English speakers reside in the US.[3] Figure 1 shows that for 3 out of the 4 countries, the majority of workers indicated they were native speakers of the majority language. The exception is India, which has many languages. Hindi is the most spoken language in India (followed by Bengali: 8% and Telugu: 6.7%) and has the larger Wikipedia corpus and a BERT model. Among the workers from India, 16% indicated they were Hindi speakers.

While the gold standard annotations are limited to 4 languages, the framework we describe in Section 3 is unsupervised and almost entirely language-agnostic. As we discuss in Section 4.3, we applied the model to additional 23 languages, selected based on the availability of a Wikipedia corpus and an LM for that language.[4]

2.2 Annotation Task

Figure 3 displays the HIT. We asked workers to identify their native language, and posed them the following questions regarding each time expression (e.g. *noon*).

1. If the native language is not English: **What is the equivalent word for *noon* in your native language?** We allowed workers to check "There is no equivalent expression in my language".

2. **What is the range of time you consider as *noon*?** Workers were required to indicate the start and end times.

We then allowed workers to add any time expression in their native language that wasn't mentioned in the HIT, as well as free text comments. To ensure the quality of annotations, we required that workers had a 95% approval rate for at least 100 prior HITs. We paid 0.3 USD per HIT.

2.3 Observations

Figure 5 displays the average start and end time for each country and each time expression. Notably, morning is quite consistent across the different countries and noon is the short period around 12 pm. The variation is higher for afternoon and evening. Many workers from Brazil noted that Portuguese uses the same word for evening and night (*noite*), and that evening turns quickly into night

---

[2] There is a recent qualification type for a few languages, such as Chinese and German. It is an expensive filter at an additional $1 fee per HIT. We tried collecting annotations for Chinese in German but got very few responses, likely due to the small number of workers that have these qualifications.

[3] Followed by the UK (17.6%), Nigeria (11.05%), Canada (6%), Australia (5%), South Africa (1.47%), Ireland (1.22%), and New Zealand (1.1%).

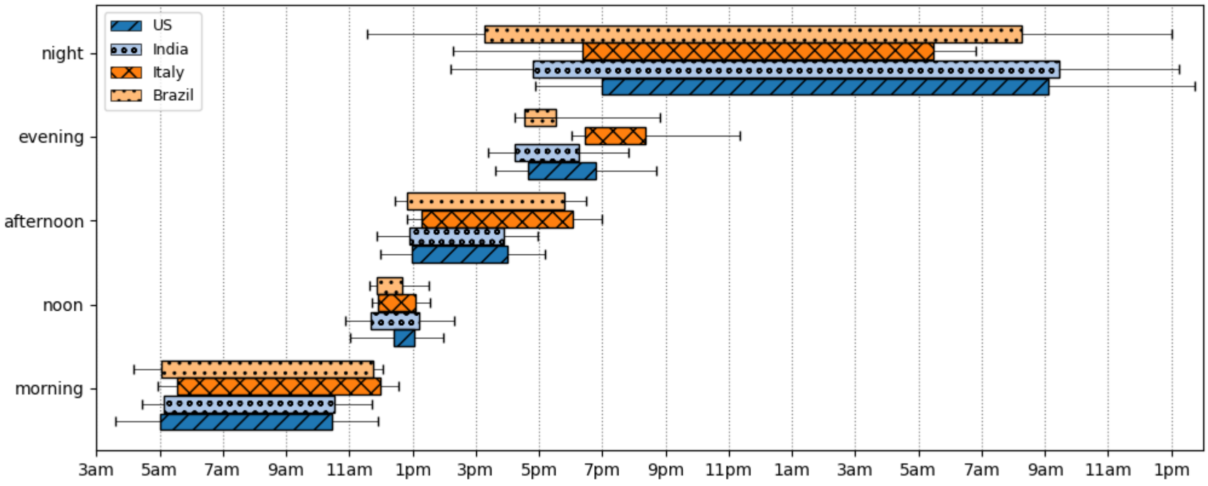

Figure 2: Start and end time distributions for each time expressions, as indicated by workers from 4 countries.

What is your native language? [Select language...]
What is the equivalent word for **morning** in your native language? ____ What is the range of time you consider as **morning**? –:– to –:– [x] There is no equivalent expression for **morning** in my native language.
What is the equivalent word for **noon** in your native language? ____ What is the range of time you consider as **noon**? –:– to –:– [x] There is no equivalent expression for **noon** in my native language.
What is the equivalent word for **afternoon** in your native language? ____ What is the range of time you consider as **afternoon**? –:– to –:– [x] There is no equivalent expression for **afternoon** in my native language.
What is the equivalent word for **evening** in your native language? ____ What is the range of time you consider as **evening**? –:– to –:– [x] There is no equivalent expression for **evening** in my native language.
What is the equivalent word for **night** in your native language? ____ What is the range of time you consider as **night**? –:– to –:– [x] There is no equivalent expression for **night** in my native language.
If there is another time expression in your native language, what is it and roughly how is it translated to English? Expression in native language: ____ English translation: ____ Time: –:– to –:–
Do you have any comments? ________________________

Figure 3: The AMT HIT used to collect the gold standard grounding of time expressions to times.

because of the country's tropical climate. This results in a very early night time in the annotations (3:16 pm), and high overlap between the afternoon, evening, and night spans.

Workers across countries suggested a missing expression that spans the time between midnight and sunrise, which they referred to as "midnight", "after midnight", "late night", "early morning", and "dawn". Other suggestions included "twilight" (6-7 pm, India), "sunrise" (5-6 am, Italy), "late morning" (11-11:59 am, Italy), "after lunch" (1:15-2 pm, Italy), and "late afternoon" (3-4 pm, Italy).

Finally, some workers commented that the interpretations of time expressions varies in different seasons because of the changes in sunrise and sunset times. The data was collected in October, and although we don't know the exact location of the workers, we can test the night start and end times against the average October sunrise and sunset times in the capital of each country. Setting aside Brazil that doesn't distinguish evening and night, there is somewhat of a match between the average **sunset** time and the average *night start* time: US: **6:30 pm**/*6:59 pm*, India: **5:52 pm**/*4:49 pm*, and Italy **6:30 pm**/*6:22 pm*. There was no such match between sunrise time and the end of the night or beginning of the morning.[5]

3 Methods

We define the time expression grounding task: given a time expression, the goal is to predict its start and end times. We developed 3 methods that differ along two dimensions: (1) the source from which the times are learned: a corpus (§3.1) or a language model (§3.2); and (2) whether to compute start and end times directly or indirectly through estimating a distribution of times.

3.1 Extractive Approach

Estimating Hour Distributions. We search Wikipedia for occurrences of a regular expression that matches a broad range of time formats, including both 24-hour and 12-hour clock formats. For each time expression X_i, we compute D_i, the distribution of hours from co-occurring time mentions within the same paragraph. For example, given the sentence "See you in the evening, at 19:30" we extract a co-occurrence of "evening" with 7 pm. We used Google Translate to translate the English time expressions to other languages, keeping multiple

---

[5] It would be interesting, given larger scale data collection, to perform finer-grained analysis of the correlation between sunrise and sunset times in specific locations within each country and the times indicated by workers in these locations.

Template
It was `[MASK]` in the `<time_exp>` .
It is `[MASK]` in the `<time_exp>` .
It happened yesterday in the `<time_exp>` , at `[MASK]` .
It happened in the `<time_exp>` , at `[MASK]` .
It will happen in the `<time_exp>` , at `[MASK]` .
Every `<time_exp>` at `[MASK]` .
The `<time_exp>` starts at `[MASK]` .
The `<time_exp>` ends at `[MASK]` .

Table 1: Templates used by the LM-based method to predict the distribution (top) or start/end times (bottom).

translations for each time expression.

Inferring Start and End. To infer the start and end times S_i and E_i from D_i, we define an optimization problem and formulate it as an integer linear programming (ILP) problem detailed below.

Input:
D_1 ... D_5: hour distribution per expression
Define: `// start and end variables`
(S_1, E_1) ... (S_5, E_5), $0 \leq S_i, E_i \leq 23$
Maximize:
$\sum_i \sum_h \text{WithinRange}(h, S_i, E_i) \cdot D_i[h]$
Constrained to:
`// start before end except at night`
$\forall_{i=1,...,4} S_i < E_i, \;\; S_5 < E_5 + 24$
`// sort expressions`
$\forall_{i=1,...,4} S_{i+1} \geq E_i$

The goal is to find a global solution for all the time expressions, with non-overlapping time ranges in which the expressions are sorted, e.g. morning comes before noon. We maximize the number of observations in D_i that are within the inferred start and end times.[6]

3.2 LM-Based Approach

We used multilingual BERT (mBERT; Devlin et al., 2019), a single BERT model trained on Wikipedia in multiple languages that achieves strong zero-shot cross-lingual transfer performance (Wu and Dredze, 2019).

Method 1: Estimating Hour Distributions. For each time expression, we query BERT for substitutes for the masked token in each template in the top part of Table 1. We translated the templates to other languages using Google Translate. For better translation quality, we assigned time expressions (morning, noon, ...) into the `<time_exp>` placeholder and hours (9:00, 12:00, ...) into the `[MASK]` placeholder.[7]

Since LM predictions are sensitive to the prompt, we follow Jiang et al. (2020) and aggregate the predictions across these various templates. We also allow for various time formats. For example, we query BERT for the substitutes of each of "It is `[MASK]`:00 in the morning", "It is `[MASK]`.00 in the morning", and "It is `[MASK]` in the morning". We sum the distributions and normalize the scores for all numbers within the range of 0 and 23.

For languages spoken mostly in countries where 12-hour clock is the norm, we computed the distribution for hours in the range of 0 and 12.[8] We then assigned each hour back into the template and predicted whether the next token is more likely to be am or pm (or its equivalent in the target language). For example, if BERT assigned 9:00 a score of 0.3 in the morning distribution, and the query "It is 9:00 `[MASK]` in the morning" predicted am with a score of 0.9 and pm with 0.1, then in the final 24-hour clock distribution, 9 has a score of $0.3 \cdot 0.9 = 0.27$ and 21 has a score of $0.3 \cdot 0.1 = 0.03$.

Finally, we use the same ILP formulation to infer the start and end times from the hour distributions.

Method 2: Directly Predict Start and End Times. For each time expression, we separately query BERT for the substitutes of the masked tokens in the start template and end template in the bottom part of Table 1. We apply the same processing as described above. The output of this step is a start time distribution SD_i and an end time distribution ED_i over 24 hours for each time expression X_i. We infer the start and end times with the same optimization problem, but with a slightly modified objective detailed below. The objective is to select the most highly scored start and end time for each expression, that adhere to the same constraints.

Maximize:
$\sum_i \sum_h (\mathbb{1}(S_i == h) \cdot SD_i[h] + \mathbb{1}(E_i == h) \cdot ED_i[h])$

---

[6] We also tried to extract start and end times directly from the corpus, but the signal was too sparse.

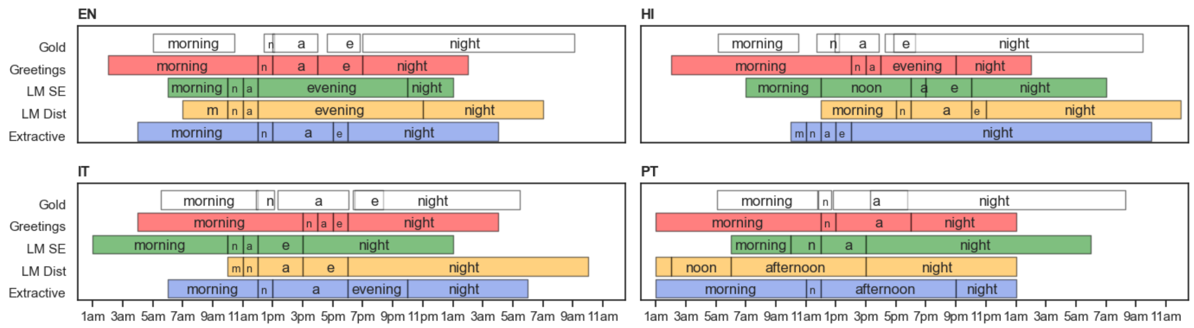

Figure 4: Start and end times for each time expressions, in English, Hindi, Italian, and Portuguese, as estimated by each method and compared to the gold standard. Note that the predicted time ranges are non-overlapping, while the gold standard ranges of certain time expressions overlap.

4 Experiments

4.1 Baseline

Our baseline is based on the Greetings method proposed by Vilares and Gómez-Rodríguez (2018). Their study focused on 4 out of the 5 time expressions used in our paper: morning, afternoon, evening, and night. We use their dataset and induce the corresponding time expression distributions. We focus on tweets in English from the US (1.34M), Portuguese from Brazil (2M), Italian from Italy (4,821), and Hindi from India (6,069). We then infer the start and end times using the ILP problem in Section 3.1. Although the dataset does not include statistics for "noon" (due to the lack of a corresponding greeting), the global objective in the ILP formulation is expected to infer the start and end times for noon based on the surrounding time expressions.

Table 2: Minute-level accuracy and differences in gold and predicted start and end times across languages.

4.2 Results

Figure 4 displays the predicted start and end times for each expression according to each method, in comparison to the gold standard times of each language. For quantitative evaluation, we define minute-level accuracy. We classify each minute of the day to a time expression based on the start and end times, and compute the accuracy compared to the gold standard minute classification. Since the gold standard grounding allows overlap between time expressions, we reward models for predicting any of the gold standard time expressions for a given minute. Table 2 shows the accuracy as well as the average differences in hours between the predicted and gold standard start (ΔStart) and end (ΔEnd) times.

There is a general preference for the extractive method, that achieves between 65% and 90% accuracy across languages. The exception is Portuguese, where this method performs worse than the others, and in particular by the LM Start-End method that performs remarkably well. The two LM-based methods perform substantially worse on the other languages. Finally, the results for India are surprisingly not bad despite the mismatch between the native languages of the annotators and the language used by our methods.

---

[7] Assigning different time expressions and hours may result in different translated templates. For example, in Italian, morning (mattina) is feminine whereas afternoon (pomeriggio) is masculine, yielding variation in the determiner - "la `<time_exp>` " vs. "il `<time_exp>` ".

[8] In this paper, such languages are English and Hindi.

Table 3: Start and end time for various languages, as predicted by the extractive method, along with the percent of corpus occurrences for each expression.

4.3 Application to Other Languages

We applied our proposed methods to additional unlabelled languages detailed in Table 3. The languages are sorted according to their Wikipedia corpus size. The Table shows the predicted start and end time for each language and each time expression.[9]

Without labelled data it is hard to judge the correctness of the predictions, but the predictions of some languages seem more reasonable than others. In particular, we observed that some time expressions appeared in the corpus more frequently than others, causing the model to dedicate most of the 24 hours to such expressions. The percent column in Table 3 show the percent of all corpus occurrences dedicated to each expression. For instance, 81.9% of the occurrences found for Finnish are for night, and the model predicted a 20 hour night. It could be a result of the extremely short days in Finland during the winter, but this is likely exaggerated by the bias in corpus occurrences.

5 Analysis

5.1 Uniformity of Time Distributions

Figure 5 presents the hour distribution for each expression in Italian, as estimated using the extractive (blue) and LM-Dist (orange) methods. As the figure demonstrates, the LM-predicted distribution is more uniform than the extractive one. This is true across most languages: the average entropy of the extractive distributions across languages is 2.78 ± 0.3, and 3.09 ± 0.05 for the LM-Based distributions. For comparison, a uniform distribution across all 24 hours yields an entropy of 3.18.

The uniform distributions predicted by BERT are possibly caused by the similarity between the different inputs (time expressions) and the different outputs (numbers). Previous work showed that BERT confuses semantically-similar but mutually-exclusive concepts such as colors (Shwartz and Choi, 2020). The representation of numbers in distributional models is also suboptimal (Naik et al., 2019; Thawani et al., 2021).

5.2 Analysis of Extracted Sentences

We sampled 25 English sentences extracted by the extractive method (§3.1), and manually analyzed them to determine whether they are valid, i.e., the sentence discusses a time and refers to it as a (reasonable) time expression. Among the invalid sen-

[9] An alternative map-based visualization is available at https://www.cs.ubc.ca/~vshwartz/resources/time_expression_map.html

Type	%	Example	
① Valid	72%	Every evening at 18:45	
② Reference error	16%	suffered apoplectic fit on the morning of 2 February, and died at 11:45 am, 4 days later	
③ Verse	12%	“Book of Signs” (1:19–12:50); the account of Jesus’ final night	
④ 12-hr clock without am/pm		下午1:00-5:00開放	Between 1:00-5:00 in the afternoon.
⑤ WSD error		ערב המלחמה... בשעה 17:00 הגיע הכוח	Before the war... at 17:00, the force arrived
⑥ Imperfect time expression mapping		매주 토요일, 오후 19:00-21:30.	Every Saturday at 19:00-21:30 pm.

Table 4: **Top**: Manual categorization of a sample of the English sentences extracted in the extractive method, along with a (slightly shortened) example of each category. **Bottom**: additional error examples in other languages.

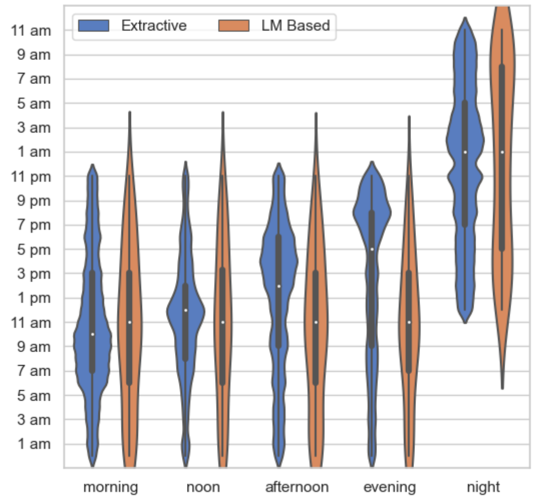

Figure 5: Distribution of hours per time expressions in Italian as estimated by the extractive (blue) and LM-based Dist (orange) methods.

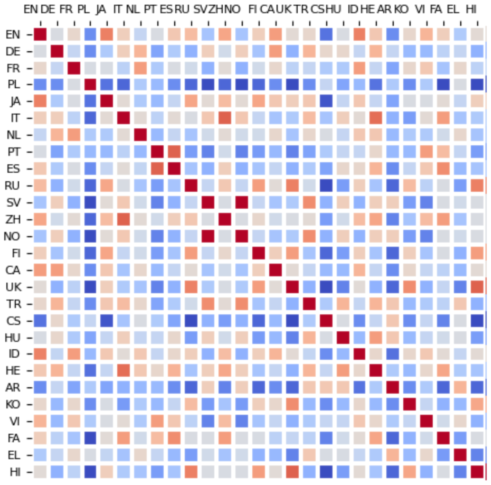

Figure 6: A heatmap showing the accuracy of predicting start and end times for each language from the times of each other language. Dark red indicates 100% accuracy while dark blue indicates 0% accuracy.

tence, we manually categorized the types of errors.

Table 4 presents the percents of each category, along with representative examples. In accordance with the results in Table 2, most of the extractions were valid. Among the errors, 4 sentences contained reference errors, for instance reporting on someone being injured in the morning and dying at another time of the day a few days later. Three sentences included a citation from the Bible or the New Testament, treating the chapter and verse separated by a colon as a time mention.

We repeated the same analysis for languages spoken by members of our research group: Chinese, Korean, Russian, Hebrew, and Italian. The percent of valid sentences ranged from 52% (Chinese) to 80% (Korean). Across languages, reference was a common error in longer paragraphs, but in preliminary experiments we found that splitting the paragraphs to sentences yields a sparse signal. In Chinese, that uses both 12-hour and 24-hour notations, the 12-hour clock was sometimes used without specifying am or pm in unambiguous contexts such as “5:00 in the afternoon”. In Hebrew, the word for “evening” has a rarer meaning of “before” which led to WSD error. In Korean, we translated “afternoon” to 오후 that more broadly means “pm”.

5.3 Similarity Across Languages

Using the predictions from the extractive method (§3.1), we compute the accuracy of predicting the start and end times of each language from the times of each other language. Figure 6 shows a heatmap of the most similar and most dissimilar languages with respect to time ranges.

The most similar language pairs in terms of time ranges are pairs of closely related languages: Norwegian and Swedish (100%) followed by Portuguese and Spanish (92%). In particular, the latter two don’t distinguish evening from night.

The similarity between Italian and Chinese (92%) might be explained by the similarity between the average times of waking up and going to bed in both countries: both Italian men and Chinese women go to sleep close to midnight and wake up around 7:30 on average (Walch et al., 2016).

Finally, Hindi and Ukrainian have similar predictions as well (92%), but considering the extremely early night start time predicted for both (2 pm and 1 pm), we conjecture that this is mostly due to noise in the data. The same pattern emerges between pairs of dissimilar languages such as Czech and Russian or Farsi and Polish (36%), where the model of each language devotes most of its 24 hours to a single time expression.

6 Related Work

Temporal Commonsense. Work on temporal reasoning ranges from extracting and normalizing temporal expressions (Strötgen and Gertz, 2010; Angeli et al., 2012; Vashishtha et al., 2019), to inferring possibly explicit temporal attributes of events, including their order (Ning et al., 2018; Vashishtha et al., 2019), duration (Chambers and Jurafsky, 2008; Vashishtha et al., 2019), and typical times or frequencies (Zhou et al., 2019).

Various benchmarks were proposed to measure models' temporal reasoning abilities. The bAbI suite contains a task that requires reasoning about the order of time expressions (Weston et al., 2015). MC-TACO is a reading comprehension task pertaining to ordering, duration, stationarity, frequency, and typical times of events (Zhou et al., 2019). TIMEDIAL (Qin et al., 2021) is a dialogue QA task focusing on temporal commonsense. Zhou et al. (2021) and Thukral et al. (2021) both cast the temporal ordering task as an NLI task. In another line of work, tracking state changes in procedural text is also related to temporal ordering (Dalvi et al., 2018; Zhang et al., 2020). Despite the success of pre-trained LMs on language understanding tasks, their performance on these benchmarks is limited, maybe due to the fact that many temporal relations are not explicitly stated in text (Davis and Marcus, 2015). A promising direction is to train LMs explicitly on temporal knowledge (Zhou et al., 2020).

Cultural Commonsense. Language has a social function, yet, there is little focus on culture-dependant language processing (Hovy and Yang, 2021). Several recent papers start addressing this gap. Yin et al. (2021) and Liu et al. (2021) extended existing visual question answering datasets with images from non-Western cultures. Models trained to answer questions regarding images in the original datasets learned Western commonsense knowledge such as the association between weddings and white dresses. As a result, their performance drops on non-Western images, such as an Indian wedding ceremony where the bride is wearing a red sari.

With respect to temporal commonsense, Acharya et al. (2021) surveyed crowdsourcing workers in the US and India regarding rituals that are commonly found across cultures such as birth, marriage, and funerals. In particular, they asked questions pertaining to temporal aspects such as typical time and duration of each event. The paper presented anecdotal differences such that a wedding lasts a few hours in the US but a few days in India. The focus of both Vilares and Gómez-Rodríguez (2018) and Acharya et al. (2021) is on analyzing such cultural differences. Conversely, we formulated cultural-differences in the grounding of time expressions into a task, for which we collected gold standard annotations and proposed several methods.

Language Grounding and World Knowledge. Our work is related to language grounding (Roy and Reiter, 2005) and to extracting world knowledge from text corpora (Carlson et al., 2010; Tandon et al., 2014). In the intersection of these two lines of work, Forbes and Choi (2017) extracted from a corpus physical commonsense knowledge about actions and objects along five dimensions (size, weight, strength, rigidness, and speed), while Elazar et al. (2019) induced distributions of typical values of various quantitative attributes such as time, duration, length, and speed. In particular, Elazar et al. (2019) mention cultural differences that arose when crowdsourcing workers were asked to estimate whether an item's price was expensive or not: annotators from India judged prices differently from annotators in the US.

7 Discussion and Conclusion

We addressed the task of grounding time expressions such as "morning" and "noon" in different languages to explicit hours. Our extractive method achieves good performance on languages for which we collected gold annotations. We dedicate the remainder of the paper to discuss various limitations and considerations for future work.

Temporal and Seasonal Factors. As discussed in §2.3, some workers mentioned that their interpretation of time expressions depends on the season, e.g., night starts earlier in the winter in the Northern Hemisphere. In addition, the time of day in which the workers answered the survey might have introduced some bias. The batches were published according to the authors' timezone and working hours, which might have been outside working hours for some countries. An early riser answering an AMT survey at 5 am or a night owl that answers it at 2 am might not be representative of the population. Finally, Vilares and Gómez-Rodríguez (2018) showed that tweets greeting "good morning" appeared later in the day during weekends and holidays, indicating later wake up times. It is possible that such factors will also affect the judgement of survey respondents.

Languages and Countries. Although there is no direct mapping between culture and language, one can often teach about the other. For example, in ConceptNet (Speer et al., 2017), a multilingual commonsense knowledge base, the English entry for breakfast specifies pancakes as breakfast food, while the Chinese entry mentions noodles.[10]

In this paper, we treated language as a proxy for culture, making the simplifying assumption that the grounding of time expressions to times is similar across speakers of the same language. This assumption is challenged for countries with multiple languages and for languages spoken across multiple countries. For example, we can expect a Portuguese speaker from Brazil and a Portuguese speaker from Portugal to perceive time expressions differently due to the different time zones in which they live.

The alternative approach of using country as a proxy for culture is not applicable since corpora and language models are available for languages rather than countries. We can therefore assume that the models' predictions for each language are dominated by the country with the larger number of speakers (or more precisely, with the larger number of Wikipedia contributors). For example, the grounding of time expressions of the Portuguese model is likely dominated by speakers in Brazil and doesn't represent speakers in Portugal faithfully.

Reporting Bias. Every method that learns about the world from texts (or from language models, trained on text corpora), suffers from reporting bias (Gordon and Van Durme, 2013; Shwartz and Choi, 2020). The frequency of occurrences in a corpus is an imperfect proxy for measuring the quantity or frequency of things in the world. In our case, it may be that some hours are less spoken of in general: perhaps fewer newsworthy events happen late at night? Some time expressions might be less ambiguous than others and therefor appear less frequently with an exact time mention.

Inducing time distributions from greetings also confounds other cultural factors such as politeness. The mapping between greetings and time expressions is not perfect, e.g. as Vilares and Gómez-Rodríguez (2018) note, "bonjour" in French means "good morning" but is also used throughout the day to mean "hello". Finally, Twitter memes might use a greeting with a different intention, as in the famous "good morning to everyone except" meme.[11]

Differences in Performance across Languages. While the methods in this paper are language-agnostic, they are designed based on English, and they don't produce equally good predictions for all languages. First, the automatic translation of time expressions and templates from English to other languages may introduce some errors. Second, beyond the differences in the set of commonly used time expressions in each language (e.g., "evening" being missing from Spanish, or "dawn" being commonly used in other languages), time might also be discussed differently in different languages. In some languages it may be more common to use cardinals to discuss hours, as in "It is two in the afternoon". Finally, the success of our methods also depends on the availability of large text corpora and the quality of the LM. We used mBERT because it is available for 104 languages, but we focused on relatively high-resource languages. This model doesn't perform equally well across all languages (Wu and Dredze, 2020). In the future, we plan to find alternative sources for collecting gold standard annotations for additional languages, which will facilitate evaluating the performance of our methods on a broader range of languages.

Acknowledgements

This work was supported in part by a research gift from the Allen Institute for AI (AI2). We thank Wen Xiao, Grigorii Guz, Hyeju Jang, and Giuseppe Carenini for helping with the error analysis in different languages, and Yuval Pinter and Daniel Hershcovich for insightful feedback.

Extracting Person Names from User Generated Text: Named-Entity Recognition for Combating Human Trafficking

Yifei Li

Mila – Quebec AI Institute

Abstract

Online escort advertisement websites are widely used for advertising victims of human trafficking. Domain experts agree that advertising multiple people in the same ad is a strong indicator of trafficking. Thus, extracting person names from the text of these ads can provide valuable clues for further analysis. However, Named-Entity Recognition (NER) on escort ads is challenging because the text can be noisy, colloquial and often lacking proper grammar and punctuation. Most existing state-of-the-art NER models fail to demonstrate satisfactory performance in this task. In this paper, we propose NEAT (Name Extraction Against Trafficking) for extracting person names. It effectively combines classic rule-based and dictionary extractors with a contextualized language model to capture ambiguous names (e.g penny, hazel) and adapts to adversarial changes in the text by expanding its dictionary. NEAT shows 19% improvement on average in the F1 classification score for name extraction compared to previous state-of-the-art in two domain-specific datasets.

1 Introduction

There are approximately 4.8 million people being trafficked around the world for commercial sex, a global industry estimated to be worth $99 billion USD (Office, 2017). Technology has been a critical tool for traffickers to recruit, advertise and exploit victims (on Drugs and Crime, 2020) and the majority of human trafficking (HT) victims are advertised on online escort websites (Rhodes and Rhodes, 2016). Recently, there have been multiple efforts to leverage AI techniques for analyzing the online advertising market and providing law enforcement with actionable intelligence to counter human trafficking (Tong et al., 2017; Rabbany et al., 2018; Lee et al., 2021). One of the key tasks in this domain is *extracting information from the online escort ads* e.g. names, phone numbers, locations, prices and activity types, which are critical for higher level analysis and modus operandi detection. This information needs to be extracted from the text of the ads, and it plays a vital role in tasks such as identifying groups of related ads and finding links between them. However, this is a challenging task since in order to avoid detection, this data is made:

- *noisy* and *obscured* e.g. using 'rose' symbols as a proxy for dollar sign and spelling variations such as 'Cathy' and 'Kathy.'
- *evolving* and *adversarial* e.g. traffickers are actively introducing new patterns and intentional misspellings to avoid detection, e.g. adapting new phrases to indicate underage victims such as 'amber alert' or intentionally misspelling 'miss' as 'mizz.'

Names have a particular importance. Trafficking is an organized activity (Lee et al., 2021) and multiple people being involved in an escort ad is a strong indicator of human trafficking. Also, the more victims involved in a case, the higher priority of investigation it needs to be given in order to minimize the harm. Hence, accurately retrieving all the names in an advertisement is critical for further analysis and action.

Thus, while the general task of Named Entity Recognition (NER) usually includes diverse entities such as person names, organizations, and geolocations, in this paper, we focus on person name extraction from escort ads for combating human trafficking.

Most advanced NER models are trained on annotated structured text corpora and/or rely on contextual information for identifying entities. However, escort advertisements are usually colloquial and consist of segmented phrases instead of continuous sentences. The state-of-the-art extractor in this domain (TJBatch Nagpal et al., 2017) is rule-based

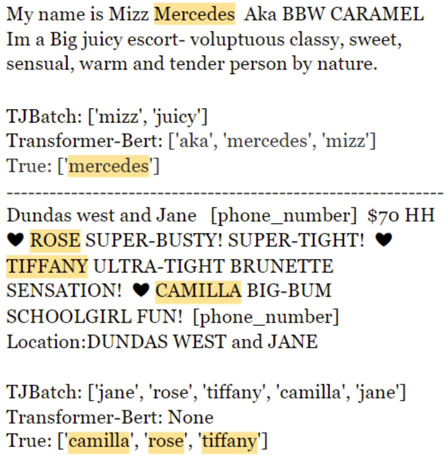
but has limited dictionaries and has difficulty dealing with ambiguity such as distinguishing person names from location names. Therefore, simple rule-based extractors or machine learning models that are context-based alone will fail in several instances in this domain. To better illustrate this, we compared the results from TJBatch and Transformer-bert (a baseline NLP model) on two example ads collected from an escort advertisement website:

- TJBatch – The state-of-the-art named entity extractor (Dubrawski et al., 2015; Chambers et al., 2019) in the human trafficking domain. This method extracts words from a dictionary and is based on manually designed regex rules.
- Transformer-Bert – A BERT model (Devlin et al., 2018) fine-tuned on the English version of the standard CoNLL-2003 Named Entity Recognition dataset.



My name is Mizz Mercedes Aka BBW CARAMEL
Im a Big juicy escort- voluptuous classy, sweet, sensual, warm and tender person by nature.

TJBatch: ['mizz', 'juicy']
Transformer-Bert: ['aka', 'mercedes', 'mizz']
True: ['mercedes']

Dundas west and Jane [phone_number] $70 HH
♥ ROSE SUPER-BUSTY! SUPER-TIGHT! ♥
TIFFANY ULTRA-TIGHT BRUNETTE
SENSATION! ♥ CAMILLA BIG-BUM
SCHOOLGIRL FUN! [phone_number]
Location:DUNDAS WEST and JANE

TJBatch: ['jane', 'rose', 'tiffany', 'camilla', 'jane']
Transformer-Bert: None
True: ['camilla', 'rose', 'tiffany']

Figure 1: State-of-the-art tools fail to precisely and accurately extract all person names in an escort ads

The results (Figure 1) show that both the domain-specific and general NER models fail in identifying certain person names in the ad. In this paper, we focus on designing an improved technique for name extraction from noisy escort advertisements The main contributions of this paper are three-fold.

- We show that existing state-of-the-art tools and language models fall short in accurately identifying names from extremely noisy and unstructured escort advertisement text.
- We introduce a name extractor, NEAT (Name Extraction Against Trafficking), that enhances a core rule-based extractor with masked language models to perform disambiguation.
- We show that NEAT outperforms the previous state-of-the-art NER model for name extraction from escort advertisements, with an average of 19% improvement in F1 for our two domain-specific datasets.

2 Related Work

There have been several surveys and systematic reviews of the problem of named entity recognition (NER) from text (Goyal et al., 2018; Li et al., 2020; Yadav and Bethard, 2019; Saju and Shaja, 2017) which all tend to outline three broad techniques: rule-based, learning-based and hybrid approaches (Goyal et al., 2018). We group the related works as:

Rule-based NER: Rule-based approaches involve predefined lists, dictionaries and/or rules based on syntactic-lexical patterns which text snippets are matched against. These methods have the obvious limitation of missing out on uncommon rules and never-seen-before dictionary keys. These methods tend to fail especially in applications where text may be informal and unstructured and need to be fortified with additional modules.

Statistical learning models for NER: Some of the methods used for the general NER problem include Hidden Markov Models (HMM) (Wang et al., 2014), Support Vector Machines (SVM) (Saha et al., 2010), Conditional Random Fields (CRF) (Majumder et al., 2012; Wang et al., 2014), Maximum Entropy Markov Models (MEMM) (Saha et al., 2009) and Logistic Regression based systems (Ek et al., 2011). In semi-supervised approaches, a small set of the training data is first used for extracting word and context features and the rest of the data is used for training a learning algorithm in a supervised fashion (Goyal et al., 2018). However, these methods require large quantities of labelled data for training which is difficult to achieve in many real world applications, including our domain of interest.

Embedding Models for NER: Embedding methods such as Word2Vec (Mikolov et al., 2013a,b), GloVe (Pennington et al., 2014), and FastText (Joulin et al., 2017) generate fixed vectors for each input token and more recent methods such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018) and its variations give context-aware embeddings and have been shown to improve entity extraction. A more recent work, LUKE (Yamada et al., 2020), based on a transformer model that treats not only words but also entities as independent tokens. It computes intermediate and output representations for all tokens, and reports the state-of-the-art results in general NER. Other popular architectures for NER include bidirectional LSTM + CRF (Lample et al., 2016), enhanced with character-level contextualized representations (Akbik et al., 2018) and contextualized word representations (CWR) based on a bidirectional transformer (Alexei et al., 2019).

Applying pre-trained models directly on escort ads performs poorly because of the very limited amount of labeled data available for training. Non-context-aware models are limited in this domain due to a significant number of names that are also common nouns which may occur with an abnormal frequency due to the adversarial and pseudonymous nature of the domain (e.g. Amber, Joy, Angel...).

NER for noisy text: Kumar et al. (2020) conducted experiments to explore the sensitivity of BERT to synthetic noise (such as spelling mistakes) in text data and showed that performance decreases drastically with increase in noise. Mishra and Diesner (2016) introduced a linear CRF model called TwitterNER that uses random feature dropout and a modified encoding scheme in combination with semi-supervised learning from unlabelled data to handle noisy and unstructured user-generated text such as tweets. However, the low F1-score in HT datasets, as shown in Table 2, show that it is not best suited for this domain. It is worth mentioning that there are also recent efforts (Liu et al., 2021) to deal with noisy labelled NER, which is a different setting from ours.

NER for Combating Human Trafficking: Apart from a few, there haven't been significant efforts towards extracting names and other entities from noisy escort advertisement text. Dubrawski et al. (2015) and Nagpal et al. (2017) used rule-based approaches specifically designed for tackling this problem. This work suffers from the shortcomings of any rule-based approaches as discussed before. Kejriwal and Kapoor (2019) proposed a network-based approach that focused on the assessment of NER algorithms in the human trafficking domain that can overcome the lack of labeled evaluation data. There have also been efforts in extracting entities for general illegal activity from data scraped from Tor Darknet (Al-Nabki et al., 2020, 2019). NEAT draws on both domain-specific rule-based approaches as well embedding based models to address the shortcomings and limitations of current methods.

3 Problem Definition

In this section, we formally define the problem of person name extraction in the human trafficking domain both at the word-level and at the ad-level.

Word-level definition: Given an *advertisement* $A = (a_1, a_2, a_3, ..., a_n)$, where a_i represents a sequence of words in the given ad, the NER task is to output a sequence with labels $Y = (y_1, y_2, y_3, ..., y_n)$ where $y_i \in \{0, 1\}$ ($\neg$*Person Name*, *Person Name*).

Since our focus is in correctly retrieving all the names in a given escort ad, we also consider a slightly reformulated problem:

Ad-level definition: Given an advertisement $A = (a_1, a_2, a_3, ..., a_n)$, we want to find a list of names that have appeared in this ad. The corresponding NER task is to output a set of words $N = \{a_i | a_i \in A \wedge y_i = 1\}$.

The language used in a typical escort ad may be both unstructured and ambiguous. The sentences are usually short and segmented using white spaces or special characters, making it harder to tokenize. It has a free choice in syntax and many person names appear in the text without a proper context. In the second example in Figure 1 the names 'Rose', 'Tiffany' and 'Camilla' are not particularly in context. Additionally, some names may be similar to location names ('Jane' in Figure 1) or adjectives (Olive, Hazel). Such names cannot simply be omitted from the dictionary either without hurting the recall. [1]

4 Proposed Method

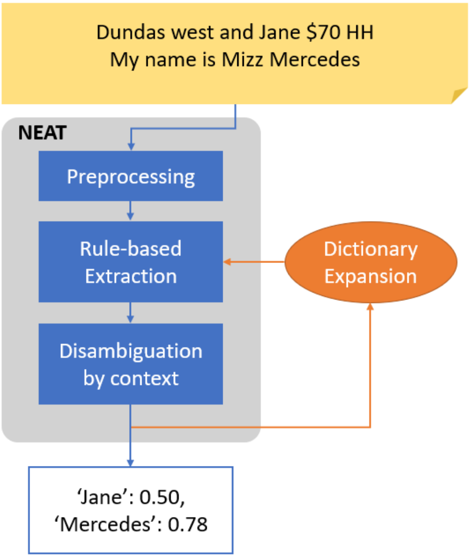
We propose a person name recognition system (Figure 2) for combating human trafficking. This system consists of three modules – a rule-based extractor, a disambiguation layer and a dictionary expansion procedure. The first two modules handle named-entity recognition and disambiguation of names respectively. The third module is designed to adapt the system to evolving changes in the advertisement text like newly introduced (pseudo)names.

Preprocessing: Due to its colloquial nature, the input text needs to undergo preprocessing. Contractions related to a person name context are expanded (e.g "I'm" is changed to "I am") to fit the rule-based extractor, and all special characters and emojis are

---

[1] We define the properties of Advertisements and what we consider as a Person name in the Appendix A.

Figure 2: NEAT Overview



removed. The text is also true-cased as the extractor relies on correct part-of-speech tags.

Rule-based extraction: Our base extractor draws on the rule-based extraction process of TJ-Batch (Nagpal et al., 2017). It consists of 2 parts – regular expression (regex) rule matching and gazetteer matching (person name dictionary). For the regex rule matching, we manually created 15 rules, including common titles for women (e.g. 'miss') and patterns like 'my name is + NNP'. For the gazetteer matching, we collected a list of common female names as the gazetteer. The rule-based extractors find exactly matched word tokens from the input text.

Confidence estimation: We further measure the degree to which a pattern from the base extractors appears to be used consistently as a true person name throughout the training corpus. For a rule-based matching pattern i where i can be either a word in the dictionary or a regex-rule, we define its weight as:

$$p_i = \frac{cpf(i) + 1}{ctf(i) + 2}$$

where $cpf(i)$ denotes the number of times that a word is correctly predicted by the pattern i, and $ctf(i)$ is the number of occurrence of the pattern i in the entire training corpus. Here, we are using the Laplace smoothing to account for unseen patterns.

These patterns' weights are used to assign a confidence to extracted words. More specifically, each extracted word j will have two associated weights: p^n_j from the pattern it is matched to with gazetteer/dictionary extractor and p^r_j from the pattern it is matched to with regex-rule extractor (zero if not matched in both cases). The arithmetic mean of these two weights is considered as the total confidence of the base module on this word being a name, i.e. $p^b_j = {}^1\!/_2(p^n_j + p^r_j)$.

The simple rule-based strategy, although effective, often wrongly tags certain ambiguous words as names (e.g. hazel, penny).

Disambiguation layer: The disambiguation layer helps to distinguish if a word extracted by the rule-based extractors is in fact a proper person name in its context. For this, we exploit masked word prediction capabilities resulting from a standard training procedure for language models such as BERT (Devlin et al., 2018). In this procedure, individual words are masked, and the model learns to predict them. Although this is typically done for training a language model on a large unlabeled corpus, we use it differently, for disambiguation.

Specifically, we use RoBERTa (Liu et al., 2019), a variant of BERT with improved pre-training, fine-tuned for the task of NER on a dataset consisting of collected escort ads (please see Section 5 for details). We call this model HT-bert.

After training, we can mask a word and get a vector of word probabilities where the highest probabilities suggest words that could reasonably replace the masked word. Therefore, if we mask a potential name, we can examine if the probable replacements are words that we are confident are names (suggesting the masked word is also a name) or that we are confident are *not* names (suggesting the masked work might not be a name) [2].

Calibrating the confidence estimation: Next, we re-estimate the confidence of an extracted word being a proper person name given its context based on the weight returned by the disambiguation layer, as shown in Algorithm 1. For an extracted word j, we calculate the weight for the disambiguation step p^d_j, by measuring the proportion of the predicted words in the context that are known names in our dictionary. Given the p^d_j from the disambiguation step and p^b_j from the base extractor, we recalibrate our confidence in j being a name again as the mean of the two, i.e. $w_j = {}^1\!/_2(p^b_j + p^d_j)$. Further, we set $p^d_j = -1$ if the masked word appears in the predicted words list, resulting in a final w_j smaller than or equal to zero. Since it is highly unlikely

---

[2] More details on this model can be found in Appendix C

```
Input: a word $j$ and its context
Require: fill_mask function
Require: $k$, the number of words to predict
Require: $ND$, a dictionary of names
predictions = fill_mask(context of $j$);
$counter$ = 0;
for each word w in predictions do
    if w is in ND then
        $counter$++;
    end
end
$p^d_j$ = $counter$ / $k$;
for each word w in predictions do
    if w is equal to j then
        $p^d_j$ = -1
    end
end
Return: $p^d_j$
```

Algorithm 1: Disambiguation based on a contextual language model's fill_mask function.

for the language model to predict the exact person name based on the context. Finally, each word j is accepted as a person name if w_j is higher that a set threshold, which is a hyperparameter.

Dictionary expansion: We design a dictionary expansion module to deal with out-of-dictionary(OOD) names. Using our confidence on how likely a word is a name, w_j, we simply apply a different threshold/hyperparameter to add some of the more confident OOD names to our dictionary[3]; which we call **HT_filter**. We also consider combining this with two common dictionary expansion techniques: (i) **W2V** (Gentile et al., 2019) expands the dictionary by finding the neighbors of known dictionary names in the embedding space learned by a Word2Vec model, and (ii) **PFIDF** (Minkov et al., 2005) computes a Pf-Idf score that takes into consideration both the probability of a word being a name from a regex-rule extractor, and how common it is in the training corpus.

5 Experiment Setting

Evaluation metrics: We use two evaluation criteria to compare the performance of NEAT and all baseline models for person name extraction.

Word level evaluation: Given a list of ads $A = \{A_1, A_2, ..., A_n\}$, for an ad A_i, let $\hat{Y}_{A_i}$ represent the predicted set of person names and Y_{A_i} represent the set of true person names. A word w is defined as a True Positive (TP) instance if $w \in Y_{A_i} \cap \hat{Y}_{A_i}$, a False Negative (FN) instance if $w \in Y_{A_i} \setminus \hat{Y}_{A_i}$, and a False Positive (FP) instance if $w \in \hat{Y}_{A_i} \setminus Y_{A_i}$. Here, we report precision, recall and F1-score of word-level classification as in general NER models.

Ad-level evaluation: Since the proposed system is defined for a noisy text setting, we define an evaluation metric which measures the performance on a document level or an ad level. We use Intersection over Union (IoU) as the ratio of the number of common words and total number of words in the predicted set $\hat{Y}_A$ and ground truth set Y_A. Before calculating IoU, we split each string in $\hat{Y}_{A_i}$ and Y_{A_i} by space and compute IoU based on the individual words.

$$IoU_{A_i} = \frac{Y_{A_i} \cap \hat{Y}_{A_i}}{Y_{A_i} \cup \hat{Y}_{A_i}}$$

We define the prediction of an ad A_i to be a TP if $IoU_{A_i} \geq 0.5$ and a FP if $IoU_{A_i} < 0.5$. A prediction will be counted as a FN if $\hat{Y}_{A_i} = \emptyset$ and $Y_{A_i} \neq \emptyset$ and TN if $\hat{Y}_{A_i} = \emptyset$ and $Y_{A_i} = \emptyset$.
In addition to precision, recall, and F1-score, we also report F2-score for the ad-level evaluation.

$$\text{F2 score} = \frac{5 \times \text{precision} \times \text{ recall}}{4 \times \text{precision} + \text{recall}}$$

This assigns more importance to recall than F1. In trafficking detection applications, it is often important to extract all the names in the text correctly (have strong recall) as this serves as the basis for downstream tasks like detecting micro-clusters of related ads (Lee et al., 2021) or finding links between connected ads (Rabbany et al., 2018).

While we acknowledge that span-level evaluation is considered standard for NER, we believe a token-level evaluation is better suited for our application. We discuss about this choice in Appendix F.

Baselines: We compared NEAT variants with five types of baselines, ordered by their appearance in our result tables.

General-purpose NER packages:

- **Stanza** (Qi et al., 2020)
- **Spacy**[4]

BERT-based models fine-tuned for NER:

- **Transformer-bert** (Devlin et al., 2018) – designed for general NER, trained on CoNLL2003.

---

[3] Details of parameter tuning is provided in Appendix D

Table 1: Dataset statistics for both domain specific and generic benchmarks.

- **Fine-tuned-bert** – 'bert-base-uncased' model fine-tuned for NER.
- **Whole-mask-bert** – bert trained by masking of whole words instead of tokens, fine-tuned for NER.

NER algorithms based on language models:

- **Flair** (Akbik et al., 2018) – trained character language model that learns contextualized string embeddings tuned for NER.
- **ELMo** (Peters et al., 2018) – model that learns contextualized word representations tuned for NER.
- **LUKE** (Yamada et al., 2020) – transformer based model that learns contextualized embeddings, fine-tuned on TACRED dataset (Zhang et al., 2017).

NER models for noisy text:

- **TwitterNER** (Mishra and Diesner, 2016) – semi-supervised approach that combines text cluster information and word embeddings and uses a CRF for NER.
- **TJBatch** (Nagpal et al., 2017) – state-of-the-art rule-based named entity extractor in the human trafficking domain.

RoBERTa with and without domain adaptation:

- **Fine-tuned-roberta** (Liu et al., 2019) – RoBERTa language model with improved pre-training, fine-tuned for NER.
- **HT-bert** – RoBERTa model further trained on unsupervised masked word prediction with 1.1 million escort ads[5], then fine-tuned for NER.

NEAT *variants:*

- **NEAT-base** - rule-based extractors only that returns all the matched words regardless of the confidence threshold.
- **NEAT-fixed** - NEAT model including disambiguation layer and confidence threshold. The dictionary used is fixed across all datasets.
- **NEAT-update** - full NEAT model with augmented dictionary using true names from the training set. The weights of newly added words are computed by the same method used to compute p_i.
- **NEAT** - full NEAT model with augmented dictionary using one pass of dictionary expansion module.

Datasets: The performance of NEAT and all baseline models was evaluated on four datasets – two new escort ad datasets we curated ourselves and two general NER datasets common in the literature (CoNLL 2003 Sang and Meulder, 2003 and WNUT17 Derczynski et al., 2017). We split all datasets 80-20 train-test. For hyperparameter tuning, we split another 20% from the train set for validation. The summary of the datasets can be found in Table 1. In particular, we have:

- **HT1K:** 994 examples crawled from an escort advertisement website.[5] Names were annotated by crowdsourcing through Amazon Mechanical Turk, plus a member of our team resolving conflicting cases. 75.6% of the examples were labeled with the majority of crowd workers in agreement, 12.2% were resolved manually, and the remaining 12.2% were excluded from the test set. More details on the annotation process can be found in Appendix B.

  For training HT-bert, a separate batch of 1.1 million escort ads were also crawled from this source.
- **HT2K:** 1970 examples crawled from a different escort advertisement website,[6] with annotations similar to the HT1K dataset. In this case 88.7%

---

[5] We omit the website name here to avoid any potential impacts on the website or on individuals in our data

of the labels use the crowd worker majority, 6.8% were resolved manually, and the last 4.5% were excluded from the test set.

- **CoNLL2003**: 6000 examples. The general dataset includes many types of entities; we evaluate both this general prediction (for models that are not designed specifically for names) and the names only (the B-PER and I-PER annotations).
- **WNUT17:** 5689 examples. We restrict evaluation to the names (B-PER and I-PER).

6 Results and Discussion

Name Extraction: We evaluate the performance of the baseline models and NEAT for name extraction from text and display the results in tables 2, 3 and 4. We see that NEAT gives the best overall F1 score performance in the word-level evaluation (Table 2) on both domain-specific datasets: HT1K and HT2K. In Table 3, we perform equally well in ad-level evaluation on HT1K and HT2K in both F1 and F2 metrics.

It's worth mentioning that NEAT has better performance on HT2K than on HT1K. This outcome is not surprising because our weight assignments are trained with HT2K training set explicitly. Since advertisements from different websites have different language features and it is unrealistic for our tool to be retrained on every new website we crawl, it's important for our proposed system to do effective transfer learning. Results in Table 2 and Table 3 support that even though the assignments are trained on HT2K, NEAT still performs relatively well in F1 (and F2), outperforming all other models.

Conversely, both NEAT and TJBatch perform worse on the non-HT datasets. This is likely because their rule-based components are specifically designed to capture patterns common in escort ads but less so in generic data. We found that using our regex-rule extractor alone, without the rest of our model, NEAT would only extract 3 words from all of CoNLL and 10 from all of WNUT17, confirming the rules do not fit these datasets. The dictionary component of our model also lacks many traditional male names and last names of all genders.

We include an ablation study to review the effectiveness of modules. Results from **NEAT-base** and **NEAT-fixed** performs well on the domain datasets but poorly on the generic datasets due to the reason mentioned above. **NEAT-fixed** in general performs better than **NEAT-base** because of the additional disambiguation module.

Finally, we see that HT-bert, as well as the other BERT-based models, gives mediocre performance in this domain. This shows that standard methods for domain adaptation of language models (i.e. unsupervised training on a domain-specific corpus, and supervised fine-tuning) are insufficient to produce optimal results. An approach that can leverage stronger domain adaptation, like ours, is needed.

Parameter tuning: We investigate the consequence of adding weight components and experiment with different parameter combinations (of threshold and k) on the HT2K dataset. The threshold is the minimum score a word extracted by NEAT needs to have to be considered a candidate in the list of words predicted by HT-bert 'fill_mask'. The dataset is split into train, validation and test sets. M_{base} represents the performance measures of the base extractors alone without weights. $M_{weighted}$ denotes the performance measures of the proposed weighted extractor. The results in Table 5 are relative changes in the metrics calculated as $(M_{weighted} - M_{base})/M_{base}$. The table demonstrates that adding weight components can effectively disambiguate the output words thereby increasing precision. The F1-score increase reaches its peak when the weights threshold is set to be 0.1. On the other hand, when the parameter k of fill_mask equals 40, the relative metrics have the best overall scores. The results in the preceding section use this best parameter pair.

Dictionary Expansion: We study the effect of dictionary expansion and experiment with different methods on the HT2K dataset as shown in Table 6. We first randomly remove half of the names in the dictionary and run the dictionary expansion using three methods: W2V, PFIDF, and NEAT. The threshold value is tuned on the validation set for each method (tuning results for W2V and PFIDF are shown in Appendix D). M_{half_dict} represents the performance measures of the dictionary extractor using only half of the original dictionary. $M_{expanded}$ denotes the performance measures of dictionary extractor after dictionary expansion. The results in Table 6 are relative metrics calculated by $(M_{expanded} - M_{half\_dict})/M_{half\_dict}$ and 'count' indicates the number of new words added to the dictionary after expansion. The goal for dictionary expansion is to tackle the unseen word problem in a gazetteer based extractor and increase the recall rate. From the experiment results, recall is greatly

Table 3: Ad-level match results: F2 score, Precision, Recall. As in the previous table, NEAT gives a significant improvement on HT domain datasets (HT1K and HT2K).

increased as expected. It is also worth noticing the NEAT_filter method has a slight increase in precision after the expansion. This result shows that most of the expanded words from NEAT_filter are actual person names in their context. NEAT_filter also has the highest F1 increase among the three primary methods. However, PFIDF finds more words than NEAT_filter while having a comparable F1 increase. By combining both, we get the highest increase in F1 and recall.

While this seems effective for improving this halved version of our dictionary, we found it did not significantly improve the performance of our overall model with the full dictionary as the result of **NEAT** suggests. We hypothesize this is because the full dictionary is already saturated for the domain specific datasets and hard to improve. Also, since regex-rule can only match a few instances in the generic corpus, the corresponding candidate pool for expanding the dictionary is limited. Nonetheless, these results show this procedure can be helpful as obscuration and adversarial strategies evolve and the dictionary needs improvement.

An additional observation is that after we included all the true names from the training sets and rerun NEAT, the performance of **NEAT-update** shows significant performance increases in the generic datasets. This suggests that we can adapt our system to other topic specific corpus by choosing the appropriate dictionary.

7 Conclusions

We presented NEAT, which addresses the problem of name extraction from noisy, adversarial escort advertisement text. NEAT consists of two main components - a rule-based extractor (combining a dictionary of names and regex matching) and a disambiguation layer.

NEAT significantly improves on the previous state-of-the-art for this task, with around 19 percentage points at the word-level and 9 percentage points at the ad-level improvements in F1 score on two datasets. Both our method and the previous state-of-the-art outperform generic methods, highlighting the continued need for and benefit of domain-driven approaches.

By modifying the dictionary and regex matching, our pipeline can be adapted to other domains and tasks to a greater extent than is possible with many generic models and methods. In future work, we plan to investigate this further, by examining other tasks (such as extracting locations as well as person names) and domains (such as more generic but still noisy, Twitter data).

Reproducibility: Our code is made available online at `https://github.com/tudou0002/NEAT`. The domain related data used in this paper contains person identifying information and can be made available for research purposes only, based on a data-sharing agreement. Please reach out to the authors of the paper for getting access to this data.

A Appendix: Terminology

Here we define key terminology used in the scope of this work and briefly discuss some of its properties.

- *Advertisement*. In the scope of this paper, an online *advertisement* is defined as a notice or announcement in a public website promoting a sexual service.

  Unstructured Text. The sentences in online escort ads are usually short and segmented using white spaces or special characters, making it harder to split the sentences correctly. Also, since online advertisement has a relatively free choice in syntax, many person names appear in the text without a proper context. Since we cannot accurately predict the next word based on the context, a simple language model cannot play to its strength in these scenarios. In the second example in Figure 1 the names 'Rose', 'Tiffany' and 'Camilla' are not particularly in context.

  Ambiguity. Another significant challenge is the ambiguity in the text. Person names can be very similar to some of the location names ('Jane' in 1). Additionally, certain names may also be adjectives (Penny, Hazel), thus confusing dictionary and rule-based extractors. Removing these ambiguous words from the dictionary can partially solve this, but then we face a decrease in the recall rate.
- *Person Name*. A *Person Name* that appears in an advertisement is usually associated with other pronouns or adjectives. We declare a word as a person name if it is both a person name in a regular context and a word that refers to the person mentioned in the advertisement. Some names may also have varying spellings or be misspelled.

B Appendix: Annotated Process

As noted in the main paper, to get the base for HT1K, we randomly selected 1000 examples from a large dataset of escort advertisements crawled from a single website. We followed the same procedure for HT2K, but with 2000 examples and from another website. We then crowdsourced annotations with Amazon Mechanical Turk. Examples were preprocessed to remove special characters, such as emoji, which could not be input into Mechanical Turk. Each example was annotated by 3 different workers using IE-Turk,[6] a package that gives workers an interface where they can click on or highlight named entities to mark them. Workers were required to be Mechanical Turk Masters (a designation Amazon awards for consistent quality) and to have at least an 85% approval rate on all tasks. Amazon also requires workers to have Adult Content Qualification for a task like this with sensitive content. Workers were paid $0.03 per example, which lead to fast completion.

The short-form instructions were "Select (or click) all person names in the text." The long-form instructions were:

> Select all words in the text that name a person, including repeats. Some names may contain spaces, other characters, or have other issues with the writing. Please ignore those issues and

---

[6] https://github.com/Varal7/ieturk

> select the name anyways. For example, if the text contains "Alex ander" or "Alex@nder" or "HiImAlexander" or "Alexander@email.com," please select all of them. In the latter two cases, it will only let you select the entire "word," but that is fine. Pronouns like she/her/he/his do not count as names. Not all text will contain names; if there is no name, please check the "There is no person name" box and continue.
>
> Your annotations will be used for research to help fight human trafficking.

IE-Turk does not differentiate between two successive names and a first name plus last name. Therefore, similar to other NER datasets like CoNLL and WNUT17, our labels are individual words.

The annotator agreement is given in Table 7. There are four cases. When none of the annotators agree, we take one randomly for training examples, and do not use them for evaluation. When two of the annotators find the same names, or all three annotators agree, we follow the standard procedure of taking the majority vote.

The most complex case is when two of the annotators agree on an empty set (i.e. find no names) but the third does find one or more names. The conventional approach might be to still take the majority vote, but we observed many valid names among the minority annotation. Therefore, one of our team members manually resolved the labels for these cases to produce a more accurate result. Based on these stronger labels, these cases are likely to contain a name: 82.6% of such cases in HT1K, and 56.1% in HT2K, contained at least one name. This suggests that if additional annotation is not possible, it will be optimal to use the label from the single annotator who found one or more names, rather than the majority who found no names. However, for best quality, it is necessary to either drop or re-annotate these cases, as we did for these datasets.

A small number of examples which produced errors or ambiguity during the annotation or its post-processing were removed, leaving 994 and 1970 examples in HT1K and HT2K respectively.

The "Two (non-empty)" and "All" categories, which reflect the strongest agreement from the crowd workers, comprise most of the examples – over 75% in HT1K and over 88% in HT2K. Thus, this crowdsourcing is effective in producing accurate labeled examples for this domain. In combination with our manual resolutions for the "Two (empty)" category, we obtain accurate labels for over 85% and 95% of the original data.

Workers in Agreement	HT1K	HT2K
None	121 (12.2%)	88 (4.5%)
Two (empty)	121 (12.2%)	134 (7.0 %)
Two (non-empty)	302 (30.4%)	399 (20.3%)
All	450 (45.2%)	1349 (68.5%)

Table 7: Number of examples grouped by worker agreement. Two or more workers agree on the majority of examples.

C Appendix: Disambiguation with Masked Word Prediction

We exploit masked word prediction capabilities resulting from a standard training procedure for language models such as BERT (Devlin et al., 2018). In this procedure, individual words are masked, and the model learns to predict them. This is typically done using weight tying (Levine et al., 2020; Inan et al., 2017; Press and Wolf, 2017). First, one-hot vectors representing each token, including the special mask token, are converted to input embedding vectors through multiplication by a matrix W. After adding a positional encoding, these embeddings are passed through the core transformer part of the model. This produces output embeddings for each token. In weight tying, the output embedding of the mask token is then decoded to word predictions using W^T, the transpose of the matrix that encodes the inputs. Finally, after applying a softmax, the predictions are trained with a cross-entropy loss to approach the one-hot coding of the real token that was masked.

Typically, this procedure provides an effective way of training a language model on a large unlabeled corpus. We use it differently, for disambiguation. For each word extracted by the rule-extractor as a potential name, we mask it in its sentence and use HT-bert 'fill_mask' to obtain a confidence score for that word being a valid person name.

D Appendix: Parameter Tuning for other Dictionary Expansion Methods

Table 8 shows the parameter tuning for dictionary expansion using Word2Vec, Table 9 shows results for different thresholds using PF-IDF and Table 10 shows results with different thresholds on weights

Thres Top_k	2	5	8
5	+1.0%	-3.0%	+7.0%
10	-10.8%	-3.1%	+4.3%
15	-14.9%	+0.1%	+6.1%

Table 8: Parameter tuning for W2V. The best/bold setting is used for Table 6. Change in F1-score using different parameters for the Word2Vec method.

Threshold	F1	Precision	Recall
0.1	+13.8%	-0.6%	+26.0%
0.3	+3.1%	-3.2%	+8.0%
0.5	+1.6%	-1.7%	+4.0%

Table 9: Parameter tuning for PF-IDF. The best/bold setting is used for Table 6. The table shows percentage change in metrics using different threshold for Pfidf.

in NEAT.

E Appendix: Baseline models

General-purpose NER packages:

- **Stanza** (Qi et al., 2020) is a collection of accurate and efficient tools for the linguistic analysis developed by Stanford NLP group. The named entity recognition (NER) module in Stanza recognizes mention spans of a particular entity type in the input sentence.
- **Spacy** is an open-source python-based software library for NLP tasks including NER.

BERT-based models fine-tuned for NER:

- **Transformer-bert** (Devlin et al., 2018) uses the BERT model from the NER pipeline as implemented by Huggingface
- **Fine-tuned-bert** (Devlin et al., 2018) is a 'bert-base-uncased' model that has been fine-tuned for NER using a combination of CoNLL2003 and names extracted from escort advertisements.
- **Whole-mask-bert** (Devlin et al., 2018) uses a BERT model that has been trained by masking entire words at random instead of tokens. We use the 'bert-large-cased-whole-word-masking' model and fine-tune it for the task of NER using the same combined dataset as the other baselines.

Threshold	F1	Precision	Recall
0.10	+10.1%	-3.7%	+21.9%
0.12	+11.2%	+2.5%	+28.0%
0.14	+9.8%	+1.8%	+16.0%

Table 10: Parameter tuning for dictionary expansion using NEAT. The overall best/bold setting is used for Table 6. Change in metrics using different threshold on weights in NEAT.

NER algorithms based on language models:

- **ELMo** (Peters et al., 2018) is a context word representation based on deep bidirectional LSTM used for the downstream task of NER.
- **LUKE** (Yamada et al., 2020) is a transformer based model that treats words and entities as independent tokens and learns contextualized representations. The LUKE model fine-tuned on TACRED dataset (Zhang et al., 2017) as implemented in the Hugging Face library is used for the experiments.
- **Flair** (Akbik et al., 2018) uses the internal states of a trained character language model to produce a novel type of word embedding known as as contextual string embeddings which is used for the downstream task of NER.

NER models for noisy text:

- **TwitterNER** (Mishra and Diesner, 2016) designed for noisy and unstructured text such as tweets uses a semi-supervised approach which includes text cluster information along with word embeddings and employs random feature dropout and a CRF for entity recognition.
- **TJBatch** (Nagpal et al., 2017) The state-of-the-art named entity extractor in the human trafficking domain. It is able to extract more than 20 kinds of entity types using the rule-based strategy. We only consider the person name entity type in our experiment.

RoBERTa with and without domain adaptation:

- **Roberta-base** (Liu et al., 2019) is a language model based on BERT, with modifications to the pre-training to improve efficiency and performance. We fine-tune it for NER in the same way as fine-tuned-bert.
- **HT-bert** adapts Roberta-base to the HT domain by training unsupervised masked word prediction on 1.1 million ListCrawler escort ads. It is then fine-tuned for name extraction, again as with fine-tuned-bert.

As a pre-processing step, all emojis and non-ASCII characters are removed from the advertisement texts before passing them through the NER models. Each dataset was split into 80-20 train-test split and the train set was used to fine-tune the BERT-based models. We do-not distinguish between ‘B-PER’ and ’I-PER’ in the labels (i.e if they appear in the beginning or in the middle of the text). For evaluation, both the predicted and ground truth names are converted to lower case.

F Appendix: Token-level Evaluation Metric

Due to the informal language nature of the escort advertisements, most, if not all, of the person name in the descriptions are first name or nickname basis. In these cases, the token-level evaluation and the span-level evaluation will end up having the same performance. For example, “*Lia available now*” with “*Lia*” predicted as **PER** has the same precision and recall score irrespective of whether the true label sequence is [B-PER, O, O] or [PER, O, O].

Moreover, the token-level evaluation can be considered as a partial span-level evaluation where the constraints on the entity boundaries are loosened. We still gain valid information about a person being advertised even if the prediction model gets the entity boundary wrong. For example, using our token-level evaluation, “*Jane Smith left*” with a true label [B-PER, I-PER, O] will have the same performance metric whether the predicted sequence is [B-PER, O, O] or [O, B-PER, O].

Lastly, in the context of name extraction from escort ads, it is common to see the same name appearing multiple times consecutively in a single ad. This could be done in order to make a better impression of the persons being advertised. The span-level sequence evaluation may count every correctly predicted occurrence of a name, regardless of whether it has already been extracted. This may give extra false credibility to the extraction algorithm since what we really want to measure is the individual being advertised.

OneAligner: Zero-shot Cross-lingual Transfer with One Rich-Resource Language Pair for Low-Resource Sentence Retrieval

Tong Niu **Kazuma Hashimoto** **Yingbo Zhou** **Caiming Xiong**

Salesforce Research

`{tniu, k.hashimoto, yingbo.zhou, cxiong}@salesforce.com`

Abstract

Aligning parallel sentences in multilingual corpora is essential to curating data for downstream applications such as Machine Translation. In this work, we present OneAligner, an alignment model specially designed for sentence retrieval tasks. This model is able to train on only one language pair and transfers, in a cross-lingual fashion, to low-resource language pairs with negligible degradation in performance. When trained with all language pairs of a large-scale parallel multilingual corpus (OPUS-100), this model achieves the state-of-the-art result on the Tateoba dataset, outperforming an equally-sized previous model by 8.0 points in accuracy while using less than 0.6% of their parallel data. When finetuned on a single rich-resource language pair, be it English-centered or not, our model is able to match the performance of the ones finetuned on all language pairs under the same data budget with less than 2.0 points decrease in accuracy. Furthermore, with the same setup, scaling up the number of rich-resource language pairs monotonically improves the performance, reaching a minimum of 0.4 points discrepancy in accuracy, making it less mandatory to collect any low-resource parallel data. Finally, we conclude through empirical results and analyses that the performance of the sentence alignment task depends mostly on the monolingual and parallel data size, up to a certain size threshold, rather than on what language pairs are used for training or evaluation.

1 Introduction

Cross-lingual sentence retrieval aims at aligning parallel sentence pairs that are translations of each other from unlabeled multilingual documents. Such mined data can be used in multiple downstream applications such as Machine Translation and cross-lingual Word Sense Disambiguation (Fan et al., 2020; Tran et al., 2020; Schwenk et al., 2021a,b). Even under a half-automated setting with human-in-the-loop, a faithful aligner can help narrow down the candidate pool so that humans do not need to deal with an enormous search space such as cross-lingual web-document pairs (El-Kishky et al., 2020) or the entire internet. A retrieval model has also been used to filter existing parallel corpora to improve their quality (Schwenk, 2018) or to perform Quality Estimation (Fomicheva et al., 2020) where the reference translations are not available.

For sentence retrieval tasks, a majority of recent work is either completely unsupervised (Hu et al., 2020; Tran et al., 2020; Lewis et al., 2020) or leverages all parallel data available (Artetxe and Schwenk, 2019; Ouyang et al., 2021), sometimes to the extent of 879 language pairs (Luo et al., 2021). The unsupervised approach has the benefit of not collecting any parallel data; yet it usually achieves relatively low accuracies on standard benchmark datasets such as Tatoeba (Artetxe and Schwenk, 2019), which evaluates on 36 language pairs including multiple low-resource ones. The supervised approach, on the other hand, assumes data access to a plethora of low-resource language pairs, which by definition is difficult to acquire and to ensure their quality. This all-or-nothing choice between the unsupervised and supervised approaches leaves a significant gap on whether zero-shot cross-lingual transfer works for such tasks. Our work aims to shed light on a recipe of how to distribute the efforts for cross-lingual parallel data collection: (1) How much monolingual data is enough for each language? (2) How many finetuning language pairs are enough? (3) Is it necessary to collect low-resource language pairs? (4) To what extent does the amount of parallel data matter? (5) Should these language pairs be centered around English?

To have a strong enough model to perform analyses that address the above questions, we propose **OneAligner**,[1] a classifier that is able to **align** cross-lingual sentences by training on parallel examples

---

[1] We will make our code publicly available.

Findings of the Association for Computational Linguistics: ACL 2022, pages 2869 - 2882
May 22-27, 2022

of only **one** language pair. OneAligner is built on top of XLM-RoBERTa (XLM-R) (Conneau et al., 2020a) with its architecture tailored to the alignment task: the model leverages a supervised version of BERT-score (Zhang et al., 2020) to compute semantic similarity and builds a normalization layer into its architecture to counteract the *popular sentence effect*, where some sentences in the source language tend to have a high similarity score with any sentence in the target language. Though not our main contribution, these additions lead to the state-of-the-art accuracy 94.9[2] on the Tatoeba dataset when trained on all language pairs from OPUS-100 (Tiedemann, 2012), outperforming models that are trained with 180 times more parallel examples (Luo et al., 2021) by 8.0 points. When trained on any single rich-resource language pair, this model is able to match the performance of a model (within a 2.0 gap in accuracy) trained on all language pairs under the same data budget.

To further close the already-narrow gap between using one language pair and all pairs while adhering to the rich-resource-only constraint, we scale up the number of language pairs with the top-k rich-resource ones, reaching a 94.0 accuracy on Tatoeba, only 0.4 off as compared to training on all language pairs under the same data budget.

We also explore either training or evaluating on language pairs that are *not* centered around English. We find that whether to train on an English-centered language pair and whether the training pair overlaps with the evaluation pair do not influence model performance – the model will perform similarly as long as two conditions are met: (1) the amount of parallel data size crosses a certain threshold; and (2) the pretraining monolingual data that corresponds to the evaluation languages also surpasses a size threshold.

2 Model

2.1 Base Model

To align sentences in different languages, it is beneficial to start with a model that has already learned cross-lingual representations to some extent. Our OneAligner thus builds on top of XLM-R (Conneau et al., 2020a), a Transformer-based model (Vaswani et al., 2017) pre-trained on the monolingual CC-100 dataset (Wenzek et al., 2020) covering 100 languages. This model obtained state-of-the-art performance on cross-lingual classification, sequence labeling, and question answering.

2.2 Calculation of Semantic Similarity

Cross-lingual BERT-score The *de facto* way of calculating semantic similarity adopts a Siamese architecture, which separately encodes the source and target sentences with the same encoder to obtain two outputs. These outputs go through a mean pooling layer along the sequence length dimension, and the similarity is obtained by computing the cosine distance between the two pooled vectors (Reimers and Gurevych, 2019). This approach is fast and agnostic to the order of source and target sentences but lacks cross-attention which is crucial for alignment tasks. On the other hand, encoding both sequences with a $[sep]$ token in-between implies *full* cross-attention, which runs slow due to the extra computation. Such a method is only suitable for filtering existing parallel corpora for better data quality (Schwenk, 2018). Besides, due to positional encoding, this method is *not* agnostic to the order of the two sentences such that during inference, one needs to pay special attention to which sentence comes first.

Our similarity calculation marries the strengths of both methods and builds on top of BERT-score (Zhang et al., 2020), an unsupervised automatic evaluation metric originally designed to compute the similarity between two sentences of the same language. We re-purpose this metric to compute cross-lingual semantic similarity. More specifically, let $s = \{s_1, s_2, ..., s_M\}$ and $t = \{t_1, t_2, ..., t_N\}$ be two sequences, each consisting of a list of tokens in the source and target language, respectively. BERT-score computes the pairwise token-level cosine distance between s and t as follows:

$$P = \frac{1}{|t|} \sum_{t_j \in t} \max_{s_i \in s} s_i^T t_j$$

$$R = \frac{1}{|s|} \sum_{s_i \in s} \max_{t_j \in t} s_i^T t_j$$

$$F = 2 \frac{PR}{P + R}$$

We use F as the similarity. From the equations we can see that because BERT-score is only applied after the last encoding layer of the Transformer model, this metric serves as a *shallow* cross-attention layer that is much faster than *full* cross-attention. The resulting model also remains agnos-

---

[2] Throughout the paper we will omit the "%" for accuracy. Hence 94.9 means 94.9% in accuracy.

tic to the order of the input sentences.

In-Batch Normalization In bitext alignment, we observe that some sentences in one language tend to have a high similarity score with any sentence in the other language. This phenomenon, which we name the "*popular sentence effect*",[3] causes the ranking of candidates in the target language to be inaccurate. To offset this bias, we subtract a scaled average of similarity scores between each sentence in one language and all sentences in the other. More specifically, let $S = \{S_1, S_2, ..., S_M\}$ and $T = \{T_1, T_2, ..., T_N\}$ be a batch of sequences in the source and target language, respectively. We compute the pairwise similarity between S_i and T_j as follows:

$$S_{ij} = f(S_i, T_j) - \alpha \left(\frac{1}{|T|} \sum_{T_n \in T} f(S_i, T_n) + \frac{1}{|S|} \sum_{S_m \in S} f(S_m, T_j) \right)$$

where f stands for the function that computes semantic similarity (BERT-score in our case) and α is a hyperparameter that determines the *normalization strength*. We tuned this parameter on the OPUS-100 development set and found that $\alpha = 0.75$ on average gives the best results.[4] Note that this normalization step is built into the model architecture rather than serving only as a *post hoc* manipulation during inference. In practice, the number of sentences M and N could be quite large during inference, significantly slowing down the normalization step, not to mention that the evaluation data is not guaranteed be served in an offline fashion. Hence we instead perform *in-batch* normalization for each similarity score so that M and N only depend on the batch size during inference. In our early experiments (not presented in the paper), we found that this in-batch normalization incurs no performance loss as long as we maintain a reasonable evaluation batch size.

2.3 Justification of Model Design

We perform an ablation study on how similarity is calculated and on whether to include a normalization step. We conduct the comparison with three model variances (without finetuning on any parallel data), namely mBERT (Devlin et al., 2019), XLM-R-base, and XLM-R-large (Conneau et al., 2020a). Following Hu et al. (2020), who find that certain early layers of Transform perform better on cross-lingual tasks than the last layer,[5] we use the 8th layer for mBERT and XLM-R-base, and 17th layer for XLM-R-large.[6] Table 1 shows that the combination of BERT-score and normalization step leads to consistently and significantly higher performance, indicating that these modifications build a beneficial inductive bias into the model.

2.4 Classification with In-Batch Negatives

One challenge in training an aligner with only positive parallel data is that there are no carefully-designed negative examples. To address this challenge, our aligner adopts a contrastive learning approach and trains on a classification task with in-batch negatives (Chen et al., 2020). The intuition behind this approach is that a pair of sentences that are translations of each other can be interpreted as two "views" of the same underlying semantics. More specifically, let $S = \{S_1, S_2, ..., S_N\}$ and $T = \{T_1, T_2, ..., T_N\}$ be a batch of sentences in the source and target language, respectively, where S_i is aligned with T_i for each i. We compute the pairwise BERT-score between S and T and apply the in-batch normalization (as introduced in Section 2.2) to obtain N^2 similarity scores, including N scores for the positive alignments and $N^2 - N$ for the negative ones. During training, we treat these scores as logits and pair each positive logit with *all* negative logits. We use these logits to compute the cross-entropy loss. Note that standard contrastive learning employs *one-dimensional* in-batch negatives where each positive logit is paired with $N - 1$ negative logits (Chen et al., 2020) (i.e., only the ones that are relevant to the positive example). However, we found that by adopting *global* in-batch negatives, which include all $N^2 - N$ negative logits for each positive logit, it is much easier for the model to establish a global score threshold to align cross-lingual sentences. This is especially

---

[3] We hypothesize that this effect is not restricted to natural language, but also for data of other modes such as image and voice. Hence we encourage future work to experiment with normalization steps similar to our formulation.

[4] In practice, we also add back a term $(2\alpha - 1)\frac{1}{MN}\sum_{S_m \in S, T_n \in T} f(S_m, T_n)$ to keep S_{ij} around 0. This extra term does not affect evaluation, but makes a difference during training.

[5] Jawahar et al. (2019) and Zhang et al. (2020) find similar phenomena for English.

[6] By investigating performance comparisons among different layers in Jawahar et al. (2019); Zhang et al. (2020), we provide a rule-of-thumb: usually the best layer is between 1 below and above $2/3$ of the total number of layers. For example, for a 12-layer Transformer, the fastest way is to try layers 7, 8, and 9. Thanks to each new language model trying to follow its previous work on hyperparameter settings, all models with which we experiment have the number of layers divisible by 3.

important for alignment tasks where a sentence in one language is not guaranteed to have a translation in the other language (e.g., the BUCC 2018 dataset to be introduced in Section 3.1).

3 Experimental Setup

3.1 Data

Training Data We experiment with both English-centered and non-English-centered training corpora. For English-centered data we use OPUS-100, a multilingual corpus covering 100 languages. This corpus was randomly sampled from the OPUS collection (Tiedemann, 2012),[7], which is comprised of diverse corpora ranging from movie subtitles to GNOME documentation. OPUS-100 contains approximately 55M sentence pairs. Of the 99 language pairs, 44 have 1M sentence pairs of training data, 73 have at least 100k, and 95 have at least 10k. For non-English-centered data, we employ the v2021-08-07 version of the Tatoeba Challenge (Tiedemann, 2020),[8] which we refer to as the New-Tatoeba (since it is new). This is a challenge set that contains 29G translation units in $3,708$ bitexts covering 557 languages. The package includes a release of 631 test sets that cover 134 languages. Note that for training purposes, we only keep language pairs where both the source and the target language are present in CC-100 (Wenzek et al., 2020),[9] the corpus used to pretrain XLM-R. This is because the tokenization of XLM-R is accustomed to these languages by design.

Following OPUS-100, all experiments are performed under a fixed 1M examples budget (unless otherwise specified), regardless of how many language pairs are used. This constant data size cap makes it easier to compare among different settings. To remove noisy and uninformative data, we also aggressively remove any examples that contain less than 5 tokens in either the source or the target language. Note that this step is done after we sample the 1M examples, since when the number of language pairs piles up, it becomes too expensive to tokenize the entire corpus to count how many tokens there are in each sentence.[10]

Evaluation Data We evaluate on three datasets. The first one is the Tatoeba dataset from the XTREME benchmark (Hu et al., 2020), which we refer to as **Tatoeba-36** since it contains 36 language pairs, including multiple low-resource ones such as *sv-en* and *jv-en*. We keep this historical version to make it easier to compare with previous work.

The second dataset is the combination of development and test sets in New-Tatoeba. We only keep language pairs that have $\geq$ 1K examples in the development and test sets combined, because the smaller the evaluation set is, the easier it is to rank among candidates. When we have a collection of evaluation data that do not share roughly the same difficulty, averaging their accuracies makes less sense. Following Tatoeba-36, where most language pairs have 1K test examples, we randomly sample 1K for each language pair from New-Tatoeba.[11] The resulting evaluation set covers 223 language pairs, including 49 pairs that are English-centered, 174 pairs that are not, and 58 pairs considered low-resource by the Tatoeba Challenge. To our best knowledge, we are the first to evaluate sentence alignment models on this dataset.

The third dataset is BUCC 2018 (Zweigenbaum et al., 2018) in the XTREME benchmark (Hu et al., 2020). This is a cross-lingual bitext mining task. We include this task because the two Tatoeba datasets are both ranking tasks, while BUCC requires a universal similarity score to serve as a decision boundary to either accept or reject an alignment of sentences. This is a more realistic scenario for web mining because a sentence in the source language does not necessarily have a translation

[8] `https://github.com/Helsinki-NLP/Tatoeba-Challenge`

[9] `http://data.statmt.org/cc-100/`

[10] Resorting to counting the number of spaces will not work because quite a few languages do not have spaces between words.

[11] We will release the test example indices with respect to the original dataset along with the code.

Model	VECO	ERNIE-M	OneAligner	
			1M Budget	No Budget
# Parameters	550M	550M	550M	550M
# Languages	50	96	100	100
Mono. Data Size	1.36TB	1.56TB	2.34TB	2.34TB
Parallel Data Size	1TB	68.8GB	145MB	4.9GB

Table 2: Comparison of model and data sizes between OneAligner and previous models.

in the target language. Hence this dataset contains way more *distraction sentences* than the ones that actually align with some other sentences in the other language. That said, the drawback of BUCC is that it only involves 4 language pairs, all of which are highly rich-resource. Since our work focuses more on low-resource languages, this dataset only serves as a sanity check for our models.

Note that since both training corpora were created without Tatoeba-36 and BUCC evaluation data in mind, we remove any examples from the training set where either the source or the target is in any of the test sets. This process gets rid of less than 2.5k examples from each training set.

3.2 Hyperparameters

We perform all experiments with a single A100 GPU. The number of training epochs is 3, the training batch size is 64, and the evaluation batch size is 256. These are the largest number of examples we can fit in a batch with A100. Not surprisingly, having a smaller training batch size will lead to lower performance not only because previous work has found that large batch size benefit training due to its more stable gradients (Devlin et al., 2019), but also that a larger batch size enables a more accurate estimation of the in-batch normalization term and allows more in-batch negatives to pair with each positive example, making the model converge faster with additional contrastive learning signals. We set the softmax temperature to 5.0 and the learning rate to $3e$-6 for all experiments.[12] The maximum sequence length for both source and target languages is set to 100.

3.3 Dot Product vs. Cosine Similarity

When computing the semantic distance between sentences, Sentence-BERT (Reimers and Gurevych, 2019) applies a Siamese encoding scheme to each sentence followed by mean pooling and computation of cosine distance between the two pooled vectors. However, during training they do not normalize the sentence vectors before taking the dot product, while during evaluation they do. We also observed that this different handling of training and evaluation phase led to better performance. Hence when computing the BERT-score during training, we also do not pre-normalize the vectors before taking the dot product.

3.4 Baseline Models

We compare with VECO (Luo et al., 2021) and ERNIE-M (Ouyang et al., 2021), the strongest models at the time of submission on the XTREME benchmark leaderboard (Hu et al., 2020) sentence retrieval tasks.[13] Like OneAligner, ERNIE-M is built on top of XLM-R and is trained on 96 languages. The monolingual corpus is extracted from CC-100 (Wenzek et al., 2020), while the bilingual corpora include MultiUN (Ziemski et al., 2016), IIT Bombay (Kunchukuttan et al., 2018), OPUS (Tiedemann, 2012), and WikiMatrix (Schwenk et al., 2021a). VECO shares the same model size as ours[14] and is trained on 50 languages (possibly to avoid capacity dilution). The monolingual data is extracted from CC-100, while the bilingual data is collected from the OPUS website.[15] There are 6.4G parallel examples covering 879 language pairs. We summarize the basic statistics of each model in Table 2.

4 Results and Analysis

4.1 All Language Pair Performance

To justify our model design and obtain a performance upper bound with which single-pair models can compare, we first train OneAligner on the entire OPUS-100 dataset, either with or without the 1M budget. Table 3 shows that both models achieve state-of-the-art results on the Tatoeba-36 dataset. Because there is only a 0.5 difference in accuracy between the two settings, it is reasonable to apply

---

[12] The temperature and the learning rate are tuned on the OPUS-100 development set. Our early experiments showed that having a larger learning rate, e.g., $3e$-5, would make the model converge faster (more data-efficient) but eventually arrive at slightly lower performance.

[13] The leaderboard can be visited at `https://sites.research.google/xtreme`. We ignore submissions that do not link to any paper or code.

[14] There are two versions of VECO, namely VECOout and VECOin. VECOout is of the same size as our model while VECOin is 20% larger in size. Hence throughout the paper, whenever we mention VECO, we are referring to the more comparable VECOout version. As a side note, our best model is able to outperform VECOin on Tatoeba-36 by 3.8 points in accuracy.

the fixed budget to save computational cost. When we put Table 2 and 3 side-by-side, we can also see that OneAligner is more data-efficient as compared to the other two models.

4.2 Single Language Pair Performance

English-centered Language Pairs Table 4 shows Tatoeba-36 performance for models trained on the OPUS-100 dataset for each of the top-16 rich-resource language pairs in the intersection of OPUS-100 and CC-100 languages.[16] We can see that the performance is consistent across language pairs, which translates to the suggestion that one can finetune OneAligner with almost any rich-resource language pair at hand and arrive at a similar performance. Figure 1 presents a scatter plot of Table 4 against the data availability of each language pair. We observe that after reaching a certain data size threshold (somewhere between 10k and 20k), all language pairs perform similarly. This is partially expected because our model design does not introduce any new parameters to XLM-R, obviating the need to train any randomly initialized layers.

Language Pairs Not Centered around English English is with no doubt the most widely adopted language. However, in a real-world scenario, we cannot always assume that the parallel data contains English. Similar to Table 4, we present in Table 5 the accuracies of OneAligner trained on each of the Top-16 rich-resource non-English-centered pairs from the New-Tatoeba dataset. We can see that the performance is again consistent across language pairs, indicating that we can train on a non-English language pair and still obtain similar performance on an evaluation set centered around English. This raises a natural follow-up question: is the reverse true? In other words, does a model trained on English-centered data perform just as well on non-English evaluation data?

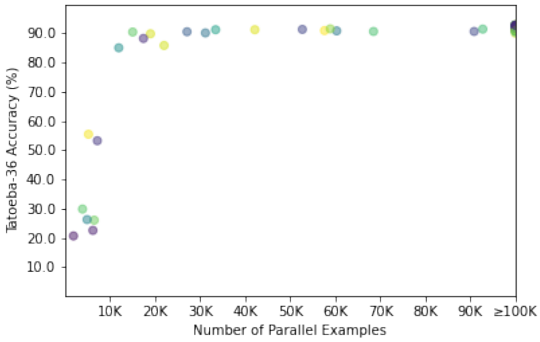

Figure 1: Scatter plot of single-pair Tatoeba-36 performance against English-centered single-pair **parallel** data size (as measured in the number of training examples) for each language pair in the OPUS-100 dataset.

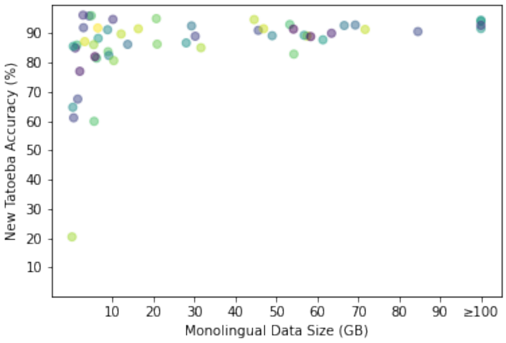

Figure 2: Scatter plot of Top1-Eng New-Tatoeba performance against **monolingual** data size (as measured in **GB**) for each language in the CC-100 dataset.

guage pair or whether there is an overlap between finetuning and evaluation languages. When comparing each model **evaluated** on either English-centered or non-English-centered language pairs, we can see that both models perform better on English-centered language pairs.[17] We hypothesize that this is because English dominates the monolingual data during the pretraining of XLM-R.

Before diving into an analysis that verifies this hypothesis, we need to "expand our vocabulary": rather than dividing in a bipolar fashion between "English-centered" and "non-English-centered", we describe the setting with a spectrum and explore X-centered, where X could be any language. We define the *accuracy* for language X as the average of accuracies of all language pairs that involve X. Figure 2 shows the scatter plot of Top-1-Eng New-Tatoeba performance against **monolingual** data size for each language in the CC-100 dataset. Similar to Figure 1, the New-Tatoeba performance is positively correlated with the monolingual data size up to a certain data threshold.

4.3 Scaling up the Number of Language Pairs

The single-pair Tatoeba results are already promising. However, what if we aim for even better performance without violating the rich-resource-only assumption? We find that adding other rich-resource pairs can help. Unfortunately, OPUS-100 does not provide us with a ranking on the data availability of language pairs.[18] Hence we resort to the New-Tatoeba dataset and rank based on the availability of each English-centered pair.[19] In Table 7 we present performance of *combined* top-1 through top-32 rich-resource language pairs on Tatoeba-36.[20] We can see that the performance monotonically increases as we include more language pairs, until reaching an accuracy of 94.0 – only 0.4 point off of the best performance when training with all language pairs under the 1M data budget. Note that the least rich-resource language *uk* in the top-32 list is still in the "highest"-resource range as defined in the Tateoba Challenge[21] and contains around 34M training examples, so we are still far from violating the rich-resource restrictions. Hence at least given the sentence alignment task and the current models, the marginal cost of improving for that 0.4 point in accuracy does not seem to justify the effort of extensively collecting more parallel data for the low-resource language pairs. This observation motivates future work to develop new approaches that leverage low-resource data more effectively.

Language	Top1	Top2	Top4	Top8	Top16	Top32	All
Avg. Acc.	92.4	92.5	92.9	93.2	93.4	94.0	94.4

Table 7: Tatoeba-36 performance when the model is trained on Top-k rich-resource, English-centered language pairs. "All" stands for all language pairs combined. All results are under a fixed 1M data budget.

4.4 BUCC Results

As a sanity check, we report BUCC F1 scores of the two top-1 models as compared to previous work in Table 8. We can see that both models outperform VECO by 1.2 points. Recall that the two models are trained on *en-es* and *fr-es*, respectively. In other words, neither model has seen a single parallel example between *en* and each of the BUCC

---

[17] Interested readers can refer to Table 10 in the Appendix for a comprehensive list of accuracies for each language pair in the New-Tatoeba test set.

[18] The size of each language pair in OPUS-100 is capped at 1M, and the original paper did not include the data statistics before sampling.

[19] The training data size for each language pair is listed in the table at `https://github.com/Helsinki-NLP/Tatoeba-Challenge/tree/master/data`.

[20] The top-32 languages are *es*, *fr*, *de*, *pt*, *it*, *nl*, *ru*, *pl*, *cs*, *sv*, *sh*, *el*, *ro*, *da*, *zh*, *no*, *ar*, *ms*, *hu*, *bg*, *tr*, *fi*, *sl*, *vi*, *he*, *ja*, *et*, *lt*, *lv*, *fa*, *ko*, *uk*, in the order of descending data availability.

Model	de	fr	ru	zh	**Avg.**
XLM-R-large	67.5	66.5	73.5	56.7	66.1
VECO	**93.0**	88.7	**89.9**	85.7	89.3
Top1 (Eng)	91.7	**90.0**	89.5	**90.9**	**90.5**
Top1 (¬ Eng)	**93.0**	89.8	88.7	90.6	**90.5**

Table 8: BUCC F1 Results. Best scores in each column are boldfaced. Below the dashed line are our model results, where "¬ Eng" stands for "non-English-centered". Note that ERNIE-M did not evaluate on BUCC, hence not included in this table.

target languages $\{de, fr, ru, zh\}$, while VECO is trained extensively on each of the language pairs. This result is consistent with the observation that OneAligner is able to perform cross-lingual transfer with performance on par with in-language models regardless of whether the finetuning language pair is English-centered.

5 Related work

5.1 Multilingual Representation Learning

There have been extensive effort in learning massive cross-lingual representations. Such models are pretrained with a large amount of unlabeled data from multiple languages with the intention to benefit low-resource languages with the rich-resource languages through shared vocabulary, genetic relatedness (Nguyen and Chiang, 2017) or contact relatedness (Goyal et al., 2020). Some of the widely adopted models are mBERT (Devlin et al., 2019), XLM (Conneau and Lample, 2019), mBART (Liu et al., 2020), MARGE (Lewis et al., 2020), XLM-R (Conneau et al., 2020a), and mT5 (Xue et al., 2021). Other models also leverage cross-lingual signals (large-scale parallel data) with a translation language model objective, including LASER (Artetxe and Schwenk, 2019), VECO (Luo et al., 2021) and ERNIE-M (Ouyang et al., 2021).

5.2 Parallel Corpus Mining

A major downstream application of a massively multilingual model is parallel corpus mining. There have been efforts to mine parallel sentences from the entire web (Bañón et al., 2020; Wenzek et al., 2020; Tran et al., 2020). Such approaches are inadvertently forced to handle an enormous search space. Consequently, some models adopt the mean pooling followed by the cosine distance approach and leverage approximation algorithms like FAISS (Johnson et al., 2019) to compute cosine distance faster. There have also been efforts such as WikiMatrix (Schwenk et al., 2021a) and CCAligned (El-Kishky et al., 2019) that divide the mining process into two steps. The first step is to align text on the document level, which significantly reduces the search space, while the second step is to deploy a sentence retrieval model as usual.

Apart from aligning text at the document and sentence level, there has also been models that focus on a higher level of granularity and target word alignment (Dou and Neubig, 2021). Such work can be used for downstream tasks such as automatically building preliminary bilingual dictionaries.

5.3 Zero-Shot Cross-lingual Transfer

The standard zero-shot cross-lingual transfer assumes no in-language data and consists of two steps: (1) finetune a multi-lingual pretrained model on task-specific data in the source language; and (2) evaluate it on the test data in the target language.

Another alternative to the implicit transfer requires a Machine Translation system (Hu et al., 2020; Luo et al., 2021), which itself demands parallel data to train in the first place. There are two settings: (1) *translate-train*: machine translate the task-specific training data from the source to the target language and train on that noisy data; and (2) *translate-test*: train on task-specific data in the source language and evaluate on data translated from the target to the source language.

Several benchmark datasets have been released to test cross-lingual transfer capability, including XGLUE (Liang et al., 2020), XTREME (Hu et al., 2020), and XTREME-R (Ruder et al., 2021). They include diverse tasks such as Natural Language Inference, Relation Extraction, Named Entity Recognition, Part of Speech Tagging, Question Answering, and Sentence Retrieval.

There has been extensive work devoted to analyzing the mechanism behind cross-lingual transfer (K et al., 2020; Muller et al., 2021). For example, Pires et al. (2019) and Wu and Dredze (2020) show that the amount of shared vocabulary between the source and target language plays an important role in the transfer. However, some other works suggest the opposite. For instance, Conneau et al. (2020b) show that the transfer happens even if there is no shared vocabulary while the training and evaluation data can also come from distinct domains.

6 Conclusion

We present OneAligner, an alignment model tailored to sentence retrieval tasks. We show that this model transfers well under a cross-lingual setting even when trained on a single language pair. Through experiments and analyses, our work helps uncover what factors influence sentence alignment performance and identifies monolingual data size, parallel data size, and the number of rich-resource language pairs as the top priorities to which one should distribute their data collection efforts. Though having covered a broad range of languages and settings, this work still leaves many unexplored territories: (1) How do we deal with languages not present in the pretraining phase given that the vocabulary is not constructed toward them? (2) Why is the cross-lingual transfer successful in the first place? What has the model learned during finetuning? (3) Does OneAligner generalize to other retrieval tasks other than cross-lingual sentence alignment? We leave these as future work.

Suum Cuique: Studying Bias in Taboo Detection with a Community Perspective⋆

Osama Khalid†, **Jonathan Rusert**†, **Padmini Srinivasan**
University of Iowa
{osama-khalid, jonathan-rusert, padmini-srinivasan}@uiowa.edu

Abstract

Prior research has discussed and illustrated the need to consider linguistic norms at the community level when studying *taboo* (hateful/offensive/toxic etc.) language. However, a methodology for doing so, that is firmly founded on community language norms is still largely absent. This can lead both to biases in taboo text classification and limitations in our understanding of the causes of bias. We propose a method to study bias in taboo classification and annotation where a community perspective is front and center. This is accomplished by using special classifiers tuned for each community's language. In essence, these classifiers represent community level language norms. We use these to study bias and find, for example, biases are largest against African Americans (7/10 datasets and all 3 classifiers examined). In contrast to previous papers we also study other communities and find, for example, strong biases against South Asians. In a small scale user study we illustrate our key idea which is that common utterances, i.e., those with high alignment scores with a community (community classifier confidence scores) are unlikely to be regarded taboo. Annotators who are community members contradict taboo classification decisions and annotations in a majority of instances. This paper is a significant step toward reducing false positive taboo decisions that over time harm minority communities.

⋆ This paper examines taboo language as a case study. The reader is cautioned that the paper contains strong language.

† Equal Contribution.

1 Introduction

Members of a community rely on a shared language for communication, one which evolves naturally, *in situ*, and is shaped by the norms and mores of the community (Gumperz, 1968). Norms promote *Entitativity*, the perception of group identity (Allan and Burridge, 2006). Norms may be explicit and codified into law or so subtle that while members may be unable to specify them they can still recognize violations (Chandrasekharan et al., 2018). Utterances violating a these norms may be considered *taboo* from that community's perspective.[1]

Communities often self-regulate by censuring norm violating *taboo* language (Allan and Burridge, 2006). This censuring may be subtle such as ignoring taboo utterances leaving the individual somewhat isolated and ineffective. Self-regulation could also be explicit and even severe such as expulsion from the community.

Taboos are community-specific: Perceptions of taboos in language use are influenced by community (Allan and Burridge, 2006). Utterances that are benign in one community might be taboo in another[2]. E.g., 'autistic' is considered derogatory on most of reddit, its use usually leads to censure. However, on the subreddit /r/wallstreetbets, it is not and is instead used as a self-descriptor by members. The importance of considering the author's community when studying taboo is emphasized in a recent critical survey of bias in NLP papers (Blodgett et al., 2020); it urges us to understand how social hierarchy relates to language use. Our research is a step in this direction.

Taboo utterance detection and biases: Several papers especially from OffensEval (Zampieri et al., 2019b, 2020) have led to the development of state of the art taboo classifiers for moderating online speech. Alongside, an active research stream studies the presence of bias in taboo detection. Biases, specifically having higher false positive rates for a minority community compared to the majority, have been detected particularly against African Americans and also to some extent women (Dixon et al., 2018; Zhou et al., 2021; Bolukbasi et al., 2016; Xia et al., 2020; Chuang et al., 2021). Bias

---

[1] We include hate, offense, sexism, toxicity, and abusive utterances in *taboo* while acknowledging their nuanced differences (Fortuna et al., 2020).

[2] Even individuals within a community may differ in their norms and taboos, with some enforcing more constraints.

Findings of the Association for Computational Linguistics: ACL 2022, pages 2883 - 2896
May 22-27, 2022

is clearly harmful as penalties over false positives could over time discourage/constrain minority participation on social media platforms, and in turn reinforce the majority's norms and values.

Limitations in bias assessment research: A limitation is that community language norms are rarely considered. While recent research on taboo detection discuss and illustrate the importance of community perspective (Davidson et al., 2017; Sap et al., 2019; Badjatiya et al., 2019) we do not yet have bias detection methods that are firmly founded on community language norms. This methodological gap underlies not only the design of state-of-the-art taboo detection tools but perhaps more crucially even in the methodologies for the *study* of bias in taboo detection. Not only are the taboo annotated datasets largely devoid of community, culture or social contexts (i.e., characterization) (Zampieri et al., 2019b, 2020), the study of bias itself needs strengthening with methods wherein a community perspective stays front and center, consistent with the urging in the survey (Blodgett et al., 2020).

Contributions:

1. We propose a new method that is firmly grounded on community-specific language norms for studying bias in taboo detection.
2. We use our method to assess bias against five minority communities in three taboo text classifiers and ten taboo annotated datasets. In contrast, prior research has largely about bias against the African American community, possibly due to reliance on two race estimated/labelled datasets (Blodgett et al., 2016; Preoţiuc-Pietro and Ungar, 2018).
3. We find, for example, that all three taboo classifiers are biased against the African American community. Additionally, 2 classifiers are biased against the South Asian communities and one against Hispanics. Overall, only 3 of the 15 classifier - community combinations tested were somewhat unbiased.
4. Eight out of 10 taboo annotated test sets are strongly biased against African Americans, while at least 3 are biased against South Asians. We did not find any remarkable dataset biases against Hispanics but we found single instances of bias against Native American and Hawaiian communities.

2 Community Centered Approach for Studying Bias

We build community-specific classification models (CLCs) which capture the community's language. We use these to compute text alignment scores for assessing bias. A text alignment score is the classifier's confidence in deciding if the text has been generated by a member of the community or not. Higher confidence scores imply greater alignment with the language norm's of the community.

Our intuition is as follows. Given moderation and self-regulation in communities we expect taboo utterances to be *infrequent* in a community's discourse. Such utterances will thus have low alignment scores when classified by a model trained on the community's language. However, since new topics of interest will also result in low-frequency utterances we view low alignment scores with a community model as *necessary* but *insufficient* for an utterance to be considered taboo from that community's perspective. Crucially, utterances with high alignment scores adhere to the norms and therefore should not be considered taboo. Reference classifier models allow us to estimate the extent of alignment with community language norms.

Two points to note. We do not attempt to separate style from topic in the utterances since it is often in their interplay that taboo is decided. For example, *"happy birthday to a bad bitch"* and *"Fuck off, you are a little bitch."* have somewhat related styles but different topics. Our 'contextual' community-language classification models estimate scores for full utterances. Second, while we study race/ethnicity based communities, our approach can be applied to communities defined broadly, using other criteria such as professional communities and internet subcultures. Specific details for measuring bias are given next.

Measuring bias in taboo classifiers: We assess the extent of taboo classifier bias against a community by computing Pearson correlation between the taboo classifier confidence scores and community classifier confidence scores. We do this with instances that the former classifier declares as taboo. Ideally, we expect a negative correlation - higher taboo classifier confidence mapping to lower community alignment scores and vice versa. The extent to which correlations deviate from this expectation reflects the extent to which the classifier does not consider the norms of the community.

Measuring bias in taboo datasets: Given a dataset, we compute the proportion of taboo labelled texts that are highly aligned with each community classifier model. We expect these proportions to be tending towards zero since high align-

Community	No. of Subreddits	Training set size	Validation set size
NA	2	44k	1.4k
HI	4	95k	6k
HA	1	80k	2k
SA	1	101k	6k
AA	11	70k	5k

Table 1: Dataset details for each community.

ment means common utterance and thus within the norms. A second point to note is that if these proportions are uneven across communities then the bias is more against those with larger proportions. This is consistent with the theory that all communities engage in similar norms of communication (Mills, 2009). Specifically, we measure the mean and standard deviations (SD) of proportion of aligned comments. In sum, if the proportions are not close to zero this indicates bias. Additionally, if the proportions are not even then bias is targeting some communities more than others.

3 Community Language Classifiers

3.1 Model Construction

We build our community classification models using BERT (Devlin et al., 2019)[3]. Experiments using XLNet (Yang et al., 2019) gave comparable results. Thus, we only report BERT results. BERT is a transformer-based model which has shown to perform well in NLP based tasks (Devlin et al., 2019; Kaliyar, 2020). BERT leverages context (on top of words)[4]. We fine-tune BERT-base-uncased [5] with a linear layer on top. A softmax function is used to make a binary classification as to whether or not the input text belongs to the community. Each community has its own classifier representing its language norms.

We build our models with publicly available data from select subreddit comments obtained using Pushshift (Baumgartner et al., 2020)[6]. We group subreddits into communities based on shared cultural/ethnic heritage determined using subreddit descriptions (subreddits are listed in appendix A). While we acknowledge that subreddits are not inclusive of all members of communities of interest, they can still be considered as fairly representative in terms of language use. We do not have to be exact about the data used to represent a community as long as we are confident that the collection is mostly produced by its members[7].

We build models for: Native American (NA), Hispanic (HI), Hawaii (HA), South Asian[8](SA), and African American (AA) communities. We obtained comments from 2018 using the first 11 months as training data for the models and the last as validation. As the data for NA was smaller than the rest, we added 2015, 2016, and 2017 data again with the first 11 months for each year as training and last 1 month for validation. Comments were lowercased and stripped of punctuations.

Since subreddit sizes vary, the amount of data collected for each community varies as well. HI, HA, SA, and AA are the closest in size and NA the smallest. When training a community model we generate negative samples (texts not from the community) by sampling equally from the other communities till we reach a 1:1 ratio of positive to negative text samples. A summary of the datasets is in Table 1. Note that the training set size indicated includes both positive and negatives examples (at a 1:1 ratio) while the validation sets only contain positive (aligned) examples.

3.2 Model Characteristics

Figure 1 presents the complementary cumulative distribution function (CCDF) of alignment scores (classifier confidence scores) for the CLCs using validation data. For example, 62.9% and 66.2% of the HA and the HI texts have scores ≥ 0.7. All CCDFs follow a similar distributional pattern. We introduce a threshold on alignment scores to decide which texts are 'highly aligned' with a model. Higher thresholds imply fewer comments will be regarded as following the community's norms. We choose 0.85 as threshold since at least 52% of the comments for each community are then regarded as highly aligned (range: 52% - 64%). When we reduce the threshold to 0.65, two-thirds of the comments are highly aligned. But this increases the

---

[3] Our code and data are available at: https://github.com/JonRusert/SuumCuique

[4] For example, while "is that all you have to contribute" and "contribute this have that is to you all" have the same set of words, BERT will find the former more likely.

[5] Models were trained on GeForce GTX 1080 Ti's, and took at most 3 hours to train. Parameter configuration is that of base-BERT, we use a dropout of 0.3 before the linear layer.

[6] In our experiments, we do not use any data beyond that which is available on Pushshift. Pushshift is a public Reddit data repository.

[7] We also acknowledge that Reddit itself has some language norms. However, these norms should apply across all of our community subreddit datasets and so should not influence our results in significantly.

[8] South Asian English is considered non-standard compared to mainstream English.

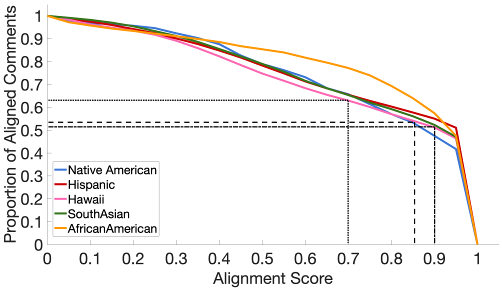

Figure 1: Complementary cumulative distribution function of community-language alignment scores for the five community models using the community specific validation datasets. An alignment score indicates the proportion of the community's comments that the model classifies as belonging to that community within a given threshold. The dotted/dotted-dashed lines (0.7, 0.9) show the proportion of comments at those thresholds. The dashed line (0.85) indicates the chosen threshold for our experiments.

risk of overlap across communities in their highly aligned comments. Taking the SA CLC model as an example in Figure 2, we can see that with 0.85 cutoff, 60.7% of comments from the South Asian community are highly aligned, while including no more than 14% (range: 2% - 14%) of comments from the other communities. While not strictly comparable, our 0.85 threshold is more conservative than the 0.80 used in Blodgett et al. (2016).

3.3 Model Validation

Results with our validation datasets (shown in Table 1) are in Table 2 with cell values representing proportions. For example, 51.8% of the NA validation set is highly aligned (alignment score ≥ 0.85) with its own community model. Column values do not necessarily add up to 100% as a text may be highly aligned to more than one community model or even to none.

As expected, proportions at the diagonal representing homogenous model - dataset combinations are high, ranging from 52 to 64%. Also as expected, the off-diagonal entries representing heterogeneous combinations, are low. Most are less than 10% and more than half less than 6%. The three noticeable exceptions are between AA and SA and also between NA texts and the HA model. The sociological literature observes linguistic exchanges between minority communities (Bucholtz, 1999; Coleman, 1998; Igoudin, 2011; Lee, 2011). For example, (Shrikant, 2015) discuss a tendency of South Asians to adopt the features of African American Vernacular English (AAVE). This is particularly relevant to the AA and SA overlaps. Next we use these validated models to estimate bias in classifiers and in datasets.

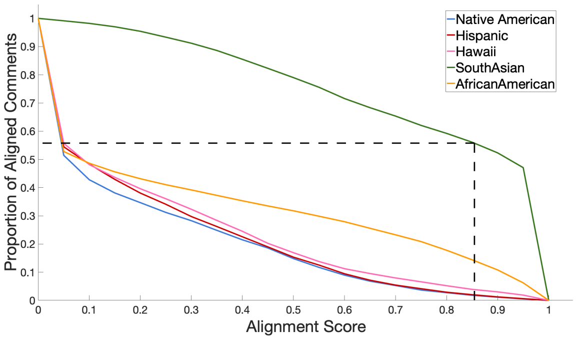

Figure 2: Complementary cumulative distribution function of alignment scores for all five minority community validation sets as gauged against the South Asian community's CLC.

	Reddit Validation Sets				
CLC	NA	HI	HA	SA	AA
NA	**51.8**	1.8	4.5	1.8	2.2
HI	4.3	**58.2**	2.1	2.3	2.2
HA	15.1	6.2	**58.1**	5.1	6.9
SA	6.1	5.2	5.8	**60.7**	20.7
AA	9.8	7.1	8.1	14.4	**64.0**

Table 2: Proportion of each validation set that is highly aligned with each CLC. An alignment score threshold of 0.85 is used to determine high alignment. A text may be aligned with 0 or more models, so column numbers need not sum to 100.

4 Experiments and Results

4.1 Taboo Classifier Bias Assessment

We test 3 SOTA offensive language classifiers:

NULI (Liu et al., 2019): A BERT (Devlin et al., 2019) based system trained on offensive language (OLID (Zampieri et al., 2019a)). It was the top-ranked system in OffensEval (Zampieri et al., 2019b).

MIDAS (Mahata et al., 2019): An ensemble of three deep learning models: a BLSTM, a BLSTM fed into a BGRU, and a CNN all three trained on offensive language. This system was the top non-BERT based system at OffensEval.

Perspective (Perspective): An API provided by Google, which when given text, returns a toxicity score. The current model in production uses a CNN trained with fine-tuned GloVe word embeddings.

We trained MIDAS and NULI on the OLID training data which is consistent with their training for

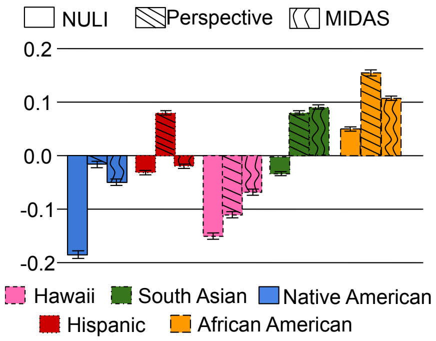

Figure 3: Correlations of taboo classifier scores with community-language classifier scores. Error bars: 95% confidence intervals.

Dataset	Labels	Sizes	Prior Work
Davidson (2017)	Offense Hate	20716 1537	Sap (2019) Davidson (2019)
OLID (2019a)	Offense	4640	None
SOLID (2020)	Offense	3002	None
Gab (2018)	Hate	2337	Jin (2020)
Founta (2018)	Hate Abuse	27150 4965	Sap (2019)
Wiki Toxic[9]	Toxic Hate	15295 1405	Vaidya (2020)
Waseem (2016)	Sexist	2673	Davidson (2019)

Table 3: Details of examined datasets. Samples of prior work which also examined these sets for bias are indicated in the final column.

OffensEval. Our implementations perform within 1% of the published results. We then applied the classifiers to the validation datasets listed in Table 1. Correlations between classifier confidence (for Perspective we use its toxicity score) and language model alignment scores were analyzed.

4.2 Taboo Classifier Bias Results

Classifiers' correlations show bias. Figure 3 shows the correlations with community models for the five communities for different taboo classifiers with 95% confidence intervals computed using 10,000 bootstrapped samples. Instead of strong negative correlations, which would indicate no bias, we see several instances of positive or near zero correlations across community models and classifiers. Zero correlations while better than positive are still not ideal, since they indicate that the taboo classifier is not taking community alignment into account.

NULI is relatively less biased than Perspective or MIDAS. These correlations indicate that the taboo speech classifiers largely do not consider the language norms of the community.

Taboo classifiers have highest bias against the African American community. All three taboo classifiers tested show higher positive correlations for AA compared with other communities. This disagreement with the AA community model reflects bias in the classifiers, an observation that is consistent with those made in prior literature (Davidson et al., 2019; Sap et al., 2019).

Perspective shows highest bias. On average, Perspective, is the least in accordance - having the most positive correlations - with the CLC models. When compared with MIDAS and NULI, the only community model for which Perspective has a lower bias is HA. This is particularly concerning as Perspective is publicly available and has already been deployed to monitor comment sections (Delgado, 2019; Etim, 2019).

4.3 Dataset Bias Assessments and Results

We generate ten test sets from seven text collections annotated for taboo. A test set consists of instances labeled with one taboo label (such as hateful, offensive, sexist etc.). A summary of the datasets can be found in Table 3.

Table 4 presents bias assessment results. Each row identifies the CLC used to estimate alignment of taboo instances in the column datasets. For example, 14% of the texts labelled as HATE in the Davidson dataset are highly aligned with the Native American model. We remind the reader that we use a community classifier score threshold of 0.85 (see section 3.2). Again column sums need not be 100 as an instance may be highly aligned with 0 or more models. The table also shows average and standard deviation. Cells in bold are more than one standard deviation from the mean.

As a reminder, for any community we would like the proportion of taboo labeled instances that are highly aligned with that community's language to be close to 0. Additionally, if this is not possible, we check to see if these proportions are unequal across communities. Inequality would indicate that bias is particularly targeted at some communities - those with highest proportions.

4.3.1 Taboo text and model alignments

Many of the proportions are large indicating bias. When examining Table 4, we find that 64% of the

	Davidson				Gab	Founta		Wiki Toxic		Waseem
CLC	HATE	OFF	OLID	SOLID	Hate	Hate	Abuse	Toxic	Hate	Sexism
NA	14.0	3.9	3.4	1.4	7.6	4.4	3.9	8.0	**13.3**	5.1
HI	5.5	5.2	8.3	3.5	5.5	5.4	6.6	4.9	6.3	3.9
HA	4.3	3.1	6.3	5.1	3.9	6.0	4.6	**9.4**	3.4	4.2
SA	4.2	2.2	**16.3**	5.8	**25.4**	14.5	5.4	8.5	**13.0**	13.9
AA	**20.7**	**29.9**	15.2	**30.4**	12.2	**32.6**	**22.5**	4.9	5.3	**45.5**
Average	9.7	8.9	9.9	9.2	13.2	12.6	8.6	7.1	8.3	14.5
Std. Dev.	7.4	11.8	5.6	11.9	8.7	11.9	7.8	2.1	4.6	17.8

Table 4: Proportion of Taboo datasets with high alignment scores for each CLC. Note, a given text may have high alignment with 0 or more communities. Thus column proportions need not sum to 100.

cells have proportions $> 5\%$. Even with a stronger threshold of $> 10\%$ on the proportions, close to a third of the cells still exhibit bias. The least biased – closest proportion to 0, is 1.4 for SOLID gauged against the NA model. The highest is 45.5 for Waseem gauged against the AA model. Examining each dataset, we see that all have large proportions of taboo text that are highly aligned with at least one community; some datasets are biased against two communities. For example, Wiki Toxic - Hate has high proportions when gauged against both NA and SA. When examining averages across datasets Waseem is the most biased (average of 14.5), followed next by Gab. Wiki Toxic - Toxic is the least biased — with the lowest average. Overall, all datasets exhibit biases with proportions that are far from 0.

4.3.2 Uneveness of alignment proportions

Datasets are heavily biased against African Americans. As seen in table 4, six out of the ten datasets have disproportionate high-alignment with the AA CLC model with a seventh (OLID) coming close to crossing the 1 SD mark. The two datasets with lower than average proportions are from the Wiki Toxic collection. The highest proportions are with the Waseem dataset followed by the Founta Hate dataset. Telling too is that the top six in bias have more than 20% of their instances highly aligned with the AA model. This level and consistency of bias against the AA model is remarkable.

Datasets also biased against South Asians. Next to the AA community, the largest bias is against the SA community. This community takes the top position with Gab Hate; over a fourth of the data is highly aligned with the community (25.4%). Looking down the column this proportion for SA stands out, with the next highest — AA, at 12.2%. In OLID and Wiki Toxic Hate, SA proportions are more than 1 SD from average. SA alignments are lower than average for 5 datasets such as Davidson and Founta Abuse. This analysis brings to light that bias is not limited to the AA community, but extends to other communities as well. This is noteworthy as previous works such as (Davidson et al., 2017; Sap et al., 2019) have solely focused on the bias against AA while ignoring others like SA.

Low bias communities exist. The HI and HA communities face less bias in comparison with AA and SA. In fact, for HI the proportions are lower than average across all datasets. NA has proportions 1 SD higher than average for one dataset: Wiki Toxic - Hate. Otherwise, the alignment proportions are almost always lower than average.

Results are largely comparable with previous bias results. Comparisons are limited as prior work largely focuses on bias towards AA. We make the following general observations.

Our results are generally consistent with those of Davidson et al. (2019) and Sap et al. (2019) on the Davidson dataset. E.g., all three find high rates of AA tweets as labelled offensive (between 17% and 46%). We observe similar agreements for the Founta and Waseem sets. There exists some disagreement, however, where we find the “hate” labeled portion of Davidson and Founta datasets to show bias against AA, while Sap et al. (2019) did not. The reasons for this difference are unclear. However, it is puzzling to note that Sap et al. (2019) found bias against a community for one taboo class (offense) but not another (hate). The authors do not provide an explanation for this.

Huang et al. (2020) examining the Waseem and Founta datasets for bias against race find BERT to show the least bias compared to CNN and RNN based classifiers. Our results are consistent as the BERT based classifier, NULI, shows lower bias than MIDAS, which is an ensemble of a CNN, and BLSTM/BGRUs.

Overall, our results indicate that the datasets are largely insensitive to the norms of African Americans (overwhelmingly so) and then to the South

Asian communities. Subsequently, taboo classifiers built on these datasets are more likely to be biased against these two communities.

4.4 Small scale user study

We present a small scale user study intended only to illustrate our main hypothesis, that texts highly aligned with a CLC should be less likely to be considered taboo from the perspective of members of that community. A rigorous user study with intra and inter community judgements and many judges is left for future work.

Classifier bias. Focusing on Figure 3, we selected a mixture of comments from OLID/SOLID and from reddit that had the highest model alignment scores (> 0.85) with their respective CLCs. We selected 80 comments for AA and 78 for SA, all of which had high taboo classifier confidence scores (> 0.76) with MIDAS and Perspective, i.e., they contributed the most to the positive correlation bars in the graphs. We asked two African Americans and two South Asians, who were active Reddit users, to judge their respective sets as offense/hate or not. The annotators were selected by word of mouth. Given high alignment we expect annotators to contradict the classifier and judge these as not taboo.

As expected, both SA annotators disagreed with the classifier assigned taboo labels in 60/78 cases (76.9%) agreeing only in 3/78 comments (3.8%) and giving mixed judgements in the remaining 19% of comments. AA annotators disagreed with the classifiers for 27/80 (33.8%) comments. While non trivial, this percentage is noticeably less than 76.9% for SA. They agreed with the classifier's taboo decision 31/80 times (38.8%) and gave mixed judgements in 25% of cases (more than for AA). Overall, judges contradicted the classifiers 55% of the time.

Analysis of classifier contradictions. In a majority of the contradictions the classifier did not recognize benign contexts of words such as 'fuck' and 'shit'. E.g., in SA are: *"how the fuck are Indians minorities'* and *'how is an accent shitty"*. From AA: *"... drop this fake ass bitch and move on"*. Annotators did not label these as offensive.

A second reason for contradictions appears to be because culturally subtle contexts are challenging for classifiers. Both SA annotators marked the comment *"this is exactly the reason i don't fuck with Biryani"* as non-taboo. The classifier does not recognize this as a statement on the authenticity of a food item - 'Biryani', a rice-based South Asian dish. Similarly the AA annotators marked: *"I'm so fucking tired of side chick culture"* as not taboo. The classifier does not recognize this as a critique of extra-marital intimacy and not an attack on a 'culture'. Note that all these statements have model alignment scores that are very high (> 0.94).

Dataset Bias. Focusing on OLID (biased against South Asians) and SOLID (biased against African Americans), see table 1, we explore if community consistent judges will contradict dataset annotations. We selected 50 SOLID and 23 OLID tweets annotated in the datasets as taboo and with CLC model alignment score ≥ 0.85.

Both AA annotators contradicted taboo annotations for 66% (30/50) SOLID tweets and agreed with only 9/50 (18%). They mutually disagreed on the remaining 11 tweets. Both SA annotators contradicted 83% (19 of 23) of OLID taboo annotations. They mutually disagreed on the remaining 4. Overall 67% of community-specific annotator decisions contradicted taboo annotations. These contradictions are also illustrative of our expectations of 'not taboo' decisions for high alignment posts.

Analysis of annotation contradictions. AA annotators chose 'not taboo' in several SOLID cases based on context and their norms. E.g., *"this bitch just cut her hair short by herself"*. Perhaps the presence of language likely considered offensive in a more general setting resulted in the taboo label. In another example, the AA annotators contradicted the SOLID taboo label for the tweet *"Niggas be so depressed on this lil app ..."*. We see a similar phenomenon with the SA annotators. For example, they contradicted the taboo label for the tweet *"All these sick ass ppl from school gave me something and now I have to chug down this nasty drink so it can go away"*.

Additional examples of contradictions by AA and SA annotators are in the appendix (B and C). While a larger user-level study with suitable controls is planned for the future, these preliminary results illustrate our hypothesis that using a community perspective on taboo decisions is important and that this can be achieved using CLC model alignment scores.

4.5 Bias mitigation - initial thoughts

Our empirical results and case study illustrate a potential approach for bias mitigation. The idea is to include 'reset' strategies for taboo classifiers and for annotations. If an instance that is classified or annotated as taboo has high alignment score with a CLC then a reset strategy is invoked to examine the decision further. This can be manual analysis by a community member knowledgeable of its norms and contexts - a step that can be labour expensive. Alternatively, a downstream algorithm that is more community centric may be invoked - a step that may computationally more expensive. We plan to explore these in future.

5 Related Work

The study of bias in taboo classifiers is an active area of research (Wiegand et al., 2019; Huang et al., 2020; Blodgett et al., 2020; Park et al., 2018). Since our focus is on bias detection we do not cover areas such as bias mitigation (Tsvetkov, 2020; Chuang et al., 2021) and allied problems such as bias in embedding spaces (Park et al., 2018; Caliskan et al., 2017) and the source of bias (Binns et al., 2017; Waseem, 2016). Instead we focus on bias detection - particularly on their methodologies. Note as most papers combine methods our binning is not intended as mutually exclusive classes.

Bias detection focused on individual words: Dixon et al. (2018) working with Wikipedia Talk Pages show that toxicity classifiers disproportionately misclassify text with identity terms such as 'gay' and 'muslim' when they appear in benign contexts. A reason for this bias is because of their dominant occurrence in hateful, toxic or otherwise taboo contexts, thereby skewing training datasets. They show this can be countered by augmenting data with benign examples using these identity words. Park et al. (2018), and Kennedy et al. (2018) also study similar biases in the data. Badjatiya et al., (2019) extend this analysis to words in general, finding strings like '@ABC' and 'dirty' stereotypical of hate. The general approach in these papers is to compare classifiers built from skewed and synthetically augmented/corrected non-skewed datasets. In contrast to focusing on specific words, we analyze texts contextually with CLCs.

Bias detection using an external race/gender labeled dataset: Davidson et al. (2019) examine five datasets including the Davidson and Founta datasets we study. Their strategy is to build a classifier (regularlized logistic regressor) on each dataset and test them on the Blodgett et al. (2016) black-white-race-aligned dataset. They observed that 'black-aligned' tweets were 1.8 to 2.6 times more likely to be classified as taboo. Using similar methodology, Sap et al. (2019) also found bias against AA in neural network classifiers trained on the Founta and Davidson datasets when tested against the same Blodgett et al. (2016) dataset.

Using a slightly different approach Kim et al. (2020) trained a classifier on the Blodgett et al. (2016) dataset to identify AA-leaning tweets in the Founta dataset. They found that AA tweets were 3.7 times more likely to be labeled as taboo. Additionally, they also annotated the Founta dataset for gender. They found that AA male-aligned tweets were 77% more likely to be labeled as taboo. In contrast to these works, our approach does not rely on access to race labeled datasets such as the Blodgett et al. (2016) dataset.

Other approaches: As in Kim et al. (2020), Sap et al. (2019) used classifiers trained on Blodgett et al. (2016) to identify 'black-aligned' tweets in the Founta and Davidson datasets. The difference is that they then computed correlation of probabilities of 'black-aligned' tweets and the taboo language annotations and found these to be strong positive. We also compute Pearson correlations between classifier scores and community alignment scores. But we differ in that we are not relying on the Blodgett et al. (2016) dataset. Instead, we use alignment scores estimated using CLCs.

While the above works highlight limitations in using a single standard English model they do not propose alternative methods founded on the language norms of specific communities. We address this gap with a community-specific method using CLCs which allows us to study bias for any community. Moreover, unlike the works reviewed, and more recent papers on debiasing strategies (Zhou et al. (2021); Xu et al. (2021)), where the emphasis is on bias against AA, we study bias against five different minority communities.

6 Limitations and Conclusions

We presented a new methodology for studying bias in taboo text identification. Its strength is that it is centred on community language norms - a strategy consistent with (Blodgett et al., 2020) to consider social hierarchy when studying bias and natural languages. Using it we assessed the extent to which biases against five minority communities are present - both in classifier taboo decisions and in dataset taboo annotations. We found many instances of bias with the community most targeted being African Americans. But we also found significant biases against others such as South Asians. Notably, Hispanics seems least affected though there was to some degree classifier bias.

A small scale 'illustrative' user study provides initial support for our key idea which is that common utterances, i.e., those with high alignment with the community's language classifier, are unlikely to be viewed as taboo from that community's perspective. Annotators who are community members contradicted classifier and annotator decisions in a majority of instances.

Our work is limited to analyzing communities defined by race and ethnicity, but is generalizable; we will explore bias against other communities in future research. We also plan to conduct a large-scale user study to better understand community perspective for taboo texts. We plan to investigate the bias mitigation strategies shown in section 4.5.

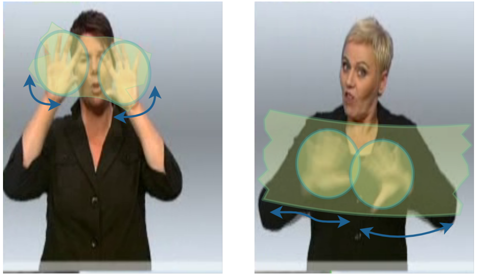
Abstract

End-to-end sign language generation models do not accurately represent the prosody in sign language. A lack of temporal and spatial variations leads to poor-quality generated presentations that confuse human interpreters. In this paper, we aim to improve the prosody in generated sign languages by modeling *intensification* in a data-driven manner. We present different strategies grounded in linguistics of sign language that inform how intensity modifiers can be represented in gloss annotations. To employ our strategies, we first annotate a subset of the benchmark PHOENIX-14T, a German Sign Language dataset, with different levels of intensification. We then use a supervised intensity tagger to extend the annotated dataset and obtain labels for the remaining portion of it. This enhanced dataset is then used to train state-of-the-art transformer models for sign language generation. We find that our efforts in intensification modeling yield better results when evaluated with automatic metrics. Human evaluation also indicates a higher preference of the videos generated using our model.



less clouds **`WOLKE`**	very cloudy **`WOLKE`**
10 video frames	17 video frames
Sign Not Repeated	Sign Repeated
No Delay	Delayed Beginning
Smaller Space Use	Larger Space Use

Figure 1: In sign language, modifiers are represented spatially and temporally. Here, two signers from PHOENIX-14T manually sign German "less clouds", and "very cloudy". Both of these signs have the same gloss representation: `WOLKE` (cloud in German). They are figuratively the same sign, but the duration, repetition, temporal pauses, and continuations determine the exact meaning. This information is lost during sign language translation and evaluation.

1 Introduction

Similar to spoken languages, sign language has rich grammar rules and unique linguistic structures (Yin et al., 2021a; Emmorey, 2001). Elements of prosody such as rhythm, stress, or lengthening play important roles in distinguishing meaning and signaling intensification in sign language (Figure 1), similar to spoken languages (Brentari et al., 2018). Thus, it is important for sign language generation (SLG) systems to be able to learn accurately from the data and generate presentations that respect prosody.

Much of the current study on prosodic markers such as intensifiers (Bolinger, 1972; Rett, 2008; Ghesquière and Davidse, 2011) are based on linguistic theories of spoken languages and need to be adapted to signed languages, as prosody is represented in the visual modality (Wennerstrom, 2001). Semantic differences are signaled in the visual modality using spatial and temporal presentations such as iconicity, gesture duration, as well as temporal pauses (Wilbur et al., 2012). Such distinctive properties present challenges in SLG systems to generate presentations with better prosody.

Several SLG systems have been proposed in recent years motivated by their importance to the Deaf and Hard of Hearing (DHH) communities (Stoll et al., 2018; Zelinka and Kanis, 2020; Stoll et al., 2020; Saunders et al., 2021). Transformer-based models (Saunders et al., 2020b) have been shown to outperform other neural models (Stoll

Findings of the Association for Computational Linguistics: ACL 2022, pages 2897 - 2911

et al., 2020) in generating sign language from gloss annotations —a shortened approximation of spoken language that has mappings to signs. One of the key limitations of the state-of-the-art models is that the prosody of the sign videos generated by these models does not change with the semantics of the signs (Duarte et al., 2021). In this paper, we take a step toward the goal of modeling prosody in sign language generation by modeling *intensification*. We refer to intensification as the presence of *intensity modifiers* that quantify nouns, adjectives or adverbs in a sentence. The intensity modifiers can either be an amplifier (e.g., lot of rain) or a diminisher (e.g., little rain). Studies in the linguistics of signed languages show that intensity modifiers change the duration and tactile emphasis in the produced sign (Wilbur et al., 2012). Thus, intensification modeling can impact prosody of generated signs. However, this potential of intensification is not realized within current models because they depend on gloss representation. Intensity modifiers are often excluded in gloss representation because they are a sparse approximation of spoken language. As shown in Figure 1, the spatial and temporal properties of signs differ dramatically even when they map to the same gloss. State-of-the-art models cannot be aware of this temporal and spatial manipulation by modifiers if they are not represented in the gloss training data.

Our initial analysis of the PHOENIX-14T (Camgoz et al., 2018), a German Sign Language dataset, reveals that 23% of the data has at least one adjective or adverb in the text transcript, but none in the gloss representation. Since adjectives and adverbs (e.g., little) often act as intensity modifiers, they are likely to be under-represented in the gloss as well. This observation motivates the need for explicit modeling of intensification in the gloss representation and modifying state-of-the-art models to incorporate this additional information. We hypothesize this to have an overall improvement in the models' performance both quantitatively in terms of automated metrics and qualitatively in terms of human evaluation. To this end, drawing on linguistics and cognitive science studies of sign language, we

1. introduce gloss enhancement strategies grounded in linguistics that respect the role of modifiers with various levels of intensity.
2. present a supervised tagging model to improve a given gloss dataset with modifier intensity levels using strategies we have identified.
3. make available an enhanced version of the PHOENIX-14T dataset where the glosses are tagged with intensity levels of modifiers.
4. incorporate modifier information into the Progressive Transformer (PT) model. We also propose a novel model that can dynamically select the generated poses with different gloss enhancement as input. We make our code and data publicly available.[1]

2 Related Work

Prosody of Sign Language Prosodic information in sign language has been studied through the lenses of cognitive sciences and linguistics. Using brain images, Newman et al. (2010) show that prosodic signed information is processed by signers in much the same way as it is by hearing speakers. In (Sandler, 1999), the intertwined nature of prosody is observed in a multifaceted manner for semantics, neurological basis and syntactic understanding of sign languages. Nicodemus et al., (2009) note that prosodic markers play an important role as delimiting units during the production and perception of the signs. These works study the importance of prosodic markers during the producing and processing sign language by humans from a cognitive science perspective. In our work, we model intensification as a prosodic marker computationally.

In linguistics research, studies have focused on the relationship between prosody and syntax in sign language (Sandler, 2010), role of prosody in identifying breakpoints in discourse, and detection of salient events (Ormel and Crasborn, 2012). Sandler et al. (2020) suggest that pragmatic notions related to information structure are a part of prosody in sign language. Although there has been limited work that highlight the importance of intensity modifiers in sign language prosody (Wilbur et al., 2012), our work is the first data-driven empirical study that studies a large dataset, annotates, then quantifies and characterizes data-driven strategies for modeling intensification. Our work is the first that presents a Transformer-based model for intensification as a step toward modeling prosody.

Sign Language Generation Many works have looked at sign language processing, such as coref-

---

[1] `https://github.com/Merterm/Modeling-Intensification-for-SLG`

erence resolution (Yin et al., 2021b) or gloss augmentation for translating gloss into text (Moryossef et al., 2021). However, prosody is still understudied in the field of sign language generation and processing.

The primary aim of SLG is generating sign poses from texts. Earlier work has explored methods to generate animated avatars (Cox et al., 2002; Glauert et al., 2006; McDonald et al., 2015) from speech or text inputs, but were restricted by the rule-based systems and the modest size of sign pose libraries. More recently, with the introduction of larger corpora such as PHOENIX-14T (Camgoz et al., 2018), and advanced deep learning model architectures, generating more accurate and expressive human skeletal sequences from spoken language transcripts or annotated glosses has become possible (Stoll et al., 2018, 2020; Zelinka and Kanis, 2020; Saunders et al., 2020a,b, 2021) while also including facial expressions (Viegas et al., 2022). Yet, none of these works attempt at modeling intensification or any other indicator of prosody in hand gestures. Our work is the first that combines linguistic and cognitive findings and proposes a deep learning model that dynamically selects intensification strategies to generate skeletons with variations for different levels of intensifiers based on augmented glosses.

3 Intensification in Sign Language

Gloss annotations in the German Sign Language weather forecast corpus, PHOENIX-14T, are simple German words that often do not capture the subtleties of sign language. For example, "very cloudy" and "slightly cloudy" are both represented by a single gloss "WOLKE" (CLOUD). Our analysis shows that in 23 percent of the data, the gloss representation does not contain any adjectives or adverbs present in the text transcript. Since intensity modifiers are usually adjectives/adverbs that quantify intensity of other words, we expect them to be missing from the gloss representation as well. Hence, in order for the model to represent intensity modifiers in its latent space, it is necessary to include them in the training data.

3.1 Gloss Enhancement Strategies

In a data-driven manner, we analyze the best ways of representing intensity modifiers in gloss annotations based on linguistic theories, cognitive science and neuroscience perspectives of intensities in sign language. We discover that the choice of order for the additional gloss modifier tokens matter. Linguistic analysis of American Sign Language also shows the importance of this.

Wilbur et al. (2012) explain that depending on the degree of the adjective, there is a "sharp movement to a stop" in the final timing of the sign, which is coined as *end-marking*. They also show that the initial time interval of a sign also gets modified with a slight pause in the beginning and a faster continuation of the sign, which is termed as a *delayed-release*. Also, there exists other datasets with different annotation schemes, one of which –Public DGS Corpus– uses a gloss annotation convention where the phonemes and synonyms that have different signs contain a number that is added as a suffix to the end of the gloss (Konrad et al., 2020). Finally, as described by (Nicodemus et al., 2014) during the end-marking and elongation phase, a sign might be reiterated to mark the intensification.

Inspired by these previous works in linguistics of signed languages and in analyzing the dataset with sign language researchers, we came up with four strategies to better represent intensity modifiers in glosses. We use these strategies in four alternative ways, as shown in Table 1 and are introduced below:

- **End-Marking**, where an additional token of `<HIGH-INT>` or `<LOW-INT>` is added *after* the intensity-modified gloss to represent the change in the final timing of the sign as shown in (Wilbur et al., 2012).
- **Delayed Release**, where the additional intensity modifier token of `<HIGH-INT>` or `<LOW-INT>` is added *before* the original gloss, as described in (Wilbur et al., 2012) to represent the delayed release in the initial timing of the sign.
- **Suffixation**, where an `INT` suffix is added at the end of the gloss with an additional numerical value (1 or 2) corresponding to the degree of intensification. This is analogous to the Public DGS Corpus annotation (Konrad et al., 2020).
- **Reiteration**, where we repeat the intensity-modified gloss token twice to capture this in the gloss representation as described by (Nicodemus et al., 2014).

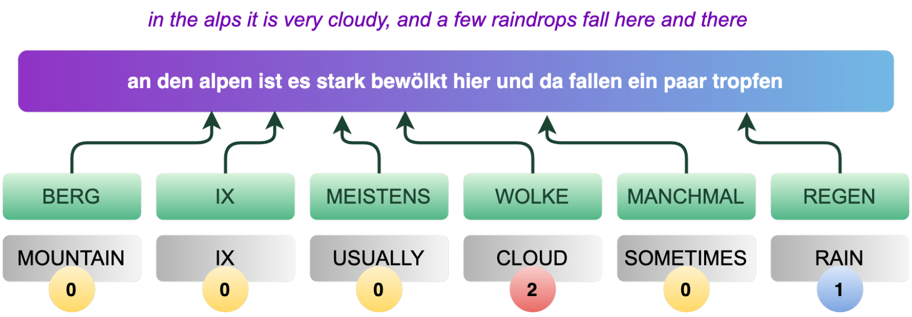

Figure 2: This figure shows an example annotation. German transcript text and gloss are provided as context along with their English translations. Each English gloss in the sentence are tagged with 0, 1, 2, corresponding to the degree of intensification.

Approach	**Example**
Text	very cloudy
Original Gloss	`WOLKE` (cloud)
Suffi.	`WOLKE-INT2`
End-mark.	`WOLKE <INT2>`
Delay.-rel.	`<INT2> WOLKE`
Suffix.-reiter.	`WOLKE-INT2 WOLKE-INT2`

Table 1: Gloss Enhancement examples.

3.2 Data Annotation

We start by selecting a subset of the publicly available PHOENIX-14T dataset (Camgoz et al., 2018) for the annotations of intensity modification.

Data Sampling. Initial analysis demonstrates that gloss annotations tend to ignore the adjectives/adverbs, which are signals of intensity modification. We hypothesize that for samples where the number of adjectives/adverbs is zero in gloss annotations but more than zero in texts, the intensity information is more likely to be missed. We use Spacy (Honnibal and Montani, 2017) part-of-speech (POS) tagger to tag the text and gloss pairs, then utilize the hypothesis mentioned above to filter the data. In the end, we acquire 1557 samples in the train set, 132 samples in the development set, and 157 samples in the test set. Afterwards, the gloss sequences are split into individual gloss tokens. These gloss tokens are paired with the full text transcripts, which yields a total of 12.8K gloss token to sentence pairs – 10.8K from the 1557 instances in train, 1K from the 132 instances in dev and 1K from the 157 instances test set.

Annotation Protocol. For each of the gloss token to sentence pair, we ask at least one annotator to assign labels to the gloss token from the following categories: (i) `2` as "high intensity" if there is an intensity modifier such as "high" in the text surrounding the gloss; (ii) `1` as "low intensity" if the intensifier in the text marks a low degree intensity; or (iii) `0` if there is no corresponding modifiers in the text transcripts.[2] Figure 2 shows an example of the annotation.

Annotator Agreement. Three expert annotators were recruited according to the rules and regulations of our institution's human-subject board. To assess the inter-annotator agreement, we randomly sampled 700 token-sentence pairs and asked all three annotators to annotate. The resulting Fleiss' Kappa (Fleiss, 1974) coefficient is 69.2, which suggests a substantial agreement among the annotators.

3.3 Full Corpus Intensity Enhancement

Utilizing the annotated pairs, we train a battery of classifiers to automatically predict the gloss labels for the remaining data points. Having an automated classifier saves us resources that would otherwise be needed to tag the whole dataset.

Classifiers. We frame the task as a text pair classification problem. Given the original text transcript and a gloss token, the goal is to predict a label from: `0` (no intensity modification), `1` (low degree intensity) and `2` (high degree intensity). We experimented with multiple classification baselines, including fastText (Joulin et al., 2017), Bidirectional LSTM and two versions of fine-tuned BERT (Devlin et al., 2019) models – German BERT (G-BERT) and multilingual BERT (M-BERT). All models are trained on the manually annotated 10.8K training pairs and results are reported on the 1K test subset.

---

[2] We translated the German transcriptions and glosses into English using the Google Translate API `https://cloud.google.com/translate`

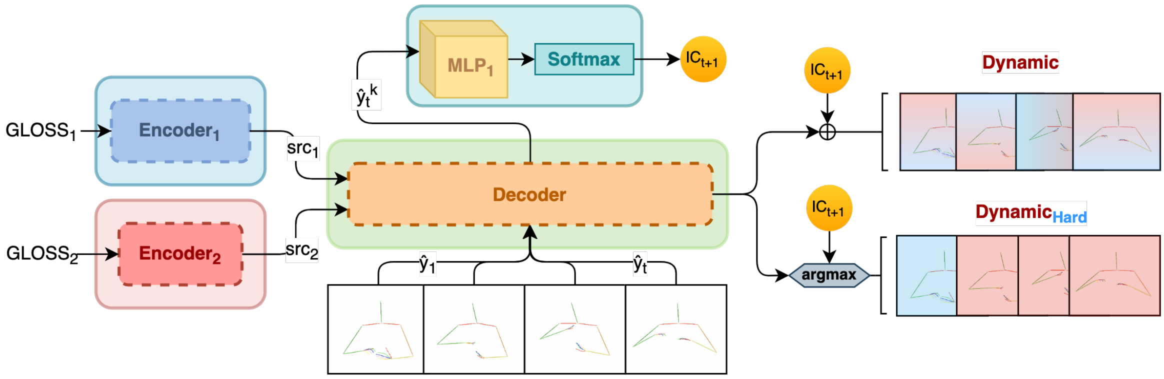

Figure 3: This figure shows the architecture of the Dynamic Selection model. The overall architecture is similar to the Progressive Transformer, except having two Encoders to select between two different types of strategies. MLP layer is the decisive step on selecting the strategy from the encoders. Dynamic model uses a weighted mixture of the decoder outputs (represented with a gradient of blue and red). Dynamic$_{hard}$ uses an argmax to pick a source.

Table 2 shows the experiments with different classifiers. Fine-tuned transformers G-BERT and M-BERT outperform others by a large margin. The performance improvement of M-BERT compared to G-BERT is statistically significant according to a permutation test.

Error Analysis of Gloss Enhancement We manually categorize 100 errors made by our best classifier, M-BERT. The key observations are: i) 30% of the errors are due to ambiguity that annotators may have for hard cases. E.g., "The wind blows weakly to moderately" can be annotated as either low-intensity (weakly) or no-intensity (moderately). ii) aligning gloss tokens with text can be difficult (24%). For example, in "partial snow or freezing rain", the classifier may consider "partial" to be aligned with rain, assigning it the label of "low-intensity" (should be "no-intensity"). Further, presence of negation (e.g., "not much rain") and multiple occurrences of the same word (e.g., "in the Bergland, it snows partly, on the alps it snows for a long time.") can make alignment a difficult task for the classifier, and iii) 12% of the errors can be attributed to noise in original PHOENIX-14T data. E.g., the gloss representation can contain tokens that are not related to the transcript. We could not assign a specific category to 34% of the errors.

Model	Features	Prec.	Recall	F1
FastText	embed	60.5	62.0	61.0
BiLSTM	embed	62.1	66.6	64.1
G-BERT	–	**74.3**	74.2	74.2
M-BERT	–	74.2	**76.4**	**75.3**

Table 2: GLOSS intensifier classification results. Embeddings for FastText and BiLSTM are learned during training.

Enhancement. We tag all the remaining glosses with the best-performing classifier, M-BERT, in the original PHOENIX-14T dataset. We end up with four versions of enhanced gloss sequences by incorporating the aforementioned strategies in section §3, namely *Suffixation*, *End-marking*, *Delayed Release* and *Suffixation with Reiteration*.

4 Model

In this section, we first introduce a baseline model that has been widely adopted for the sign language generation task (section §4.1). To better model the signer's dynamic intensification choices during sign production, we further propose a dynamic selection model (Figure 3) that makes use of inputs with different intensity modification strategies.

4.1 Progressive Transformer Baseline

The main goal of the sign language generation model is to transform a gloss or text sequence into skeletal pose coordinates per each frame of the signing video. Formally, given a gloss sequence $X = [x_1, ...x_N]$, a sign language generation model aims to learn the conditional probability $p = (Y|X)$ where Y represents the corresponding skeletal pose coordinate sequence $Y = [y_1, ...y_T]$. We use the Progressive Transformer (PT) (Saunders et al., 2020b) model as our baseline. The model employs an encoder-decoder architecture to generate a sign language sequence $\hat{Y} = [\hat{y}_1, ..., \hat{y}_T]$ in an auto-regressive manner. The encoder is composed of L transformer layers, each with one Multi-Head Attention (MHA) and a feed-forward layer. The computed representation of the source sequence is fed into a modified transformer decoder, which employs a counter-based decoding mechanism to guide the generation of continuous joint sequences $\hat{y}_{1:T}$ and to decide the end of the generated sequence. This strategy can be formulated as:

$$[\hat{y}_{t+1}, \hat{c}_{t+1}] = PT(\hat{y}_t | \hat{y}_{1:t-1}, x_{1:N}) \tag{1}$$

where $\hat{y}_{t+1}$ and $\hat{c}_{t+1}$ are the generated joint sequence and the counter value for the generated frame $t+1$. The model is trained using the mean square error (MSE) loss between the generated sequence $\hat{y}_{1:T}$ and the ground truth $y_{1:T}$:

$$L_{MSE} = \frac{1}{T}\sum_{i=1}^{T}(y_i - \hat{y}_i)^2 \tag{2}$$

It is worth noting that, as stated by (Huang et al., 2021), the proposed decoding mechanism provides weak supervisions with the initial ground-truth frame and guided counter sequences during the inference time.

4.2 Dynamic Selection Generator

The PT baseline can generate sign poses from a single source of gloss end-to-end. However, in different scenarios, the signers may employ diverse intensification strategies to present meanings for the same gloss word (i.e. they may use a gesture with a delayed-release to represent “heavy thunderstorm” and later employ an end-marking to strengthen the intensity of another sign). To model this, we propose a new structure on top of the PT baseline. Given a text sequence, we mix k sources of glosses with different information goals and generate signed languages that dynamically pick the source gloss. In general, we can have multiple encoders, $Encoder_{1 \cdots k}$, to encode the glosses separately and obtain the representations $src_{1 \cdots k}$. We utilize a single decoder to decode the output representation k times from k sources of encoders, each with a different encoded input representation:

$$src_k = Encoder(x^k_{1:N}) \tag{3}$$

$$\hat{y}^k_{t+1} = Decoder(\hat{y}^k_t | \hat{y}^k_{1:t-1}, src_k) \tag{4}$$

We employ a multi-layer perceptron (MLP) followed by a softmax activation function to generate selection probability distributions of each source for individual frames, which we call as *importance coefficients*, IC_{t+1}, that are conditioned on the decoded representations $\{\hat{y}^k_{t+1}\}$:

$$IC_{t+1} = \{\alpha^1_{t+1}, ..., \alpha^k_{t+1}\} = IC(\{\hat{y}^k_{t+1}\}) \tag{5}$$

This strategy is different from (Saunders et al., 2021) where our decoded representation y^k_{t+1} aims at generating source-dependent sequences, while (Saunders et al., 2021) applies the self-attention on the decoded sequences only. We have two variants while generating the weighted output: Dynamic and Dynamic$_{hard}$. The final dynamic output is a weighted mixture of the two candidate sequences:

$$\hat{y}_{t+1} = \sum_{i=1}^{K} \alpha^k_{t+1}\hat{y}^k_{t+1} \tag{6}$$

In this specific model we set the k to be 2. For the Dynamic$_{hard}$ variant of the model which picks the most plausible view at each frame as $\hat{y}_{t+1} = \hat{y}^k_{t+1}$ where $k = \arg\max_i\{\alpha^i_{t+1}\}$.

5 Evaluations and Results

Evaluation of sign language generation is challenging due to the lack of an automatic metric to assess the quality of generated signs. The standard practice (Saunders et al., 2020b) is to translate the poses back to the text domain and compare with ground truth text. This is called back-translation. Such automatic evaluation however, cannot accurately capture the quality of the generated signs (Yin et al., 2021b). Thus, to complement our automatic evaluation, we ask sign language experts to evaluate the generated signs. Lastly, we perform a qualitative analysis of the back translated text to i) confirm increased presence of intensity modifiers, ii) identify limitations of our models, and iii) pitfalls of existing metrics.

5.1 Automatic Evaluation

Splits and Metrics. Prior analysis on a subset of the PHOENIX-14T’s dev set unveils the imbalanced distribution of data regarding the intensity modification phenomena. Thus, results on the original data split could not faithfully evaluate the model’s capability to generate intensification-specific sentences. To this end, we develop a new data split – we collect data points which have at least one gloss labeled as either low or high intensity to construct the "with intensification" subset, and leave the remaining in a "without intensification" group. We report the BLEU-1, BLEU-4 (Papineni et al., 2002), ROUGE (Lin, 2004) on the back translated texts. We retrain the Sign Language Transformer (Camgoz et al., 2020) (SLT) to translate the sign skeletal sequences back into German

Table 3: Gloss to pose (G2P) model performances with different enhanced gloss as input. The original dev/test instances are split based on whether it contains tagged gloss generated by our best tagger in section §3.3. B_1, B_4, RG and BS refer to BLEU-1, BLEU-4, ROUGE and BERTScore respectively. The marks * and ** denote that the results are significant comparing to baseline with the significance level $p < 0.1$ and $p < 0.05$ respectively. Best performances are shown in bold typeface.

texts. For the more fine-grained settings of *intensification*-focused evaluation, we additionally report the BertScore (Zhang* et al., 2020), an automatic metric for text generation that correlates better with human judgements, to measure the semantic similarities. We report statistical significance with bootstrap resampling on both 90% and 95% confidence levels (Efron and Tibshirani, 1993; Koehn, 2004).

Result. We train a baseline PT model on the original dataset and compare it to others which are trained on the enhanced data. We observe that, as shown in *full* columns of Table 3, the enhanced glosses improve the quality of skeleton generation on the original split of dataset. We can see that our proposed intensification enhancement techniques obtain an average of 0.6 improvement on BLEU-4 score over the dev set, with significant improvement of more than 1.6 on ROUGE. We do not observe a significant difference in the test set evaluations. Our proposed models obtain the highest ROUGE score, with negligible drop of BLEU scores comparing to models based on single source of gloss on dev set.

Regarding the new “with” and “without intensification” splits, we first observe that there exists a considerable score difference across all three metrics between the two groups. We hypothesize that current sign language generation models are biased towards reconstructing sentences without any intensification modifiers and lack the capability to represent the intensity modification. Over the “with intensification” subset, most enhanced data obtain significant improvements on BLEU-1 and ROGUE score. Meanwhile, *Suffixation* results in stable performance gain over the “without intensification” subset. This demonstrates the model’s capability to distinguish between different intensified texts, such that the difference between *rain* and *shower* signs can be obtained while the provided glosses remain the same. The harnessing of repetitions on top of *Suffixation* glosses bring in minor improvements on “with intensification” dev cases, and major gains are attributed to the “without intensification” test cases. In the end, our proposed *Dynamic* model obtains the highest test set performance, where the gains are mainly attributed to the improvements over the “with intensification” subgroup.

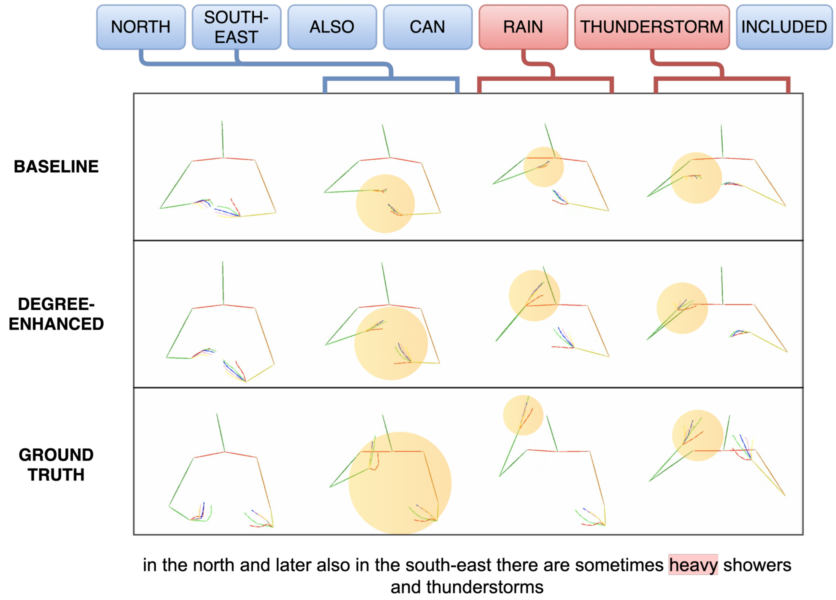

Figure 4: This figure illustrates the comparison between baseline and the intensification-enhanced model. Gloss annotations are linked to their corresponding frames. Here, ground truth skeleton uses wider movements due to the "heavy" modifier, and the intensification-enhanced outputs replicate the phenomena better than baseline.

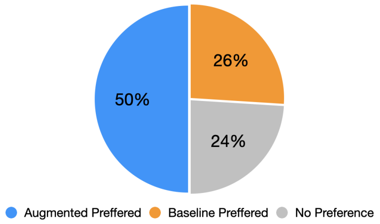

Figure 5: Human evaluation results for the generated skeletons.

5.2 Human Evaluation

We carry out a comparative human evaluation over 50 skeleton videos generated by both the baseline and our best performing model for human annotations. For each paired video, we ask deaf sign language users to identify the video that they found to be better than the other. They are specifically instructed to observe the following qualities and make their decisions: naturalness of the hand movements, alignment of the hand movements (excluding finger movements) with the ground truth, representation of intensity by the hand movements, and overall understandability.

As shown in Figure 5, outputs generated by our model trained on the enhanced glosses were preferred by signers (50% for our model vs. 26% for baseline). This difference is statistically different from chance as shown from a chi-squared test with p = .00017. This further suggests that a qualitative improvement using our enhancement strategies is evident. Aspects that are not fully captured by the metric-based evaluations are more clear in the human evaluations which show that incorporating intensity into the model is crucial. Enhanced glosses can generate more natural videos that depict the intensity of the signs. It should be noted that the solution to the problem at hand needs further improvement as suggested by the considerable number of "no preference" votes.

5.3 Backtranslation Analysis

We hypothesize that due to enhanced glosses, there should be more intensity modifiers in the back translated text. To verify this, we compare the numbers of adjectives/adverbs in back translated text as an approximation of counting intensity modifiers. We observe that more adjectives/adverbs which appear in the original transcript are being generated in the "with intensification" partition by our model (an average of 0.79 per sentence compared to 0.75 of the baseline). As expected, we see less of a difference in the "without intensification" partition (0.87 compared to 0.86). This suggests our model is better at producing adjectives/adverbs that may act as intensity modifiers.

To better understand our model's behavior, we manually inspect 100 instances randomly drawn from the “with intensification” cases for a qualitative analysis. We compare the back translated texts

	Examples (Translated from German)	**B_1**	**B_4**	**RG**	**BS**
Better capture of intensity modifiers

Baseline	The wind blows weak to moderate	47.8	0	55.7	81.9
Enhanced	The wind usually blows weakly from different directions.	100	100	100	100
Model hallucinations					
G. Truth	The wind blows **weak to moderate** at the sea also fresh	-	-	-	-
Baseline	On the Alps and in the south, the wind blows weak to moderate	50	0	46.2	81.7
Enhanced	The wind blows in the south weak otherwise weak to moderately sometimes fresh to strong gusty from south to West	36.8	0	50.1	81.9
Metrics failure					
G. Truth	Tonight there are still **a few** thunderstorms possible in the south, otherwise rain only falls **here and there**, in places fog forms	-	-	-	-
Baseline	Tonight, especially in the south and east there are rain or snow or freezing rain	37.9	15.4	39.6	75.4
Enhanced	Tonight, especially in the south and east here and there a few drops or flakes	32	0	36.9	75.6

Table 4: Examples of qualitative analysis over 100 back translated texts from the videos generated by baseline and our intensification enhanced model. **Bold** texts refer to the intensity modifiers that are missing in the gloss, blue highlight marks good generations and red highlight marks the errors. Our model can better retain the intensity information than the baseline. Meanwhile, as shown in the third example, n-grams based metrics may fail to reward the better intensity modifier representation.

generated by the baseline and $Dynamic_{hard}$. We evaluate the presence and correctness of modifiers instead of the overall quality of the back translated text. The key observations are: i) in 30% of the cases, back translated text generated by our model has better representation of intensity modifiers compared to baseline, ii) in 3% of the cases, our model hallucinates and over-generates intensity modifiers, and iii) in 23% of the cases, at least two of the four automatic metrics did not reward $Dynamic_{hard}$ for having better intensification. Table 4 shows examples of these observations.

6 Discussion and Conclusion

One limitation of our study is the lack of spatial and temporal context in the automatic back-translation evaluation. The lack of a proper evaluation metric is a problem that needs to be addressed by an orchestrated effort from different fields surrounding the sign language research community. The necessity of more research in related fields is further highlighted by the fact that there are very few publicly available resources for sign language with glosses, limiting our choice and scope of datasets to the PHOENIX-14T dataset. Some corpora exists for American Sign Language such as How2sign (Duarte et al., 2021), but without glosses, it renders certain sign language processing infeasible. Another limitation is the cumulative error propagation that dissipates through the intensity classifier, progressive transformer and back-translation, amplifying the total error. There is no dataset or method to do individual error analyses for each part of this pipeline. Thus, our error analyses were conducted in an incremental fashion as the errors in later stages of the pipeline depend on earlier errors.

Despite these limitations, we show that the strategies of intensification, grounded in the linguistics of signed languages, contribute to the improvement of end-to-end sign language generation systems. This modeling effort is supported by our metric-based and human evaluation results. For future work, we plan to further analyze the effects of these strategies on the perception of sign language understanding. We also plan to expand on the intensity modifier paradigm to further research in modeling prosody in sign language.

Acknowledgement

This project was partly supported by the University of Pittsburgh Momentum fund for research towards reducing language obstacles that Deaf students face when developing scientific competencies. We also acknowledge the Center for Research Computing at the University of Pittsburgh for providing part of the required computational resources. The author affiliated with Gallaudet University was partly supported by NSF Award IIS-2118742. We would also like to thank Sarah Miller and Carly Leannah for their contributions for the human evaluation annotations.

Ethical Considerations

Our work advocates for the need for more thoughtfulness of linguistic phenomena during the generation of sign videos. All models and analyses are built on a publicly available benchmarking dataset. We acknowledge that some modules of our model depend on pre-trained models such as word embeddings. These models are known to reproduce and even magnify societal bias present in their original training data (Li et al., 2021).

A Error Analysis of Gloss Enhancement

We manually categorized 100 errors made by our best classifier, M-BERT. The key observations are: i) 30% of the errors are due to ambiguity that annotators may have for hard cases. E.g., "The wind blows weakly to moderately" can be annotated as either low-intensity (weakly) or no-intensity (moderately). ii) aligning gloss tokens with text can be difficult (24%). For example, in "partial snow or freezing rain", the classifier may consider "partial" to be aligned with rain, assigning it label of "low-intensity" (should be "no-intensity"). Further, presence of negation (e.g., "not much rain") and multiple occurrences of same word (e.g., "in the Bergland, it snows partly, on the alps it snows for a long time.") can make alignment a difficult task for the classifier, and iii) 12% of the errors can be attributed to noise in original PHOENIX data. E.g., the gloss representation can contain tokens that are not related to the transcript. We could not assign a specific category to 34% of the errors.

B Gloss Classifier Implementation

SVM Baselines To construct the features for our text pair classification, we first concatenate the gloss token with the german text. Then we use term frequency-inverse document frequency (tf-idf) vectorizer to generate word and character n-gram vectors. These vectors are then used to train linear SVM classifiers. We use scikit-learn [3] implementation with default parameters for training. The SVM models primarily serve as baselines. The SVM results are shown in Table 5.

Model	**Features**	**Prec.**	**Recall**	**F1**
SVM	W[2-5]	70.0	45.6	50.4
SVM	C[2-5]	63.8	54.0	57.2

Table 5: GLOSS intensifier classification results for SVMs. W and C represent word and character.

FastText In our implementation, we use two separate embedding layers. One for the text and one for the gloss token. The embeddings for the text is averaged using pooling and then concatenated with the embedding of gloss token. This concatenated vector is then passed through a linear layer and sigmoid function to generate the predictions. We

---

[3] `https://scikit-learn.org/stable/modules/generated/sklearn.svm.LinearSVC.html`

use embedding size of 100 and train for 10 epochs. We cross-entropy loss and ADAM optimizer with default learning rate. We use PyTorch [4] for our implementation.

Bidirectional LSTM Similar to FastText, we have two separate embedding layers of size 100 for the text and the gloss token. the difference is that the output of text embedding layers are passed through a 2-layer bidirectional LSTM with hidden size of 300, dropout of 0.3. The output of the LSTM layers are then concatenated with the output of gloss embedding layer. The concatenated output is then passed through ReLU activation function and then passed through a linear layer. Similar to FastText, we train for 10 epochs, use cross-entropy loss and ADAM optimizer with default learning rate. PyTorch is used for implementation.

Fine-Tuned Transformers For our task. we fine-tune bert-base-multilingual (M-BERT) and german-bert-base-uncased (G-BERT) [5]. M-BERT is pretrained on Wikipedia text from 104 languages (including German). G-BERT is pretrained on Wikipedia dump, EU Bookshop corpus, Open Subtitles, CommonCrawl, ParaCrawl and News Crawl. The architecture of both models consists of 12 transformer blocks, hidden size of 768 and 12 self-attention heads. Since our task is classifying a pairs of texts, we fine-tune the models for sentence-pair classification. We use PyTorch implementation by HuggingFace [6] for the fine-tuning. We fine-tune for 5 epochs with learning rate of 5e-05.

Computational resources and running time Given our training data is small, the SVM baselines are very fast to train. They take less than 5 minutes to train. With an NVIDIA 2070 RTX GPU, the fastText and BiLSTM models take less than 10 minutes each. Fine-tuning each pre-trained BERT model with the same GPU but fewer epochs (5) take less than 10 minutes.

C Dataset Statistics

We use the publicly available benchmark, PHOENIX14T (Camgoz et al., 2018) dataset. This dataset comprises a collection of weather forecast videos in German Sign Language (DGS), segmented into sentences and accompanied by German transcripts from the news anchor and sign-gloss annotations. It contains videos of 9 different signers with 1066 different sign glosses and 2887 different German words. The video resolution is 210 by 260 pixels per frame and 30 frames per second. The dataset is partitioned into training, validation, and test set with 7,096, 519, and 642 sentences, respectively.

D Transformer (Re-)Implementation

We implemented Progressive Transformers models for sign language generation task (§4.1) based on the code [7] released by (Saunders et al., 2020b). We used the hyper-parameters from (Saunders et al., 2020b) and aimed at reproducing their reported results. To the best of our knowledge, albeit still slightly below on ROUGE-L F1 scores, our reported results on the baseline model are the nearest to the high value reported in the original paper, which does not have any checkpoint releasing. Both encoder and decoder are built with 2 layers, 4 heads and embedding size of 512. We apply Gaussian noise with a noise rate of 5, as proposed by Saunders et al. (2020b). All parts of the network are trained with Xavier initialisation (Glorot and Bengio, 2010), Adam optimization (Kingma and Ba, 2015) with default parameters and a learning rate of 1e-3. The model takes 5 hours to train on 1 NVIDIA GeForce 1080Ti GPU. For our proposed Dynamic Selection model, to control the model size and make it a fair comparison, we halve the encoder and decoder's embedding size to 256. The Multi-Layer Percetron (MLP) model is composed of two linear layers with dimension of 256 and a ReLU activation. The model takes 8 hours to train on 1 NVIDIA GeForce 1080Ti GPU. We implemented the back-translation model on top of the original SLT code (Camgoz et al., 2020). The transformer models are built with 1 layer, 2 head and embedding size of 128. The feature size is changed to 150, which is the sequence length of generated skeleton joints sequence. The recognition loss weight and translation loss weight are set to 5 and 1 respectively. The model takes around 1 hour for training and evaluation. All models introduced above are implemented with Pytorch (Paszke et al., 2019).

Dynamic model	
Soft	6.2 M
Hard	6.2 M

Table 6: Models Parameter Comparison.

E Parameter Comparison and Dynamic Model Experiment

The total parameter number of each model is presented in Table 6. For PT-based model, the parameter differs due to the varied size of the vocabulary sizes. Regarding the dynamic model, our early experiments show that duplicating the encoder and keeping other parameters fixed lead to worse results than the baseline model with a single encoder. This could be attributed to the limited size of our training data. We carefully tune the parameters, find that two smaller encoders could result in a stably better performance across multiple runs.

To verify the effects of mixing up two different strategies, we retrain a Dynamic$_{\text{hard}}$ model with duplicated suffixation enhanced data. This differs from the original model which combines suffixation and end-marking strategies. As shown in in Table 7, on the “with intensificaiton” split, the original *Dynamic* model performs better than the one with duplicated inputs. In the “without intensification” split, the duplicated split gives comparable results with the baseline which is trained on the original data.

F Retrained SLT model

Given the different versions of degree enhanced dataset (§3.3, besides the baseline which is trained with the original gloss, we further retrain different versions of SLT models on the original text, skeleton joints sequence and the new gloss triples. This can serve as an estimation of the model’s back translation quality given the oracle sign sequence. Table 8 shows the results.

Abstract

To guide the generation of large pretrained language models (LM), previous work has focused on directly fine-tuning the language model or utilizing an attribute discriminator. In this work, we propose a novel lightweight framework for controllable GPT2 (Radford et al., 2019) generation, which utilizes a set of small attribute-specific vectors, called prefixes (Li and Liang, 2021), to steer natural language generation. Different from Li and Liang (2021), where each prefix is trained independently, we take the relationship among prefixes into consideration and train multiple prefixes simultaneously, as illustrated in Figure 1. We propose a novel supervised method and also an unsupervised method to train the prefixes for single-aspect control while the combination of these two methods can achieve multi-aspect control. Experimental results on both single-aspect and multi-aspect control show that our methods can guide generation towards the desired attributes while keeping high linguistic quality.

1 Introduction

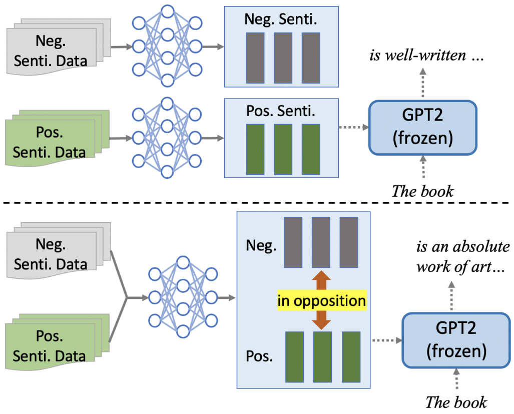

Figure 1: A comparison of prefix-tuning (Li and Liang, 2021) (top) and our framework (bottom) on sentiment control. The solid arrows show the training process, while the dashed ones show the inference (generation) process. In our proposed framework, the training can be supervised, semi-supervised, or unsupervised.

The goal of controllable Natural Language Generation (NLG) is to guide generation towards the desired attributes in the concerned aspects of the text. For example, the aspect can be topic or sentiment, and sentiment may have two attributes: positive and negative. Previous work has focused on directly fine-tuning the existing models (Keskar et al., 2019; Hu et al., 2017; Ficler and Goldberg, 2017) or using a discriminator to guide generation (Dathathri et al., 2020; Krause et al., 2020; Holtzman et al., 2018). CTRL (Keskar et al., 2019) achieves controllability at the expense of training a large conditional LM. GeDi (Krause et al., 2020) also trains conditional LMs but uses them as discriminators to guide generation, introducing additional 345M parameters. Besides, GeDi focuses on single-aspect control, ignoring the need for multi-aspect control. PPLM (Dathathri et al., 2020) guides generation by iteratively updating the LM's hidden activations. However, this decoding strategy is extremely computationally intensive, resulting in a slow generation speed (Gehman et al., 2020).

Prefix-tuning (Li and Liang, 2021) proposes to optimize a prefix, which is a small continuous task-specific vector, as a lightweight alternative to fine-tuning an NLG task, such as table-to-text generation or summarization. Inspired by Li and Liang (2021), we propose to use prefixes, a set of small continuous attribute-specific vectors, to steer NLG. Compared with using an attribute model or a generative discriminator (Dathathri et al., 2020; Krause et al., 2020), using learned prefixes to achieve controllability has the following benefits. First, it introduces fewer additional parameters (~0.2%-2% of GPT2 parameters in our experiments). Second, using prefixes keeps the inference speed comparable to that of the original GPT2 model.

In a general sense, prefix-tuning (Li and Liang, 2021) can be considered as controlling the genera-

Findings of the Association for Computational Linguistics: ACL 2022, pages 2912 - 2924
May 22-27, 2022

tion of language models. Prefix-tuning views each prefix as an independent control task thus trains each prefix separately (top in Figure 1). However, one aspect of controllability in NLG involves multiple attributes, which might have a relationship with each other. For example, the sentiment aspect usually has two attributes: positive and negative, which are in opposition to each other. We think that this opposite relationship can be helpful to improve the controllability of a prefix. Therefore, we propose a novel supervised method and a novel unsupervised one in our framework, which takes the relationship among prefixes into consideration and trains multiple prefixes simultaneously with novel training objectives, as illustrated in Figure 1.

Experimental results on the single-aspect control tasks (sentiment control, detoxification, and topic control) show that our proposed methods can guide generation towards the target attribute while keeping high linguistic quality, even when only several dozen labeled examples are available. In addition to single-aspect control, multi-aspect control can be achieved by combining the proposed supervised method with the unsupervised method in our framework. Experimental results on the sentiment and topic control show that the prefixes trained with our method can successfully control these two aspects simultaneously.

Our main contributions are as follows:

- We propose a novel framework that utilizes prefixes with frozen LMs as a lightweight alternative for controllable GPT2 generation.
- We propose a supervised method and an unsupervised method with novel objectives for prefix training, where the relationship among prefixes are considered and multiple prefixes are trained simultaneously.
- This work provides a unified perspective for single-aspect control and multi-aspect control. Experimental results show that our methods can effectively guide generation in both single-aspect control and multi-aspect control.

2 Related Work

Ficler and Goldberg (2017) control the stylistic aspects of the generated text with a conditioned RNN (Recurrent Neural Network) LM. Holtzman et al. (2018) compose a committee of discriminators to guide an RNN generator towards the generations with the desired linguistic quality. Hu et al. (2017) aim at controlling the sentiment and tense of the generated text by combining variational autoencoders (VAE) and attribute discriminators.

More recently, with the advent of Transformers and large pretrained language models, such as GPT2, an extensive body of work has focused on controlling the generation of these Transformer-based models. Keskar et al. (2019) train a 1.63 billion-parameter conditional transformer LM from scratch with 55 attribute control codes to guide generation. However, this method is expensive and lacks flexibility since the control codes are fixed. Dathathri et al. (2020) address these limitations by developing a plug-and-play model which leverages an attribute discriminator to perturb the LM's hidden activations. However, updating gradients at the token level results in slow inference. Instead of updating the hidden activations, Krause et al. (2020); Yang and Klein (2021); Lin and Riedl (2021) introduce generative discriminators to re-weight the next token distributions on the fly during inference, thus improving the inference speed.

Our work is mostly related to Yu et al. (2021); Li and Liang (2021). Yu et al. (2021) use a pretrained LM followed by an attribute alignment function to encode the tokens of the target attributes and the resulting hidden states are used to control generation. Different from their work, we do not take the tokens of the target attributes as input. Instead, we directly train a set of parameters, which acts as the prepended hidden states of GPT2, to control generation. Avoiding using attribute tokens can circumvent the problems when it is difficult to describe the desired attribute with only one word. Besides, Yu et al. (2021) focus on attributes disentanglement, which is not a focus in our work, so our training methods are different. Prefix-tuning (Li and Liang, 2021) can, in a general sense, be viewed as controlling the generation of LMs, where the LM is controlled to depict a specific NLG task, while in this work, the LM is controlled to carry specific attributes in a generation. Besides, our proposed methods for prefix training are different from Li and Liang (2021), as stated in Section 1.

3 Method

Our method uses prefixes to guide GPT2 generation, where a prefix is a continuous attribute-specific vector prepended to the activations of GPT2. Prefixes are free parameters denoted as H_θ. Different from Li and Liang (2021), where each prefix is trained independently, we consider the relationship among attributes and train multiple prefixes simultaneously, so H_θ is of dimension $N \times M \times D$, where N is the number of prefixes. In single-aspect control, N equals the number of attributes in the concerned aspect. M is the length of a prefix. $D = 2 \times L \times E$ is the dimension of the activation in GPT2, where L is the number of transformer layers, E is the hidden size, and 2 indicates one key vector and one value vector. Following Li and Liang (2021), we reparametrize $H_\theta[i, j, :] = W_i H'_\theta[i, j, :]$ by a smaller parameter (H'_θ) composed with a large matrix (W_i). After the training finishes, only H_θ needs to be saved for generation while W and H'_θ can be discarded. Since the GPT2 parameters are kept frozen during training, they do not need to be saved either. Figure 2 shows an example of the generation process under the control of a trained prefix. The prefixes can be trained in a supervised, semi-supervised, or unsupervised way. Since the semi-supervised method is a combination of the supervised and the unsupervised method, we introduce the supervised and the unsupervised method in this section. For clarity, we introduce these methods under the single-aspect control setting.

3.1 Supervised Method

Suppose the concerned aspect has the attribute set Y, each training example is a pair of (x, y) where x is the input text and $y \in Y$ is the attribute label of x. Note that the attribute label also indicates the ground truth index of the prefix in H_θ, so y also refers to the prefix index in the following description. As mentioned in Section 1, we introduce an additional discriminative loss to train multiple prefixes simultaneously. Therefore, the training loss $\mathcal{L}_{sup}$ is a weighted sum of the language model loss $\mathcal{L}_{LM}$ and the discriminative loss $\mathcal{L}_d$:

$$\mathcal{L}_{sup} = \omega_1 \mathcal{L}_{LM} + \omega_2 \mathcal{L}_d \tag{1}$$

$$\mathcal{L}_{LM} = -\sum_{t=1}^{T} \log p(x_t | x_{<t}, y) \tag{2}$$

$$\mathcal{L}_d = -\log \frac{p(y)p(x|y)}{\sum_{y' \in Y} p(y')p(x|y')} \tag{3}$$

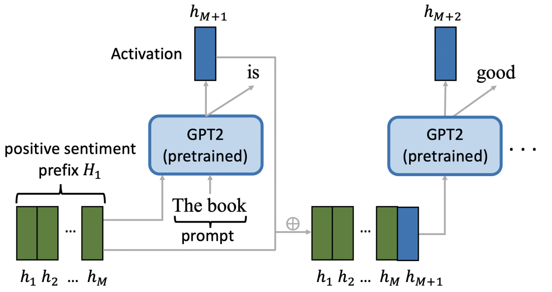

Figure 2: An illustration of the GPT2 generation process unfolded through time, controlled by a positive sentiment prefix $H_1 = H_\theta[1, :, :]$. *"The book"* is the given prompt. *"is good"* is the generated completion.

The computation of $\log p(x_t|x_{<t}, y)$ is parameterized as $\log p_{\theta,\gamma}(x_t|x_{<t}, H_\theta[y, :, :])$, where γ is the set of fixed GPT2 parameters, and θ represents learnable prefix parameters. $\log p(x|y) = \sum_t \log p(x_t|x_{<t}, y)$, so the parameterization of $\log p(x|y)$ is the sum of $\log p_{\theta,\gamma}(x_t|x_{<t}, H_\theta[y, :, :])$ over t.

Note that each prefix can be trained independently using $\mathcal{L}_{LM}$ alone, which would be the same as prefix-tuning (Li and Liang, 2021). Intuitively, prefixes trained by $\mathcal{L}_{LM}$ are infused with the information of what is encouraged to generate. However, we observe that in controllable NLG, it is helpful to also infuse a prefix with the information of what is discouraged to generate. Given a training example (x, y), the prefix $H_\theta[y, :, :]$ should be optimized towards generating x, while the other prefixes should be discouraged to generate x. To achieve this goal, all the prefixes in H_θ should be trained simultaneously. Therefore, the discriminative loss $\mathcal{L}_d$ is introduced. As in equation 3, optimizing $\mathcal{L}_d$ improves the attribute alignment $p(y|x)$ by increasing $p(x|y)$ and lowering $p(x|\bar{y})$, $\bar{y} \in Y \backslash \{y\}$ at the same time. We assume uniform prior, so $p(y)$ and $p(y')$ can be canceled out in Equation 3. Figure 3 illustrates the training process with two prefixes.

3.2 Unsupervised Method

In the unsupervised setting, we assume the attribute set Y of the concerned aspect is known. The training example consists of input text x only. The attribute label y is no longer available and thus the index of the prefix associated with x is unknown. In other words, the index of the prefix corresponding to x is a latent variable z, whose posterior distribution follows a categorical distribution. Inspired by VQ-VAE (van den Oord et al., 2017), we consider the prefixes as discrete latent representations. We take the backbone model in the above supervised method as the decoder and introduce an encoder to parameterize the categorical distribution $q(z|x)$. According to $q(z|x)$, a prefix index z is selected and the prefix $H_\theta[z, :, :]$ is then fed into the decoder

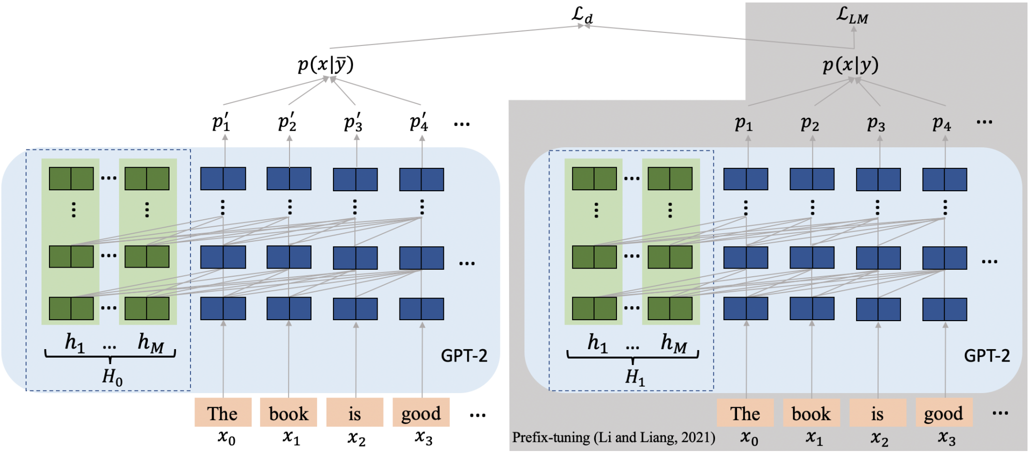

Figure 3: An illustration of the supervised training method on sentiment control. H_0 is the prefix of negative sentiment. H_1 is the prefix of positive sentiment. Note that training without $\mathcal{L}_d$ is equivalent to Li and Liang (2021), where H_0 and H_1 are trained separately. The GPT2 is pretrained, and its parameters are frozen.

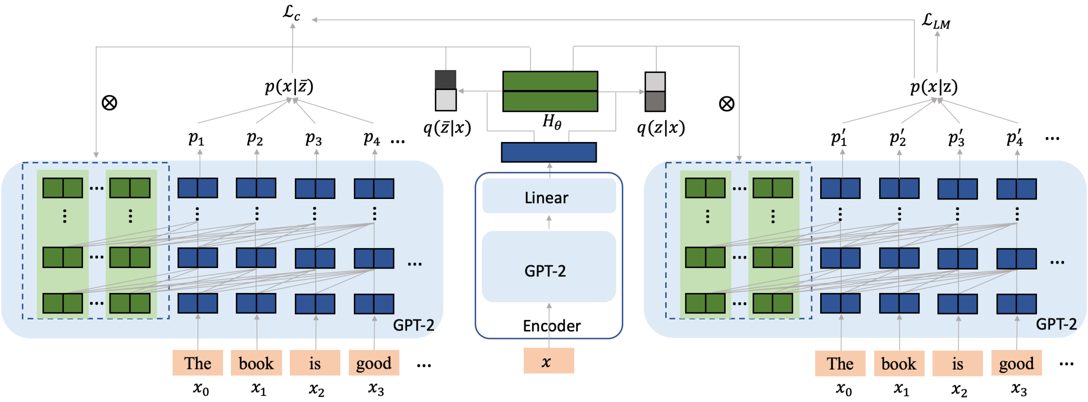

Figure 4: An illustration of the unsupervised training method. H_θ denotes the 2 prefixes. z is the latent variable indicating the index of the prefix corresponding to the input text x. $\bar{z}$ is the latent variable indicating the index of the opposite prefix. ⊗ is matrix multiplication. $\mathcal{L}_{KL}$ is not shown in this figure for clarity.

to reconstruct the input text x. Since the selection process of the prefixes is non-differentiable, we use Gumbel-Softmax (GS) relaxation (Jang et al., 2017; Maddison et al., 2017) following Sønderby et al. (2017); Ramesh et al. (2021). Formally, $q(z|x)$ is computed as follows:

$$q(z|x) = GS(-\|Enc(x) - H_\theta\|_2, \tau) \quad (4)$$

where τ is the temperature of Gumbel-Softmax, and Enc is the encoder function. We use a pre-trained GPT-2 model followed by a linear layer as the encoder. To train the prefixes, the loss function is a weighted sum of the three loss terms:

$$\mathcal{L}_{uns} = \omega_1 \mathcal{L}_{LM} + \omega_2 \mathcal{L}_{KL} + \omega_3 \mathcal{L}_c \quad (5)$$

$$\mathcal{L}_{LM} = -\sum_{t=1}^{T} \log p(x_t|x_{<t}, z) \quad (6)$$

$$\mathcal{L}_{KL} = KL[q(z|x)||p(z)] \quad (7)$$

where $\mathcal{L}_{LM}$ is the language model loss. Similar as that in the supervised method, the computation of $\log p(x_t|x_{<t}, z)$ is parameterized as $\log p_{\theta,\gamma}(x_t|x_{<t}, H_\theta[z, :, :])$. $\mathcal{L}_{KL}$ is the Kullback-Leibler divergence, where we assume the prior $p(z)$ to be uniform. Note that these two terms constitute the loss function of VAE. Optimizing these two loss terms improves the evidence lower bound of $\log p(x)$. Similar to the intuition behind $\mathcal{L}_d$ in the supervised method, if the ground truth prefix for x is $H_\theta[y, :, :]$, then the other prefixes should be discouraged to generate x. However, $\mathcal{L}_d$ requires the ground truth label y for computation. Instead, we introduce an unsupervised contrastive loss $\mathcal{L}_c$.

$$\mathcal{L}_c = \max(m - \|p(z|x) - p(\bar{z}|x)\|_2, 0)^2 \quad (8)$$

where m is a pre-set margin and $\bar{z}$ is another latent variable indicating the index of the opposite prefix of x. $q(\bar{z}|x)$ is computed as follows:

$$q(\bar{z}|x) = GS(\|Enc(x) - H_\theta\|_2, \tau) \tag{9}$$

$\mathcal{L}_c$ is aimed at increasing the attribute alignment by pushing $p(z|x)$ away from $p(\bar{z}|x)$ by a margin. The computation of $p(z|x)$ is as follows:

$$p(z|x) = \frac{p(z)p(x|z)}{\sum_{z' \in Y} p(z')p(x|z')} \tag{10}$$

We assume uniform prior, so $p(z)$ and $p(z')$ can be canceled out. Similar as the parameterization of $\log p(x|y)$ in the supervised method, the parameterization of $\log p(x|z)$ is the sum of $\log p_{\theta,\gamma}(x_t|x_{<t}, H_\theta[z,:,:])$ over t. The training process is illustrated in Figure 4.

4 Experiments

We experiment with three tasks: sentiment control, detoxification, and topic control. We compare our method to GPT2, PPLM, and GeDi. We focus on English text in all the experiments and we experiment with GPT2-medium (345M parameters) for all the methods. We use the original implementation of PPLM and GeDi released by Dathathri et al. (2020) and Krause et al. (2020), and the hyperparameters are set to the reported value in the original paper. The detailed hyperparameters in each task are listed in appendix A. For the GPT2 model, we do experiments under two settings. First, the GPT2 model generates completions of each prompt in the evaluation dataset, which is denoted as *GPT2-medium*. Second, *GPT2-medium + prompt engineering* prepends a guiding sentence to each testing prompt and then generates completions of each augmented prompt. We evaluate the linguistic quality and attribute alignment of the generation. The linguistic quality is evaluated using the perplexity calculated by GPT2-large (774M parameters).

To evaluate the robustness of our supervised method with the size of the training dataset, we experiment with the following three different settings: 1) using the complete training dataset; 2) using 1,000 examples per attribute for training; 3) using 24 examples per attribute for training. We evaluate our unsupervised method on the sentiment control task and the detoxification task, which are binary tasks. Note that different from the supervised method, our unsupervised method does not use any attribute labels, so the order of the attributes in the trained prefixes is undetermined. After the prefixes finish training using the unsupervised method, we manually check the order of the attributes.

4.1 Single-Aspect Control

4.1.1 Tasks

Sentiment Control Same as GeDi, we use IMDb movie reviews (Maas et al., 2011) to train our model. The number of prefixes is 2. Note that GeDi only uses 11.25k examples from the dataset for training. To be a fair comparison, we randomly sample 11.25k examples from the dataset to train our model. To evaluate the sentiment alignment of the generated text, we finetune a RoBERTa (Liu et al., 2019) classifier using the Yelp Review dataset (Zhang et al., 2015). The prompts used for evaluation are the same as those in the PPLM experiment (Dathathri et al., 2020). For each of the 15 prompts, 45 completions are generated. In the *GPT2-medium + prompt engineering* setting, we prepend each prompt with the guiding sentence *"This is a negative review:"* for negative sentiment control, and similarly, we prepend each prompt with *"This is a positive review:"* for positive sentiment control.

Detoxification We use Jigsaw Toxic Comment Classification Challenge Dataset[1] to train our model. The number of prefixes is 2. Google Perspective API[2] is used for toxicity evaluation. The testing prompts are collected from RealToxicityPrompts (Gehman et al., 2020). We use the prompts categorized as "challenging" in the dataset. We further filter out the prompts with toxicity larger than 0.5, scored by Perspective. The resulted evaluation dataset consists of 203 prompts. For each of these prompts, 20 completions are generated. In the *GPT2-medium + prompt engineering* setting, we prepend each prompt with the guiding sentence *"This is a non-toxic comment:"*.

Topic Control We experiment with the AGNews dataset and DBPedia dataset (Zhang et al., 2015). The number of prefixes is 4 and 14, respectively. The prompts used for evaluation are the same as those in the PPLM experiment (Dathathri et al., 2020). For each of the 20 prompts, 45 completions are generated. Same as that in GeDi, we split each of the original training datasets in half. One half is used to train prefixes, while the other half is used to train a RoBERTa topic classifier for topic relevance evaluation. In the *GPT2-medium + prompt engineering* setting, the guiding sentence follows

---

[1] https://www.kaggle.com/c/jigsaw-toxic-comment-classification-challenge/

[2] https://www.perspectiveapi.com

the template *"The following is about [TOPIC]"*. We do not compare with PPLM in the topic control task since PPLM uses a bag-of-words attribute model to do topic control, where the 7 predefined topics are different from the topics in the AGNews dataset or the DBPedia dataset.

All the experiments are conducted on NVIDIA Tesla V100 GPUs. The detailed hyper-parameters for each experiment are listed in appendix A.

4.1.2 Results

In the unsupervised setting, *GPT2-medium + prompt engineering* shows controllability on sentiment control (Table 1) and topic control (Table 3). However, this method does not work on the detoxification task (Table 2). Our unsupervised method significantly lowers the toxicity on the detoxification task and the ablation study shows that the contrastive loss $\mathcal{L}_c$ is crucial. On the sentiment control task, our unsupervised method does not achieve good attribute alignment when the target sentiment is negative, but it performs well when the target sentiment is positive. One possible reason is that compared with the differences between toxic and normal sentences, the difference between positive sentiment and negative sentiment is more subtle, so it is more challenging for the GPT2 encoder in our unsupervised model to accurately separate the unlabeled data into two sentiments. As a result, the encoder's implicit criterion to categorize the input text may not be exactly the sentiment, which is also the reason that after removing the contrastive loss $\mathcal{L}_c$ in the unsupervised loss function, the attribute relevance on the negative sentiment is higher while that on the positive sentiment is lower.

In the supervised setting with full data, our supervised method consistently achieves better controllability than PPLM while maintaining the linguistic quality of the generations (Table 1, 2). Although GeDi achieves a high attribute alignment score on the three tasks, it severely sacrifices the linguistic quality, as indicated by the high perplexity. In the few-shot setting, where the number of labeled training examples is reduced to 1000 or 24 examples per attribute, our supervised method can still maintain good controllability on the three tasks, showing the robustness of our method to the size of the training data.

Ablation study shows the importance of the discriminative loss $\mathcal{L}_d$ in our supervised method. As mentioned in section 3, training without $\mathcal{L}_d$ is equivalent to prefix-tuning. Comparing the results of $Ours - \mathcal{L}_d$ and *GPT2-medium* show that directly using prefix-tuning can achieve controllability on the sentiment or the topic. However, it is less effective on detoxification. The reason is that different from topic control or sentiment control, detoxification requires the model to avoid generating some words or phrases according to the context, which can not be achieved by prefix-tuning. $\mathcal{L}_d$ fills this gap by increasing $p(x|y)$ and lowering $p(x|\bar{y})$ at the same time. Therefore, incorporating $\mathcal{L}_d$ is of critical importance to the detoxification task. In the DBPedia topic control task, adding $\mathcal{L}_d$ also achieves a large improvement on attribute alignment. The number of attributes in this task is much larger than that in the other tasks, so incorporating $\mathcal{L}_d$ can effectively push the prefixes to capture the unique features of each topic.

We compare the average inference speed of our methods with the baselines (Table 5). The inference speed of PPLM is several dozen times slower than that of the original GPT2 model. GeDi's inference speed is much faster than that of PPLM. The inference speed of our method is the closest to that of the original GPT2.

4.1.3 Human Evaluation

Besides automatic evaluation, we also conduct human evaluations on Amazon Mechanical Turk to compare the performance of the baselines and our methods. In each task, workers are presented with a prompt along with the completions generated by different methods. Workers are instructed to answer two questions: *"Which one has the best linguistic quality?"* and *"The target attribute is [ATT]. Which one aligns best with the target attribute?"*. *[ATT]* is the control attribute used when generating the completions. In order to evaluate the linguistic quality and the attribute alignment separately, the workers are instructed not to consider the control aspect or the factual errors when answering the first question and not to consider the linguistic quality when answering the second question. The user interface provided to the workers is shown in the appendix (Figure 5). We conduct human evaluations on the results of the sentiment control experiment and those of the AGNews topic control experiment separately. 100 tasks are randomly sampled from the results of each control experiment. Each task is assigned to 3 different Mechanical Turk workers and the annotations are aggregated by majority voting. To ensure data quality, we restrict the workers to be in Canada or United States with

a HIT approval rate higher than 95%. In total, 81 workers participated in the human evaluation. For the sentiment control task, we compare the results of *GPT2-medium + prompt engineering*, PPLM, GeDi, and our supervised method (with full training dataset). For the AGNews topic control task, PPLM is not evaluated as explained above. The results are shown in Table 4. The inter-annotator agreement on the sentiment task and the AGNews task is 0.39 and 0.30 in Fleiss' κ, respectively. Appendix B lists other details of the human evaluation.

In the sentiment control task, the result of human evaluation on linguistic quality is generally consistent with the result of automatic evaluation. However, different from the result of the automatic evaluation, annotators are more inclined to select *Ours* and *GPT2 + prompt engineering* when evaluating attribute alignment. Although the annotators are instructed not to consider linguistic quality when evaluating sentiment alignment, they tend to select the one with better linguistic quality when multiple completions exhibits equally good attribute alignment. In the AGNews topic control task, the result of human evaluation on attribute alignment is generally consistent with the result of automatic evaluation. However, in more than half of the linguistic quality questions, the annotators select *Ours*, although *GPT2-medium + prompt engineering* achieves lower perplexity than *Ours*. On inspection, we find that *GPT2-medium + prompt*

Table 6: Experimental results of the multi-aspect control task. "PPL.": perplexity scores. "Senti. Rel.": sentiment relevance. "Topic Rel.": topic relevance. "$-\mathcal{L}_d$ / $-\mathcal{L}_{enc}$": ablating loss terms as described in Eq. 3 and Eq. 12.

engineering in this task exhibits a more severe repetition problem compared to that in the sentiment control task. This inconsistency shows the limitation of using automatic evaluations, as alluded to in Welbl et al. (2021).

Both human evaluation and automatic evaluation show that the linguistic quality of GeDi is inferior to that of the other methods. One possible reason is the length of the prompt. In the original experiment in Krause et al. (2020), each prompt is at least 150 characters for sentiment control evaluation and at least 30 characters for topic control evaluation. However, we use the prompts as in Dathathri et al. (2020), where the average prompt length is 11.8 characters for sentiment control evaluation and 14.5 characters for topic control evaluation. The generated examples are shown in the appendix (Table 7).

4.2 Multi-Aspect Control

Our method can also be applied to multi-aspect control. Directly applying our supervised method to multi-aspect control requires training examples with multi-aspect labels. However, such datasets are usually not readily available since most of the datasets are labeled for a single task. Although multi-aspect labeled examples are limited, we have training examples with single-aspect labels from multiple aspects, which can be utilized to achieve multi-aspect control. One method is to train a set of prefixes for each aspect separately using our supervised method and then concatenate the prefixes from different aspects for generation. This method is denoted as *Ours (concatenation)* in the result table. Another method is to train the prefixes of multiple aspects simultaneously by considering each single-aspect labeled example as partially labeled. We use a semi-supervised method for training, which is a combination of our supervised method and unsupervised method in Section 3. The model structure is the same as in the unsupervised method (Figure 4). The loss function is as follows:

$$\mathcal{L} = \omega_1 \mathcal{L}_{LM} + \omega_2 \mathcal{L}_d + \omega_3 \mathcal{L}_{enc} \quad (11)$$

$$\mathcal{L}_{enc} = -\log q(z_{sup} = y|x) \quad (12)$$

$$q(z|x) = \sigma(-\|Enc(x) - H_\theta\|_2) \quad (13)$$

where the latent variable z is the concatenation of the latent variable of each aspect, including both the supervised aspects and the unsupervised ones $z = [z_{sup}; z_{uns}]$. $\mathcal{L}_{enc}$ is used to train the encoder. It is introduced because the partially labeled examples imply the ground truth indexes of the prefixes in the labeled aspect, providing supervision for both the prefix and the encoder. σ is the softmax function.

We experiment with controlling the following two aspects simultaneously: sentiment and topic. We use the binary sentiment dataset from Amazon review (Zhang et al., 2015) and the DBPedia topic dataset. The prompts used for evaluation are the same as those in the topic control experiment. For each of the 20 prompts, 45 completions are generated. In the *GPT2-medium + prompt engineering* setting, the guiding sentence follows the template *"This is a [SENTIMENT] review on [TOPIC]:"*. In *Ours (concatenation)*, the sentiment prefixes and the topic prefixes are trained separately using our supervised method and then concatenated as multi-aspect prefixes. In *Ours (semi-supervised)*, we reuse the prefixes trained in the single-aspect control tasks to initialize H_θ. All the experiments are conducted on NVIDIA Tesla V100 GPUs. The hyper-parameters are listed in appendix A.

Experimental results on multi-aspect control (Table 6) show that simply concatenating the prefixes trained for single-aspect control can effectively control the sentiment and topic simultaneously, and our experiments show that the order of the prefixes does not impact the result. On the other hand, training using the combination of our supervised and unsupervised methods can further improve the attribute alignment without sacrificing too much linguistic quality. Same as the observations stated in Section 4.1.2, removing the discriminative loss $\mathcal{L}_d$ will significantly degrade the attribute relevance, especially the topic relevance. Removing the encoder loss $\mathcal{L}_{enc}$ may achieve higher overall attribute relevance at the cost of linguistic quality, indicated by a higher perplexity. We present the generated examples in the appendix (Table 7).

5 Conclusion

We propose a novel framework for controllable GPT2 generation with frozen LMs, which utilizes contrastive prefixes to guide generation. Experimental results show that our framework can not only successfully guide generation from a single aspect but also achieve promising results on multi-aspect control tasks. Besides the control tasks we experimented with, our proposed framework can be freely applied to other desired attributes.

6 Ethical Considerations

With our controlling methods, it is not one hundred percent guaranteed that the generations will have the desired attributes, but the probability for the generations to exhibit the desired attributes will increase. When applied to detoxification, although the probability of toxicity degeneration will decrease, the controlled language model may still produce unsafe text. We would like to clarify that the offensive language generated by the language model controlled with our methods does not represent any opinion of the authors.

Besides, our proposed methods control the high-level attributes of the generation, such as toxicity, topic, or sentiment, but there is no guarantee of factual accuracy for the generation, which is a well-known problem in NLG models. Our controlling methods may not be used for factual accuracy controlling. While reducing hallucination is not the focus of this work, knowledge-grounded generation techniques can be used to alleviate this problem.

Appendix

A Hyperparameters

For PPLM and GeDi, we use the hyperparameters reported in their original work (Dathathri et al., 2020; Krause et al., 2020). Note that GeDi has multiple versions of submission available online and we refer to the latest one on OpenReivew.

Our methods are implemented using the Hugging face Transformers package. In all the experiments with our methods, the random seed is fixed to 42, and the optimizer is AdamW with a learning rate of 2e-5. $D = 24 \times 2 \times 1024$, where 24 is the number of hidden layers in GPT2-medium, 1024 is the size of hidden states in GPT2-medium, and 2 represent one key and one value. In the sentiment control task and the topic control tasks, the maximum generation length is set to 50 during evaluation while in the detoxification task the maximum generation length is set to 20. Unless stated otherwise, the prefix length $M = 10$.

Sentiment Control In the *Ours (unsupervised)* setting, the training batch size is 8. $\omega_1 = 0.8$, $\omega_3 = 2.0$. The weight of the KL loss term ω_2 anneals from 0.001 to 0.1 during training while the temperature τ reduces from 1.0 to 0.5. The number of training epochs is 60. During training, we randomly mask the input tokens when computing the next token probabilities so as to force the prefix to preserve the key information of the input text. The mask rate is 0.5.

In the *Ours (supervised)* setting, the training batch size is 8. $\omega_1 = 0.8$, $\omega_2 = 0.2$. The number of training epochs is 50.

For PPLM, we use the hyperparameters reported by Dathathri et al. (2020).$\gamma = 1.0$, $m = 10$, $\alpha = 0.03$, $\lambda_{kl} = 0.01$, and $\gamma_{gm} = 0.95$.

For GeDi, we use the hyperparameters reported by Krause et al. (2020). $\omega = 20$ and $\rho = 0.7$.

Detoxification In the *Ours (unsupervised)* setting, the training batch size is 8. $\omega_1 = 0.8$, $\omega_3 = 2.0$. The weight of the KL loss term ω_2 anneals from 0.001 to 0.1 during training while the temperature τ reduces from 1.0 to 0.5. The number of training epochs is 4. Same as in the sentiment control task, the mask rate is 0.5.

In the *Ours (supervised)* setting, the training batch size is 8. $\omega_1 = 0.8$, $\omega_2 = 0.2$. The number of training epochs is 5.

For PPLM, we use the hyperparameters reported by Dathathri et al. (2020). $\gamma = 1.0$, $m = 10$, $\alpha = 0.02$, $\lambda_{kl} = 0.01$, and $\gamma_{gm} = 0.9$.

For GeDi, we use the hyperparameters reported by Krause et al. (2020). $\omega = 30$ and $\rho = 0.8$.

AGNews Topic Control In the *Ours (supervised)* setting, the training batch size is 4. $\omega_1 = 0.8$, $\omega_2 = 0.2$. The number of training epochs is 8.

For GeDi, we use the hyperparameters reported by Krause et al. (2020). $\omega = 150$ and $\rho = 0.8$.

DBPedia Topic Control In the *Ours (supervised)* setting, the training batch size is 4. $\omega_1 = 0.8$, $\omega_2 = 0.2$. The number of training epochs is 2.

Multi-Aspect Control In the *Ours (concatenation)* setting, the sentiment prefix with length $M = 10$ and the topic prefix with length $M = 10$ are concatenated, so the resultant multi-aspect prefix has a length $M = 20$.

In the *Ours (semi-supervised)* setting, the prefix length $M = 10$. The training batch size is 4. In the first 80,000 training steps, $\omega_1 = 0$, $\omega_2 = 0$, $\omega_3 = 1$, which means only the encoder is trained. After that, the model is updated by another 80,000 steps with $\omega_1 = 0.8$, $\omega_2 = 0.2$, $\omega_3 = 0.4$. We add a top-k filter and a top-p filter on $q(z|x)$ for each aspect. For sentiment, $k = 1$, $p = 0.8$. For topic, $k = 1$, $p = 0.5$.

B Human Evaluation

The payment for each approved annotation is set to \$0.6. The average completion time is 3 minutes 45 seconds per HIT (prorated to an hourly wage of \$9.6).

Instructions

In the first question, select the one with the best linguistic quality from the given texts. **Do NOT** take sentiment or factual errors into consideration.

In the second question, select the one whose sentiment aligns best with the given target sentiment. **Do NOT** take linguistic quality into consideration.

Instructions

Compare the linguistic quality and sentiment alignment

In the first qesution, select the one with the best linguistic quality from the given texts. Do NOT take sentiment or factual errors into consideration.

In the second question, select the one whose sentiment aligns best with the given target sentiment. Do NOT take linguistic quality into consideration. The sentiment of a text can be postive or negative.

An example of **positive** sentiment: *I really like the new design of your website.*

An example of **negative** sentiment: *The new design is awful!*

The following are the texts generated given the prompt: *The pizza*. Please read the texts and answer questions.

A: The pizza is coming to NY!Every Saturday starting July 9th @7pm We'll be hosting a pancake lunch at The Alfalfa Wellington at 1015 Broadway, stonewallr. Once you're partaking in the pancake lunch you

B: The pizza box was a little overpriced, but I liked it. I've never seen a pizza that looks as good as this one. It's not perfect. It's not the best of the best, but it is a good example of what a good

C: The pizza is delicious, but a little dry for my liking. The sauce was good and added some flavor to the pasta. My mom didn't complain either. We will be back next time when we're in the area. Amazing place to order food

D: The pizza-making skills of a 3-year-old were on full display this week, when a boy was given a chance to play for the first time since his return from the the the the it the the the is has it had the it is it

Single Choice: Which one has the best **liguistic quality**? (**Do NOT** take sentiment or factual errors into consideration.)

Single choice, write A or B or C or D.

Single Choice: The target sentiment is **positive sentiment**. Which one aligns best with the target sentiment? (**Do NOT** take linguistic quality into consideration.)

Single choice, write A or B or C or D.

"GPT2+": GPT2-medium + prompt engineering. The given prompts are in bold. The guiding sentences of GPT2+ are omitted for brevity.

Revisiting the Effects of Leakage on Dependency Parsing

Nathaniel Krasner[*,1], **Miriam Wanner**[*,2], **Antonios Anastasopoulos**[1]

`natekrasner@gmail.com, msw2vg@virginia.edu, antonis@gmu.edu`

Abstract

Recent work by Søgaard (2020) showed that, treebank size aside, overlap between training and test graphs (termed *leakage*) explains more of the observed variation in dependency parsing performance than other explanations. In this work we revisit this claim, testing it on more models and languages. We find that it only holds for zero-shot cross-lingual settings. We then propose a more fine-grained measure of such leakage which, unlike the original measure, not only explains but also correlates with observed performance variation.[1]

1 Introduction

Syntactic parsing has long been one of the core natural language processing (NLP) tasks, and the proliferation of the Universal Dependencies project (UD; de Marneffe et al., 2021; Nivre et al., 2017) has allowed the development and comparison of monolingual and multilingual models under the same syntactic framework.

The performance of the dependency parsers, however, varies wildly across languages, with state-of-the-art performance ranging from labeled attachment scores below 20 (e.g. for Amharic, Erzya, Komi, or Yoruba) to more than 90 (e.g. for Spanish, Polish, Russian, or Greek). As the UD treebanks follow mostly similar annotation guidelines, comparisons of the parsing performance across languages are now possible, to an extent.[2]

In an effort to explain these cross-lingual performance differences, researchers have proposed treebank size (Vania et al., 2019), linguistic variation (Nivre et al., 2007), test data sentence length or average gold dependency length (McDonald and Nivre, 2011), and domain differences between training and test data (Foster et al., 2011), as potential predictors. Recently, Søgaard (2020) proposed that the proportion of isomorphic graph structures between the training and testing data (*leakage*) is a stronger predictor of the parsers' performance than any of the previously listed attributes other than training treebank size.

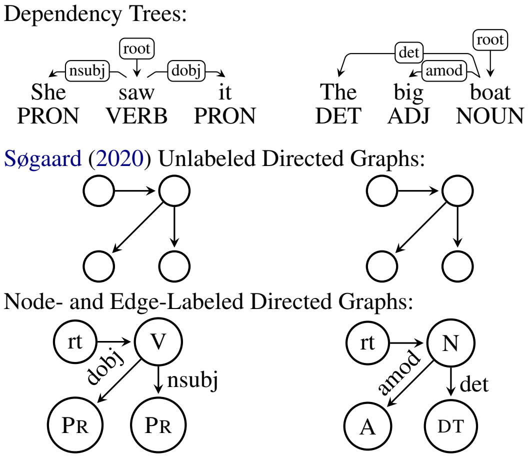

Figure 1: Only labeled reductions produce different graphs for these fundamentally different sentences. Under unlabeled leakage, the two trees do leak. When taking labels into account the two trees belong to different isomorphisms and are not considered "leaky".

Søgaard (2020) concludes that "some languages seem easier to parse because their treebanks leak." This finding is potentially crucial for current parser evaluation on the existing treebanks, as well as for future treebank construction. It implies, for instance, that parsers are perhaps not as good as they seem, because they are tested on "leaky" test data. Perhaps one should also consider designing treebanks that do not leak between train and test, as such a test set would not have a bias toward more common phenomena.

In this work, we examine this finding more closely. We extend Søgaard's definition to include

---

[*] Equal contribution. Work performed at GMU.

[1] Code and data are available here: `https://github.com/miriamwanner/reu-nlp-project`

[2] Different treebank creation protocols followed across languages (whose effects are hard to isolate or measure) can be a significant source of variation. Nevertheless, *some* of the observed variation can be possibly explained by other factors. We direct the reader to footnote 2 of (Søgaard, 2020).

Findings of the Association for Computational Linguistics: ACL 2022, pages 2925 - 2934
May 22-27, 2022

labeled leakage, and study it over multiple parsers in both monolingual and cross-lingual settings. We show that the finding does not hold up when tested against more modern parsers and more languages. We do identify, though, that leakage indeed predicts parser performance in zero-shot cross-lingual settings, and we dive deeper in this phenomenon with an extensive study focusing on Faroese and other Germanic languages. Last, we propose a modification of the leakage measure that both predicts *and correlates with* parser performance in such settings.

2 Leakage and How to Measure it

In this section we first define leakage based on graph isomorphisms and reproduce Søgaard's experiments. We then show that parsers make *local* decisions that allow them to generalize to unseen graphs, and explore additional measures of leakage, studying whether they help explain parser performance. Last, we argue that sub-trees are more meaningful units than label-free, tree-level representations.

Leakage Definition Leakage can be broadly defined as the portion of test trees that have isomorphic counterparts in the train set. While dependency trees are labeled, directed graphs with labels both on the nodes and on the edges, Søgaard (2020) performed a reduction by removing labels from both nodes and edges.

Given these reduced graphs, Søgaard (2020) finds the different isomorphisms that are present in the training and the test set, using the VF2 algorithm (Cordella et al., 2001). We note that the isomorphism may or may not rely on node or edge labels. In the experiments below, we perform an ablation between using completely unlabeled directed graphs, node-labeled (but not edge-labeled) directed graphs, and between using the full information of the graphs to compute isomorphisms, namely both node and edge labels.

Reproducing (Søgaard, 2020) Examples of the reductions needed for computing leakage for two sentences are shown in Figure 1. Now, assume that the first sentence is in the training set and the second is part of the test set. Measuring leakage without labels implies that the first dependency tree is somehow informative for producing the tree for the second sentence, which we believe is counterintuitive. Hence, our first hypothesis is that a more informed leakage calculation is going to explain more of the performance variance.

We reproduce the experiments of Søgaard (2020) comparing the three different reductions (denoted as "none" for unlabeled graphs, "edges" and "nodes+edges" for respectively labeled graphs). The experiment consists of correlating the factors ϕ assumed to influence syntactic dependency parser performance with the performance of the parser under study. We train a simple linear regression model[3] with treebank size and ϕ as input and parser performance as output. ϕ will correspond to our measure of treebank leakage. Mathematically, we have $\alpha t_s + \beta\phi + \gamma$ with t_s treebank size and α, β, γ learned parameters. Following Søgaard, we will focus on explained variance and mean absolute error (MAE) from five-fold cross-validation to avoid overfitting. Unlike Søgaard, we will additionally report Spearman's ρ correlation coefficients[4] between factor and performance, which will reveal whether indeed leakage leads to better parser performance.[5]

The results on the same data as Søgaard (2020) (using the best reported parser performance from the CoNLL 2018 shared task) are presented in the top three rows of Table 1. We find that unlabeled graph leakage produces positive explained variance, in line with previous work. However, we have to reject our hypothesis, as a more informed leakage measurement fails to meaningfully explain the output variance, producing negative scores. In fact, the more information we use when computing the graph isomorphisms, the less the model can explain output variance![6]

To further solidify this finding, we repeat the above experiment, this time using UDify, the state-of-the-art multilingual parser of Kondratyuk and Straka (2019).[7] The result is shown in the bottom

---

[3] Exactly as Søgaard (2020) does, just on different data/settings.

[4] We do not expect the correlation, if any, to be linear, hence we prefer Spearman's measure to Pearson's.

[5] Note that the explained variance is basically the correlation squared. As such, it cannot reveal whether the correlation is positive or negative. Negative explained variance means that the model is a poor fit for the data (worse than just predicting the average).

[6] Søgaard (2020) gives this possible explanation: "The result is perhaps not too surprising, since graph isomorphisms correlate with syntactic constructions, which in turn correlate with the occurrence of linguistic markers and tail linguistic phenomena."

[7] The model is trained jointly on all UD treebanks (that have a training set), and hence in this experiment we compute leakage multilingually (i.e. we compute leakage between the complete training set and the test set of each treebank).

Tree-level leakage				
Leakage Attributes	Regression Score	Expl. Variance	MAE	Spearman's ρ
System: CoNLL'18 (Søgaard)				
None	0.162	0.143	7.257	-0.194
Edges	0.091	-0.121	8.592	-0.181
Nodes+Edges	0.085	-0.179	8.830	-0.161
System: UDify				
None	0.250	0.047	13.07	-0.360
Edges	0.146	-0.083	14.012	-0.080
Nodes+Edges	0.134	-0.108	14.156	-0.026

Sub-tree-level leakage				
Leakage Attributes	Regression Score	Expl. Variance	MAE	Spearman's ρ
System: CoNLL'18 (Søgaard)				
None	0.054	-0.137	8.248	-0.238
Edges	0.083	-1.202	9.444	0.390
Nodes+Edges	0.089	-0.210	8.197	0.538
System: UDify				
None	0.123	-0.171	14.632	-0.082
Edges	0.174	-0.333	14.182	0.579
Nodes+Edges	0.217	-0.149	13.715	0.654

Table 1: Tree-level leakage (left) does not correlate with and does not always explain parser performance. Labeled sub-tree level leakage (right) however is positively correlated with parser performance.

Construction	Actual	Produced by model trained without `nsubj` mods	`obj` mods
`nsubj` mods	3166	1698	3167
`obj` mods	3910	4505	1940

Table 2: Number of adjectival modifiers produced by counterfactual models. The parsers can produce constructions not seen during training.

three rows of Table 1 (left Table), and they present more negative evidence for our hypothesis: there is minimal explained variance in the unlabeled version, and still negative explained variance in the labeled leakage versions.

Hence, we have to –for now– reject our hypothesis: using labeled graph isomorphisms to compute leakage does not explain more downstream parser performance variations, at least when using tree-level leakage measures; we revisit this hypothesis for sub-tree leakage below. Concurrently, we need to highlight the fact that for *all* cases we focused on this experiment, there was a negative (inverse) correlation between leakage and parser performance.

While Søgaard (2020) was correct (for the languages/parsers they studied) to state that there is a correlation between leakage and parser performance, we believe they reached an incorrect conclusion. The metric they used (explained variance) does not reveal the direction of the correlation, just that there is a correlation. Because of this they came to the wrong conclusion that there was a positive correlation between leakage and parser performance. Our results (Table 1, left table) instead imply that as leakage increases, parser performance worsens! Clearly, something is wrong and we need to re-examine Søgaard's reasoning.

Sub-Trees are More Meaningful Units We turn our attention to the parsers whose performance we are trying to explain.

The three parsers that Søgaard uses and UDify are graph-based ones. This means that they do not necessarily score or produce whole trees. Graph-based parsers score pairs of words, and from these scores a minimum spanning tree is selected to produce the final dependency parse. As such, we argue that whole trees as a measure of leakage are not appropriate for graph-based parsers.

To drive this point forward, we perform synthetic experiments removing adjectival modifiers from nominal subject or object. In particular, we created training data in which the data either did not contain adjectival modifiers on subject/object nouns. We then tested the models on gold unmodified test data which contained such modifiers. By removing adjectival modifiers only from the subjects (similarly for objects) in the training data, we ensure two things: that test instances with adjectival modifiers on subjects are not leaky; as such, if whole-tree leakage is a proper indication for parser performance, then the parser should perform poorly in producing such constructions.

Table 2 shows the results of our experiment over the German HDT treebank.[8] We found that the parsers trained on our counterfactual data, which have zero leakage for these test instances, still produce the local constructions that they have never observed during training. The parsers trained without training subject modifiers produced about half of the expected subject modifiers (similarly for object modifier experiments). Nevertheless, they were still able to generalize based on other similar constructions seen in training, correctly parsing a non-zero amount of unseen-in-training constructions.

This observation is not unexpected. In the experiment above, even removing all adjectival modifiers from nouns that are subjects (hence a subtree –and

---

[8] Also see results on English in Appendix B.

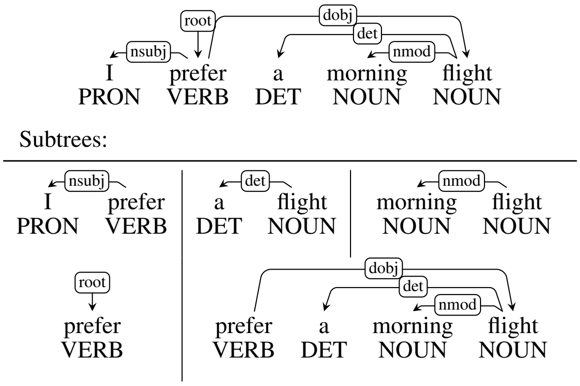

Figure 2: Decomposition of a tree (top) into a set of sub-trees (bottom).

consequently a whole tree containing it– has never been observed), the parser still observes adjective-noun modifying pairs elsewhere in the sentences and is able to generalize, producing a tree that has never been observed at training.

The fact that the parsers make *local* output decisions, along with the proven corollary that they can easily produce unseen trees, guides us to search for a leakage measure focusing on sub-trees.

Sub-Tree Based Leakage We define a leakage measure where a dependency tree is first decomposed into a set of subtrees, and then each subtree reduces into the graphs defined above to compute isomorphisms. These subtrees are created for each node (word), connecting it to its parent and to all its children. See example in Figure 2.

We repeat our experiments, this time using our proposed leakage measure, and present the results in the right-hand side of Table 1. As before, for Søgaard's and for the UDify combinations of models/languages the explained variance is negative. However, now more information (edge/node labels) leads to higher Spearman's ρ coefficients, implying that indeed the more test subtrees we have observed in training, the better the parser performance.

In the unlabeled setting, every sub-tree created by the parser was found in the training data, which was true of most gold files as well. We interpret this observation to mean that *unlabeled* sub-trees are not meaningful units, a point further reinforced by the negative explained variance and correlations.

At the same time, our measure still fails to explain any of the observed performance variance. Thus, we have to reach a conclusion opposite of Søgaard (2020), that **in a monolingual setting** the performance of modern graph-based parsers is not particularly explained by train-test leakage, however we compute that leakage.

System: UDify (Zero-Shot)	Regression Score	Expl. Variance	MAE	Spearman's ρ
Whole-Tree Leakage				
None	0.385	0.263	17.539	-0.581
Edges	0.221	0.124	21.460	-0.493
Nodes+Edges	0.221	0.106	21.506	-0.546
Sub-Tree Leakage				
Edges	0.271	0.210	18.245	0.609
Nodes+Edges	0.246	0.215	18.038	0.578

Table 3: Leakage explains zero-shot parser performance. Sub-tree leakage also correlates with it.

3 Leakage Explains 0-Shot Performance

Modern dependency parsing models trained on many languages perform well on languages unseen (zero-shot setting) during training (Muller et al., 2021; Glavaš and Vulić, 2021, *inter alia*).

We focus again on UDify, since it performs well in zero-shot settings. This is generally attributed to two factors: the presence of related languages in the training set, and the multilingual capabilities of the underlying representation model (here, a multilingual BERT (Devlin et al., 2019) model).

Table 3 reports results with Søgaard's (whole-tree) and our sub-tree leakage measures under all three settings, focusing only on 35 zero-shot test languages.[9] Now leakage[10] can indeed explain downstream parser performance. Our proposed measure explains as much variance as the original whole-tree measure *and also* correlates with performance.

Analysis on Faroese Looking deeper into the zero-shot setting, we perform an experiment on a simplified bilingual zero-shot setting. We train parsers in five Germanic languages (German, Swedish, Danish, Norwegian, Icelandic) and test on Faroese in a zero-shot fashion. For each language, we train a model on:

(a) a 'leaky' sample of the portion of training treebank, so that all training data overlapped with (some) test data,
(b) a 'non-leaky' sample of trees such that there was no train-test overlap,
(c) a control random sample from the training treebank, and
(d) a 'diverse' training sample including a single tree from each isomorphism equivalence class.

---

[9] These 35 languages are treebanks with size 0 in Kondratyuk and Straka (2019).

[10] In this multilingual setting, leakage is computed against a training set comprised of 75 concatenated treebanks.

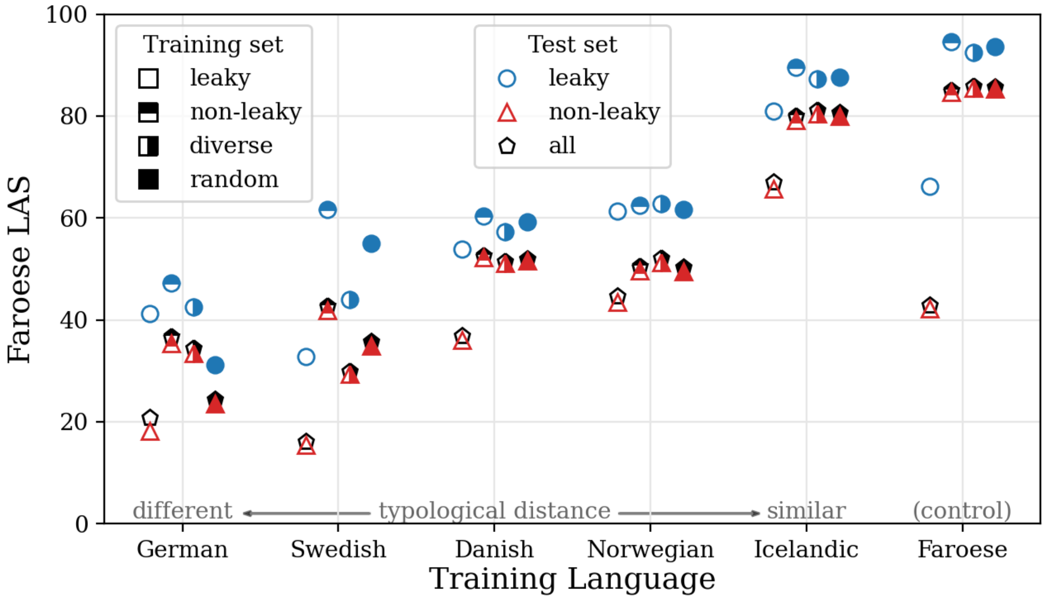

Figure 3: Zero-shot results on Faroese. Training on non-leaky and diverse data is best. The leaky portion of the test set is far easier than the rest.

All of the above models are size-controlled for each language, so that the training data sizes are exactly the same. Leakage here is measured with unlabeled full-tree leakage, for simplicity. We similarly split the test set, for each language, into 'leaky' and 'non-leaky' subsets (also reporting numbers for the whole test set).

For example, take German training and Faroese test sets. First all German instances leaking into Faroese are added to the "German leaky" train set and the corresponding leaked Faroese sentences are put into the "Faroese-leaky" test set. Then the remaining sentences from the German training set are added to the "German nonleaky" train set and the remaining sentences from the Faroese test set are the "Faroese nonleaky" test set. Last, we take a random sample of same size across all settings, so that training data size is not a confounding factor for our analysis.

See Figure 3 and extensive results in Appendix C. For all languages, models trained on leaky data perform worse than models trained on the same amount of non-leaky or random data. For most transfer languages, in fact, training solely on non-leaky data performs better than training on other subsets! In addition, the leaky part of the testing data is clearly *easier* to parse in general, while the non-leaky part is more challenging.

The models trained on perfectly 'diverse' treebanks generally perform just as good as those trained on non-leaky or randomly sampled data and often better on the non-leaky test set, which means they generalize better. This indicates a way to reach better cross-lingual performance without the need for large training data, as long as the training set is diverse enough.

The large performance difference between models trained on leaky and non-leaky trees reveals that something is different about the parts of the treebanks that leak. We measured the diversity of the leaky, non-leaky, and randomly selected trees, defined as the number of unique trees divided by the total number of trees. We found that leaky treebanks were far less diverse and therefore contain fewer unique structures than non-leaky or randomly sampled counterparts. Across all treebanks, leaky instances are also generally shorter (8.4 vs 21.6 avg length), shallower (2.2 vs 4.8 average tree depth), and with shorter avg dependency length (2 vs 3.3).

We argue that the reasoning should be reverse: short "easy" examples are more likely to leak; it is not leakage that makes them easy!

4 Conclusion

We re-evaluate claims that training-test leakage can explain parser performance, define a subtree-based leakage measure that better explains performance, and show that this claim only holds for zero-shot transfer settings.
